Preface to the Ninth Edition

After 45 years in publication, this text continues to provide postgraduate students of obstetrics and gynaecology with the basic knowledge they need to progress in the specialty and also reference for established practitioners who will always feel the need to enhance their knowledge. Although the field is now populated with many sub-specialists, and individual areas of study advance independently, there continues to be the need for coordinating knowledge so every aspect can be considered in the overall context of the specialty. It is the continuing philosophy of this book to try to adhere to an integrated approach, which helps to deliver the highest possible care to patients.

This ninth edition has two new co-editors, Christoph Lees and Tom Bourne, and this was deemed necessary in the light of diverse sub-specialist knowledge, which needs to be edited in a way that balances basic knowledge with up-to-date advances. Since the last edition, there have been a number of obstetric breakthroughs but we still strive to improve outcomes for women and their babies. Maternal and perinatal mortality remain somewhat unchanged in the Western world but, thankfully, there are improvements in developing countries, which are to be encouraged. However, there is still a very long way to go to achieve the Millennium Goals and we hope that this edition can contribute to these aims.

The ninth edition has been restructured to reflect the reality of clinical practice and we are indebted to the authors who have contributed to this book. We offer our thanks and gratitude for all their efforts. We hope that we have produced a textbook for current obstetricians and gynaecologists, which will help them on their way to making a significant contribution to women's health.

Finally, we would like to thank the editorial staff at Wiley for all their support and help, particularly Mirjana Misina.

Keith Edmonds
Christoph Lees
Tom Bourne

Preface to the First Edition

Our purpose in writing this book has been to produce a comprehensive account of what the specialist in training in obstetrics and gynaecology must know. Unfortunately for him, he must now know a great deal, not only about his own subject, but about certain aspects of closely allied specialties such as endocrinology, biochemistry, cytogenetics, psychiatry, etc. Accordingly we have tried to offer the postgraduate student not only an advanced textbook in obstetrics and gynaecology but one which integrates the relevant aspects of other subjects which nowadays impinge more and more on the clinical field.

To achieve this aim within, we hope, a reasonable compass we have assumed some basic knowledge which the reader will have assimilated throughout his medical training, and we have taken matters on from there. Fundamental facts not in question are stated as briefly as is compatible with accuracy and clarity, and discussion is then devoted to more advanced aspects. We acknowledge that it is not possible even in this way to provide all the detail some readers may wish, so an appropriate bibliography is provided with each chapter. Wherever possible we have tried to give a positive opinion and our reasons for holding it, but to discuss nonetheless other important views; this we believe to be more helpful than a complete account of all possible opinions which may be held. We have chosen moreover to lay emphasis on fundamental aspects of the natural and the disease processes which are discussed; we believe concentration on these basic physiological and pathological features to be important to the proper training of a specialist. Clinical matters are, of course, dealt with in detail too, whenever theoretical discussion of them is rewarding. There are, however, some clinical aspects which cannot, at specialist level, be considered in theory with real benefit; examples of these are how to palpate a pregnant woman's abdomen and how to apply obstetric forceps. In general these matters are considered very briefly or perhaps not at all; this is not a book on *how* things are done, but on how correct treatment is chosen, what advantages one choice has over another, what complications are to be expected, etc. Practical matters, we believe, are better learnt in practice and with occasional reference to specialized textbooks devoted solely to them.

A word may be helpful about the manner in which the book is set out. We would willingly have followed the advice given to Alice when about to testify at the trial of the Knave of Hearts in Wonderland, 'Begin at the beginning, keep on until you come to the end and then stop'. But this advice is difficult to follow when attempting to find the beginning of complex subjects such as those to which this book is devoted. Does the beginning lie with fertilization; or with the events which lead up to it; or with the genital organs upon the correct function of which any pregnancy must depend; or does it lie somewhere else? And which direction must we follow then? The disorders of reproduction do not lie in a separate compartment from genital tract disease, but each is clearly associated with the other for at least part of a woman's life. Although we have attempted to integrate obstetrics with gynaecology and with their associated specialties, some separation is essential in writing about them, and the plan we have followed is broadly this – we begin with the female child *in utero*, follow her through childhood to puberty, through adolescence to maturity, through pregnancy to motherhood, through her reproductive years to the climacteric and into old age. Some events have had to be taken out of order, however, although reiteration has been avoided by indicating to the reader where in the book are to be found other sections dealing with different aspects of any subject under consideration. We hope that our efforts will provide a coherent, integrated account of the field we have attempted to cover which will be to the satisfaction of our readers.

Sir John Dewhurst
1972

Section 1

Obstetrics

Part 1

Basic Science

1

Maternal Physiology

Fiona Broughton Pipkin

Department of Obstetrics and Gynaecology, Maternity Unit, City Hospital, Nottingham, UK

The physiological changes of pregnancy are strongly proactive, not reactive, with the luteal phase of every ovulatory menstrual cycle 'rehearsing' for pregnancy. Most pregnancy-driven changes are qualitatively in place by the end of the first trimester, only maturing in magnitude thereafter [1]. This chapter gives a brief overview of the major changes.

Maternal response to pregnancy

Normal pregnancy evokes a systemic inflammatory response, which includes the endothelium [2]. This may explain the greater risk of cardiovascular disease in later life of parous women in comparison with nulliparous women. Markers of oxidative 'stress' rise progressively throughout the first and second trimesters, but plasma concentrations of some endogenous antioxidants, such as superoxide dismutase, rise in parallel. The free radical superoxide is generated through a variety of pathways, including placental ones, but is more damaging when converted to the peroxide radical, a reaction catalysed by free iron in the plasma. Increasing concern is being expressed about over-supplementation with iron, especially in conjunction with vitamin C (which increases absorption) in pregnant women without evidence of iron deficiency and several studies have shown evidence of increased oxidative stress in such women [3]. Conversely, the low dietary selenium intake in women in the UK may predispose to lower activity of the antioxidant glutathione peroxidase and thioredoxin systems in pregnancy.

Immunology

Only two types of fetal tissue come into direct contact with maternal tissues: the villous trophoblast and the extravillous trophoblast. Villous trophoblast, which is a continuous syncytium, is bathed in maternal blood but seems to be immunologically inert and never expresses HLA class I or class II molecules. Extravillous trophoblast is directly in contact with maternal endometrial/decidual tissues and does not express the major T-cell ligands, HLA-A or HLA-B; the HLA class I molecules which are expressed are the trophoblast-specific HLA-G and HLA-C and HLA-E. The decidual uterine natural killer (NK) cells, the main type of decidual lymphocyte, differ from those in the systemic circulation. They express surface killer immunoglobulin-like receptors (KIRs), which bind to HLA-C and HLA-G on trophoblast. HLA-E and HLA-G are effectively monomorphic, but HLA-C is polymorphic, with two main groups, HLA-C1 and HLA-C2. The KIRs are very highly polymorphic, but again fall into two main classes, KIR-A (non-activating) and KIR-B (multiply activating). Thus the very polymorphic KIR in maternal tissues and the polymorphic HLA-C in the fetus make up a potentially very variable receptor–ligand system.

The effect of this on implantation has been inferred from indirect evidence. Both recurrent miscarriage and pre-eclampsia are associated with poor trophoblast invasion. The maternal KIR genotype may be AA, AB or BB. Since the identifiable trophoblast HLA-C allotypes are HLA-C1 and HLA-C2, there are nine possible combinations. It has been shown that if the maternal KIR haplotype is AA, and the trophoblast expresses any HLA-C2, then the possibility of miscarriage or pre-eclampsia is significantly increased. However, even one KIR-B provides protection [4]. HLA-C2 is highly inhibitory to trophoblast migration, and thus appears to need 'activating KIR' to overcome it.

NK cells appear and disappear in the endometrial decidua every ovulatory menstrual cycle, and the populations are maintained should conception occur. When progesterone is at its peak, they associate with the spiral arteries and uterine glands. Human data are limited, and animal studies of immunological phenomena must be

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

viewed with especial caution in pregnancy, so the precise role of NK cells is not yet known. However, timed human endometrial sampling at 8–10 weeks' gestation has shown them to be major producers of a variety of angiogenic factors, expressing transcripts of *VEGFC* (vascular endothelial growth factor C), *PlGF* (placental growth factor) and *ANG2* (angiopoietin 2). This has ceased by 12–14 weeks. It has been suggested that NK cells are essential for spiral artery remodelling (for a review see Zhang *et al.* [5]).

The uterus

The first-trimester human embryo appears to gain nutrients histiotrophically, from the endometrial glands. These glandular secretions are rich in carbohydrates, lipids and growth factors and can well support early growth while the conceptus is small [6]. The inner third of the myometrium, as well as the endometrium, is anatomically changed by pregnancy, and once a pregnancy has gone beyond the first trimester, these changes appear to be irreversible. The most striking change is in the spiral arteries, which undergo extensive remodelling. Extravillous trophoblast attacks these vessels as interstitial cells within the stroma, and as endovascular cells within the vascular lumen. In normal pregnancy, the summed effects are the conversion of these vessels into floppy thin-walled vessels, more closely resembling veins than arteries, that do not respond to vasoconstrictor stimuli, so allowing the maximum flow to reach the placenta. This remodelling is only completed in the early second trimester, but is impaired in both pre-eclampsia and normotensive intrauterine growth restriction.

The uterus must be maintained in quiescence until labour is initiated. The mechanisms responsible for this have not been fully elucidated, although progesterone plays a central role, but include locally generated nitric oxide, probably acting through cyclic GMP or voltage-gated potassium channels such as Kv7 and Kv11, while a number of hormones such as brain natriuretic peptide, prostacyclin, prostaglandin (PG)E_2 and calcitonin gene-related peptide act through G_s receptors, and are relaxatory.

The cardiovascular system

There is much less information about the normal functioning of the cardiovascular system in young women than in young men, partly because they have been perceived as being 'more difficult' to study as a result of the monthly ovulatory cycle. However, an increasing number of studies have been initiated prior to conception and continuing thereafter. These are very demanding, but also extremely valuable. Such studies also underline the inherent errors in using data obtained at the first antenatal clinic visit, often late in the first trimester, as true baseline.

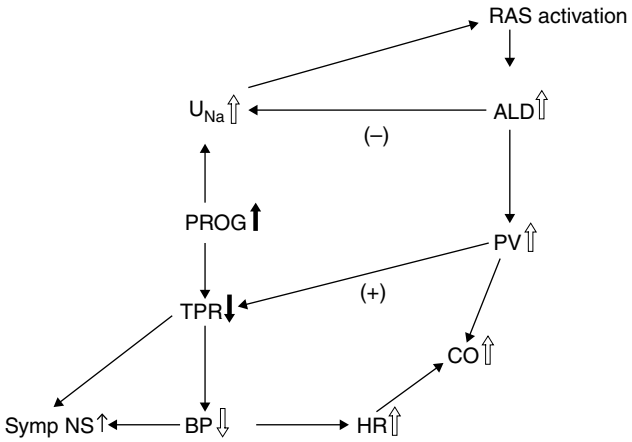

Fig. 1.1 Flow chart of the probable sequence of initial cardiovascular activation. ALD, aldosterone; BP, systemic arterial blood pressure; CO, cardiac output; HR, heart rate; PROG, progesterone; PV, plasma volume; RAS, renin–angiotensin system; Symp NS, sympathetic nervous system; TPR, total peripheral resistance; U_{Na}, urinary sodium excretion.

There is a significant fall in total peripheral resistance by 6 weeks' gestation to a nadir of about 40% by mid-gestation, resulting in a fall in afterload. This is 'perceived' as circulatory underfilling, which activates the renin–angiotensin–aldosterone system and allows the necessary expansion of plasma volume (PV) (Fig. 1.1) [7,8]. By the late third trimester, the PV has increased from its baseline by about 50% in a first pregnancy and 60% in a second or subsequent pregnancy. The bigger the expansion, the bigger, on average, the birthweight of the baby. The total extracellular fluid volume rises by about 16% by term, so the percentage rise in PV is disproportionate to the whole. The plasma osmolality falls by about 10 mosmol/kg as water is retained.

The heart rate rises synchronously, by 10–15 bpm, so the cardiac output begins to rise [9]. There is probably a fall in baroreflex sensitivity as pregnancy progresses, and heart rate variability falls. Stroke volume rises a little later in the first trimester. These two factors push the cardiac output up by 35–40% in a first pregnancy, and by about 50% in later pregnancies; it can rise by a further third in labour (Fig. 1.2). Table 1.1 summarizes the percentage changes in some cardiovascular variables during pregnancy [9].

Measuring brachial systemic arterial blood pressure in pregnancy is notoriously difficult, but there is now broad consensus that Korotkoff 5 should be used with auscultatory techniques [10]. However measured, there is a small fall in systolic, and a greater fall in diastolic, blood

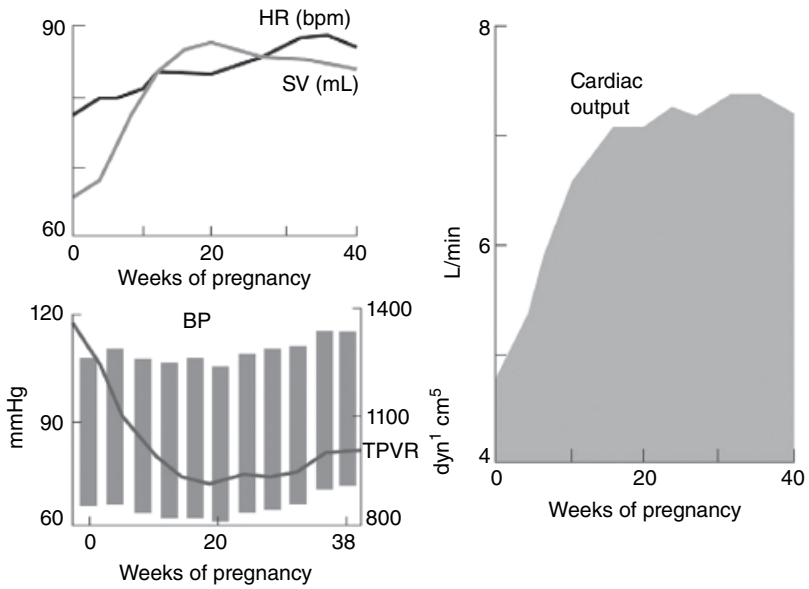

Fig. 1.2 Major haemodynamic changes associated with normal human pregnancy. The marked augmentation of cardiac output results from asynchronous increases in both heart rate (HR) and stroke volume (SV). Despite the increases in cardiac output, blood pressure (BP) decreases for most of pregnancy. This implies a very substantial reduction in total peripheral vascular resistance (TPVR).

Table 1.1 Percentage changes in some cardiovascular variables during pregnancy.

	First trimester	Second trimester	Third trimester
Heart rate (bpm)	+11	+13	+16
Stroke volume (mL)	+31	+29	+27
Cardiac output (L/min)	+45	+47	+48
Systolic blood pressure (mmHg)	−1	−1	+6
Diastolic blood pressure (mmHg)	−6	−3	+7
MPAP (mmHg)	+5	+5	+5
Total peripheral resistance (resistance units)	−27	−27	−29

MPAP, mean pulmonary artery pressure. Data are derived from studies in which pre-conception values were determined. The mean values shown are those at the end of each trimester and are thus not necessarily the maxima. Note that most changes are near maximal by the end of the first trimester.

pressure, initiated during the luteal phase, being mainly complete by 6–7 weeks' gestation, but continuing more slowlyto the late second trimester, resulting in an increased pulse pressure. The blood pressure then rises steadily, in parallel with an increase in peripheral sympathetic activity, and even in normotensive women there may be some late overshoot of non-pregnant values. Supine hypotension occurs in about 8% of women in late gestation as the uterus falls back onto the inferior vena cava, reducing venous return.

There is increasing interest in large artery function, measured as aortic pulse wave velocity (aPWV), and wave reflections, measured as the augmentation index (AIx). The central blood pressure can be estimated non-invasively, and has been suggested to be superior to the brachial blood pressure in predicting future adverse cardiovascular events outside pregnancy. Central blood pressure falls significantly more during the first 6 weeks of pregnancy than brachial blood pressure, but also reaches a nadir in the late second trimester. The AIx, adjusted for heart rate, falls significantly by 6–7 weeks' gestation, again reaching a nadir in the late second trimester; the aPWV, adjusted for mean blood pressure, does not change significantly [11].

The pressor response to angiotensin II is reduced in normal pregnancy but is unchanged to noradrenaline. The reduced sensitivity to angiotensin II presumably protects against the potentially pressor levels of angiotensin II found in normal pregnancy and is associated with lower receptor density; plasma noradrenaline is not increased in normal pregnancy. Pregnancy does not alter the response of intramyometrial arteries to a variety of vasoconstrictors. Nitric oxide may modulate myogenic tone and flow-mediated responses in the resistance vasculature of the uterine circulation in normal pregnancy.

The venous pressure in the lower circulation rises, for both mechanical and hydrodynamic reasons. The pulmonary circulation is able to absorb high rates of flow without an increase in pressure so pressure in the right ventricle, and the pulmonary arteries and capillaries, does not change. Pulmonary resistance falls in early pregnancy, and does not change thereafter. There is progressive venodilatation and rises in venous distensibility and capacitance throughout a normal pregnancy, possibly because of increased local nitric oxide synthesis.

The respiratory system

Tidal volume rises by about 30% in early pregnancy to 40–50% above non-pregnant values by term, with a fall in expiratory reserve and residual volume (Fig. 1.3) [12]. Neither forced expiratory volume in 1 s (FEV_1) nor peak expiratory flow rate are affected by pregnancy, even in women with asthma. The rise in tidal volume is largely driven by progesterone, which appears to decrease the threshold and increase the sensitivity of the medulla oblongata to carbon dioxide. Respiratory rate does not change, so the minute ventilation rises by a similar amount. This over-breathing begins in every luteal phase; the PCO_2 is lowest in early gestation. Progesterone also increases erythrocyte carbonic anhydrase concentration, which will also lower PCO_2. Carbon dioxide production rises sharply during the third trimester, as fetal metabolism increases. The fall in maternal PCO_2 allows more efficient placental transfer of carbon dioxide from the fetus, which has a PCO_2 of around 55 mmHg (7.3 kPa). The fall in PCO_2, together with an increased renal excretion of bicarbonate, results in a fall in plasma bicarbonate concentration (to about 18–22 mmol/L compared with the non-pregnant range of 24–28 mmol/L), which contributes to the fall in plasma osmolality and reduces buffering capacity. The peripheral venous pH rises slightly (Table 1.2 and Fig. 1.4).

The increased alveolar ventilation results in a much smaller proportional rise in PO_2 from about 96.7 to 101.8 mmHg (12.9–13.6 kPa). This increase is offset by the rightward shift of the maternal oxyhaemoglobin dissociation curve caused by an increase in 2,3-diphosphoglycerate (2,3-DPG) in the erythrocytes and the lower plasma bicarbonate concentration. This facilitates oxygen unloading to the fetus, which has both a much lower PO_2 (25–30 mmHg, 3.3–4.0 kPa) and a marked leftward shift of the oxyhaemoglobin dissociation curve, due to the lower sensitivity of fetal haemoglobin to 2,3-DPG.

There is an increase of about 16% in oxygen consumption by term due to increasing maternal and fetal demands. Since the increase in oxygen-carrying capacity

Table 1.2 The influence of pregnancy on some respiratory variables.

	Non-pregnant	Pregnant – term
PO_2 (mmHg)	93 (12.5 kPa)	102 (13.6 kPa)
O_2 consumption (mL/min)	200	250
PCO_2 (mmHg)	35–40 (4.7–5.3 kPa)	30 (4.0 kPa)
Venous pH	7.35	7.38

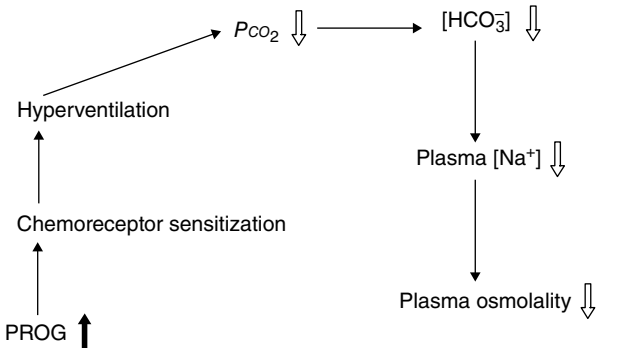

Fig. 1.4 Flow chart of the effects of over-breathing in pregnancy. HCO_3^-, bicarbonate; Na^+, sodium; PCO_2, carbon dioxide tension; PROG, progesterone.

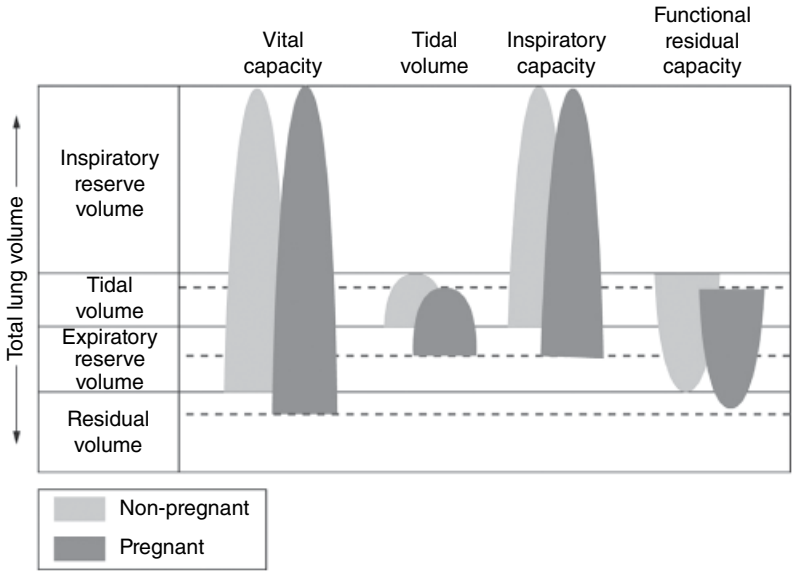

Fig. 1.3 Alterations in lung volumes associated with normal human pregnancy. In general terms, inspiratory reserve and tidal volumes increase at the expense of expiratory reserve and residual volumes.

Table 1.3 Although the increases in resting cardiac output and minute ventilation are of the same order of magnitude in pregnancy, there is less spare capacity for increases in cardiac output on moderate exercise than for increases in respiration.

	Resting	Exercise
Cardiac output	+33% (4.5–6 L/min)	+167% (up to 12 L/min)
Minute ventilation	+40% (7.5–10.5 L/min)	+1000% (up to ~ 80 L/min)

of the blood (see section Haematology) is about 18%, there is actually a fall in arteriovenous oxygen difference. Pulmonary blood flow, of course, rises in parallel with cardiac output and enhances gas transfer.

Pregnancy places greater demands on the cardiovascular than the respiratory system [13]. This is shown in the response to moderate exercise (Table 1.3).

Haematology

The circulating red cell mass rises by 20–30% during pregnancy, with increases in both cell number and size. It rises more in women with multiple pregnancies, and substantially more with iron supplementation (~29% compared with 17%). Serum iron concentration falls, the absorption of iron from the gut rises and iron-binding capacity rises in a normal pregnancy, since there is increased synthesis of the β_1-globulin transferrin. Nevertheless, 75% of diagnosed anaemia in pregnancy arises from iron deficiency. Plasma folate concentration halves by term, because of greater renal clearance, although red cell folate concentrations fall less. In the late 1990s, one-fifth of the female population aged 16–64 in the UK were estimated to have serum ferritin levels below 15 μg/L, indicative of low iron stores [14]; a similar proportion was reported in 2008 [15]. Pregnant adolescents seem to be at particular risk of iron deficiency. Even relatively mild maternal anaemia is associated with increased placental weight/birthweight ratios and decreased birthweight. However, inappropriate supplementation can itself be associated with pregnancy problems (see above) [16]. The National Institute for Health and Care Excellence (NICE) recommends that iron supplementation should be considered for women with haemoglobin concentrations below 110 g/L in the first trimester and 105 g/L at 28 weeks [17].

Erythropoietin rises in pregnancy, more so if iron supplementation is not taken (55% compared with 25%) but the changes in red cell mass antedate this; human placental lactogen may stimulate haematopoiesis.

Pro rata, the PV increases more than the red cell mass, which leads to a fall in the various concentration measures that incorporate the PV, such as the haematocrit, haemoglobin concentration and red cell count. The fall in packed cell volume from about 36% in early pregnancy to about 32% in the third trimester is a sign of normal PV expansion.

The total white cell count rises, mainly because of increased polymorphonuclear leucocytes. Neutrophil numbers rise with oestrogen concentrations and peak at about 33 weeks, stabilizing after that until labour and the early puerperium, when they rise sharply. Their phagocytic function increases during gestation. T and B lymphocyte counts do not change but their function is suppressed, making pregnant women more susceptible to viral infections, malaria and leprosy. The uterine NK cells express receptors that recognize the otherwise anomalous combination of human lymphocyte antigens (HLA-C, HLA-E and HLA-G) expressed by the invasive cytotrophoblasts. This is likely to be central to maternal recognition of the conceptus [18] (see above).

Platelet count and platelet volume are largely unchanged in most pregnant women, although their survival is reduced. Platelet reactivity is increased in the second and third trimesters and does not return to normal until about 12 weeks after delivery.

Coagulation

The changes in coagulation profile during pregnancy are most complex at the time of labour and delivery, with the urgent need to prevent life-threatening haemorrhage from the placental separation site, while avoiding excessive activation and thrombosis. Coagulation in pregnancy has recently been reviewed [19]. Continuing low-grade coagulopathy is a feature of normal pregnancy [20]. Several of the potent procoagulatory factors rise from at least the end of the first trimester [21] (Fig. 1.5). For example, factors VII, VIII and X all rise, and absolute plasma fibrinogen doubles, while antithrombin III, an inhibitor of coagulation, falls. The erythrocyte sedimentation rate rises early in pregnancy due to the increase in fibrinogen and other physiological changes. Protein C, which inactivates factors V and VIII, is probably unchanged in pregnancy, but concentrations of protein S, one of its cofactors, fall during the first two trimesters. An estimated 5–10% of total circulating fibrinogen is consumed during placental separation, and thromboembolism is one of the main causes of maternal death in the UK. Plasma fibrinolytic activity is decreased during pregnancy and labour, but returns to non-pregnant values within an hour of delivery of the placenta, suggesting strongly that the control of fibrinolysis during pregnancy is significantly affected by placentally derived mediators. Table 1.4 summarizes changes in some coagulation and fibrinolytic variables during pregnancy [22].

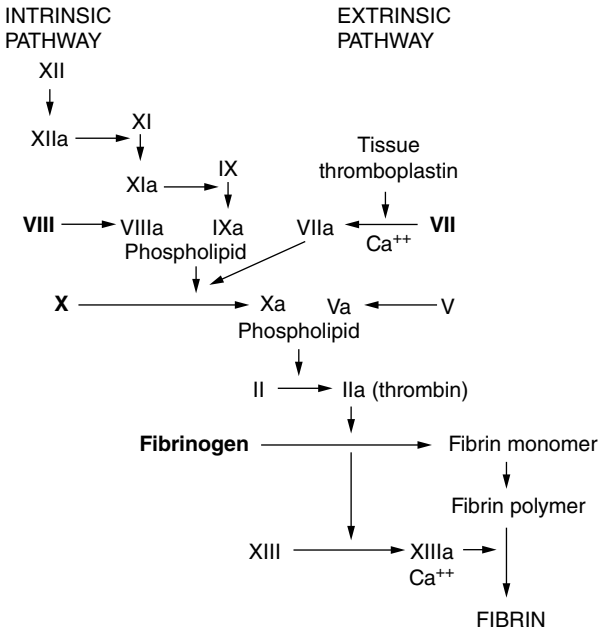

Fig. 1.5 Alterations in the coagulation pathways associated with human pregnancy. Factors which increase during normal pregnancy are in bold type. *Source:* Chamberlain, G. and Broughton Pipkin, F. *Clinical Physiology in Obstetrics*, 3rd edn. Oxford: Wiley, 1998. The renal system

The kidneys increase in size in pregnancy mainly because renal parenchymal volume rises by about 70%, with marked dilatation of the calyces, renal pelvis and ureters in most women [23]. Ureteric tone does not decrease, but bladder tone does. The effective renal plasma flow (ERPF) is increased by at least 6 weeks' gestation and rises to some 80% by mid-pregnancy falling thereafter to about 65% above non-pregnant values (Fig. 1.6). This increase is proportionally greater than the increase in cardiac output, presumably reflecting specific vasodilatation, probably via increased local prostacyclin or nitric oxide synthesis. The glomerular filtration rate (GFR) also increases, by about 45% by the ninth week, only rising thereafter by another 5–10%, but this is largely maintained to term, so the filtration fraction falls during the first trimester, is stable during the second, and rises thereafter, possibly to levels above non-pregnant. However, these major increments do not exhaust the renal reserve. The differential changes in ERPF and GFR in late pregnancy suggest a mechanism acting preferentially at the efferent arterioles, possibly through angiotensin II.

The filtered load of metabolites therefore increases markedly, and reabsorptive mechanisms frequently do not keep up (e.g. glucose and amino acids; see section Energy requirements). These changes have profound

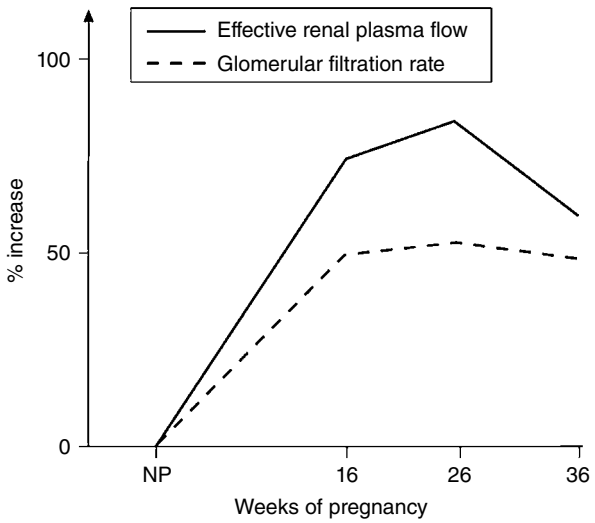

Fig. 1.6 The changes in renal function during pregnancy are largely complete by the end of the first trimester and are thus proactive not reactive to the demands of pregnancy. The filtration fraction falls during the first trimester but begins to return to non-pregnant levels during the third trimester. *Source:* Chamberlain, G. and Broughton Pipkin, F. *Clinical Physiology in Obstetrics*, 3rd edn. Oxford: Wiley, 1998. Reproduced with permission of John Wiley & Sons.

effects on the concentrations of certain plasma metabolites and electrolytes and 'normal' laboratory reference ranges may thus be inappropriate in pregnancy. For example, plasma creatinine concentration falls significantly by the fourth week of gestation and continues to fall to mid-pregnancy, to below 50 mmol/L, but creatinine clearance begins to fall during the last couple of months of pregnancy, so plasma creatinine concentration rises again.

Total body water rises by about 20% during pregnancy (~8.5 L) with a very sharp fall in plasma osmolality between weeks 4 and 6 after conception, possibly through the actions of human chorionic gonadotrophin (hCG). The volume-sensing arginine vasopressin (AVP) release mechanisms evidently adjust as pregnancy progresses, with a lowering of the osmotic threshold for AVP and thirst. As well as water present in the fetus, amniotic fluid, placenta and maternal tissues, there is also oedema fluid and increased hydration of the connective tissue ground substance with laxity and swelling of connective tissue.

The pregnant woman accumulates some 950 mmol of sodium in the face of high circulating concentrations of progesterone, which competes with aldosterone at the distal tubule. The potentially natriuretic prostacyclin also rises markedly, with a significant rise in atrial natriuretic peptide (ANP). This stimulates the renin–angiotensin system, with increased synthesis and release of aldosterone from the first trimester. The raised plasma prolactin may also contribute to sodium retention. It is assumed that glomerulotubular balance must also change in pregnancy to allow the sodium retention that actually occurs. There is a fall of some 4–5 mmol/L in plasma sodium by term, but plasma chloride does not change. Curiously, some 350 mmol of potassium are also retained during pregnancy, in the face of the much-increased GFR, substantially raised aldosterone concentrations and a relatively alkaline urine. Renal tubular potassium reabsorption evidently adjusts appropriately to the increased filtered potassium load.

Serum uric acid concentration falls by about one-quarter in early pregnancy, with an increase in its fractional excretion secondary to a decrease in net tubular reabsorption. The kidney excretes a progressively smaller proportion of the filtered uric acid, so some rise in serum uric acid concentration during the second half of pregnancy is normal. The developing fetus and placenta contribute to the load. A similar pattern is seen in relation to urea, which is also partly reabsorbed in the nephron.

Glucose excretion may rise 10-fold as the greater filtered load exceeds the proximal tubular T_{max} for glucose (~1.6–1.9 mmol/min). If the urine of pregnant women is tested sufficiently often, glycosuria will be detected in 50%. The excretion of most amino acids increases, which is curious since these are used by the fetus to synthesize protein. The pattern of excretion is not constant, and differs between individual amino acids. Excretion of the water-soluble vitamins is also increased. The mechanism for all these is inadequate tubular reabsorption in the face of a 50% rise in GFR.

Urinary calcium excretion is also twofold to threefold higher in normal pregnancy than in the non-pregnant woman, even though tubular reabsorption is enhanced, presumably under the influence of the increased concentrations of 1,25-dihydroxyvitamin D. To counter this, intestinal absorption doubles by 24 weeks, after which it stabilizes. Renal bicarbonate reabsorption and hydrogen ion excretion appear to be unaltered during pregnancy. Although pregnant women can acidify their urine, it is usually mildly alkaline.

Total protein and albumin excretion both rise during pregnancy, to at least 36 weeks, due to the increased GFR, and changes in both glomerular and tubular function. Thus in late pregnancy, an upper limit of normal of 200 mg total protein excretion per 24-hour collection is accepted. The assessment of absolute proteinuria in pregnancy using dipsticks has been shown to give highly variable data. Studies in which urinary protein/creatinine and albumin/creatinine ratios were measured in order to identify developing pre-eclampsia have also shown marked heterogeneity in test accuracy and thus diagnosis of the disease [24].

The cerebral circulation

The brain is responsible for approximately 20% of total oxygen consumption outside pregnancy. It has a relatively limited capacity to tolerate changes in blood flow, ion or water balance, and is enclosed by a rigid container. It is thus potentially very vulnerable. Its response to the substantial changes in PV and circulating hormone concentrations, both vasoconstrictor and vasodilator, is distinct from that of other vascular beds and is geared to maintaining the status quo through autoregulation. Cerebral blood flow does appear to be unchanged during pregnancy [25].

The gastrointestinal system

Taste often alters very early in pregnancy. The whole intestinal tract has decreased motility during the first two trimesters, with increased absorption of water and salt, tending to increase constipation. Heartburn is common as a result of increased intragastric pressure. Hepatic synthesis of albumin, plasma globulin and fibrinogen increases, the latter two sufficiently to give

increased plasma concentrations despite the increase in PV. Total hepatic synthesis of globulin increases under oestrogen stimulation, so the hormone-binding globulins rise. There is decreased hepatic extraction of circulating amino acids.

The gallbladder increases in size and empties more slowly during pregnancy but the secretion of bile is unchanged. Cholestasis is almost physiological in pregnancy and may be associated with generalized pruritus but only rarely produces jaundice. However, when cholestasis of pregnancy is severe, adverse pregnancy outcomes are increasingly likely [26].

Energy requirements

The energy cost of pregnancy includes 'stored' energy in maternal and fetal tissues, and the greater energy expenditure needed for maintenance and physical activity. The weight gained during pregnancy arises from the products of conception, the increased size of maternal tissues such as the uterus and breasts, and the greater maternal fat stores. The basal metabolic rate has risen by about 5% by the end of pregnancy in a woman of normal weight [27]. The average weight gain over pregnancy in a woman of normal body mass index (BMI) is about 12.5 kg. The average weight gain from pre-pregnancy values at 6–18 months after delivery is 1–2 kg, but in about one-fifth of women can be 5 kg or more [28]. Obese women usually put on less weight during pregnancy, but retain more post partum, partly dependent on the distribution of abdominal fat before pregnancy. A 5-year follow-up of nearly 3000 women found that parous women gained 2–3 kg more than nulliparous women during this time. They also had significantly greater increases in waist/hip ratio, an independent risk factor for future cardiovascular disease [29].

Carbohydrates/insulin resistance

Pregnancy is hyperlipidaemic and glucosuric. Although neither the absorption of glucose from the gut nor the half-life of insulin seem to change and the insulin response is well maintained, by 6–12 weeks' gestation fasting plasma glucose concentrations have fallen by 0.11 mmol/L, and by the end of the first trimester the increase in blood glucose following a carbohydrate load is less than outside pregnancy [30]. This increased sensitivity stimulates glycogen synthesis and storage, deposition of fat and transport of amino acids into cells. The uptake of amino acids by the mother for gluconeogenesis may also be enhanced. After mid-pregnancy, resistance to the action of insulin develops progressively and plasma glucose concentrations rise, though remaining below non-pregnant levels (Fig. 1.7). Glucose crosses the placenta readily and the fetus uses glucose as its primary energy substrate, so this rise is presumably beneficial to the fetus. Fetal and maternal glucose concentrations are significantly correlated.

The insulin resistance is presumably largely endocrine driven, possibly via increased cortisol or human placental lactogen. Plasma leptin concentrations are directly correlated with insulin resistance during pregnancy [31] while concentrations of glucagon and the catecholamines are unaltered. Serum adiponectin, which enhances insulin sensitivity and stimulates glucose uptake in skeletal muscle, is increased in early pregnancy, falling over the second half of gestation. Adiponectin concentrations are also low in other insulin-resistant states, but whether this is cause or effect is still uncertain. High concentrations of adiponectin in early pregnancy may enhance

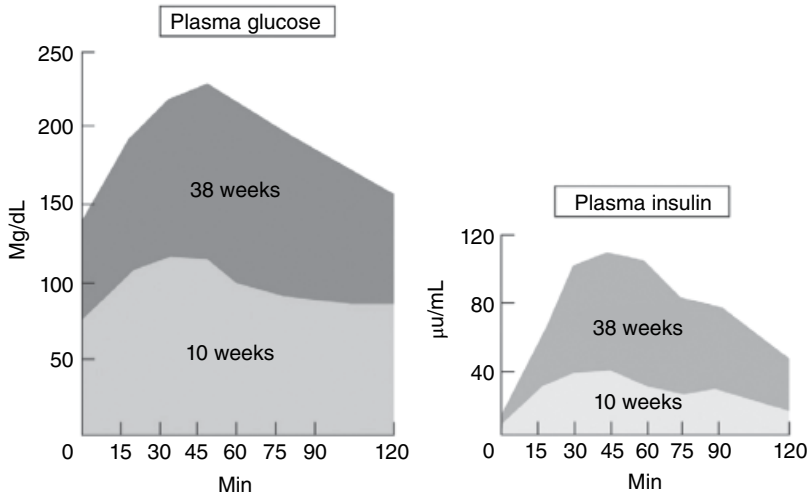

Fig. 1.7 Responses in normal pregnant women to a 50-g oral glucose load during early and late pregnancy. During early pregnancy there is a normal plasma insulin response with a relative reduction in plasma glucose concentrations compared with the non-pregnant state. In contrast, during late pregnancy plasma glucose concentrations reach higher levels after a delay despite a considerably enhanced insulin response, a pattern which could be explained by relative resistance to insulin.

maternal accumulation of nutrients, while the subsequent fall in adiponectin facilitates allocation of nutrients to the fetus. There is an inverse association between maternal serum adiponectin and fetal growth across the full range of birthweights [32].

Lipids

Serum total and low-density lipoprotein (LDL) cholesterol fall early in pregnancy, reaching their lowest levels at 6–8 weeks, but then rising to term; the early fall in AIx has been linked to the fall in LDL [11]. Conversely, high-density lipoprotein (HDL) cholesterol rises significantly by 6–8 weeks. There is a striking increase in circulating free fatty acids and complex lipids in pregnancy, with approximately threefold increases in very low density lipoprotein (VLDL) triglycerides and a 50% increase in VLDL cholesterol by 36 weeks [33], which is probably driven by oestrogens. Birthweight and placental weight are directly related to maternal VLDL triglyceride levels at term. The hyperlipidaemia of normal pregnancy is not atherogenic because the pattern of increase is not that of atherogenesis, although pregnancy can unmask pathological hyperlipidaemia.

Lipids undergo peroxidation in all tissues as part of normal cellular function. Excess production of lipid can result in oxidative stress, with damage to the cell membrane. During normal pregnancy, increases in plasma lipid peroxides appear by the second trimester in step with the general rise in lipids and may taper off later in gestation [34]. As the peroxide levels rise so do those of vitamin E and some other antioxidants; this rise is proportionately greater than that of peroxides so physiological activities are protected. Lipid peroxidation is also active in the placenta, increasing with gestation. Since the placenta contains high concentrations of unsaturated fats under conditions of low PaO_2, antioxidants such as vitamin A, the carotenoids and provitamin A carotenoids are required to protect both mother and fetus from free radical activity.

Early in pregnancy fat is deposited but from mid-pregnancy it is also used as a source of energy, mainly by the mother so that glucose is available for the growing fetus [35] and to provide energy stores for the high metabolic demands of late pregnancy and lactation. The accurate measurement of pregnancy-related fat deposition is technically difficult, but total accretion is estimated at about 2–6 kg. The absorption of fat from the intestine is not directly altered during pregnancy. The hormone leptin acts as a sensor, alerting the brain to the extent of body fat stores. Concentrations rise threefold during pregnancy and are directly correlated with total body fat; they are not related to the basal metabolic rate during gestation. Recent animal studies suggest that the hypothalamus, which contains the appetite-regulating centres, is desensitized to the effects of leptin in pregnancy. This allows the mother to eat more than she otherwise would consider doing, with consequent fat deposition.

Endocrine systems

The placenta is a powerhouse of hormone production from the beginning of gestation and challenges the mother's autonomy.

Placental hormones

hCG is the signal for pregnancy, but indirect effects, such as the oestrogen-driven increased hepatic synthesis of the binding globulins for thyroxine, corticosteroids and the sex steroids, also affect the mother's endocrinological function. The fetoplacental unit synthesizes very large amounts of oestrogens and progesterone, both probably being concerned with uterine growth and quiescence and with mammary gland development. However, they also stimulate synthesis of a variety of other important hormones. Oestrogens stimulate both the synthesis of the pro-angiogenic vascular endothelial growth factor (VEGF) and its tyrosine kinase receptors (see below) and angiogenesis; the two are linked. VEGF appears to interact with other placentally produced hormones and angiopoietin 2 as major players in the development of the villous capillary bed in early human pregnancy. Trophoblasts express the transmembrane tyrosine kinase receptor Flt-1 which mediates the response to VEGF-A and placental growth factor (PlGF). The soluble isoform sFlt-1 also binds VEGF-A and PlGF, but antagonizes their pro-angiogenic actions due to lack of intracellular effector regions. Levels of sFlt-1 released to the maternal circulation rise during normal pregnancy. The oxygen-sensitive transcriptional activator hypoxia-inducible factor (HIF)-1 plays a major part in the response to hypoxic conditions and is a primary regulator of angiogenesis, acting synergistically with VEGF, PlGF and the angiopoietins [36].

The peroxisome proliferator-activated receptor γ (PPARγ) is a member of the nuclear receptor superfamily and has an important role in modulating expression of numerous other genes. It is expressed in human villous and extravillous cytotrophoblast. PPARγ binds to, and is activated by, natural ligands such as eicosanoids, fatty acids and oxidized LDLs. Studies in knockout mice have shown it to be essential for placental development.

The corpus luteum, uterus and placenta synthesize relaxin, structurally very similar to insulin, during pregnancy, plasma concentrations peaking at the end of the first trimester. It is thought to regulate VEGF in very

early pregnancy and, by its effects on extracellular matrix components, stimulate uterine growth and remodelling of the spiral arteries. It may also be concerned with the systemic vascular response to pregnancy. There is wide inter-species variability, and data from animal studies should be viewed with caution [37].

The hypothalamus and pituitary gland

The pituitary gland increases in weight by 30% in first pregnancies and by 50% subsequently. The number of lactotrophs is increased and plasma prolactin begins to rise within a few days of conception and by term may be 10–20 times as high as in the non-pregnant woman; the secretion of other anterior pituitary hormones is unchanged or reduced. hCG and the gonadotrophins share a common α-subunit, and the rapidly rising hCG concentration suppresses secretion of both follicle-stimulating hormone and luteinizing hormone, thus inhibiting ovarian follicle development by a blunting of response to gonadotrophin-releasing hormone. Thyroid-stimulating hormone (TSH) secretion responds normally to hypothalamic thyrotropin-releasing hormone (also synthesized in the placenta). Adrenocorticotrophic hormone (ACTH) concentrations rise during pregnancy, partly because of placental synthesis of ACTH and of a corticotrophin-releasing hormone and do not respond to normal control mechanisms.

The adrenal gland

Both the plasma total and the unbound cortisol and other corticosteroid concentrations rise in pregnancy, from about the end of the first trimester. Concentrations of cortisol-binding globulin double. Excess glucocorticoid exposure *in utero* appears to inhibit fetal growth in both animals and humans. However, the normal placenta synthesizes a pregnancy-specific 11β-hydroxysteroid dehydrogenase, which inhibits transfer of maternal cortisol. The marked rise in secretion of the mineralocorticoid aldosterone in pregnancy has already been mentioned. Synthesis of the weaker mineralocorticoid 11-deoxycorticosterone is also increased by the eighth week of pregnancy, and actually increases proportionally more than any other cortical steroid, possibly due to placental synthesis.

The measurement of plasma catecholamines has inherent difficulties, but there is now broad consensus that plasma catecholamine concentrations fall from the first to the third trimester. There is some blunting of the rise in noradrenaline (reflecting mainly sympathetic nerve activity) seen on standing and isometric exercise in pregnancy, but the adrenaline response (predominantly adrenal) is unaltered [38].

The thyroid gland

hCG may suppress TSH in early pregnancy because they share a common α-subunit. The thyroid remains normally responsive to stimulation by TSH and suppression by triiodothyronine (T3). There is a threefold rise in the thyroid's clearance of iodine, allowing the absolute iodine uptake to remain within the non-pregnant range. Thyroid-binding globulin concentrations double during pregnancy, but other thyroid-binding proteins do not increase. Overall, free plasma T3 and thyroxine (T4) concentrations remain at the same levels as outside pregnancy (although total levels are raised), and most pregnant women are euthyroid. Free T4 may fall in late gestation [39].

Calcitonin, another thyroid hormone, rises during the first trimester, peaks in the second and falls thereafter, although the changes are not large. It may contribute to the regulation of 1,25-dihydroxyvitamin D.

The parathyroid glands and calcium metabolism

Calcium homeostasis changes markedly in pregnancy [40,41]. Maternal total plasma calcium falls because albumin concentration falls, but unbound ionized calcium is unchanged. Synthesis of 1,25-dihydroxycholecalciferol increases, promoting enhanced gastrointestinal calcium absorption. Parathyroid hormone (PTH) regulates the synthesis of 1,25-dihydroxyvitamin D in the proximal convoluted tubule. There is a fall in intact PTH during pregnancy but a doubling of 1,25-dihydroxyvitamin D; PTH-related protein (PTHrP) is also present in the maternal circulation. The main sources of PTHrP are the fetal parathyroid gland and the placenta. It is presumably placentally derived PTHrP that is transferred into the maternal circulation and affects calcium homeostasis by acting through the PTH receptor.

Renal hormones

The renin–angiotensin system is activated from very early in pregnancy (see section Cardiovascular system). A vasodilator component to the renin–angiotensin system has recently been described in which angiotensin 1–7 is the agonist; angiotensin 1–7 rises during pregnancy and may stimulate release of both nitric oxide and prostacyclin. Synthesis of erythropoietin appears to be stimulated by hCG; its concentration rises from the first trimester, peaking in mid-gestation and falling somewhat thereafter. Prostacyclin is a potent vasodilator, synthesized mainly in the renal endothelium. Concentrations begin to rise rapidly by 8–10 weeks of gestation, being

fourfold higher than non-pregnant values by the end of the first trimester.

The pancreas

The size of the islets of Langerhans and the number of β cells increase during pregnancy, as does the number of receptor sites for insulin. The functions of the pancreas in pregnancy are considered above.

The endothelium

The endothelium synthesizes a variety of hormones, both vasodilator (e.g. prostacyclin, VEGF-A, nitric oxide) and vasoconstrictor (e.g. endothelin-1). The vasodilators are mostly upregulated in pregnancy, and allow the early fall in total peripheral resistance. Interestingly, although the lipid profile in pregnancy appears to be atherogenic, endothelial function in normal pregnancy, as assessed by flow-mediated dilatation, is not impaired. This may be due to the increased estradiol concentrations, which upregulate endothelial nitric oxide synthase.

Conclusion

This chapter attempts, very briefly, to outline the physiology of normal pregnancy. The changes mostly begin very early indeed, and it may be that two of the major problems of pregnancy – intrauterine growth retardation and pre-eclampsia – are initiated even before the woman knows that she is pregnant. Better understanding of the mechanisms of very early normal pregnancy adaptation may help us to understand the abnormal.

Summary box 1.1

- Each ovulatory menstrual cycle prepares the potential mother for the physiological changes of pregnancy. Progesterone is the prime mover, and before conception initiates such changes as increased tidal volume, heart rate and GFR, as well as endometrial priming. These changes are proactive, not reactive, and in normal pregnancy are greater than physiologically necessary.
- Early pregnancy is associated with a systemic inflammatory response. The mother's immune response is altered to allow implantation and placentation and the remodelling of the spiral arteries.
- Total peripheral resistance falls very early, followed by the peripheral and central blood pressure; plasma volume and cardiac output rise. Alveolar ventilation and oxygen-carrying capacity increase more than oxygen consumption. Even normal pregnancy is associated with low-grade coagulopathy.
- Renal filtration increases very early. The rise in filtered sodium load activates the renin–angiotensin system, allowing sodium retention and the increased plasma volume. Plasma concentrations of various analytes are reduced because of both increased filtration and plasma volume expansion. Aminoaciduria and glycosuria are common.
- The average weight gain over pregnancy in a woman of normal BMI is about 12.5 kg. Some of this is usually retained after delivery. Pregnancy is associated with insulin resistance and hyperlipidaemia; there is considerable fat deposition.
- The placenta is a powerhouse of hormone and cytokine synthesis, modifying the mother's physiology for the demands of pregnancy.

The Placenta and Fetal Membranes

Berthold Huppertz[1] *and John C.P. Kingdom*[2]

[1] *Department of Cell Biology, Histology and Embryology, Gottfried Schatz Research Center, Medical University of Graz, Graz, Austria*
[2] *Department of Obstetrics and Gynaecology, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada*

The placenta was already recognized and venerated by the early Egyptians, while it was the Greek physician Diogenes of Apollonia (*c.* 480 BC) who first ascribed the function of fetal nutrition to the organ. Aristotle (384 to 322 BC) reported that the chorionic membranes fully enclose the fetus, but it was only in 1559 during the Renaissance that Realdus Columbus introduced the term 'placenta', derived from the Latin for a flat cake.

Structural characteristics of the human placenta

Placental shape

On the gross anatomical level, the placenta of eutherian animals can be classified according to the physical interactions between fetal and maternal tissues [1]. Such interactions may be restricted to specific sites or may be found covering the whole surface of the chorionic sac and the inner uterine surface. On this gross anatomical level, the human placenta is classified as a *discoidal* placenta, confining interactions to a more or less circular area (Fig. 2.1a).

Materno-fetal interdigitations

The next level of classification is based on the interdigitations between maternal and fetal tissues [1]. In the human placenta maternal and fetal tissues are arranged is such a way that there are three-dimensional tree-like structures called *villous trees* of fetallly derived tissues that float in a vascular space filled with maternal blood. Like the structure of a tree with leaves, the placental villi repeatedly branch into progressively smaller and slender gas-exchanging villi (Fig. 2.1b). On the maternal side blood vessels are eroded, resulting in an open circulation of maternal blood within the vascular space of the placenta. The placental villi are in direct contact with maternal blood with no intervening layer of maternal endothelial cells.

Materno-fetal barrier

Following implantation of the blastocyst within the decidualized endometrium, the outer trophoblast cells gradually erode into the surrounding maternal uterine stroma, breaching capillaries to direct maternal blood towards the placenta where the developing villi are forming. At the cellular level, this type of implantation is termed *invasive placentation* [1]. The fetally derived epithelial layer, termed villous trophoblast, covers the placental villi; it comes into direct contact with maternal blood and functions as the placental barrier between maternal and fetal tissues (Fig. 2.1c).

This type of placentation is termed *haemomonochorial* since on the maternal side blood makes direct contact rather than via blood vessels (haemo) while on the fetal side there is a single intact layer of trophoblast (monochorial) between maternal blood and the fetal vascular compartment (Fig. 2.1c).

Vascular arrangement

The diffusion efficiency of the human placenta depends on the extent of elaboration and development of the placental villi, with the more specialized terminal villi being the site of maximal diffusional exchange. An additional important determinant is the direction of maternal and fetal blood flows in relation to each other [1]. The optimal

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

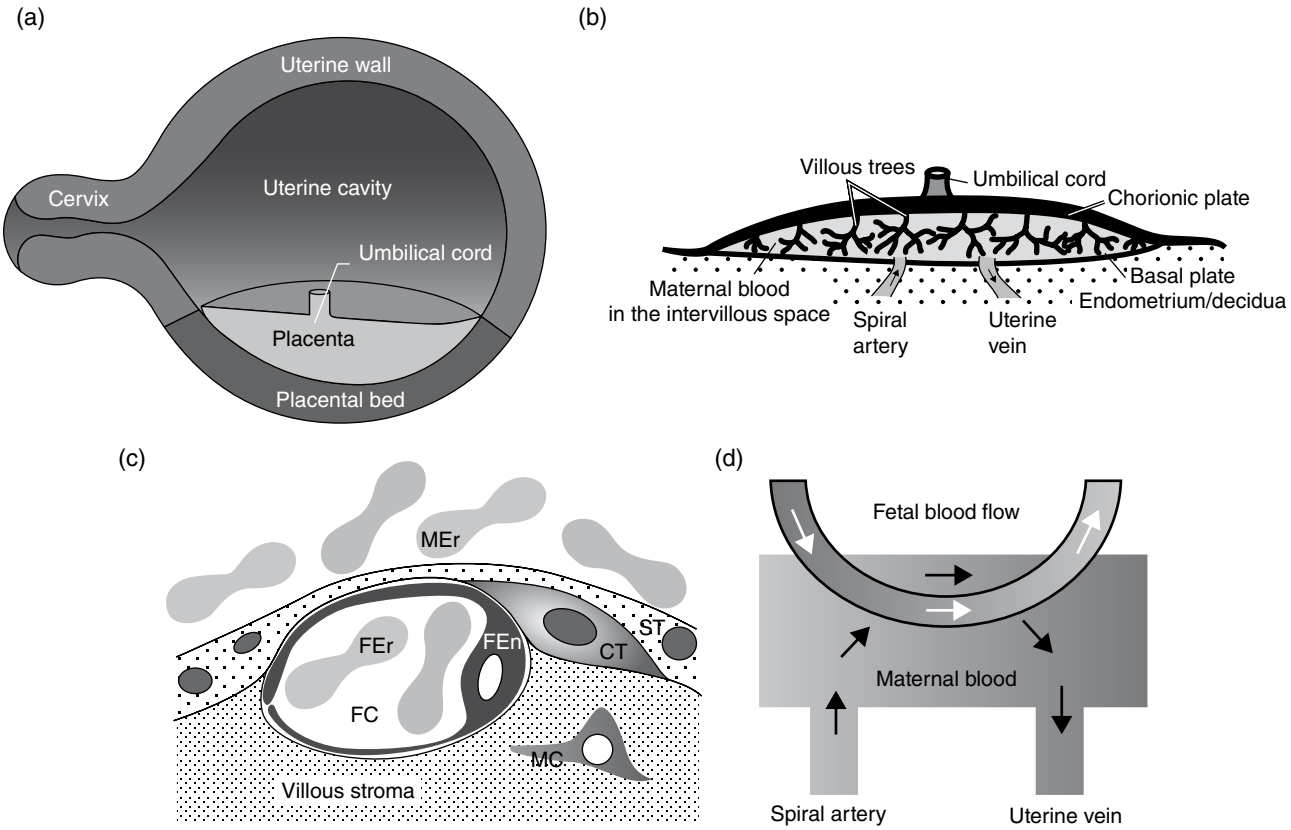

Fig. 2.1 Schematic representation of the structural characteristics of the human placenta. (a) The human placenta displays a discoidal shape. (b) The materno-fetal interdigitations are arranged in villous trees bathing in maternal blood that floats through the intervillous space. (c) The haemochorial type of placentation results in a materno-fetal barrier composed of villous trophoblast in direct contact with maternal blood. (d) Fetal and maternal blood flows are arranged in a multivillous flow. CT, cytotrophoblast; FC, fetal capillary; FEn, fetal endothelium; FEr, fetal erythrocyte; MC, mesenchymal cells; MEr, maternal erythrocyte; ST, syncytiotrophoblast.

design is counter-current, but due to the complex arrangement of the human placental villous trees, this is less efficient than in some other species, such as the guinea pig. The variable flow pattern in humans has been termed *multivillous flow* (Fig. 2.1d).

Summary box 2.1

- Macroscopically, the human placenta has a discoidal shape.
- The interdigitations between maternal and fetal tissues are arranged as follows: tree-like structures (villous trees) of the placenta are surrounded by a multivillous flow pattern of maternal blood.
- The epithelial covering of the villous trees, the villous trophoblast, represents the placental barrier between maternal blood and fetal tissues (haemomonochorial placentation).

Macroscopic features of the term placenta

Measures

The placenta displays typical macroscopic features after delivery at term [1]. The term placenta shows a round disc-like appearance, with the insertion of the umbilical cord in a slightly eccentric position on the fetal side of the placenta. The average measurements of a delivered placenta at term are as follows: diameter 22 cm, central thickness 2.5 cm, and weight 450–500 g. One has to keep in mind, though, that considerable variation in gross placental structure can occur in normal term pregnancies. In part, this is due to the fact that the human placenta comprises 30–50 operational units termed *placentomes*, whose aggregated shape may vary without compromise to the function of individual units.

Tissue arrangements

The tissues of the term placenta display a specific organization [1]. On the fetal side of the placenta, the *amnion* covers the *chorionic plate*. The amnion is assembled by a single-layered cuboidal epithelium fixed to an avascular layer of mesenchymal tissue. Beneath the amnion, the chorionic mesenchymal tissue layer contains the chorionic plate vessels that are direct continuations of those within the umbilical cord. These chorionic plate vessels penetrate to supply the fetally derived vessels within the villous trees where the capillary system, between arteries and veins, is located within the so-called gas-exchanging terminal villi. Hence, the chorionic vessels connect the fetal circulation (via the umbilical cord) with the placental circulation within the villous trees of the placenta. The villous trees hang down from the chorionic plate, floating within a vascular space filled with maternal blood. The villous trees are connected via a major trunk (stem villus) to the chorionic plate and display multiple sites of branching, finally ending in terminal villi. On the maternal side of the placenta, the *basal plate* is located (Fig. 2.1b). It is an artificial surface generated by separation of the placenta from the uterine wall during delivery. The basal plate is a colourful mixture of fetal trophoblasts and maternal cells of the decidua, all of which are embedded in trophoblast-secreted matrix-type fibrinoid, decidual extracellular matrices, and blood-derived fibrin-type fibrinoid. At the placental margin, chorionic plate and basal plate fuse with each other, thereby closing the intervillous space such that the remainder of the uterine cavity is lined by the *fetal membranes* or *chorion laeve*.

Summary box 2.2

The layers of a delivered placenta from the fetal to the maternal side comprise:

- avascular amnion (epithelium and mesenchyme)
- vascularized chorionic plate (mesenchyme with blood vessels)
- villous trees directly connected to the chorionic plate
- maternal blood in the intervillous space surrounding the villous trees
- basal plate with a mixture of fetal and maternal cells.

Placental development

Trophoblast lineage

At the transition between morula and blastocyst, the trophoblast lineage is the first to differentiate from the inner cell mass or embryoblast (Fig. 2.2) [1]. Following attachment of the blastocyst to the endometrial epithelium, further differentiation of the trophoblast occurs. Exact knowledge of the underlying molecular processes in the human is still lacking, but at this stage the first event is the creation of an outer layer of fused trophoblast cells, termed the *outer syncytiotrophoblast*. This outer syncytiotrophoblast generated by fused trophoblasts is in direct contact with maternal tissues and thus is the first layer from the conceptus to encounter and subsequently penetrate the uterine epithelium capillaries (Fig. 2.2).

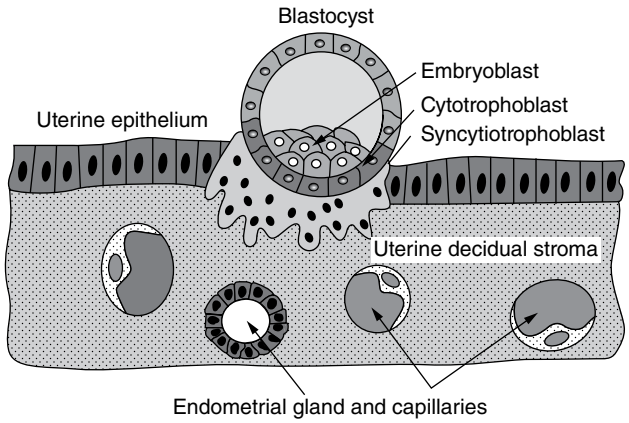

Fig. 2.2 During implantation of the blastocyst, trophoblast cells in direct contact with maternal tissues syncytially fuse and give rise to the syncytiotrophoblast. Only this multinucleated tissue is able to penetrate the uterine epithelium and to implant the developing embryo.

Prelacunar stage

At day 7–8 post conception, the blastocyst has completely crossed the uterine epithelium to become embedded within the decidualized endometrial stroma. The developing embryo is completely surrounded by the growing placenta, which at that stage consists of the two fundamental subtypes of the trophoblast. The multinucleated syncytiotrophoblast is in direct contact with maternal tissues, while the mononucleated cytotrophoblast as the stem cell layer of the trophoblast is directed towards the embryo.

All the differentiation and developmental stages of the placenta described so far take place before fluid-filled spaces within the syncytiotrophoblast develop. This is why this stage is termed 'prelacunar' [1].

Lacunar stage

At day 8–9 post conception, the syncytiotrophoblast generates a number of fluid-filled spaces within its mass (*lacunar stage*) [1]. These spaces flow together forming larger lacunae, and finally embed parts of the

syncytiotrophoblast (trabeculae) that cross the syncytial mass from the embryonic to the maternal side.

At the end of this stage, at day 12 post conception, the process of implantation is completed. The developing embryo with its surrounding extraembryonic tissues is completely embedded in the decidualized endometrium, and the syncytiotrophoblast surrounds the whole surface of the conceptus. Mesenchymal cells derived from the embryo spread over the inner surface of the trophoblast (extraembryonic mesoderm), thus generating an additional mesenchymal layer on top of the inner surface of the trophoblast, termed *chorion*.

The development of the lacunar system subdivides the placenta into its three compartments.

1) The embryonically oriented part of the trophoblast together with the extraembryonic mesoderm (chorion) will develop into the *chorionic plate*.
2) The trabeculae will become the anchoring villi, attaching the placenta proper to the uterine wall. The side branches growing out of the trabeculae will develop into *floating villi*. The lacunae surrounding the villi will turn into the *intervillous space* that will subsequently fill with maternal blood at the end of the first trimester.
3) The maternally oriented part of the trophoblast together with components of maternal decidual tissues will develop into the *basal plate*.

Early villous stage

Very early in pregnancy, specific types of villi develop as the forerunners of the placental villous tissues seen later in pregnancy [1]. Starting at day 12 post conception, proliferation of cytotrophoblast pushes trophoblasts to penetrate the syncytial trabeculae, reaching the maternal side of the syncytiotrophoblast by day 14. Further proliferation of trophoblasts inside the trabeculae (day 13) stretches the trabeculae, resulting in the development of syncytial side branches filled with cytotrophoblasts (*primary villi*).

Shortly after, the mesenchymal cells from the chorion follow the cytotrophoblast and penetrate the trabeculae and the primary villi, thus generating *secondary villi* with a mesenchymal core. At this stage, there is always a complete cytotrophoblast layer between penetrating mesenchyme and syncytiotrophoblast.

Around day 20–21 post conception, vascularization (development of new vessels from haemangioblastic precursor cells) within the villous mesenchyme gives rise to the formation of the first placental vessels (*tertiary villi*). Only later will the proximal connection to the vascular system of the embryo proper be established via the umbilical cord.

Placental villi are organized in villous trees that cluster together into a series of spherical units known as lobules or placentomes. Each placentome originates from the chorionic plate by a thick villous trunk stemming from a trabecula. Continuous branching of the main trunk results in the formation of floating villi that branch and end freely as terminal villi in the intervillous space.

Trophoblastic cell columns

During penetration of the syncytial trabeculae, the cytotrophoblasts reach the maternal decidual tissues while the subsequently penetrating mesenchymal cells do not infiltrate to the tips of the trabeculae [1]. Hence, at the tips of the anchoring villi multiple layers of cytotrophoblasts develop, referred to as trophoblastic *cell columns* (Fig. 2.3) [1]. Only those cytotrophoblasts remain as proliferative stem cells that are in direct contact with the basement membrane separating trophoblast from mesenchyme of the anchoring villi.

Subtypes of extravillous trophoblast

The formation of cell columns does not always result in a complete layer of trophoblastic shell but rather may be organized as separated columns from which extravillous trophoblasts invade into maternal uterine tissues (Fig. 2.3). All these cells migrate as *interstitial trophoblast* into the decidual stroma [1]. The interstitial trophoblast invades the whole thickness of the decidua and penetrates the inner third of the myometrium. Here, invasion normally stops and no extravillous trophoblast can be seen in the outer third of the myometrium.

Following this main direction of invasion, extravillous trophoblasts may invade via other specific routes. One subset of interstitial trophoblasts penetrates the walls of uterine spiral arteries and veins (*intramural trophoblast*), finally reaching the vessel lumen (*endovascular trophoblast*) (Fig. 2.3) [2]. Another subset of interstitial trophoblasts penetrates the walls of uterine glands, finally opening such glands towards the intervillous space (*endoglandular trophoblast*) (Fig. 2.4) [3]. Finally, some of the interstitial trophoblasts may fuse and thus develop into *multinucleated trophoblast giant cells* (Fig. 2.4) at the boundary between endometrium/decidua and myometrium [1].

Plugging of spiral arteries

Invasion of extravillous trophoblasts is the ultimate means to transform maternal arteries into large-bore conduits to enable adequate supply of oxygen and nutrients to the placenta and the fetus [1,2]. However, free transfer of maternal blood to the intervillous space is

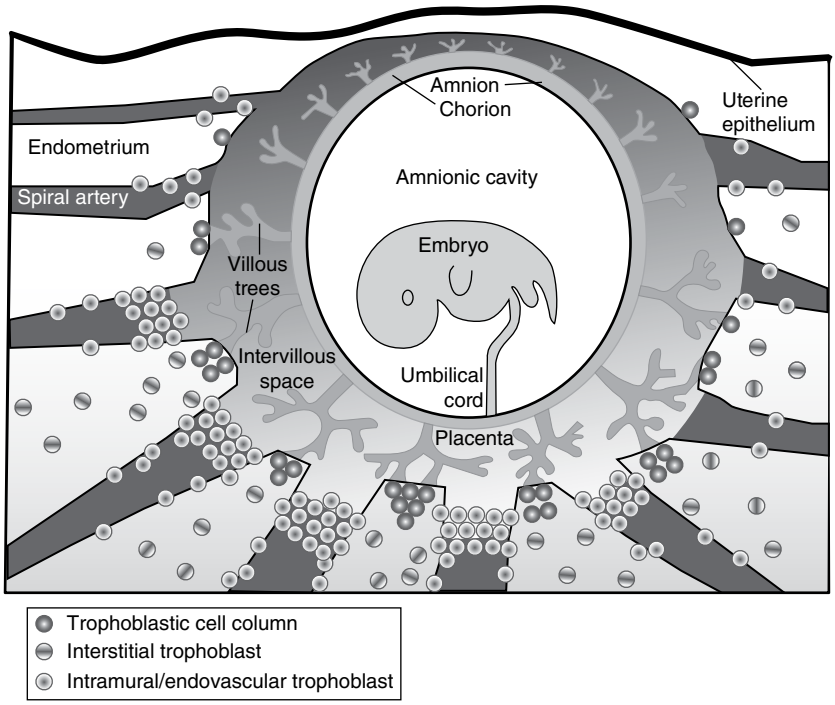

Fig. 2.3 Schematic representation of the developing embryo and its surrounding tissues at about 8–10 weeks of pregnancy. The amnionic cavity with the embryo inside is marked off by the amnion that has already contacted the chorion. From the chorion, villous trees protrude into the intervillous space where some villi have direct contact with the basal plate (anchoring villi). At these sites trophoblastic cell columns are the source for all extravillous trophoblast cells invading maternal tissues. Interstitial trophoblast cells derived from these columns invade endometrium and myometrium, while a subset of these cells penetrates the uterine arteries and veins first as intramural and then as endovascular trophoblast cells. Onset of maternal blood flow into the placenta starts in the upper regions of the placenta (the abembryonic pole) where development is slightly delayed. The locally high concentrations of oxygen contribute to the regression of villi at the abembryonic pole. This in turn leads to the formation of the smooth chorion, the fetal membranes.

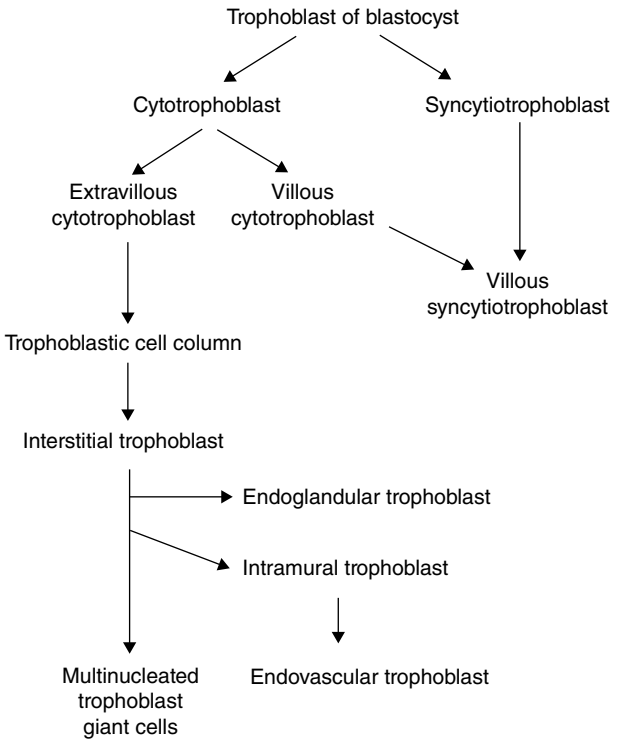

Fig. 2.4 Trophoblast differentiation and subtypes. The trophoblast lineage is the first to develop at the blastocyst stage. From this stage onwards, further differentiation leads to the generation of the syncytiotrophoblast and subsequently to the two main trophoblast types of placental villi, villous cytotrophoblast and villous syncytiotrophoblast. The trophoblast cells that start to invade maternal tissues are termed extravillous trophoblast. From the interstititat trophoblast all other subtypes of extravillous trophoblast develop.

only established at the end of the first trimester of pregnancy [4]. Before that, the extent of invasion and thus the number of endovascular trophoblasts is so great that the trophoblasts aggregate within the arterial lumen, plugging the distal segments of the spiral arteries (Fig. 2.3). Hence, before about 12 weeks of gestation, the intervillous space contains mostly a plasma filtrate that is free of maternal blood cells. To aid in nutritional support of the embryo, glandular secretion products from eroded uterine glands (*histiotrophic nutrition*) add to the fluids filling the intervillous space (Fig. 2.3) [3,5].

The reason for such paradoxical plugging of already eroded and transformed arteries may be because the lack of blood cells keeps the placenta and the embryo in a low oxygen environment of less than 20 mmHg in the first trimester of pregnancy. This low oxygen environment may be necessary to drive angiogenesis and at the same time reduce formation of free radicals that could damage the growing embryo in this critical stage of tissue and organ development [6].

Onset of maternal blood flow

At the end of the first trimester trophoblastic plugs within the spiral arteries break up to allow maternal blood cells to enter the intervillous space, thereby establishing the first arterial blood flow to the placenta (*haemotrophic nutrition*) [4]. The inflow starts in those upper parts of the placenta that are closer to the endometrial epithelium (the *abembryonic pole* of the placenta) (Fig. 2.3) [6]. These sites are characterized by a slight

delay in development since the deeper parts at the *embryonic pole* have been the first to develop directly after implantation (Fig. 2.3). Therefore, at these upper sites the plugs inside the vessels contain fewer cells, enabling blood cells to penetrate the plugs earlier, and blood flow starts at these sites first, maybe even weeks prior to the embryonic pole. Because of the massive increase in oxygenation at this time (around weeks 8–10) at the abembryonic pole, placental villi degenerate in larger parts and the chorion becomes secondarily smooth. The regression leads to the formation of the fetal membrane or *chorion laeve* [6]. The remaining part of the placenta develops into the *chorion frondosum*, the definitive disc-shaped placenta.

Summary box 2.3

- Blastocyst stage: differentiation of the trophoblast lineage.
- Day 7–8 post conception: prelacunar stage of placental development.
- Day 8–9 post conception: lacunar stage of placental development.
- Day 12 post conception: implantation completed, embryo completely surrounded by placenta.
- Day 14 post conception: differentiation of extravillous trophoblast.
- Day 20 post conception: development of placental vessels and blood cells independent of vessel development in the embryo proper.
- First trimester: histiotrophic nutrition.
- Week 12: onset of maternal flow within the intervillous space, development of the chorion laeve.
- Second and third trimester: haemotrophic nutrition.

Basic structure of villi

Villous trophoblast

The branches of the syncytial trabeculae are the forerunners of the placental villi [1]. Throughout gestation the syncytial cover remains and forms the placental barrier between maternal blood in the intervillous space and the fetal vessels within the mesenchymal core of the villi.

Villous cytotrophoblast

The layer of mononucleated villous cytotrophoblast cells is the basal layer of the villous trophoblast compartment resting on the basement membrane underneath the multinucleated layer of syncytiotrophoblast (see Fig. 2.1c) [1]. Villous cytotrophoblasts are a heterogeneous population: a subset proliferates throughout gestation (in contrast to the mouse, which terminally differentiates its chorionic trophoblast in mid-gestation), some exhibit a progenitor status because they can be induced to differentiate along the extravillous pathway, while others are in varying stages of differentiation, preparing for syncytial fusion directed by the transcription factor GCM1 (glial cell missing-1) [7].

The number of villous cytotrophoblasts continuously increases during pregnancy, from about 1×10^9 at 13–16 weeks to about 6×10^9 at 37–41 weeks of gestation [1]. These cells are gradually dispersed into a discontinuous layer in the third trimester due to the rapid expansion and specialization of the villous core that can mostly be found in combination with peripheral placental villi responsible for gas and nutrient exchange.

Villous cytotrophoblasts do not normally come into direct contact with maternal blood, unless focal damage occurs to the overlying syncytiotrophoblast: if focal areas of syncytiotrophoblast are lost, for example due to focal necrosis, the deficit is filled with *fibrin-type fibrinoid* (a maternal blood clot product) that covers the exposed cytotrophoblasts [1].

Villous syncytiotrophoblast

The *syncytiotrophoblast* is a multinucleated layer without lateral cell borders, hence there is a single syncytiotrophoblast covering all villi of a single placenta [1]. Microvilli on its apical surface provide amplification of the surface (sevenfold) and are in direct contact with maternal blood floating within the intervillous space (see Fig. 2.1c). Growth and maintenance of the syncytiotrophoblast is dependent on fusion with the underlying cytotrophoblasts, since syncytial nuclei do not divide and thus the syncytiotrophoblast does not proliferate.

Within the syncytiotrophoblast the incorporated nuclei first exhibit a large and ovoid shape, while during maturation they become smaller and denser. Finally, they display envelope convolution, increased packing density and increased heterochromatinization [8]. These are typical features of progression along the apoptosis pathway, a physiological process in the normal placenta. Interestingly, late apoptosis is extremely rare in the cytotrophoblast but may occur in a subset of cytotrophoblasts that fail to undergo syncytial fusion [9].

During gestation, syncytial fusion of cytotrophoblasts with the overlying syncytiotrophoblast more than meets the needs for growth of the placental villi [1]. Continuous syncytial fusion brings new cellular material into the syncytiotrophoblast including proteins related to apoptosis, such as caspase 8 or Bcl-2 and Mcl-1, the latter two of which focally retard apoptosis [9,10]. Those syncytial nuclei that have very recently entered the syncytial layer are still capable of RNA trancription [11,12]. However,

syncytial fusion remains critical for maintaining the functional and structural integrity of the syncytiotrophoblast, for example secretion of hormones such as chorionic gonadotrophin and the surface expression of energy-dependent transporters for the uptake of molecules such as glucose or amino acids. Consequently, nuclei that are incorporated into the syncytiotrophoblast remain within this layer for about 3–4 weeks. Then, the older nuclei accumulate and are packed into protrusions of the apical membrane known as *syncytial knots* [1,8].

Villous trophoblast turnover

Like every epithelium, the villous trophoblast exhibits the phenomenon of continuous turnover, comprising the following steps [8]:

1) proliferation of a subset of cytotrophoblast progenitor cells;
2) differentiation of post-proliferative mononucleated daughter cytotrophoblasts (2–3 days);
3) syncytial fusion of finally differentiated cytotrophoblasts with the overlying syncytiotrophoblast;
4) further differentiation and maturation of cellular components and organelles within the syncytiotrophoblast (3–4 weeks);
5) ageing and late apoptosis at specific sites of the syncytiotrophoblast;
6) packing of older material into syncytial knots; and finally
7) syncytial knots and smaller micro-particle fractions may be extruded or secreted into the maternal circulation [1].

Syncytial knots that complete the apoptosis cascade may be extruded from the syncytiotrophoblast surface into the maternal circulation [8]. In pathological pregnancies the molecular control of trophoblast differentiation may be altered. In cases of severe early-onset fetal growth restriction (FGR) this physiology is likely disturbed in favour of greater apoptotic shedding, while in cases of pre-eclampsia this physiology is disturbed in favour of both greater apoptotic shedding combined with the release of necrotic and aponecrotic material into the maternal circulation [13,14].

Trophoblast release

Throughout gestation, syncytial knots are released into the maternal circulation and may become lodged in the capillary bed of the lungs. Hence, they can be found in uterine vein blood but not in arterial or peripheral venous blood of a pregnant woman. It has been estimated that in late gestation up to 150 000 such corpuscles or 2–3 g of trophoblast material enter the maternal circulation each day [1].

Current knowledge places the multinucleated syncytial knots as products generated by apoptotic mechanisms [8]. As such, they are surrounded by a tightly sealed plasma membrane and do not release any content into the maternal blood. Hence, induction of an inflammatory response in the mother is not a normal feature of pregnancy. However, during placental pathologies with a disturbed trophoblast turnover such as pre-eclampsia, the release of syncytiotrophoblast material is altered. This necrotic or aponecrotic release of trophoblast material may well contribute to the systemic inflammation and widespread endothelial damage typical in severe pre-eclampsia [8,14].

Villous stroma

The stromal villous core comprises a population of fixed and moving connective tissue cells, including [1]:

- mesenchymal cells and fibroblasts in different stages of differentiation up to myofibroblasts;
- placental macrophages (Hofbauer cells); and
- placental vessels with smooth muscle cells and endothelial cells.

Oxygen as regulator of villous development

There is increasing recognition of the role that oxidative stress inside the placenta plays in the pathophysiology of pregnancy disorders, ranging from miscarriage to pre-eclampsia [1,4,14,15]. During the first trimester, villous trophoblast is well adapted to low oxygen, and it appears that trophoblast is more susceptible to raised oxygen rather than low oxygen [16]. The abembryonic part of the placenta is already oxygenated after mid first trimester (around week 8) by the onset of maternal blood flow [4,6]. Hence, villi at this site display increased evidence of oxidative stress, become avascular, and finally regress. These physiological changes result in the formation of the smooth chorion, the chorion laeve (Fig. 2.3) [4,6].

Maternal blood flow into the embryonic part of the placenta only starts at the transition from the first to the second trimester, at around week 12 [4]. At this time, signs of oxidative stress are obvious within the placenta; however, the placenta proper can cope with these oxygen changes and starts differentiation towards exchange of nutrients and gases. However, if early onset of maternal blood flow and consequently early onset of oxygenation also occurs in the embryonic part of the placenta, damage to the whole placenta will result [4,6]. The most severe cases end up in missed miscarriages, while less severe cases may continue but may lead to pathologies such as pre-eclampsia and IUGR [4,6]. It is becoming increasingly evident that the aetiology of pre-eclampsia

involves increased oxidative stress, mostly without changes in the extravillous subset of trophoblast [14]. Recent data point to hyperoxic changes or to the occurrence of fluctuating oxygen concentrations [17,18].

Summary box 2.4

Villous trophoblast as the outermost epithelial layer of placental villi

- Cytotrophoblast: progenitor cells to maintain the syncytiotrophoblast throughout pregnancy.
- Syncytiotrophoblast: multinucleated, in direct contact with maternal blood.
- Syncytiotrophoblast: shedding of apoptotic material into maternal blood, at the end of gestation about 3 g daily.
- Pre-eclampsia: quantity and quality of syncytial shedding are altered. More non-apoptotic fragments are released, mostly due to necrosis and aponecrosis.
- IUGR: poor development of placental villi reduces oxygen transfer to the fetus with relative placental hyperoxia (rather than placental hypoxia).

Villous stroma

- Mesenchymal cells and fibroblasts.
- Macrophages (Hofbauer cells).
- Vessels with media and endothelium.

Fetal membranes

During early embryonic development, the *amnionic cavity* increases in size and finally surrounds and encases the complete embryo [1]. Fluid accumulation within the amnionic cavity leads to complete separation of the embryo from surrounding extraembryonic tissues, leaving only the developing umbilical cord as the connection between placenta and embryo. The amnionic mesenchyme comes into direct contact with the chorionic mesoderm lining the inner surface of the chorionic sac (Fig. 2.3).

As described earlier, it is only at the implantation/embryonic pole that the definitive placenta develops. The rest of the surface of the chorionic sac (about 70%) displays regression of villi due to early increase in oxygen followed by collapse of the intervillous space at these sites. Subsequently, this results in merging of the early chorionic plate and the amnion on the fetal side with remnants of villi and the covering decidual tissues (*capsular decidua*). This multilayered compact structure is now termed the chorion laeve or fetal membranes [1].

Layers of the chorion laeve

The layers of the chorion laeve, from the fetal to the maternal side, are as follows (Fig. 2.5) [1].

1) *Amnionic epithelium*. A single cuboideal epithelium that secretes and resorbs the amnionic fluid and is involved in removal of carbon dioxide and pH regulation of the amnionic fluid.
2) *Amnionic mesoderm*. A thin layer of avascular connective tissue separated from the amnionic epithelium by a basement membrane.
3) *Chorionic mesoderm*. This second layer of connective tissue is separated from the amnionic mesoderm by slender fluid-filled clefts. It is continuous with the connective tissue of the chorionic plate, which contains the branching vessels to and from the umbilical and villous vessels.
4) *Extravillous trophoblast of the fetal membranes*. This specific type of extravillous trophoblast does not display invasive properties and is separated from the chorionic mesoderm by a basement membrane.
5) *Capsular decidua*. This layer of maternal cells is directly attached to the extravillous trophoblast. At the end of the implantation process, the decidua closes again over the abembryonic pole of the developing embryo, generating the capsular decidua. During the early second trimester, the capsular decidua comes into direct contact with the opposite wall of the uterus, causing obliteration of the uterine cavity.

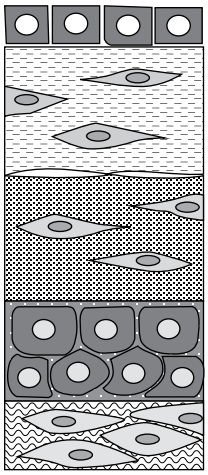

Fig. 2.5 Layers of the fetal membranes. The amnionic epithelium is a simple epithelium that secretes and resorbs the amnionic fluid. The two layers of connective tissues (amnionic and chorionic mesoderm) are separated by fluid-filled clefts. The extravillous trophoblast of the fetal membranes displays a non-invasive phenotype and is embedded in a self-secreted matrix, termed matrix-type fibrinoid. Finally, on the maternal side, the fetal membranes are covered by the capsular decidua of maternal origin.

Characteristics of the chorion laeve

After separation from the uterine wall, the fetal membranes have a mean thickness of about 200–300 μm at term. The presence of the capsular decidua on the outer surface of the fetal membranes after delivery indicates that separation of the membranes takes place between maternal tissues rather than along the materno-fetal interface. Because of the absence of vascular structures inside the connective tissues of the fetal membranes, all paraplacental exchange between fetal membranes and fetus has to pass the amnionic fluid.

Summary box 2.5

Layers of the fetal membranes, the chorion laeve

- Amnionic epithelium
- Amnionic mesoderm
- Chorionic mesoderm
- Extravillous trophoblast
- Decidua capsularis (maternal tissues)

Ultrasound

Transvaginal ultrasound can detect the gestational sac implanting within the decidualized endometrium at the 5–6 week postmenstrual stage of pregnancy. Developmental changes in the structure and organization of the placenta and membranes during the first trimester of pregnancy can be seen by ultrasound [19]. In the second trimester, the organization of the placenta and umbilical cord, together with its maternal blood supply, can be readily defined [20]. Minor anatomical variations, such as cysts and lakes, can readily be distinguished from lesions that destroy functioning villous tissue, such as infarcts and intervillous thrombi. Small placentas typically have eccentric cords, due to chorionic regression, and are a risk factor for early-onset FGR [21]. It is important to document placental location (for placenta praevia) and cord insertion (for vasa praevia) for ongoing management. Pathological placental invasion (placenta percreta), typically in association with placenta praevia and previous caesarean deliveries, may be suspected by ultrasound [22], and can be confirmed by magnetic resonance imaging (MRI) [23].

Doppler ultrasound

Pulsed and colour Doppler ultrasound are valuable techniques for placental assessment [24]. Umbilical cord flow can be visualized at 7–8 weeks, though end-diastolic flow (EDF) is not established until 14 weeks. Early-onset FGR may be characterized by absent EDF in the umbilical arteries even by 22 weeks, associated with small malformed placentas, and defective angiogenesis in the gas-exchanging terminal villi [21].

A major role for Doppler ultrasound in placental assessment is to determine impedance flow in the uterine arteries. This screening test is performed either at the 18–20 week anatomical ultrasound, or at a separate 22-week visit [19]. Integration of placental ultrasound, uterine artery Doppler and first and second trimester biochemistry screening tests (PAPP-A, hCG, PGF) is increasingly appreciated as an effective way of screening for serious placental insufficiency syndromes before achieving fetal viability, thereby directing ongoing care to a tertiary high-risk pregnancy unit [25]. However, in 2015 the American College of Obstetrics and Gynecology concluded that these resource-intensive placental health screening activities should not be adopted in low-risk women, opting instead for the utility of clinical risk assessment methods alone [26].

Subsets of high-risk pregnancies with multiparameter placental dysfunction in the 19–22 week window have up to a 40% positive predictive value for delivery before 32 weeks due to clinical complications of placental insufficiency (FGR, pre-eclampsia, abruption, stillbirth). Placental villous infarction complicates over 60% of such cases yet maternal thrombophilia is rare [25]. Since the normal healthy placenta expresses surface anticoagulant proteins, abnormal formation and perfusion of the placenta may be the underlying cause of multifocal placental infarction. If this is the case, multiparameter placental function testing in subsequent pregnancies may be a better determinant of future risk than maternal thrombophilia screening in the non-pregnant period.

Colour power Doppler

Colour power angiography (CPA) is an extented application in Doppler ultrasound and velocimetry. CPA can be used to map the vasculature within the placenta when combined with three-dimensional reconstruction (Fig. 2.6). This technique is able to identify red blood cells in vessels with a diameter of more than 200 μm [24]. Because the technique is three-dimensional, it can also be used to map the abnormal surface vascular arrangements that are typically seen in pregnancies with invasive placentation [22].

Summary box 2.6

Ultrasound (including Doppler and colour power Doppler ultrasound)

- Week 3: visualization of the gestational sac.
- Week 7–8: visualization of blood flow in the umbilical cord.
- Week 13 until delivery: visualization of placental vessels with a diameter larger than 200 μm.
- Week 14: establishment of EDF in the umbilical arteries.
- Week 18–22: screening of uterine arteries for pathological flow patterns.
- Week 22: early-onset FGR can be predicted by absent EDF in the umbilical arteries.

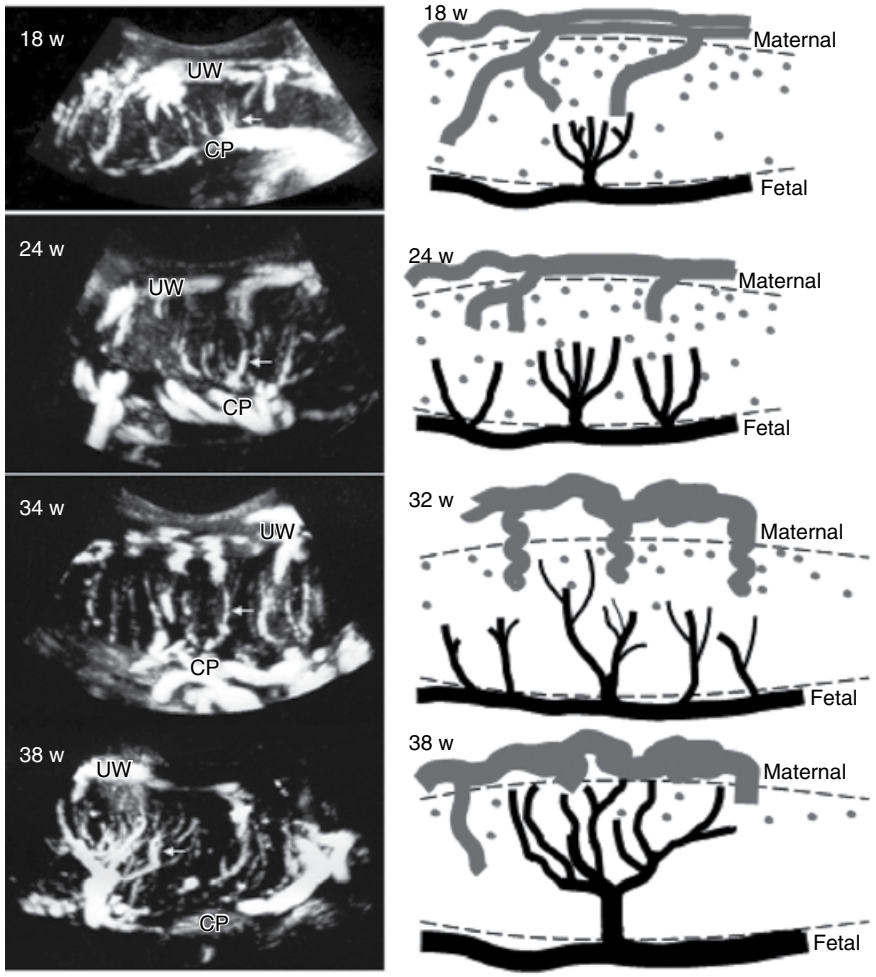

Fig. 2.6 Development of placental blood flow. *Left column*: Typical three-dimensional power Doppler scans from placentas of normal pregnant women at weeks 18, 24, 34 and 38. The flow signals within placental villi (white arrows) increase in extent, intensity, width and height with advancing pregnancy. At term (38 weeks) tree-like structures can be visualized. Since only anterior placentas have been used for these scans, the uterine wall (UW) is always at the top of the scan while the chorionic plate (CP) is always at the bottom of the scan. *Right column*: Synoptic view of characteristic features of placental blood flow throughout pregnancy as depicted by three-dimensional power Doppler. *Source:* Edmonds DK. *Dewhurst's Textbook of Obstetrics and Gynaecology*, 8th edn. Normal Pregnancy

3

Healthy Fetal Growth

Aris T. Papageorghiou

Nuffield Department of Women's and Reproductive Health, University of Oxford, John Radcliffe Hospital, Oxford, UK

In healthy pregnancy, fetal growth follows distinct patterns. Initially, fetal weight increases mainly due to skeletal and muscle growth and is related to placental glucose and amino acid transport. After 20 weeks of gestation there is deposition of fetal adipose tissue, which occurs alongside increases in fatty acid transport; later, fetal growth and adipose tissue deposition coincide with increasing conversion of glucose into fat [1].

Assessment of fetal size (at one point during pregnancy) and fetal growth (a dynamic process that assesses change of size over a time interval) are key elements of pregnancy care. The aim of this assessment is to identify babies that are too small or too large, due to an abnormal growth pattern. This is because it puts them at higher risk of adverse pregnancy outcome and, in the case of poor fetal growth, increased rates of perinatal mortality.

In many epidemiological studies, small (or, to a lesser degree, large) babies are defined as being of below (or above) certain birthweight thresholds, for example babies of low birthweight (below 2500 g) or very low birthweight (1500 g) [2]. These are practical cut-offs and useful for international comparisons, and are linked to adverse outcome; for example, newborns weighing less than 2500 g are approximately 20 times more likely to die than heavier babies and are also at higher risk of a range of poor health outcomes [3].

However, the value of such cut-offs in monitoring and comparing perinatal health between countries or over time has been questioned. This is because they are unable to distinguish those babies that are small due to preterm birth from those that are small due to fetal growth restriction (FGR), or indeed whether the two conditions coexist. In order to discriminate between these phenotypes, the gestational age must be known. This allows the size to be defined according to gestational age: small for gestational age (SGA), average for gestational age (AGA) or large for gestational age (LGA). These are usually defined as below the 10th centile, between the 10th and 90th centiles, and above the 90th centile, respectively.

Thus, in order to differentiate the normally growing fetus from the abnormal, three things must be known: (i) accurate gestational age; (ii) measurement of the fetus; and (iii) whether the measurements of size (or growth) are within the normal range compared to a standard or reference.

Summary box 3.1

- Assessment of fetal size, at one point during pregnancy, is different from assessment of fetal growth (i.e. change of size over time).
- Using birthweight cut-offs to classify newborns (e.g. <2.0 kg) does not distinguish between preterm normal size babies from term small babies.

Estimation of gestational age

Accurate estimation of gestational age is not only important in the assessment of fetal size and growth, but also guides decisions regarding other obstetric interventions, such as prenatal testing, whether administration of prophylactic corticosteroids for fetal lung maturity and transfer to another healthcare setting is appropriate in cases of preterm labour, or when labour induction in prolonged pregnancy should occur [4]. It is also important in interpretation of results of first-trimester screening for chromosomal abnormalities using a combination of nuchal translucency, pregnancy-associated plasma protein-A and free β-human chorionic gonadotrophin (hCG) [5].

The typical length of gestation after conception is 266 days or 38 weeks (i.e. 'conceptual age'). However,

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

gestational age is traditionally estimated from the last menstrual period (LMP), adding 2 weeks to 'postmenstrual age', giving 280 days or 40 weeks. This assumes that ovulation and conception occur 14 days after LMP. This is not always the case: irregular menses, unknown or uncertain dates, oral contraceptive use or recent pregnancy or breastfeeding may all influence the accuracy of this method, and this inaccuracy is significant in a large proportion of women [6,7]. Bleeding during the first trimester can also add to difficulty in confirming gestational age clinically based on the period of amenorrhoea.

Because of this, guidelines in most developed countries support the estimation of gestational age by first-trimester ultrasound using crown–rump length (CRL). Although this is more accurate at estimating gestational age at population level, it is important to recognize that this method too has limitations when interpreting individual results. For instance, there is an underlying assumption that all fetuses of the same size are of the same gestation, ignoring physiological differences and biological variability in size. In addition, aberrations in normal growth at very early stages of pregnancy exist and are associated with adverse outcome.

It is generally the case that assessment of gestational age in late pregnancy is less accurate than late pregnancy dating. This is because fetal ultrasound measurements are associated with a larger absolute error with advancing gestation, and because fetal growth disturbances become more prevalent, meaning that an abnormally small fetus could be misjudged to have lower gestational age (while a macrosomic fetus may be ascribed a more advanced gestational age). This limitation is of particular relevance in women who attend for their first antenatal care visit late in pregnancy and where no other reliable estimation of gestational age is available. It is known that unreliable reporting of LMP and late antenatal care are both associated with adverse pregnancy outcome; because of this, a clinically cautious approach is important when gestational age is assigned late, and particularly in the third trimester. Thus, the potential for error should be taken into account in order to ensure safe obstetric practice: for example, in preterm labour where late estimation of gestational age suggests a value above 34 weeks, prophylactic steroids or neonatal transfer should still be carried out as the gestational age may be lower by 2 weeks; in contrast, post-dates labour induction may be appropriate at 39 weeks after late assessment of gestational age, as this could be as late as 41 weeks [8].

Although a CRL measurement may be the most accurate measure of gestational age in most pregnancies, it has been argued that clinical judgement is required in practice to determine the best approximation of the true gestational age. First, the earliest reliable ultrasound scan should be used to ascribe an estimated due date and this should not be changed subsequently as this can lead to potential dating errors. Second, all information collected at the time of that first visit (including the reported LMP and assessment of its reliability) should be taken into account. When a reliable LMP and ultrasound estimate concur, small discrepancies with actual gestational age may still exist due to inherent CRL measurement variability. Conversely, an apparently reliable and accurate LMP with a substantial difference in estimated gestational age based on CRL should be considered as an indicator of possible growth disturbance or underlying pathology that may merit further assessment [9].

Summary box 3.2

Knowing the gestational age is important for:

- interpretation of prenatal screening tests;
- assessment of fetal growth;
- decision-making that requires knowledge of gestation, for example around the limits of viability, and post term.

Estimation of gestational age by first-trimester ultrasound using CRL is usually more accurate than menstrual history.

Measurement of the fetus

The most common methods for estimating fetal size at any one time are by measuring fetal biometry using ultrasound; or clinically, but also less accurately, by measurement of the maternal fundal height. It has been shown that universal third-trimester ultrasound (compared with selective ultrasound, which is only carried out based on risk factors or abnormal symphysis fundal height) is associated with greater diagnostic effectiveness as a screening test for SGA: those fetuses with reduced growth velocity were at increased risk of neonatal morbidity [10]. Nevertheless, meta-analysis of randomized trials has failed to demonstrate benefit of routine late pregnancy ultrasound in low-risk or unselected populations, in terms of perinatal mortality, preterm birth less than 37 weeks, caesarean section rates, and induction of labour rates [11]. It is possible that these two seemingly contradictory findings are the result of previous randomized trials lacking the use of an effective intervention after screening, or other flaws such as lack of statistical power [10].

Ultrasound

Estimation of the fetal head circumference (HC), abdominal circumference (AC), and femur length (FL) is undertaken using standard ultrasonographic planes (Fig. 3.1).

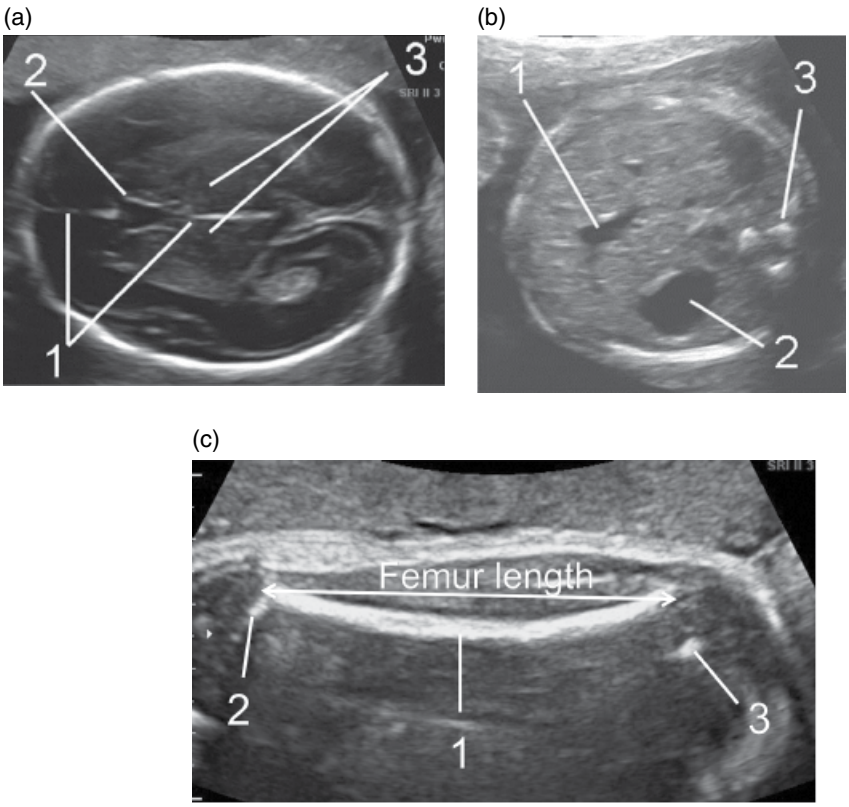

Fig. 3.1 (a) Correct ultrasound image for the measurement of the fetal head: the image is well magnified and the head is horizontal, oval in shape and symmetrical. The landmarks are (1) centrally positioned, continuous midline echo (falx cerebri); (2) midline echo broken anteriorly at one-third of its length by the cavum septum pellucidum; (3) thalami located symmetrically on each side of the midline. (b) Correct ultrasound image for the measurement of the fetal abdomen: the image is well magnified and the cross-section is circular. The landmarks are (1) a short segment of umbilical vein in the anterior third of the abdomen; (2) the stomach bubble is visible; (3) the spine is seen. Note that the bladder and kidneys should not be visible in this axial cross-section. (c) Correct ultrasound image of femur length: (1) the ossified diaphysis of the femur; in the third trimester the greater trochanter (2) and distal ossification centre (3) can be seen and this allows better orientation of the imaging plane.

Based on these parameters it is possible to calculate an estimated fetal weight (EFW). Although there are some advantages in using this estimation (for example, it is helpful in counselling parents and enabling paediatricians to make management decisions), there are disadvantages of using only a single summary measure of size. This is because individual measurement errors are compounded, resulting in 95% confidence intervals for random error in the region of 14% of birthweight. Importantly, this error is highest in exactly those pregnancies where accurate estimation is more important, namely babies with low and high birthweight [12]. Additional ultrasound measurements, including assessment of amniotic fluid and Doppler studies of uteroplacental and fetal blood flow, may aid in the clinical management of fetuses with (or at risk of) abnormal growth.

Fundal height

Depending on the availability of ultrasound, the setting and risk level of pregnancies, serial measurement of symphysis–fundal height (SFH) is often recommended as a simple, inexpensive, first-level screening tool. If this is abnormal, referral for ultrasound is then carried out. Observational cohort studies show that the use of SFH measurement is associated with very wide ranges of detection of SGA babies, from as low as 17% to as high as 93%. The marked heterogeneity in these studies is thought to be due to the variety of methodologies applied, including the use of different fundal height charts, varying thresholds for defining SGA, and a suggestion of publication bias [13]. The single randomized trial in the literature, involving 1639 women, showed no reduction in the incidence of SGA between those screened and not screened with SFH measurement, and no difference in the number of perinatal deaths [14]. Although the conclusion is that there is insufficient evidence to determine whether SFH measurement is effective, it has been argued that 'there is no suggestion that it should not be used as a screening tool', on the basis that the method is not resource intensive [15]. This view is upheld by a number of national guidelines [16,17].

Summary box 3.3

- Clinical assessment of fetal growth using SFH measurement is associated with very wide ranges of detection of SGA babies.
- Ultrasound assessment of fetal size is based on fetal HC, AC, and FL; these can be combined to calculate EFW.

Comparing the measurement to a standard or reference

Determining whether fetal growth is healthy or pathological can be challenging. This is not least because fetuses with SGA (i.e. those below the 10th centile of size) are not the same as those with FGR (i.e. those that fail to reach growth potential): it is possible for a fetus to be SGA but healthy, rather than FGR; conversely, it is possible for a fetus not to meet its growth potential yet remain in the AGA range. As it is not possible to accurately define growth potential, SGA is most often used as a surrogate. A more difficult scenario occurs in fetuses that exhibit a relative decrease in size over time by 'crossing centiles' but which remain above this cut-off of the 10th centile. In these cases careful clinical assessment is required; it is not known how many centiles (or standard deviations) can be crossed before the risk of adverse outcome increases significantly.

It is important here to highlight the difference between charts based on birthweight from those based on intrauterine EFW. Birthweight charts should not be used for assessment of fetuses. This is because in birthweight charts those with poor growth are over-represented at preterm gestations, even when excluding those births that are indicated for growth restriction; in other words, babies born prematurely are (by definition) not representative of healthy fetuses that remain *in utero* (Fig. 3.2).

One way to avoid this confusion is to assess the individual biometric variables, such as biparietal diameter (BPD), HC, AC and FL. However, this too is not straightforward, as there are a large number of available reference charts with differing results: in one study it was shown that, using three different charts, the proportion of fetuses classified with a BPD lower than the 5th centile at 20–24 weeks ranged from 6.6 to 23.7% [18]. In a systematic review of 83 fetal growth charts identified in 2012, Ioannou *et al.* [19] showed that differences in study design, data analysis and presentation contributed to these significant discrepancies between studies. A similar problem with a multitude of reference charts exists in EFW, SFH and newborn charts [20–22]. In order to overcome these issues, the concept of developing growth standards (rather than references) is discussed.

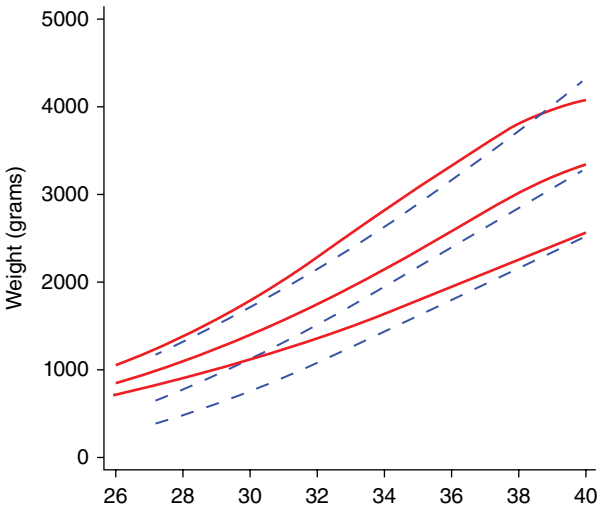

Fig. 3.2 Gestational age-specific centiles for estimated fetal weight (solid line) and birthweight of preterm born infants at the same gestation (dashed line). This demonstrates that at preterm gestations, birthweight is lower than EFW; at term these differences become very small.

Summary box 3.4

- Fetal growth charts should be based on ultrasound, not on charts of birthweight; this is because in birthweight charts, babies with poor growth are over-represented at preterm gestations.
- It is recommended that growth, including in fetuses, should be assessed using prescriptive standards which show how fetuses *should* grow when nutritional, environmental and health constraints on growth are minimal. This is different from references that represent the distribution of biometry within a population.

International standards of fetal growth and newborn size

The World Health Organization recommends the use of standards to assess human growth [23]. While references describe how fetuses (or newborns or infants) have grown at a particular time and/or place, standards describe how they *should* grow when nutritional, environmental and health constraints on growth are minimal. Thus, standards are prescriptive: they demonstrate how growth should occur under near optimal conditions. It is important to note that the distribution of biometry within a population does not constitute a standard; this is because populations at high risk may exhibit growth that is suboptimal and is associated with higher rates of adverse perinatal outcome. While the concept of growth standards has been widely accepted in paediatrics [24], until recently there has been a relative lack of knowledge regarding optimal fetal growth.

Since 2009, the INTERGROWTH-21st Project has undertaken a series of studies to address this gap in our understanding of early human growth. The overarching aim is to determine healthy fetal growth, newborn size, preterm postnatal growth and neurodevelopment in the

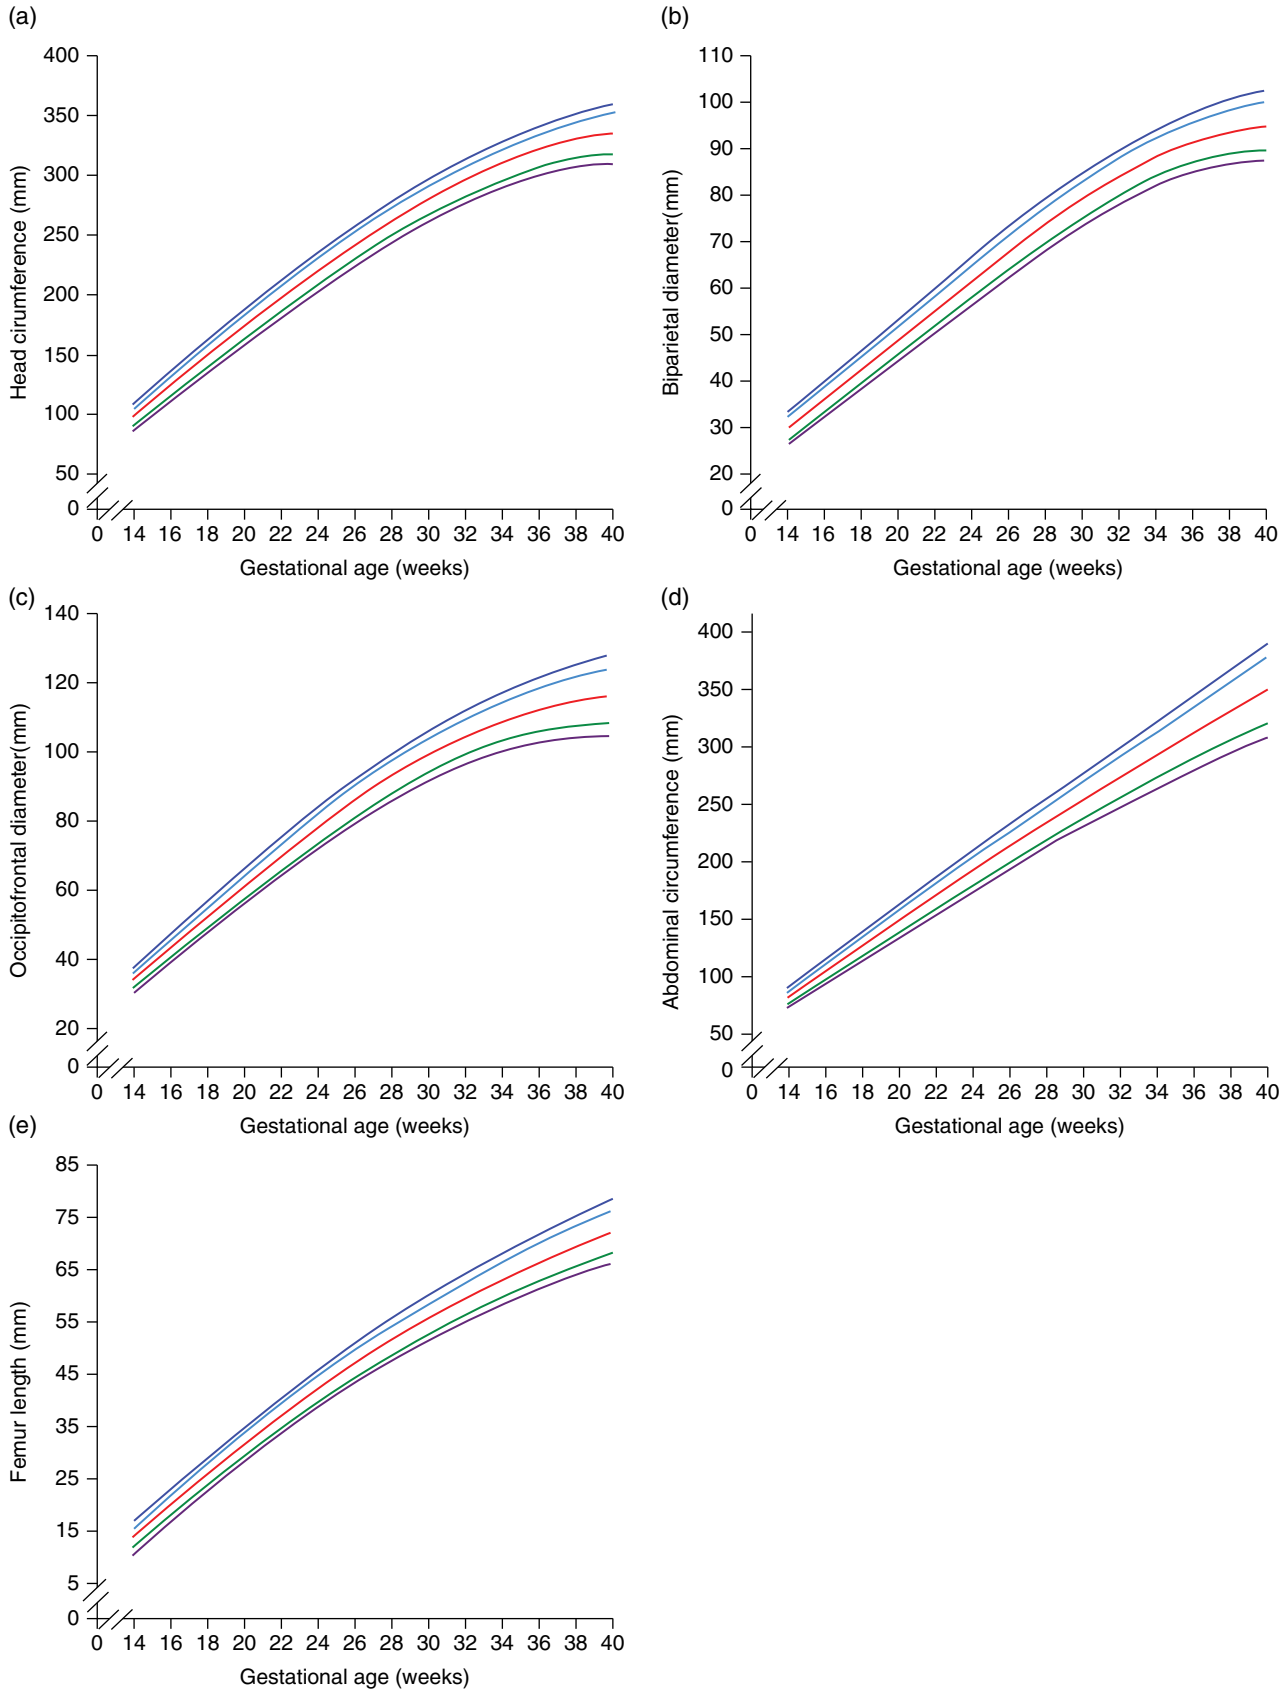

Fig. 3.3 International fetal growth standards, measured by ultrasound, from the INTERGROWTH-21st project: (a) head circumference, (b) fetal biparietal diameter, (c) fetal occipitofrontal diameter, (d) fetal abdominal circumference, and (e) fetal femur length. The lines show the 3rd, 10th, 50th, 90th and 97th smoothed centile curves.

first 1000 days of life in healthy mothers, under healthy conditions. Selection was firstly based at population level: eight diverse urban populations living in demarcated geographical or political areas were selected based on healthy environments free from pollutants, altitude less than 1600 m, and low perinatal morbidity and mortality (the selected sites were Pelotas, Brazil; Shunyi County, Beijing, China; Central Nagpur District, India; Turin, Italy; Parklands Suburb, Nairobi; Muscat, Oman; Oxford, UK, and Seattle, USA). Secondly, healthy women with a naturally conceived singleton pregnancy, and who met the individual inclusion criteria, were prospectively recruited from these healthy populations into the Fetal Growth Longitudinal Study from 9 weeks of gestation. Fetal biometry was measured every 5 weeks by ultrasound using highly standardized, blinded and scientifically rigorous protocols [25]. At birth, the same rigour was applied to measure the weight, length and head circumference of all newborns born in the entire population [26]. Infants were then followed up to the age of 2 years for detailed assessment of growth and neurodevelopment.

The studies of the INTERGROWTH-21st project have produced a uniquely detailed set of global tools and standards, based on the same healthy populations, and demonstrate healthy fetal growth (Fig. 3.3) and development from early pregnancy through to evaluation of fetal growth and EFW by ultrasound, fundal height, maternal weight gain, newborn size, as well as preterm postnatal growth. These standards challenge the perception of optimal fetal growth and also how growth problems should be identified and defined.

Pre-conception Counselling

Mandish K. Dhanjal[1,2]

[1] *Queen Charlotte's and Chelsea Hospital, Imperial College Healthcare NHS Trust, London, UK*
[2] *Imperial College London, London, UK*

A woman who enters pregnancy in a good state of health with a healthy diet and well-controlled medical disease is more likely to have a healthy pregnancy and a good outcome than a woman who enters pregnancy with an unhealthy lifestyle and uncontrolled medical disease. Pre-conception or pre-pregnancy counselling involves seeing women several months prior to conception in order to discuss and modify lifestyle choices and assess and improve medical health before pregnancy. The National Institute for Health and Care Excellence (NICE) has identified pre-conception counselling as an important area in their antenatal guidelines [1] and the importance of pre-conception health was highlighted in the Chief Medical Officer's Annual Report in 2014 [2].

Purpose of pre-conception counselling

All women considering having a baby should see their general practitioner (GP), and if they have a medical disease a specialist in the management of their particular disease, for pre-pregnancy counselling prior to conceiving. The purpose of these consultations is to:

- inform the woman and her partner of general advice, and advice about lifestyle behaviours including exercise, diet, smoking and drinking;
- detect any mental health or medical issues that will impact on pregnancy and advise if pregnancy should not be contemplated at present;
- assess any known medical conditions and optimize the state of the disease, in particular adjusting medications;
- discuss how the above may impact on the pregnancy, fetus and the mother;
- identify couples who are at risk of having babies with genetic disorders and refer them for genetic advice before they embark on pregnancy; and
- discuss contraception if it is considered that pregnancy is not advisable at present or if the woman prefers not to get pregnant yet.

Broadly, for any medical condition, there should be a discussion about whether becoming pregnant has risks for the mother or fetus.

- Mother: disease exacerbation (antenatally or postnatally), appropriate mode of delivery, maternal mortality.
- Fetus: malformations (genetic, teratogens), *in utero* fetal growth restriction, preterm delivery, stillbirth, neonatal morbidity and mortality.

Pre-pregnancy counselling will inform women of their risks, empowering them to make an informed decision whether or not to proceed with pregnancy. It will allow planning or prevention of pregnancy, and access to the appropriate multidisciplinary specialized services if necessary. Importantly, it is a conduit to influencing the health outcomes of the future generation, as improving maternal health and in particular obesity can impact on reducing the burden of some non-communicable diseases in the offspring.

Summary box 4.1

- All women should have pre-conception counselling to inform them of their own health, the health of their fetus in pregnancy, and the health of their offspring, empowering them to make an informed decision whether or not to proceed with pregnancy.
- It allows planning or prevention of pregnancy, and access to the appropriate multidisciplinary specialized services if necessary.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Who needs pre-conception counselling?

All women will benefit from the general advice offered by GPs. The confidential enquiry reporting maternal deaths has specifically recommended that pre-conception counselling be provided for women of childbearing age with pre-existing serious medical or mental health conditions that may be aggravated by pregnancy, in particular the commoner conditions including epilepsy, diabetes, congenital or known acquired cardiac disease, autoimmune disorders, obesity with body mass index (BMI) of 30 or more, and severe pre-existing or past mental illness [3]. The recommendation especially applies to women prior to having assisted reproduction and other fertility treatments.

Timing of pre-conception counselling

This should ideally take place 3–6 months prior to conceiving; however, few women are sufficiently motivated to see a doctor prior to getting pregnant, even if they have a medical illness. Dedicated pre-pregnancy clinics or pre-pregnancy health check clinics would be ideal, but very few health authorities offer this service. Additionally, it is estimated that 25–40% of pregnancies are unplanned. Unplanned pregnancies are associated with adverse outcomes, including low birthweight babies, preterm delivery and postnatal depression [2]. Pre-conception advice should therefore occur opportunistically when women of childbearing age attend their GP for contraception or for baby and toddler checks, attend their specialist for review of their medical disease or if they are referred to infertility clinics.

The average age of first sexual intercourse is 16 years and 0.44% of girls under the age of 16 years in England and Wales get pregnant [4]. Two-thirds of these girls undergo a termination of pregnancy [3]. The UK has the highest teenage pregnancy rate in western Europe despite a fall of 25% in the last decade. Some medical conditions, such as complex congenital heart disease, would necessitate a discussion about pregnancy during adolescence (12–15 years old) depending on the degree of maturity of the child. This is not to encourage pregnancy in these teenagers, but to educate them of the risks that unintended pregnancy may hold for them.

Implicit in any discussion is the need for adequate contraception (see Chapter 65). Long-acting reversible contraceptive agents, including progesterone-containing implants, intrauterine devices and injections, are 20–100 times more effective in preventing pregnancy than contraceptive pills or barrier methods such as condoms [2].

Healthcare professionals who should undertake pre-conception counselling

GPs are best placed to do this as they have a long-term relationship with their patients and will usually be seeing them for contraceptive advice and for other medical conditions. Specialists also have a role, particularly diabetologists, neurologists and cardiologists, who will be seeing adolescents and women of reproductive age for regular checks of their diabetes, epilepsy or heart disease. Pre-conception counselling is vital in these groups as it can directly influence pregnancy outcome. Unfortunately some specialists may be reluctant to discuss the implications of medical disease and the associated medications in pregnancy because they are not up to date with current evidence in pregnancy, whereas some others may give incorrect advice despite not being up to date.

Misadvice is of significant concern and thus maternal medicine specialists and obstetric physicians are ideally placed to offer pre-conception advice to women with medical disease. They are well informed as to the effects of various medical diseases in pregnancy and are aware of the implications of drug use in pregnancy. Many will have dedicated pre-conception clinics in tertiary care. Many maternal medicine specialists will also be able to offer detailed contraceptive advice and in many instances are able to administer long-acting contraceptives, avoiding delay in gaining effective contraception.

General pre-conception advice

Diet

Women intending to conceive should be encouraged to eat fruit, vegetables, starchy foods (bread, pasta, rice and potatoes), protein (lean meat, fish, beans and lentils), fibre (wholegrain breads, fruit and vegetables) and dairy foods (pasteurized milk, yoghurt and hard, cottage or processed cheese) [1]. These will assist in increasing the stores of vitamins, iron and calcium. Continuing a healthy diet in pregnancy can have beneficial effects on childhood cardiovascular function [2].

The unpredictability regarding the exact moment a woman becomes pregnant leads to the recommendation that women trying to conceive should avoid the foods listed in Table 4.1, which may contain organisms or substances that can be harmful in early gestation. Even a planned pregnancy is not detected until 5–6 weeks of gestation, at which stage vulnerable organs, particularly the central nervous system, have already started developing and the neural tube is completely formed.

Table 4.1 Foods that can affect the fetus in very early pregnancy.

Food	Risk of containing	Fetal risk in early pregnancy
Unpasteurized milk Soft mould-ripened cheeses (e.g. Camembert, Brie, blue-veined cheese) Pâté (including vegetable pâté) Uncooked or under-cooked ready made meals	*Listeria*	Miscarriage
Raw shellfish (e.g. oysters)		
Uncooked or cured meat (e.g. salami)	*Toxoplasma*	Fetal CNS defects
Liver and liver products	Excess vitamin A	Cranial–neural crest tissue defects
Shark, swordfish and marlin	Methylmercury	Fetal CNS defects

CNS, central nervous system.

Vegetarians and vegans are at risk of nutritional deficiencies, particularly of vitamins B_{12} and D, and may benefit from advice from a dietitian.

Women who have a heavy intake of caffeine should be advised to cut down before pregnancy. The Food Standards Agency recommends that pregnant women should limit their consumption of caffeine in pregnancy to 300 mg daily or less (four cups of coffee, eight cups of tea, or eight cans of cola) [1]. High caffeine intake mildly increases the risk of fetal growth restriction.

Supplements

Folic acid

Folic acid 0.4 mg daily is recommended to all women trying to conceive and should be continued until 12 weeks' gestation along with an increase in folate-containing foods as this has been shown in randomized controlled trials to significantly reduce the incidence of fetal neural tube defects (NTDs) such as spina bifida and anencephaly [5]. A higher dose of folic acid (5 mg daily) is required in women:

- with a previous pregnancy affected by an NTD [6];
- who themselves are affected with an NTD;
- with a sibling or parent affected with an NTD;
- taking antifolate drugs (e.g. most antiepileptic agents, sulfasalazine);
- with diabetes [7];
- with a raised BMI (>35 kg/m^2);
- with thalassaemia trait throughout pregnancy;
- with thalassaemia or sickle cell disease throughout pregnancy.

Some countries have fortified certain foods (e.g. flour, cereals) with folate in order to help protect those women who cannot afford medical supplementation and those who have an unplanned pregnancy [8]. There is some evidence that the risk of other congenital malformations may be reduced with folate and multivitamin supplementation [9].

Vitamin D

Vitamin D 10 µg (400 IU) daily is recommended by the UK Department of Health for pregnant and breastfeeding women [10]. Vitamin D deficiency results in osteomalacia that can present with muscle and bony pain [1]. Vitamin D may play a role in early placental development, and subsequently the development of pre-eclampsia. Studies show that vitamin D levels are lower in women with pre-eclampsia compared with normotensive women, and meta-analyses have shown that women who received vitamin D supplements plus calcium compared with no supplements halve their risk of developing pre-eclampsia [11,12]. Maternal vitamin D deficiency can also result in fetal vitamin D deficiency, which is associated with hypocalcaemic seizures and childhood rickets [11].

The primary source of vitamin D is from exposure to sunlight, although it can be found in fatty fish, mushrooms, egg yolk and liver. Routine screening for vitamin D deficiency in pregnancy is not recommended. Women with the following risk factors will need to empirically take a higher dose of vitamin D (at least 1000 IU daily) [11]:

- skin pigmentation (melanin reduces the absorption of ultraviolet B sunlight and reduces cholecalciferol production by at least 90%);
- poor sun exposure (e.g. covered skin);
- factors affecting its absorption (gastrointestinal disease, phytates in chapatti flour);
- obesity (vitamin D is deposited in fat stores in obese individuals, making it less bioavailable);
- previous child with rickets or vitamin D deficiency;
- previous child who had neonatal fractures at delivery.

Women with renal disease may not metabolize vitamin D effectively and will require the use of active vitamin D metabolites instead [11].

Smoking

Women should be advised to stop smoking prior to pregnancy. They are usually aware of the risks to their own health, but are often less aware of the risks to the fetus, which include miscarriage, placental abruption, placenta praevia, premature rupture of membranes, preterm delivery, low birthweight, cleft lip and cleft palate, perinatal mortality, sudden infant death syndrome and

impaired cognitive development [1]. Discussion of these risks often provides a strong motivation to pregnant women to stop smoking. It is estimated that if all pregnant women stopped smoking there would be a 10% reduction in fetal and infant deaths. Advice from the doctor, smoking cessation programmes and self-help manuals have been shown to help women stop smoking. Nicotine replacement therapy including nicotine patches and e-cigarettes, can help wean women off tobacco.

Alcohol

The UK Department of Health advice recommends that women who are pregnant or planning pregnancy should be advised that the safest approach is not to drink alcohol at all [13]. In the first trimester there may be an increased risk of miscarriage. Thereafter, although there is no evidence of fetal harm with drinking one to two standard units of alcohol once or twice per week, there is no clear scientific evidence to support a quantified limit for drinking in pregnancy. The dangers to the fetus of drinking alcohol in pregnancy occur with greater consumption, so that women who binge drink (more than five standard drinks or 7.5 UK units on a single occasion) or drink heavily are at risk of subfertility, miscarriage, aneuploidy, structural congenital anomalies, fetal growth restriction, perinatal death and developmental delay [1,13]. Binge drinkers are more likely to have an unplanned pregnancy and hence may continue to drink erratically in the first trimester without knowing they are pregnant. Fetal alcohol syndrome occurs in 0.6 per 1000 live births (Canadian data) and is characterized by distinctive facial features, low birthweight, and behavioural and intellectual difficulties in later life. There is a further spectrum of fetal alcohol disorders [13]. Alcohol misuse can result in maternal ill health and is a significant cause of maternal death [3].

Body weight

Women should be advised to enter pregnancy with a normal BMI of 18.5–24.9 kg/m^2 [2].

Underweight

Women who are underweight (BMI <18.5 kg/m^2) may find it difficult to conceive due to anovulatory cycles. They are at risk of osteoporosis and nutritional deficiencies. They have an increased chance of fetal intrauterine growth restriction and low birthweight babies. They should be assessed for eating disorders.

Obesity

Overweight women (BMI 25–29.9 kg/m^2) and obese women (BMI ≥30 kg/m^2) should lose weight by dieting and exercise before conceiving. They may require referral to a dietitian. They should be informed of the adverse pregnancy outcomes associated with obesity (Table 4.2) [14].

Table 4.2 Risks of obesity to mother and her offspring.

Maternal risks of obesity
Subfertility
Miscarriage
Hypertensive disease
Gestational diabetes
Thromboembolism
Infection
Cardiac disease
Instrumental deliveries
Caesarean section
Postpartum haemorrhage
Maternal death
Risks to fetus of maternal obesity
Neural tube defects
Large for dates
Preterm delivery
Shoulder dystocia
Increase in birthweight
Stillbirth
Risks to offspring of maternal obesity
Neonatal hypoglycaemia
Obesity as children and adults
Diabetes
Hypertension

For women who are morbidly obese (obesity grade III) with a BMI of 40 kg/m^2 or more it is very difficult to achieve a normal BMI. In addition to referral to a dietitian, they should be assisted to lose weight by a variety of methods including prescription of weight reduction medication in a carefully supervised manner and referral for bariatric surgery. They should be strongly advised to defer pregnancy until they have lost weight.

Bariatric surgery results in weight loss either by reducing gastric capacity (e.g. sleeve gastrectomy, laparoscopic adjustable gastric banding) or by malabsorption (e.g. Roux-en-Y gastric bypass, biliopancreatic diversion) and this weight loss results in improved fertility [15]. However, women should be advised not to get pregnant whilst they are losing weight following surgery. They should use adequate contraception, preferably a non-oral method, and wait until their BMI stabilizes to prevent nutritional deficiencies affecting the fetus. Maternal and fetal outcomes improve following bariatric surgery, with reduced rates of gestational diabetes, pre-eclampsia, and large for gestational age babies. Studies have shown an increased incidence of small for gestational age babies and an increased chance of pretem birth following bariatric surgery [15]. Women should be recommended to remain on vitamin supplementation.

The method of bariatric surgery may influence outcomes, although few studies have compared pregnancy

outcomes after different types of surgery. There is less anaemia and vitamin and micronutrient deficiency with sleeve gastrectomy and gastric banding compared with Roux-en-Y gastric bypass or biliopancreatic diversion, which are more effective at achieving long-term weight loss [15].

Summary box 4.2

Women should modify their diet, stop or reduce smoking and alcohol intake, aim to enter pregnancy with a normal BMI and take folic acid supplementation peri-conceptionally.

Advice regarding medications

It is a misconception that most drugs are harmful in pregnancy. Unfortunately, this inaccurate belief is held by the public and many health professionals including doctors. Many women will discontinue vital medications as soon as they realize they are pregnant and risk a flare of their disease, which will cause harm to them and their babies.

Women with medical diseases on treatment should have a discussion regarding the safety profile of the medications in pregnancy before they conceive. There are valid concerns about the safety of some drugs in pregnancy, but most commonly used medications have good safety data and can continue to be taken in pregnancy. Even if a drug is known to have a risk of teratogenicity, the consequences of discontinuing it may be worse than the effects of taking it, justifying continuation of therapy (e.g. antiepileptic drugs). The smallest effective dose should be used. If a drug with a better safety profile is available, it should be used instead.

Drugs that are harmful to the fetus may have an effect depending on the time of exposure.

- Pre-embryonic stage (0–14 days after conception): can result in miscarriage, e.g. methotrexate, misoprostol, mifepristone, thalidomide, retinoids.
- First trimester: affect organogenesis, resulting in congenital malformation (teratogen), e.g. antiepileptic drugs, angiotensin-converting enzyme (ACE) inhibitors, warfarin.
- Second and third trimester: can cause growth restriction, affect neuropsychological behaviour (e.g. sodium valproate, dose related) or have toxic effects on fetal tissues (e.g. ACE inhibitors, tetracycline).

It is important to know when harmful drugs carry a risk of fetal harm as use of an individual drug at a different stage in pregnancy may have no effect on the fetus, for example a teratogen will bear the risk of congenital malformation with first-trimester use, but may be safe to use thereafter if required. A list of known teratogens and drugs that are safe to use in pregnancy is shown in Table 4.3.

Table 4.3 Drug safety in pregnancy.

Drugs that are harmful in pregnancy
NSAIDs after 28–30 weeks' gestation
Warfarin
Tetracycline, doxycycline, ciprofloxacin
Paroxetine
ACE inhibitors, angiotensin receptor blockers
Statins
Retinoids
Mycophenolate mofetil
Drugs that can be used in pregnancy (if clinically necessary: benefits outweigh risks)
Analgesics: paracetamol, codeine
Antacids, ranitidine, omeprazole
Most antibiotics (avoid trimethoprim in first trimester and avoid nitrofurantoin at term)
Most antidepressants (some SSRIs, tricyclic antidepressants)
Antihypertensives: methyldopa, nifedipine, labetalol, doxazosin, prazosin, hydralazine
Antiemetics: cyclizine, promethazine, prochlorperazine, metoclopramide, domperidone, ondansetron
Antihistamines
Beta-agonists
Inhaled and oral steroids
Hormones (insulin, thyroxine)
Laxatives
Low-dose aspirin
Some biologics

ACE, angiotensin-converting enzyme; NSAID, non-steroidal anti-inflammatory drug; SSRI, selective serotonin reuptake inhibitor.

Summary box 4.3

- Most commonly used medications have good safety data and can continue to be taken in pregnancy in the smallest effective dose.
- Inform women of any risks to pregnancy of medications they are taking.
- Change teratogenic medications before pregnancy if possible.

Advice related to maternal age

Delaying childbirth is associated with worsening reproductive outcomes, with more infertility, miscarriage and medical comorbidity and an increase in maternal and fetal morbidity and mortality.

Table 4.4 shows the dramatic decline in fertility and rise in miscarriage rate in women over the age of 40 years [16]. The fertility rate is taken from 10 different populations that did not use contraception between the seventeenth and twentieth centuries. This provides the best approximation of the ability of women to conceive.

Table 4.4 Risk of infertility and spontaneous miscarriage with age [12].

Maternal age (years)	Fertility rate per 1000 married women	Spontaneous miscarriages (%)
20–24	470	11
25–29	440	12
30–34	400	15
35–39	330	25
40–44	190	51
≥45	40	93

Table 4.5 Risk of pregnancy-specific diseases with age [18].

	Maternal age	
Pregnancy-related disease	20–29 years	>40 years
Pre-eclampsia	3.4%	5.4%
Gestational diabetes	1.7%	7%

In current times, the fertility rate in older women is increasing as many older women resort to assisted reproductive technologies (ART) (see Chapter 52) such as *in vitro* fertilization in order to conceive. The risks of ART include an increased incidence of ovarian hyperstimulation syndrome and multiple pregnancies, which further compounds all maternal age-related risks.

The risk of pre-existing hypertension, obesity, diabetes, ischaemic heart disease and cancer all increase with age and are twofold to fivefold greater in women over the age of 40 compared with women in their twenties [17]. These risks need to be put into context, as the absolute incidences of these diseases are low. Table 4.5 shows how the risks of pre-eclampsia and gestational diabetes increase with maternal age. Maternal death in women over 40 years of age, though rare, is triple that of women in their early twenties [3].

Chromosomal abnormalities increase dramatically with increasing maternal age (Table 4.6). Women should be informed of these risks and advised that prenatal diagnosis, both screening and definitive testing, is available in pregnancy (see Chapter 6). The option of termination or continuation of pregnancy in the event of an affected fetus should be discussed.

Older mothers have poorer uterine contractility and a higher incidence of assisted vaginal deliveries and caesarean sections compared with younger mothers. The babies of older mothers are more likely to be of low birthweight and the stillbirth rate at all gestations is higher. At 41 weeks' gestation, the risk of a stillbirth in women aged 35–39 years is nearly double that of a woman in her twenties. The risk rises to 3.5-fold higher in women over 40 years [19]. However, it is important to remember that the absolute risk of stillbirth is still small.

Table 4.6 Risk of Down's syndrome (trisomy 21) with maternal age.

Maternal age (years)	Risk of chromosomal abnormality	Risk of Down's syndrome
15–24	1 in 500	1 in 1500
25–29	1 in 385	1 in 1100
35	1 in 178	1 in 350
40	1 in 63	1 in 100
45	1 in 18	1 in 25

The Royal College of Obstetricians and Gynaecologists states that women who start a family in their twenties or complete it by age 35 years face significantly reduced risks. Women contemplating delaying pregnancy should be told the health consequences of this and advised that completion of childbearing in their twenties will vastly reduce their obstetric and medical risks. If they do delay pregnancy to their forties for whatever reason, they should be supported. The absolute risks to the mother remain small, although risks of miscarriage and aneuploidy are high.

Summary box 4.4

Delaying childbirth is associated with worsening reproductive outcomes, with more infertility, miscarriage, chromosomal abnormalities and medical comorbidity and an increase in maternal and fetal morbidity and mortality.

Genetic counselling

Couples who have had a previous child with a chromosomal abnormality, an inherited disease such as cystic fibrosis or Fanconi's anaemia, or with a family history of a genetic disorder should be referred for genetic counselling so that they can be informed of the risks of recurrence and whether prenatal diagnosis is available for detection of the disorder. In some cases pre-implantation genetic diagnosis is available (see Chapter 52).

Advice regarding access to maternity care

The importance of accessing maternity care early should be emphasized to women of childbearing age contemplating pregnancy. They should aim to book for antenatal

care as soon as possible, particularly if they have a pre-existing medical disorder, but certainly by 10 weeks' gestation to allow the relevant screening tests to be performed.

Conditions where pregnancy is not recommended

There are some conditions where pregnancy is not recommended due to the high risks of maternal and fetal morbidity and mortality.

- Pulmonary arterial hypertension (mortality approximately 25%).
- Severe systemic ventricular dysfunction.
- Previous peripartum cardiomyopathy with any residual impairment of left ventricular function.
- Severe left heart obstruction, e.g. aortic/mitral stenosis with valve area <1 cm^2.
- Marfan syndrome with aortic dilatation >4 cm.
- Diabetes with HbA_{1c} >10%.
- Severe respiratory compromise, e.g. forced vital capacity <1 L.
- Breast cancer within last 2 years.
- Severe renal failure (creatinine >250 mmol/L).
- Recurrent uterine scar rupture.

The most effective contraceptive should be used in these circumstances. Other methods of having a family, including surrogacy and adoption, should be discussed if pregnancy is not recommended. If maternal life expectancy is limited, discussion on the appropriateness of having a baby (by pregnancy, surrogacy or adoption) as well as issues of childcare in the event of maternal mortality or severe morbidity should be discussed.

There may be women who choose, after full counselling, to conceive. They should be reassured that they will be looked after in a multidisciplinary team if this is their choice.

Summary box 4.5

If pregnancy is not recommended due to severe maternal or fetal risks:

- use the most effective contraceptive;
- discuss surrogacy and adoption if maternal life expectancy is not severely limited.

Specific medical diseases

In general, pregnancy outcome is better if women conceive when their medical disease is quiescent, for example connective tissue diseases such as systemic lupus erythematosus. Women who conceive when their disease is actively flaring are more likely to further clinically deteriorate in pregnancy, have a growth restricted baby or have a miscarriage or preterm birth compared with women whose disease is well controlled.

Diabetes

There are many international guidelines on pre-conception care of women with diabetes, the latest being from NICE [7] and the American Diabetes Association [20]. Pre-pregnancy control of diabetes directly influences miscarriage and congenital malformation rates. NICE recommends weight reduction for women with a BMI over 27 kg/m^2, monitoring of metabolic control and achieving an HbA_{1c} target of less than 6.1% before conception to help reduce these risks. Metformin and insulin are safe to use before conception and throughout pregnancy. All other blood glucose-lowering medications should be stopped before pregnancy and replaced with insulin. The woman and her partner should be taught about awareness and management of hypoglycaemia. Pregnancy is not recommended in women with HbA_{1c} over 10% and adequate contraception should be provided until target glucose and HbA_{1c} levels are achieved. Women should take a higher dose of folic acid around conception as diabetes is associated with an increased incidence of NTDs.

Diabetic complications should be reviewed and managed before pregnancy. Pre-existing retinopathy can progress rapidly in pregnancy and should be treated before pregnancy [7]. Urine should be tested for microalbuminuria. Women should be warned that diabetic nephropathy can progress in pregnancy, especially as ACE inhibitors need to be discontinued.

Pre-eclampsia

Women with a low dietary intake of calcium given calcium supplements at a dose of at least 1 g before and during pregnancy can halve their risk of developing pre-eclampsia [21]. Women who have had pre-eclampsia in a previous pregnancy have a 10% chance of recurrence. The recurrence is higher if the onset was early (<34 weeks' gestation), and in this group administration of low-dose aspirin from early pregnancy is associated with reduced risks of developing pre-eclampsia [22]. Women should be advised to start aspirin as soon as their pregnancy test is positive. They should not take it before conception as this may increase their risk of luteinized unruptured follicle syndrome, which can lead to female subfertility. Women at high risk of pre-eclampsia should also take at least 800 IU of vitamin D combined with calcium [11].

Hypertension

Women with pre-existing hypertension should have had secondary causes excluded and an assessment made of end-organ damage in those with long-standing hypertension. Their current drug treatment and blood pressure control needs to be reviewed, with replacement of teratogenic drugs (e.g. ACE inhibitors, angiotensin receptor blockers) with safer agents [23]. They should be informed of the increased risk of pre-eclampsia and how this can be reduced by taking low-dose aspirin once pregnant.

Renal impairment

Women with renal disease should be advised to conceive when their degree of renal impairment is mild to moderate. Delaying pregnancy may result in further loss of renal function. A pregnancy in these circumstances not only increases the risk of pre-eclampsia, fetal growth restriction and preterm delivery, but also the chances of accelerating the onset of end-stage renal failure. There are some women who conceive whilst on renal dialysis. However, maternal and fetal outcomes are much improved if they conceive 2 years following a renal transplant.

Cardiac disease

Women with cardiac disease should have a risk assessment, with full history, examination and investigations as appropriate (e.g. ECG, echocardiogram, MRI). The effects of the cardiac disease on pregnancy and the effects of the pregnancy on the cardiac disease should be assessed, particularly the risk of deterioration, the effect of treatment or intervention in pregnancy in the event of deterioration, and fetal and maternal mortality risk. Some cardiac conditions may require surgical correction prior to pregnancy, for example severe mitral stenosis requiring valvuloplasty or valve replacement. Other conditions may require planning for alteration of anticoagulation in early pregnancy (e.g. metal heart valves). Some conditions have such a high maternal mortality associated with them that pregnancy is not recommended (e.g. pulmonary arterial hypertension). A decision should be reached whether pregnancy should be contemplated, delayed or avoided, with adequate contraceptive advice [24].

The long-term prognosis following pregnancy is important. Despite one successful pregnancy, some conditions have a high recurrence risk (e.g. peripartum cardiomyopathy) and others can deteriorate with age, increasing the risk to future pregnancies. Referral should be made to a geneticist where there is a family history of heart disease with features suggesting an underlying genetic or chromosomal abnormality.

Summary box 4.6

Pre-existing medical disease

- Fully assess, and optimize medical and surgical treatment before conception.
- Discuss impact of disease and medications on the pregnancy, fetus and mother.
- Conceive when disease quiescent or well controlled.

Previous pregnancy-related disease

- Discuss recurrence risks and strategies for prevention of recurrence.

Previous poor obstetric history

Women who have had a previous traumatic delivery or adverse pregnancy outcome may benefit from a discussion with an obstetrician prior to conception. They should all have had a debrief following the delivery, but may have unresolved issues or uncertainties regarding the risks of another pregnancy. This visit would allow plans for frequency of antenatal care, requirements for fetal surveillance and delivery plans to be discussed, allowing couples to make an informed decision prior to contemplating further pregnancy.

Antenatal Care

George Attilakos[1] and Timothy G. Overton[2]

[1] *Fetal Medicine Unit, University College London Hospital NHS Foundation Trust, London, UK*
[2] *St Michael's Hospital, University Hospitals Bristol NHS Foundation Trust, Bristol, UK*

The care of pregnant women presents a unique challenge to modern medicine. Most women will progress through pregnancy in an uncomplicated fashion and deliver a healthy infant requiring little medical or midwifery intervention. Unfortunately, a significant number will have medical problems that will complicate their pregnancy or develop such serious conditions that the lives of both themselves and their unborn child will be threatened. In 1928, a pregnant woman faced a 1 in 290 chance of dying from an obstetric complication related to the pregnancy; the most recent surveillance of maternal deaths between 2011 and 2013 put this figure at 1 in 34,394 [1]. Undoubtedly, good antenatal care has made a significant contribution to this reduction. The current challenge of antenatal care is to identify those women who will require specialist support and help while allowing uncomplicated pregnancies to progress with minimal interference. The antenatal period also allows the opportunity for women, especially those in their first pregnancy, to receive information from a variety of healthcare professionals regarding pregnancy, childbirth and parenthood.

Aims of antenatal care

Antenatal education

Provision of information

Women and their partners have the right to be involved in all decisions regarding their antenatal care. They need to be able to make informed decisions concerning where they will be seen, who will undertake their care, which screening tests to have and where they plan to give birth. Women must have access to evidence-based information in a format they can understand. Current evidence suggests that insufficient written information is available especially at the beginning of pregnancy and information provided can be misleading or inaccurate. *The Pregnancy Book* [2] provides information on the developing fetus, antenatal care and classes, rights and benefits as well as a list of useful organizations. Many leaflets have been produced by the Midwives Information and Resource Service (MIDIRS) that helps women to make informed objective decisions during pregnancy. The Royal College of Obstetricians and Gynaecologists (RCOG) has also produced many pregnancy-related patient information leaflets, most of them accompanying the relevant 'Green-top guidelines' for clinicians. Written information is particularly important to help women understand the purpose of screening tests and the options that are available and to advise on lifestyle considerations including dietary recommendations. Available information needs to be provided at first contact and must take into account cultural and language barriers. Local services should endeavour to provide information that is understandable to those whose first language is not English and to those with physical, cognitive and sensory disabilities. Translators will be frequently required in clinics with an ethnic mix.

There will be greater emphasis in the future in providing electronic sources of information. Women will want to be able to access their medical records digitally on smartphones and relevant information on pregnancy and childbirth through apps. While this would allow women to access up-to-date information enabling informed choices, it will require careful governance to ensure personal data safety, the accuracy of the information and availability for all.

Couples should also be offered the opportunity to attend antenatal classes. Ideally such classes should discuss physiological and psychological changes during pregnancy, fetal development, labour and childbirth and how to care for the newborn baby. Evidence

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

shows a greater acquisition of knowledge in women who have attended such classes compared with those who have not.

Lifestyle concerns

At an early stage in the pregnancy women require lifestyle advice, including information on diet and food, work during pregnancy and social aspects, for example smoking, alcohol, exercise and sexual activity.

Women should be advised of the benefits of eating a balanced diet that contains plenty of fruit and vegetables, starchy foods such as pasta, bread, rice and potatoes, protein, fibre and dairy foods. They should be informed of foods that could put their fetus at risk. Listeriosis is caused by the bacterium *Listeria monocytogenes* which can present with a mild flu-like illness but is associated with miscarriage, stillbirth and severe illness in the newborn. Contaminated food is the usual source including unpasteurized milk, ripened soft cheeses and pâté. Toxoplasmosis contracted through contact with infected cat litter or undercooked meat can lead to permanent neurological and visual problems in the newborn if the mother contracts the infection during pregnancy. To reduce the risk, pregnant women should be advised to thoroughly wash all fruits and vegetables before eating and to cook all meats thoroughly, including ready-prepared chilled meats. Written information from the UK Food Standards Agency (*Eating While you are Pregnant*) can also be helpful. For example, the Food Standards Agency advises women to reduce the consumption of caffeine to 200 mg/day (equivalent to two mugs of instant coffee), because of its association with low birthweight and miscarriage.

Women who have not had a baby with spina bifida should be advised to take folic acid 400 μg/day from preconception until 12 weeks of gestation to reduce the chance of fetal neural tube defects (NTDs). However, research analysis of the population incidence of NTDs has failed to show the efficacy of this strategy. This may be due to inadequate pre-conceptual intake of folate and/or poor compliance. Suggestions of adding folate to certain foods (e.g. flour) to ensure population compliance (already occurring in some countries including the USA and Canada) remain debatable.

Current evidence does not support routine iron supplementation for all pregnant women and can be associated with some unpleasant side effects such as constipation. However, any woman who is iron deficient must be encouraged to take iron therapy prior to the onset of labour as any excess blood loss at delivery will increase maternal morbidity. The intake of vitamin A (liver and liver products) should be limited in pregnancy to approximately 700 mg/day because of fetal teratogenicity.

Women should be informed at the booking visit about the importance for their own and their baby's health of maintaining adequate vitamin D stores during pregnancy and while breastfeeding. Women are advised to take 10 μg of vitamin D per day as found in the Healthy Start multivitamin supplement. This is particularly important in those most at risk, including women with limited exposure to sunlight, a body mass index (BMI) above 30 kg/m^2, those of South Asian, African, Caribbean or Middle Eastern family origin and those with poor dietary intake of vitamin D.

Because alcohol passes freely across the placenta, women should be advised not to drink excessively during pregnancy. The current UK Chief Medical Officer's advice for pregnant women is that if a woman is pregnant or planning a pregnancy, the safest approach is not to drink alcohol at all, to keep risks to the baby to a minimum. Binge drinking and continuous heavy drinking cause the fetal alcohol syndrome, characterized by low birthweight, a specific facies, and intellectual and behavioural difficulties later in life. Although the evidence of harm from low levels of alcohol consumption is lacking, it is highlighted that 'the safer option is not to drink alcohol at all during pregnancy'.

Approximately 27% of women are smokers at the time of birth of their baby. Smoking is significantly associated with a number of adverse outcomes in pregnancy, including increased risk of perinatal mortality, placental abruption, preterm delivery, preterm premature rupture of the membranes, placenta praevia and low birthweight. While there is evidence to suggest that smoking may decrease the incidence of pre-eclampsia, this must be balanced against the far greater number of negative associations. The recent NHS England care bundle for reducing stillbirth recommends carbon monoxide testing of all pregnant women at the antenatal booking appointment followed by referral, as appropriate, to a Stop Smoking service/specialist, based on an opt-out system [3]. Although there is mixed evidence for the effectiveness of smoking cessation programmes, women should be encouraged to use local NHS Stop Smoking services and the NHS pregnancy smoking helpline [4]. Pregnant women who are unable to stop smoking should be informed of the benefits of reducing the number of cigarettes they smoke. A 50% reduction can significantly reduce the fetal nicotine concentration and is associated with an increase in the birthweight.

Women who use recreational drugs must be advised to stop or be directed to rehabilitation programmes. Evidence shows adverse effects on the fetus and its subsequent development.

Continuing moderate exercise in pregnancy or regular sexual intercourse does not appear to be associated with any adverse outcomes. Certain physical activity should

be avoided such as contact sports which may cause unexpected abdominal trauma. Scuba diving should also be avoided because of the risk of fetal decompression disease and an increased risk of birth defects.

Physically demanding work, particularly those jobs with prolonged periods of standing, may be associated with poorer outcomes such as preterm birth, hypertension and pre-eclampsia, and small-for-gestational-age babies but the evidence is weak and employment per se has not been associated with increased risks in pregnancy. Women require information regarding their employment rights in pregnancy and healthcare professionals need to be aware of the current legislation.

Help for the socially disadvantaged and single mothers must be organized and ideally a one-to-one midwife allocated to support these women. The midwife should be able to liaise with other social services to ensure the best environment for the mother and her newborn child. Similar individual help is needed for pregnant teenagers and midwife programmes need to provide appropriate support for these vulnerable mothers.

Common symptoms in pregnancy

It is common for pregnant women to experience unpleasant symptoms in pregnancy caused by the normal physiological changes. However, these symptoms can be quite debilitating and lead to anxiety. It is important that healthcare professionals are aware of such symptoms, can advise appropriate treatment and know when to initiate further investigations.

Extreme tiredness is one of the first symptoms of pregnancy and affects almost all women. It lasts for approximately 12–14 weeks and then resolves in the majority.

Nausea and vomiting in pregnancy is one of the commonest early symptoms. While it is thought that this may be caused by rising levels of human chorionic gonadotrophin (hCG), the evidence for this is conflicting. Hyperemesis gravidarum, where fluid and electrolyte imbalance and nutritional deficiency occur, is far less common, complicating approximately 3.5 per 1000 pregnancies. Nausea and vomiting in pregnancy varies in severity but usually presents within 8 weeks of the last menstrual period. Cessation of symptoms is reported by most by about 16–20 weeks. Various non-medical treatments have been advocated but the ones which appear to be effective are ginger and P6 (wrist) acupressure. According to the NICE antenatal care guideline, antihistamines (prochlorperazine, promethazine and metoclopramide) appear to be the pharmacological agents of choice, as they reduce nausea and are safe in relation to teratogenicity (metoclopramide has insufficient safety data to be recommended as a first-line agent but no association with malformations has been reported), although they are associated with drowsiness [4]. However, the recent Cochrane review concludes there is a lack of high-quality evidence to support any particular intervention [5].

Constipation complicates approximately one-third of pregnancies, usually decreasing in severity with advancing gestation. It is thought to be related in part to poor dietary fibre intake and reduction in gut motility caused by rising levels of progesterone. Diet modification with bran and wheat fibre supplementation helps, as well as increasing daily fluid intake.

Heartburn is also a common symptom in pregnancy but, unlike constipation, occurs more frequently as the pregnancy progresses. It is estimated to complicate one-fifth of pregnancies in the first trimester, rising to about 75% by the third trimester. It is due to the increasing pressure caused by the enlarging uterus combined with the hormonal changes, leading to gastro-oesophageal reflux. It is important to distinguish this symptom from the epigastric pain associated with pre-eclampsia which will usually be associated with hypertension and proteinuria. Symptoms can be improved by simple lifestyle modifications such as maintaining an upright posture especially after meals, lying propped up in bed, eating small frequent meals and avoiding fatty foods. Proprietary antacid formulations, histamine H_2-receptor antagonists and proton-pump inhibitors are all effective, although it is recommended that the latter be used only when other treatments have failed because of their unproven safety in pregnancy.

Haemorrhoids are experienced by 1 in 10 women in the last trimester of pregnancy. There is little evidence for either the beneficial effects of topical creams in pregnancy or indeed their safety. Diet modification may help and in extreme circumstances surgical treatment considered, although this is unusual since the haemorrhoids often resolve after delivery.

Varicose veins occur frequently in pregnancy. They do not cause harm and while compression stockings may help symptoms they unfortunately do not prevent varicose veins from appearing.

The nature of physiological vaginal discharge changes in pregnancy. However, if it becomes itchy, malodorous or is associated with pain on micturition, it may be due to an underlying infection such as trichomoniasis, bacterial vaginosis or candidiasis. Appropriate investigations and treatment should be instigated.

Backache is another potentially debilitating symptom, with an estimated prevalence of up to 61% in pregnancy. There is limited research on effective interventions for backache, but massage therapy, exercise in water and back care classes may be helpful in symptom relief.

Domestic violence

The UK Government defines domestic violence as:

> Any incident or pattern of incidents of controlling, coercive, threatening behaviour, violence or abuse, between those aged 16 or over who are or have been intimate partners or family members regardless of gender or sexuality. The abuse can encompass, but is not limited to: psychological, physical, sexual, financial or emotional (Home Office 2013).

This includes issues of concern to black and minority ethnic communities, such as so-called honour-based violence, female genital mutilation and forced marriage. Family members are defined as mother, father, son, daughter, brother, sister and grandparents, whether directly related, in-laws or stepfamily.

Whatever form it takes, domestic abuse is rarely a one-off incident and should instead be seen as a pattern of abusive and controlling behaviour through which the abuser seeks power over their victim. Typically the abuse involves a pattern of abusive and controlling behaviour which tends to get worse over time. The abuse can begin at any time – in the first year or after many years together. It may begin, continue or escalate after a couple have separated and may take place not only in the home but also in a public place.

Domestic abuse occurs across society regardless of age, gender, race, sexuality, wealth and geography. However, the figures show that it consists mainly of violence by men against women. Children are also affected both directly and indirectly, and there is also a strong correlation between domestic violence and child abuse, with suggested overlap rates of between 40 and 60%.

At least one in four women have experienced domestic violence and this figure is likely to be an underestimate because all types of domestic violence and abuse are under-reported in health and social research, to the police and to other services.

Pregnancy represents a particularly vulnerable time for women. A woman who is experiencing domestic abuse may have difficulties using antenatal care services because the perpetrator of the abuse may try to prevent her from attending appointments. The woman may be afraid that disclosure of the abuse will worsen her situation. Every hospital should have a domestic violence policy promoting the safeguarding welfare of adults at risk of harm, children and young people, and the unborn baby. All healthcare professionals should be alert to the symptoms or signs of domestic violence and have a clear understanding of local safeguarding policies to support vulnerable patients.

Women should be given the opportunity to disclose domestic violence in an environment in which they feel secure. This can be encouraged by making available information and support tailored to women suspected to be experiencing domestic abuse and providing more flexible appointments if needed. Sources of support for women, including addresses and telephone numbers for social services, the police, support groups and women's refuges, should be displayed in appropriate areas. A telephone number that is agreed with the woman and on which it is safe to contact her should be obtained from those at risk.

When domestic violence is either suspected or known, an opportunity must be provided for discussions about individual circumstances in a quiet and private environment, and where the woman can be seen alone. The presence of a partner or a relative may constrain discussion of domestic violence and could place the woman in greater danger. The limitations of confidentiality must be clearly explained at the outset of the discussion. Women often find it difficult to disclose abuse even when they are asked about it and may deny that it is happening. Asking about abuse sends a clear message that abuse is wrong, and that the healthcare professional concerned takes the subject very seriously, giving a clear message that she can come back to the service when she feels ready to disclose. Practitioners may need to screen for domestic violence more than once and this should be a routine part of good clinical practice.

In asking questions it is important that practitioners remain non-judgemental, are empathetic, and listen and be aware of the woman's reaction.

If a woman discloses domestic abuse, immediate safety actions to reduce and manage the risk may be necessary. Actions will depend on whether the practitioner is present with the woman and she is safe in the immediate future, or whether she is still in a vulnerable location (e.g. with the perpetrator). Actions may include the following.

- Calling hospital security or the police in the event of an emergency.
- Is the person in need of immediate treatment for an injury?
- Are there children or vulnerable adults present? Consider if you need to make an onward safeguarding referral: contact the hospital safeguarding team for advice.
- Does the woman have somewhere safe to stay tonight?
- Can she stay with friends or family?
- Does she need temporary accommodation?

A supportive action plan should be discussed and agreed with the woman. The healthcare professional will need

to ensure that the risks to the individual and any children are not increased following disclosure and should discuss their immediate and longer-term safety and the options available and appropriate for them.

The plan of follow-up and action should be documented to provide clarity around any actions to be taken. If an agreed action plan is not followed up, the individual may feel that she has not been listened to. If the individual is unable to follow through with actions discussed, this should be documented and further follow-up and support offered.

Such women need to be supported in their use of antenatal services by training healthcare professionals in the identification and care of at-risk women. All hospital staff should be aware of their responsibilities in relation to safeguarding, including domestic violence. They will be able to achieve this through full compliance with the policy and procedures of their employing organization and attendance at appropriate mandatory training days. Recognition of the signs of domestic violence are now a required competency in Core Module 8: Antenatal Care in the RCOG Curriculum for Trainees. In addition, those undertaking the Advanced Training Skills Module in Forensic Gynaecology will be required to demonstrate significant skill in the recognition and management of domestic violence.

Female genital mutilation

Female genital mutilation (FGM) is defined by the World Health Organization (WHO) as 'all procedures involving partial or total removal of the external female genitalia or other injury to the female genital organs for non-medical reasons' [6]. The WHO classification of FGM is shown in Table 5.1.

FGM is a human rights violation and a form of child abuse because it breaches the United Nations Convention on the Rights of the Child. FGM is practised in 29 African countries but is also performed in non-African countries. It is estimated that over 125 million women and girls have undergone FGM worldwide [7]. In England and Wales it is estimated that there are 137 000 women and girls living with FGM, as they were born in countries where FGM is practised.

Table 5.1 WHO classification of female genital mutilation.

Type 1	Partial or total removal of the clitoris and/or the prepuce (clitoridectomy)
Type 2	Partial or total removal of the clitoris and the labia minora, with or without excision of the labia majora (excision)
Type 3	Narrowing of the vaginal orifice with creation of a covering seal by cutting and appositioning the labia minora and/or the labia majora, with or without excision of the clitoris (infibulation)
Type 4	All other harmful procedures to the female genitalia for non-medical purposes, for example pricking, piercing, incising, scraping and cauterization

FGM is associated with many complications, both short term (e.g. bleeding and infection) and long term (e.g. genital scarring, urinary problems, dyspareunia, menstrual problems and obstetric complications). In 2015, the RCOG published the second edition of the Green-top guideline on FGM and its management [8].

The obstetric complications include prolonged labour, perineal trauma, postpartum haemorrhage, increased risk of caesarean section, increased need for neonatal resuscitation and risk of early neonatal death and stillbirth. Given the potential severity of the obstetric complications, it is important that women with FGM are identified in the antenatal period. This is equally important for the protection of the unborn female child as she will be at risk of FGM as a child.

All women should be asked about a history of FGM at their booking visit, irrespective of the country of origin. Ideally, they will be referred to a dedicated multidisciplinary service and the majority will require consultant-led care. Some will require psychological support and some may require antenatal de-infibulation, especially women with FGM type 3, if it is considered that vaginal assessment in labour is likely to be difficult. The RCOG Green-top guideline also recommends screening for hepatitis C in addition to the routine antenatal infection screening tests. All women should have a documented plan of care for the antenatal, intrapartum and postnatal periods.

FGM is illegal in the UK and many other countries. UK healthcare professionals have certain responsibilities when women with FGM are identified in the antenatal period or at other times. They must explain the UK law on FGM to the woman and be familiar with the requirements of the Health and Social Care Information Centre (HSCIC) FGM Enhanced Dataset. This requires the submission of non-anonymized personal data and this must be explained to the woman. The recording of the data is different to reporting of the woman to the police or social services. The latter is not mandatory unless there is risk to the unborn child or existing children. The UK Department of Health has produced safeguarding risk assessment tools for this purpose (https://www.gov.uk/government/publications/safeguarding-women-and-girls-at-risk-of-fgm). If FGM is confirmed in a girl under the age of 18, reporting to the police is mandatory [8].

Screening for maternal complications

Anaemia

Maternal iron requirements increase in pregnancy because of the demands of the developing fetus, the formation of the placenta and the increase in the maternal red cell mass. With an increase in maternal plasma volume of up to 50% there is a physiological drop in the haemoglobin (Hb) concentration during pregnancy. It is generally recommended that an Hb level below 110 g/L up to 12 weeks' gestation or less than 105 g/L at 28 weeks signifies anaemia and warrants further investigation. A low Hb (85–105 g/L) may be associated with preterm labour and low birthweight. Routine screening should be performed at the booking visit and at 28 weeks' gestation. While there are many causes of anaemia, including thalassaemia and sickle cell disease, iron deficiency remains the commonest. Serum ferritin is the best way of assessing maternal iron stores and if found to be low, iron supplementation should be considered. Routine iron supplementation in women with a normal Hb in pregnancy has not been shown to improve maternal or fetal outcome and is currently not recommended.

Blood group and red cell alloantibodies

Identifying the maternal blood group and screening for the presence of atypical antibodies is important in the prevention of haemolytic disease, particularly from rhesus alloimmunization. Routine antibody screening should take place at booking in all women and again at 28 weeks' gestation irrespective of their rhesus D (RhD) status. Detection of clinically significant atypical antibodies should prompt referral to a specialist fetal medicine unit for further investigation and management. In the UK, 15% of women are RhD negative and should be offered anti-D prophylaxis after potentially sensitizing events (e.g. amniocentesis or antepartum haemorrhage) and routinely at either 28 and 34 weeks' gestation or once at 32 weeks depending on the dosage of anti-D immunoglobulin used [4]. Consideration should also be given to offering partner testing, as anti-D prophylaxis will not be necessary if the biological father is RhD negative. In the future, all RhD-negative women may have routine diagnosis of fetal RhD status by analysing free fetal DNA in the maternal plasma. This will allow targeted anti-D administration to women with RhD-positive fetuses, which may result in cost savings and allow many women to avoid an unnecessary blood product. An observational service implementation pilot in three NHS units showed that at least 35% of RhD-negative women can avoid unnecessary anti-D administration and this service could be implemented with little additional cost and probably a saving, if the cost of the fetal DNA test is less than the cost of each anti-D injection [9].

Haemoglobinopathies

Screening for sickle cell disease and thalassaemias is important and each country will have a different screening strategy depending on the prevalence of these conditions. In the UK, this screening should be offered to all women as early as possible in pregnancy. If the regional sickle cell disease prevalence is high, laboratory screening should be offered. If the regional sickle cell disease prevalence is low, the initial screening should be based on the Family Origin Questionnaire; if this indicates high risk, then laboratory screening should be offered.

Infection

Maternal blood should be taken early in pregnancy and with consent screened for hepatitis B, HIV and syphilis. Identification of women who are hepatitis B carriers can lead to a 95% reduction in mother-to-infant transmission following appropriate postnatal administration of vaccine and immunoglobulin to the baby. Women who are HIV positive can be offered treatment with antiretroviral drugs which, when combined with delivery by caesarean section (unless undetectable viral load) and avoidance of breastfeeding, can reduce maternal transmission rates from approximately 25% to 1% [10]. Such women need to be managed by appropriate specialist teams. Routine screening for rubella ended in England in April 2016, primarily because rubella infection levels in the UK are so low that they are defined as eliminated by the WHO criteria.

Although the incidence of infectious syphilis is low, there have been a number of recent outbreaks in England and Wales. Untreated syphilis is associated with congenital syphilis, neonatal death, stillbirth and preterm delivery. Following positive screening for syphilis, testing of a second specimen is required for confirmation. Interpretation of results can be difficult and referral to specialist genitourinary medicine clinics is recommended. Current evidence does not support routine screening for cytomegalovirus, hepatitis C, toxoplasmosis or group B *Streptococcus*.

Asymptomatic bacteriuria occurs in approximately 2–5% of pregnant women and when untreated is associated with pyelonephritis and preterm labour. Appropriate treatment will reduce the risk of preterm birth. Screening should be offered early in pregnancy by midstream urine culture.

Hypertensive disease

Chronic hypertension pre-dates pregnancy or appears in the first 20 weeks, whereas pregnancy-induced hypertension develops in the pregnancy, resolves after delivery and is not associated with proteinuria. Pre-eclampsia is defined as hypertension that is associated with proteinuria occurring after 20 weeks and resolving after birth. Pre-eclampsia occurs in 2–10% of pregnancies and is associated with both maternal and neonatal morbidity and mortality [11]. Risk factors include nulliparity, age 40 years and above, family history of pre-eclampsia, history of pre-eclampsia in a prior pregnancy, BMI greater than 35, multiple pregnancy and pre-existing diabetes or hypertension. Hypertension is often an early sign that pre-dates the development of serious maternal and fetal disease and should be assessed regularly in pregnancy. There is little evidence as to how frequently blood pressure should be checked and so it is important to identify risk factors for pre-eclampsia early in pregnancy. In the absence of these, blood pressure measurement and urine analysis for protein should be performed at each routine antenatal visit and mothers should be warned of the advanced symptoms of pre-eclampsia (frontal headache, epigastric pain, vomiting and visual disturbances). However, when risk factors are present, more frequent blood pressure measurements and urine analyses should be considered in addition to low-dose aspirin prophylaxis (see Chapter 7).

Gestational diabetes

Currently there is little agreement as to the definition of gestational diabetes, whether and how we should screen for it and how to diagnose and manage it. However, there has been increasing evidence that 'treating' gestational diabetes is more beneficial than expectant management [12]. Consequently, the National Institute for Health and Care Excellence (NICE) recommends screening for gestational diabetes using risk factors (such as BMI >30 kg/m^2 or previous gestational diabetes) in a healthy population [4]. Women with risk factors should be tested for gestational diabetes using the 2-hour 75-g oral glucose tolerance test.

Psychiatric illness

The importance of psychiatric conditions related to pregnancy was highlighted in the 2000–2002 Confidential Enquiry into Maternal and Child Health [13]. A significant number of maternal deaths due to or associated with psychiatric causes were also reported in the most recent enquiry [1]. At booking, women should be asked about history of significant mental illness, previous psychiatric treatment or a family history of perinatal mental health illness. If mental illness is suspected, further referral for assessment should be made. Good communication, particularly with primary care, is paramount.

Screening for fetal complications

Confirmation of fetal viability

All women should be offered a 'dating' scan. This is best performed between 10 and 13 weeks' gestation and the crown–rump length measured when the fetus is in a neutral position (i.e. not curled up or hyperextended). Current evidence shows that the estimated day of delivery predicted by ultrasound at this gestation will reduce the need for induction of labour at 41 weeks when compared with the due date predicted by the last menstrual period. In addition, a dating scan will improve the reliability of Down's syndrome screening, diagnose multiple pregnancy and allow accurate determination of chorionicity and diagnose up to 80% of major fetal abnormalities. Women who present after 14 weeks' gestation should be offered a dating scan where the estimated date of delivery is calculated by the ultrasound measurement of the head circumference.

Screening for Down's syndrome

Current recommendations from NICE advocate that all women in the UK are offered the combined screening test for Down's syndrome between 11 weeks and 13 weeks 6 days of gestation. Those that book later should be offered serum screening between 15 and 20 weeks' gestation. The National Screening Committee further refined these guidelines in 2010, stating that the detection rate should be 90% for a screen-positive rate of 2%. Because screening for Down's syndrome is a complex issue, healthcare professionals must have a clear understanding of the options available to their patients. Unbiased, evidence-based information must be given to the woman at the beginning of the pregnancy so that she has time to consider whether to opt for screening and the opportunity to clarify any areas of confusion before the deadline for the test passes. Recognizing the importance of this, NICE currently recommends that the first two antenatal appointments take place before 12 weeks' gestation to allow the woman adequate time to make an informed decision about whether to have screening. Following a 'screen-positive' result the woman needs careful counselling to explain that the test result does not mean the fetus has Down's syndrome and to explain the

options for further testing. A positive screen test does not mean further testing is mandatory. Likewise, a woman with a 'screen-negative' result must understand that the fetus may still have Down's syndrome.

The recent introduction of fetal DNA non-invasive prenatal testing (NIPT) allows another option prior to or instead of invasive testing because of the high sensitivity and low screen-positive rate. Universal screening with NIPT may increase the detection rate to above 99% for the screened population but it has cost implications for publicly funded healthcare systems and has a significant failure rate. Contingent screening (offering NIPT to women with high-risk combined screening) would have lower cost at the expense of lower detection rate. The detection rate would depend on the chosen cut-off value of risk (e.g 1 in 150) for offering NIPT. With either strategy, the number of invasive procedures would be lower and hence there would be fewer miscarriages of healthy fetuses as a result of screening. The UK National Screening Committee commissioned a systematic review and cost-consequence assessment of fetal DNA testing (https://legacyscreening.phe.org.uk/policydb_download.php?doc=552) and recommended offering NIPT to pregnant women whose chance of having a baby with Down's, Edwards' or Patau's syndrome is greater than 1 in 150 [14].

Screening for structural abnormalities

The identification of fetal structural abnormalities allows the opportunity for *in utero* therapy, planning for delivery, for example when the fetus has major congenital heart disease, parental preparation and the option of termination of pregnancy should a severe problem be diagnosed. Major structural anomalies are present in about 3% of fetuses screened at 20 weeks' gestation. Detection rates vary depending on the system examined, skill of the operator, time allowed for the scan and quality of the ultrasound equipment. Follow-up data are important for auditing the quality of the service. Women must appreciate the limitations of such scans. Local detection rates of various anomalies such as spina bifida, heart disease or facial clefting should be made available. Written information should be given to women early in pregnancy explaining the nature and purpose of such scans, highlighting conditions that are not detected such as cerebral palsy and many genetic conditions. It is important to appreciate that the fetal anomaly scan is a screening test which women should opt for rather than have as a routine part of antenatal care without appropriate counselling. In 2010 the NHS Fetal Anomaly Screening Programme published a document for national standards and guidance for the mid-trimester fetal anomaly scan; this was updated in 2015 [15]. These standards set out the basis for the ultrasound screening service in England, describing what can and, importantly, what cannot be achieved.

Screening for fetal growth restriction

Each antenatal clinic attendance allows the opportunity to screen for fetal well-being. Auscultation for the fetal heart will confirm that the fetus is alive and can usually be detected from about 14 weeks of gestation. While hearing the fetal heart may be reassuring, there is no evidence of a clinical or predictive value. Likewise there is no evidence to support the use of routine cardiotocography in uncomplicated pregnancies. Physical examination of the abdomen by inspection and palpation will identify approximately 30% of small-for-gestational age fetuses [16]. Measurement of the symphysis–fundal height in centimetres starting at the uterine fundus and ending on the fixed point of the symphysis pubis has a sensitivity and specificity of approximately 27 and 88%, respectively, although serial measurements may improve accuracy. A risk stratification algorithm is recommended by the recent NHS England care bundle for reducing stillbirth [3] as well as the RCOG Green-top guideline [16]. Women with one or more risk factors should have serial ultrasound scans to assess fetal growth, whereas low-risk women should have growth assessment by antenatal symphysis–fundal height charts (customized or other established growth chart). Customized growth charts make adjustments for maternal height, weight, ethnicity and parity. However, there is no good-quality evidence that their use improves perinatal outcomes [4].

Traditionally, women have been advised to note the frequency of fetal movements in the third trimester and report reduced fetal movements. Raising awareness of reduced fetal movement has been another element of the NHS England care bundle for reducing stillbirth [3]. Women should be given information and advice leaflet by week 24 of pregnancy and reduced fetal movements should be discussed at every subsequent visit. A protocol based on the relevant RCOG guideline should be in place for these women; this will lead to ultrasound scan for fetal growth, amniotic fluid and umbilical artery Doppler assessment if there are additional risk factors for fetal growth restriction or stillbirth.

Organization of antenatal care

Antenatal care has been traditionally provided by a combination of general practitioners, community midwives, hospital midwives and obstetricians. The balance has depended on the perceived normality of the pregnancy at booking. However, pregnancy and childbirth is to a

certain extent an unpredictable process. The frequency of antenatal visits and appropriate carer must be planned carefully, allowing the opportunity for early detection of problems without becoming over-intrusive.

Who should provide the antenatal care?

A meta-analysis comparing pregnancy outcome in two groups of low-risk women, one with community-led antenatal care (midwife and general practitioner) and the other with hospital-led care, did not show any differences in terms of preterm birth, caesarean section, anaemia, antepartum haemorrhage, urinary tract infections and perinatal mortality. The first group had a lower rate of pregnancy-induced hypertension and pre-eclampsia, which could reflect a lower incidence or lower detection [17]. However, clear referral pathways need to be developed that allow appropriate referral to specialists when either fetal or maternal problems are detected.

There is little evidence regarding women's views on who should provide antenatal care. Unfortunately, care is usually provided by a number of different professionals often in different settings. Studies evaluating the impact of continuity of care do not generally separate the antenatal period from labour. The studies consistently show that with fewer caregivers women are better informed and prepared for labour, attend more antenatal classes, have fewer antenatal admissions to hospital and have higher satisfaction rates. Differences in clinical endpoints such as caesarean section rates, postpartum haemorrhage, admission to the neonatal unit and perinatal mortality are generally insignificant [4]. While it would appear advantageous for women to be seen by the same midwife throughout pregnancy and childbirth, there are practical and economic considerations that need to be taken into account. Nevertheless, where possible, care should be provided by a small group of professionals.

Documentation of antenatal care

The antenatal record needs to document clearly the care the woman has received from all those involved. It will also serve as a legal document, a source of useful information for the woman and a mechanism of communication between different healthcare professionals. There is now good evidence that women should be allowed to carry their own notes. Women feel more in control of their pregnancy and do not lose the notes any more often than the hospital! In addition, useful information will be available to clinicians should the woman require emergency care while away from home. Many areas of the UK are endeavouring to work towards a standard format for the records. This would be of benefit to those women who move between hospitals so that caregivers would automatically be familiar with the style of the notes. If we are to move to an electronic patient record, there must be general agreement in a minimum dataset and a standard antenatal record would be a step in this direction.

Frequency and timing of antenatal visits

There has been little change in how frequently women are seen in pregnancy for the last 50 years. In 2003, NICE produced a clinical guideline entitled *Antenatal Care: Routine Care for the Healthy Pregnant Woman*, which was revised in 2008 [4] and updated in 2013. This document recognized the large amount of information that needs to be discussed at the beginning of pregnancy, particularly with regard to screening tests. The first appointment needs to be early in pregnancy, certainly before 12 weeks if possible. This initial appointment should be regarded as an opportunity for imparting general information about the pregnancy such as diet, smoking and folic acid supplementation. A crucial aim is to identify those women who will require additional care during the pregnancy. A list of conditions for which additional care will be needed is provided at the NICE website (https://www.nice.org.uk/guidance/cg62/chapter/Appendix-C-Women-requiring-additional-care). A urine test should be sent for bacteriological screen and a dating ultrasound scan arranged. Sufficient time should be set aside for an impartial discussion of the screening tests available, including those for anaemia, red-cell antibodies, syphilis, HIV and hepatitis. Because of the complexity of Down's syndrome screening, this too should be discussed in detail and supplemented with written information. Ideally another follow-up appointment should be arranged before the screening tests need to be performed to allow further questions and to arrange a time for the tests following maternal consent.

The next appointment needs to be around 16 weeks' gestation to discuss the results of the screening tests. In addition, information about antenatal classes should be given and a plan of action made for the timing and frequency of future antenatal visits, including who should see the woman. As with each antenatal visit, the blood pressure should be measured and the urine tested for protein. The 20-week anomaly scan should also be discussed and arranged and women should understand its limitations.

At each visit the symphysis–fundal height is plotted, the blood pressure measured and the urine tested for protein. At 28 weeks' gestation, blood should be taken for haemoglobin estimation and atypical red-cell antibodies. Anti-D prophylaxis should be offered to women who are rhesus negative. A follow-up appointment at 34 weeks will allow the opportunity to discuss these results.

At 36 weeks, the position of the baby needs to be checked and if there is uncertainty an ultrasound scan arranged to exclude breech presentation. If a breech is confirmed, external cephalic version should be considered. For women who have not given birth by 41 weeks, both a membrane sweep and induction of labour should be discussed and offered. Additional appointments at 25, 31 and 40 weeks are proposed for nulliparous women.

In summary, a total of 10 appointments is recommended for nulliparous women and seven appointments for multiparous women, assuming they have uncomplicated pregnancies.

Summary box 5.1

- The administration of folic acid 400 µg/day is recommended to reduce the incidence of NTDs.
- Women should be informed of the harmful effects of smoking in pregnancy.
- Nulliparous women require more antenatal appointments.
- Women with risk factors should be referred to specialist obstetric care.
- At booking, women should be asked about history of significant mental illness, previous psychiatric treatment or family history of perinatal mental illness.
- Women with FGM should be referred to a specialist multidisciplinary service.
- Dating scan should be performed between 10 and 13 weeks' gestation by measuring the crown–rump length.
- All women in the UK should be offered the combined screening test for Down's syndrome between 11 and 14 weeks' gestation.
- Antihistamines (prochlorperazine, promethazine and metoclopramide) appear to be the pharmacological agents of choice for nausea and vomiting in pregnancy.
- It is recommended that women are offered estimation of fetal size by symphysis–fundal height measurement at each antenatal visit; when there is suspicion of a small fetus, they are referred for formal ultrasound assessment.

First Trimester Antenatal Screening

T.K. Lau

Fetal Medicine Centre, Paramount Medical Centre, Hong Kong

A large part of normal obstetric care consists of a series of screening tests designed to identify those pregnant women who are at risk of various maternal, obstetric or fetal complications so that early interventions can be initiated so as to minimize maternal and fetal mortality and morbidities. This series of 'screening' tests includes not just blood tests and ultrasound scans but also history-taking and physical examination. Many of these screening tests have been discussed in other chapters in this book under specific conditions and therefore will not be repeated here. This chapter focuses on the antenatal screening of chromosomal abnormalities.

In deciding what diseases to screen for, one should balance the potential benefits and harms that a screening test may result in people who are otherwise well. The most widely used set of principles at present is the one described by Wilson and Jungner in a 1968 report commissioned by the World Health Organization (WHO). These principles are as follows.

1) The condition sought should be an important health problem.
2) There should be an accepted treatment for patients with recognized disease.
3) Facilities for diagnosis and treatment should be available.
4) There should be a recognizable latent or early symptomatic stage.
5) There should be a suitable test or examination.
6) The test should be acceptable to the population.
7) The natural history of the condition, including development from latent to declared disease, should be adequately understood.
8) There should be an agreed policy on whom to treat as patients.
9) The cost of case-finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole.
10) Case-finding should be a continuing process and not a 'once and for all' project.

A screening test will categorize the testing population into a high-risk (or test-positive) group and a low-risk (or test-negative) group. Further investigations and diagnostic tests should be considered for those in the high-risk group. There are four important parameters in assessing the performance of a screening test, namely the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV).

Sensitivity, or detection rate or true positive rate, refers to the proportion of affected subjects that are correctly identified by the screening test, while specificity refers to the proportion of negatives that are correctly identified as such. Specificity, or true negative rate, equals (1 – false-positive rate). Sensitivity and specificity are determined by the screening test itself. A high sensitivity indicates a lower chance of missing an affected subject, while a high specificity will lead to less false alarms and therefore less harm. PPV refers to the proportion of screened high-risk subjects who are indeed affected by the condition or disease, while NPV refers to the proportion of screened low-risk subjects who are indeed free of the condition. Both PPV and NPV are not only affected by the sensitivity and specificity of the test but also by the prevalence of the condition in the testing population. For example, the PPV for a screening test with a sensitivity of 95% and a specificity of 95% will be 1.87% (1 in 53), 16.1% (1 in 6) and 67.9% (1 in 1.5) when the disease prevalence in the testing population is 0.1, 1 and 10%, respectively.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Summary box 6.1

- The effectiveness of a screening test is determined by its sensitivity and specificity.
- The majority of screen-positive subjects are false positives. The PPV is affected by the prevalence of the condition.

First-trimester Down's syndrome screening

Overview

Screening for fetal Down's syndrome has become part of routine antenatal care in many countries. Down's syndrome has been considered the commonest genetic cause of intellectual disability. Without screening, the incidence is about 1 in 600 to 1 in 800 live births. The incidence of Down's syndrome increases with maternal age, being relatively stable before age 30 but increasing exponentially after age 35. About 30% of affected pregnancies result in miscarriage or intrauterine fetal death and therefore the incidence of Down's syndrome decreases with advancing gestational age.

In over 95% of individuals with Down's syndrome the condition is due to trisomy 21 – the presence of one extra chromosome 21 – which is typically due to an error, namely non-disjunction, during cell division. About 95% of the non-disjunctions are meiotic errors, of which over 90% are maternal in origin. The remaining 5% of non-disjunctions are due to mitotic errors. Although trisomy 21 is not an inherited condition, a history of an affected pregnancy increases the chance of having another affected pregnancy by about 0.75%. Previous trisomy 21 not only increases the risk of trisomy 21 (relative risk or RR, 2.2) but also other different trisomies such as trisomy 13 or 18 (RR 1.4) in subsequent pregnancies [1]. This suggests that some individuals are more prone to non-disjunction during meiosis, or some trisomies are due to underlying maternal gonadal mosaicism.

About 2–3% of Down's syndrome cases are due to Robertsonian translocations, in which part of chromosome 21 is translocated to another chromosome, most commonly chromosome 14. About two-thirds of these cases are *de novo* events, while one-third are inherited from one of the parents who is a carrier of a balanced translocation. If the mother is the carrier, there is about a 10–15% chance of recurrence in future pregnancies. If the father is the carrier, the risk is much lower, estimated to be at most 3% although some believe that the additional risk is negligible. If an individual is a carrier of a very special form of balanced Robertsonian translocation involving two chromosomes 21, there will be 100% risk of having pregnancies with Down's syndrome.

About 2–3% of Down's syndrome are mosaic. The phenotype may be milder, especially among those with low percentage of the abnormal cell line.

All individuals with Down's syndrome have similar facial characteristics and some degree of intellectual disability, most common in the moderate degree range. About 40% are in the mild range with IQ between 50 and 70. Other medical problems are common, including hearing loss (up to 70%), obstructive sleep apnoea (50%), congenital heart diseases (50%), hypothyroidism, otitis media, cataracts and visual problems. They are at higher risk of developing leukaemia and Alzheimer's disease.

In the past, the outcome of individuals with Down's syndrome was poor, mostly due to the lack of medical care and support. In the early 1900s, affected individuals seldom survived to their teenage years. However, the prognosis of individuals with Down's syndrome has improved significantly over the last century. Currently in developed countries the average lifespan of affected individuals is already over 50, and many of them are living with their families or independently with varying degree of support.

Such improvement relies on the availability of appropriate and adequate medical care, early interventional programmes, education, financial support, social support and employment opportunities. Such interventions not only are important determining factors for the prognosis of affected individuals, but also affect the well-being of the family as a whole. In developed countries with adequate medical and social support, most families with children with Down's syndrome are able to find enough resources to help them in coping with the additional demands and challenges, resulting in an ordinary family life in themselves. However, about 30–40% of families still have significant stress and distress.

Even with all necessary social and medical support, Down's syndrome remains a condition with multiple medical problems that poses significant stress and challenges to the family. At present, it is medically possible to identify affected pregnancy in the antenatal period, and pregnancy termination of affected pregnancies is legal in many countries. Almost all published studies have confirmed that prenatal Down's syndrome screening is cost-effective. On the other hand, Down's syndrome is a non-lethal condition, and there is continuous debate about the ethics of terminating affected pregnancies. It is beyond the scope of this chapter to elaborate on the ethics of Down's syndrome screening. The discussion will therefore focus on the scientific basis and details of implementation of Down's syndrome screening in the first trimester of pregnancy.

Uptake of screening and ethical issues

Not all women want to undergo screening so any programme must recognize those wishing to 'opt out'. In the UK this group comprises 10–40% of the pregnant population, depending on local demographics. In this case these women can have an early scan but the fetal nuchal translucency (NT) is not measured.

First-trimester combined screening programmes

First-trimester combined screening test, or first-trimester combined screening (FTCS), is the commonest form of first-trimester screening, in which the risk of Down's syndrome is estimated based on the measurement of fetal NT and maternal serum markers, including pregnancy-associated plasma protein A (PAPP-A) and free β-human chorionic gonadotrophins (fb-hCG). The typical changes associated with fetal Down's syndrome are increased NT and maternal fb-hCG, and a reduction in maternal PAPP-A.

Most first-trimester combined screening programmes are performed between 11 and 13^{+6} weeks of gestation, or at a crown–rump length of 45–84 mm.

Down's syndrome screening is a risk estimation process. This starts with the estimation of the a priori risk or pre-test odds of Down's syndrome of a test subject based on her age, gestational age and history of affected pregnancies. Then, multiple markers are measured. The deviation of each marker from the expected value of a normal pregnancy is calculated, based on which a likelihood ratio (LR) is estimated. The LR tells how much more likely a pregnancy is affected by Down's syndrome given the value of the measurement. LR of 1 means that there is no change in risk. LR above 1 denotes an increased risk, while LR below 1 denotes a reduced risk. An individualized risk or post-test odds is calculated based on the following formula:

$$\text{Post-test odds} = \text{pre-test odds} \times \text{LR}_{\text{NT}} \times \text{LR}_{\text{PAPP-A}} \times \text{LR}_{\text{fb-HCG}} \cdots$$

Most Down's syndrome screening algorithms use a similar approach, although more complicated mathematical modelling may be involved to take into account the interactions between different markers.

A cut-off value of the individualized risk is chosen to categorize a test subject as high or low risk. There are many ways to determine the cut-off value. Moving the cut-off will change the sensitivity and specificity at the same time. For example, assuming that the sensitivity and specificity are 75% and 95%, respectively, at a cut-off of 1 in 250, moving the cut-off to 1 in 400 may increase the sensitivity to 85% but also reduce the specificity to 80%. Moving the cut-off to 1 in 100 may reduce the sensitivity to 65% but also increase the specificity to 98%. These numbers are only hypothetical, and the true effect in a screening programme can be analysed by the ROC (receiver operating characteristic) curve. The choice of cut-off is therefore a compromise between high sensitivity and high specificity.

It is important to realize that using the same screening test with the same cut-off in populations with different maternal age may result in different sensitivities and specificities. For example, using a fixed cut-off, the same screening test will result in higher sensitivity and lower specificity among those aged 35 or above compared to those aged 25 or below. Some argue that there should not be a recommended cut-off, and screened subjects should simply make their own judgement based on their own individualized risk to determine if further diagnostic tests are necessary. However, most screened subjects would probably be less confused with a suggested cut-off and a simple result of high or low risk.

NT is one of the best single markers of fetal Down's syndrome. NT is due to a thin layer of fluid beneath the fetal nuchal skin. It is present in all fetuses in the late first and early second trimester, and then gradually disappears. NT must be differentiated from nuchal fold thickness, which is a mid-second trimester marker measuring the fetal nuchal skin but not fluid collection. When properly performed, NT alone enables the detection of 70–80% of pregnancies affected by Down's syndrome at a 5% false-positive rate (FPR). Increased NT is also detected in about 70–75% of fetuses with trisomy 13 and trisomy 18, and 80–90% of those with Turner's syndrome. Overall, about 5–8% of those with increased NT will have chromosomal abnormalities.

Risk assessment by NT should only be undertaken by those who have been trained and accredited, with continuous auditing of performance and recertification. The most commonly used protocol is listed in Table 6.1, which should be followed strictly. Unlike maternal biochemistry, NT is not significantly affected by maternal characteristics.

Risk assessment by maternal serum biochemistry using PAPP-A and fb-hCG alone has a performance comparable to that of screening using NT alone, with a sensitivity of about 70% at 5% FPR. Maternal serum markers are significantly affected by maternal characteristics, including ethnicity, maternal weight, medical disease such as diabetes and the mode of conception. Most risk calculation algorithms provide adjustment for these factors, to maximize the test performance. All laboratories performing Down's syndrome screening biochemistry should have continuous internal and external quality assurance programmes (such as the United Kingdom National External Quality Assessment Service,

Table 6.1 The standard protocol for proper first-trimester nuchal translucency (NT) measurement used in prenatal Down's syndrome screening.

The measurement must be taken at a gestation between 11 weeks and 13 weeks 6 days
The measurement must be taken when the fetal crown–rump length is between 45 and 84 mm
The image must be taken in a good sagittal section, with the baby lying horizontally
The image must be magnified to include the fetal head and upper thorax only
The measurement should be taken when the neck is in a neutral position
The NT must be clearly shown
The calliper is placed *on* the line that defines the NT thickness: the crossbar of the calliper should be such that it is hardly visible as it merges with the white line of the border, not in the nuchal fluid
The measurement should be taken where the NT is thickest
The NT should be measured three times and the largest one is taken as the NT of the fetus
The amnion should not be confused with the skin, which will overestimate the NT

UKNEQAS) in place to ensure the stability of their assay. It is important for all clinicians involved in prenatal screenings to ensure that the biochemical laboratories they are using are well qualified and have satisfactory quality control.

Combining NT, PAPP-A and fb-hCG as the FTCS, the sensitivity is about 90% at 5% FPR. Screening centres should participate in appropriate quality assurance programmes.

Variations of first-trimester combined screening

The common variations include the following.

Approach using ultrasound markers alone

In addition to thickened NT, other sonographic markers, including absence of nasal bone (NB), tricuspid regurgitation (TR), abnormal waveform of ductus venosus (DV), increased frontomaxillary facial angle, the presence of aberrant right subclavian artery and many others, have been found to be associated with fetal Down's syndrome. Algorithms have been developed to use solely sonographic markers in calculating the individualized risk of Down's syndrome, commonly incorporating NT, NB, DV, TR and fetal heart rate, achieving a test performance similar to that of the FTCS programme. The advantage of this approach is that the test result is immediately available, and the assessment is fetus-specific. It is particularly useful in cases of multiple pregnancies, or a vanished twin pregnancy. The disadvantage is that ultrasound is a highly operator-dependent test, for which quality control is more difficult than for biochemistry-based tests. Since the throughput of an accredited sonographer is much lower than that of an accredited biochemical laboratory, an ultrasound-only approach is more difficult to implement in populated-based screening programmes. Furthermore, this approach has not been tested as vigorously in different ethnic populations as the FTCS. The effect of ethnicity on some of the markers, such as NB, is substantial.

Biochemistry-based approach

FTCS is not feasible if there are insufficient accredited sonographers for NT measurement. Under such circumstances, first-trimester screening can only be performed based on biochemistry alone. Compared with second-trimester screening, this offers earlier screening but there is no major additional benefit in terms of test performance. Even with biochemistry alone, a simple dating scan will improve the screening performance by confirming the number of fetuses and accurate dating.

Integrated or sequential screening

Different markers, both sonographic and biochemical, are tested at different gestational ages, typically in both first and second trimesters. Only one individualized risk is calculated when information from all markers is available. The advantage is improved performance, with estimated sensitivity above 90% and specificity above 98%. However, this approach involves more visits, more complicated logistic and administrative arrangements, higher chance of dropout, and high chance of deviation from protocol based on results from the first part of the study.

Special conditions

1) *Multiple pregnancies*. First-trimester combined screening can be used in twin pregnancies, although both sensitivity and specificity are lower, 75% and 90–97%, respectively. The chorionicity must be known for proper risk calculation. For higher-order pregnancies, no reliable data are available for adjustment of biochemistry. Ultrasound-based screening is the only available option.
2) *Vanished twin*. At the time of first-trimester combined screening, the presence of an empty second gestational sac does not appear to significantly affect the serum level of biochemical markers and therefore these pregnancies can be tested as singleton. However, if the second sac contains a dead fetus, the serum marker levels are affected unpredictably and no reliable adjustment can be made. In such situations, only ultrasound-based screening test should be performed.

3) *First-trimester vaginal bleeding*. This does not appear to significantly affect the serum biochemistry and therefore first-trimester combined screening can be performed even with such history.
4) *NT of 3.5 mm or above*. It is well known that increased NT is not only associated with chromosomal abnormalities, but also increased risk of intrauterine death, miscarriage, and fetal structural or genetic anomalies, in particular fetal cardiac defects. Overall, about 20% of those with increased NT but normal karyotype have an adverse outcome. This incidence varies with the initial NT value, being 8% for NT up to 3.5 mm, 20% for NT of 3.5–4.4 mm, 30% for 4.5–5.4 mm, 40% for 5.5–6.4 mm and 80% for those with NT above 6.5 mm [2]. When NT is 3.5 mm or above, the majority will be screened positive even when combined with biochemistry. Therefore, those with NT of 3.5 mm or above may be given a choice either to complete the FTCS by taking the biochemical test, or to have a diagnostic test directly. In any case, they should be referred for a detailed sonographic examination to exclude cardiac and other structural abnormalities. For those with additional abnormalities, specific genetic tests, such as Noonan syndrome tests, may be necessary. However, pregnant women can be reassured that if a detailed second-trimester scan is completely normal, the chance of having a healthy normal baby is about 96%.

Common questions and misconceptions about first-trimester screening of Down's syndrome

1) Using a single cut-off of NT: since the NT value in normal pregnancies increases with gestational age even between 11 and 13^{+6} weeks, a single cut-off of NT should not be used to define high-risk or low-risk groups. Increased NT should be defined by an NT measurement above the 95th percentile based on a gestation-specific reference chart. Incidentally, the 99th percentile of NT is roughly stable at 3.5 mm.
2) NT larger than +2SD (standard deviation) indicates Down's syndrome: many doctors and couples are horrified by an NT measurement that is above the +2SD level. Although a value above the 2SD level is usually defined statistically as abnormal, most individuals in this group are in fact normal. This is particularly true if the NT is below 3.5 mm. Most individuals will still be screened negative when combined with biochemistry, and have a normal baby.
3) Increased NT indicates cardiac defects: there is no doubt that there is a positive relationship between NT and the incidence of congenital heart defect (CHD), being 1.5% at NT of 2.5–3.4 mm, 3.4% at 3.5–4.4 mm, 7.5% at 4.5–5.4 mm, 15% at 5.5–6.4 mm, 19% at 6.5–8.4 mm and 64% at 8.5 mm or above. Unfortunately, the detecting rate of CHD using NT as the sole screening test is disappointing, being 31% if the NT cut-off is set at 3.5 mm which corresponds to the 99th percentile, or 37% if the cut-off is set at the 95th percentile [3]. In other words, the incidence of CHD is still below 2% among those with an NT between +2SD and the 99th percentile. Even with NT of 3.5–4.4 mm, over 95% will still have a normal heart. Irrespective of the NT value, every pregnancy should have a proper fetal structural assessment in the mid-trimester. Using NT as a screening tool for CHD should not be considered if there are insufficient competent sonographers able to perform first-trimester fetal echocardiography.
4) Absence of nasal bone: many couples interpret this as a malformation of the nose. Absence of nasal bone is a misnomer. It is not a structural anomaly. It only refers to the lack of calcification of the nasal cartilage, making the nasal bone less echogenic than usual. Absence of nasal bone does not imply abnormalities of the nose, or facial abnormalities. In fact, those with absence of nasal bone generally have a normal external appearance. In the majority of such cases, the nasal bone will become visible with increasing gestation. Although absence of nasal bone is a strong marker for fetal Down's syndrome, the great majority of those with absence of nasal bone are still normal fetuses. If the fetal karyotype is normal, there is no clinical significance associated with this sonographic marker.
5) Reliability of blood tests using maternal serum biochemical markers: the reliability of these assay results relies not only on the quality of the laboratory, but also the way blood samples are collected, stored and transported before they reach the laboratory. Some markers such as fb-hCG are particularly vulnerable to external factors, including ambient temperature and duration of storage [4]. All screening centres and health professionals should carefully prepare blood samples according to standard protocols to ensure best screening performance.

Screen-positive results

All women who are screened positive should be counselled and referred for a confirmatory diagnostic test. The final decision whether to have a diagnostic test or not is wholly a decision of the couple, which is a balance between the risk of losing a normal baby due to the diagnostic test and the chance of having an affected child. This balance could be difficult for many couples and is influenced by many factors, including (i) their reproductive history, (ii) how high the individualized risk

is, (iii) how the result of the diagnostic test will affect their decision and well-being, (iv) the risk of the diagnostic test, (v) the type of diagnostic test and (vi) the reporting time. There are two diagnostic tests to choose from, amniocentesis and chorionic villous sampling.

Summary box 6.2

- Clinicians have a duty to ensure that all sonographic markers are measured only by accredited sonographers, and that biochemical laboratories they are using are well qualified and have satisfactory quality control.
- NT is the best single marker for fetal Down's syndrome.
- Increased NT is associated with CHD, but the performance of NT as a screening test for CHD is inadequate.

First-trimester screening of aneuploidies other than Down's syndrome

Trisomy 13 and 18 are serious chromosomal abnormalities, usually with multiple structural abnormalities detectable by ultrasound examination in the first or early second trimester. Since the majority of pregnancies with trisomy 13 and 18 results in either spontaneous pregnancy losses or early neonatal death, a dedicated screening programme solely for these conditions is not justified and is not cost-effective.

However, both trisomy 13 and 18 are associated with increased NT, low PAPP-A and low fb-hCG. Therefore, these conditions can be identified by FTCS for Down's syndrome. Trisomy 13 is also associated with an increased fetal heart rate, and 85.2% have a heart rate above the 95th percentile. The detection rate for trisomy 13 and 18, using FTCS markers and an algorithm optimized for trisomy 21 detection, are 78 and 79% respectively at 5% FPR. The detection rate can be increased to 95% for trisomy 18 and 87% for trisomy 13, using similar markers but different algorithms optimized for the detection of these two types of trisomies [5]. In fact the role of biochemistry is limited for these two types of trisomy if a detailed first-trimester scan is performed. The median NT is 4.8 mm and 6.8 mm in trisomy 18 and 13 fetuses, respectively [6]. In expert hands, 100% of trisomy 13 and 82.5% of trisomy 18 pregnancies have at least one structural anomaly detectable in the first trimester [6]. These common defects include central nervous system (CNS) anomalies, facial defects, cardiac defects, and abnormal limbs.

Turner's syndrome (45X) is a common chromosomal abnormality but the majority of cases result in early pregnancy failure. Over 85% are detectable during the NT scan as part of the FTCS for Down's syndrome, and present with very thickened NT or cystic hygroma, together with generalized oedema and fetal hydrops. For those with 45X who survive, the major problems are ovarian failure, amenorrhoea, infertility and short stature. However, intelligence is normal. Therefore, a dedicated screening programme for this condition alone is not justified.

Summary box 6.3

- First-trimester screening for Down's syndrome can also detect other aneuploidies, including trisomy 13, trisomy 18 and 45X.
- Ultrasound plays a significant role in detecting trisomy 13 and 18, and those with 45X with unfavourable outcome.

Diagnostic tests

Amniocentesis and chorionic villous sampling

Amniocentesis is typically performed at or after 15 weeks of gestation. Amniocentesis at earlier gestation is not recommended as a routine test because of higher associated fetal loss rate, but may be offered in exceptional situations after careful counselling. Amniocentesis should be performed under strict aseptic techniques and should be under continuous ultrasound guidance. A small needle, most commonly 22G, is inserted into the amniotic cavity, avoiding the placenta and the fetus whenever possible. About 10–20 mL of amniotic fluid is aspirated depending on the test required.

Chorionic villous sampling (CVS) is typically performed between 11 and 14 weeks of gestation to obtain a placental tissue sample for further study. The transabdominal approach is the most common and preferred approach because transcervical CVS is associated with a higher incidence of post-procedural bleeding and miscarriage. In cases where transabdominal CVS is not possible or where it may be associated with significant risk of maternal internal organ damage, transcervical CVS may be considered for an early diagnosis. Ultrasound guidance is essential. CVS requires a higher level of skill than amniocentesis. CVS samples also require meticulous treatment in the laboratory to isolate pure chorionic villi to avoid maternal contamination.

CVS should preferably be performed after 11 weeks of gestation but not before 10 weeks of gestation. Early CVS

has been associated with fetal limb reduction defects. The risk and the severity are highest when CVS is performed before 9 weeks of gestation. When performed after 10 weeks, the relative risk of limb reduction defect is 2.4 with an absolute risk of 0.07%. The excess risk is negligible after 11 weeks of gestation.

Cytogenetic and molecular cytogenetic tests

Both amniotic fluid and CVS samples may be sent for cell culture and full karyotyping, or rapid karyotyping, or both. Karyotyping, which examines all 23 pairs of chromosomes to exclude aneuploidies or large chromosomal rearrangements, used to be the gold standard prenatal test. The major disadvantage is the long reporting time, 10–14 days or longer in most laboratories. Two types of rapid karyotyping techniques are in common use: quantitative-fluorescent polymerase chain reaction (QF-PCR) or fluorescence *in situ* hybridization (FISH). Both FISH and QF-PCR enable the exclusion or confirmation of aneuploidy of selected chromosomes, usually 13, 18, 21 and the sex chromosomes. The major advantages of rapid karyotyping are the short reporting time, usually 1–2 days, and the low cost. The major disadvantage is that other chromosomal abnormalities are not examined. In publicly funded services, it is increasingly common that rapid karyotyping is only performed for cases in which amniocentesis and CVS are indicated solely for high risk of Down's syndrome without fetal structural anomalies. However, the limitation of such practice needs to be explained clearly to the couples concerned and they should be given a chance to request a full karyotyping or chromosomal microarray if they are willing to pay for that additional information.

If rapid karyotyping confirms aneuploidy, karyotyping should always be performed to determine if the aneuploidy is due to typical trisomy or Robertsonian translocation. For typical trisomy 21, the risk of recurrence is about 0.75% in addition to the age-specific risk. For Robertsonian translocations, the recurrent risk is low for *de novo* events, and is 10–15% if maternally inherited.

Discordance in genetic constitution between amniocentesis and CVS samples

In a normal pregnancy, both the placenta and the fetus develop from the same fertilized egg. Therefore, theoretically, they should all have the same genetic composition. Mosaicism refers to the presence of two or more population of cells with different genetic or chromosomal constitutions in one individual. Mosaicism is detected in 1–2% of all CVS samples, and in at least 4.8% of term placentas. Based on a study of 1317 mosaic results from 60 347 CVS samples, it was found that mosaicism was confined to the placenta (CPM) in 87%, while fetal mosaic was confirmed in only 13% [7]. Uniparental disomy (UPD) was confirmed in 2% of the fetuses [7].

Mosaicism occurs either because of post-fertilization mitotic non-disjunction of a normal gestation, or in a trisomic gestation due to meiotic error with trisomic rescue. Depending on the distribution of normal and abnormal cell populations, the ultimate pregnancy may result in CPM or true fetal mosaicism. In the majority of cases, discordances between fetal and placental chromosomal status are accompanied by mosaicism in CVS. Therefore, amniocentesis should be considered whenever mosacisim is detected on CVS. In the most extreme scenario, there could be complete discordance in chromosomal constitution between the fetus and the placenta, in which the CVS result is non-mosaic normal or abnormal while the fetus has the opposite non-mosaic status. This is an extremely rare situation but has been reported in the literature. This rare event should not prevent the use of CVS as a diagnostic test. However, if there is any uncertainty or suspicion, such as a negative CVS result in a fetus with multiple sonographic markers, further confirmation by amniocentesis should be considered.

Risks of amniocentesis and CVS

Procedure-related fetal loss is probably the only significant complication of amniocentesis and CVS. Other major complications, such as bowel perforation, internal bleeding or haemorrhage, have been reported but are extremely rare. The most commonly quoted figure for amniocentesis-related fetal loss is 1%, based on a single randomized trial published in 1986 by Tabor *et al.* [8]. However, most recent studies have suggested a much lower complication rate. A recent systematic review of 42 716 amniocentesis and 8899 CVS tests estimated that the procedure-related risks of miscarriage for amniocentesis and CVS were 0.11% and 0.22%, respectively [9].

Diagnostic tests in multiple pregnancies

Both amniocentesis and CVS can be performed safely in multiple pregnancies. However, these procedures should only be performed by experienced operators. The position of placenta and gestational sac, the fetal sex and the presence of any markers of structural anomalies should be recorded clearly to avoid sampling of the same gestational sac or placenta twice and to allow correct identification of the abnormal fetus when fetal reduction is required subsequently. The associated risk of miscarriage is higher than in singleton pregnancy, and has been estimated to be about 1% for both amniocentesis and CVS [10].

Summary box 6.4

- The risk of amniocentesis and CVS is commonly overstated. Risk is likely to be about 0.2% or lower in both.
- CVS is an acceptable diagnostic test, but the possibility of CPM should always be considered.

Non-invasive prenatal testing

Non-invasive prenatal testing (NIPT) is not a first-trimester screening test in the conventional sense because it can be done at any gestation. It is included here because it can be performed in the first trimester and it is going to replace conventional first-trimester screening for Down's syndrome. NIPT, also called non-invasive prenatal screening (NIPS) or non-invasive DNA testing (NIDT), is a newly developed technology which is still evolving. It is a highly accurate screening test for fetal Down's syndrome, with both sensitivity and specificity over 99%. It can be performed at any time during pregnancy after the minimal gestational age. It is a relatively simple test from the perspective of clinicians and pregnant women. The major limitation of using NIPT as a primary screening tool is the cost, which nevertheless is likely to be comparable to current first-trimester screening tests in the very near future.

All NIPT tests available today in clinical use are based on the study of cell-free DNA (cfDNA) fragments in maternal plasma instead of intact fetal cells in the maternal circulation. DNA is not only present in the nucleus of cells but also in plasma. During pregnancy, the presence of fetal cfDNA in maternal plasma can be detected as early as week 4 of pregnancy [11] and can be used for accurate fetal sex determination from 7 weeks onwards. From 10 weeks onwards, on average approximately 10% of maternal cfDNA is of fetal origin.

cfDNA is fragmented. It has been shown that the relative contribution of each chromosome of a genome is maintained in the cfDNA compartment. If a fetus is affected by trisomy 21, the fetal cfDNA will also have a higher contribution of fragments from chromosome 21, about 50% more. After being diluted by the normal maternal cfDNA background, an affected pregnancy will still lead to a slight increase in the proportion of chromosome 21 fragments in the maternal plasma. Such small difference can be detected using the latest molecular technologies.

It is now known that the principal source of fetal DNA in maternal plasma is from the trophoblastic cells of the placenta. Therefore, NIPT is just like examining the chromosomal status of a mixture of maternal and trophoblastic DNA fragments. Fetal chromosomal status is inferred based on the assumptions that (i) the fetal and trophoblastic chromosomal constitutions are identical and (ii) maternal constitution is normal (if the counting method is used, see following section). These assumptions are generally correct, but exceptions do occur which will result in false-positive NIPT results. The issue of CPM is particularly important for autosomal trisomies involving chromosomes other than 13, 18 and 21, and the issue of false positives due to maternal contribution is particularly important in sex chromosomal aneuploidies and microdeletion syndrome (see subsequent sections for more details).

NIPT methods for screening of fetal Down's syndrome

The commonest method is by simple counting, using either genome-wide massively parallel sequencing (MPS) or targeted MPS. With MPS, millions of DNA fragments within a maternal plasma sample are sequenced, and then compared against the human genome to determine their original chromosomal locations. The percentage representation of chromosome 21 is calculated, and compared against the expected value, or compared against the percentage representation of a reference chromosome. Different bioinformatics pipelines have been developed to determine if the chromosome 21 percentage is higher than expected, which signifies that the fetus is at high risk of having Down's syndrome. The advantage of this approach is simplicity in bioinformatics. However, this method does not differentiate fetal from maternal cfDNA and the NIPT result could be affected by the chromosomal status of the pregnant woman herself.

Another NIPT method that has been used clinically is the SNP (single nucleotide polymorphism) approach. SNPs are variations in a single nucleotide that occurs in a specific position in the human genome. There are about 10 million SNPs in the human genome. Most SNPs locate between genes and have no known biological effect. Different individuals have different SNP patterns. Using a panel of selected SNPs, fetal and maternal DNA fragments can be differentiated, and by studying the SNP pattern the trisomy or disomy status of the fetus can be estimated. This approach is attractive in that it differentiates fetal from maternal DNA. However, there is no evidence that this approach provides any superiority in performance as a screening test for fetal Down's syndrome. It does enable the detection of vanished twin, dichorionic twin or triploidy pregnancies, that the counting method is unable to do. This method is not suitable for donor egg pregnancies, and may not be feasible in couples who have highly similar SNP patterns, such as marriage between close relatives.

Other NIPT methods have been investigated and reported, including quantitative methylation-specific

PCR, methylated DNA immunoprecipitation, microarray-based methods and RNA-based methods. In general, relevant clinical data are either lacking or limited and will not be elaborated further here.

Performance of NIPT as a screening test for fetal Down's syndrome

The majority of published data are based on the counting method, although with much variations in methodology. The most recent systematic review showed a sensitivity and specificity of 99.3% and 99.9%, respectively, very similar to the results of early experimental studies [12].

It must be emphasized that NIPT is only a screening test. It is highly sensitive but definitely not diagnostic. Furthermore, there is still rapid development and modification of NIPT procedures, and the performance of NIPT using different methodologies requires further confirmation.

NIPT is highly sensitive. It is likely it will detect more placental mosaicisms and lower levels of maternal mosaicisms than conventional screening tests, which could contribute to false positives.

Implementation of NIPT as a Down's syndrome screening tool

Scientifically, it is beyond doubt that the performance of NIPT is far superior to any other existing Down's syndrome screening test. The only barrier for its clinical use at present is the relatively high cost in most countries. However, there is no reason why pregnant women cannot use NIPT as the primary screening test at their own cost, with the balance between cost and benefit being their personal preference.

Similarly, there is no reason why pregnant women cannot use NIPT as a secondary screening test in a sequential or contingent manner at their own cost. In the sequential model, NIPT is offered to those who are tested high risk by traditional screening tests, which in general have a lower detection rate and higher FPR. The sequential model will substantially reduce the overall FPR and the number of invasive tests needed. In other words, using NIPT sequentially cannot improve the overall detection rate, which is limited by the primary screening test. This approach will be useful to those who are satisfied with the detection rate of the traditional screening tests, but would like to avoid invasive tests as much as possible. In the contingent screening model, NIPT is also used as a second-line test but includes those who are screened high risk or borderline risk by the primary test, thereby increasing the overall sensitivity and specificity.

The incorporation of NIPT into publicly funded programmes requires solid proof of cost-effectiveness. All published studies on cost-effectiveness support the use of NIPT as a secondary screening test but not as a primary screening test at the current cost. In the Chinese territory of Macau, NIPT as a secondary screening test has already been incorporated into their screening programme. When the cost of NIPT is reduced to the level equivalent to traditional screening tests, there will be no reason not to replace them by NIPT even in publicly funded programmes. This situation is imminent. In fact in mainland China, some provinces have started, or are about to start, offering NIPT as a primary screening test at a cost (not user price) as low as RMB500, which is lower than the cost of traditional screening tests in many developed countries. It is foreseeable that NIPT will become the most cost-effective primary screening test for Down's syndrome within the next 5 years if not earlier.

Most commercial NIPT providers accept a test request from 10 weeks or even 9 weeks of pregnancy onwards. There is no upper gestational limit. However, most published studies include pregnant subjects at 12 weeks or beyond. There are very limited published data before 12 weeks of gestation, in particular at 10 weeks of gestation. It is possible that the detection rate may be lower in the first trimester, by about 1.3% for trisomy 21 [12].

Diagnostic tests for those who are high risk for NIPT

If pregnancy is at or after 15 weeks, amniocentesis should be the diagnostic method of choice. If pregnancy is at 14+ weeks, it is preferable to advise the woman to wait for an amniocentesis at 15 weeks.

Before 14 weeks, CVS is an acceptable diagnostic test, in particular if sonographic markers of Down's syndrome are present. This allows earlier diagnosis and intervention. If there is no sonographic marker present, the woman may choose CVS, mid-trimester amniocentesis or early amniocentesis. CVS could still be used since non-mosaic trisomy confined only to the placenta without affecting the fetus is a very rare event for chromosome 21 but the pregnant women must fully understand the implication. Delaying to 15 weeks for an amniocentesis could be psychologically stressful during the period of waiting, but this approach will completely avoid the possibility of trisomy confined to the placenta resulting in termination of a normal fetus. Early amniocentesis can be performed at the same gestation as CVS, and it avoids the disadvantage of both CVS and mid-trimester amniocentesis. However, early amniocentesis is associated with a higher risk of miscarriage and increased risk of fetal talipes.

In general, a detailed ultrasound scan should be performed when NIPT is high risk, and the ultrasound findings may assist the patient in deciding which diagnostic test to have.

Confirmatory test is essential

Although the sensitivity and specificity of NIPT are both greater than 99%, it is still a screening test and therefore confirmation by a diagnostic test is essential before pregnancy termination. With sensitivity of 99% and specificity of 99.9%, the PPV is 66.7% and 83.4% at disease prevalences of 0.2% and 0.5%, respectively (Table 6.2), indicating that one in three and one in six test-positive subjects are in fact false positives. This estimation is very close to the published PPV of NIPT on clinical datasets, i.e. approximately 70–80%. It is predicted that when NIPT is being used more extensively in average-risk populations, the PPV will reduce further to around 60–70%. Although a PPV of 80% is very high already, the one in six chance of being false positive warrants a diagnostic test before pregnancy termination. The only exception to this rule is when pregnancy termination is medically acceptable irrespective of the karyotype findings, such as the presence of major structural abnormalities.

Causes of positive NIPT

A positive NIPT for trisomy 21 may be due to (i) a truly affected fetus; (ii) a fetus affected by mosaic trisomy 21; (iii) CPM; (iv) vanished twin; (v) abnormalities of the maternal chromosome if the counting method is used, such as mosaic of an aneuploidy, asymptomatic carrier of a microdeletion or presence of cell-free tumour DNA from an underlying malignancy; and (vi) false positive related to the nature and limitation of the technology. With meticulous examination, it is usually possible to identify a biological cause in most cases with positive NIPT result.

In daily clinical practice, it may not be feasible to exclude all possible causes due to the additional cost implication. But such sources of false positives must be considered during the post-test counselling and when making a decision for the type of diagnostic test.

Table 6.2 The positive predictive value (PPV) of a screening test with a sensitivity of 99%. The PPV changes with the specificity and the prevalence of disease in the screened population. The possibility of false positives is significant even at a specificity of 99.9%.

		PPV	
Specificity (%)	False-positive rate (%)	Prevalence 0.2%	Prevalence 0.5%
99	1.00	16.7%	33.4%
99.5	0.5	28.6%	50.1%
99.9	0.1	66.7%	83.4%
99.99	0.01	95.3%	98.1%

Extending NIPT to other chromosomal abnormalities

Although originally developed for trisomy 21, the same NIPT algorithm could be modified to detect trisomy 13, trisomy 18, 45X syndrome, and other aneuploidies. With further modifications, NIPT can be extended to detect large unbalanced chromosomal rearrangements, microdeletions, microduplications and even single gene disorders.

Performance of NIPT for trisomy 18 appears to be slightly lower than that for trisomy 21, with an estimated sensitivity of 97% [12]. Performance for trisomy 13 is more variable, with sensitivity of 90–97% [12,13]. Sensitivity for 45X syndrome in general is lower, reported to be 75–90% [14].

Extending NIPT to 45X syndrome is common but worth further consideration. For those with typical sonographic features of 45X syndrome, including very high NT, cystic hygroma or early hydrops, the prognosis is poor and diagnostic tests should be considered instead of NIPT because of the relatively low detection rate. Pregnancies with 45X syndrome and normal first-trimester ultrasound examination usually proceed normally and the majority of babies will be liveborn with normal intelligence. It is a non-lethal condition although ovarian failure is almost certain. The decision to continue with pregnancy is common even with confirmed 45X after prenatal diagnosis, and therefore it is controversial if prenatal screening is necessary. When counselling a woman who is high risk for 45X, the following should be considered:

1) in the absence of songoraphic abnormalities, the overall prognosis in general is good in terms of survival and function other than ovarian failure;
2) the implications of ovarian failure and the treatments available;
3) 10% are due to low-level maternal mosaicism (if the counting method is used), and is more common with advancing maternal age due to somatic changes;
4) a significant proportion, as high as 40%, are due to mosaicism, which could be simple X/XX mosaic, or more complicated such as X/XY [15].

Extending NIPT to other sex chromosomal abnormalities (SCAs) is common in commercially available NIPT

products. The true detection rate is uncertain because many of the affected individuals are asymptomatic at birth. Most individuals with SCA are normal, although some may have problems with fertility, ambiguous genitalia or increased risk of learning difficulties in specific areas. Although scientifically it is controversial whether screening of SCA is worthwhile, the great majority of pregnant women want to be informed if NIPT results in suspicion of SCA so that they can make informed choices and are better prepared [16].

Extending NIPT to aneuploidy involving other chromosomes appears logical if the genome-wide MPS method is used, since sequencing data is necessarily available. The laboratory cost for the additional bioinformatics analysis and reporting is minimal. Aneuploidy involving other chromosomes usually results in early pregnancy losses and in the majority of such cases the cause is CPM. However, about 30% of these cases will have early-onset fetal growth restriction that requires early delivery, and some may be accompanied by fetal mosaicism or UPD due to trisomic rescue. UPD may result in the expression of recessively inherited diseases, and UPD of specific chromosomes such as 11 or 15 may result in significant imprinting disorders. Therefore, the additional information on other chromosomes may be clinically important. However, it must be realized that patient counselling is particularly difficult, and couples may request pregnancy termination for uncertainty only, such as UPD. Therefore, the risks and benefits of disclosing information about other chromosomes need to be carefully considered.

Detection of large chromosomal rearrangements, microdeletions and single gene disorders are possible with NIPT. This application is rapidly changing and is beyond the scope of this chapter.

Failure rate

In early reports, NIPT generates no report in 1–10% of cases for various reasons; the figure is approximately 1–3% in more recent studies. There is some evidence that those who fail to have an interpretable NIPT result are at higher risk of aneuploidy. The management of these pregnancies may include repeat blood sampling or a diagnostic test.

Factors affecting NIPT accuracy

The methodology used, stringency in quality control and sequencing depth are important determining factors but this information is rarely available in sufficient detail to be useful to end users.

Fetal fraction is obviously an important factor. Fetal fraction is negatively correlated with maternal weight, being 11.7% at 60 kg and 3.9% at 160 kg. The fetal fraction was found to be below 4% in 0.7, 7.1 and 51.1% of samples from women weighing 60, 100 and 150 kg respectively [17]. Adequate fetal genetic material in the sample is the prerequisite for an interpretable and reliable result. However, the definition of 'adequate' is affected by other factors as well, in particular the nature of the molecular test, sequencing depth and the bioinformatics methodology used. The common belief that a fetal fraction of 4% is required for NIPT is simple, but was based on a specific testing algorithm only. For example, an early study showed that false-negative cases had a significantly lower fetal fraction, all below 7% [18], while a more recent study showed that mean fetal fraction was 10.2% among the false-negative cases and low fetal fraction was not a cause for false negativity [19].

Sample preparation, storage and transportation significantly affect the fetal fraction due to breakdown of maternal nucleated cells in the sample. Various methods have been implemented to stabilize the fetal fraction, and it is the duty of the physicians to ensure that such protocols are strictly followed.

Twin pregnancies

There are limited published data on the performance of NIPT in multiple pregnancies. The sensitivity for trisomy 21 detection in twin pregnancy may be lower than in singleton pregnancy but is likely to be 95–99% with FPR below 1% [20]. In comparison, conventional screening tests have much higher FPR and lower detection rate. Therefore there is no reason why NIPT cannot be used or offered to those with twin pregnancies.

Role of first-trimester ultrasound in NIPT

NIPT is just one of the components of first-trimester screening. A first-trimester scan should be part of the screening package. The ultrasound will provide important information, including viability and gestational age of the pregnancy, the number of fetuses, presence of vanished twin, presence of thickened NT, or structural anomalies. All this information will be significant after deciding whether NIPT is appropriate and the timing of NIPT.

For those women who decide not to have first-trimester Down's syndrome screening, they should still have at least a basic first-trimester ultrasound to confirm the location and number of gestations, estimate gestational age, and determine chorionicity and amnionicity in cases of multiple pregnancy.

Summary box 6.5

- NIPT is a highly sensitive and specific screening test for Down's syndrome.
- All NIPT-positive cases must be confirmed by a diagnostic test before pregnancy termination.

First-trimester screening of fetal structural anomalies

Approximately 60% of major structural abnormalities can be diagnosed in the first trimester of pregnancy, such as anencephaly, omphalocele or limb defects. The potential benefit is an earlier diagnosis which will provide more time for the couple to undergo further tests and to consider further management plans, allow early intervention including pregnancy termination, and possibly lead to better outcome or less physical or psychological trauma. Pregnant women should be given a chance to decide if they would like to have this extra examination. However, there are many potential problems that need to be considered.

1) The detection rate of fetal anomalies in the first trimester can never reach that of second-trimester scan. A proper mid-trimester scan is still essential. This must be explained clearly to the pregnant women to avoid misunderstanding.
2) Timing of the scan is important. An almost complete fetal morphological assessment is usually feasible towards the end of 13 weeks of gestation, but is much more technically challenging at 11 weeks of gestation.
3) Confirmation of anomalies at such early gestation may not be feasible after pregnancy termination, especially if a surgical method is used.
4) A first-trimester scan may detect suspicious findings that require further evaluation and assessment when the gestation is more advanced. This may result in significant psychological stress and emotional disturbance.

Further details of prenatal diagnosis of fetal structural anomalies is discussed in Chapter 20.

First-trimester screening of late obstetric complications

There is increasing interest in first-trimester screening of late obstetric complications, in particular hypertensive disorders and fetal growth restriction. In general, screening using single markers does not produce adequate sensitivity for routine clinical use. Recent studies have suggested that risk assessment based on algorithms combining previous obstetric and medical history, personal demographic data, sonographic signs and biochemical markers may be an effective screening tool [21]. Further details will be discussed under specific conditions.

First-trimester screening of single gene disorders

Expanded carrier screening (ECS) is still in the early stages of development. This will certainly become routine in the near future when the cost becomes more affordable. ECS is best performed before pregnancy. In reality, most pregnant women do not have a proper preconception assessment. The first trimester may be the first time to discuss ECS with them. For further details, refer to Chapter 4.

Conclusion

The arrival of NIPT radically changes first-trimester screening for fetal Down's syndrome. The technology is rapidly evolving, and is being expanded rapidly to cover other chromosomal, genomic and single gene disorders. By the time this book is published, some of the details stated here might have become outdated. However, the principle remains that pregnant women should be given adequate information for them to make their own choices concerning prenatal screening of genetic conditions.

Hypertensive Disorders

Pre-eclampsia is an idiopathic disorder of pregnancy characterized by proteinuric hypertension. Recent estimates indicate that over 30 000 women die worldwide each year because of pre-eclampsia and its complications, with 98% of these occurring in developing countries [1]. Globally, pre-eclampsia has been estimated to cause between 10 and 25% of perinatal loss [2,3]. In the UK, despite improvements over recent years, pre-eclampsia remains a significant cause of direct maternal death, with six cases reported in the latest triennial report [4]. Up to 5% of women will develop pre-eclampsia in their first pregnancy and although the overwhelming majority of these will have successful pregnancy outcomes, the condition can give rise to severe multisystem complications including cerebral haemorrhage, hepatic and renal dysfunction and respiratory compromise. The development of strategies to prevent and treat the disorder has been challenging due to an incomplete understanding of the underlying pathogenesis.

Pathophysiology

The pathogenesis of pre-eclampsia originates in the placenta. The disease can occur in the absence of fetal tissue (molar pregnancy) and manifestations of the disease will only resolve following delivery of the placenta. The blueprint for establishing pre-eclampsia is determined at the outset of pregnancy when placental trophoblast invades the maternal uterine spiral arteries at the time of implantation. In pregnancies destined to be complicated by pre-eclampsia, transformation of the spiral arteries is impaired, with suboptimal remodelling of small-capacitance constricted vessels into dilated large-capacitance conduits. The prevailing theory has been that the subsequent relative placental ischaemia causes release of vasoactive factors into the circulation which then give rise to endothelial-mediated end-organ damage and clinical manifestations of the disease. Scientific endeavours to determine these elusive vasoactive factors have largely been responsible for pre-eclampsia being known as the 'disease of theories'.

Several candidates have been considered in the role of a key circulating vasoactive factor, including interleukins, tumour necrosis factor (TNF)-α and components of the angiotensin pathway. Whilst all these elements are subject to modification in pre-eclamptic pregnancies, it has not been possible to demonstrate that any have an initiating role in the disease process. Pre-eclampsia is a disease of higher primates only and the lack of a clinically relevant animal model has been a significant research obstacle. The discovery of soluble fms-like tyrosine kinase (sFlt)-1 has been particularly exciting because it is the first candidate that has been demonstrated to cause a pre-eclampsia phenotype in an animal model [5].

sFlt-1 is variant of vascular endothelial growth factor receptor (VEGFR)-1, which has an extracellular ligand-binding domain but lacks the transmembrane and cytoplasmic domains. Circulating sFlt-1 is therefore able to competitively bind to VEGF and placental growth factor (PGF) and therefore reduce biologically active binding of these factors that usually promote angiogenesis and placentation. Women with pre-eclampsia have increased circulating levels of sFlt-1 and reduced circulating free VEGF and PGF. VEGF is important in maintaining normal fenestration of the glomerular endothelium [6,7] and it has been suggested that the early renal manifestations of pre-eclampsia may be a consequence of the particular sensitivity of the kidney to reduced levels of VEGF. In animals it has been shown that both VEGF and PGF must be reduced to cause a pre-eclampsia phenotype [5]. *In vitro* and *in vivo* studies [8] have shown that the hypoxic placenta produces increased levels of sFlt-1 and primate studies [9] indicate that this may be sufficient to produce

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

a pre-eclampsia phenotype. Another factor in this story is endoglin (sEng), a modified form of the transforming growth factor (TGF)-β coreceptor. sEng is also increased in pre-eclampsia and has been shown to augment the effect of sFlt-1 and is particularly associated with hepatic endothelial damage [10]. Importantly, sFlt-1, PGF and sEng have been shown to be elevated in the serum of women destined to suffer pre-eclampsia several weeks in advance of clinically evident disease [11].

Summary box 7.1

- The pathogenesis of pre-eclampsia remains elusive but a greater scientific knowledge of the condition is emerging.
- Pre-eclampsia accounts for approximately 25% of all very low birthweight infants, a significant number of preterm births and has a high perinatal mortality.
- Pre-eclampsia is the second most frequent cause of direct maternal death.
- These deaths are avoidable as substandard care complicates 90% of these deaths.

An intriguing aspect of this hypothesis is its link to a potential explanation as to why smokers have a reduced incidence of pre-eclampsia. The combustible component of cigarette smoke induces haemoxidase (HO)-1. This is a stress response gene that has a cellular protective role, particularly against hypoxic injury. HO-1 degrades haem into biliverdin, carbon monoxide (CO) and free iron. Both biliverdin and CO have been demonstrated to reduce endothelial expression of sFlt-1 and sEng [12]. Appreciation of the potential role of the HO-1 pathway has led to the suggestion that pharmacological agents known to have HO-1 activity might be useful in ameliorating pre-eclampsia. Statins are widely used outside obstetrics to reduce serum lipids and forthcoming studies will evaluate whether their theoretical potential can be translated safely and usefully into pregnancy.

Defining hypertensive disease in pregnancy

There has always been considerable debate over the most appropriate definition of the hypertensive disorders in pregnancy. It has been recognized that there are benefits in having a broader clinical definition whilst retaining a very tight phenotypic research definition. Hypertension complicates 6–12% of all pregnancies [13], and includes two relatively benign conditions (chronic and gestational hypertension) and the more severe conditions of pre-eclampsia or eclampsia. Pre-eclampsia complicates 3–5% of all pregnancies, and is characterized by placental and maternal vascular dysfunction that may lead to adverse outcomes such as severe hypertension, stroke, seizure (eclampsia), renal and hepatic injury, haemorrhage, fetal growth restriction, or even death [14].

The diagnosis of pre-eclampsia, and hence the prediction of adverse events, is based on traditional but somewhat unreliable and non-specific clinical markers such as blood pressure, urine protein excretion, and symptoms. For example, more than 20% of women who have eclampsia will fail to meet the common diagnostic criteria of pre-eclampsia prior to their event, making the prediction of this adverse outcome extremely difficult [15]. Conversely, only 0.7–5.0% of women with classically defined pre-eclampsia will experience any composite adverse outcomes [16].

For this reason consistency is required both for clinical management and to allow the comparison of outcomes from clinical units/regions. The National Institute for Health and Care Excellence (NICE) Clinical Guideline 107 [17] has defined management pathways for hypertension in pregnancy in the UK. The list that follows outlines the NICE definitions associated with hypertension in pregnancy used in this chapter.

- *Gestational hypertension*: new hypertension presenting after 20 weeks without significant proteinuria.
- *Pre-eclampsia*: new hypertension presenting after 20 weeks with significant proteinuria.
- *Chronic hypertension*: hypertension present at the booking visit or before 20 weeks or if the woman is already taking antihypertensive medication when referred to maternity services. It can be primary or secondary in aetiology.
- *Eclampsia*: a convulsive condition associated with pre-eclampsia.
- *HELLP syndrome*: haemolysis, elevated liver enzymes and low platelet count.
- *Severe pre-eclampsia*: pre-eclampsia with severe hypertension and/or with symptoms, and/or biochemical and/or haematological impairment.
- *Significant proteinuria*: defined as a urinary protein/creatinine ratio of greater than 30 mg/mmol or a validated 24-hour urine collection result showing greater than 300 mg protein.
- *Mild hypertension*: diastolic blood pressure 90–99 mmHg, systolic blood pressure 140–149 mmHg.
- *Moderate hypertension*: diastolic blood pressure 100–109 mmHg, systolic blood pressure 150–159 mmHg.
- *Severe hypertension*: diastolic blood pressure 110 mmHg or greater, systolic blood pressure 160 mmHg or greater.

Summary box 7.2

- Pre-eclampsia is a multisystem disease diagnosed by the characteristic appearance of gestational hypertension and gestational proteinuria.
- Gestational hypertension is a persistent *de novo* blood pressure >140/90 mmHg occurring after 20/40 gestation in pregnancy. On its own it carries little additional morbidity.
- Gestational proteinuria is a protein excretion above 300 mg per 24 hours (equivalent to a protein/creatinine ratio of 30 mg/mmol).
- There are errors associated with the measurement of both blood pressure and proteinuria in pregnancy which can be minimized by a combination of good technique and automated devices.
- All the above conditions can occur superimposed on chronic hypertension, making diagnosis difficult.
- Postnatal follow-up is essential to confirm the 'pregnancy diagnosis' and to advise about long-term risk.

Measuring blood pressure and proteinuria in pregnancy and pre-eclampsia

The errors associated with blood pressure measurement have been well described in both non-pregnant and pregnant populations. Care in taking these measurements will reduce false-positive and false-negative results and improve clinical care. Machine/device errors have led to strict validation protocols for automated blood pressure devices in specific populations and clinical settings [18] and the human errors inherent in manual readings have led to guidelines on the measurement of blood pressure with both manual and automated devices in clinical practice [19]. Digit preference (the practice of rounding the final digit of blood pressure to zero) occurs in the vast majority of antenatal measurements and simply taking care to avoid this will limit inaccurate diagnoses. Using a standard bladder in a sphygmomanometer cuff will systematically undercuff 25% of an average antenatal population. Having large cuffs available and using them will prevent the over-diagnosis of hypertension [20]. Keeping the rate of deflation to 2–3 mmHg/s will prevent over-diagnosis of diastolic hypertension, as will using Korotkoff 5, which is now universally recommended for diagnosing diastolic hypertension. Korotkoff 4 (the muffling of the sound) is less reproducible, and randomized controlled trials confirmed that it is safe to abandon it, except in those rare situations when the blood pressure approaches zero [21,22].

The reliable detection of proteinuria is essential in differentiating those pregnancies with pre-eclampsia from those with gestational or chronic hypertension and, in the process, identifying those pregnancies most prone to adverse outcome. The measurement of significant proteinuria, traditionally 300 mg excretion in a 24-hour period, is also prone to collection and measurement error. The collection of 24-hour urine samples is not practical as a routine test and so urine dipstick screening is employed as a first-line screening test with secondary tests employed to confirm positive dipstick diagnoses. Visual dipstick reading is unreliable [23] but the use of automated dipstick readers significantly improves the accuracy of dipstick testing and as such is recommended by NICE for use in pregnancy [24]. NICE also recommends that quantification of proteinuria should follow diagnosis. There are two methods that NICE supports. The first is the 24-hour urine protein estimation and this requires that an assessment of sample completeness is undertaken, with measurement of creatinine excretion being the most common. NICE also supports the use of the protein/creatinine ratio test. This test is done on a 'spot' urine sample and is therefore much quicker. This test has been shown in numerous studies to be comparable to the 24-hour urine protein estimation [25]. The threshold for defining significant proteinuria by this test is 30 mg protein/mmol creatinine.

Risk assessment and risk reduction

There have been attempts to screen the antenatal population for pre-eclampsia over the past 60 years, with over 100 potential biochemical, biophysical or epidemiological candidate tests. Despite not yet having a single universal test to apply, it is still possible to advise women regarding their risk of pre-eclampsia from their clinical history and some investigations.

NICE guidelines for routine antenatal care [26] emphasize that a woman's risk of pre-eclampsia should be evaluated. Several risk factors for pre-eclampsia are known and these have been incorporated into the NICE recommendations [27,28]. Table 7.1 outlines risk factors that should be identified at booking to identify women at risk of pre-eclampsia. Many of the risk factors listed in this table are modifiable and may lead to a reduction in risk either prior to or between pregnancies.

Individual risk is not a simple numerical addition. A family history of pre-eclampsia in a first-degree relative is significant and two relatives even more so, whilst

Table 7.1 Risk factors for identifying women at increased risk of pre-eclampsia.

Any single high-risk factor
Hypertensive disease during a previous pregnancy
Chronic kidney disease
Autoimmune disease such as systemic lupus erythematosus or antiphospholipid syndrome
Type 1 or type 2 diabetes
Chronic hypertension
Or two or more moderate-risk factors
First pregnancy
Age 40 years or older
Pregnancy interval of more than 10 years
Body mass index (BMI) of 35 kg/m^2 or more at first visit
Family history of pre-eclampsia
Multiple pregnancy

Table 7.2 Relative risks of developing pre-eclampsia.

	Relative risk	Confidence intervals
Antiphospholipid syndrome	9.72	4.34–21.75
Previous history of pre-eclampsia	7.19	5.83–8.83
Pre-existing diabetes	3.56	2.54–4.99
Multiple pregnancy	2.93	2.04–4.21
Nulliparity	2.91	1.28–6.61
Family history	2.90	1.70–4.93
Raised BMI		
Before pregnancy	2.47	1.66–3.67
At booking	1.55	1.28–1.88
Age over 40	1.96	1.34–2.87
Raised diastolic blood pressure (>80 mmHg)	1.38	1.01–1.87

exposure over time to paternal antigen through increased periods of cohabitation and non-barrier contraception can reduce risk as can prior miscarriage or termination of pregnancy. Pre-eclampsia is more common at the extremes of reproductive age and is increased further following *in vitro* fertilization (IVF) treatment, particularly with donor sperm. Other factors often associated with increasing age, such as obesity, gestational and pregestational diabetes, and any disease affecting the cardiovascular system are potent risk factors for pre-eclampsia. The relative risk for pre-eclampsia for some of these risk factors is shown in Table 7.2 [28].

Clearly, from the relative risks quoted, the majority of women who are high risk will still not develop pre-eclampsia whilst a considerable number of cases will arise *de novo* in the 'low-risk' population. Identifying women at risk will allow increase in surveillance and use of prophylactic therapies can be considered. If adequate preventive measures become available, then these screening tests will become increasingly important. Tests that might be employed to screen the population (high or low risk) for pre-eclampsia centre on the identification of poor placental function, which is an almost universal prerequisite for the clinical condition. Doppler assessment of the maternal uterine circulation is considered to be a promising test. This test when 'positive' demonstrates the high resistance in the uterine arteries as well as a 'notch' apparent within the Doppler waveform. These two features have been used in isolation and combination to screen low- and high-risk populations. Early studies suggested that approximately one in five women who have an abnormal Doppler at 20 weeks' gestation will develop pre-eclampsia [29], and at 24 weeks' gestation the prediction value is greater. In 2008, NICE recommended that uterine artery Doppler screening should not be employed universally for low-risk women [26]. More recently NICE Clinical Guideline 107 recommended that this test should not be universally employed in high-risk women based on the relatively poor quality of the studies performed to date. However, it did recognize its potential and made a research recommendation regarding its use in the management of high-risk women.

No other biophysical test other than accurate measurement of blood pressure in the first trimester has either any clinical application or is practical enough to employ in clinical practice. Numerous haematological and biochemical markers have been used to both predict and evaluate pre-eclampsia. For example, in women who have chronic hypertension the measurement of uric acid and platelets can help in determining those who suffer superimposed pre-eclampsia; again the tests lack sensitivity and specificity [30]. Furthermore, very few of these markers have been independently evaluated for their ability to separately predict the timing or severity of specific adverse outcomes such as placental abruption, severe hypertension, neurological injury and fetal growth restriction. The reason for this is that the biomarkers previously studied were mostly generic indicators of vascular activation and dysfunction, which arise late in the pre-eclamptic disease process and which are not specific to pre-eclampsia or even to pregnancy.

As outlined previously, recent advances have identified a class of pregnancy-specific angiogenic and anti-angiogenic factors (e.g. PlGF, VEGF) that are produced by the placenta and which closely correlate with the preclinical and clinical stages of pre-eclampsia [11,31–36]. Assays of these markers are currently under assessment as tools to predict and/or diagnose pre-eclampsia prior to the onset of clinical disease and significant morbidity. The FASTER trial of 2003 demonstrated that, when measured as part of the quadruple aneuploidy screen at 15–18 weeks'

gestation, the odds ratios for the development of pre-eclampsia when inhibin-A and β-human chorionic gonadotrophin (hCG) levels are above the 95th centile were 3.42 (95% CI 2.7 and 4.3) and 2.20 (95% CI 1.7 and 2.9), respectively [37].

In 2008, the Society of Obstetricians and Gynaecologists of Canada Genetics Committee, following systematic review, suggested that abnormal uterine artery Doppler in combination with an elevated α-fetoprotein (AFP), hCG and inhibin-A, or decreased pregnancy-associated plasma protein A (PAPP-A), identify a group of women at increased risk of intrauterine growth restriction and pre-eclampsia. They also stated that multiple maternal serum screening markers at present should not be used for population-based screening as false-positive rates are high, sensitivities are low and no protocols have shown improved outcome [38].

Screening is important to focus resources on high-risk women as well as to identify those in whom prophylactic therapies might have some benefit. Aspirin and calcium have been found to have a beneficial effect whilst other agents, most recently antioxidants, have not proven useful. NICE Clinical Guideline 107 recommends low-dose aspirin therapy (75 mg/day) for all high-risk women from 12 weeks' gestation. Antiplatelet agents were associated with statistically significant reductions in the risk of pre-eclampsia in moderate-risk women and in high-risk women (moderate-risk women: 25 studies, $N = 28\,469$, RR 0.86, 95% CI 0.79–0.95; high-risk women: 18 studies, $N = 4121$, RR 0.75, 95% CI 0.66–0.85).

A meta-analysis using individual-patient data from 32 217 women and their 32 819 babies found a statistically significant reduction in risk of developing pre-eclampsia (RR 0.90, 95% CI 0.84–0.97). The data from this study suggest that one case of pre-eclampsia would be prevented for every 114 women treated with antiplatelet agents. In addition to the 10% reduction in pre-eclampsia in high-risk women receiving antiplatelet agents, there was a 10% reduction in preterm birth. No particular subgroup of women in the high-risk group was substantially more or less likely to benefit from antiplatelet agents. There was no statistically significant difference between women who started treatment before 20 weeks (RR 0.87, 95% CI 0.79–0.96) and those who started treatment after 20 weeks (RR 0.95, 95% CI 0.85–1.06; $P = 0.24$). Of importance, there were no statistically significant differences between women receiving antiplatelet agents and those receiving placebo in the incidence of potential adverse effects such as antepartum haemorrhage, placental abruption or postpartum haemorrhage, but there was a reduction in the risk of preterm birth before 37 weeks (RR 0.93, 95% CI 0.89–0.98) [39].

Trials of calcium to prevent pre-eclampsia are more controversial. There is good evidence that in areas where the dietary intake of calcium is low, calcium supplementation reduces the risk of pre-eclampsia but this is also influenced by prior risk status. In studies conducted where dietary calcium intake is normal, supplementation was not found to be of benefit. No other intervention can be recommended, including magnesium, folic acid, antioxidants (vitamins C and E), fish oils or bed rest. Diet or lifestyle changes may be beneficial for general health and weight loss may reduce the prior risk of hypertensive disease but modifications such as a low-salt diet have no proven benefit.

Chronic hypertension

Women with chronic hypertension should receive pre-pregnancy care. This should aim to determine the severity and cause of the hypertension; review potentially teratogenic medications such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (three times the risk of congenital abnormality) and diuretics; inform women of the risk associated with pregnancy and of prophylactic strategies (all should receive low-dose aspirin in pregnancy); and to assess comorbidities such as renal impairment, obesity or coexistent diabetes.

The main risk is of superimposed pre-eclampsia, but even in its absence the perinatal mortality is increased. Drugs appropriate for treating hypertension in pregnancy include methyldopa, labetalol, nifedipine and hydralazine. Safety data on other antihypertensives are lacking but there are several where no association with congenital abnormality has been established and so they can be used when clinically indicated.

Blood pressure control should be tailored to the individual. Where the chronic hypertension is secondary to other disease, then the care should be multidisciplinary with the appropriate physician aiming to keep blood pressure below 140/90 mmHg and often at lower limits. When the chronic hypertension is uncomplicated (usually essential) the target should be 150–155/80–100 mmHg [17].

There is a recognized risk of fetal growth restriction (FGR) in this group and so serial fetal biometry is recommended and women should be seen with increased frequency to maintain blood pressure control and to screen for pre-eclampsia. Delivery should be for either fetal indications or for poor hypertension control once corticosteroids for fetal lung maturity have been given if less than 34 weeks' gestation.

At term, NICE recommends delivery after 37 weeks when agreed with the individual, so long as blood pressure control is maintained. Following delivery blood pressure should be maintained below 140/90 mmHg and medication should be reviewed and optimized for both blood pressure control and breastfeeding.

Gestational hypertension

Gestational hypertension is relatively common and as such most units will assess women identified in the community in their day unit. Here, the first assessment is of proteinuria to identify those with pre-eclampsia. In the absence of proteinuria NICE Clinical Guideline 107 recommends an integrated package of care dependent on blood pressure.

- If blood pressure 140–149/90–99 mmHg, then review weekly and test for proteinuria only (as described above).
- If blood pressure 150–159/100–109 mmHg, then treat with labetalol as first line and target blood pressure is 140–150/80–100 mmHg. Check urea and electrolytes, liver function tests and full blood count once, then review twice weekly testing for proteinuria only.
- If blood pressure >160/>110 mmHg, then admit until below 159/109 mmHg and treat as above. When controlled, review twice weekly as above. Test for proteinuria each visit and also retest bloods weekly.

The guideline also recognizes that the earlier the presentation, the greater the likelihood of progression to pre-eclampsia and the frequency of visits should be adjusted accordingly. Gestational hypertension does not require aspirin prophylaxis and patients do not require routine hospital admission if blood pressure is controlled.

Fetal monitoring is also controversial. The suspected small baby (from customized symphysis–fundal height measurment) should be investigated with fetal biometry. No benefit (reduction in perinatal mortality) has been shown in trials where additional monitoring is offered to women with gestational hypertension where FGR was absent. As such the generic advice given to all pregnant women regarding awareness of fetal movements is all that NICE Clinical Guideline 107 recommends.

CHIPS (Control of Hypertension in Pregnancy Study) [40] was a large international trial that has recently reported. Investigators randomized 987 women with non-severe, non-proteinuric hypertension presenting before 34 weeks to less-tight (target diastolic pressure 100 mmHg) or tight (target diastolic pressure 85 mmHg) control. The study found no significant differences between the two groups with regard to adverse perinatal outcome or serious maternal complications. Women in the less-tight control group had an almost twofold increased incidence of severe hypertension (40.6% vs. 27.5%), representing a significant number of women exposed to increased risk of stroke and requiring urgent antihypertensive treatment.

A large randomized controlled trial, the HYPITAT study [41], compared delivery at term (by induction of labour) with conservative care for gestational hypertension and mild pre-eclampsia. This study showed a reduction in severe hypertension in pre-eclamptic women but not gestational hypertension and no neonatal benefits were noted. Following this NICE suggests that women are not induced prior to 37 weeks unless blood pressure is uncontrolled and beyond 37 weeks that time of delivery is a balanced judgement of risk agreed between the obstetrician and the woman.

It is imperative that women with gestational hypertension are followed up with a postnatal visit where their blood pressure is checked. Those who remain hypertensive require specialist review and a percentage of these women will be found to have chronic hypertension and they require cardiovascular risk assessment and advice.

Summary box 7.3

- Pre-eclampsia requires admission to hospital but gestational hypertension does not.
- Blood pressure of 140–149/90–99 mmHg does not require pharmacological treatment.
- Blood pressure of 150–159/100–109 mmHg requires treatment to achieve a target blood pressure of 130–149/80–99 mmHg.
- Blood pressure of ≥160/≥110 mmHg requires urgent treatment to achieve target blood pressure as above.

Pre-eclampsia

Pre-eclampsia is diagnosed when there is significant proteinuria in the presence of gestational hypertension. The relationship between the level of proteinuria and maternal and fetal complications is poor. One systematic review [42] found that there was an increased risk of stillbirth with proteinuria and a reduced likelihood of stillbirth in the absence of proteinuria (at a level of 5 g per 24 hours). Because of this NICE recommends that when pre-eclampsia has been diagnosed women should be admitted to hospital, blood pressure should be treated as for gestational hypertension and proteinuria does not need to be requantified. NICE recommends conservative care up to 34 weeks' gestation with steroid administration for fetal lung maturity as well as individualized plans for fetal monitoring, recognizing the increased risk associated with coincident FGR. NICE recommends delivery with a stable blood pressure when hypertension is severe after 34 weeks and after 37 weeks when hypertension is mild or moderate. When women present late (after 37 weeks) they should be delivered after 24–48 hours of stabilization [41].

Planning delivery

Delivery of the placenta remains the only intervention which leads to resolution of both the clinical and biochemical manifestations of pre-eclampsia. Unfortunately, some women will initially deteriorate in the immediate postpartum period before the recovery phase and all the serious complications of pre-eclampsia can be encountered at this time. It is therefore important that women are delivered in an environment where they can be closely monitored and appropriately managed. In most cases this will be a consultant-led delivery facility able to provide continuing postnatal surveillance, although some women will require high dependency or intensive care particularly if systemic complications develop. The mode of delivery will depend upon gestation, severity of maternal disease, degree of fetal compromise as well as maternal and clinician preference.

Isolated controlled hypertension or mild pre-eclampsia

Women with treated hypertension or mild pre-eclamspsia at term who labour spontaneously or following induction of labour should continue their antihypertensive medication and have their blood pressure monitored hourly. Haematological and biochemical parameters should only be checked in women who have not previously been under surveillance or in whom those investigations are not up to date [17]. Cardiotocography is recommended during active labour, particularly if there is any suspicion of FGR and labour attendants should be vigilant for signs of abruption. Providing hypertension remains well controlled, there is no evidence to support routine limitation of the duration of second stage and many women should therefore be able to achieve delivery without instrumentation.

Active third-stage management is encouraged as women with pre-eclampsia will be less tolerant of postpartum haemorrhage. Ergometrine is associated with exacerbation of hypertension and should not be used routinely. Oxytocin is the recommended drug for routine management of the third stage in the UK and this also applies to hypertensive women. In the event of postpartum haemorrhage it should be remembered that pharmacological uterotonic alternatives to ergometrine such as misoprostol can also be associated with hypertension.

Severe pre-eclampsia

The diagnosis of severe pre-eclampsia is usually made along with a decision to deliver once the maternal condition has been stabilized. Women should be managed in a high-dependency environment by a multidisciplinary team of senior clinicians including high-risk midwifery staff, obstetricians and anaesthetists in a clinical setting where additional support can be obtained if needed from intensivists, nephrologists, haematologists, hepatologists, neurologists and neonatologists. Care is focused around careful fluid management, treatment of hypertension, prevention/treatment of eclamptic fits and prompt recognition and supportive management of any complications which arise prior to the recovery phase.

Treatment of hypertension

Uncontrolled hypertension, particularly persistent systolic pressures above 160 mmHg or mean arterial pressures sustained above 125 mmHg, lead to compromised cerebral autoregulation. The associated complications of cerebral haemorrhage and encephalopathy are the leading cause of maternal mortality in hypertensive pregnancies in the UK and it is for this reason that one of the key recommendations from the most recent MBRRACE report [4] was that severe hypertension should be more actively controlled. The aim of treatment is to gradually reduce blood pressure and sustain levels in the region of 150/80–100 mmHg.

The most common antihypertensive agents used in the UK for acute management of hypertension in pregnancy are labetalol (α- and β-receptor blocker), hydralazine (α-receptor blocker) and calcium channel blockers (nifedipine). The available meta-analyses have failed to demonstrate that one agent is a more effective antihypertensive in this population and the choice of drug therefore depends on the pharmacological profile and anticipated side effects in an individual clinical scenario. Labetalol can be administered by oral and intravenous routes, nifedipine is given orally and hydralazine is reserved for intravenous administration in UK obstetric practice. Prior to delivery it is important to prevent precipitous drops in blood pressure, which will be associated with a reduction in placental perfusion and can give rise to fetal distress, particularly in growth-restricted babies. Rapid reduction in blood pressure is most commonly seen following hydralazine and this has led some clinicians to recommend that a 500-mL bolus of colloid is given before or at the same time as the first dose of hydralazine. It is currently unclear if this practice reduces the incidence of fetal compromise or if the practice is associated with any increased maternal morbidity especially fluid overload. Certainly there is no role for fluid preloading following delivery of the baby. Precipitous drops in blood pressure can also be a feature of nifedipine, especially if they are coadministered with magnesium sulfate when potentiation of the vasodilative action can be problematic. Labetalol has therefore emerged as the first-line agent (in non-asthmatics) and is currently the only agent in this group to be licensed in the UK for the acute treatment of hypertension in pregnancy.

Prevention and treatment of eclamptic fits

Magnesium sulfate is the recommended drug to treat and prevent eclampsia. The Magpie (Magnesium Sulphate for Prevention of Eclampsia) trial [15] recruited 10 141 women with pre-eclampsia and randomized them to receive magnesium sulfate or placebo. The incidence of eclampsia was significantly lower in women who received magnesium sulfate. The greatest effect was seen in women who were at the highest risk: 63 women with severe pre-eclampsia needed to be treated to prevent a fit in contrast to 100 women with mild or moderate disease. No benefit was seen in other outcomes including maternal or neonatal morbidity or mortality.

Cochrane reviews have reported that magnesium sulfate is superior to diazepam or phenytoin for the treatment of eclampsia [43]. The incidence of recurrent maternal fits is reduced and improved neonatal outcomes, including reduced need for admission to special care baby unit or ventilation, are seen in women who delivered following magnesium sulfate.

The precise mechanisms by which magnesium sulfate acts to reduce cerebral irritability is unclear. It is a vasodilating agent and contributes to reduction of cerebral perfusion pressures but it also has other relevant properties including membrane stabilization. Magnesium sulfate is emerging as a potential agent to reduce rates of cerebral palsy in preterm infants, although the mechanism and optimal dose for this purpose remain unclear. These properties may contribute to improved neonatal outcomes in women who deliver preterm due to pre-eclampsia.

Magnesium is given intravenously as a 4-g loading dose over 5 min followed by an infusion of 1 g/hour which is usually maintained for 24 hours. Recurrent seizures should be treated with a further dose of 2–4 g over 5 min and diazepam should be reserved for use in women who continue to fit despite magnesium sulfate. The therapeutic range for magnesium plasma levels is 4–8 mg/dL; toxicity causes loss of deep tendon reflexes at 10 mg/dL and respiratory paralysis at 15 mg/dL. The drug is excreted in the urine and toxicity is therefore more likely in women who have renal manifestations of pre-eclampsia. Calcium gluconate 1 g (10 mL of 10% solution) over 2 min is administered to reverse magnesium toxicity with ventilatory support if required.

Summary box 7.4

- Magnesium sulfate is the drug of choice for the treatment of eclamptic seizures.
- Magnesium sulfate is the drug of choice for the prevention of eclamptic seizures.
- Over 25% of eclamptic seizures will occur postnatally.

Fluid management

The combination of vascular endothelial injury and the normal physiological fluid shifts during the early postpartum period make pre-eclamptic women particularly vulnerable to pulmonary oedema at this time. Six deaths were reported to the Confidential Enquiry into Maternal Deaths in the UK between 1994 and 1996 and in all women injudicious fluid management in pre-eclampsia was felt to be a significant contributory factor. Encouragingly, following recommendations made in that report for tighter fluid management there were no deaths in this group of patients in the following triennial report attributed to iatrogenic fluid overload.

The current recommended practice is to restrict fluid intake to 80 mL/hour until a postpartum diuresis is established. In women where there are ongoing losses or where persistent minimal urine output raises concerns about renal injury, invasive monitoring may help guide fluid replenishment whilst avoiding overload.

Anaesthetic issues

Both regional and general anaesthesia can be problematic in the pre-eclamptic patient. Epidural anaesthesia is often advocated for labouring pre-eclamptic women due to the belief that it will contribute to lowering of blood pressure by reducing both pain-associated anxiety and peripheral vasodilatation. Whilst there may be a modest antihypertensive effect there do not appear to be any significant improvements in maternal or fetal outcomes in women who have epidural anaesthesia for labour. As in the general obstetric population, epidural anaesthesia is associated with a longer second stage and increased incidence of instrumental delivery. There is therefore no evidence to recommend the routine use of epidural anaesthesia in labouring pre-eclamptic women and the diagnosis should not influence the woman's choice of analgesia for labour. An important exception to this is women who have severe pre-eclampsia with thrombocytopenia. A platelet count below 80×10^9/L is a contraindication to regional anaesthesia due to the increased risk of spinal haematoma.

General anaesthesia can be complicated by exacerbation of severe hypertension in response to intubation. Furthermore, laryngeal oedema can make intubation technically difficult and should only be undertaken by senior anaesthetic clinicians. The greatest risks are seen in women who have not been appropriately stabilized prior to anaesthesia.

Complications

Hepatic

Approximately 12% of women with severe pre-eclampsia will develop HELLP syndrome, characterized

by haemolysis, elevated liver enzymes and low platelet count. Not all components are necessarily evident at presentation and the diagnosis is not necessarily associated with the most severe hypertensive presentations. Many affected women will be asymptomatic or will present with non-specific malaise and nausea, although a few will describe classical epigastric and right upper quadrant tenderness. The diagnosis is based on laboratory investigations including a blood film, platelet count and measurement of liver transaminases. Treatment is largely supportive. High-dose steroids have been used to try to hasten the recovery of thrombocytopenia but this has not been shown to be associated with any improved maternal outcomes and is not recommended.

Rarely, liver ischaemia can cause intrahepatic haemorrhage and subcapsular haematoma. This complication is associated with a significant risk of maternal mortality. Conservative management with ultrasound surveillance may be appropriate in the postpartum patient who is haemodynamically stable and where the haematoma is not expanding. Measures described to achieve haemostasis at laparotomy include compression, haemostatic sutures, application of topical coagulation agents, embolization or lobectomy.

Renal

Although glomerular capillary endotheliosis is a classic pathological feature of pre-eclampsia and relative oliguria is common in the early postpartum period, these features usually resolve spontaneously. Acute renal failure is a rare complication of pre-eclampsia, with an estimated incidence of 1 in 10 000–15 000 pregnancies. Obstetric haemorrhage is a much more common precipitating factor in this population. Treatment is supportive; meticulous fluid management along with a high-protein, low-potassium diet and daily electrolyte monitoring will usually be sufficient whilst awaiting spontaneous resolution. Dialysis is rarely required in women who do not have pre-existing renal pathology.

Neurological

Neurological sequelae of pre-eclampsia, other than fits, include cerebral haemorrhage, encephalopathy and temporary blindness (amaurosis). Disruption of cerebral autoregulation, increased perfusion pressures and increased vascular permeability are contributory factors but the aetiology is complicated by haemoconcentration predisposing to thrombosis and vasospasm associated with fits. Any focal neurological signs should be investigated with cranial imaging to exclude other pathologies but no specific treatment is recommended.

Postnatal management

One-third of women who have had pregnancy-induced hypertension or pre-eclampsia will sustain hypertension in the postnatal period and this increases to over 75% in women who have had preterm delivery triggered by maternal hypertensive disease. Poorly managed hypertension causes anxiety for the woman and her carers, delays discharge to the community and can occasionally put her at risk of significant complications. There is little evidence to inform clinicians when managing postpartum hypertension and until such evidence is available a pragmatic approach has been recommended [17]. Women should remain in hospital until they are asymptomatic, their blood pressure is stable within safe limits and their biochemical indices are resolving.

All women who have been prescribed antenatal antihypertensives should have these continued in the postnatal period. Women who have been given methydopa should be changed to an alternative agent before the third postnatal day due to the association of methyldopa with postpartum depression. If the blood pressure is persistently below 140/90 mmHg, then reduce the dose. Most women will not require medication beyond 6 weeks. Commonly prescribed antihypertensive agents which have no known effects on breastfeeding infants include labetalol, atenolol, metoprolol, nifedipine, enalapril and captopril.

Women who have not previously been treated with antihypertensives should have their blood pressure monitored four times daily while an inpatient and should be treated if blood pressure is above 150/100 mmHg. Women in the community should have their blood pressure measured once between days 3 and 5 using a similar threshold for treatment. If medication is initiated, follow-up should be within 48 hours to ensure an appropriate response.

Over 25% of eclampsia will present in the postnatal period, often in women who have not been previously identified as having hypertensive disease [44]. Any woman describing severe headache or epigastric pain postnatally should have pre-eclampsia excluded. Women who have developed pre-eclampsia should be offered an obstetric review around 6 weeks after birth. This affords the opportunity to confirm that hypertension and proteinuria have resolved, or to arrange referral for further investigation if there are concerns about underlying pathology. Women should be made aware of their risk of developing pre-eclampsia in future pregnancies; overall the risk of recurrence is around 16% but this increases to 55% if they were delivered before 28 weeks' gestation due to hypertensive disease. This discussion should also identify any other modifiable risk factors which might be addressed prior to embarking on another pregnancy, for example weight management.

Finally, women should be made aware of the emerging evidence that pre-eclampsia identifies a group of women who are at increased risk of future cardiovascular morbidity. A single pregnancy complicated by pre-eclampsia doubles the risk of a future cardiovascular event [45]. Coexisting FGR or early-onset, severe or recurrent disease increases the risk further. The proposed pathogenic hypotheses include shared genetic risk factors for pre-eclampsia and cardiovascular disease causing pregnancy to reveal an underlying susceptibility [46], persistence of circulating factors that promote endothelial dysfunction [47] or altered endothelial progenitor cell function activity [48]. Alternatively, persistent subclinical impairment of cardiac function [49] may represent a premorbid state which over time manifests as heart failure. Both the American College of Obstetricians and Gynecologists [50] and NICE [17] recommend that women should be offered a postnatal cardiovascular risk assessment following a pregnancy complicated by pre-eclampsia. There remains a paucity of evidence as to which health professionals are best placed to carry out the assessment and what should be included beyond informing the woman of her increased risk. Whatever the underlying pathogenesis, it seems plausible that targeting monitoring and lifestyle modifications to this group of women might ameliorate future cardiovascular events.

Although pregnancies complicated by significant heart disease are rare in the UK, Europe and the developed world, cardiac disease remains the leading cause of maternal death in the UK [1]. There were 49 indirect deaths attributed to cardiac disease in 2011–2013, giving a death rate of 2.1 per 100 000 maternities [1]. The maternal mortality rate from cardiac disease has continued to rise since the early 1980s though may now be stabilizing. The major causes of cardiac deaths over the last 15 years are cardiomyopathy (predominantly peripartum), myocardial infarction and ischaemic heart disease, dissection of the thoracic aorta and sudden adult death syndrome [2]. In the UK, rheumatic heart disease is now extremely rare in women of childbearing age and mostly confined to migrants.

Women with congenital heart disease who have undergone corrective or palliative surgery in childhood and who have survived into adulthood are encountered more frequently. These women may have complicated pregnancies yet mortality remains low, probably due to extensive multidisciplanary pre-pregnancy counselling and clear pathways of care for those with adult congenital heart disease. Women with metal prosthetic valves face difficult decisions regarding anticoagulation in pregnancy and have a greatly increased risk of haemorrhage, valve failure and fetal loss.

Because of significant physiological changes in pregnancy, symptoms such as palpitations, fatigue and shortness of breath are very common and innocent findings. Not all women with significant heart disease are able to meet these increased physiological demands. The significance of orthopnoea and paroxysmal nocturnal dyspnoea as symptoms of pulmonary oedema may not be appreciated by maternity staff. The care of the pregnant and parturient woman with heart disease requires a multidisciplinary approach involving obstetricians, cardiologists, anaesthetists and specialist midwives, preferably in a dedicated antenatal cardiac clinic. This allows formulation of an agreed and documented management plan encompassing management of both planned and emergency delivery.

The most common and important cardiac conditions encountered in pregnancy are discussed in this chapter.

Physiological adaptations to pregnancy, labour and delivery

Blood volume starts to rise by the fifth week after conception secondary to oestrogen- and prostaglandin-induced relaxation of smooth muscle that increases the capacitance of the venous bed. Plasma volume increases and red cell mass rises but to a lesser degree, thus explaining the physiological anaemia of pregnancy. Relaxation of smooth muscle on the arterial side results in a profound fall in systemic vascular resistance and together with the increase in blood volume determines the early increase in cardiac output. Blood pressure falls slightly, but by term has usually returned to the pre-pregnancy value. The increased cardiac output is achieved by an increase in stroke volume and a lesser increase in resting heart rate of 10–20 bpm. By the end of the second trimester the blood volume and stroke volume have risen by between 30 and 50%. This increase correlates with the size and weight of the products of conception and is therefore considerably greater in multiple pregnancies as is the risk of heart failure in women with concomitant heart disease [3].

Although there is no increase in pulmonary capillary wedge pressure, serum colloid osmotic pressure is reduced. The gradient between colloid oncotic pressure and pulmonary capillary wedge pressure is reduced by 28%, making pregnant women particularly susceptible to pulmonary oedema. Pulmonary oedema will be precipitated if there

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

is an increase in cardiac preload (such as infusion of fluids), increased pulmonary capillary permeability (such as in pre-eclampsia), or both.

In late pregnancy in the supine position, pressure of the gravid uterus on the inferior vena cava (IVC) causes a reduction in venous return to the heart and a consequent fall in stroke volume and cardiac output. Turning from the lateral to the supine position may result in a 25% reduction in cardiac output. Pregnant women should therefore be nursed in the left or right lateral position wherever possible. If the mother has to be kept on her back, the pelvis should be rotated so that the uterus drops forward and cardiac output as well as uteroplacental blood flow is optimized. Reduced cardiac output is associated with reduction in uterine blood flow and therefore placental perfusion; this can compromise the fetus.

Labour is associated with further increases in cardiac output (15% in the first stage and 50% in the second stage). Uterine contractions lead to autotransfusion of 300–500 mL of blood back into the circulation and the sympathetic response to pain and anxiety further elevate heart rate and blood pressure. Cardiac output is increased more during contractions but also between contractions. The rise in stroke volume with each contraction is attenuated by good pain relief and further reduced by epidural analgesia and the supine position. Epidural analgesia or anaesthesia causes arterial vasodilatation and a fall in blood pressure [4]. General anaesthesia is associated with a rise in blood pressure and heart rate during induction but cardiovascular stability thereafter. Prostaglandins given to induce labour have little effect on haemodynamics but ergometrine causes vasoconstriction and Syntocinon can cause vasodilation and fluid retention.

In the third stage up to 1 L of blood may be returned to the circulation due to the relief of IVC obstruction and contraction of the uterus. The intrathoracic and cardiac blood volumes rise, and cardiac output increases by 60–80% followed by a rapid decline to pre-labour values within about 1 hour of delivery. Transfer of fluid from the extravascular space increases venous return and stroke volume further. Those women with cardiovascular compromise are therefore most at risk of pulmonary oedema during the third stage of labour and the immediate postpartum period. All the changes revert quite rapidly during the first week and more slowly over the following 6 weeks, but even at 1 year significant changes still persist and are enhanced by a subsequent pregnancy [5].

Normal findings on examination of the cardiovascular system in pregnancy

These may include a loud first heart sound with exaggerated splitting of the second heart sound and a physiological third heart sound at the apex. A systolic ejection murmur at the left sternal edge is heard in nearly all women and may be remarkably loud and be audible all over the precordium. It varies with posture and if unaccompanied by any other abnormality reflects the increased stroke output. However, diastolic murmurs are virtually always pathological. Venous hums and mammary souffles may be heard. Because of the peripheral vasodilatation the pulse may be bounding and in addition ectopic beats are very common in pregnancy. Ankle swelling is common in the normal pregnant woman but if accompanied by hypertension consider pre-eclampsia.

Cardiac investigations in pregnancy

The ECG axis shifts slightly to the left (superiorly) in late pregnancy due to a more horizontal position of the heart. Small Q waves and T-wave inversion in the inferior leads are not uncommon. Atrial and ventricular ectopics are both common. Troponin is not affected by pregnancy and remains a valid test for myocardial ischaemia.

The amount of radiation received by the fetus during a maternal chest X-ray (CXR) is negligible and CXR should never be withheld if clinically indicated in pregnancy. Transthoracic echocardiography is the investigation of choice for excluding, confirming or monitoring structural heart disease in pregnancy. Transoesophageal echocardiography is also safe with the usual precautions to avoid aspiration. Magnetic resonance imaging (MRI) and chest computed tomography (CT) are safe in pregnancy. Routine investigation with electrophysiological studies are normally postponed until after pregnancy but angiography should not be withheld in, for example, acute coronary syndromes.

General considerations in pregnant women with heart disease

The outcome and safety of pregnancy are related to:

- presence and severity of pulmonary hypertension;
- presence of cyanosis;
- haemodynamic significance of the lesion;
- functional NYHA (New York Heart Association) class as determined by the level of activity that leads to dyspnoea [6].

Most women with pre-existing cardiac disease tolerate pregnancy well if they are asymptomatic or only mildly symptomatic (NYHA class II or less) before the pregnancy, but important exceptions are pulmonary hypertension, Marfan's syndrome with a dilated aortic root, and some women with mitral or aortic stenosis. Women with cyanosis (oxygen saturation below 80–85%) have an increased

risk of fetal growth restriction, fetal loss, and thromboembolism secondary to the reactive polycythaemia. Their chance of a live birth in one study was less than 20% [7].

A number of scores have been developed to predict cardiac events. The CARPREG score identified an increased risk of cardiac events if the woman was classified as above NYHA class II, had cyanosis, had a left ventricular ejection fraction less than 40%, or had signficant left heart obstruction [8]. The total score predicted the risk of events such as stroke, arrhythmia, pulmonary oedema and death complicating pregnancies in women with structural heart disease. This was followed by the Zahara I score which included the first three parameters but added the presence of valvular regurgitation, mechanical valve prosthesis, cyanotic heart disease and cardiac medication required before pregnancy [9].

Finally, the simple modified World Health Organization (WHO) criteria were developed and when tested in a clinical cohort of pregnant women [10] appeared to predict risk better than the former two scoring systems [11]. Whichever score is used, all risk estimations show increased risk for the women with increasing class, risk score or number of predictors. The presence of these identified factors therefore also act as reasons to refer to specialist centres for counselling and management of the pregnancy.

Women with the above risk factors for adverse cardiac or obstetric events should be managed and counselled by a multidisciplinary team including cardiologists with expertise in pregnancy, obstetricians with expertise in cardiac disease, fetal medicine specialists and paediatricians. There should be early involvement of obstetric anaesthetists and a carefully documented plan for delivery.

Specific cardiac conditions

Congenital heart disease

Asymptomatic acyanotic women with simple defects usually tolerate pregnancy well. Many defects will have been treated surgically or by the interventional paediatric cardiologist but others are first discovered during pregnancy. Women with congenital heart disease are at increased risk of having a baby with congenital heart disease and should therefore be offered genetic counselling if possible before pregnancy [12] and detailed scanning for fetal cardiac anomalies with fetal echocardiography by 18–20 weeks' gestation. The risk of congenital heart disease in the child is higher with left-sided lesions such as coarctation of the aorta and is 50% in women with Marfan's syndrome. Those lesions associated with a reduced cardiac output are associated with an increased risk of fetal growth restriction.

Acyanotic congenital heart disease

Atrial septal defect

After bicuspid aortic valve, secundum atrial septal defect (ASD) is the commonest congenital cardiac defect in adults. Paradoxical embolism is rare and arrhythmias do not usually develop until middle age. Mitral regurgitation caused by mitral leaflet prolapse develops in up to 15% of uncorrected ASDs. Pulmonary hypertension is rare.

No problems are anticipated during pregnancy but acute blood loss is poorly tolerated. It can cause massive increase in left-to-right shunting and a precipitous fall in left ventricular output, blood pressure and coronary blood flow and even lead to cardiac arrest.

Ventricular septal defect and patent ductus

Like regurgitant valve disease, these defects, which increase the volume load of the right ventricle, are well tolerated in pregnancy unless the defects are large and complicated by pulmonary vascular disease.

Pulmonary stenosis

Pulmonary stenosis does not usually give rise to symptoms during pregnancy. However, when severe and causing right ventricular failure, balloon pulmonary valvotomy has been successfully carried out during pregnancy. The procedure is best performed during the second trimester.

Aortic stenosis

Left ventricular outflow tract obstruction at any level can cause problems during pregnancy. Pre-pregnancy assessment is the ideal. Significant obstruction results if aortic valve area is less than 1 cm^2 or if the non-pregnant mean gradient across the valve is above 50 mmHg. Indications that pregnancy will be high risk include failure to achieve a normal rise in blood pressure without the development of ST- or T-wave changes during exercise, impaired left ventricular function, and symptoms including chest pain, syncope or pre-syncope.

The ECG will normally show left ventricular hypertrophy and the Doppler transaortic valve velocity will rise during pregnancy if the stroke volume increases in normal fashion. Therefore the measured gradients in pregnancy will increase and should always be compared to pre-pregnancy where possible. If left ventricular systolic function is impaired, the left ventricle may not be capable of generating a high gradient across the valve, and a low gradient may therefore be falsely reassuring.

Any patient who develops angina, dyspnoea or resting tachycardia should be admitted to hospital for rest. Administration of a β-adrenergic blocking drug will increase diastolic coronary flow time and left ventricular filling with resultant improvement in angina and left ventricular function. If despite these measures angina,

pulmonary congestion and left ventricular failure persist or progress, balloon aortic valvotomy needs to be considered [13]. These valves are intrinsically not ideal and severe aortic regurgitation may be created, but if successful the procedure may buy time and allow completion of the pregnancy.

Coarctation of the aorta

Most cases encountered will already have been surgically corrected, although residual narrowing is not uncommon and may not have been identified before pregnancy if the woman has not had regular follow-up. Ideally, any narrowing or pre- or post-stenotic dilatation or aneurysm formation should be assessed with MRI prior to pregnancy. Aortic coarctation may first be diagnosed during pregnancy and should always be considered when raised blood pressure is recorded at booking, especially if investigation for secondary causes of pre-existing hypertension has not previously been undertaken.

Although the blood pressure can be lowered, adequate control cannot be maintained during exercise, which increases the risk of cerebral haemorrhage or aortic dissection [14]. Women with uncorrected coarctation should therefore be advised to rest and avoid exertion. The risk of dissection is increased in patients with pre-existing aortic abnormality associated with coarctation, Marfan's syndrome or other inherited connective tissue disorders.

Hypertension should be aggressively treated, and to minimize the risk of rupture and dissection beta-blockers are the ideal agents. Left ventricular failure is unlikely in the absence of an associated stenotic bicuspid aortic valve or endocardial fibroelastosis with impaired left ventricular function. Normal delivery is usually possible, although severe coarctation would indicate a shortened second stage.

Marfan's syndrome

The majority (80%) of patients with Marfan's syndrome have some cardiac involvement, most commonly mitral valve prolapse and regurgitation. Pregnancy increases the risk of aortic rupture or dissection, usually in the third trimester or early after birth. The risk of type A aortic dissection in pregnant women with Marfan's syndrome is around 1%, even in the absence of a dilated aortic root [6]. Progressive aortic root dilatation and an aortic root dimension above 4 cm are associated with increased risk (10%) [15]. Women with aortic roots greater than 4.6 cm should be advised to delay pregnancy until after aortic root repair or root replacement with resuspension of the aortic valve [16].

Conversely, in women with minimal cardiac involvement and an aortic root of less than 4 cm pregnancy outcome is usually good, although those with a family history of aortic dissection or sudden death are also at increased risk, since in some families aortic root dissection occurs in the absence of preliminary aortic dilatation [6].

Management should include counselling regarding the dominant inheritance of the condition, echocardiography every 4–6 weeks to assess the aortic root in those with cardiac involvement, and beta-blockers for those with hypertension or aortic root dilatation. Vaginal delivery for those with stable aortic root measurements is possible but elective caesarean section with regional anaesthesia is recommended if there is an enlarged or dilating aortic root.

Cyanotic congenital heart disease

Cyanotic congenital heart disease in the adult is usually associated with either pulmonary hypertension (as in Eisenmenger's syndrome) or pulmonary stenosis (as in tetralogy of Fallot). Patients with single ventricle, transposition of the great arteries and complex pulmonary atresias with systemic blood supply to the lungs may all survive to adult life with or without previous palliative surgery.

Tetralogy of Fallot

Tetralogy of Fallot is the association of severe right ventricular outflow tract obstruction with a large subaortic ventricular septal defect (VSD) and overriding aorta causing right ventricular hypertrophy and right-to-left shunting with cyanosis. Pregnancy is tolerated well but fetal growth is poor with a high rate of miscarriage, prematurity and small-for-dates babies. The haematocrit tends to rise during pregnancy in cyanosed women because systemic vasodilatation leads to an increase in right-to-left shunting. Women with a resting arterial saturation of 85% or more, haemoglobin below 18 g/dL and haematocrit below 55% have a reasonable chance of a successful outcome. Arterial saturation falls markedly on effort so rest is prescribed to optimize fetal growth but subcutaneous low-molecular-weight heparin (LMWH) should be given to prevent venous thrombosis and paradoxical embolism. Most women will have had previous surgical correction of tetralogy of Fallot and do well in pregnancy providing they have no signficant pulmonary stenosis or right ventricular failure [17].

Postoperative congenital heart disease

Survivors of neonatal palliative surgery for complex congenital heart disease need individual assessment. Echocardiography by a paediatric or adult congenital cardiologist enables a detailed assessment to be made.

Following the Fontan operation for tricuspid atresia or transposition with pulmonary stenosis, the right ventricle is bypassed and the left ventricle provides the pump for

both the systemic and pulmonary circulations. Increases in venous pressure can lead to hepatic congestion and gross oedema but pregnancy can be successful. It is important that women with a Fontan circulation are kept well filled peripartum as without optimal preload the left ventricle cannot adequately drive the pulmonary circulation. These women are usually anticoagulated with warfarin outside pregnancy and LMWH in pregnancy.

Eisenmenger's syndrome and pulmonary hypertension

Pulmonary vascular disease, whether secondary to a reversed large left-to-right shunt such as a VSD (Eisenmenger's syndrome) or to lung or connective tissue disease (e.g. scleroderma) or due to idiopathic arterial pulmonary hypertension, is extremely dangerous in pregnancy and women known to have significant pulmonary vascular disease should be advised from an early age to avoid pregnancy and be given appropriate contraceptive advice [10]. Maternal mortality was around 25–40% [18], but with a highly specialized team managing these women with aggressive drug regimens, the reported mortality rate has fallen to around 17% [19]. This mortality rate is still high and therefore the advice to these women not to undergo a pregnancy still stands.

The danger relates to fixed pulmonary vascular resistance that cannot fall in response to pregnancy, and a consequent inability to increase pulmonary blood flow with refractory hypoxaemia. Pulmonary hypertension is defined as a non-pregnant elevation of mean (not systolic) pulmonary artery pressure of 25 mmHg or more at rest or 30 mmHg on exercise in the absence of a left-to-right shunt. Pulmonary artery systolic (not mean) pressure is usually estimated using Doppler ultrasound to measure the regurgitant jet velocity across the tricuspid valve. This should be considered a screening test. There is no agreed relation between the mean pulmonary pressure and the estimated systolic pulmonary pressure. If the systolic pulmonary pressure estimated by Doppler is thought to indicate pulmonary hypertension, a specialist cardiac opinion is recommended. If there is pulmonary hypertension in the presence of a left-to-right shunt, the diagnosis of pulmonary vascular disease is particularly difficult and further investigation including cardiac catheterization to calculate pulmonary vascular resistance is likely to be necessary. Pulmonary hypertension as defined by Doppler studies may also occur in mitral stenosis and with large left-to-right shunts that have not reversed. Women with pulmonary hypertension who still have predominant left-to-right shunts are at lesser risk and may do well during pregnancy, but although such women may not have pulmonary vascular disease and a fixed pulmonary vascular resistance (or this may not have been established prior to pregnancy), they have the potential to develop it and require very careful monitoring.

Modern management of pulmonary hypertension includes drugs such as sildenafil/tadalfil and bosentan/macitentan. With such therapies, pulmonary pressures can be reduced to within the normal range, and therefore pregnancy may be safely negotiated. Although bosentan is teratogenic in animals, the benefit of continuing therapy in pregnancy probably outweighs this risk. In the event of unplanned pregnancy a therapeutic termination should be offered. Elective termination carries a 7% risk of mortality, hence the importance of avoiding pregnancy if possible. If such advice is declined, multidisciplinary care, elective admission for bed rest, oxygen and thromboprophylaxis with LMWH are recommended [20]. Fetal growth should be carefully monitored.

Most fatalities occur during delivery or the first week after birth. There is no evidence that monitoring the pulmonary artery pressure before or during delivery improves outcome; indeed insertion of a pulmonary artery catheter increases the risk of thrombosis, which may be fatal in such women. Vasodilators given to reduce pulmonary artery pressure will (with the exception of inhaled nitric oxide and prostacyclin) inevitably result in a concomitant lowering of the systemic pressure, exacerbating hypoxaemia.

There is no evidence that abdominal or vaginal delivery or regional versus general anaesthesia improve outcome in pregnant women with pulmonary hypertension. Great care must be taken to avoid systemic vasodilatation. The patient should be nursed in an intensive care unit after delivery. Nebulized prostacyclin can be used to try to prevent pulmonary vasoconstriction. When sudden deterioration occurs (usually in the postpartum period) resuscitation is rarely successful and no additional cause is found at post-mortem, although there may be concomitant thromboembolism, hypovolaemia or pre-eclampsia. Death is usually preceded by vagal slowing, a fall in blood pressure and oxygen saturation, followed by ventricular fibrillation.

Acquired valve disease

Mitral valve prolapse

This common condition may also be called 'floppy mitral valve' and may be sporadic or inherited as a dominant condition in some families with variants of Marfan's syndrome. Pregnancy is well tolerated and for women with isolated mitral valve prolapse there are no implications for the mother or fetus in pregnancy.

Rheumatic heart disease

Mitral stenosis

Worldwide, mitral stenosis remains the most common potentially lethal pre-existing heart condition in

pregnancy. There are many pitfalls because (i) an asymptomatic patient may deteriorate in pregnancy, (ii) mitral stenosis may have increased in severity since a previous uncomplicated pregnancy, (iii) stenosis can recur or worsen after valvuloplasty or valvotomy, and (iv) mitral stenosis that may previously not have been recognized may be missed during routine antenatal examination because the murmur is low-pitched, usually quiet, diastolic and submammary.

Women may deteriorate secondary to tachycardia (related to pain, anxiety, exercise or intercurrent infection), arrhythmias or the increased cardiac output of pregnancy. Sinus tachycardia at rest should prompt concern. Tachycardia is the reflex response to failure to increase stroke volume and it reduces the time for left atrial emptying during diastole so that left ventricular stroke volume falls, the reflex sinus tachycardia accelerates and left atrial pressure climbs. This creates a vicious circle of increasing heart rate and left atrial pressure and can precipitate pulmonary oedema. The anxiety caused by the dyspnoea increases the tachycardia and exacerbates the problem (Fig. 8.1). Pulmonary oedema may also be precipitated by increased volume (such as occurs during the third stage of labour or following injudicious intravenous fluid therapy) [21]. The risks are increased with severe mitral stenosis (mitral valve area $<1\,cm^2$), moderate or severe symptoms prior to pregnancy, and in those diagnosed late in pregnancy.

The ECG in mitral stenosis shows left atrial P waves and right axis deviation. The CXR shows a small heart but with prominence of the left atrial appendage and left atrium and pulmonary congestion or oedema. The diagnosis is confirmed with transthoracic echocardiography.

Women with severe mitral stenosis should be advised to delay pregnancy until after balloon, open or closed mitral valvotomy, or if the valve is not amenable to valvotomy until after mitral valve replacement. Beta-blockers decrease heart rate, increase diastolic filling time and decrease the risk of pulmonary oedema [21] and should be given in pregnancy to maintain a heart rate of under 90 bpm. Diuretics should be commenced or continued if indicated. It is also important that the woman does not over-exert herself.

In the event of pulmonary oedema, the patient should be sat up, oxygen should be given and the heart rate slowed by relief of anxiety with diamorphine, and intravenous furosemide 20 mg administered. Digoxin should only be used if atrial fibrillation occurs as it does not slow the heart in sinus rhythm (because increased sympathetic drive easily overcomes its mild vagotonic effect).

If medical therapy fails or for those with severe mitral stenosis, balloon mitral valvotomy may be safely and successfully used in pregnancy if the valve is suitable [22], although this will require transfer to a hospital with major cardiac facilities. Percutaneous balloon valvotomy carries a risk of major complications of about 1%, whereas for surgical valvotomy the risks are as follows.

- Closed valvotomy: fetal mortality 5–15%, maternal mortality 3%.
- Open valvotomy: fetal mortality 15–33%, maternal mortality 5%.

If an open operation on the mitral valve is likely to be required, this should be deferred if possible until after delivery.

Women with mitral stenosis should avoid the supine and lithotomy positions as much as possible for labour and delivery. Fluid overload must be avoided; even in the presence of oliguria, without significant blood loss, the temptation to give intravenous colloid must be resisted. Cautious epidural analgesia or anaesthesia is suitable for the patient with mitral stenosis as is vaginal delivery but limitation of maternal effort with an instrumental delivery may be indicated.

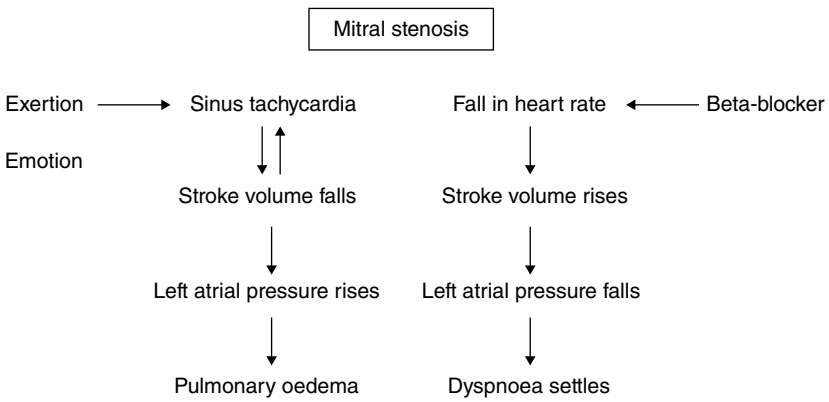

Fig. 8.1 Mitral stenosis.

Regurgitant valve disease

Patients with regurgitant valve disease, either mitral or aortic, tolerate pregnancy much better than patients with valvular stenosis. The systemic vasodilatation in pregnancy reduces regurgitant flow as does tachycardia in patients with aortic regurgitation. When the valve disease is of rheumatic origin the advent of sudden atrial fibrillation may precipitate pulmonary oedema. Similarly, monitoring of left ventricular function is important in those with severe mitral or aortic regurgitation.

Mechanical heart valves

Most women with prosthetic heart valves have sufficient cardiovascular reserve to accomplish pregnancy safely. The optimal strategy for anticoagulation in women with metal heart valve replacements in pregnancy is controversial since the interests of the mother and the fetus are in conflict. These women require lifelong anticoagulation and this must be continued in pregnancy because of the increased risk of thrombosis. However, warfarin is associated with warfarin embryopathy (chondrodysplasia punctata) if given during the period of organogenesis (6–12 weeks' gestation) [23] and with fetal intracerebral haemorrhage in the second and third trimesters.

Despite a maternal international normalized ratio (INR) within the therapeutic range, there is a greater anticoagulant effect on the fetus than on the mother because the immature fetal liver produces only low levels of vitamin K-dependent clotting factors and maternal procoagulants do not cross the placenta due to their large molecular size. The fetal risk from warfarin is dose dependent. Women requiring more than 5 mg daily are at increased risk of teratogenesis, miscarriage and stillbirth [24,25].

Heparin and LMWH do not cross the placenta and are therefore an attractive option. However, even in full anticoagulant doses, they are associated with an increased risk of valve thrombosis and embolic events [23,24,26]. Heparins can also cause retroplacental haemorrhage so the risk of fetal loss is not eliminated. Further disadvantages of unfractionated heparin include a need for parenteral administration, powerful but short duration of action, narrow therapeutic index, a steep dose–response curve, increasing dose requirement during pregnancy, and lack of agreed optimal test or target for safe and effective activity. Overshooting with incremental dosage brings a risk of bleeding. High doses of unfractionated heparin long term may also cause osteoporosis.

LMWHs have a better safety profile in pregnancy and provided there is close monitoring of anti-Xa levels with appropriate dose adjustments and good compliance with twice-daily injections, recent data would suggest a lower risk of thrombotic events [26,27]. Most clinicians use concomitant low-dose aspirin and many women need an increase in the LMWH dose in order to maintain peak anti-Xa levels of 0.8–1.2 IU/mL [27].

There are three basic options for anticoagulation management.

1) Continue warfarin throughout pregnancy, stopping only for delivery. This is the safest option for the mother [23,24].
2) Replace warfarin with high-dose LMWH from 6 to 12 weeks' gestation to avoid warfarin embryopathy but continue until prior to delivery when LMWH is used again.
3) Use high-dose LMWH throughout pregnancy.

Whilst the registry of pregnancy and cardiac disease (ROPAC) found a high rate of pregnancy loss in women using vitamin K antagonsists in the entire first trimester, no specific regimen turned out to be clearly safest [28]. Currently, therefore, the choice of regimen depends on several factors.

- *Type of mechanical valve*. The risk of thrombosis is less with the newer bileaflet valves (e.g. CarboMedics) than with first-generation ball and cage (e.g. Starr–Edwards) or second-generation single tilting disc (e.g. Björk–Shiley) valves.
- *Position of the valve replacement*. Valves in the aortic rather than the mitral position are associated with a lower risk of thrombosis [27].
- *Size of the mechanical valve*. If a valve was replaced before the woman had finished growing, it may be relatively small and this increases the risk of thrombosis.
- *Number of mechanical valves*. Two valves give a higher risk of thrombosis.
- *Dose of warfarin* required to maintain a therapeutic INR. If this is less than 5 mg, the risk to the fetus is reduced.
- Any previous history of embolic events.

If warfarin is used in pregnancy, serial fetal scans are indicated to detect embryopathy and intracerebral haemorrhage. Warfarin should be discontinued and substituted for LMWH for 10 days prior to delivery to allow clearance of warfarin from the fetal circulation. For delivery itself, LMWH therapy is interrupted.

Conversion from LMWH back to warfarin should be delayed for at least 5 days after delivery to minimize the risk of obstetric haemorrhage. There is a high risk of antenatal but particularly postpartum bleeding in women with mechanical valves [27].

In the event of bleeding or the need for urgent delivery in a fully anticoagulated patient, warfarin may be reversed with recombinant human factor VIIa, fresh frozen plasma and vitamin K, and heparin with protamine

sulfate. High doses of vitamin K should be avoided if possible since it renders the woman extremely difficult to anticoagulate with warfarin after delivery.

Thrombolytic treatment can be used for prosthetic valve thrombosis during pregnancy, and although it may cause embolism or bleeding or placental separation, the risks are lower than those of cardiothoracic surgery.

Coronary artery disease

Myocardial infarction and ischaemic heart disease are now seen more commonly in pregnant and postpartum women and pregnancy increases the risk of myocardial infarction [29]. When myocardial infarction occurs in pregnancy it often develops without a preceding history of typical angina. Pregnant women may present with atypical features as they often do outside of pregnancy. These include epigastric pain, nausea or dizziness as well as with more classical chest, neck and left arm pain. In pregnancy the underlying cause may be due to non-atherosclerotic conditions and thus can occur in a young individual without risk factors. These include spontaneous coronary artery dissection and coronary artery thrombosis, both of which are more common in pregnancy [2,30]. Most occur during late pregnancy or around or after delivery. Coronary ischaemia may also be associated with drug abuse from crack cocaine. Where there is thrombus on a normal coronary artery, embolic occlusion should always be considered and an embolic source such as mitral stenosis or infective endocarditis sought.

The risk factors for ischaemic heart disease in pregnancy are the same as those for the non-pregnant woman. The risk is increased in older multigravid women and in those who smoke and those with diabetes, obesity, hypertension, hypercholesterolaemia or a family history of coronary artery disease [29,31]. There should be a low threshold for investigating chest pain and other symptoms that could be due to acute coronary syndrome particularly in women with risk factors. Troponin is not affected by pregnancy and this should be requested along with serial ECGs in women in whom acute coronary syndrome is suspected. A raised troponin should therefore raise concern regarding an acute coronary syndrome and investigated appropriately.

The management of acute myocardial infarction and acute coronary syndrome is as for the non-pregnant woman. Coronary angiography should be undertaken without hesitation in order to define the pathology and determine management. Intravenous and intracoronary thrombolysis and percutaneous coronary intervention (PCI) and stenting have all been successfully performed in pregnancy. PCI is preferred as it has clinical superiority over thrombolysis outside of pregnancy but also coronary artery dissection is probably best treated with PCI. Both aspirin and beta-blockers are safe in pregnancy. Clopidogrel also appears to be safe but no data exist for the newer agents such as prasugrel or ticagrelor. The data for glycoprotein IIb/IIIa inhibitors are limited to case reports and these drugs are normally avoided where possible. It was thought statins should be discontinued for the duration of pregnancy as they are associated with an increased risk of malformations [32]. However, new safety data seem to be reassuring, but until we have more robust evidence, suspension of treatment is still advisable [33].

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant disease characterized by hypertrophy of the undilated left ventricle in the absence of an abnormal haemodynamic load and with underlying myocyte and myofibrillar disarray. Family studies, now sometimes aided by genetic identification of a responsible mutant gene, have indicated the broad spectrum of phenotypic abnormality that exists not only between individuals at different ages but within families. Patient series previously described from specialist centres represented a highly skewed population of high-risk patients referred because of disabling symptoms or a malignant family history. In the years before echocardiography only gross examples of the disorder could be identified but these patients formed the basis of many of the published natural history studies.

HCM is not infrequently first diagnosed in pregnancy when a systolic murmur leads to an ECG and echocardiographic study. Most patients are asymptomatic and do well. HCM used to be regarded as a rare disease with a high risk of sudden death but is now recognized to be relatively common, being found in 1 in 500 young adults in a recent study and in most patients the disorder is benign.

Patients with HCM respond well to pregnancy by a useful increase in their normally reduced left ventricular cavity size and stroke volume. The danger relates to left ventricular outflow tract obstruction that may be precipitated by hypotension or hypovolaemia. Symptoms of shortness of breath, chest pain, dizziness or syncope indicate the need for a beta-blocker [34]. Ventricular arrhythmias are commoner in older patients but uncommon in the young. Sudden death has only very rarely been reported during pregnancy. It is most important in all patients to avoid vasodilatation during labour and

delivery and during regional anaesthesia/analgesia. Any hypovolaemia will have the same effect and should be rapidly and adequately corrected. Equally, some HCM patients have a stiff ventricle and can therefore develop pulmonary oedema if they receive large volume loads. It is most unusual to find hypertrophy in the infants of mothers with HCM.

Peripartum cardiomyopathy

This pregnancy-specific condition is defined as the development of cardiac dysfunction towards the end of pregnancy or in the months following delivery, in the absence of an identifiable cause or recognizable heart disease prior to the last month of pregnancy, and left ventricular systolic dysfunction demonstrated by echocardiographic criteria [35]. The left ventricle may not be dilated but left ventricular ejection fraction is nearly always reduced (<45%). Echocardiography may show dilatation that usually involves all four chambers but is dominated by left ventricular hypokinesia, which may be global or most marked in a particular territory.

The condition is rare but the true incidence is unknown as mild cases undoubtedly go unrecognized. Recognized risk factors include multiple pregnancy, hypertension (pre-existing or related to pregnancy or pre-eclampsia), multiparity, increased age and Afro-Caribbean race.

Peripartum cardiomyopathy does not differ clinically from dilated cardiomyopathy except in its temporal relationship to pregnancy. The severity varies from catastrophic to subclinical, when it may be discovered only fortuitously through echocardiography. Diagnosis should be suspected in the peripartum patient with breathlessness, tachycardia or signs of heart failure. Pulmonary oedema is often a major feature and may be precipitated by the use of Syntocinon or by fluids given to maintain cardiac output during spinal anaesthesia for delivery. The CXR shows an enlarged heart with pulmonary congestion or oedema and often bilateral pleural effusions. Systemic embolism from mural thrombus may herald the onset of ventricular arrhythmias or precede the development of clinical heart failure and pulmonary embolism may further complicate the clinical picture.

The differential diagnosis includes pre-existing but undiagnosed dilated cardiomyopathy, pulmonary thromboembolism, amniotic fluid embolism, myocardial infarction and pulmonary oedema related to pre-eclampsia or β_2-agonist therapy for preterm labour. Echocardiography immediately implicates the left ventricle and excludes pulmonary embolism as the cause. Pre-eclampsia may rarely cause transient impairment of left ventricular function but this normally recovers rapidly after delivery.

Management is as for other causes of heart failure, with oxygen, diuretics, vasodilators and angiotensin-converting enzyme (ACE) inhibitors if post partum. Thromboprophylaxis is imperative. The cautious addition of a cardioselective β-adrenergic blocking drug may be helpful if tachycardia persists, particularly if the cardiac output is well preserved. The most gravely ill patients will need intubation, ventilation and monitoring with use of inotropes and sometimes temporary support from an intra-aortic balloon pump, ECMO (extracorporeal membrane oxygenation) or ventricular assist device. Heart transplantation may be the only chance of survival in severe cases.

More recently, the role of bromocriptine in peripartum cardiomyopathy has been investigated. Animal studies have suggested that oxidative stress raises the 16-kDa cleaved form of prolactin, which is angiostatic and pro-apoptotic, thus providing a plausible aetiology for the condition. A proof of concept pilot study was then undertaken which concluded that the addition of bromocriptine to standard heart failure treatment appeared to improve left ventricular ejection fraction and we now await a larger randomized trial [36].

Currently, about 50% of women make a spontaneous and full recovery. Most case fatalities occur close to presentation and cardiomyopathy is the cause of almost one-quarter of maternal cardiac deaths [2]. Recent data show a 5-year survival of 94% [37]. Patients should remain on an ACE inhibitor for as long as left ventricular function remains abnormal. Prognosis and recurrence depend on the normalization of left ventricular size, which may continue to improve for several years after delivery [38,39]. Those women with severe myocardial dysfunction (defined as left ventricular end-diastolic dimension ≥6 cm and fractional shortening ≤21%) are unlikely to regain normal cardiac function on follow-up [40]. Those whose left ventricular function and size do not return to normal within 6 months and prior to a subsequent pregnancy are at significant risk of worsening heart failure (50%) and death (25%) or recurrent peripartum cardiomyopathy in the next pregnancy. They should therefore be advised against pregnancy [38]. Women who have recovered normal left ventricular size and function should have their functional reserve assessed using stress (exercise) echocardiography. Even if this is normal there is a risk of recurrent heart failure in subsequent pregnancies [34].

Arrhythmias

Atrial and ventricular premature complexes are common in pregnancy. Many pregnant women are symptomatic from forceful heart beats that occur following a compensatory

pause after a ventricular premature complex. Most women with symptomatic episodes of dizziness, syncope and palpitations do not have arrhythmias [41].

A sinus tachycardia requires investigation for possible underlying pathology such as blood loss, infection, heart failure, thyrotoxicosis or pulmonary embolus. The commonest arrhythmia encountered in pregnancy is supraventricular tachycardia (SVT). First onset of SVT (both accessory pathway mediated and atrioventricular nodal re-entrant) is rare in pregnancy but exacerbation of symptoms is common in pregnancy [41]. Half of SVTs do not respond to vagal manoeuvres.

Propranolol, verapamil and adenosine have Food and Drug Administration approval for acute termination of SVT. Adenosine has advantages over verapamil, including probable lack of placental transfer, and may be safely used in pregnancy for SVTs that do not respond to vagal stimulation [42]. For prevention of SVTs, beta-blockers or verapamil may be used. Flecainide is safe and is used in the treatment of fetal tachycardias. Propafenone and amiodarone should be avoided [43], the latter because of interference with fetal thyroid function [44]. Temporary and permanent pacing, cardioversion and automatic implantable defibrillators are also safe in pregnancy. Care is needed when bipolar diathermy is used at caesarean section since this may be misinterpreted by the implantable defibrillator as ventricular fibrillation leading to deployment of a shock. The device is therefore usually inactivated during caesarean section.

Cardiac arrest

This should be managed according to the same protocols as used in the non-pregnant woman. Pregnant women (especially those in advanced pregnancy) should be 'wedged' to relieve any obstruction to venous return from pressure of the gravid uterus on the IVC. This can be most rapidly achieved by turning the patient into the left lateral position. If cardiopulmonary resuscitation is required, then the pelvis can be tilted while keeping the torso flat to allow external chest compressions. Emergency caesarean section may be required to aid maternal resuscitation.

Endocarditis prophylaxis

Infective endocarditis (IE) is rare in pregnancy but threatens the life of both mother and child. Fatal cases of endocarditis in pregnancy have occurred antenatally, rather than as a consequence of infection acquired at the time of delivery [2]. Treatment is essentially the same as outside pregnancy, with emergency valve replacement if indicated. As always, the baby should be delivered if viable before the maternal operation.

The current UK recommendations from the National Institute for Health and Care Excellence [45] are that antibiotic prophylaxis against IE is not required for childbirth. The British Society for Antimicrobial Chemotherapy [46] and the American Heart Association have recommended cover only for patients deemed to be at high risk of developing IE (such as women with previous IE) and for those who have the poorest outcome if they develop IE (such as those with cyanotic congenital heart disease). If antibiotic prophylaxis is used it should be with amoxicillin 2 g i.v. plus gentamicin 120 mg i.v. at the onset of labour or ruptured membranes or prior to caesarean section, followed by amoxicillin 500 mg orally (or i.m/i.v. depending on the patient's condition) 6 hours later. For women who are allergic to penicillin, vancomycin 1 g i.v. or teicoplanin 400 mg i.v. may be used instead of amoxicillin.

Summary box 8.1

- Cardiac disease is the commonest cause of death in pregnancy or the puerperium in the UK.
- Mortality of pulmonary hypertension in pregnancy is historically reported to be as high as 25–40%.
- Women with Marfan's syndrome are at risk of aortic dissection in pregnancy, particularly if they have a dilated aortic root.
- Women with mitral stenosis are at risk of pulmonary oedema in mid-pregnancy and during or immediately after delivery.
- If women with mechanical valves in pregnancy are managed with therapeutic doses of LMWH, this should be closely monitored and doses adjusted to maintain therapeutic levels. These women have an increased risk of bleeding, particularly after delivery.

Diabetes in Pregnancy

Sarah N. Ali[1] *and Anne Dornhorst*[2]

[1] *Department of Diabetes and Endocrinology/General Internal Medicine, Royal Free London NHS Foundation Trust, London, UK*
[2] *Division of Diabetes, Endocrinology and Metabolism, Hammersmith Hospital, London, UK*

Diabetes in pregnancy poses major health risks to both the mother and the growing fetus, and influences the future health of the child [1–4]. The risk of diabetes to pregnancy outcome increases with increasing maternal hyperglycaemia [5,6], and thus the risk from pre-gestational diabetes, whether type 1 diabetes (type 1 DM) or type 2 diabetes (type 2 DM), is greater than gestational diabetes mellitus (GDM) which develops during the pregnancy [7].

In 1989 the St Vincent Declaration pledged to improve pregnancy outcomes for women with diabetes to those of non-diabetic women [8]. Despite major advances in obstetric, neonatal and diabetic care, this has not happened. While some improvement for women with type 1 DM have been reported, in general congenital abnormalities, stillbirths and perinatal deaths remain twofold to fourfold higher among women with pre-gestational diabetes [9]. Recent years has seen a rapid rise in type 2 DM among women of childbearing age who have additional risk factors that adversely affect pregnancy, including high maternal age, weight, parity, levels of social deprivation and belonging to non-white ethnic minority groups [6,10,11] (Fig. 9.1). These risk factors are similar to those associated with GDM. Because of changing demographics in European urban cities, women with pre-gestational type 2 DM now outnumber those with type 1 DM while those with GDM account for the majority of women attending an obstetric diabetes antenatal clinic [7,12].

The consequences of a diabetic pregnancy in women with type 1 DM, type 2 DM or GDM extend beyond the pregnancy. Approximately 40% of all births to women with pre-gestational diabetes have evidence of growth acceleration, with approximately half above the 90th percentile for gestational age. High birthweight and infant adiposity is associated not only with shoulder dystocia and caesarean section rates above 60% but also with early-onset obesity, metabolic dysfunction and diabetes in the child in later life [3,6,13–15].

Optimal glycaemic control prior to conception and throughout pregnancy improves pregnancy outcome [6,16,17]. All professionals caring for women of childbearing age with either known diabetes or at risk of GDM need to emphasize the importance of pregnancy planning and good glycaemic control prior to pregnancy and the need for GDM screening for those at risk.

This chapter covers the clinical management of pregnancies complicated by pre-gestational diabetes, as well as the screening and management of GDM. Finally, the long-term health consequences for the child of a diabetic pregnancy are discussed.

Classification of diabetes in pregnancy

The diabetic and obstetric management is influenced by the type of diabetes. The main types of diabetes seen in obstetric practice are shown in Table 9.1.

Diabetes in pregnancy can be defined as pre-gestational (i.e. pre-existing) diabetes or GDM. Most women with pre-gestational diabetes have type 1 or type 2 DM. However, a small percentage have monogenetic or mitochondrial forms of diabetes that require genetic screening for correct diagnosis. The importance of recognizing this cohort of women is that their pregnancy outcomes are determined as much by their genetic mutation as by their diabetic control [18–20]. GDM is defined as diabetes or glucose intolerance occurring or first recognized in pregnancy, a definition that includes those with previously unrecognized diabetes [21].

The numbers of women with pre-gestational DM and GDM is increasing, with the largest proportional

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

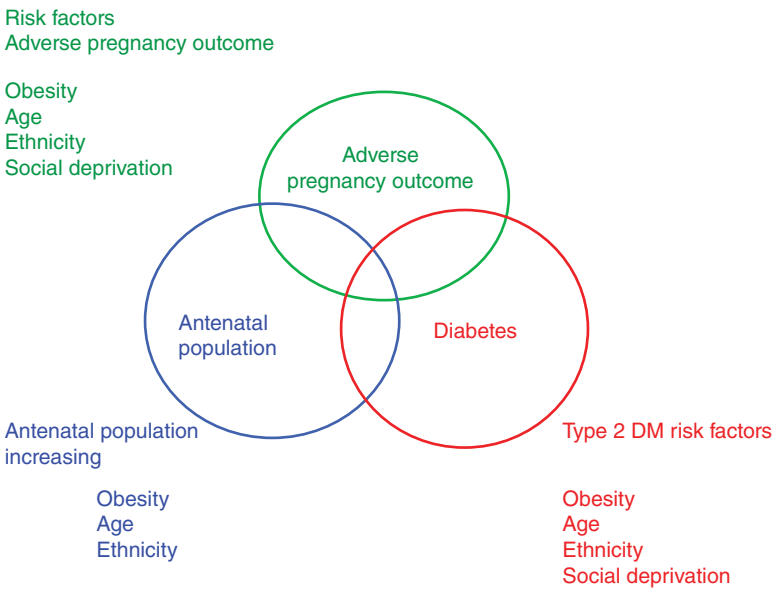

Fig. 9.1 Venn diagram illustrating the relationship between the demographics of the antenatal population and the risk factors for diabetes and those for adverse pregnancy outcomes.

Table 9.1 The types of diabetes encountered in obstetric practice.

Type 1 diabetes Absolute insulin deficiency due to autoimmune destruction of the pancreatic β-cell. Presents typically under the age of 20 years old, and only 10% have a first-degree relative affected. Not associated with obesity. Accounts for approximately 5% of all diabetes outside pregnancy
Type 2 diabetes Relative insulin deficiency and decreased insulin sensitivity. Presents typically over the age of 20 years, and >50% have a first-degree relative affected. Strongly associated with obesity. Accounts for approximately 90% of all diabetes outside pregnancy
Monogenetic diabetes Maturity-onset diabetes of the young (MODY). Results from a single gene mutation causing defects in pancreatic β-cell insulin secretion. Present from birth and typically diagnosed within the second and third decade. Autosomal dominant with approximately 95% having a first-degree relative affected. Not associated with obesity. Accounts for 1–2% of all diabetes outside pregnancy
Mitochondrial diabetes Arises from a mutation in mitochondrial DNA leading to a defect in insulin secretion. Associated with a number of other medical problems including neural sensory deafness, a tendency for stroke and lactic acidosis. Diabetes develops at approximately 35 years old, and is maternally inherited. Not associated with obesity. Accounts for less than 1% of all diabetes outside pregnancy
Secondary diabetes Diabetes due to other medical conditions, i.e. pancreatitis, cystic fibrosis, glucocorticoids and other drugs. Accounts for approximately 2% of all diabetes outside pregnancy

rise in those with pre-gestational type 2 DM and GDM, driven predominantly by the rise in obesity [22]. There is also a slower rise in the prevalence of type 1 DM, whose incidence is estimated at 3–4% per annum in Europe [23].

The prevalence of GDM across Europe in 2012 varied between 2 and 6% [24], influenced by the demographics of the antenatal population and the diagnostic criteria used [25]. This prevalence is anticipated to increase as more universal screening and testing for GDM is introduced. Annual audit data from England and Wales in 2015 estimated that approximately 35 000 pregnant women had either pre-gestational DM or GDM, the latter making up approximately 80% of cases [26].

While GDM typically arises in the late second trimester due to physiological changes in maternal carbohydrate metabolism [27], the number of women with undiagnosed type 2 DM becoming pregnant will increase as the age of onset of type 2 DM falls [28]. It is important to recognize this high-risk group as the clinical management needs to be similar to women with pre-existing type 2 DM.

Summary box 9.1

- Diabetes in pregnancy poses major health risks to both the mother and the growing fetus, and influences the future health of the child.
- Diabetes in pregnancy can be defined as pre-gestational (includes type 1 DM, type 2 DM and other rare forms of diabetes that precede pregnancy, i.e. monogenic diabetes) or gestational diabetes (glucose intolerance of diabetes first recognized in pregnancy).
- In general, congenital abnormalities, stillbirths and perinatal deaths remain twofold to fourfold higher among women with pre-gestational diabetes.
- Optimal glycaemic control prior to conception and throughout pregnancy improves pregnancy outcome.

Diagnosing diabetes and gestational diabetes

While the definition of GDM is not controversial, how and who to screen for GDM remains contentious [29]. Outside pregnancy the diagnosis of diabetes is made by [18]:

- fasting plasma glucose of 7.0 mmol/L or greater;
- 2-hour plasma glucose of 11.1 mmol/L or greater during a 75-g oral glucose tolerance test (OGTT);
- random plasma glucose of 11.1 mmol/L or greater in the presence of hyperglycaemic symptoms;
- HbA_{1c} of 6.5% (48 mmol/mol) or greater.

The distinction between type 1 and type 2 DM can usually be made clinically based on history and recognized risk factors; when there is uncertainty, testing for the specific pancreatic islet autoantibodies GAD, IA-2 and ZnT8 can help confirm the diagnosis of type 1 DM in approximately 80% of cases. It is increasingly recognized that new-onset type 1 DM after the age of 30 years may account for up to 50% of all type 1 DM in the white population.

Two large randomized controlled trials, one Australian and the other Canadian, have provided evidence that diagnosing and treating GDM improves pregnancy outcomes. These two randomized trials used different diagnostic criteria for GDM and randomized women between 24 and 34 weeks' gestation to active management with diet, glucose monitoring and insulin if required or to routine antenatal care [16,17]. The Australian trial of 1000 women diagnosed by World Health Organization (WHO) criteria for impaired glucose tolerance showed that serious perinatal complications were lower among the 490 pregnancies in the intervention group than among the infants of the 510 women assigned to routine care (1% vs. 4%; relative risk adjusted for maternal age, race or ethnic group, and parity). The intervention group had a 10% higher rate of induction of labour with a similar caesarean section rate compared with women receiving routine care [16]. The Canadian study of 958 women identified as having mild gestational diabetes showed that active treatment reduced mean birthweight (3302 vs. 3408 g), neonatal fat mass (427 vs. 464 g), frequency of large-for-gestational-age infants (7.1% vs. 14.5%), birthweight greater than 4000 g (5.9% vs. 14.3%), shoulder dystocia (1.5% vs. 4.0%), and caesarean delivery (26.9% vs. 33.8%). Active treatment was also associated with reduced rates of pre-eclampsia and gestational hypertension [17].

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study was designed to establish internationally agreed diagnostic criteria for GDM [5]. This observational study analysed over 23 000 non-diabetic pregnant women between 2000 and 2006 from nine countries. All women underwent a 2-hour 75-g OGTT between 24 and 32 weeks' gestation. The results were analysed to clarify associations between maternal glucose values (below those diagnostic of diabetes) and four primary perinatal outcomes: macrosomia (corrected birthweight >90th centile), primary caesarean delivery, clinical neonatal hypoglycaemia and hyperinsulinaemia (assessed by cord serum C-peptide >90th centile for the whole study group). Analysis showed a continuous gradient between maternal glucose levels (at fasting, 1 hour and 2 hours post 75-g glucose load) and all four primary outcomes. Using these results new diagnostic criteria for GDM were drawn up by the International Association of Diabetes and Pregnancy Study Groups (IADPSG) that have been subsequently endorsed by the American Diabetes Association (ADA) and WHO [30]. However, the IADPSG criteria for GDM differ from those recommended in 2015 by the National Institute of Health and Care Excellence (NICE) in England that proposed a higher fasting value, a lower 2-hour value, and no 1-hour value. The NICE criteria were based on published intervention studies and cost-effective analyses. The IADPSG and NICE criteria for GDM diagnosis are summarised in Table 9.2.

The decision to screen universally for GDM or only perform the test in women with recognized risk factors remains unresolved. The NICE criteria advocate using universal screening based on risk factors identified at the initial antenatal visit, which includes body mass index (BMI) above 30 kg/m^2, previous macrosomic baby weighing 4.5 kg or above, previous GDM, family history of diabetes (first-degree relative with diabetes) and a minority ethnic family origin with a high prevalence of diabetes. Only women with one or more of these factors are advised to have a 75-g OGTT between 24 and 28 weeks [26]. An OGTT at 16 weeks is also recommended

Table 9.2 The IADPSG and NICE criteria for GDM diagnosis.

	IADPSG criteria	NICE 2015 criteria
Screening	None	Risk factors at first antenatal clinic BMI >30 kg/m^2 GDM in a previous pregnancy Previous macrosomic baby ≥4.5 kg Family history (first-degree relative with diabetes) Ethnicity: family origin with a high prevalence of diabetes
75-g OGTT	Universal at 24–28 weeks	Selective testing 26–28 weeks Based on the presence of risk factors
Plasma glucose	IADPSG criteria: one or more of the following thresholds be met or exceeded:	NICE 2015 criteria: one or more of the following thresholds be met or exceeded:
0 min	5.1 mmol/L (92 mg/dL)	5.6 mmol/L (100 mg/dL)
60 min	10 mmol/L (180 mg/dL)	
120 min	8.5 mmol/L (153 mg/dL)	7.8 mmol/L (140 mg/dL)

for women with a history of GDM, which should be repeated at 24–28 weeks if the initial test is normal. The list of risk factors recommended by NICE is not exhaustive as they omit maternal age [31,32] and polycystic ovary syndrome [33]. This perhaps explains why using NICE risk factor screening alone can miss up to 25% of women identified with GDM on an OGTT [29,34]. The frequency of GDM among the original HAPO cohort using the IADPSG criteria was 17.8% (9.3–25.5%) depending on the country of origin [25]. The IADPSG criteria diagnose women with a fasting glucose between 5.1 and 5.6 mmol/L and these women are missed using the NICE criteria; 38% of these pregnancies result in a large-for-gestational-age infant despite the 2-hour value being below 7.8 mmol/L, this group of women tending to be obese [35]. The debate on the benefits of treating women with lesser degrees of glucose intolerance than identified by the NICE criteria continues [36].

Summary box 9.2

- GDM is defined as diabetes or glucose intolerance occurring or first recognized in pregnancy.
- GDM is diagnosed by a 75-g OGTT using the following criteria:
  - NICE 2015: fasting blood glucose ≥5.6 mmol/L and/or 120-min blood glucose ≥7.8 mmol/L.
  - IADPSG: fasting blood glucose ≥5.1 mmol/L, 60-min blood glucose ≥10 mmol/L and/or 120-min blood glucose ≥8.5 mmol/L.
- Risk factors for GDM include BMI >30 kg/m^2, GDM in a previous pregnancy, previous macrosomic baby ≥4.5 kg, family history (first-degree relative with diabetes) and family ethnic origin with a high prevalence of diabetes.

The significance of maternal type of diabetes

The 2002 CEMACH audit of 3800 pregnancies in England, Wales and Northern Ireland showed similar fetal complications (perinatal mortality, stillbirth and neonatal mortality) among women with type 1 and type 2 DM, emphasizing that the major determinant of fetal complications is maternal hyperglycaemia rather than type of diabetes [6] (Fig. 9.2). Maternal and social risk factors that can impact on pregnancy do nonetheless differ between women with type 1 DM and those with type 2 DM, and include being more obese, socially deprived and less prepared for pregnancy. This is especially true among adolescents and young adults with type 2 DM, a particularly vulnerable group whose pregnancy outcomes are extremely poor, with fetal malformation rates in excess of 20% [37]. Women with type 1 DM are at greater risk of recurrent and severe hypoglycaemia and retinopathy.

The principles of maternal glycaemic control

Maternal hyperglycaemia affects all aspects of pregnancy, from fertilization and implantation to birth (Fig. 9.3). There is growing evidence that maternal hyperglycaemia, via fetal programming, can cause changes in gene expression that increase the fetus's future susceptibility to obesity, diabetes and other health problems [3,38]. Hence a principal tenet for management of diabetes in pregnancy is to strive for euglycaemia throughout the whole of pregnancy. Congenital abnormalities, miscarriage,

accelerated fetal growth, late stillbirth, birth trauma and neonatal hypoglycaemia all increase as maternal glycaemia rises (Table 9.3). This risk can be further increased by the presence of obesity [39].

In a systemic review involving 1977 diabetic pregnancies from seven USA cohort studies between 1986 and 2006, the mean fetal malformation rate rose from 3% to 10% as peri-conception HbA_{1c} levels rose from two standard deviations (2SD) to 8SD above the normal 2% range, respectively (Fig. 9.4) [40]. This strong correlation between peri-conception glycaemic control and congenital anomaly was also seen in England among 1677 births to diabetic women between 1996 and 2008 [41]. High peri-conception HbA_{1c} values are also a predictor of stillbirth [2,6].

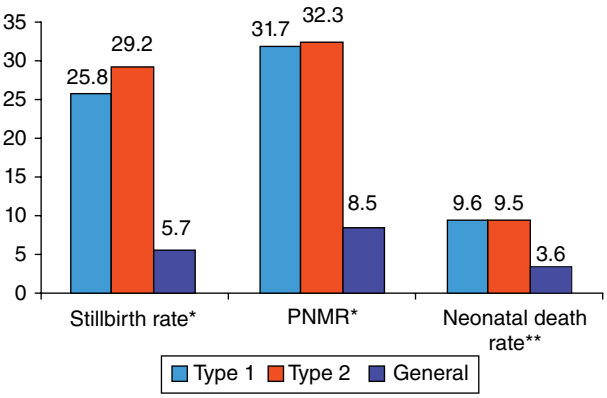

Fig. 9.2 Data from the Confidential Enquiry into Maternal and Child Health (CEMACH) Diabetes Audit. PNMR, perinatal mortality rates, stillbirth rates and neonatal death rates for mothers with type 1 and type 2 DM (delivered or booked between 1 March 2002 and 28 February 2003 in England, Wales and Northern Ireland). Maternal age adjusted: *, per 1000 total births; **, per 1000 live births [6].

Alongside glycaemic management, screening for and treating specific diabetic complications is also important. The association between pre-pregnancy levels of glycaemia and congenital malformations begins at the upper level of the normal non-diabetic range [41]. The teratogenic effect of hyperglycaemia occurs in the first 12 weeks of gestation at the time of blastocyst formation, embryogenesis and organogenesis. In order to significantly limit early fetal loss and congenital abnormalities women need optimal glycaemic control prior to pregnancy. To achieve this, women with pre-gestational diabetes ideally need to plan their pregnancies, be given pre-conception counselling and continue contraception until good glycaemic control has been achieved [26].

Pre-conception counselling

As half of all pregnancies are unplanned, discussing pregnancy planning should be an integral part of all diabetic reviews for women of childbearing age, whether in primary or secondary care [42]. Congenital malformations and preterm delivery are reduced when

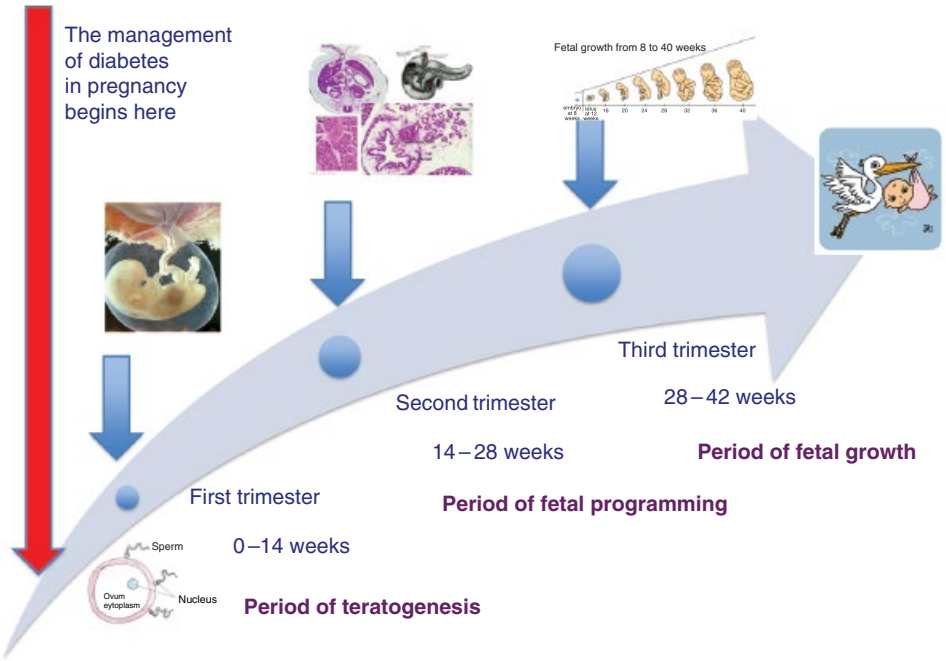

Fig. 9.3 Maternal hyperglycaemia affects all aspects of pregnancy from fertilization and implantation to birth.

Table 9.3 The role of maternal hyperglycaemia on maternal and fetal complications.

First trimester	
Implantation	Inhibits trophectoderm differentiation
Embryogenesis	Increases oxidative stress, affecting expression of critical genes essential for embryogenesis
Organogenesis	Activates the DAG–PKC cascade, increasing congenital defects
Miscarriage	Increases premature programmed cell death of key progenitor cells of the blastocyst
Second trimester	
Endocrine pancreas	Stimulates fetal β-cells
Fetal growth	Stimulates fetal hyperinsulinaemia, which results in growth acceleration seen on ultrasound by 26 weeks
Third trimester	
Fetal growth	Major fetal substrate and determinant of accelerated fetal growth
Adipose disposition	Stimulates hyperinsulinaemia, which promotes fat deposition including intra-abdominal fat
Lung maturation	Stimulates hyperinsulinaemia, which delays lung maturation by inhibiting surfactant proteins
Stillbirth	Is associated with defects in placental maturation that increase the risk of fetal hypoxia
Delivery	
Birth trauma	By causing accelerated fetal growth, there is an increased risk of shoulder dystocia, predisposing to birth trauma and asphyxia
Neonate	
Hypoglycaemia	Stimulates fetal hyperinsulinaemia, which predisposes to neonatal hypoglycaemia
Hypocalcaemia	Alters the placental expression of calbindin mRNA, which affects calcium status at birth
Polycythaemia	Stimulates fetal hyperinsulinaemia, which enhances antepartum haemopoiesis as does fetal hypoxia
Cardiomyopathy	Stimulates fetal hyperinsulinaemia, which predisposes to hypertrophic cardiomyopathy
Adolescence/adulthood	
Obesity	Intrauterine exposure predisposes to the metabolic syndrome, independent of any genetic susceptibility
Type 2 diabetes	Intrauterine exposure predisposes to type 2 diabetes, independent of any genetic susceptibility

DAG, diacylglycerol; PKC, protein kinase C.

women receive pre-conception counselling [43]. These clinics provide a supportive environment to discuss pregnancy care pathways, emphasize the need and timing for increased fetal and maternal surveillance, and offer reassurance that good glycaemic control can reduce the potential risks of a diabetic pregnancy. Glycaemic control can be intensified, high-dose folic acid supplements (5 mg) prescribed and potentially teratogenic drugs, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers and statins (HMG-CoA reductase inhibitor), stopped or switched to safer alternatives [44,45] (Table 9.4). Diabetic complications can be assessed as can the need for aspirin or heparin for women at high risk of pre-eclampsia or thrombophilia or who have significant proteinuria (>4 g per 24 hours) [26]. Unfortunately, women with type 2 DM, those from ethnic minority groups and those with the highest social deprivation scores are less likely to access these services [46].

Summary box 9.3

- The tetratogenic effects of hyperglycaemia occur in the first 12 weeks of gestation.
- Pre-conception planning is essential in women with pre-existing diabetes and should be integrated into every diabetic review for women of childbearing age.
- Congenital malformations and preterm delivery are reduced when women receive pre-conception counselling.
- Pre-conception care includes optimizing glycaemic control, prescribing folic acid 5 mg supplements and stopping all potentially teratogenic drugs or switching to safer alternatives.
- Aspirin or heparin may be required for women at high risk of pre-eclampsia or thrombophilia or if significant proteinuria is present.

Optimizing glycaemia control
Reviewing all medications
Screening and management of diabetic complications
Information on optimal weight and weight gain
Information on pregnancy risk to the mother
Information on pregnancy risk to the baby

Achieving optimal glycaemic control

The level of glycaemic control required from pre-conception to birth mandates continual blood glucose monitoring and dose adjustment of insulin. Providing education and training to women with pre-gestational diabetes to enable them to self-manage and adjust their own insulin to match their carbohydrate intake is key to improving glycaemic control and reducing the risk of hypoglycaemia [47–52].

Based on the association between HbA_{1c} and major fetal anomalies, the 2015 NICE guidance strongly advises women with an HbA_{1c} above 86 mmol/mol (10%) not to become pregnant, while recommending an HbA_{1c} below 48 mmol/mol (6.5%) if achievable without causing problematic hypoglycaemia [6]. For women with type 1 DM, current recommended targets are as follows: fasting plasma glucose of 5–7 mmol/L on waking and a plasma glucose of 4–7 mmol/L before meals at other times. For women with type 1 DM to achieve this level of glycaemic

control requires four to five daily insulin injections (multiple-dose insulin, MDI) or a continuous subcutaneous insulin infusion (CSII) pump. With the MDI regimen, a long-acting basal insulin analogue is usually given at night or as a split morning and evening dose, with rapid-acting bolus insulin given with each meal. The recent advances in insulin pump technology, glucose monitoring and bolus insulin calculators that recommend a rapid-acting insulin dose based on the amount of carbohydrate may all assist women achieve better control. In the future, advances in the technologies of closed-loop insulin delivery, which combines real-time continuous glucose monitoring (CGM) with CSII using a computer algorithm, have the potential to normalize glycaemic control while reducing the risk of hypoglycaemia [53–55].

For women with type 2 DM, achieving an HbA_{1c} below 48 mmol/mol (6.5%) prior to pregnancy is easier, as these women are at less risk of hypoglycaemia [56]. While metformin can be continued in pregnancy, women previously on other oral hypoglycaemic agents, such as sulphonylureas, will need to be switched to insulin using MDI regimens.

Summary box 9.4

- A target HbA_{1c} below 48 mmol/mol (6.5%) should be set for women with pre-existing diabetes if achievable without problematic hypoglycaemia.
- For all women with diabetes, aim for fasting capillary blood glucose (CBG) levels to be <5.3 mmol/L and 1-hour postprandial CBG <7.8 mmol/L.
- Advise pregnant women with diabetes who are on insulin or glibenclamide to maintain their CBG level above 4 mmol/L.
- Target glycaemic control can be achieved by using metformin and an MDI regimen in women with GDM and type 2 DM.
- Women with type 1 DM should continue on an MDI regimen.
- Glibenclamide can be considered in women with GDM or type 2 DM where insulin initiation is problematic.

Screening for diabetic complications

Diabetic complications differ in women with type 1 DM and type 2 DM. Women with type 1 DM are more likely to have had diabetes for longer and since diabetic complications increase over time diabetic microvascular disease is more common in women with type 1 DM than those with type 2 DM. This may change as the onset of type 2 DM continues to fall. Pre-pregnancy counselling reduces the progression of both diabetic retinopathy and nephropathy in pregnancy. Women with long-standing type 1 DM and older obese women with type 2 DM and previous GDM are potentially at increased risk of diabetic macrovascular disease, including coronary heart disease.

Diabetic retinopathy

A dilated retinal examination should be performed prior to pregnancy, in early pregnancy and again at 28 weeks' gestation if no retinopathy was detected initially. However, in the presence of retinopathy a check is required at 16 weeks in addition to the one at 28 weeks' gestation. The risk factors for the development or worsening of retinopathy are pre-existing hypertension, duration of diabetes and a rapid fall in HbA_{1c} between the first and third trimester. However, diabetic retinopathy should not be considered a contraindication for rapid optimization of glycaemic control in pregnancy or a contraindication to pregnancy or a vaginal birth.

As duration of type 1 DM increases, background and proliferative diabetic retinopathy increases. Women with type 2 DM are more prone to diabetic maculopathy, which is less duration dependent. Rapidly improving glycaemic control during the pre-conception period and in pregnancy can worsen retinopathy, although long-term detrimental effects are rare post partum. Laser treatment before pregnancy protects against retinopathy progression in pregnancy and if needed should be performed before conception. When diabetic retinopathy develops *de novo* in pregnancy, it is usually not severe and laser treatment is safe if required [57–59].

Diabetic nephropathy

An assessment of renal function, comprising urinary protein/creatinine ratio and estimated glomerular filtration rate (eGFR), should be performed prior to pregnancy and in early pregnancy. The presence of proteinuria and/or reduced eGFR is a significant risk factor for nephrotic syndrome, hypertension, pre-eclampsia, placental insufficiency, preterm delivery and neonatal morbidity and mortality [60]. Intensive glycaemic control before and throughout pregnancy, low-dose aspirin from 12 gestational weeks, and intensive antihypertensive treatment can reduce these risks [61].

During a healthy non-diabetic pregnancy, structural, functional and hemodynamic changes to renal physiology occur; by term, eGFR is 40% higher, with an increase seen from 12 weeks alongside an associated rise in creatinine clearance and protein excretion rate [62]. Women with normal or mild renal impairment before pregnancy

usually preserve their renal function post partum and can anticipate a successful pregnancy outcome. When microalbuminuria is present that is not attributable to a urinary tract infection, serial urinary protein/creatinine ratios should be performed throughout the remaining pregnancy to quantify the degree of proteinuria. Those with moderate to severe diabetic nephropathy [serum creatinine >124 µmol/L (1.5 mg/dL) or proteinuria >3 g per 24 hours] are most at risk of perinatal death and irreversible deterioration in renal function after pregnancy (especially with serum creatinine >176 µmol/L). If accelerated progression of nephropathy occurs in pregnancy, renal intervention with dialysis may be required [61,63]. A pre-conception microalbumin measurement is also helpful as it assists with the diagnoses of pre-eclampsia, which can be difficult to distinguish from diabetic nephropathy in later pregnancy.

Diabetic neuropathy

Diabetic neuropathy can manifest as either a peripheral sensory neuropathy or an autonomic neuropathy and both increase with duration of diabetes [64]. Diabetic autonomic neuropathy can affect the cardiovascular, gastrointestinal and urogenital systems and sudomotor function. Cardiac involvement is associated with overall mortality while gastrointestinal involvement is a recognized cause of gastroparesis [64]. Historically, autonomic gastroparesis has been associated with poor pregnancy outcomes [65]. Gastroparesis causes erratic absorption of meals, resulting in episodes of hyperglycaemia and hypoglycaemia due to a mismatch between food intake and the short-acting pre-meal insulin. Although the suggestion that autonomic neuropathy causes hypoglycaemia unawareness has recently been challenged [66], the intensity of autonomic symptoms in response to hypoglycaemia decreases with duration of diabetes and this reduces the threshold at which hypoglycaemic symptoms occur [67]. Achieving good glycaemic control in early pregnancy, at a time when nausea and vomiting is common in women with autonomic gastroparesis, is challenging and hypoglycaemia is frequent.

Diabetic macrovascular disease

Diabetes is associated with premature cardiovascular disease. Women with over 20 years' duration of type 1 DM aged over 40 years are likely to have a degree of coronary artery calcification and coronary artery disease (CAD), independently of other risk factors. Older women with type 2 DM and GDM are also at increased risk of CAD. A previous history of CAD or its diagnosis in pregnancy is associated with significant maternal morbidity [68–70].

Hypoglycaemia

Hypoglycaemia affects up to 70% of pregnant women with pre-existing diabetes and is associated with excess maternal mortality. Hypoglycaemic symptoms change in pregnancy, especially if autonomic neuropathy is present. The risk of hypoglycaemia is greatest in the first 20 weeks of pregnancy and immediately post partum. Women with type 1 DM may benefit from an insulin pump and or continuous glucose sensors.

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is a rare but a serious complication in pregnancy, with an associated fetal mortality in excess of 10% [71]. It usually occurs in women with type 1 DM, and can be the first presentation of type 1 DM; rarely it can occur in women with type 2 DM and even GDM. In pregnancy, DKA can occur at normal blood glucose levels (euglycaemic DKA), and thus it should be excluded in any pregnant woman with pre-gestational diabetes and persistent nausea and vomiting and considered in all cases of unexplained maternal acidosis. The risk of DKA is increased during pregnancy because of increased insulin demands and enhanced lipolysis. Other risk factors include infection, vomiting, use of beta-mimetic agents and insulin pump failures. The treatment of DKA is the same as for non-pregnant patients, with insulin administration, fluid replacement, correction of electrolyte imbalance and treatment of the underlying cause. Fetal monitoring and assessment should continue alongside maternal treatment.

Screening for non-diabetic comorbidities

Women with type 1 DM are at increased risk of autoimmune diseases. All women should be screened prior to pregnancy for thyroid disease; if they are already being treated for thyroid disease, this should be repeated in early pregnancy. There should be a high level of suspicion to screen for other autoimmune diseases if clinically indicated.

Women with type 2 DM are likely to have other metabolic risk factors, including obesity, hypertension, dyslipidaemia and insulin resistance as are those with a previous history of GDM. Obesity, independently of diabetes, is a risk factor for hypertension, late stillbirth, induction of labour, caesarean section, birth trauma and maternal complications post partum [72,73]. Advising obese and overweight women on weight management prior to pregnancy is an important part of pre-conception

counselling. The hypertriglyceridaemia associated with obesity is a source of glycerol and fatty acids, both fetal metabolic substrates that in excess can contribute to accelerated fetal growth, and therefore maternal weight management prior to pregnancy will help.

Risks to the fetus of a diabetic pregnancy

Maternal glucose crosses the placental barrier but insulin does not, so increases in maternal glucose stimulate fetal insulin production and hyperplasia of insulin-sensitive tissues [74,75]. Maternal hyperglycaemia also enhances production of human placental growth hormone, fetal insulin-like growth factor and tumour necrosis factor. As with insulin, these hormones act as fetal growth factors, resulting in accelerated fetal growth, macrosomia and organomegaly.

The commonest malformations secondary to maternal hyperglycaemia are cardiac and those involving the central nervous system [1]. Cardiac malformations include transposition of the great vessels, ventricular septal defect and dextrocardia, while the central nervous system anomalies include anencephaly, spina bifida, hydrocephaly and holoprosencephaly; malformations of the genitourinary system and the skeleton also occur [76]. Caudal regression, a rare malformation, has the strongest association with diabetes, occurring roughly 200 times more frequently in infants of diabetic mothers than in other infants [76].

Both liquor and fetal cord blood insulin or C-peptide at birth correlate with the risk of neonatal hypoglycaemia, respiratory distress, polycythaemia, hypocalcaemia and hyperbilirubinaemia, emphasizing the impact of maternal hyperglycaemia and secondary fetal hyperinsulinaemia on neonatal well-being. The long-term effects of a diabetic pregnancy on the child are only now being evaluated.

Table 9.5 A structured approach to the management of diabetic pregnancies.

Prior to pregnancy
Pre-conception counselling
Review of all medications
Folic acid 5 mg once daily
Screening for diabetic complications, including treatment of diabetic retinopathy
First trimester
Referral to a combined multidisciplinary diabetic obstetric antenatal clinic
Dating scan at 6–8 weeks, confirming viability and gestational age
Screening for diabetic complications
Screening for non-diabetic comorbidities
Assessment and optimization of glycaemia
Advice on hypoglycaemia prevention
Second trimester
Optimization of glycaemic control
Screening for diabetic complications
Repeat digital retinal assessment at 16 weeks if initial retinal screen was abnormal
Surveillance for medical obstetric complications, including hypertension
Screening for congenital abnormalities, including ultrasonographic examination of the fetal heart at 18–22 weeks
Assessment of fetal growth
Third trimester
Optimization of glycaemic control
Screening for diabetic complications, with repeat digital retinal screening
Assessment of fetal growth and amniotic fluid volume at 28, 32 and 36 weeks' gestation
Timing and mode of delivery to be discussed at 36 weeks' gestation
Document any changes to hypoglycaemic therapy during delivery and post partum, including breastfeeding
Delivery
Protocols for insulin during labour and delivery
Post partum
Adjustment of insulin dosage
Breastfeeding
Discuss contraception

Managing diabetes in pregnancy

First trimester

Referral to a combined multidisciplinary diabetic obstetric antenatal clinic

Pregnancy outcomes are improved when women with diabetes attend a hospital-based multidisciplinary consultant-led diabetic obstetric antenatal clinic working to locally agreed guidelines based on national and international guidelines (Table 9.5). The team comprises an obstetrician, diabetologist, specialist midwife, diabetes specialist nurse and dietitian and all are jointly involved in the care. Rapid access to this clinic is critical to ensure optimization of glycaemic control during the period of fetal organogenesis. Women need to be seen or phoned by the diabetes specialist nurse or midwife on a weekly basis throughout the first trimester, with access to the other members of the team as required.

Dating ultrasound scan

Ideally, a dating scan should be performed within the first 10 weeks of gestation to confirm viability of the pregnancy and to accurately assess gestational age. Relying on ultrasound scanning later in a diabetic pregnancy is less accurate because fetal growth restriction or growth promotion may be present.

Screening for chromosomal anomalies

Chromosomal abnormalities are not increased in women with diabetes. Routine antenatal blood tests plus nuchal translucency ultrasound scan for Down's syndrome between 11 and 14 weeks of pregnancy should be offered as part of routine antenatal care. Calculating the risk of Down's syndrome based on the standard formula of gestational age, mother's age and levels of unconjugated estriol, α-fetoprotein (AFP) and human chorionic gonadotrophin (hCG) is less accurate, as plasma levels of both AFP and unconjugated estriol are lower in diabetic pregnancies.

Summary box 9.5

- Women with pre-existing diabetes should have a dating scan at 6–8 weeks' gestation and ultrasonographic examination of the fetal heart at 18–22 weeks' gestation.
- All pregnant women with diabetes should have ultrasound monitoring of fetal growth and amniotic fluid volume every 4 weeks from 28 to 36 weeks.
- All women with pre-existing diabetes should have digital retinal assessment in the first and third trimesters, with an additional assessment at 16 weeks if the initial screen was abnormal.
- All women with pre-existing diabetes should have blood tests for renal function and urine albumin creatinine ratios in each trimester.

Assessment and optimization of glycaemia

Measurement of HbA_{1c} at booking assesses the risk of major congenital malformations [40,41]. Intensive capillary home blood glucose monitoring (HBGM) needs to be started once pregnancy is confirmed and continued throughout pregnancy. For women already on insulin, a minimum of a fasting value and 1-hour HBGM reading after each meal is required. Recent advances in CGM are increasingly available for clinical use and can provide semi-continuous interstitial fluid glucose measurements; some devices reduce the need for daily HBGM readings. However, the intermittent use of real-time CGM in pregnancy has not yet been shown to improve fetal or maternal outcomes [77,78]. However, the future development of CGM devices that signal wirelessly to insulin pumps to control the insulin infusion hold great promise [55,78].

The goal of glycaemic management is euglycaemia while avoiding hypoglycaemia [16]. NICE guidelines based on current evidence recommend maintaining fasting maternal plasma glucose levels below 5.3 mmol/L and 1-hour postprandial levels below 7.8 mmol/L [26], which has been shown in the first trimester to be associated with a reduced fetal malformation rate [79]. Achieving these targets during the first trimester is particular challenging for women with type 1 DM as insulin requirements actually drop by around 10% from week 7 through to week 15 gestation [80,81]. Even in the presence of nausea, vomiting and a reduced food intake, women with type 1 DM must never stop their insulin.

The majority of women with type 1 DM will already be on a basal bolus insulin regimen consisting of a basal analogue insulin and a rapid-acting analogue insulin with meals or a CSII insulin pump. These women can maintain their pre-pregnancy insulin regimens once pregnant, and adjust as needed. Women with type 2 DM may not be on insulin but will require insulin at some time during their pregnancy. Most women will have become pregnant while on the oral agent metformin and current advice is that this can be continued while other oral agents, especially the newer drugs such as the thiazolidinediones, DPP-IV inhibitors and SGLT2 inhibitors, must be discontinued as no safety data are available for their use in pregnancy. The majority of women on two or more oral hypoglycaemic agents will need to start a basal bolus insulin regimen once pregnancy is confirmed.

Women with a previous history of GDM should be offered the opportunity to start HBGM in the first trimester and to receive dietary and physical activity advice. Should this fail to achieve HBGM targets, then an oral hypoglycaemic agent with or without insulin should be started.

The oral hypoglycaemics metformin and glibenclamide (known as glyburide in the USA) are considered safe and efficacious in pregnancy [26,82,83]. Metformin improves insulin sensitivity, increases peripheral glucose uptake and inhibits hepatic gluconeogenesis. Metformin is generally well tolerated, easy to use, has a low risk of hypoglycaemia and is inexpensive; it also limits maternal weight retention post partum [82]. Although not licensed for pregnancy, experience of its use in treating pregnant women with polycystic ovaries, type 2 DM and GDM is increasing and there is growing evidence for its effectiveness and safety in pregnancy [84]. It forms part of the NICE guidelines for glycaemic control in type 2 DM and GDM [26]. Theoretical concerns about the use of metformin continue because it crosses the placenta, so despite good short-term results long-term follow-up studies are required [85]. Glibenclamide does not currently have UK marketing authorization for use in pregnancy, although it can be used if a women is reluctant to start insulin [26].

All women with type 1 DM should be aware of the risk of DKA and to know how to test for blood ketones and when to seek urgent medical attention if unwell with persistently raised blood ketones [71].

Advice on prevention of hypoglycaemia

Women need to be aware of the risk of hypoglycaemia as they intensify their insulin management. Severe hypoglycaemia is three times as frequent in early pregnancy than prior to pregnancy and is more frequent during the first trimester than during the rest of pregnancy [86–88]. While hypoglycaemia is not harmful to the fetus it can be life-threatening for the woman [81]. During the last 30 years in the UK, the Confidential Enquiry into Maternal Deaths and Morbidity has continued to report hypoglycaemia as a cause of death among type 1 diabetic women. The greatest risk factors for severe hypoglycaemia are previous hypoglycaemia and poor hypoglycaemic awareness [87]. Long duration of type 1 DM, autonomic neuropathy, gastroparesis, renal impairment and sleeping alone are other recognized risk factors. The use of rapid analogue insulin is associated with fewer severe nocturnal hypoglycaemic episodes in pregnancy [89].

Individual advice on meal and snack timing and exercise to minimize hypoglycaemia needs to be given and family members instructed on how and when to administer glucagon. Women should carry identification cards specifying that they are taking insulin and what to do if they become hypoglycaemic. Specific advice on driving should be given, including not to drive if experiencing hypoglycaemic episodes without warning signs.

Second trimester

Optimization of glycaemic control

By the start of the second trimester in non-diabetic pregnancies there is a fall in fasting glucose and a rise in postprandial glucose values. By the middle of the second trimester maternal insulin resistance starts to increase due to high concentrations of circulating maternal fatty acids and placental hormones. Women whose diabetes is well controlled may not need to increase their overall insulin dosage until 20 weeks' gestation when insulin requirements begin to rise and continue to rise throughout the rest of the pregnancy. Insulin requirements are frequently threefold higher by the end of pregnancy than at the start [27,81]. Women need the knowledge and confidence to self-adjust their insulin in response to HBGM. As the basal night-time insulin is increased, it may be necessary to give half this dose in the morning to avoid nocturnal hypoglycaemia.

Women with type 2 DM are usually insulin resistant at the start of pregnancy. By the second trimester, when insulin resistance starts to increase, oral hypoglycaemic agents are usually unable to achieve adequate glycaemic control. By the end of pregnancy, daily insulin doses in women with type 2 DM may exceed 300 units daily. Metformin potentially has the beneficial effect of reducing the total insulin dose required through its effect on hepatic glucose output and on insulin-sensitive tissues.

Screening for congenital abnormalities

A detailed ultrasound scan that includes a four-chamber view of the heart and the ventricular outflow tracts should be offered at 18–20 weeks' gestation to look for major congenital abnormalities.

Surveillance for medical obstetric complications

Women with diabetes have an increased risk of hypertension in pregnancy, including pre-eclampsia. In addition to serial clinic blood pressure measurements and urinalysis for protein, uterine Doppler waveform analysis at 20 weeks may be helpful in identifying those women most at risk.

Assessment of fetal growth

Ultrasound scans for assessment for fetal growth usually start at the end of the second trimester and are repeated every 4 weeks, or more frequently if needed. Baseline measurement of fetal abdominal circumference at 28 weeks expressed as a percentile can be compared with later scans to provide evidence for growth acceleration or restriction. Measurement of liquor volume should also be serially recorded as polyhydramnios is more common in diabetic pregnancies.

Third trimester

Optimization of glycaemic control

During the third trimester maternal insulin resistance continues to increase along with insulin requirements. Glycaemic control tends to become easier as the insulin resistance protects women from severe hypoglycaemic episodes. If insulin requirements begin to fall in the late third trimester, this can be a sign of marked fetal hyperinsulinaemia lowering maternal blood glucose levels secondary to an increased glucose gradient across the placenta [90] or to placental dysfunction [91]. A fall in insulin requirements is potentially a stimulus to consider advancing the timing of birth.

When glucocorticoid steroids are required for lung maturation, insulin requirements over the following 72 hours may double. For example, if two 12-mg beclometasone injections are given at 24-hour intervals, either the insulin dose needs to be proactively increased or the woman admitted and a variable-rate intravenous insulin infusion (previously termed insulin sliding scale) administered over the 72 hours, which can be given in addition to her normal insulin dose.

Assessment of fetal growth

Evidence on serial ultrasound scans of a rising abdominal circumference (AC) percentile in relation to the head circumference or biparietal diameter is indicative of accelerated fetal growth due to fetal hyperinsulinaemia. Excessive fat deposition within the abdomen and enlargement of the liver and heart are a direct result of excess fetal insulin. While the term 'macrosomia' is used clinically and in the literature to describe infants of diabetic mothers, the precise definition of macrosomia remains poorly characterized, with definitions varying from an absolute birthweight of less than 4 kg, 4.5 kg or greater than 5 kg, to a percentile birthweight in excess of 90%, 95% or 97.5%. As birthweight is dependent on gestational age, sex, ethnic origin, parental height and maternal weight, any definition based on absolute weight is best avoided. In clinical practice it is the trend of fetal growth rather than the absolute or percentile birthweight that is important. The influence of maternal obesity alone accounts for the high birthweights of many of the infants of mothers with type 2 DM and GDM [39].

Serial ultrasound can also help identify those women who have an infant with fetal growth restriction or asymmetrical growth restriction (poor increase in AC centile growth compared with head circumference). Such growth patterns are suggestive of uteroplacental insufficiency and may be seen in type 1 diabetic women with renal impairment, vascular disease or hypertension. If detected, early delivery may be necessary.

Timing and mode of delivery

Women with diabetes should be made aware early in pregnancy that it is potentially harmful to the baby for the pregnancy to go beyond term. While women should be encouraged to be actively involved in their birth plans, they need to appreciate that the exact timing and mode of delivery is best deferred to after the 36-week growth scan when a more informed discussion can take place based on maternal and fetal well-being.

The risk of late unexpected stillbirth among women with diabetes is approximately fourfold higher than for the non-diabetic population [2,6,92]. It is for this reason that most authorities advocate delivery between 38 and 39 completed weeks for women on insulin. Induction at 38 weeks' gestation in a nulliparous woman with type 1 DM is often slow and/or unsuccessful. Caesarean section following failed induction is therefore high among these women and this contributes to the greater than 50% caesarean rate among women with type 1 DM [6]. In contrast, women with type 2 DM are more likely to be multiparous and induction of labour before term is more likely to be successful. Women with GDM controlled on metformin or diet alone, with otherwise uncomplicated pregnancies, may be able to go safely to term (40 completed weeks) with the hope of achieving a spontaneous labour.

The risk of birth trauma increases with increasing birthweight. Maternal diabetes mellitus increases the likelihood of shoulder dystocia several fold over that of the non-diabetic population [93]. This is partly explained by the chest-to-head and shoulder-to-head ratios being increased in fetuses of women with diabetes. The risk of shoulder dystocia is approximately 3% for birthweights of 4–4.5 kg, and is 10–14% for birthweights above 4.5 kg. However, a caesarean section policy based purely on estimated birthweight by ultrasound (4000 or 4500 g) would result in an unacceptable caesarean section rate. For the diabetic mother of a large baby detected on ultrasound, planning the delivery needs to be an obstetric decision based on maternal obstetric history, her own size and personal preference [13,93].

Birth

Protocols for insulin during labour and delivery

High maternal glucose levels during labour are associated with neonatal hypoglycaemia [94]. Therefore, the 2015 NICE guidelines recommend monitoring capillary plasma glucose during labour and birth in women with diabetes to ensure that maternal glucose levels are maintained between 4 and 7 mmol/L [26].

As most women with diabetes will be given a date for delivery, be it induction or caesarean section, there needs to be clear written guidelines for both the woman and the labour ward on how insulin requirements are managed during labour. While there is no absolute right or wrong way to give insulin during this period, it is usual hospital policy to start a variable-rate intravenous insulin infusion (VRIII) with 5% dextrose during active labour and during an operative delivery that is carried on into the perioperative period before the mother starts taking meals. During this time, hourly blood glucose monitoring should be performed. Once delivered, for women who were on insulin before pregnancy, the insulin dose must be reduced, as insulin requirements drop to approximately 20–30% below pre-pregnancy values immediately after birth. As most pregnant women prior to delivery are taking a night-time long-acting basal insulin and quick-acting basal insulin with their evening meal, women being admitted for a planned induction should be encouraged to take their normal insulin doses the night before. Once admitted, they should continue with their short-acting bolus insulin to cover meals, only switching to VRIII once in labour or a decision has been

taken to perform a caesarean section. The increased use of insulin pumps and continuous glucose sensors in labour will help to maintain blood glucose levels within target [95].

Most women with GDM, particularly women on diet or metformin alone, will not require intravenous insulin. Insulin-treated women with GDM requiring less than 1.0 unit/kg daily of insulin can usually be monitored without intravenous insulin, with a VRIII commenced only if required [94].

Ideally, elective caesarean section should be planned for early morning, with the woman instructed to take her normal bolus insulin with her evening meal and two-thirds of her usual basal insulin the night before admission. Once on the ward, a VRIII can be started, with the dose reduced straight after delivery.

Postpartum care

Insulin requirements drop immediately to below pre-pregnancy values following delivery of the placenta. Women with type 1 DM can recommence their pre-pregnancy insulin as soon as they are eating and drinking normally, although the dose needs to be decreased by at least 25%. In women who are well controlled prior to pregnancy, the drop in total daily insulin dose after birth may be even greater, with the biggest reduction seen in the bolus insulin [96].

The dose of insulin after birth should be clearly written in the notes as part of the delivery plan. Women with type 2 DM previously on oral agents can restart these following pregnancy if choosing not to breastfeed; if these women were not previously taking these agents, then insulin can be stopped. Insulin is not excreted into breast milk and is considered completely safe for use during breastfeeding. Insulin requirements often fall in mothers with type 1 DM who breastfeed, due to the small increase in metabolic rate that occurs with lactation. The use of metformin by breastfeeding mothers is also considered safe, as very little of the drug is excreted in breast milk [97]. The sulphonylurea oral agents are highly protein bound, and as this binding is non-ionic these agents are unlikely to be displaced by other drugs and to pass into breast milk. Theoretically, oral secretagogue agents could cause neonatal hypoglycaemia, but the evidence for this is poor [97]. Currently, metformin and glibenclamide are the only oral agents endorsed by the 2015 NICE guidelines for glycaemic control while breastfeeding [26].

The postpartum period is also a time when contraceptive advice should be offered.

The management of gestational diabetes

The glycaemic targets set for GDM in pregnancy should be similar to those for all diabetic women, namely a fasting blood glucose below 5.3 mmol/L and a 1-hour postprandial glucose below 7.8 mmol/L [26]. While some women with GDM can be controlled by lifestyle changes to diet and exercise, many require insulin to reach these targets. The exact role of oral hypoglycaemic agents remains controversial in some countries. Although the newer sulphonylurea agents appear safe when given after 15 weeks' gestation [97,98], their use with or without metformin is still felt by many to be less effective and flexible than prescribing insulin. However, in parts of the world where access to insulin is limited, oral hypoglycaemic agents provide a necessary alternative therapeutic option [99,100].

Women identified as having GDM, who do not have previously undiagnosed diabetes, usually revert to having normal glucose tolerance after delivery. However, over the subsequent 20 years the majority will develop type 2 DM [101]. GDM is one of the most predictive factors for the development of type 2 DM later in life. All women with GDM should therefore be offered postnatal assessment for diabetes, with a fasting blood sugar or HbA_{1c} 6 weeks after delivery and repeated yearly thereafter [26].

Lifestyle intervention that minimizes weight gain and encourages physical activity has been shown to reduce the progression rate to diabetes over the subsequent 4–5 years [102,103]. It is therefore important that women who have GDM receive basic lifestyle advice post partum and are informed about the need to be screened annually for diabetes.

Neonatal and longer-term consequences of a diabetic pregnancy

The neonate of the diabetic mother, in addition to the increased risk of congenital abnormalities, is at increased risk of a number of neonatal metabolic conditions (Table 9.3) [104,105]. The commonest of these, neonatal hypoglycaemia, is a consequence of persistent postnatal fetal hyperinsulinaemia when the maternal transfer of glucose has ceased. This and the other neonatal metabolic conditions can be attributed to excess transfer of fetal metabolic substrates from mother to fetus and fetal hyperinsulinaemia and are usually transient. Another common problem is neonatal hypertrophic cardiomyopathy, although this is frequently transient and

asymptomatic but can occasionally lead to severe morbidity and even mortality [105].

Recent studies on children of both type 1 and type 2 diabetic mothers have shown that there is an increased risk of childhood obesity and metabolic disturbances in adolescence, including an increased risk of glucose intolerance [3,15,106]. This risk increases among children of poorly controlled diabetic mothers. As young adults, children of diabetic mothers have an increased risk of type 2 DM. The emergence of diabetes in these children is at an earlier age than that of their mother [37].

The children of women who have had GDM are also at increased long-term risk of developing obesity, type 2 DM and the metabolic syndrome. The association of childhood obesity and gestational diabetes is also seen in the multi-ethnic EPOCH study, where children of mothers with primarily GDM had a higher increase in BMI and growth velocity than unexposed controls, with the increase starting at the age of 10–13 years. Offspring of Caucasian women with GDM have a twofold increased risk of developing obesity and a fourfold increased risk of the metabolic syndrome compared with the background population, suggesting that genetics plays a major role in the development of the metabolic syndrome and obesity together with an effect of intrauterine hyperglycaemia [107].

Animal studies have convincingly shown that intrauterine exposure to maternal diabetes is associated with an increased risk of abnormal glucose tolerance, diabetes and obesity in offspring. Although it is difficult to study the effect of intrauterine hyperglycaemia separately from a genetic effect in humans, there is evidence to suggest an epigenetic mode of diabetes transmission from mother to child due to perinatal programming of the fetus, and further strengthens the need to optimize glycaemic control in all diabetic pregnancies.

Summary box 9.6

- The risk of late unexpected stillbirth among women with diabetes is approximately fourfold higher than for the non-diabetic population.
- Women on insulin should be delivered between 38 and 39 completed weeks.
- Women controlled on metformin or diet alone with otherwise uncomplicated pregnancies may be able to go safely to 40 completed weeks.
- Immediately after delivery, women with pre-gestational diabetes must reduce their insulin dose to 25–30% of their pregnancy dose.
- After birth-, women with GDM will most likely be able to stop the diabetic medications; some women with type 2 DM will be able to stop insulin.
- Metformin, glibenclamide and insulin are safe for women who are breastfeeding.
- Women with GDM require a fasting blood glucose level or HbA_{1c} 6 weeks post partum and then yearly thereafter.

Conclusion

Diabetes in pregnancy is increasing and this requires an increase in awareness of the associated health risks for the mother, the growing fetus and the impact poorly controlled diabetes may have on the future child. This chapter has highlighted the essential aspects of the management of diabetic pregnancies, from before conception to the postpartum period, including screening for gestational diabetes. Integral to this is the use of the consultant-led multidisciplinary team and the implementation of national evidence-based clinical guidelines to optimize glycaemic control and mimimize the risk of maternal diabetic complications.

LIVER DISEASE IN PREGNANCY

Normal physiological changes in pregnancy

In pregnancy, physiological changes occur that mimic the changes seen in decompensated chronic liver disease and cirrhosis. These changes peak in the second trimester. Blood volume increases by 50% yet blood flow to the liver remains constant and typically the liver is not palpable during the pregnancy. Examination changes of telangiectasia, spider angiomas and palmar erythema are normal, and may be confused with the presence of cirrhosis. There is an increased tendency to bile lithogenicity and there is an increased incidence of gallstone formation as a consequence [1,2]. Similarly, the contractility of the gallbladder is reduced. These findings are all related to increasing oestrogen.

In a normal pregnancy, plasma volume results in a fall in many serum markers including albumin levels. Alkaline phosphatase activity increases due to placental secretion. Aminotransferase levels (alanine aminotransferase, ALT, and aspartate aminotransferase, AST), bilirubin and gamma-glutamyl transpeptidase (GGT) all remain normal throughout pregnancy. When abnormalities exist in these parameters, further investigation is warranted. Liver histology typically is normal.

Table 10.1 summarizes the laboratory changes occurring in pregnancy.

Investigation of liver disease in pregnancy

Imaging of the liver is a frequent requirement. Ultrasound is the safest modality but should further imaging be required, magnetic resonance imaging (MRI) without contrast is safe. Gadolinium-enhanced MRI should be avoided unless essential due to transplacental transfer and the unknown effects on the fetus, although increasing evidence suggests that in the third trimester it is possible to do this safely. Computed tomography (CT) and endoscopic retrograde cholangiopancreatography (ERCP) can also be used during pregnancy. However, precautions should be taken to shield the fetus from radiation or to provide dosimetry estimates if significant exposure is likely.

Approach to the patient with suspected liver disease in pregnancy

The presence of liver enlargement is always an abnormal finding in pregnancy, and hepatomegaly if identified may signify an infiltrative process ranging from acute fatty liver of pregnancy in the correct context to viral hepatitis, or even an infiltrative process such as lymphoma or cancer. Since pregnancy itself is a procoagulant state, consideration also needs to be given to outflow obstruction of the hepatic veins in the form of Budd–Chiari syndrome. Jaundice and scleral icterus are abnormal findings and always warrant further evaluation.

It is very rare that a liver biopsy is actually needed in the management of patients with liver disease in pregnancy. It is unusual for a liver biopsy to influence the timing or decision to proceed with delivery. However, liver biopsy can be undertaken if clinically indicated.

Pregnancy-related liver disease

The typical biochemical features of pregnancy-specific liver diseases are summarized in Table 10.2.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 10.1 Liver function test results in normal pregnancy.

Test	Not pregnant	First trimester	Second trimester	Third trimester
AST (IU/L)	7–40	10–28	11–29	11–30
ALT (IU/L)	0–40	6–32	6–32	6–32
Bilirubin (μmol/L)	0–17	4–16	3–13	3–14
GGT (IU/L)	11–50	5–37	5–43	5–41
Alkaline phosphatase (IU/L)	30–130	32–100	43–135	130–418
Bile acids (μmol/L)	0–9	0–9	0–9	0–9

ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, gamma-glutamyl transpeptidase.
Source: adapted from Girling *et al.* [1] and Walker *et al.* [19].

Table 10.2 Characteristic timings and diagnostic laboratory features in the liver diseases unique to pregnancy.

Disease	Trimester	Diagnostics
Hyperemesis gravidarum	1, 2	↑ Bilirubin (×5) ↑ ALT/AST (×2–4)
Intrahepatic cholestasis of pregnancy	2, 3	↑ ALT/AST (×6) ↑ Bile acids
Pre-eclampsia	2, 3	↑ Bilirubin (×2–5) ↑ ALT/AST (×10–50) ↑ Platelets
HELLP syndrome	2, 3	↑ ALT/AST (×10–20) ↑ LDH ↑ Platelets ↑ Urate
Acute fatty liver of pregnancy	2, 3	↑ Bilirubin (×5–10) ↑ ALT/AST (×5–10), rarely >20×

HELLP, haemolysis, elevated liver enzymes and low platelets; ALT, alanine aminotransferase; AST, aspartate aminotransferase; LDH, lactate dehydrogenase.

Hyperemesis gravidarum

Nausea and vomiting are common in pregnancy. However, exact estimates vary in relation to the prevalence of hyperemesis gravidarum (HG). Reports range from 0.3 to 2% of all pregnancies, typically within the first trimester [3,4]. Under-reporting of symptoms may in fact account for the variation in incidence in the literature.

One of the most frequently used definitions of HG is intractable vomiting, resulting in ketosis, dehydration and weight loss of 5% or greater of body weight. The aetiology remains unclear but a combination of abnormal gastric motility, hormonal factors and changes in the autonomic nervous system are all thought to play a key role. Risk factors include increased body mass index (BMI), psychiatric illness, molar pregnancy, pre-existing diabetes and multiple pregnancies whilst hyperthyroidism is identified in an estimated 60% of cases [5–8]. Higher serum concentrations of human chorionic gonadotrophin (hCG) may stimulate the thyroid in pregnancy, accounting for this finding [8].

Clinical features, diagnosis and management

HG typically occurs from the fourth week of gestation, resolving by week 18. Although AST and ALT may be elevated by as much as 20 times the upper limit of normal, this is rare, as is jaundice. Dehydration can contribute to raised serum urea and creatinine levels, and there may be associated hypophosphataemia, hypomagnesaemia and hypokalaemia. Abnormalities in biochemistry typically resolve on resolution of vomiting. Failure to resolve abnormalities in liver biochemistry should alert the physician to alternative diagnoses such as viral hepatitis. Liver biopsy is not indicated, but if performed shows non-specific changes. Persistence of symptoms beyond 18 weeks should warrant consideration of a gastroscopy to exclude mechanical obstruction.

Management

Overall management of HG is supportive and includes intravenous rehydration, antiemetics and gradual reintroduction of oral intake. Vitamin supplementation, especially thiamine, is mandatory to prevent Wernicke's encephalopathy. Most patients will require 5–8 days of hospital admission, but relapse is common. Recurrence in subsequent pregnancies is also common. Attention should be given to the development of refeeding syndrome for patients that have a protracted clinical course.

Overlap syndromes with liver dysfunction

Pre-eclampsia, HELLP (haemolysis, elevated liver enzymes, and low platelets) syndrome, acute fatty liver of pregnancy (AFLP), and liver rupture are separate but similar conditions that usually occur during the third trimester and after delivery. Often associated with hypertension, elevated liver enzymes are common. Low platelets may occur irrespective of the presentation and these conditions typically recover following delivery. In

some situations, progressive disease may occur with multisystem organ failure and in the extreme maternal death. HELLP syndrome is most often considered a variant of severe pre-eclampsia since hypertension and proteinuria are generally accompanying features. To complicate matters, there may also be overlap clinically and biochemically between AFLP and pre-eclampsia, and up to 50% of patients with AFLP will have pre-eclampsia [9,10]. It is essential for the clinician to recognize and differentiate the overlap syndromes from unrelated conditions which do not improve after delivery. For severe cases, a multidisciplinary team approach is warranted.

Fatty acid oxidation pathways

Disorders of fatty acid oxidation play a key role in the aetiology of AFLP, HELLP syndrome and pre-eclampsia. In the presence of oxygen, fatty acids are metabolized to carbon dioxide and water, and approximately 40% of the free energy produced in this process is conserved as adenosine triphosphate (ATP), whereas the remainder is released as heat within the mitochondrion.

An enzyme that plays a central role in this pathway is long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD) [11,12]. It is part of an enzyme complex that constitutes the mitochondrial trifunctional protein (MTP), located on the inner mitochondrial membrane. In LCHAD deficiency, there is accumulation of long-chain hydroxyl-acylcarnitines, free plasma hydroxyl-long-chain fatty acids, and dicarboxylic acids, which results in cell toxicity. Defects in the trifunctional protein are inherited as autosomal recessive conditions and cause non-ketotic hypoglycaemia and hepatic encephalopathy in early infancy that may progress to coma and death if untreated [12]. They can also cause cardiomyopathy, peripheral neuropathy, myopathy and sudden death, although the latter clinical features are not characteristically seen in isolated LCHAD deficiency [12]. It is important to diagnose MTP disorders because the clinical complications can be avoided with dietary manipulation.

An increased prevalence of AFLP, HELLP syndrome and severe pre-eclampsia has been identified among heterozygous mothers of children who are homozygous for LCHAD deficiency [11–13]. A subsequent study of 27 pregnancies complicated by AFLP demonstrated that five women had fetuses with MTP mutations and that at least one copy of the common E474Q mutation was present in each case [14]. The study authors recommended that the neonates of women whose pregnancies are complicated by AFLP should be screened for MTP disorders or for the E474Q mutation. Routine screening of offspring of women whose pregnancies are complicated by HELLP syndrome is not recommended since MTP disorders are not common in the fetuses [14–16].

Outwith mitochondrial β-oxidation defects, other defects such as short-chain and medium-chain defects have been described in AFLP; in a series of 50 infants whose mothers had severe liver disease, long-chain defects were 50 times more likely than in controls and defects in short-chain and medium-chain pathways were 12 times more likely to be present [17].

Acute fatty liver of pregnancy

AFLP is a rare, potentially life-threatening, pregnancy-related disease that affects 1 in 7000 to 1 in 16 000 pregnancies [18]. It is more likely to occur in a first pregnancy, multiple pregnancies, and pregnancies carrying a male fetus [18,19]. In two case series of 32 and 16 affected women admitted to tertiary centres, the maternal mortality rate was 12.5% [9]. Perinatal mortality rates are reported as approximately 10% in the latest series, [9,10,20], although other series report higher mortality possibly related to premature delivery [17].

Pathogenesis

The pathogenesis of AFLP is not completely understood. It is clear that fatty acid oxidation disorders contribute to approximately 20% of cases of AFLP [14]. In these cases, it is likely that the heterozygous mother has a reduced hepatic ability to metabolize long-chain fatty acids. Although there is sufficient capacity in the non-pregnant state, when a heterozygous woman becomes pregnant, her liver is required to metabolize fatty acids from the placenta as well as her own circulation. Accumulation of fatty acids and the increased metabolite load likely results in hepatotoxicity. This may be further compounded by the alterations in lipid metabolism that occur in normal pregnancy.

Diagnosis

AFLP typically manifests in the third trimester with symptoms of nausea and anorexia. Other later symptoms include vomiting and abdominal pain whereas polydipsia and polyuria may also occur. Liver function tests should be requested for any pregnant woman reporting these symptoms because rapid diagnosis of an acute fatty liver allows stabilization of the patient and rapid delivery.

It is often difficult to differentiate AFLP from HELLP syndrome. Patients with AFLP more commonly have high levels of bilirubin, creatinine, uric acid and neutrophils; a prolonged prothrombin time (PT); acidosis; and hypoglycaemia. Patients frequently exhibit disseminated intravascular coagulation. Although levels of liver transaminases can be markedly increased, this can be variable. Moreover, the level of ALT or AST does not reflect disease severity since hepatocytes cannot release transaminases if they have already been destroyed by severe injury. Diagnostic criteria for AFLP have been created and are summarized in Table 10.3.

Table 10.3 Swansea criteria for the diagnosis of acute fatty liver of pregnancy.

Six or more criteria required in the absence of another cause:
• Vomiting
• Abdominal pain
• Polydipsia/polyuria
• Encephalopathy
• Elevated bilirubin >14 μmol/L
• Hypoglycaemia <4 mmol/L
• Elevated urea >340 μmol/L
• Leucocytosis $>11 \times 10^9$/L
• Ascites or bright liver on ultrasound scan
• Elevated transaminases (AST or ALT) >42 IU/L
• Elevated ammonia >47 μmol/L
• Renal impairment; creatinine >150 μmol/L
• Coagulopathy; prothrombin time >14 s or APPT >34 s
• Microvesicular steatosis on liver biopsy

ALT, alanine aminotransferase; AST, aspartate aminotransferase; APTT activated partial thromboplastin time.
Source: adapted from Ch'ng *et al.* [21].

Imaging modalities that have been used to diagnose AFLP include liver ultrasound, MRI and CT. Liver biopsy may be used to obtain a definitive diagnosis using an oil red stain, although delivery should not be delayed to facilitate biopsy. It is also pertinent to consider alternative diagnoses even in patients with suspected AFLP. In a series of 32 patients, six had an additional diagnosis, two patients having malignancy, one alcohol-induced fatty liver, another veno-occlusive disease with antiphospholipid syndrome, and another acute viral hepatitis A infection [9]. Poisoning with acetaminophen can produce a clinical presentation that is hard to distinguish from AFLP and should always be considered in the context of an AST or ALT level above 1000 IU/L.

Management

Women with AFLP should be managed by a multidisciplinary team that includes obstetricians, hepatologists, anaesthetists, obstetric physicians, neonatologists and intensivists. In severe disease, the mother should be cared for in an intensive care unit (ITU). Biochemical and haematological monitoring is critical. It is essential to monitor the international normalized ratio (INR) or PT and other markers of coagulopathy. Similarly, plasma glucose levels, platelets, creatinine, liver function test results, and arterial blood gases including lactate are appropriate. Fresh-frozen plasma should be given as required. Women often require large amounts of glucose intravenously to correct hypoglycaemia. If multisystem failure develops, it may be necessary to use dialysis and support with mechanical ventilation. *N*-Acetylcysteine is often used by liver units to treat AFLP, and we advocate its use.

Patients with AFLP should be assessed regularly for encephalopathy. It is advisable to consult with a liver unit specialist at the time of presentation of patients who have severe AFLP, hypoglycaemia and/or encephalopathy for advice on detailed management of fulminant liver failure and because assessment of suitability for liver transplantation may be necessary. In a study of 56 admissions to a liver failure unit in the UK, the presence of encephalopathy in conjunction with the presence of an elevated blood lactate level was highly associated with a poor prognosis and a need for liver transplantation [20]. The most important management strategy is delivery of the infant. The decision about the mode of delivery is often complex because the mother is likely to have a coagulopathy. Although vaginal delivery reduces the risk of haemorrhage, induction of labour often takes longer and prompt delivery can improve the maternal outcome. Regional anaesthesia should be avoided or used with caution and in conjunction with close monitoring. Blood tests should be performed frequently to ensure that coagulopathy is rapidly corrected in the days after delivery.

Prevention

AFLP does not commonly recur in subsequent pregnancies, although there are recurrent cases reported in the literature. In women who are heterozygous for disorders of fatty acid oxidation, it may be possible to establish whether the fetus is affected, and this can indicate the magnitude of the mother's risk. Mothers who deliver an affected fetus have a greater chance of recurrence. For heterozygous mothers who do not have affected fetuses and for others who do not have a fatty acid oxidation disorder, the recurrence risk is lower. However, the disease has potentially disastrous consequences, and women who have had one affected pregnancy should be managed in an obstetric clinic specializing in high-risk pregnancies.

Pre-eclampsia and HELLP syndrome

Liver involvement often occurs in the context of severe pre-eclampsia. Although severe hypertension may be absent in women with HELLP syndrome, in most instances there is some degree of accompanying hypertension that helps to differentiate this disorder from other diseases. Similarly, as discussed earlier, there may be overlap between HELLP syndrome and AFLP yet isolated serum AST/ALT elevations in severe pre-eclampsia rarely exceed 500 IU/L. Bilirubin levels rise in women with the HELLP syndrome, partly as a consequence of liver damage and partly in response to haemolysis, but bilirubin levels are usually higher in AFLP [14].

Table 10.4 Classification systems used in HELLP syndrome.

Tennessee System	
AST >70 IU/L	
LDH >600 IU/L	
Platelets $<100 \times 10^9$/L	
All three components: complete	
One or two components: partial	
Mississippi System	
Class I: Platelets $<50 \times 10^9$/L	and AST >40 IU/L and LDH >600 IU/L
Class II: Platelets $50–100 \times 10^9$/L	
Class III: Platelets $100–150 \times 10^9$/L	

AST, aspartate aminotransferase; LDH, lactate dehydrogenase.

Hepatic failure with encephalopathy and coagulopathy are uncommon in pre-eclampsia and should prompt consideration of a different diagnosis, including fatty liver and other causes of hepatic dysfunction. Table 10.4 summarizes classification systems for HELLP syndrome.

Hepatic involvement occurs in approximately 10% of women with severe pre-eclampsia [22]. The presence of right upper quadrant pain usually signifies liver involvement. Increased AST/ALT levels may occur several hours after the onset of pain and, where performed, liver biopsy shows periportal haemorrhage, sinusoidal fibrin deposition and cellular necrosis [23]. However, in practice, liver biopsy is rarely warranted.

Women with pre-eclampsia and liver involvement should usually undergo prompt delivery, with steroids administered as protocol to promote fetal lung maturity. Laboratory values improve within 1 week of delivery, but may persist for weeks. Because HELLP syndrome may develop during the postpartum period in 20% of cases, liver function testing and imaging should be undertaken if abdominal pain, thrombocytopenia or other clinical features suggesting pre-eclampsia occur after delivery.

Liver rupture and infarction

Epidemiology

Rupture of the liver during pregnancy is a rare but often catastrophic event, with substantial risk for fetal and maternal death [20,24]. The majority of cases during pregnancy occur with pre-eclampsia or HELLP syndrome [25]. Liver rupture occurs in only a small proportion of women with pre-eclampsia, 4 of 442 (<1%) in one series [26]. Hepatic haematoma and rupture may rarely also occur after uncomplicated pregnancy, in association with biliary disease, infection, aneurysm and hepatic neoplasm [26–29].

Pathogenesis and clinical features

Although the pathogenesis of hepatic rupture remains unclear, subcapsular haemorrhage is a common finding at post-mortem in cases of pre-eclampsia. Hypertension may not be present, and the presence of severe right upper quadrant pain and hypotension should trigger thoughts on this outcome. Other symptoms include nausea, vomiting, shoulder pain and headache. Haemoperitoneum produces peritoneal signs and hypovolaemic shock.

Diagnosis

Diagnostic imaging is required to establish a diagnosis [30]. CT or MRI is the preferred technique for visualizing liver haematomas. Paracentesis and the finding of blood may occasionally be helpful. Laboratory evaluation of women with subcapsular haematoma or rupture reveals thrombocytopenia, hypofibrinogenaemia or INR/PT. Anaemia and haemolysis are typically present, and levels of bilirubin, lactate dehydrogenase and liver transaminases are elevated. The differential diagnosis for unruptured liver haematoma includes AFLP, placental abruption with coagulopathy, thrombotic thrombocytopenic purpura, and cholangitis with sepsis.

Management

An intact haematoma without rupture may be managed conservatively, particularly if the patient is haemodynamically stable [30]. Patients should be managed in ITU, with serial imaging studies to define the extent of the subcapsular haemorrhage, its progression and whether leaking has occurred. Management options for hepatic rupture include embolization of the hepatic artery, hepatic resection, hepatic artery ligation, and exploration with digital compression of the hepatic artery and portal vein to temporarily arrest the haemorrhage (i.e. Pringle manoeuvre). Surgical exploration and evacuation of haematoma and temporary packing of the liver is often appropriate. Fluid replacement, multiple transfusions and correction of coagulopathy are necessary components in conjunction with an attempt to control the hepatic bleeding. In a patient who is relatively stable, angiography may be attempted while making preparations for potential laparotomy. Mortality rates approach 50% in cases of liver rupture. In a series of seven cases, the four survivors were managed with packing and drainage [24]. The three women undergoing hepatic lobectomy did not survive. In another series of 10 patients, nine were treated surgically with a combination of stitching of the lesion, omental patching, hepatic artery embolization, and ligation. The tenth patient was dead on arrival at hospital. Five patients were treated with hepatic artery ligation and all survived [31]. Evaluation of the literature suggests that patients who receive arterial embolization, whether performed with or without a laparotomy, have a better prognosis than patients managed by other strategies in isolation.

Death is often caused by massive blood loss and coagulopathy. Patients who survive commonly experience

respiratory insufficiency from adult respiratory distress syndrome or pulmonary oedema and acute liver failure. Hospital stay is significantly prolonged [22].

Liver infarction

Infarction involving many areas of liver parenchyma may be a feature of severe pre-eclampsia or HELLP syndrome [32]. Presenting signs usually include abdominal pain and fever. CT demonstrates clearly demarcated areas of poor vascularization involving many liver segments. Histological evaluation of these areas demonstrates haemorrhage and leucocyte infiltration in areas adjacent to haemorrhage. In the setting of HELLP syndrome, many adjacent areas of periportal haemorrhage most likely form these infarcted segments. Improvement after delivery can be expected, even in the face of laboratory evidence of severe liver inflammation.

Intrahepatic cholestasis of pregnancy

Intrahepatic cholestasis of pregnancy (ICP), also called obstetric cholestasis, is the commonest liver-specific disorder in pregnancy [33]. It affects approximately 1 in 140 women in the UK, but there is geographical variability in prevalence, with higher rates in women from South America, particularly Chile, and Asia. The condition is more rarely seen in women of African/Caribbean origin.

Pathogenesis

The aetiology of ICP has a genetic component, with a 17-fold increase of developing the disease in parous first-degree relatives. Mutations have been identified in biliary transporters, most commonly in ABCB11/BSEP and ABCB4/MDR3, which transport bile acids and phosphatidylcholine from the hepatocyte into bile, respectively [34]. There is evidence that raised reproductive hormones in pregnancy impact the normal pathways of bile acid homeostasis resulting in the development of cholestasis, and this is likely to be more severe in genetically predisposed women.

Diagnosis

The commonest presenting symptom of ICP is pruritus. This has varying severity but can be sufficiently severe to result in marked excoriations (Fig. 10.1) and sleep deprivation. Most women develop pruritus in the third trimester, but ICP can present as early as 8 weeks' gestation. Women commonly also complain of dark urine and approximately 25% have pale stools secondary to steatorrhoea. If ICP is suspected, the liver function tests and serum bile acids should be checked. The condition is characterized by raised serum bile acids, and most women also have elevated liver transaminases. Approximately 10% have raised bilirubin concentrations, consistent with jaundice being a relatively rare symptom. Those with severe disease may have abnormal coagulation with a prolonged PT.

Fig. 10.1 Typical appearance of excoriations on skin in a woman with severe pruritus in ICP. Reproduced with permission of ICP Support.

The largest population studies in ICP, one in Sweden [35] and one in the UK [36], both demonstrated increased risk of adverse pregnancy outcomes in pregnancies in which the maternal serum bile acid concentration is 40 μmol/L or greater. The risk of spontaneous and preterm labour, stillbirth, meconium-stained amniotic fluid and prolonged admission to the neonatal unit were increased in these pregnancies. Both studies also demonstrated that the risk of an adverse outcome was greater as the maternal serum bile acid concentration became higher. Although liver transaminases were also raised in most cases, there was a less clear-cut relationship with adverse outcome compared with bile acids. The rise in serum bile acids can occur several weeks after onset of symptoms, and therefore it is advisable to continue to measure the serum bile acids weekly in women with ICP, including after making the diagnosis as otherwise severe cases (bile acids ≥40 μmol/L) may be missed.

ICP is a diagnosis of exclusion, and therefore other hepatic disorders must be discounted. Women should have blood tests to exclude hepatitis C and autoimmune hepatitis and an ultrasound scan to ensure they do not have gallstones.

Management

The drug with the best evidence to support its use is ursodeoxycholic acid (UDCA). Most studies demonstrate that UDCA treatment improves maternal pruritus and improves biochemical derangements [37]. There are currently no completed trials to establish whether UDCA treatment can reduce the frequency of adverse pregnancy outcome in ICP, although one meta-analysis [38] and a pilot trial of UDCA versus placebo [39] suggested that some adverse outcomes may be less frequent in ICP pregnancies in which the mother was treated. Specifically, the meta-analysis combined the data from eight trials of UDCA versus another treatment (placebo or another drug, e.g. cholestyramine, dexamethasone or *S*-adenosyl-methionine), and included data from 207 UDCA-treated and 70 placebo-treated ICP cases. This study reported reduced rates of all preterm labour (including iatrogenic), fetal distress and duration of admission to the neonatal unit [38]. The UDCA versus placebo pilot trial, although underpowered to investigate an effect on pregnancy outcome, did show reduced rates of meconium-stained liquor and a trend for reduction in neonatal unit admission and preterm labour in UDCA-treated women [39]. A large randomized controlled trial is currently underway with the aim of establishing whether UDCA treatment reduces adverse pregnancy outcome in ICP.

As most stillbirths have been shown to occur at later gestational weeks, it has been proposed that induction of labour at 37–38 weeks' gestation may reduce the risk of fetal death. There are no prospective studies to support or refute this practice. Several studies have recently evaluated the merits of elective delivery with the aim of reducing the risk of stillbirth in ICP, and all concluded that elective delivery at 36 weeks' gestation is associated with reduced risk. Specifically, a retrospective cohort study of 1 604 386 singleton pregnancies in California between 34 and 36 weeks' gestation with and without ICP demonstrated an increased risk of stillbirth in ICP at each gestational age from 34 weeks after adjusting for race, maternal age, hypertension, diabetes mellitus, parity and limited perinatal care [40]. This study also reported that the risk of mortality associated with delivery is lower than the risk of expectant management from 36 weeks' gestation. This was supported by retrospective reports of pregnancy outcomes in centres adopting a strategy of delivery at 36 or 37 weeks [41,42], and by the findings of a team that used a decision-analytic model to compare different decision strategies, which concluded that the optimal strategy for ICP pregnancies is immediate delivery at 36 weeks, without fetal lung maturity testing or steroid administration [43].

The pruritus and hepatic impairment usually resolve within a small number of weeks after delivery. Women should be advised that ICP has a high recurrence risk in subsequent pregnancies and they are at increased risk of hepatobiliary disease in later life, in particular gallstones. They should also be aware that they have an increased risk of cholestasis if they take the combined oral contraceptive pill. However, progesterone-containing contraception can be used.

Liver diseases incidental to pregnancy

Viral hepatitis in pregnancy

Viral hepatitis is the commonest cause of jaundice in pregnancy worldwide. Presentation, clinical features and general outcome for hepatitis A virus, hepatitis B virus (HBV), hepatitis C virus (HCV), cytomegalovirus or Epstein–Barr virus infection in pregnancy is similar to that in the non-pregnant state [44].

Hepatitis B virus

HBV can present in an acute or chronic form. For patients with acute hepatitis B, transmission of the virus to the child occurs in 50% of cases, with 70% of children infected if acute HBV infection occurs in the third trimester. For patients with chronic HBV, transmission of virus is dependent on the degree of viral replication and the quantity of HBV DNA detectable in the serum of the mother. Transmission rates above 90% have been reported from mothers who are HBV DNA positive and these are typically hepatitis B E antigen positive (HBeAg+).

Vaccination programmes throughout Southeast Asia and in the developed world have reduced transmission rates dramatically. Following vertical transmission, up to 80% of children become chronic carriers. Two strategies exist to reduce transmission rates. Firstly, the use of antiviral therapy such as tenofovir disoproxil fumarate (245 mg daily) that decreases HBV DNA level in the third trimester for appropriate patients reduces viral load and vertical transmission. Secondly, the use of hepatitis B immunoglobulin with hepatitis B vaccination in the neonate within 7 days of birth and at 1, 2 and 12 months of age also reduces the transmission rate significantly.

Hepatitis C virus

Chronic HCV infection in chronic carriers occurs in 8% of cases. Vertical transmission is highest in those patients with higher viral loads. Mother-to-child transmission of HCV has become the leading cause of paediatric infection, at an approximate rate of 5%, with maternal HIV co-infection a significant risk factor for mother-to-child transmission. However, anti-HIV therapy during pregnancy can reduce the transmission rate of both viruses. A high maternal viral load is an important but unpreventable risk factor since no anti-HCV treatment can currently be administered in pregnancy. With obstetric

procedures such as amniocentesis or internal fetal monitoring that could expose the fetus to maternal blood, caution should be undertaken, although evidence is lacking on the real risk of single obstetric practices. Mode of delivery and type of feeding do not represent significant risk factors for mother-to-child transmission. Therefore, there is no reason to offer elective caesarean section or discourage breastfeeding in HCV-infected patients. Antibody conversion of infants following transmission may take 6–12 months, although measurement of HCV RNA levels will allow for early diagnosis.

Hepatitis E virus

Hepatitis E virus is problematic in pregnancy, typically occurring in epidemic form in Southeast Asia, the Indian subcontinent and the Middle East. The development of acute liver failure in the second and third trimester can be associated with a mortality of up to 20%.

Pregnancy in patients with cirrhosis

Many patients with chronic liver disease and cirrhosis are infertile. However, patients with autoimmune liver diseases such as autoimmune hepatitis, primary sclerosing cholangitis and primary biliary cirrhosis may become pregnant. Patients with autoimmune hepatitis should be maintained on baseline immunosuppression throughout pregnancy (azathioprine with or without prednisolone). For patients treated with mycophenolate mofetil before pregnancy, they should be converted to an alternative immunosuppressant such as azathioprine, tacrolimus or cyclosporin prior to planned pregnancy. A 20–25% risk of flare in autoimmune hepatitis occurs following delivery in the first 3 months post partum, and this is reduced if immunosuppressive treatment is maintained.

Since varices develop even in normal pregnancy as a consequence of changes in cardiac output, azygos blood flow, increased circulating blood volume and changes in splanchnic haemodynamics, an increased risk of variceal bleeding in cirrhotic patients can be anticipated. Patients with established cirrhosis should be screened for varices in the second trimester. This is to facilitate and guide appropriate peripartum care. The presence of small varices in otherwise well-compensated cirrhotic patients should not preclude a vaginal delivery. However, close monitoring in pregnancy is warranted.

For patients with non-cirrhotic portal hypertension, a bleeding rate in pregnancy of 13% has been reported. In cirrhotic patients contemplating pregnancy, pre-pregnancy screening and appropriate treatment of large varices should be undertaken. Propranolol is not contraindicated in pregnancy and episodes of variceal bleeding should be treated with normal endoscopic approaches including endoscopic band ligation or histoacryl glue, whereas transjugular intrahepatic shunts should be reserved for rescue therapy and field endoscopic treatment. There are limited safety data for vasoconstrictors such as terlipressin, but they may be used in women with life-threatening haemorrhage in pregnancy.

Pregnancy following liver transplantation

Successful pregnancy following liver transplantation has been widely reported and fertility will return typically within 6 months of transplant. Best outcomes are reported for pregnancies undertaken more than 1 year after the transplant operation since it reduces the risk of acute cellular rejection and other infective complications. Tacrolimus, cyclosporin, azathioprine and corticosteroid therapy are widely and safely used in pregnancy. Specific complications in pregnancy related to a higher prevalence of hypertension/pre-eclampsia and preterm delivery have been reported. Patients on mycophenolate should be converted to an alternative immunosuppressant prior to pursuing pregnancy.

Summary box 10.1

- Tests of liver function should be evaluated using normal ranges for pregnancy.
- Women with hyperemesis gravidarum should be treated with thiamine, and thromboprophylaxis should be considered in addition to correction of electrolyte disturbance and use of antiemetics with good safety data.
- It is advisable to discuss patients who have severe AFLP, hypoglycaemia and/or encephalopathy with a liver unit specialist at the time of presentation.
- In AFLP and HELLP syndrome the presence of encephalopathy in conjunction with an elevated blood lactate level is associated with a poor prognosis and a need for liver transplantation.
- Women with ICP with serum bile acids ≥40 µmol/L have an increased risk of adverse pregnancy outcome, including spontaneous preterm labour, stillbirth and prolonged neonatal unit admission.
- Women with cirrhosis should be screened for varices in the second trimester.
- Variceal bleeding should be treated with normal endoscopic approaches including endoscopic band ligation and histoacryl glue. Beta-blockers are not contraindicated, and terlipressin can be used in women with life-threatening haemorrhage in pregnancy, although there are more limited safety data.
- Pregnancy should be deferred for 1 year after liver transplantation, and women who have had a transplant and are planning pregnancy should be advised to change mycophenolate to an alternative immunosuppressant.

ENDOCRINE DISORDERS IN PREGNANCY

Thyroid disease

The normal ranges for thyroid function tests alter in pregnancy, in part related to elevation in hCG – and associated stimulation of the thyroid-stimulating hormone (TSH) receptor causing a transient increase in thyroxine and suppression of TSH in the first trimester – and also haemodilution in the second and third trimesters. Thyroid-binding globulin increases in pregnancy, likely secondary to elevated oestrogen levels, and therefore free thyroxine measurement should be used. The normal ranges of thyroid function tests in each trimester of pregnancy are summarized in Table 10.5.

Autoimmune hypothyroidism

Autoimmune hypothyroidism affects 1% of pregnancies. While well-controlled patients have good pregnancy outcomes, overt hypothyroidism is associated with increased risks of adverse pregnancy outcome, including miscarriage, pre-eclampsia, placental abruption and low birthweight [48], in addition to having an adverse impact on the subsequent intelligence of the baby [49]. Therefore it is important to ensure that affected women are adequately treated. However, it should be borne in mind that over-treatment is associated with iatrogenic maternal hyperthyroidism, and this should be avoided as well [50]. The impact of subclinical hypothyroidism on subsequent intelligence of the fetus is not clearly established, and a recent well-powered UK study that evaluated the impact of thyroxine replacement from the end of the first trimester for subclinical hypothyroidism did not show any difference in subsequent intelligence of the offspring at 3 years of age, nor was there any impact on birthweight or the rate of preterm birth [51]. Therefore, it is clearly important to ensure that women with hypothyroidism receive treatment with thyroxine to maintain their thyroid function tests in the normal range for pregnancy, but there is no evidence for treatment of women with normal thyroid function tests.

Table 10.5 Normal ranges for thyroid function tests in pregnancy.

Normal range*	FT4 (pmol/L)	TSH (mU/L)
Non-pregnant	11–23	0–4
First trimester	11–22	0–1.6
Second trimester	9–19	0.1–1.2
Third trimester	7–15	0.7–5.5

*Normal ranges may vary according to ethnic group.
Source: based on data from Parker [45], Chan & Swaminathan [46], Soldin *et al.* [47].

Management

As the thyroid-binding globulin concentration is elevated, some women will need an increase in thyroxine dose. However, it is not necessary to increase the dose in all women and this should be guided by testing the thyroid function tests before pregnancy and in each trimester. A study that addressed the need for increased dose of thyroxine in 100 pregnancies in women with autoimmune hypothyroidism found that 50% of women needed more thyroxine, but in the majority of cases this was due to inadequate replacement prior to pregnancy, poor compliance, or recent diagnosis with insufficient time to optimize treatment, rather than a consequence of a gestation-specific need for an increased dose [41]. The thyroxine dose should be adjusted in those that are deficient using normal ranges for pregnancy.

Occasionally a woman will present in early pregnancy with overt hypothyroidism and elevated TSH above the normal range for pregnancy. The principal concern in this group is whether the hypothyroidism will impact the subsequent intelligence of the child. Unfortunately, there are limited research data about this but it is likely that the impact will be minimal if thyroxine replacement is optimized in the second and third trimesters.

There is evidence that pregnant women positive for thyroid autoantibodies are more likely to have miscarriage and preterm delivery [52]. This may be partly due to coexisting autoimmune disorders, such as antiphospholipid syndrome.

Hyperthyroidism

Hyperthyroidism affects 1 in 800 pregnancies, and the majority of cases have Graves' disease. This may also be secondary to toxic nodule, thyroid adenoma, carcinoma or subacute thyroiditis. The presenting symptoms of hyperthyroidism include palpitations, heat intolerance and palmar erythema, all of which can also be seen in normal pregnancy. However, eye signs and pre-tibial myxoedema are specific to autoimmune thyroid disease and weight loss does not occur in normal pregnancy.

Management

There is some debate about the best drug to treat hyperthyroidism in pregnancy. Carbimazole and propylthiouracil are used to treat hyperthyroidism. Both drugs are associated with an approximately doubled risk of congenital abnormalities [53,54] and these have been more consistently reported in women treated with carbimazole. Propylthiouracil is known to be occasionally complicated by fulminant hepatic failure in 1 in 10 000 adults and 1 in 2000 children and therefore is not recommended as first-line therapy. However, the American

Thyroid Association has recommended that it could be preferable to carbimazole in pregnant women given that there are more data to suggest that carbimazole is teratogenic. However, it should be noted that propylthiouracil can also cause congenital abnormalities [53,54]. Therefore, a sensible management approach is to continue carbimazole in women who are already taking it prior to conception, while either carbimazole or propylthiouracil can be used for newly diagnosed cases in the first trimester of pregnancy, with appropriate advice about the risk of congenital malformations. Given that carbimazole is the preferred treatment outside pregnancy, this is important to consider and often will be the most sensible choice. It is important to ensure that women with hyperthyroidism are adequately treated, as untreated thyrotoxicosis is associated with increased risk of fetal loss, growth restriction and preterm labour while severe cases may develop the life-threatening complication of thyroid storm. As with other autoimmune conditions, many women with hyperthyroidism improve during pregnancy and in some the dose of antithyroid drugs may be reduced or even stopped. However, the requirement for treatment usually returns post partum.

Women with autoimmune thyroid disease should have TSH receptor antibodies checked as they can cross the placenta and stimulate the fetal thyroid. The impact of this often depends on whether the mother is taking antithyroid drugs. If she is, the drugs will also cross the placenta, so the maternal antibodies are unlikely to cause problems until after delivery, but there is a risk of neonatal thyrotoxicosis 2–4 days post partum. This is because the drugs will be cleared from the neonatal circulation rapidly, but the maternal antibodies will remain for approximately 3 months. As a consequence it is important to involve neonatologists in early fetal assessment. In contrast, if a woman is not taking antithyroid drugs, for example because she has previously had surgery or radioiodine treatment, her pregnancy should be closely monitored for fetal hyperthyroidism or goitre because TSH receptor antibodies can cross the placenta and there will be no antithyroid drugs to prevent fetal disease.

Carbimazole and propylthiouracil can be given to lactating women. There are no concerns about transfer to the baby with low, maintenance doses of either drug, but if high doses are used the baby's thyroid function should be monitored.

Pituitary disease

Pituitary tumours are often diagnosed in women of reproductive age as they cause menstrual irregularity. The commonest is prolactinoma, subdivided into microprolactinoma (<10 mm diameter) and macroprolactinoma (≥10 mm diameter). Both are treated with dopamine agonists, and this typically results in a return to normal menstruation and fertility. While microprolactinomas rarely undergo enlargement in pregnancy, symptomatic enlargement occurs in approximately 15% of women with macroprolactinoma [55]. Therefore, this latter group of women should have formal visual tests performed each trimester. Many clinicians also continue dopamine agonist treatment in women with macroprolactinomas. The next most common pituitary tumour that is identified in pregnant women is non-functioning tumour. These tumours can result in symptomatic visual impairment, likely secondary to gestational enlargement of surrounding pituitary tissue. Cushing's disease, acromegaly and TSH-oma are very rare and commonly result in visual impairment or cause symptoms secondary to hormone excess. Treatment should be coordinated in collaboration with an endocrinologist. Women with pituitary tumours may develop pituitary apoplexy. This medical emergency presents with visual impairment, headache and neurological defects.

Women with hypopituitarism who receive adequate hormone replacement can become pregnant. It is important to ensure that women who are deficient in glucocorticoids receive an increased dose at times of stress, when vomiting or at the time of delivery. Lymphocytic hypophysitis is an autoimmune disorder that can present with features of hypopituitarism and more commonly occurs in pregnancy. It responds to treatment with glucocorticoids or immunosuppression, but often recurs after treatment is stopped. It may resolve spontaneously. It is important to ensure that women with lymphocytic hypophysitis are not incorrectly diagnosed as having a pituitary tumour as surgery will make them worse. Diabetes insipidus secondary to vasopressin deficiency often requires additional treatment in pregnancy, likely a consequence of placental secretion of vasopressinase. If affected women increase the dose of desmopressin during pregnancy this should be reduced to the pre-pregnancy dose immediately after delivery.

Adrenal disease

Adrenal insufficiency affects approximately 1 in 3000 pregnant women. In developed countries this is most commonly caused by autoimmune destruction of the adrenal glands, a condition described as Addison's disease. Most women with adrenal insufficiency will have presented prior to pregnancy. Typical presenting symptoms are non-specific and include fatigue, hypotension, nausea, vomiting, weakness and hyperpigmentation. Affected women frequently also have hyponatraemia. Many of

these clinical features are reported in normal pregnancy, so *de novo* diagnosis can be difficult but is essential. Women with a prior diagnosis of adrenal insufficiency who are taking glucocorticoid replacement usually have good pregnancy outcomes providing they are able to continue adequate treatment doses. This can be a challenge if they develop hyperemesis gravidarum, and it may necessitate parenteral or intramuscular administration of glucocorticoids. Women will require an increased replacement dose of glucocorticoids to cover intercurrent illnesses and they should be given an increased dose to cover the stress of labour.

Adrenal tumours are very rare in pregnancy, but should be considered in women with atypical or severe hypertension [56]. Phaeochromocytoma can cause paroxysmal severe hypertension. Urinary or plasma catecholamines can be used for diagnosis. Management should involve a multidisciplinary team, and alpha-blockade should be started prior to beta-blockade. Other hormone-secreting tumours are primary hyperaldosteronism and adrenal Cushing's syndrome. Both cause severe hypertension. Primary hyperaldosteronism can also cause hypokalaemia and affected women often need potassium replacement as well as treatment with antihypertensive drugs. Surgical removal is the treatment of choice for Cushing's syndrome caused by an adrenal tumour. For the other hormone-secreting adrenal tumours in pregnancy, surgery may be performed in pregnancy or post partum, providing the disease is controlled with appropriate medical therapy.

Parathyroid disease

Hyperparathyroidism is usually caused by a parathyroid adenoma, but it may occur in women with parathyroid hyperplasia or carcinoma. Women develop hypercalcaemia, but this is usually less severe than in non-pregnant individuals due to reduced circulating albumin concentrations and transplacental transfer of calcium to the fetus. The mother may develop hypertension and nephrolithiasis, and treatment should be given if the corrected calcium concentration is persistently raised despite high fluid intake. Surgical assessment should be given as many women are cured by removal of the tumour. However, it is important to establish the location of the tumour as some women have mediastinal tumours that necessitate a much more complex surgical approach, and in these cases it may be more appropriate to defer surgery until after delivery. The concerns with medical management are intractable hypercalcaemia or increased risk of stillbirth [57]. This is thought to be due to fetal hypercalcaemia, as is the increased risk of neonatal tetany.

Summary box 10.2

- In women with autoimmune hypothyroidism, replacement doses of thyroxine should be monitored with the use of normal pregnancy reference ranges with the aim of staying within the normal range.
- Transplacental transfer should be considered in women with elevated titres of TSH receptor antibodies:
  - Women with previous radioiodine treatment or thyroid surgery for autoimmune hyperthyroidism are at risk of fetal hyperthyroidism, and their fetuses should be assessed for the presence of goitre or growth restriction.
  - Those treated with antithyroid drugs have babies at risk of neonatal hyperthyroidism and should have neonatology review.
- In women with macroprolactinoma (tumour diameter ≥10 mm), there is a 15% chance of symptomatic enlargement and visual fields should be assessed with perimetry.
- Pituitary apoplexy can occur in a small proportion of women with pituitary tumours in pregnancy and should be managed as a medical emergency.
- Women with adrenal insufficiency are at risk of life-threatening glucocorticoid deficiency if they develop hyperemesis gravidarum, and will also require increased doses of glucocorticoids to cover the stress of labour and delivery.
- Women with hyperparathyroidism in pregnancy often have less marked hypercalcaemia, in part due to enhanced transplacental transfer. Surgery should be considered as fetal hypercalcaemia may result in stillbirth.

Conclusion

Liver and endocrine diseases can cause serious maternal and fetal morbidity and mortality. With a multidisciplinary approach the pregnancy outcome for mother and child can be improved. If a woman has a known pre-existing disease, it is important to give informed pre-pregnancy counselling. Once women with potentially life-threatening hepatic or endocrine disorders of pregnancy are identified, they should be referred for review by physicians with training and experience in the management of these diseases in pregnancy.

Renal Disease

Liz Lightstone

Centre for Inflammatory Disease, Department of Medicine, Imperial College London, London, UK

Providing care for women with underlying renal disease contemplating pregnancy or those already pregnant requires that the obstetrician has up-to-date knowledge about pregnancy physiology, antenatal care and the technology for fetal surveillance. It is essential to appreciate the need for multidisciplinary teamwork in a centre with all the necessary facilities for dealing with high-risk patients and their babies. It is estimated that chronic kidney disease (CKD) affects up to 6% of women of childbearing age in high-income counties, and has been estimated to affect 3% of pregnant women. This chapter focuses on CKD, women on dialysis and kidney transplant recipients, aiming to provide the busy clinician with information for counselling and judicious decision-making.

Summary box 11.1

- All women of childbearing age with CKD, including those on dialysis and kidney transplant recipients, should be made aware of the implications regarding reproductive health, contraception, modification of remedial risk factors and optimization of medications.
- Active preparation for pregnancy should be individualized to each woman's needs and should involve her partner.
- Multidiscplinary clinics are needed for the pre-pregnancy assessment and antenatal care of these women.

Pre-pregnancy assessment

The basic components should be analysis of risks as well as provision of health education and advice plus any interventions that might be considered helpful, all united under the banner of that much-used word 'counselling' [1]. The multidisciplinary team has to decide what is important so that active preparation for pregnancy is tailored to each woman's needs, with her being encouraged to involve her partner so that all the implications can be discussed, including potential areas of disagreement, even whether infertility treatment, if needed, would be made available.

What the woman wants to know

All healthcare professionals looking after women of childbearing age with kidney disease need to raise the issue of her plans, or not, for pregnancy. It may not be apparent to the woman that her kidney disease poses any issues for her or a baby. Once prompted, aside from what the team wants to discuss and achieve for the woman and her partner, she herself usually has four straightforward questions.

1) Should I get pregnant and when is the best time for me to get pregnant?
2) Will my pregnancy be complicated?
3) Will I have a live and healthy baby?
4) Will I have problems after my pregnancy?

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Most women focus on the third question but it is essential to ensure that all relevant information and even harsh realities are passed on, based on fact not anecdote.

What the patient needs to understand

She must understand the risks and the need to improve her own knowledge, so that she can best use the guidance and support to make any necessary changes in her behaviour, attitude and medication(s). However, knowledge, and even understanding, of the risks may not be sufficient to ensure the patient makes the changes because many other factors influence her behaviour. Even when there is an element of self-management (perhaps best exemplified with dialysis and/or diabetes) this will also be affected by the woman's repertoire of beliefs, skills, intuition and motivation and not just her so-called knowledge, however gained. The key is a strong, unwaivering, positive and supportive relationship with the team that allows pre-pregnancy advice to be included in the overall care agenda as a goal-orientated process. Thus a planned pregnancy is one that is desired well before conception, occurs when contraception is discontinued and where the woman attempts to achieve optimal health beforehand.

Even if some of the answers are not favourable, a woman, being an autonomous adult, may still choose to plan for (or proceed with) a pregnancy in an effort to re-establish a normal life in the face of chronic illness [2]. Indeed some women may not seek advice until already pregnant. Occasionally, there may be ethical dilemmas regarding the clinician's duty of care for women who ignore advice; interestingly, there are studies that have differentiated 'healthy' and 'pathological' levels of assumed risk and which have tried to understand the psychology of women who pursue parenthood despite big risks to their own health and the unborn child [3].

Normal pregnancy

The renal tract undergoes marked anatomical, haemodynamic, tubular and endocrine changes as part of the systemic upheaval of maternal adaptation to pregnancy [4,5]. The kidneys enlarge because both vascular volume and interstitial space increase but there is no accelerated renal growth nor morphological alterations akin to compensatory renal hypertrophy. The calyces, renal pelves and ureters dilate markedly, invariably more prominent on the right side, seen in 90% of women.

Glomerular filtration rate (GFR), measured as 24-hour creatinine clearance (C_{cr}), increases by 6–8 weeks' gestation. Serum creatinine (S_{cr}) and serum urea (S_{urea}), which average 70 μmol/L and 5 mmol/L respectively in non-pregnant women, decrease to mean values of 50 μmol/L and 3 mmol/L during pregnancy. Values for S_{cr} of 80 μmol/L and S_{urea} of 6 mmol/L, which are acceptable in the non-pregnant state, are suspect in pregnancy. At term, a 15–20% decrement in C_{cr} occurs, which affects S_{cr} minimally.

The 24-hour urinary total protein excretion (TPE) increases in normal pregnancy, and up to 300 mg per 24 hours can be regarded as normal [6]. So-called significant proteinuria (TPE >300 mg per 24 hours) may correlate with a protein concentration of 30 mg/dL in a 'spot' urine sample. Timed urine collections are no longer required since proteinuria can be reliably monitored with the use of 'spot' urine protein/creatinine ratios that equal 30 mg/μmol or more.

Chronic kidney disease

Renal impairment and the prospects for pregnancy and afterwards

A woman may lose up to 50% of her renal function and still maintain S_{cr} below 125 μmol/L because of hyperfiltration by the remaining nephrons; however, if renal function is more severely compromised, then further small decreases in GFR will cause S_{cr} to increase markedly [4,7–9]. In women with CKD, whilst the pathology may be both biochemically and clinically silent, the internal milieu may already be disrupted. Most individuals remain symptom-free until GFR declines to less than 25% of normal, and many serum constituents are frequently normal until a late stage of disease. However, degrees of functional impairment that do not appear to disrupt homeostasis in non-pregnant individuals can jeopardize pregnancy.

Assessment of renal impairment and its implications for CKD in pregnancy

Estimated GFR

Because a normal creatinine does not necessarily reflect normal kidney function, for the past few years it has become accepted practice to classify renal function in non-pregnant patients using estimated GFR (eGFR; units, mL/min per 1.73 m^2) calculated from a formula based on S_{cr} adjusted for age, gender and race (Black African descent or not). The so-called Modified Diet in Renal Disease (MDRD) formula was developed in the USA in a multiethnic population of women and men with moderate renal impairment and, most importantly, an eGFR below 60 mL/min per 1.73 m^2. The classification recognizes five stages of CKD (Table 11.1). In non-pregnant populations, eGFR is much less reliable in patients

Table 11.1 Stages of CKD classified according to the US National Kidney Foundation.

Stage		eGFR (mL/min per 1.73 m^2)
1	Kidney damage (structural or proteinuria) with normal or even increased GFR	≥90
2	Kidney damage (structural or proteinuria) with mild GFR decrease	60–89
3	Moderate GFR decrease	30–59
4	Severely low GFR	15–29
5	Kidney failure	<15 or dialysis

eGFR, estimated glomerular filtration rate.

with CKD stages 1 and 2 because of the poor correlation with actual GFR when it exceeds 60 mL/min [10]. In fact over 95% of women with underlying CKD becoming pregnant do have an actual GFR of 60 mL/min or more.

Unlike many prediction formulas, the MDRD equation is not individualized for body surface area and is therefore theoretically attractive for use in the obstetric population in whom increased surface area is not a reflection of increased muscle mass and therefore of increased S_{cr}. However, reports to date have not borne this out and during pregnancy the MDRD fomula substantially underestimates GFR compared with the gold standard of inulin clearance [15,16]. An important clinical concern deriving from the fact that eGFR tends to underestimate true GFR is that its use might signal to the clinician an exaggerated deterioration in GFR, perhaps promoting unnecessary delivery. Therefore, the use of the MDRD equation during pregnancy to estimate GFR in women who have known renal impairment prior to conception or who develop renal complications during pregnancy cannot be recommended. The same applies for the CKD-Epi formula [17]. In addition, the Cockroft–Gault formula, and many others, are inaccurate in pregnancy and there is disagreement about using cystatin C to monitor renal function [18]. However, in prospective studies of women with known renal function prior to pregnancy, outcomes are now being related to pre-pregnancy CKD stages based on eGFR rather than serum creatinine.

eGFR versus S_{cr}

It might seem that a system based on GFR would be superior to one based on S_{cr} and perhaps the database in the literature should be converted to this new CKD classification [13]. We would argue almost certainly not, as the great majority of pregnant women are those with mild disease (CKD stages 1 and 2) and, as mentioned already, the formulas for eGFR in women whose values are anticipated to be above 60 mL/min in the non-pregnant state are unreliable, though better with use of CKD-Epi. Furthermore, the traditional system has been easy to disseminate and is familiar to non-nephrology specialists. Whilst defending the use of S_{cr} it must nevertheless be mentioned that very small women may present with normal or mildly elevated S_{cr}, and clinicians should be suspicious of abnormal function if they see a pregnant woman with a serum creatinine greater than 80 µmol/L.

Summary box 11.2

- If pre-pregnancy renal function is normal or only mildly decreased (S_{cr} ≤125 µmol/L) and hypertension minimal and/or well controlled, then obstetric outcome is usually successful.
- There is an increased risk of antenatal complications such as pre-eclampsia, fetal growth restriction and preterm delivery.
- Offer low-dose aspirin as prophylaxis against pre-eclampsia, starting within first trimester.
- During pregnancy target blood pressure should be <140/90 mmHg, and in women with proteinuric renal disease ideally <130/80 mmHg but not less than 110/60 mmHg [19,20].
- Greater degrees of renal dysfunction (S_{cr} >125 µmol/L, and certainly >180 µmol/L) and/or the presence of poorly controlled hypertension are more ominous, at least for maternal outcome, especially long-term renal prognosis.
- The use of eGFR from the MDRD or CKD-Epi formula is not recommended for use in pregnancy.

The basic question for a woman with CKD must be: is pregnancy advisable? The timing of the pregnancy depends on whether the CKD is caused by relapsing remitting disease such as systemic lupus erythematosus (SLE) or is progressive and function likely to decline over time, for example adult polycystic kidney disease (APKD). In the latter scenario, it is clear that if all else is stable, then sooner is better as with time function will only worsen and risks increase. If the former, then disease should be inactive for several months prior to trying to conceive as active disease is associated with worse outcomes. Many women still present pregnant without prior counselling and then the question must be whether pregnancy should continue (Table 11.2).

Obstetric and long-term renal prognoses differ in women with different levels of dysfunction (for recent reviews of

pregnancy and CKD, see Hladunewich *et al.* [21] and Webster *et al.* [22]). Counselling is based on three functional parameters: the degree of renal insufficiency (Table 11.3), the presence or absence of hypertension and the underlying kidney disease. Until recently, all the data on outcomes of pregnancy in women with CKD were based on retrospective data, which traditionally and arbitrarily classified renal insufficiency solely by pre-pregnancy S_{cr}: 125 μmol/L or less as descriptive of 'mild' insufficiency, 125–250 μmol/L as 'moderate' insufficiency, and above these levels as severe insufficiency [23]. Their use has been the mainstay of pre-pregnancy counselling for over 25 years, consistently showing that normotensive women with intact or only mildly decreased but stable renal function generally do very well, experiencing more than 95% live births, about 75% of which are appropriate for gestational age. These excellent statistics also reflect a literature that has shown constantly improving perinatal outcomes from the 1980s onwards, indicative of the marked advances in both antenatal and neonatal care [24–31]. With mild insufficiency there is an increased incidence of superimposed pre-eclampsia or late pregnancy hypertension, as well as increased proteinuria, exceeding the nephrotic range (3 g per 24 hours) in 50% of women in the second half of pregnancy. Pregnancy does not appear to adversely affect the course of the CKD. However, there are exceptions to this optimistic outlook [31,32]. Indeed, the earliest prospective study of women with baseline CKD stages 3–5 covering 23 years assessed the rate of decline of maternal renal function during pregnancy in 49 white non-diabetic women with CKD stages 3–5 before pregnancy (eGFR <60 mL/min per 1.73 m^2 pre-pregnancy) to average 39 months after delivery [14]. This multicentre Italian network effort confirmed earlier observations that such women have complicated pregnancies with poor perinatal outcomes as well as an accelerated decline in renal function [33]. The main conclusion was encouraging because while the group as a whole lost function during pregnancy, the rate of loss was not affected by pregnancy. Also, 95% of the fetuses survived, albeit many were born preterm and/or growth restricted. The best outcomes were to women whose pre-pregnancy eGFR was between 60 and 40 mL/min per 1.73 m^2, corresponding to S_{cr} values between 125 and 141–150 μmol/L or proteinuria less than 1 g/day. On the other hand, women with eGFR below 40 mL/min per 1.73 m^2 and proteinuria above 1 g/day had poorer outcomes, the combination resulting in worse outcomes than either factor alone. Although these women developed renal failure faster than other groups, it was not possible to determine if pregnancy was a causal factor.

Recently however, prospective data from the TOCOS study [35] have suggested even women with CKD stage 1 (eGFR >90 mL/min and S_{cr} probably much lower than 125 μmol/L) without baseline hypertension, proteinuria above 1 g/day, or systemic disease before pregnancy had an increased risk of a combined adverse outcome (preterm, neonatal intensive care or small for gestational age) (odds ratio, OR 1.88; CI 1.27–2.79) versus women with no CKD. Additionally, the risks for preterm delivery rose further for women with CKD stage 1 associated with baseline hypertension (OR 3.42)/proteinuria (OR 3.69)/systemic disease (OR 3.13). Thus, all women with CKD should be considered high risk and be assessed for risk of adverse pregnancy outcomes.

Prognosis is poorer when there are greater degrees of renal dysfunction (reviewed in Hladunewich *et al.* [21]

Table 11.2 Pre-pregnancy considerations in chronic kidney disease.

Renal pathology under consideration
Good general health
Review and optimize pre-pregnancy drug therapy
Diastolic blood pressure ≤80 mmHg or well-controlled hypertension with 'safe' medication(s)
S_{cr} ideally <125 μmol/L, at least ≤180 μmol/L, and very concerning from 180 to ≤250 μmol/L
No or minimal proteinuria
'Well-controlled' comorbidities (e.g. diabetes mellitus, infections)
Relevance of obstetric history

Table 11.3 Pre-pregnancy kidney function (S_{cr}) in CKD patients with estimates for obstetric outcome and renal functional loss.

Renal status Dysfunction	S_{cr} (μmol/L)	Problems in pregnancy (%)	Successful obstetric outcome (%)	Permanent loss of kidney function* (>25% increment in S_{cr}*) (%)	ESRF within 1 year post partum (%)
Mild	≤125	26	96	<2	
Moderate	≥125	42	95	15	1
Severe	≥180	80	74	52	38

Estimates are based on a 26-year literature review of pregnancies (1984–2010) which attained at least 24 weeks' gestation. ESRF, end-stage renal failure.

*Compared with pre pregnancy serum creatinine.

Source: Lindheimer & Davison [34].

and Webster *et al.* [22]). With moderate impairment, live births still approach 90%, but the incidence of pre-eclampsia, fetal growth restriction and/or preterm delivery exceeds 50%. With severe dysfunction, outlook is more drastically curtailed. Although there is a paucity of data for analysis in both these categories, what has become obvious is that a cut-off S_{cr} of 250 μmol/L is too high for moderate impairment, with 180 μmol/L more appropriate, and thus there is a tendency to designate these patient groups 'moderate to severe' (Tables 11.3 and 11.4). This literature is slowly increasing and the message could not be clearer: hypertension is common by term (60%) as is significant proteinuria (50%) as well as deterioration in renal function (at times rapid and substantial) and although infant survival rates are good (80–90%), rates of premature delivery (60%) and fetal growth restriction (40%) underscore the very high potential for obstetric complications in these women [36–39]. Not previously so obvious are the facts that 30–50% of women with moderate insufficiency experience functional loss more rapidly than would be expected from the natural course of their renal disease and that poorly controlled hypertension might be a harbinger of poor outcome [40–43]. Once S_{cr} rises above 250 μmol/L there are even bigger risks of accelerated loss of renal function, and even terminating the pregnancy may not reverse the decline (Table 11.3).

Temporary dialysis

Temporary or acute dialysis has been advocated during pregnancy in the face of overall deterioration in renal function (especially when S_{urea} exceeds 20 mmol/L and/or there is refractory hyperkalaemia), severe metabolic acidosis, pulmonary oedema responding poorly to diuretics, and danger of volume overload with heart failure [5,31,39,44]. Dialysis may increase the chance of successful outcome by 'buying time' for fetal maturation but it does not arrest the inexorable decline in renal function, ultimately to end-stage failure. In trying to avoid extreme prematurity in this way, it has to be asked whether such life-threatening effects on the mother's renal prognosis can be justified. Nevertheless, the awareness by some women of progress in antenatal care and neonatal provision encourages them to anticipate good outcomes and they will say that they are prepared to take a chance and even seek assisted conception in the face of their infertility. Of importance in all the current controversies is that the literature that forms the basis of our views is primarily retrospective, with most patients only having mild dysfunction and women with severe to moderate disease being limited in number. Confirmation of guidelines and prognoses therefore requires adequate prospective trials. The prospective TOCOS study only had 10 women with advanced CKD (pre-pregnancy eGFR <30 mL/min per 1.73 m^2); however, 90% of these had adverse pregnancy outcomes and 80% had severe adverse outcomes [35]. Additionally, 20% progressed to a worse stage of kidney function at the end of pregnancy.

Antenatal strategy and decision-making

These women ideally will have had pre-pregnancy counselling to ensure optimal timing, that disease is quiescent, medications and blood pressure control optimized and that they understand the risks of pregnancy. Once pregnant, they must be seen as early as possible. Thereafter assessments should usually be performed at least every 4 weeks until 28 weeks' gestation and then every 1–2 weeks depending on the clinical circumstances [8,45].

1) Assessment of renal function by serum creatinine and by protein excretion (see Chapter 7) by a spot protein/creatinine ratio ideally on a first morning void.

Table 11.4 Pre-pregnancy kidney function (S_{cr}) in CKD patients with estimates for obstetric complications and outcome and renal functional loss.

					Loss of >25% renal function		
S_{cr} (μmol/U)	Fetal growth restriction (%)	Preterm delivery (%)	Pre-eclampsia (%)	Perinatal deaths (%)	Pregnancy (%)	Persists post partum (%)	End-stage failure in 1 year (%)
≤125	25	30	22	1	2	–	–
125–180	45	70	40	6	40	20	3
≥180	70	>90	60	12	70	55	35

Estimates are based on literature from 1985 to 2009, with all pregnancies attaining at least 24 weeks' gestation (Davison & Winfield, unpublished data). Modified and supplemented from Williams & Davison [8].

Note that from more recent analyses of women with severe CKD it is now apparent that an S_{cr} cut-off of 250 μmol/L is too high a level for 'moderate' renal impairment, a cut-off of 180 μmol/L now being recommended [1,13].

2) Careful blood pressure monitoring for early detection of hypertension (and assessment of its severity) and pre-eclampsia, with most women being offered low-dose aspirin in early pregnancy (before 12 weeks) to reduce the risk of pre-eclampsia.
3) Early detection and treatment of anaemia, usually by oral/intravenous iron therapy. Blood transfusion should be avoided as much as possible due to the risk of sensitizing a woman who may subsequently need a renal transplant. If anaemia is persistent and resistant to iron, recombinant human erythropoietin can be used but may exacerbate hypertension.
4) Early detection of covert bacteriuria or confirmation of urinary tract infection (UTI) and prompt treatment; if there are recurrent UTIs, then antibiotic prophylaxis should be given throughout pregnancy.
5) Many women with significant renal disease will have proteinuria; this may well increase due to cessation of renin–angiotensin blockers before or definitely during the first trimester. Proteinuria increases the risk of thrombosis and in the face of significant proteinuria (usually in the region of 2–3 g per 24 hours) and especially if serum albumin is low for pregnancy, women should be offered prophylactic low-molecular-weight heparin. Bear in mind that the dose should be reduced if S_{cr} is above 120 μmol/L or the patient weighs less than 50 kg.
6) Biophysical/ultrasound surveillance of fetal size, development and well-being.
7) The clinician must bear in mind the balance between maternal prognosis and fetal prognosis: the effect of pregnancy on a particular disease and the effect of that disease on pregnancy. The clinical watchpoints associated with specific renal diseases are summarized in Table 11.5.

Impact of underlying renal disease

Women with certain types of CKD face particularly increased risks with pregnancy, including those with lupus and especially those with prior lupus nephritis. In addition, women with scleroderma and classical periarteritis nodosa do poorly (particularly when there is marked renal involvement and associated hypertension and/or pulmonary hypertension) and thus should be counselled to avoid pregnancy. Furthermore, there is some disagreement about whether pregnancy adversely influences the natural history of IgA nephropathy, focal segmental glomerulosclerosis and reflux nephropathy. It seems likely that prognosis with these renal lesions is actually similar to that of women with mild impairment in general, provided pre-pregnancy function is preserved and high blood pressure absent (Table 11.5).

Reflux nephropathy often presents for the first time during pregnancy as women have recurrent UTIs and hypertension. Ultrasound may reveal scarred kidneys, hydronephrosis and function may or may not be normal. It is important to make the diagnosis not just to ensure optimal care of the woman during pregnancy but so that her baby will be appropriately screened in the first year of life – there is a strong genetic influence on the presence of reflux and early diagnosis may prevent renal scars [46].

Because SLE most commonly affects women of childbearing age and since about 60% of people with SLE will develop lupus nephritis, this is one of the commoner forms of renal disease seen in pregnant women. Recent data from a prospective cohort of 385 women with well-controlled SLE (with or without prior lupus nephritis, proteinuria <1 g/day, creatinine <106 μmol/L and taking less than 20 mg oral prednisolone at baseline) showed, in the absence of baseline hypertension or a lupus anticoagulant, that 81% of the women had successful pregnancies and flares were infrequent [47]. Moroni *et al.* [48] reported recently on 71 pregnancies in 61 Italian women all of whom had prior or active lupus nephritis and had undergone pre-pregnancy counselling. The majority (78.9%) were in complete remission and the rest had mild active lupus nephritis. Flares were seen in 19.7% of women and all responded to treatment. Pre-eclampsia was seen in 8.4% (a figure very consistent with the Mayo group systematic review published in 2010 [49]) and HELLP syndrome (haemolysis, elevated liver enzymes, low platelets) in 2.8%; both pre-eclampsia and HELLP were predicted by prior lupus nephritis, longer disease duration and baseline hypertension. Fetal loss occurred in 8.4%, preterm delivery in 28.2%, and 16.4% of babies were small for gestational age (SGA). Importantly, the use of the antimalarial hydroxychloroquine appeared to significantly reduce the probability of having an SGA baby [50]. In addition, it is known from other studies that hydroxychloroquine almost certainly reduces the risk of congenital heart block and neonatal lupus in babies born to mothers with anti-Ro antibodies. The following recommendations apply to all CKD patients.

Renal function

If renal function deteriorates significantly at any stage of pregnancy, then reversible causes, such as UTI, volume depletion or electrolyte imbalance (occasionally precipitated by inadvertent diuretic therapy), should be sought. Near term, as in normal pregnancy, a decrease in function of 15–20%, which affects S_{cr} minimally, is permissible. Failure to detect a reversible cause of a significant decrement may be an indication for early delivery. However, this will depend on the underlying renal disease, whether progression of renal impairment was expected and whether dialysis during pregnancy is an option. When proteinuria occurs and persists, but blood

Table 11.5 Chronic renal disease and pregnancy.

Renal disease	Clinical watchpoints
Chronic glomerulonephritis and focal segmental glomerular sclerosis (FSGS)	In the absence of hypertension and abnormal renal function, most of these women will have normal pregnancies though probably have a higher risk of late hypertension and pre-eclampsia. In the presence of hypertension and/or renal impairment, there may be accelerated loss of renal function possibly due to podocyte stress during pregnancy
IgA nephropathy	Some cite risks of sudden escalating or uncontrolled hypertension and renal deterioration. Most note good outcome when renal function is preserved
Chronic pyelonephritis (infectious tubulointerstitial disease)	Bacteriuria in pregnancy, recurrent urinary tract infections (often requiring prophylactic antibiotics) and frequent hypertension
Reflux nephropathy	Some have emphasized risks of sudden escalating hypertension and worsening of renal function. Consensus now is that results are satisfactory when pre-pregnancy function is only mildly affected and hypertension is absent. Vigilance for urinary tract infections is necessary
Urolithiasis	Ureteral dilatation and stasis do not seem to affect natural history, but infections can be more frequent. Stents have been successfully placed and sonograpically controlled ureterostomy has been performed during gestation
Polycystic kidney disease	Outcomes largely predicted by baseline function and hypertension. Women should be advised to have their pregnancies before they have lost function
Diabetic nephropathy	Proteinuria is likely to increase significantly during pregnancy and if nephropathy is advanced, salt and water retention may predominate. Most women with diabetes do not have overt nephropathy during their childbearing years; however, this is becoming more common as women have children later in life and the rates of type 2 diabetes in younger women increase. Increased frequency of infections, oedema or pre-eclampsia
Human immunodeficiency virus with associated nephropathy (HIVAN)	Renal component can be nephrotic syndrome or severe impairment. Need to ensure anti-retroviral treatment is optimised pre-pregnancy
Systemic lupus erythematosus	Prognosis is most favourable if disease is in remission 6 months before conception, the woman does not have lupus anticoagulant, and if non-white does not have hypertension at baseline. If the mother has anti-Ro antibodies she should be offered fetal echocardiography at 18/40 to look for early signs of congenital heart block
Systemic vasculitis (granulomatous or microscopic polyangiitis)	If in remission will have little impact on pregnancy. However, flares can occur and if severe may mandate early termination of pregnancy to allow adequate treatment of aggressive renal disease. Rare
Scleroderma	If onset during pregnancy, there can be rapid overall deterioration. Reactivation of quiescent scleroderma can occur during pregnancy and after delivery
Previous urologic surgery	Depending on original reason for surgery, there may be other malformations of the urogenital tract. Urinary tract infection is common during pregnancy and renal function may undergo reversible decrease. No significant obstructive problem, but caesarean section might be necessary for abnormal presentation or to avoid disruption of the continence mechanism if artificial sphincters or neourethras are present
After nephrectomy, solitary and pelvic kidneys	Pregnancy is well tolerated. Might be associated with other malformations of the urogenital tract. Dystocia rarely occurs with a pelvic kidney

pressure is normal and renal function preserved, pregnancy can be allowed to continue under closer scrutiny. With nephrotic-range proteinuria, prophylactic low-molecular-weight heparin is needed and should be continued for 6 weeks after delivery. The use of acute dialysis has been mentioned earlier.

Blood pressure

The conventional dividing line for obstetric hypertension has been 140/90 mmHg. Most of the specific risks of hypertension in pregnancy appear to be related to superimposed pre-eclampsia (see Chapter 7). There is confusion about the true incidence of superimposed pre-eclampsia in women with CKD. This is because the diagnosis cannot be made with certainty on clinical grounds alone: hypertension and proteinuria may be manifestations of the underlying CKD, and chronic hypertension alone has an increased pre-eclampsia risk fourfold that of normotensive pregnant women. Treatment of mild hypertension (diastolic blood pressure <95 mmHg in

the second trimester or <100 mmHg in the third) was not previously necessarily considered mandatory during normal pregnancy, but many would treat women with CKD more aggressively, believing that this preserves kidney function. The CHIPS study brought the obstetric community into closer alignment with the renal community by demonstrating fewer episodes of severe hypertension in the women assigned to the 'tight' control group (achieved blood pressure 133/85 mmHg). In non-pregnant women with renal disease, particularly those with proteinuric renal disease, the target blood pressure would be less than 130/80 mmHg so this would seem to be a reasonable target now in pregnant women [19].

Medications such as methyldopa, calcium channel blockers, labetalol and hydralazine are safe in pregnancy. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers should not be prescribed and even if patients were taking either of these in early pregnancy (to continue the so-called renal protection from before pregnancy), they should not be continued or recommended beyond the early first trimester. We advise patients with minimal proteinuria to switch from ACE inhibitors or angiotensin receptor blockers before pregnancy. In those women with heavy proteinuria and progressive renal decline, the benefit of continued renal protection probably outweighs the low risk of early first trimester exposure. In those women we advise cessation as soon as pregnant in order to avoid months pre-pregnancy with no renal protection. Recent data suggest that the excess congenital abnormalities attributed to ACE inhibitors may in fact all be explained by hypertension rather than the medication [51]. ACE inhibitors and angiotensin receptor blockers are contraindicated (except in the rare instance of a woman having scleroderma) beyond the first trimester because of the risk of a fetopathy.

Fetal surveillance and timing of delivery

Serial evaluation of fetal well-being, with regular assessment of fetal growth, amniotic fluid and Doppler, is essential. In the absence of fetal or maternal deterioration delivery should be at or near term. If complications do arise, the judicious moment for intervention might be determined by fetal status (see Chapter 28). Regardless of gestational age, most babies weighing more than 1500 g survive better in a special care nursery than a hostile intrauterine environment. Planned preterm delivery may be necessary if there is impending intrauterine fetal death, if renal function deteriorates substantially, if uncontrollable hypertension supervenes, or if pre-eclampsia occurs. Obstetric considerations should be the main determinant for delivery by caesarean section.

Role of renal biopsy in pregnancy

Experience with renal biopsy in pregnancy is relatively sparse, mainly because clinical circumstances were considered to rarely justify the risks [5,9]. However, there are now case series reporting safety in selected cases in early pregnancy. Biopsy should be considered in the first trimester if there is a suspicion of rapidly progressive glomerulonephritis or a new presentation of nephrotic syndrome. In women with known renal disease (e.g. prior lupus nephritis or previous membranous glomerulonephritis), clinical judgement may well allow a biopsy not to be undertaken in pregnancy. However, 'blind' treatment with steroids or other immunosuppressants is not without risk and having a firm diagnosis is very helpful. Beyond 18–20 weeks most would not biopsy but use clinical status and blood tests to judge most likely diagnosis and treatment. In reality, biopsy during pregnancy remains a relatively infrequent event [52] but it is imperative that women presenting with new-onset proteinuria in early pregnancy are not lost to follow-up post partum as they may well need a biopsy in due course to ensure the correct diagnosis is made and appropriate therapy given. When renal biopsy is undertaken immediately after delivery in women with well-controlled blood pressure and normal coagulation indices, the morbidity is certainly similar to that reported in non-pregnant patients.

Long-term effects of pregnancy in women with renal disease

Readers are referred to earlier sections for advice regarding the impact of pregnancy on CKD. Whilst the recent TOCOS study suggests significant impact even of CKD stage 1 on renal outcomes, in the majority of women with normal eGFR, pregnancy does not cause deterioration or otherwise affect rate of progression of CKD beyond what might be expected in the non-pregnant state, provided pre-pregnancy kidney dysfunction was minimal and/or hypertension is absent or very well controlled before pregnancy [24,31,33,44]. An important factor in long-term prognosis could be the sclerotic effect that prolonged gestational renal vasodilatation might have in the residual (intact) glomeruli of the kidneys of these women. The situation may be worse in a single diseased kidney, where more sclerosis has usually occurred within the fewer (intact) glomeruli. Although the evidence in healthy women and those with mild renal disease argues against hyperfiltration-induced damage in pregnancy, there is little doubt that in some women with moderate, and certainly severe, dysfunction there can be unpredicted, accelerated and irreversible renal decline in pregnancy or immediately afterwards.

It is also now well recognized that both CKD and pre-eclampsia influence remote prognosis in both groups in terms of cardiovascular disorders and end-stage renal failure but there is debate about whether the superimposition of pre-eclampsia on CKD hastens progression to end-stage status [53–57]. It seems that pre-eclampsia is

not a risk factor ('marker' is a better term) for progression (see Chapter 7) but can lead to a stepwise decrease in renal function in those with underlying renal disease. The TOCOS study suggested strongly that, across all levels of baseline renal function, a proportion of women will develop worse renal function post partum.

Patients on dialysis

Dialysis and the prospects for pregnancy and afterwards

Despite reduced libido and relative infertility, women on long-term dialysis do conceive and must therefore use contraception if they wish to avoid pregnancy [14,21,58,59]. Although conception is not common (an incidence of 1 in 200 patients has been quoted), its true frequency is unknown because many pregnancies in dialysis patients probably end in early spontaneous abortion. The high therapeutic abortion rate in this group of patients (which has decreased from 40% in the 1990s to under 15% today) still suggests that those who become pregnant do so inadvertently, probably because they are unaware that pregnancy is possible. Recent data on improved fertility, likely due to normalization of the hypothalamic–pituitary–gonadal axis, as evidenced by the return of regular menstrual cycles [60] with increased dialysis, have persuaded some to consider increasing dialysis hours to assist conception in those women who wish to become pregnant and who have no prospect of a renal transplant in their fertile years.

Summary box 11.3

- Incidence of conception in chronic haemo dialysis patients of childbearing age is quoted as 1 in 200.
- Pregnancy poses big maternal risks but successful obstetric outcome is now 80%, leading to a reconsideration of counselling for these patients.
- Frequency of dialysis must be increased as soon as pregnancy is diagnosed and management of anaemia, nutritional issues and hypertension is very important.

Many authorities still do not advise patients on chronic dialysis to become pregnant or to continue a pregnancy if present. In the last two decades, however, fetal survival has significantly improved from 50% to almost 80%, with 90% attaining 36 weeks' gestation, which has led to a reconsideration of counselling for these patients [61,62,66]. Favourable prognoses for obstetric success include time on dialysis of less than 5 years, age under 35 years, residual urine production and absence of or well-controlled hypertension, as well as the early diagnosis of pregnancy thus facilitating increases in frequency and duration of dialysis. There are now clear data from the Toronto group and others that increasing dialysis hours and dose leads to significantly improved maternal and fetal outomes [61,62]. Pregnant women on dialysis should be offered increased hours of dialysis, aiming for at least 24 hours per week. All such pregnancies should be considered high risk, with increased potential for volume overload, threat of preterm labour, polyhydramnios (40–70%; directly related to adequacy of dialysis), major exacerbations of hypertension and/or superimposed pre-eclampsia (50–80%) and rarely, fortunately, placental abruption.

Antenatal strategy and decision-making

If women on dialysis become pregnant, they may present for care in advanced pregnancy because it was not suspected by either the patient or her doctors. Irregular menstruation is common and missed periods are usually ignored. Urine pregnancy tests are unreliable (even if there is any urine available). Thus ultrasound evaluation is needed to confirm and date pregnancy.

Dialysis policy

Some patients have gestational GFR increments despite renal function being insufficient to sustain life without dialysis [9,23,58,63–69]. The planning of dialysis strategy has several aims.

1) Maintain S_{urea} below 20 mmol/L (some would argue <15 mmol/L), as intrauterine fetal death is more likely if values are much in excess of 20 mmol/L. A lower S_{urea} is definitely associated with higher birthweight and gestational age at delivery. Total weekly dialysis should be 24 hours or more, ideally aiming for 30 hours or more, though this is often not feasible or achievable unless offering overnight dialysis. Use a dialysate with a higher potassium, lower calcium and lower bicarbonate. There is now good evidence that nocturnal dialysis (up to 36 hours per week) is associated with much better outcomes. Increased dialysis hours, however minimal, should make control of weight gain and dietary management easier. The potential disadvantage of more dialysis is electrolyte imbalance, hence the need to scrutinize serum chemistries at all times. Heparin can be used for anticoagulation.
2) Avoid hypotension and maternal volume depletion during dialysis, and a biocompatible small-surface-area dialysis to reduce ultrafiltration per treatment may be helpful in this regard. In late pregnancy the

enlarging uterus and supine posture may aggravate hypotensive episodes by decreasing venous return.
3) Ensure tight control of blood pressure throughout pregnancy, with the diastolic blood pressure ideally maintained at 80–90 mmHg.
4) Avoid rapid fluctuations in intravascular volume by limiting inter-dialysis weight gain to about 1 kg until late pregnancy.
5) Watch serum calcium closely to avoid hypercalcaemia and remember the potential for hypophosphataemia, hypokalaemia and depletion of water-soluble vitamins as well as the hazards of magnesium sulfate infusion, if required.
6) Scrutinize carefully for preterm labour, as dialysis and uterine contractions are associated.

Anaemia

Women with CKD, and particularly those on dialysis, are usually anaemic, invariably aggravated further in pregnancy. There is some evidence of a positive correlation between maternal haemoglobin and successful obstetric outcome; however, although haemoglobin of 100 g/L or more is advisable, the upper limit of an optimal haemoglobin level has yet to be determined. Where possible, blood transfusion should be avoided, since both pregnancy and blood transfusion can sensitize a woman, making future transplantation more difficult. If needed (especially before delivery), caution is necessary as it could exacerbate hypertension and impair the ability to control circulatory overload, even with extra dialysis. Fluctuations in blood volume can be minimized if packed red cells are transfused during dialysis. Recombinant human erythropoietin has been 'safely' used to treat anaemia during pregnancy in women with CKD and on dialysis, when requirements can be higher than in the non-pregnant state. The theoretical risks of hypertension and thrombotic complications have not been encountered, nor have adverse neonatal effects. Women should also be iron replete and intravenous iron can be used to maintain a serum ferritin around 200 mg/L.

Nutrition

Despite more frequent dialysis, uncontrolled dietary intake should be discouraged [21,59]. Daily oral intakes of 1.5 g/kg protein, 1.5 g calcium, 50 mmol potassium and 80 mmol sodium are advisable, with supplements of vitamin C, riboflavin, niacin, thiamine and vitamin B_6 as well as iron and folic acid supplements. Vitamin D supplements can be difficult to judge in patients who have had parathyroidectomy. Measurement of 25-hydroxyvitamin D levels should not be neglected, with supplementation if needed. In addition, oral phosphate supplements can be used if phosphate levels are low. Daily dialysis often leads to severe hypophosphataemia which may be associated with cervical shortening. Women can liberalize their low phosphate diet, stop their phosphate binders and may need intravenous phosphate during dialysis.

Fetal surveillance and timing of delivery

The same applies as with CKD. Preterm labour is common and it may even commence during dialysis. Caesarean section should be necessary only for obstetric reasons.

Peritoneal dialysis

Young women can be managed with this approach and successful pregnancies have now been reported [70]. Outcome is not dependent on mode of dialysis (haemodialysis vs. peritoneal) but there may be more infertility in women receiving continuous ambulatory peritoneal dialysis (PD).

With PD, although anticoagulation and some of the fluid balance and volume problems of haemodialysis are avoided, these women nevertheless face the same problems of hypertension, anaemia, term labour, sudden intrauterine death and placental abruption. During pregnancy the number of PD exchanges must be increased and the fill volumes of fluid may need reducing to less than 1.5 L, which might be best achieved by switching to automated PD. The size of the enlarging uterus in late pregnancy may make PD impossible and a temporary switch to haemodialysis may be necessary. It should be remembered that peritonitis can be a severe complication of chronic ambulatory PD, accounting for the majority of therapy failures but an increased incidence has not been reported in pregnancy. If caesarean section is needed, then theoretically it should be undertaken extraperitoneally with the traditional approach requiring a switch to haemodialysis.

Kidney transplant recipients

Transplantation and the prospects for pregnancy and afterwards

Renal, endocrine and sexual functions return rapidly after transplantation and assisted conception techniques are also available. About 1 in 50 women of childbearing age with a functioning transplant will become pregnant. Of the conceptions, about 25% do not go beyond the initial trimester because of spontaneous or therapeutic abortion, but of those pregnancies in well women that do, 97% end successfully [1,3,5,9]. In early gestation there may be increased risk of ectopic pregnancy, particularly for women with pancreas and kidney transplants, because of pelvic adhesions following surgery, PD,

intrauterine contraceptive device (IUCD) and/or pelvic inflammatory disease consequent to immunosuppression. Diagnosis of ectopic pregnancy may be delayed as irregular bleeding and pain may be wrongly attributed to deteriorating renal function and/or the presence of the pelvic allograft. A renal transplant has even been performed with surgeons unaware that the recipient was in early pregnancy. Obstetric success in such cases does not negate the importance of contraception counselling for all patients with renal failure and the exclusion of pregnancy prior to the surgery.

Summary box 11.4

- About 1 in 50 women of childbearing age with a functioning transplant becomes pregnant.
- Of those pregnancies that go beyond the first trimester, 97% have successful obstetric outcome.
- Serial assessment of renal function is essential along with early diagnosis and treatment of rejection (~2%), blood pressure control and treatment of infection.
- Some immunosuppressive drugs are contraindicated in pregnancy.
- There are no obstructive problems and/or mechanical injury to the transplant during vaginal delivery.

A woman should be counselled from the time the various treatments for renal failure and the potential for optimal rehabilitation are discussed [1,22]. As mentioned at the start of this chapter, couples who want a child should be encouraged to discuss all the implications, including the harsh realities of maternal survival prospects. Guidelines vary, with the European Best Practice Guidelines recommending a delay of 24 months before conception [71], whilst the American Society of Transplantation is less conservative and suggests that women should delay conception until at least 1 year after transplantation and only when they meet the following criteria: no rejection in the previous year; adequate and stable renal function (e.g. creatinine <1.5 mg/dL or 133 mmol/L); no or minimal proteinuria; no acute fetotoxic infections; and stable function with non-teratogenic immunosuppression [2]. Most centres recommend a wait of at least 1 year after transplantation. By then, the patient will have recovered from the surgery and any sequelae, graft function will have stabilized, and imunosuppression will be at maintenance levels. Also, if function is well maintained at 2 years, there is a high probability of allograft survival at 5 years (Table 11.6). As with CKD it is preferable if pre-pregnancy S_{cr} values are below 125 μmol/L, as above this level there can be more complications and problems (Table 11.7).

Antenatal strategy and decision-making

Management requires serial assessment of renal function, early diagnosis and treatment of rejection, blood

Table 11.6 Pre-pregnancy considerations in renal transplant recipients.

Good general health for about 1 year after transplantation
Stature compatible with good obstetric outcome
No or minimal proteinuria
No or well-controlled hypertension
No evidence of graft rejection
No pelvicalyceal distension on recent ultrasound or intravenous urography
Stable graft function: S_{cr} ≤160 μmol/L, preferably ≤125 μmol/L
Drug therapy at maintenance levels: prednisolone, azathioprine, cyclosporin and tacrolimus are 'safe'
Mycophenolate mofetil and sirolimus are contraindicated

Source: Newcastle upon Tyne 1976, revised 1987 and 2006. See Damjanov *et al.* [72] and Bramham *et al.* [73].

Table 11.7 Pre-pregnancy kidney function (S_{cr}) in kidney transplant recipients with estimates for obstetric complications and outcome and loss of graft function.

					Loss of >25% renal function		
S_{cr} (μmol/L)	Fetal growth restriction (%)	Preterm delivery (%)	Pre-eclampsia (%)	Perinatal deaths (%)	Pregnancy (%)	Persists post partum (%)	End-stage failure in 1 year (%)
≤125	30	35	24	3	15	4	–
125–160	50	70	45	7	20	7	10
≥160	60	90	60	12	45	35	70

Estimates based on literature review (1991–2007) from 1076 women in 1498 pregnancies, with all pregnancies attaining at least 24 weeks' gestation.
Source: Davison (unpublished data) and Bramham *et al.* [73].

pressure control, early diagnosis or prevention of anaemia, treatment of any infection, and meticulous assessment of fetal well-being (Table 11.8). As well as at least monthly renal assessments, including trough CNI levels, liver function tests, calcium and phosphate should be checked regularly throughout pregnancy. Haematinics are needed if the various haematological indices show deficiency.

Transplant function

The sustained increase in GFR characteristic of early normal pregnancy is evident in renal transplant recipients. Immediate graft function after transplantation and the better the pre-pregnancy GFR, the greater the increment in GFR in pregnancy. Transient 20–25% reductions in GFR can occur during the third trimester and do not usually represent a deteriorating situation with permanent impairment. However, significant renal functional impairment can develop in some patients during pregnancy, and this may persist following delivery, invariably being related to pre-pregnancy S_{cr} (Table 11.7). Because a gradual decline in function is common in non-pregnant patients, it is difficult to delineate the specific role of pregnancy. Most agree that pregnancy does not compromise long-term graft progression unless graft dysfunction was already present before pregnancy [22,74,75]. Proteinuria occurs near term in 40% of patients but disappears after delivery. Delineating late-onset proteinuria from pre-eclampsia remains a challenge but if hypertension is present, then it is usually safer to assume superimposed pre-eclampsia. In the future, angiogenic factor levels may assist in differentiating pre-eclampsia from other causes of proteinuria [76] though more recent reports have suggested it is lower e.g. [78]. Whether calcineurin inhibitors are more nephrotoxic in the pregnant compared with the non-pregnant patient is not known.

Transplant rejection

A systematic review and meta-analysis suggests that rejection during pregnancy is rare, with an overall pooled incidence of acute rejection in 2412 pregnancies being only 4.2% [77] though more recent reports have suggested it is lower e.g. [78]. This should be treated with high-dose steroids as the safety profile of antibody-mediated treatments is unknown and placental transfer is likely. Plasma exchange can also be considered.

Immunosuppressive therapy (Table 11.9)

It is important to note that this section is applicable to all women on immunosuppression for their kidney disease, not just renal transplant recipients.

Immunosuppressive therapy needs to be adjusted to ensure that teratogenic medications are ceased well before conception and that appropriate doses of others are used during pregnancy. A major issue for women with renal transplants and for women with lupus nephritis is that of mycophenolate mofetil (MMF). It is widely

Table 11.8 Management summary for a renal transplant patient (generalizable in most aspects for all women with CKD, particularly those on immunosuppression).

Before pregnancy
Patients should defer pregnancy for at least 1 year after transplant, with appropriate and reliable contraception
Assessment of graft function
Recent biopsy and/or organ-specific tests
Proteinuria
S_{cr}
Hepatitis B and C, cytomegalovirus, toxoplasmosis, and herpes simplex status
Maintenance immunosuppression: Azathioprine, Cyclosporine, Tacrolimus and Corticosteroids are all acceptable
Azathioprine
Cyclosporin
Tacrolimus
Corticosteroids
Mycophenolate mofetil and sirolimus contraindicated
Comorbidities (e.g. diabetes, hypertension) should be optimally managed
Vaccinations should be given if needed (e.g. hepatitis, tetanus, pneumococcus, human papillomavirus and influenza). No live vaccines can be given to any patient on immunosuppression.
Discuss the aetiology of the original disease and genetic issues, if appropriate
Discuss the effect of pregnancy on graft function
Discuss the risks of fetal growth restriction, preterm delivery and low birthweight
Antenatal
Early diagnosis and dating of pregnancy
Clincial and laboratory monitoring of the graft and immunosuppressive drug levels every 2–4 weeks until 32 weeks, then every 1–2 weeks until delivery
Surveillance for rejection, with transplant biopsy considered if it is suspected
Surveillance for bacterial or viral infection (e.g. cytomegalovirus, toxoplasmosis, hepatitis in first trimester and repeat if signs of rejection or tenderness over graft site)
Monthly urine cultures
Fetal surveillance from 24–28 weeks onwards (e.g. non-stress test, sonographic evaluation)
Monitoring of hypertension and management
Surveillance for pre-eclampsia
Screening for gestational diabetes: steroids and calcineurin inhibitors are diabetogenic which combine with the insulin-resistant state of pregnancy to increase the risk of GDM significantly. Offer GTT at 28 weeks
Delivery
Caesarean delivery for obstetric reasons
For kidney recipients: episiotomy on side opposite to graft; caesarean section may not be easy
Should discuss operative approach with transplant surgeon in advance and ideally he or she would be present at time of delivery to ensure kidney and/or pancreas transplant protected
Post partum
Monitor immunosuppressive drug levels for 3–4 weeks after delivery, with adjustment as needed
Breastfeeding is appropriate (unless mycophenolate mofetil restarted); monitor fetal drug levels if there are concerns e.g., in very pre-term infants
Contraception counselling is essential

GDM, gestational diabetes mellitus; GTT, glucose tolerance test.
Source: modified and supplemented from Armenti *et al.* [74].

Table 11.9 Pregnancy safety information for immunosuppressive drugs used in transplantation and other renal diseases.

	Animal reproductive data	Pregnancy category
Corticosteroids (prednisolone, methylprednisolone, others)	Yes	B
Azathioprine (Imuran)	Yes	D*
Cyclosporin (Sandimmun, Neoral, others)	Yes	C
Tacrolimus (FK506, Prograf, Adoport)	Yes	C
Antithymocyte globulin (Atgam, ATG)	No	C
Antithymocyte globulin (Thymoglobulin)	No	C
Muromonab-CD3 (Orthoclone OKT3)	No	C
Mycophenolate mofetil (CellCept)	Yes	D
Mycophenolic acid (Myfortic)	Yes	D
Basiliximab (Simulect)	Yes	B
Daclizumab (Zenapax)	No	C
Sirolimus (Rapamune)	Yes	C

*Azathioprine has known impact on fetal lymphocytes and possibly thymus development. However, azathioprine is widely used in pregnancy and is generally considered safe.
B, no fetal risk, no controlled studies; C, fetal risk cannot be ruled out; D, evidence of fetal risk.
Source: US Food and Drug Administration classification. Modified from Webster *et al.* [22], Armenti *et al.* [82,83] and Coscia *et al.* [84].

used in both settings but is undoubtedly teratogenic. The existence of an MMF-associated embryopathy has been proposed with consistent key features: cleft lip and palate, microtia with atresia of the external auditory canal, micrognathia and hypertelorum [79–81]. Ocular anomalies, corpus callosum agenesis, heart defects, kidney malformations and diaphragmatic hernia could also be a part of the phenotypic spectrum, which is supported by experimental animal studies. To date, in the babies, psychomotor development and growth have been reported as normal. MMF is now classed as teratogenic by the FDA and there has been recent guidance on MMF use before pregnancy and in pregnancy prevention from the European Medicines Agency and the Medicines and Healthcare products Regulatory Agency (https://www.gov.uk/drug-safety-update/mycophenolate-mofetil-mycophenolic-acid-new-pregnancy-prevention-advice-for-women-and-men). Specifically, MMF should not be used in pregnancy unless there is no suitable alternative treatment to prevent transplant rejection. Women should not have been using MMF for at least 6 weeks prior to pregnancy. Much less evidence-based is the parallel recommendation that men who are planning a pregnancy with their partner should stop MMF 90 days prior to attempting conception. All women on MMF, whether for transplant or lupus, should be advised when starting the medication about the risks of pregnancy and to use secure contraception. Women should be tested to ensure they are not pregnant before starting MMF and should be counselled as to the safety of switching (usually to azathioprine) in advance of conception.

There are many encouraging registry and single-centre reports of (non-complicated) pregnancies in patients taking cyclosporin and tacrolimus. Numerous adverse effects are attributed to calcineurin inhibitors in non-pregnant transplant recipients, including renal toxicity, hepatic dysfunction, chronic hypertension, tremor, convulsions, diabetogenic effects, haemolytic uraemic syndrome, and neoplasia. In pregnancy, some of the maternal adaptations that normally occur may theoretically be blunted or abolished by cyclosporin especially plasma volume expansion and renal haemodynamic augmentation. There was good evidence suggesting that patients had more hypertension and smaller babies [81,82], but it is possible that the women who originally used calcineurin inhibitors had worse kidney function and that may have been a confounding factor. In the current era, lower doses are used. A very practical problem is that of dosing of tacrolimus, a calcineurin inhibitor. Tacrolimus dosing is adjusted according to serum tacrolimus levels. Since tacrolimus metabolism increases in pregnancy, levels fall and doses may need to be increased by as much as 50% (and rapidly reduced post partum). However, there is some controversy as 'free' tacrolimus levels are not measured in standard assays and may be unchanged, exposing the woman to the risk of tacrolimus toxicity. This should be considered in the face of an otherwise inexplicable rise in creatinine in a pregnant woman with a transplant.

Hypertension and pre-eclampsia

Hypertension, particularly before 28 weeks' gestation, is associated with adverse perinatal outcome. This may be due to covert cardiovascular changes that accompany, and/or are aggravated by, chronic hypertension. The appearance of hypertension in the third trimester, its relationship to deteriorating renal function, and the possibility of chronic underlying pathology and pre-eclampsia poses a diagnostic problem. Pre-eclampsia is actually diagnosed clinically in about 20–30% of pregnancies in women with renal transplants [74].

Infections

Throughout pregnancy patients should be monitored carefully for bacterial and viral infection. Prophylactic antibiotics must be given before any surgical procedure, however trivial. Asymptomatic bacteriuria is common, should be treated and, if recurrent, merits prophylactic antibiotics during pregnancy.

Diabetes mellitus

In general, women are having their children at an older age, which makes it more likely that patients with type 1 diabetes mellitus have reached end-stage renal failure and hence have had a transplant before conceiving. Pregnancy complications occur with at least twice the frequency seen in the non-diabetic patient, and this may be due to the presence of generalized cardiovascular pathology, which is part of the metabolic risk factor syndrome. Successful pregnancies have been reported after combined pancreas–kidney allografts [86].

Fetal surveillance and timing of delivery

The points discussed under CKD are equally applicable to renal transplant recipients. Preterm delivery is common (45–60%) because of intervention for obstetric reasons and the common occurrence of preterm labour or preterm rupture of membranes. Preterm labour is commonly associated with poor renal function, but in some it has been postulated that long-term immunosuppression may 'weaken' connective tissues and contribute to the increased incidence of preterm rupture of membranes.

Vaginal delivery should be the aim; usually there are no obstructive problems and/or mechanical injury to the transplant [86]. Unless there are problems, spontaneous onset of labour can be awaited but most advise not exceeding 38–39 weeks' gestation. During labour careful monitoring of fluid balance, cardiovascular status and temperature is mandatory. Aseptic technique is essential for every procedure. Surgical induction of labour (by amniotomy) and episiotomy warrant antibiotic cover. Pain relief can be conducted as for healthy women. Augmentation of steroids should not be overlooked. If required, episiotomy should be performed on the opposite side to the transplant. Caesarean section should be undertaken for obstetric reasons only and may not be easy. The operative approach should be discussed with a transplant surgeon in advance and ideally he or she would be present at delivery to ensure that the kidney and/or pancreas transplant is protected.

Post-delivery management issues

Paediatric management

Over 50% of liveborns have no neonatal problems. Preterm delivery is common (45–60%), as is fetal growth restriction (20–30%), and occasionally the two problems coexist. Lower birthweights are seen in infants born to mothers who received their transplant less than 2 years previously and the use of calcineurin inhibitors can be associated with lower birth weights [84].

Breastfeeding

There are substantial benefits to breastfeeding. It could be argued that because the baby has been exposed to immunosuppressive agents and their metabolites in pregnancy, breastfeeding should not be allowed. For cyclosporin levels in breast milk are usually greater than those in a simultaneously taken blood sample. However, we have shown that breastfeeding – certainly of term infants – by mothers taking tacrolimus is safe and very little 'seen' by the baby; similarly with azathioprine. There is a view that mothers who want to breastfeed should be encouraged, so long as the baby is thriving [87,88] and monitoring fetal drug levels could be undertaken if there are concerns. If MMF is needed by the mother in the pueperium, the current advice is not to breastfeed.

Long-term assessment

There are theoretical worries about *in utero* exposure to immunosuppressive agents, with eventual development of malignant tumours in affected offspring, autoimmune complications and/or abnormalities in reproductive performance in the next generation. Thus paediatric follow-up is needed (Table 11.10). To date, information about general progress in early childhood has been good.

Table 11.10 Neonatal problems in the newborn of kidney allograft recipients.

Preterm delivery and/or small for gestational age
Respiratory distress syndrome
Adrenocortical insufficiency
Septicaemia
Cytomegalovirus infection
Depressed haematopoiesis
Lymphoid and thymic hypoplasia
Reduced T lymphocyte and immunoglobulin levels
Chromosome aberrations in leucocytes

Maternal follow-up after pregnancy for women with transplants or CKD

The ultimate measure of transplant success is the long-term survival of the patient and the graft. As it is only 40 years since this procedure became widely employed in the management of end-stage renal failure, few long-term data from sufficiently large series exist from which to draw conclusions. Furthermore, the long-term results for renal transplantation relate to a period when many aspects of management would be unacceptable by present-day standards. Average survival figures of large numbers of patients worldwide indicate that about 95% of recipients of kidneys from related living donors are alive 5 years after transplantation. With cadaver kidneys, the figure is approximately 89%. If renal function is normal 2 years after transplant, graft survival increases further. This is why women are counselled to wait about 2 years before considering a pregnancy even though a view is now emerging that 1 year would be sufficient.

A major concern is that the mother may not survive or remain well enough to rear the child she bears. Pregnancy occasionally and sometimes unpredictably causes irreversible declines in renal function. However, the consensus is that pregnancy, whilst often complicated, has little effect on long-term graft function or survival providing function is good at baseline, it is a first transplant and hypertension is not a major issue [72,87,89]. Similarly, repeated pregnancies do not adversely affect graft function or fetal development, provided that pre-pregnancy renal function is well preserved and hypertension minimal and/or well controlled.

Contraception

Oral contraception can cause or aggravate hypertension, thromboembolism and/or subtle changes to the immune system. This does not necessarily contraindicate its use but careful surveillance is essential. Generally, oestrogen containing contraceptives are not used due to the increased risk of thrombosis. However, progesterone only methods – the mini-pill, an implant or progesterone IUCD are all highly effective and safe alternatives. IUCDs may aggravate menstrual problems, which in turn may obscure symptoms and signs of early pregnancy abnormalities, such as threatened miscarriage or ectopic pregnancy. Current data suggest that immunosuppressed women have no increased risk of pelvic inflammatory disease compared to the general population of non IUCD users [78].

Gynaecological problems

There is a danger that symptoms secondary to genuine pelvic pathology may be erroneously attributed to the transplant because of its location near the pelvis [5]. Transplant recipients receiving immunosuppressive therapy have a malignancy rate estimated to be 100 times greater than normal and the female genital tract is no exception. This association is probably related to factors such as loss of immune surveillance, chronic immunosuppression allowing tumour proliferation (especially if virally driven) and/or prolonged antigenic stimulation of the reticuloendothelial system. Regular gynaecological assessment is therefore essential and any gynaecological management should be on conventional lines, with the outcome unlikely to be influenced by stopping or reducing immunosuppression, unless the pathology is thought to be virally driven.

Kidney donors

It has always been considered that living kidney donors are low risk for almost all medical conditions. However, recent data suggest that gestational hypertension and pre-eclampsia are about twice as common in those who have donated a kidney than in those who have not. Whilst these data need to be extended, it is worth considering whether possible donors have completed their family before allowing them to donate a kidney [90].

Summary

Women with kidney disease used to be discouraged from becoming pregnant. It is now clear that with adequate pre-pregnancy planning, the vast majority can have safe pregnancies with good outcomes for the mother and baby. Ideally, pregnancy should be planned for a time of normal or stable renal function, minimal proteinuria and well-controlled blood pressure on safe drugs. Women should be followed up post partum to ensure stability of renal disease, make the renal diagnosis if they have presented for the first time during pregnancy, and to ensure an appropriate long-term care plan is in place.

Haematological Problems in Pregnancy

Sarah Davis[1] *and Sue Pavord*[2]

[1] *Milton Keynes University Hospital, Milton Keynes, UK*
[2] *Department of Haematology, Oxford University Hospitals NHS Foundation Trust, Oxford, UK*

Pregnancy is associated with physiological adaptation of the haematological system. An understanding of these changes is essential for distinguishing the normal from the pathological state. There is an increased likelihood of certain haematological complications, with thromboembolism and haemorrhage being leading causes of direct maternal deaths. This chapter covers the normal physiological changes, haematological complications of pregnancy and common haematological diseases which may impact on or be influenced by pregnancy.

Physiological changes to the blood in pregnancy

To accommodate the developing uteroplacental circulation, plasma volume increases by approximately 1250 mL (45%) and red cell mass by approximately 250 mL (10–20%) by the end of pregnancy. This produces a total blood volume increase of around 1500 mL but fall in haemoglobin concentration, as plasma volume is increased disproportionately to red cell mass (Table 12.1). Consequently, red cell count and haematocrit are lower in pregnancy. Other red cell indices remain largely stable except mean cell volume (MCV) which increases by about 4–6 fL, secondary to greater numbers of larger young red cells from the increase in red cell mass.

Expansion of red cell mass requires 450–600 mg of iron and approximately 300 mg is transferred to the fetus and placenta, mainly in the last 4 weeks. Coupled with 0.8 mg daily basal loss (240 mg over duration of pregnancy) and 250 mg average loss at delivery, this suggests that most women require 1250 mg of iron during pregnancy. Serum folate levels fall by around half, due to a twofold increase in folate requirements but red cell folate levels are relatively spared. Functional vitamin B_{12} levels change very little and it is extremely unusual for a woman to have genuine B_{12} deficiency in pregnancy, even though serum levels often appear low.

Typically, pregnancy causes a neutrophilia and therefore leucocytosis. There is usually an increase in circulating immature neutrophils (left shift) and evidence of toxic granulation. Levels may be markedly elevated after delivery but usually return to normal by 4 weeks post partum. Lymphocyte counts are often reduced, particularly in the first and second trimesters, and monocyte counts may be elevated, especially in the first trimester.

A reduction in platelet count, mainly secondary to hyperdestruction and shortened lifespan, is common and around 10% of pregnancies have a platelet count below 150×10^9/L in the third trimester. It is usually mild, with 80% of counts remaining above 115×10^9/L, and does not seem to have an adverse effect on platelet function, possibly due to increased fibrinogen levels in pregnancy.

Von Willebrand factor (vWF) and factors VII, VIII and X increase markedly with gestation and remain elevated in the early postpartum period. Factor IX remains unchanged. The natural anticoagulant protein S decreases with no change in protein C levels. This creates a prothrombotic state and activated partial thromboplastin time (APTT) is often shortened in pregnancy.

Summary box 12.1

Haematological changes in normal pregnancy

- Fall in haemoglobin concentration.
- Leucocytosis (mainly neutrophilia).
- Mild thrombocytopenia with no impairment of platelet function.
- Prothrombotic state predominantly due to increases in FVIII, vWF, fibrinogen and reduction in protein S.
- Significant requirements for iron and folate.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 12.1 Changes in blood composition with gestation.

		Gestation (weeks)		
	Non-pregnant	20	30	40
Plasma volume (mL)	2600	3150	3750	3850
Red cell mass (mL)	1400	1450	1550	1650
Total blood volume (mL)	4000	4600	5300	5500
Haematocrit	35	32	30	30

Anaemia in pregnancy

Anaemia is defined as a haemoglobin (Hb) two standard deviations below the mean for a healthy age-matched population. However, consensus on what is normal in pregnancy is lacking. The British Society of Haematology (BSH) and the US Centers for Disease Control and Prevention (CDC) use a value of less than 110 g/L in the first trimester but less than 105 g/L in the second and third trimesters as this takes into account the marked expansion in plasma volume at this stage. Postpartum anaemia is defined as Hb less than 100 g/L and African populations in general have lower Hb levels than Caucasians.

Iron deficiency anaemia

Iron requirements for pregnancy, the fetus and delivery are substantial, with the average woman requiring at least 1250 mg. Western diets typically provide 15 mg/day, of which 10% is absorbed. During pregnancy, absorption increases to around 30% by 30 weeks but this is often insufficient to meet demand. Furthermore, many women start pregnancy already iron depleted, due to poor diet, increased need, menstruation and previous pregnancies within 2 years.

Iron deficiency leads to anaemia and decreased tissue oxygen transport and affects iron-dependent enzymes in every cell. Iron deficiency anaemia is a significant problem worldwide, affecting 50% of pregnant women (56% in developing and 18% in developed countries).

The early stages of iron deficiency are often asymptomatic or show non-specific symptoms. These include fatigue, poor concentration and irritability. As the anaemia develops tiredness is common but patients also complain of headaches, palpitations, dizziness and shortness of breath. Signs, if any, are pallor of mucous membranes and a hyperdynamic circulation. Specific signs, such as angular cheilitis, glossitis and koilonychia, can occur in severe cases.

Iron deficiency may affect maternal morbidity. Cellular immunity and phagocytosis is impaired, rendering women more susceptible to infection, and its effect on iron-dependent enzymes of the nervous system may lead to poor work performance and emotional instability, especially in the postpartum period. There may also be a link between iron deficiency, low birthweight and preterm delivery but this is, as yet, unproven.

The fetus is relatively spared, as preferential delivery of iron is facilitated by upregulation of placental transferrin. However, infants born to iron-deficient mothers are more likely to develop iron deficiency in the first 3 months of life.

Diagnosis

Initially, as iron stores are depleted, serum ferritin levels fall. A low serum ferritin is diagnostic of iron deficiency but as it is an acute-phase reactant, it can be elevated in active inflammation or infection despite iron deficiency. Levels of transferrin, the iron transporter protein, increase as it attempts to deliver more iron to tissues. Anaemia develops as iron for erythropoiesis is reduced. MCV is an unreliable measure in pregnancy due to the physiological increase. Serum iron and total iron binding capacity (TIBC) are also unhelpful as they are affected by factors such as recent iron ingestion and infection.

The British Committee for Standards in Haematology (BCSH) [1] suggest the following.

- A trial of oral iron should be the first 'diagnostic test' for women with a normocytic or microcytic anaemia, with a check for Hb increase at 2 weeks.
  - Exceptions are women with known haemoglobinopathy, who should have a serum ferritin before starting iron, to confirm the diagnosis and exclude an iron loading state.
  - Anaemic women whose haemoglobinopathy status is unknown should commence a trial of iron therapy and simultaneous haemoglobinopathy screening.
- A serum ferritin level below 15 μg/L is diagnostic of established iron deficiency and a level below 30 μg/L should also prompt treatment.
- In those women at high risk of iron deficiency but who are not yet anaemic, ferritin levels should be checked and oral iron started in those with ferritin below 30 μg/L.

Treatment

The principles of treating iron deficiency are as follows:

1) establish cause;
2) correct deficiency;
3) replenish iron stores.

The recommended daily iron intake for pregnant women is 30 mg and all women should receive dietary advice on iron-rich foods and factors that aid or inhibit absorption (Table 12.2).

Table 12.2 Factors affecting iron absorption.

Factors increasing iron absorption
Haem iron (red meats, fish and poultry)
Acids, e.g vitamin C
Ferrous form (Fe^{2+})
Factors reducing iron absorption
Tannins in tea and coffee
Foods rich in calcium
Antacids

Table 12.3 Elemental iron content in oral iron preparations.

Iron preparation	Tablet size (mg)	Elemental iron per tablet (mg)
Ferrous sulfate	200	65
Ferrous fumarate	200	65
Ferrous gluconate	300	35

Iron deficiency in pregnancy cannot be corrected through diet alone so iron supplementation is necessary. Oral, intramuscular and intravenous preparations are available. For most women oral replacement is the best option because it is effective, safe and inexpensive and can be started in primary care. The optimal dose has not yet been established but the current recommendation in the UK is 100–200 mg elemental iron daily with Hb level checked in 2 weeks. Hb should rise by around 20 g/L every 3–4 weeks and treatment should continue for at least 3 months after Hb has normalized and until at least 6 weeks post partum. Non-anaemic women with low serum ferritin (<30 μg/L) should be started on 65 mg of elemental iron daily with a repeat Hb and ferritin in 8 weeks.

Postpartum women with Hb below 100 g/L who are haemodynamically stable with minimal symptoms should be offered 100–200 mg elemental iron daily for 3 months to replenish iron stores.

There are several different iron preparations available and choice should be based on dose of elemental iron and side-effect profile (Table 12.3). Around 10–20% of patients experience gastrointestinal side effects, which are mostly dose related.

To maximize absorption, patients should take tablets with orange juice on an empty stomach, avoid tea and coffee for an hour either side of the tablet and not take with other medications, especially antacids. However, if side effects do occur and lowering the dose does not help, it may be appropriate to take tablets with meals despite the reduction in absorption.

Intravenous iron is reserved for patients who fail to respond to oral iron or who are truly intolerant. Intravenous iron preparations have no licence for use in the first trimester due to concerns that oxidative free radicals could cause toxicity to placental membranes. They are relatively contraindicated in patients with chronic liver disease or active infection. The risk of anaphylaxis is exceedingly rare but other non-allergic reactions occur in around 1 in 200 000.

The older intravenous preparations do not raise Hb levels quicker than correctly taken oral iron. However, newer preparations such as iron carboxymaltose, which is given as a single dose over 15 min, produces a faster response (approximately 10 g/L improvement per week) so may be particularly beneficial for those women who present late in pregnancy.

Intramuscular iron is rarely used as it is painful, has variable absorption and can cause permanent skin staining if not given correctly.

With optimum care most women will no longer be anaemic at the point of delivery. However, women whose Hb is less than 100 g/L should deliver in hospital (<95 g/L in an obstetrician-led unit), have intravenous access, a group and save available, and active management of the third stage of labour to minimize bleeding.

Megaloblastic anaemia

Worldwide, megaloblastic anaemia during pregnancy secondary to folate deficiency is common due to poor diet and increased folate requirements. In the UK prevalence is less than 5% as many women take folate supplements to prevent neural tube defects. However, women with haemolytic disorders, malabsorption syndromes, myeloproliferative disorders and those on anticonvulsants are at high risk and should receive folate supplements.

Folate deficiency is suggested by an elevated MCV, although the physiological increase in MCV and possible coexisting iron deficiency make this an unreliable parameter for diagnosis. The blood film may show hypersegmented neutrophils and oval macrocytes, and if iron deficiency coexists a dimorphic picture (two populations of red cells). Red cell folate levels are usually reduced and unaffected by recent folate intake but sensitivity and specificity during pregnancy are poor. The gold standard is a bone marrow biopsy demonstrating megaloblastic erythropoiesis but a trial of folate supplementation with assessment of Hb response is more practical.

Patients at increased risk of folate deficiency should take 5 mg of folate daily as prophylaxis during pregnancy. Those with established folate deficiency should take 5 mg three times daily and all patients should be given dietary advice.

Vitamin B_{12} deficiency in pregnancy is extremely rare as body stores last for several years. The commonest

cause of B_{12} deficiency in the UK is pernicious anaemia, which typically affects older people. Furthermore, B_{12} deficiency is usually associated with infertility.

Summary box 12.2

- Iron deficiency in pregnancy is common.
- In established anaemia, in the absence of a known haemoglobinopathy, start oral iron supplements as both a diagnostic test and treatment.
- Oral iron is best for the majority of women and should be taken on an empty stomach, to optimise absorption.

Thrombocytopenia in pregnancy

A platelet count below 100×10^9/L occurs in less than 1% of pregnancies. Causes can be specific to or concurrent with pregnancy and can result in either isolated thrombocytopenia or thrombocytopenia in association with a systemic disorder. The majority of cases are secondary to the benign condition gestational thrombocytopenia (Fig. 12.1). However, causes may be life-threatening and thrombocytopenia has implications for mode of delivery and the bleeding risk of mother and neonate. EDTA in full blood count tubes can induce platelet clumping leading to pseudo-thrombocytopenia. Therefore, thrombocytopenia should always be confirmed with a repeat full blood count (FBC) and blood film and a citrate platelet count performed if clumping is present.

Gestational thrombocytopenia

Gestational thrombocytopenia is a benign condition. Its pathogenesis is unclear but likely reflects platelet consumption within the placental circulation, haemodilution and hormonal inhibition of megakaryocytopoiesis. It usually causes a mild thrombocytopenia in the third trimester with no symptoms of bruising or bleeding and no history of thrombocytopenia outside pregnancy. It has no pathological significance for mother or fetus. There is no diagnostic test except the platelet count normalizes within 6 weeks post partum. It is therefore a diagnosis of exclusion and may cause diagnostic difficulty with autoimmune thrombocytopenia, especially if there are no pre-pregnancy counts. It is extremely unusual for gestational thrombocytopenia to produce platelet counts below 70×10^9/L so levels below this should prompt consideration of alternative diagnoses.

Autoimmune thrombocytopenia

Immune thrombocytopenic purpura (ITP) is an autoimmune condition in which autoantibodies are directed against platelet surface glycoproteins (GPIIb/IIIa and/or GP1b/IX). This leads to premature clearance of platelets via Fc receptors in the reticuloendothelial system (mainly spleen). It is often chronic and presents a particular problem in pregnancy as the antibodies can cross the placenta rendering the fetus thrombocytopenic. It affects up to 5 in 10 000 pregnancies, two-thirds of these being women who have a previous diagnosis of ITP and one-third who have their diagnosis made during pregnancy. It is the most common cause of thrombocytopenia in the first trimester.

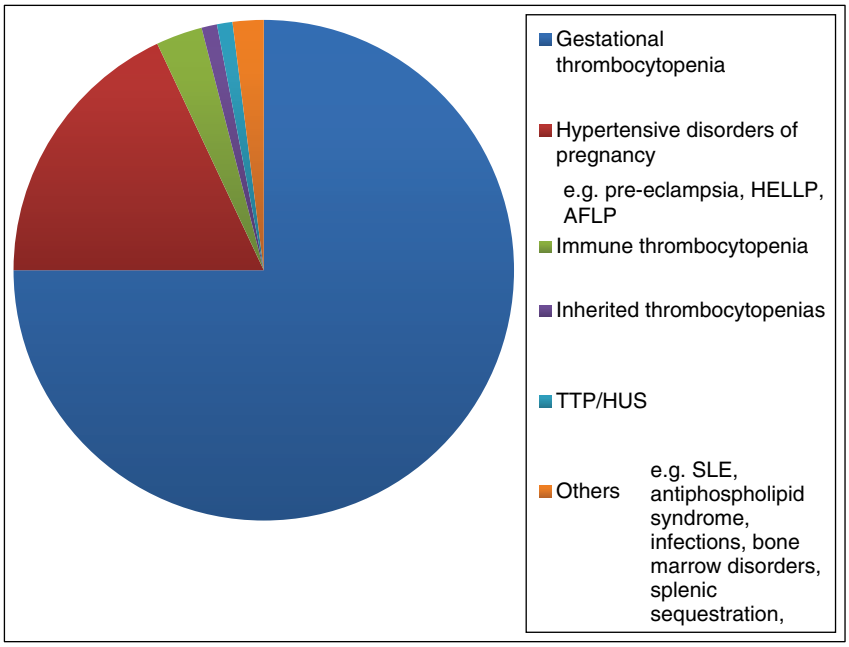

Fig. 12.1 Causes of thrombocytopenia in pregnancy. AFLP, acute fatty liver of pregnancy; HELLP, haemolysis, elevated liver enzymes, low platelet count; HUS, haemolytic uraemic syndrome; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

Table 12.4 Suggested platelet counts for immune thrombocytopenic purpura in pregnancy.

First and second trimesters of pregnancy: $>20 \times 10^9$/L
Vaginal delivery: $>40 \times 10^9$/L
Operative/instrumental delivery: $>50 \times 10^9$/L
Epidural: $>80 \times 10^9$/L

Platelet counts in ITP are usually less than 70×10^9/L and it is a diagnosis of exclusion. For women with a pre-pregnancy diagnosis of ITP, the accuracy of the diagnosis should be checked, response to treatments documented as well as the course and outcome of previous pregnancies, including neonatal platelet counts.

The aim of ITP treatment in pregnancy is to maintain the platelet count at a level that avoids haemorrhagic problems for the mother during pregnancy and allows a safe delivery. Suggested platelet counts are detailed in Table 12.4.

This approach minimizes maternal and fetal exposure to therapeutic agents. Women do not usually require treatment before 36 weeks, providing they are asymptomatic and platelet levels are above 20×10^9/L. For those that need treatment, the first line is usually oral corticosteroids, starting with prednisolone 20 mg daily and titrated to response, and/or intravenous immunoglobulin if a more immediate response is required. If a woman with ITP goes into labour with an uncorrected platelet count, intravenous immunoglobulin 1 g/kg should be given immediately and platelet transfusion if birth is imminent or haemorrhage occurs.

Mode of delivery should be led by obstetric indications. Rarely, transplacental transfer of maternal autoantibody can cause thrombocytopenia in the baby, increasing risk of intracranial haemorrhage at delivery. To minimize this risk, fetal scalp monitoring and blood sampling, ventouse and high/mid-cavity forceps should be avoided. Active management of the third stage of labour reduces bleeding risk in the mother and non-steroidal anti-inflammatory drugs should be avoided.

Because there is no correlation between maternal and fetal platelet counts, predicting which babies will have thrombocytopenia is difficult, unless the previous sibling was affected. Therefore all neonates born to mothers with ITP should have a cord blood count. If normal there is no need to repeat, but if abnormal a count should be repeated at 3–5 days of age, when the neonatal spleen has developed.

Thrombotic thrombocytopenic purpura

Thrombotic thrombocytopenic purpura (TTP) is a life-threatening condition characterized by thrombocytopenia and a microangiopathic haemolytic anaemia. Renal dysfunction, fever and neurological abnormalities also occur. Although rare, it is precipitated by pregnancy in 5–25% of cases. It can cause diagnostic confusion with other thrombotic microangiopathies such as HELLP (haemolysis, elevated liver enzymes, low platelets), pre-eclampsia and disseminated intravascular coagulation. Prompt plasma exchange can be life-saving.

Summary box 12.3

- Mild to moderate thrombocytopenia is common in pregnancy.
- A platelet count below 100×10^9/L should be investigated.
- Gestational thrombocytopenia is the commonest cause.
- ITP poses a risk to both mother and fetus and should have multidisciplinary management.

Sickle cell disorders

The sickle cell disorders (SCDs) are a group of conditions in which the sickle β gene is inherited with another abnormal haemoglobin. Sickle cell anaemia (HbSS) is the commonest and most severe, but the SCDs also includes HbSβthal and HbSC disease amongst others. HbS polymerizes at low oxygen tensions, which causes the red cells to sickle. Cells are inflexible in small blood vessels, contributing to vaso-occlusion and have a shorter lifespan, leading to a chronic haemolytic anaemia. The clinical phenotype is varied, with some patients experiencing an almost 'normal' life and others suffering frequent crises. These crises may be haemolytic, vaso-occlusive, visceral or aplastic and many patients develop chronic organ damage.

Pregnancies are high risk for both mother and fetus. Crisis frequency may increase, anaemia usually worsens, infections, especially urinary, are common (secondary to hyposplenism and a more complex immune defect), and pre-eclampsia occurs in around one-third of patients. There is also an increased thrombotic risk with both pregnancy and SCD. Patients have an increased risk of miscarriage, premature delivery and intrauterine growth restriction. Therefore, patients should be managed within a multidisciplinary team including midwives, haematologists, anaesthetists and obstetricians.

Ideally, pregnancy should be planned to allow women's health to be optimized. Patients should undergo pre-conception screening to assess end-organ damage, their vaccination status should be up to date and any medications that are potentially teratogenic should be stopped. These include hydroxycarbamide (used to control frequent crises), angiotensin-converting enzyme (ACE) inhibitors and iron chelators. Unless contraindicated,

women should continue penicillin V for infection prophylaxis and take folic acid 5 mg daily.

Antenatal care should particularly focus on continued education to avoid crisis triggers, such as dehydration from vomiting. Blood tests and monitoring for asymptomatic urinary infections, pregnancy-induced hypertension and pre-eclampsia should be carried out monthly, along with ultrasound scans to assess fetal growth and liquor volume [2]. Blood transfusions are not required routinely but regular transfusion programmes may be helpful in women with poor medical or obstetric histories in order to suppress HbS production. Examples include women previously on hydroxycarbamide, those with history of stroke or chest crisis and those with previous fetal loss or prematurity. Exchange transfusion may be preferred in these cases, depending on Hb. Acute chest crisis, pre-eclampsia or other emergencies may benefit from exchange Hb to allow more aggressive reduction in HbS levels. All patients should have an extended red cell phenotype; many will have red cell alloantibodies making it difficult to provide blood quickly and the fetus may be at risk of haemolytic disease of the newborn.

Severe crises in pregnancy are most frequent in the third trimester and may precipitate labour. The principles of treatment are the same as for a non-pregnant patient and include keeping the woman warmth, well hydrated and oxygenated, with adequate analgesia and screening for and treatment of any infection. Indications for transfusion should be discussed with a haematologist and the possibility of chest crisis should always be considered and treated as a priority. Patients are at risk of thrombosis so unless otherwise contraindicated should be on low-molecular-weight heparin (LMWH) and fetuses should be monitored with regular cardiotocography (CTG).

Mode of delivery should be led by obstetric indications and spontaneous vaginal delivery is usual. The mother should be kept warm, well hydrated and oxygenated and prolonged labour avoided. Continuous CTG monitoring is suggested and epidural anaesthesia is the pain relief of choice. There is an increased risk of postpartum haemorrhage, infection and thromboembolism so mothers should be closely monitored and attention paid to thromboprophylaxis.

Thalassaemia

The thalassaemias are a group of inherited disorders characterized by reduced or absent production of the α or β haemoglobin chains. This causes a relative excess of the remaining chain, resulting in ineffective erythropoiesis and chronic haemolysis. There are four α-globin genes and two β-globin genes. A complete absence of α-chains is incompatible with life but otherwise a wide variety of genetic abnormalities exist. For this reason thalassaemias are classified by their clinical phenotype into thalassaemia carriers, thalassaemia intermedia and thalassaemia major. The more severe intermedia patients and those with thalassaemia major are transfusion dependent and the main cause of morbidity and mortality is organ dysfunction caused by iron loading.

Carriers or those who have mild thalassaemia intermedia syndromes can be treated as 'normal' pregnancies, except that pre-conception counselling about a couple's risk of having a baby with a haemoglobinopathy should occur and women should have ferritin checked before starting on iron.

Pregnancies in women with β thalassaemia major and severe intermedia syndromes are high risk and should be managed in a multidisciplinary setting. Pre-conception counselling should be offered, covering the risk of subfertility due to hypogonadotrophic hypogonadism, fetal haemoglobinopathy and the risks pregnancy poses to life if patients have cardiac or hepatic dysfunction. Screening for iron-induced organ damage should be performed, including diabetic testing, thyroid function, cardiac and hepatic T2* MRI and echocardiography. Ideally, patients should have no myocardial and minimal liver iron before pregnancy, otherwise a pre-conception period of intensive iron chelation should be considered.

Teratogenic medications, including iron chelators, bisphosphonates and ACE inhibitors, should be stopped 3 months before conception. Folic acid 5 mg daily and calcium and vitamin D supplements, if bone density is reduced, should be taken. Extended red cell phenotyping and antibody screen should be performed.

Antenatal care should be multidisciplinary and individualized. Particular focus should be given to transfusion, cardiac and liver status, diabetes, thrombotic risk and bone problems.

Transfusion requirements often increase during pregnancy and patients who were not previously transfusion dependent may become so. Pre-transfusion haemoglobin should remain above 100 g/L and any red cell antibodies (e.g. Kell, rhesus) should be monitored and the risk of haemolytic disease of the newborn considered.

Between 6 and 8% of patients are diabetic due to iron overloading. They should be managed as per standard guidelines for diabetes in pregnancy. Transfusion-dependent patients are often osteoporotic and osteopenic and may worsen during pregnancy. Vitamin D, calcium supplements and analgesia should be given as necessary. Caesarean section is frequent as many patients have small stature due to cephalopelvic disproportion.

Thrombotic risk is significant, particularly in splenectomized transfusion-independent thalassaemia intermedia patients. The Royal College of Obstetricians and Gynaecologists guidelines recommend aspirin 75 mg/day in splenectomized patients or patients with a platelet

count above 600×10^9/L, and aspirin and LMWH prophylaxis if they have both.

Because cardiac failure and arrhythmias are the commonest cause of death, women with thalassaemia should see a cardiologist before pregnancy. Monitoring with regular echocardiography and iron chelation with desferrioxamine during pregnancy may be appropriate in those with cardiac decompensation or high liver iron (associated with significant myocardial iron).

An ultrasound scan at 7–9 weeks, for the high rate of fetal loss, and 4-weekly growth scans from 24 weeks are recommended. Delivery should be as per obstetric indications and individualized. Peripartum iron chelation to minimize the risk of iron free radicals causing myocardial damage during labour is suggested in transfusion-dependent patients. Regular iron chelation should restart post partum and breastfeeding is safe with this. Women with thalassaemia are high risk for venous thromboembolism.

Summary box 12.4

- Pregnancies in patients with haemoglobinopathies are high risk.
- A woman's health should be optimized prior to pregnancy, including discontinuation of teratogenic medication.
- Care should be multidisciplinary.
- Thromboembolism risk is increased.

Prevention of haemolytic disease of the fetus and newborn

Haemolytic disease of the fetus and newborn (HDFN) is caused by immune-mediated destruction of fetal red cells that have been 'sensitized' by maternal antibodies. Rapid haemolysis can occur, rendering the fetus hydropic, anaemic and at risk of kernicterus in the first few days of life. ABO incompatibility is common but this is usually mild. Severe HDFN is most frequent with anti-D but can occur with a variety of antibodies including anti-c, anti-E and anti-K. Antibodies are formed following exposure to non-self red cell antigens during transfusion or pregnancy. Fetomaternal haemorrhage, and therefore risk of iso-immunization, is greatest at delivery but other potentially sensitizing events are listed in Table 12.5.

Around 15% of pregnant women are RhD negative. Historically, many developed anti-D antibodies when pregnant with an RhD-positive fetus and developed HDFN in subsequent RhD-positive pregnancies. However, the use of anti-D immunoglobulin after sensitizing events and as prophylaxis, initially following delivery and then additionally during the third trimester, has all but eradicated the problem. Anti-D immunoglobulin binds to fetal RhD-positive cells and causes their removal by the reticuloendothelial system before anti-D is produced. Independent of sensitizing events, some fetal cells circulate in the maternal circulation, especially in the third trimester, providing the rationale for routine anti-D immunoprophylaxis.

Table 12.5 Potentially sensitizing events leading to iso-immunization.

Miscarriage/threatened miscarriage
Ectopic pregnancy
Hydatidiform mole
Termination of pregnancy
Amniocentesis/chorionic villous sampling
Abdominal trauma
Antepartum haemorrhage/uterine bleeding
External cephalic version
Intrauterine death
Delivery (all methods)

In the UK, all women have ABO, Rh grouping and antibody screening at booking and 28 weeks [3]. Therefore, RhD-negative mothers should be identified routinely, educated about sensitizing events and offered routine antenatal anti-D prophylaxis (RAADP). There are two schedules in use: 500 IU at 28 and 34 weeks or 1500 IU at 28 weeks. During early pregnancy, fetal blood volume is small, lessening the chance of sensitization but this risk increases throughout pregnancy. Therefore, for events up to 20 weeks 250 IU of anti-D immunoglobulin is given and there is no necessity to calculate the size of fetomaternal haemorrhage (FMH). After 20 weeks, 500 IU is given and a test for FMH performed (Kleihauer or flow cytometry). If greater than 4 mL, further anti-D should be administered (125 IU of anti-D immunoglobulin covers 1 mL of FMH). Doses should be given as soon as possible after the sensitizing event and definitely within 72 hours. However, there may be benefit up to 10 days after the event. Routine anti-D should be given regardless of recent doses for sensitizing events and at birth cord samples for ABO and Rh grouping should be sent. Mothers with RhD-positive babies should receive 500 IU anti-D, a test for FMH and more doses as necessary.

Until recently, all RhD-negative women were recommended to have anti-D immunoprophylaxis. However, approximately 40% of RhD-negative women will be carrying RhD-negative babies and therefore do not need anti-D immunoprophylaxis. It is now possible to determine fetal RhD status by detecting cell-free fetal DNA in the maternal circulation via a maternal blood test after 12 weeks' gestation. Therefore, the National Institute for Health and Care Excellence (NICE) recommends that this is routinely offered to RhD-negative women to avoid unnecessary anti-D.

Women noted to have a clinically significant antibody should be referred to a specialist, ideally before pregnancy,

Table 12.6 Risk of developing haemolytic disease of the fetus and newborn (HDFN) with clinically significant antibody levels.

Risk of developing HDFN	Anti-c	Anti-D	Anti-K
Mild	<7.5 IU/mL	<4 IU/mL	Severe fetal anaemia can occur even with low titres so refer once detected
Moderate	>7.5 to <20 IU/mL	>4 to <15 IU/mL	
Severe	>20 IU/mL	>15 IU/mL	
Level to refer to fetal medicine specialist	>7.5 IU/mL	>4 IU/mL	

to discuss HDFN risk and potential cross-matching difficulties. Despite RAADP, anti-D remains the commonest. Determining the father's red cell phenotype is useful for predicting the chances of the fetus carrying the relevant red cell antigen. However, it should be noted that the stated father may not be the biological father.

Once pregnant, if the father's antigen status is unknown or his red cells express the corresponding antigen, it is possible to determine fetal RhD, Rhc and Kell genotypes from free fetal DNA in maternal blood samples from 16 weeks. If the fetus is negative for the corresponding antigen, the parents can be reassured; if positive, the fetus and mother can be carefully monitored.

Once a clinically significant antibody is detected, an antibody titre will be determined. This correlates with the chance of developing HDFN (Table 12.6).

Anti-D, anti-c and anti-K titres should be performed every 4 weeks until 28 weeks and then fortnightly until delivery. Other antibodies should be retested at 28 weeks and referral to a fetal medicine specialist made if its presence dilutes at more than 1 : 32 or there is a previous history of HDFN. Once the antibody titre threshold is met, patients should undergo weekly ultrasound scans to assess the fetal middle cerebral artery peak systolic velocity. If this rises above 1.5 times the median threshold or there are other signs of fetal anaemia, consideration should be given to invasive treatment, i.e. intrauterine transfusion with red cells negative for the causative antigen.

Summary box 12.5

- HDFN is immune-mediated red cell destruction of fetal/newborn red cells and may cause hydrops, anaemia and kernicterus.
- The best 'treatment' is prevention and RAADP has greatly reduced the incidence.
- Anti-c, anti-D and anti-K are the most commonly encountered causes of significant HDFN.

Fetal/neonatal thrombocytopenia

Fetal/neonatal alloimmune thrombocytopenia (FNAIT) is analogous to HDFN but affects platelets rather than red cells. It is the most common cause of severe neonatal thrombocytopenia and is caused by immune-mediated destruction of fetal platelets by maternal antibodies. Human platelet antigens (HPAs) are expressed on fetal platelets from around 16 weeks' gestation and those which are paternally derived may cause maternal alloimmunization and placental transfer of maternal immunoglobulin. Approximately 80% of cases are due to HPA-1a incompatibility, detected in around 1 in 1000 live births but estimated to be considerably under-diagnosed. A further 15% are due to HPA-5b incompatibility and the remaining 5% are caused by antibodies against other HPAs.

Although it often affects first pregnancies (unlike HDFN), there is no programme for routine screening for anti-HPA antibodies in the UK and the diagnosis is considered on clinical grounds (Table 12.7) and confirmed with laboratory tests (Table 12.8).

Women with known HPA antibodies, or those whose sisters have had babies affected by FNAIT, should be referred to a haematologist and fetal maternal medicine unit, ideally before pregnancy, to discuss FNAIT risk and plans for antenatal management. Until a few years ago, this involved intrauterine assessment of fetal platelet count and transfusion of compatible platelets through the umbilical cord. Serial procedures were required for those with severe thrombocytopenia, increasing the chance of fetal death from haemorrhage or umbilical artery thrombosis from the concentrated platelet transfusion. Recent treatment strategies have been non-invasive and involve reduction of maternal immunoglobulin with intravenous immunoglobulin with or without steroids.

Table 12.7 Clinical suspicion of fetal/neonatal alloimmune thrombocytopenia.

Neonatal thrombocytopenia, unexplained by maternal autoimmune disease or drug ingestion, neonatal sepsis, DIC or congenital anomalies known to be associated with thrombocytopenia
Neonatal platelet count $<50 \times 10^9$/L
Intracranial haemorrhage in fetus or neonate
Unexplained hydrocephalus

DIC, disseminated intravascular coagulation.

Table 12.8 Laboratory tests required for diagnosis of fetal/neonatal alloimmune thrombocytopenia.

Detection and identification of the maternal HPA antibody
Determination of the HPA genotype of the mother, baby and father, depending on results and availability
Cross-match of maternal serum and paternal platelets

Summary box 12.6

- FNAIT is alloimmune-mediated destruction of fetal/newborn platelets.
- Treatment of affected pregnancies is non-invasive, with regular administration of intravenous immunoglobulin with or without steroids.
- Anti-HPA-1a and anti-HPA-5b are the most commonly encountered causes of significant FNAIT.

Haemostatic measures in obstetric haemorrhage

Major postpartum haemorrhage (>1000 mL blood loss after delivery) is a major cause of maternal death in the developed world. It has multiple aetiologies and requires a multidisciplinary team focusing on resuscitation, local control of bleeding, and haemostasis. This section considers the organizational and haemostatic measures only.

All delivery centres should have a major obstetric haemorrhage protocol. This should detail how to alert key staff, how to transport samples to the laboratory and obtain blood products quickly, the policy on non-cross-matched blood, recommended resuscitation measures and blood product use and haemostatic monitoring. Good communication is essential, with a designated team leader and person to liaise with the transfusion laboratory.

Blood component management in obstetric haemorrhage is similar to that for other causes of major haemorrhage, except that many patients have a group and save on record, enabling group-specific blood in advance, and fibrinogen replacement should be at a higher level. Fibrinogen levels rise throughout pregnancy and are around 4–6 g/L at delivery. A level of 2–3 g/L signifies significant loss and should prompt replacement with cryoprecipitate.

Initial resuscitation is with red cells and fresh frozen plasma (FFP) in a 2 : 1 ratio until bleeding is under control or coagulopathy monitoring results are available to guide product replacement. The following parameters are suggested.

- Keep APTT and prothrombin time (PT) ratio within 1.5 times normal with FFP.
- Keep platelets above 50×10^9/L with platelets.
- Keep fibrinogen above 2 g/L with cryoprecipitate.

Tranexamic acid reduces death due to bleeding in women with postpartum haemorrhage with no adverse effects. When used as a treatment for postpartum haemorrhage, it should be given as soon as possible after bleeding onset [4].

Standard coagulopathy monitoring includes platelet count, APTT, PT and fibrinogen every 30–60 min. In a massive haemorrhage setting, any delay in obtaining test results can mean they do not accurately reflect the clinical situation. Therefore, many centres are using near-patient testing such as thromboelastography or ROTEM. These measure the global viscoelastic properties of whole blood clot formation and reflect the interaction of platelets with the coagulation cascade. Common defects in coagulopathic patients, such as thrombocytopenia and increased fibrinolysis, can be easily identified and used to guide blood product replacement. They more accurately reflect the current clinical situation but are not currently recommended in guidelines due to the lack of trial data supporting their use.

Summary box 12.7

- Major obstetric haemorrhage remains a leading cause of direct maternal death.
- All centres should have an obstetric major haemorrhage protocol.
- Blood product replacement is similar to that for non-pregnant patients, except that fibrinogen replacement should be given at a higher level.

Thrombosis and thromboembolism

The leading cause of direct maternal death is venous thromboembolism (VTE), causing death in 1 in 100 000 pregnancies in 2011–2013 [5]. Half occured antenatally (50% first trimester, 25% second, 25% third) and half postnatally. Failings were shown in identifying those at risk, considering the diagnosis and implementing appropriate treatment.

Virchow's triad states that there are three components to thrombus formation: blood stasis, hypercoagulability and blood vessel wall damage. In pregnancy, blood flow in the lower limbs slows by up to 50% by 29 weeks and this persists for 6 weeks post partum. There is an increase in factor VIII and fibrinogen, reduction in protein S and impaired fibrinolysis, producing a hypercoagulable state and vessel wall damage during delivery by any means. The rate of VTE is increased fourfold to sixfold antenatally and 20-fold postnatally, although the absolute risk remains low at 1 in 1000 pregnancies.

Deep vein thrombosis (DVT) in pregnancy affects the left leg in 90% of cases (compared with 55% in non-pregnant women), due to compression of the left iliac vein by the right iliac and ovarian arteries; 70% are ileo-femoral, as opposed to 10% in non-pregnant patients, and they carry a much higher chance of pulmonary embolism (PE).

The diagnosis of VTE in pregnancy is difficult as many of the symptoms and signs, such as leg swelling, dyspnoea and chest pain, occur in normal pregnancy. Less

than 10% of pregnant women clinically suspected of having DVT and less than 5% suspected of having PE are confirmed on objective testing. However, as mortality of untreated PE is high, it is important that patients are treated with LMWH as soon as the diagnosis is suspected unless there are significant contraindications.

Compression duplex ultrasound of the entire proximal venous system should be undertaken when there is clinical suspicion of DVT. If negative but the diagnosis is likely, patients should remain anticoagulated and the scan repeated in a week. If iliac vein thrombosis is suspected, Doppler ultrasound of the iliac vein, magnetic resonance venography or conventional contrast venography should be performed.

In a haemodynamically stable patient, first-line investigations for suspected PE should be chest X-ray and ECG. Chest X-ray confers negligible radiation to the fetus, at any stage of pregnancy, and may reveal an alternative cause for the symptoms, such as pneumonia or pneumothorax. A *V*/*Q* scan can only be interpreted if the chest X-ray is normal. ECGs are more frequently abnormal in pregnant than non-pregnant women, with the most common abnormalities being T-wave inversion, S1Q3T3 and right bundle branch block.

Women with suspected DVT as well as PE should have compression duplex ultrasound of the lower limbs initially. If DVT is confirmed no further investigations are needed, as treatment for PE and DVT is the same. There is also an argument that women with suspected PE in the absence of leg symptoms should have leg scanning initially, as a positive diagnosis of DVT will negate the need for a radiation dose to the mother and fetus. However, the detection rate of this approach is very small and many centres have discontinued this practice.

In women with suspected PE and no DVT, either CT pulmonary angiography (CTPA) or *V*/*Q* scan should be performed. The choice will depend on a number of factors, including availability, local guidelines and patient preference. A *V*/*Q* scan cannot be used if the chest X-ray is abnormal.

Advantages of CTPA are that it is quick, readily available and conclusive and will identify alternative pathologies. CTPA delivers less radiation to the fetus than *V*/*Q* scanning in all stages of pregnancy. Its major disadvantage is the high radiation dose to the mother's breast tissue, which is associated with an increased lifetime risk of breast cancer of 13% above their background risk. Therefore, particularly in young women and those with a family history of breast cancer, lung perfusion scan may be the better choice. Ventilation–perfusion scans or perfusion scans alone are associated with a higher radiation dose to the fetus but this is still small (the risk of fatal cancer to the age of 15 is less than 1 in 280 000). They scans cannot evaluate other pathologies except PE but deliver a much smaller radiation dose to the breast tissue.

In non-pregnant patients, a normal D-dimer, in combination with pretest probability testing, has a high negative predictive value for VTE. However, because D-dimers rise in normal pregnancy, there are no clinically validated pretest probability scores in pregnancy and false negatives have been described in pregnant patients with VTE, D-dimer levels are not currently recommended in the pregnancy setting.

Treatment of haemodynamically stable VTE

On clinical suspicion of VTE, treatment should be instigated with LMWH unless strongly contraindicated. Bloods tests should be performed to check coagulation screen, platelet count and any evidence of renal or hepatic disease. Although half of patients who have a VTE in pregnancy will have an underlying inherited or acquired thrombophilia, thrombophilia testing is not recommended in the acute setting, as results are difficult to interpret and do not change immediate management.

LMWH is the treatment of choice in pregnancy as it is effective, easy to give, does not routinely require monitoring and has lower rates of haemorrhage, osteoporosis and heparin-induced thrombocytopenia than unfractionated heparin. Intravenous unfractionated heparin is useful in patients who might require their anticoagulation to be stopped quickly, for example those at high risk of bleeding or those in severe renal failure. Vitamin K antagonists should not be used as they cross the placenta and are associated with pregnancy loss, embryopathy and fetal haemorrhagic complications. Treatment of VTE with the new direct oral anticoagulants is becoming commonplace outside of pregnancy. However, the trials excluded pregnant patients and the teratogenicity in humans is unknown so currently they should be avoided.

LMWH should be dosed according to early pregnancy weight. Previously, dalteparin and enoxaparin were given twice daily in pregnancy due to altered renal glomerular filtration and volume of distribution but newer evidence suggests that once-daily dosing is adequate and this should be decided on a local level. Routine monitoring of LMWH with anti-Xa levels is only recommended for those at extremes of body weight (<50 or >90 kg) or with other complicating factors such as renal impairment. As the rate of heparin-induced thrombocytopenia is negligible with LMWH, platelet monitoring is not necessary.

Women on therapeutic anticoagulation require an individualized plan for delivery and the postpartum period. Women should not inject further LMWH if they think they are in labour or have any bleeding. Regional anaesthetics should not be used until 24 hours after the last therapeutic dose of LMWH or 12 hours after the last prophylactic dose. Induction of labour allows LMWH to be reduced to a prophylactic dose the day before induction and therefore facilitates the use of regional anaesthetics

with minimal interruption of anticoagulation. Epidural catheters should not be removed within 12 hours of a dose of LMWH, and LMWH should not be given until at least 4 hours post removal. Post partum, LMWH should be restarted as soon as possible. This is often a prophylactic dose 4–6 hours after delivery (assuming no bleeding concerns) and then treatment dose from 12 hours.

Women should remain on LMWH for the remainder of their pregnancy and for at least 6 weeks post partum and until at least 3 months of treatment has been given. Post partum, once-daily dosing is adequate and women may be switched to warfarin if they prefer. Before discontinuing treatment a review assessing an individual's ongoing risk of thrombosis should be performed.

Management of acute life-threatening PE

Massive PE may present with shock, refractory hypoxia and/or right ventricular dysfunction. It is a medical emergency and should be managed by a multidisciplinary team including senior medics, obstetricians and radiologists who decide on an individual basis whether a woman receives intravenous unfractionated heparin, thrombolytic therapy or thoracotomy and surgical embolectomy.

Intravenous unfractionated heparin is preferred to LMWH due to its quicker effect and easier dose adjustments but it does not reduce the size of the clot in the pulmonary circulation. Therefore, in massive life-threatening PE with cardiovascular compromise (or in limb-threatening DVT) thrombolysis should be considered. Ideally, portable echocardiography or urgent CTPA should be performed first, but in extreme circumstances immediate thrombolysis may be appropriate.

The most common agent used is streptokinase and this is followed with an intravenous heparin infusion, minus the loading dose. There are now several cases of thrombolysis in pregnancy with no maternal deaths and with rates of bleeding (which is usually minor) similar to those in non-pregnant patients (6%).

Summary box 12.8

- VTE is the leading cause of direct maternal deaths in the UK.
- Treatment-dose LMWH (unless contraindicated) should be started on suspicion of VTE and the diagnosis confirmed by objective testing.
- CTPA and *V/Q* scans can both be used to confirm the diagnosis of PE in pregnancy.
- CTPA confers an increased risk to the mother of solid tissue tumours.
- Consider thrombolysis in suspected PE with haemodynamic compromise.

Prevention of VTE in pregnancy and the puerperium

In two-thirds of women suffering a PE there are identifiable risk factors (Tables 12.9 and 12.10).

Despite very limited data from randomized controlled trials, thromboprophylaxis in at-risk pregnancies has been recommended practice for a number of years and is known to be efficacious, cost-effective and safe [3]. Women should be risk assessed for VTE in early pregnancy and this should be repeated on admission, during and after birth, and if an additional problem develops. Hospitals should have patient information sheets on VTE and prescriptions for the entire course should be issued by secondary care to avoid breaks in treatment and enable dose checking by pharmacists [2].

High-risk women, prior to pregnancy, should be counselled and given a prescription for LMWH to start as soon as the pregnancy test is positive to ensure cover for the first trimester. Women on long-term warfarin for recurrent VTE or cerebrovascular accident are at high risk of VTE during pregnancy. Their care should be individualized, with input from an obstetric haematologist, but will likely be treated with high prophylactic or full-dose LMWH.

Tables 12.9 and 12.10 outline the recommended thromboprophylaxis. Women should be educated about the reasons behind thromboprophylaxis and the risk of bleeding and taught how to inject themselves. A plan for thromboprophylaxis around delivery should be made, as detailed in the previous section. Thromboprophylaxis should be started as soon as possible after delivery, assuming no haemorrhagic concerns arise.

Summary box 12.9

- All women should be risk assessed for VTE in early pregnancy or pre-pregnancy. This should be repeated if admitted or another problem develops and during or immediately after birth.
- Thromboprophylaxis should be given depending on the level of risk.

Inherited bleeding disorders

During pregnancy, inherited bleeding disorders can increase the risk of maternal bleeding and, depending on inheritance, confer a neonatal bleeding risk [7]. The commonest disorders in the obstetric population are von Willebrand disease and haemophilia A and B.

Von Willebrand disease (vWD) is caused by either a qualitative or quantitative deficiency of vWF, required for platelet adhesion. Severity varies, depending on type.

Table 12.9 Antenatal risk factors for venous thromboembolism (VTE).

Risk factors	Management
High risk	
Any previous VTE except a single event post surgery	Antenatal prophylaxis with LMWH
Intermediate risk	
Hospital admission	Consider antenatal prophylaxis with LMWH
VTE post surgery	
High-risk thrombophilia	
Medical comorbidities, e.g. cancer, nephrotic syndrome, sickle cell disease, SLE, IVDU	
Any surgical procedure	
Ovarian hyperstimulation syndrome (first trimester)	
Lower risk	
BMI >30 kg/m^2	Four or more risk factors: prophylaxis from first trimester
Age >35	Three or more risk factors: prophylaxis from 28 weeks
Parity ≥3	Less than three risk factors: mobilize and avoid dehydration; no pharmacological thromboprophylaxis
Smoker	
Gross varicose veins	
Current pre-eclampsia	
Immobility	
Family history of unprovoked or oestrogen-provoked VTE in first-degree relative	
Low-risk thrombophilia	
Multiple pregnancy	
In vitro fertilization/assisted reproductive technology	
Current systemic infection/hyperemesis/dehydration	
Long haul flight	

BMI, body mass index; IVDU, intravenous drug user; LMWH, low-molecular-weight heparin; SLE, systemic lupus erythematosus.
Source: adapted from Royal College of Obstetricians and Gynaecologists [6].

Table 12.10 Postnatal risk factors for VTE.

Risk factors	Management
High risk	
Any previous VTE	At least 6 weeks postnatal prophylactic LMWH
Anyone on antenatal LMWH	
High-risk thrombophilia	
Low-risk thrombophilia and family history of VTE	
Intermediate risk	
Caesarean section in labour	At least 10 days postnatal prophylactic LMWH
BMI >40 kg/m^2	If persisting or more than three risk factors, consider 6 weeks prophylactic LMWH
Readmission or ≥3 day admission in puerperium	
Any surgical procedure in the puerperium except immediate perineal repair	
Medical comorbidities	
Lower risk	
BMI >30 kg/m^2	Two or more risk factors: 10 days of postnatal prophylactic LMWH
Age >35	Less than two risk factors: early mobilization and avoidance of dehydration; no pharmacological thromboprophylaxis
Parity ≥3	
Smoker	
Gross varicose veins	
Immobility	
Family history of VTE	
Low-risk thrombophilia	
Multiple pregnancy	
Current systemic infection	
Elective caesarean section	
Current pre-eclampsia	
Preterm delivery in this pregnancy (<37 weeks)	
Stillbirth in this pregnancy	
Mid-cavity rotational or operational delivery	
Prolonged labour (>24 hours)	
Postpartum bleeding >1 L or blood transfusion	

vWF levels rise during pregnancy, so many women at the milder end of the spectrum do not require intervention. However, those with an abnormal or completely absent vWF can have severe bleeding complications without treatment. Levels decrease rapidly in the postpartum period, putting women at risk of postpartum haemorrhage.

Management should be multidisciplinary and begin before conception. Principles include educating the mother on her risk of bleeding and the inheritance of her particular type of vWD, potentially offering prenatal diagnosis, monitoring vWF levels and activity, and ensuring a detailed plan for delivery and the postpartum period. Women with bleeding or inadequate factor levels who are undergoing invasive procedures or delivery require treatment. This should be directed by a haemophilia centre but usually involves desmopressin or vWF concentrate. Mode of delivery should be obstetrically determined; epidural anaesthesia requires vWF activity to be greater than 0.5 IU/mL, although should not be undertaken likely due to the risk of spinal haematoma. For neonates at risk of moderate to severe disease, fetal scalp monitoring and sampling, ventouse and rotational forceps should be avoided. Active management of the third stage is suggested and tranexamic acid for 1–2 weeks during the postpartum period reduces vaginal bleeding.

The haemophilias are X-linked and therefore male fetuses have a 50% chance of being affected and female fetuses a 50% chance of being carriers. Most affected mothers are asymptomatic but due to unequal lyonization may have low factor levels requiring haemostatic support during invasive procedures, delivery and the postpartum period. This should be directed by a haemophilia centre and tends to be greater in haemophilia B carriers as factor IX levels do not increase in pregnancy.

Women should be offered prenatal diagnosis of haemophilia. If a couple are likely to consider terminating an affected fetus, this should be in early pregnancy. Maternal blood sampling is usually used to determine fetal sex by means of free fetal DNA between 9 and 11 weeks. If female, no further testing is required, but for males chorionic villous sampling is offered between 11 and 13 weeks. Women who do not wish to have invasive early testing should be encouraged to have their fetus sexed at the 20-week scan and in some centres third-trimester amniocentesis is offered for male fetuses to determine if they are affected and plan for delivery. For male babies at risk, traumatic procedures (as for vWD) should be avoided and they should receive vitamin K orally. Women should have active management of the third stage of labour.

Summary box 12.10

- Inherited bleeding disorders confer a bleeding risk to the mother and possibly the fetus.
- Care should be multidisciplinary starting before conception and continuing through the postpartum period.
- Mothers may need haemostatic support to cover invasive procedures, delivery and the postpartum period and should be encouraged to have an active third stage.
- Traumatic procedures should be avoided during delivery for potentially affected fetuses and vitamin K should be given orally.

Myeloproliferative disorders in pregnancy

The myeloproliferative disorders are a group of conditions characterized by the clonal proliferation of one or more haemopoietic bone marrow components. The commonest conditions are polycythaemia vera, chronic myelogenous leukaemia, primary or essential thrombocythaemia and primary myelofibrosis. Thrombosis and haemorrhage are major causes of morbidity in these conditions and pregnancy outcomes have historically been poor.

An awareness of these conditions is important for obstetricians as they occasionally present in pregnancy and if the diagnosis is made and treatment implemented, pregnancy outcomes are improved. Pregnancies in patients with a known myeloproliferative disorder are also becoming more commonplace. These should be managed in a multidisciplinary setting with the input of a haematologist and obstetrician specializing in high-risk patients. Management should include pre-conception optimization of the condition, including withdrawal of potentially teratogenic medications (hydroxycarbamide and anagrelide), thrombotic risk assessment and plan to control haematocrit and platelet count during pregnancy. Venesection and/or interferon alfa are safe for haematocrit and platelet count control and aspirin with or without LMWH for the thrombotic risk.

Haematological malignancy during pregnancy

Haematological malignancies, namely acute leukaemias and lymphomas, may be diagnosed during pregnancy. Optimal treatment for the woman may result in fetal malformations or death and therefore can present a

difficult dilemma for the patient, family and medical team. Patients should be managed in a multidisciplinary setting including haematologists, obstetricians and neonatologists and given plenty of support as they make their decision. Consideration should be given to gestation, risks to the mother of waiting to treat the condition, and the risks to the fetus of maternal treatment needed. In general, chemotherapy and radiotherapy in the first trimester are associated with significant risks of congenital malformations and miscarriage and this risk lessens with advancing pregnancy. It is often recommended to terminate pregnancies in women presenting with a malignancy in the first trimester. For those presenting after 32 weeks it is often possible to deliver the baby before starting chemotherapy; for those between 24 and 32 weeks, the risk of fetal exposure to chemotherapy drugs should be balanced against the risks of premature delivery at that stage of gestation.

[2] *Fetal Medical Unit, St George's University of London, London, UK*

Perinatal infections continue to affect pregnancies in the UK and worldwide. Most perinatal infections are asymptomatic in the mother, but may have serious consequences for the fetus. Pregnant women are exposed to infections prevalent in the community but they are also likely to reside with young children and this represents a significant additional factor in exposure to infectious agents. Most infections in pregnancy resolve spontaneously without therapy or are readily treated with antimicrobial agents. Such infections usually have no effect on the developing fetus. However, the infecting organism may invade the bloodstream and subsequently infect the placenta and fetus. Transplacental spread and invasion of the bloodstream after maternal infection is the usual route by which the fetus is infected. Uncommonly, the fetus may be infected by extension of infection into adjacent maternal tissues and organs, including the peritoneum and the genitalia, during delivery, or as a result of invasive procedures, such as the use of monitors, chorionic villous biopsy, sampling of fetal blood and intrauterine transfusion. Before rupture of fetal membranes, organisms in the genital tract may invade the amniotic fluid and infect the fetus. These organisms can invade the placenta through microscopic defects in the membranes, particularly in devitalized areas overlying the cervical os.

Microorganisms of concern include those identified in the acronym TORCH: toxoplasmosis, rubella, cytomegalovirus, and herpesvirus; the 'O' in TORCH originally stood for 'other infections'. A new acronym should include other well-described causes of *in utero* infection: syphilis, hepatitis B, HIV and parvovirus. The UK screening programme for infectious disease in pregnancy advocates routine screening for HIV, hepatitis B, rubella and syphilis. The policy and standards are agreed by the National Screening Committee and published in the National Institute for Health and Care Excellence (NICE) antenatal care guidelines [1]. The prevalence of all four of these infections is still significant in the UK and particularly in inner cities such as London [2] (Table 13.1) and therefore routine antenatal screening is essential to prevent mother-to-child transmission of hepatitis B, HIV and syphilis. The screening programme also identifies women for whom postnatal MMR (measles, mumps, rubella) vaccination could protect future pregnancies. The programme stipulates the following.

1) All pregnant women are offered screening at the booking visit for rubella antibody, syphilis, HIV and hepatitis B as an integral part of their antenatal care during their first and all subsequent pregnancies regardless of immunization history.
2) Although every woman has the right to decline screening, if screening has been declined at booking, it should be re-offered at 28 weeks' gestation.
3) Pregnant women arriving in labour who have not received antenatal care elsewhere are offered screening for infectious diseases. Priority is given to hepatitis B and HIV screening and presumptive action is taken on a preliminary positive result until the result is confirmed. If an HIV test result is not available, appropriate preventive measures should be offered. In cases where consent for screening is withheld during labour, screening is offered again after delivery.
4) If there is a screen-positive result, the current national standards state a second sample should be taken for syphilis, hepatitis B and HIV to confirm the screening result. Following this result the women should be referred for specialist counselling and appropriate follow-up and management [3].

Table 13.1 Prevalence of infections in London (data based on annual reports).

Infection	Prevalence (%) 2011–2012	Prevalence (%) 2012–2013	Prevalence (%) 2013–2014
Syphilis	0.3	0.3	0.3
Hepatitis B	1.1	1.5	0.9
HIV	0.4	0.7	0.3
Susceptibility to rubella	5.1	5.9	6.5

Human immunodeficiency virus

The human immunodeficiency virus type 1 (HIV-1) pandemic remains one of the greatest public health challenges in the 21st century. The care of HIV-infected women is more effective than ever and the rates of mother-to-child transmission of HIV are lower than ever in communities with access to therapy. Because of widespread implementation of routine antenatal screening for HIV, antiretroviral therapy (ART) during pregnancy, elective caesarean section and avoidance of breastfeeding, transmission of HIV-1 from mother to child is now a rare occurrence in the UK. However, mother-to-child transmission of HIV still represents the most common source of HIV infection among infants and children. In 2014, there were an estimated 103 700 people living with HIV in the UK. The prevalence of HIV in the UK among those aged 15–44 years in 2014 was estimated to be 1.7 per 1000 women. The HIV epidemic remains largely concentrated among gay, bisexual men and men and women of black African ethnicity [4,5].

Pathogenesis and transmission

HIV is a retrovirus that infects and damages T lymphocytes, resulting in immunosuppression and eventually leading to AIDS. Two types of HIV viruses, HIV-1 and HIV-2, can cause AIDS in humans. HIV-1 and HIV-2 are lentiviruses belonging to the *Retroviridae* family and have a complex genomic structure [6]. The commonest and most virulent form is HIV-1, with HIV-2 being relatively uncommon in Western countries.

HIV can be transmitted through sexual contact or via contaminated blood, for example needle sharing. Mother-to-child transmission of HIV can occur *in utero*, during labour and delivery, or postnatally through breastfeeding. *In utero* transmission may occur through HIV infection in the placenta or fetal exposure to cell-free or cell-associated HIV in the amniotic fluid. Intrauterine transmission occurs in about 20–25% of infections and mostly occurs during the last few weeks before delivery when the vascular integrity of the placenta is disrupted. Intrapartum transmission may occur because of direct exposure of the fetus to infected maternal secretions during birth. Although numerous maternal, obstetric, infant, host genetic, and viral factors may modify perinatal HIV transmission risk, maternal plasma HIV RNA level is the strongest predictor of intrauterine and intrapartum transmission. Other maternal risk factors associated with higher rates of perinatal HIV infection include women with advanced clinical disease, acute HIV infection during pregnancy, and low $CD4^+$ counts. Obstetric risk factors associated with increased risk of transmission include vaginal delivery, prolonged rupture of membranes, chorioamnionitis and invasive obstetric procedures.

In the absence of interventions, postnatal transmission of HIV through breastfeeding can account for one-third to half of all HIV infections globally and carries an estimated transmission risk of about 15% when breastfeeding is prolonged. Risk factors for breast-milk HIV transmission include women seroconverting during lactation, high HIV DNA or RNA level in maternal plasma and breast milk, low maternal $CD4^+$ cell count, maternal symptomatic disease or AIDS, prolonged duration of breastfeeding, mixed infant feeding, oral lesions in the infant, abrupt weaning and maternal breast problems.

Diagnosis

In England, the routine offer and recommendation policy was implemented in 2000, and similar policies were subsequently adopted elsewhere in the UK. National uptake of antenatal HIV screening was reported to be 95% in 2008. Between 2000 and 2004 the majority of HIV-infected women diagnosed before delivery were identified through antenatal screening. However, by 2011, over 80% of women diagnosed before delivery were already aware of their infection before they conceived, many of them diagnosed in a previous pregnancy. Pregnant women should be offered screening for HIV infection at their booking appointment because appropriate antenatal interventions can reduce mother-to-child transmission of HIV infection. If screening has been declined at booking, it should be offered again at 28 weeks' gestation. Pregnant women arriving in labour who have not received antenatal care elsewhere should be offered screening for HIV. If an HIV test result is not available, appropriate preventive measures should be offered. In cases where consent is withheld for screening during labour, screening is offered again after delivery [5].

Management

If there is a primary laboratory screen-positive result (positive ELISA), the samples are referred for testing by a specialist laboratory to confirm the reactivity is specific

for HIV (by Western blot) involving at least two further independent assays. Obtaining a CD4 count and a viral load provides the clinician with a useful snapshot of the patient's status and medication needs when she is first encountered. All women who have confirmed positive test results should be counselled in person and offered specialist counselling and support, which is also available for their partners and family if requested. Women found to be positive are referred for specialist HIV treatment within a multidisciplinary framework. This would involve advice about management of their infection and interventions to reduce the risk of vertical and sexual transmission, including discussions on the use of antiretrovirals and caesarean section, early treatment and care for the child, and decisions about breastfeeding. It also provides an opportunity to reinforce health promotion advice and to discuss arrangements for partner notification and testing of previous children. HIV-positive results also need to be accessible to members of staff at all times to inform appropriate clinical care, particularly in the delivery suite when the woman arrives in labour. It is also important to ensure that a paediatric care plan is determined prior to the birth to ensure the mother understands and has consented for testing and potential treatment regimens after delivery.

ART has been shown to significantly reduce the rate of vertical transmission. Zidovudine chemoprophylaxis given in the prenatal and intrapartum period and to the newborn reduces vertical transmission from 27.7 to 7.9% [7]. However, zidovudine monotherapy is considered inappropriate in mothers with high viral load or low CD4 counts because it fails to suppress viral replication and increases the risk of development of viral resistance. The British HIV Association [5] recommend the use of combination ART in order to achieve prolonged viral suppression when treatment is indicated, with the aim of reducing the viral load to below detectable levels, and recommend that HIV infection in pregnant women should be treated as infection in non-pregnant patients. It is therefore recommended that advanced HIV infection in pregnant women should be treated with combination ART, which through more complete suppression of viral replication allows greater and prolonged recovery of immune function. Women requiring ART for their own health should commence treatment as soon as possible, while all pregnant women should have commenced ART by week 24 of pregnancy. Zidovudine monotherapy can be used in women planning a caesarean section who have a baseline viral load of less than 10 000 HIV RNA copies/mL and a CD4 count above 350 cells/μL.

For women with a plasma viral load of less than 50 HIV RNA copies/mL at 36 weeks, and in the absence of obstetric contraindications, a planned vaginal delivery is recommended. Where the viral load is 400 HIV RNA copies/mL or more at 36 weeks, elective caesarean delivery is recommended. Where the indication for caesarean section is the prevention of vertical transmission, delivery should be planned at 38–39 weeks' gestation. Intrapartum intravenous zidovudine infusion is recommended for women with a viral load above 1000 HIV RNA copies/mL presenting in labour, or with ruptured membranes or who are admitted for planned caesarean section; for untreated women presenting in labour or with ruptured membranes in whom the current viral load is not known; and in women on zidovudine monotherapy undergoing elective caesarean section.

Neonatal post-exposure prophylaxis (usually oral zidovudine) should be commenced very soon after birth, certainly within 4 hours and should be given for 4 weeks. All mothers known to be HIV positive, regardless of ART and infant prophylaxis, should be advised to exclusively formula feed from birth.

Summary box 13.1

- All HIV-positive women should have commenced ART by week 24 of pregnancy.
- With viral load <50 HIV RNA copies/mL at 36 weeks, a planned vaginal delivery is recommended.
- With viral load ≥400 HIV RNA copies/mL at 36 weeks, elective caesarean delivery is recommended.

Hepatitis B

Hepatitis B is an infection of the liver caused by the hepatitis B virus (HBV). Many new infections with hepatitis B are subclinical or may manifest as a flu-like illness. Jaundice only occurs in about 30–50% of adults. The UK is a very low prevalence country, but prevalence of HBsAg varies across the country. The prevalence rates found in antenatal women vary from 0.05 to 0.08% in some rural areas but rise to 1% or more in certain inner city areas. Overall, the prevalence in antenatal women in the UK is around 0.14%. The incidence of acute infection is high among those with certain lifestyle or occupational risk factors. Most reports of acute infection in the UK occur as a result of injecting drug use or sexual exposure [8].

Pathogenesis and transmission

HBV is a well-characterized, partially double-stranded DNA virus. The virus is transmitted by parenteral exposure to infected blood or body fluids. Transmission mostly occurs through vaginal or anal intercourse, as a result of blood-to-blood contact (e.g. sharing of needles

and 'needlestick' injuries) or through perinatal transmission from mother to child.

The incubation period ranges from 40 to 160 days (average 60–90 days). Current infection can be detected by the presence of HBsAg in the serum. Blood and body fluids from HBsAg-positive individuals should be considered to be infectious. In most cases, infection will resolve and HBsAg disappears from the serum, but the virus persists in some patients who become chronically infected. Chronic hepatitis B infection is defined as persistence of HBsAg in the serum for 6 months or more. Individuals with chronic infection are referred to as chronic carriers. Among those who are HBsAg positive, those in whom hepatitis B e-antigen (HBeAg) is also detected in the serum are the most infectious. Those who are HBsAg positive and HBeAg negative (usually anti-HBe positive) are infectious but generally of lower infectivity. A proportion of chronically infected people who are HBeAg negative will have high HBV DNA levels, and may be more infectious. Around 20–25% of individuals with chronic HBV infection worldwide have progressive liver disease, leading to cirrhosis in some patients. The risk of progression is related to the level of active viral replication in the liver. Individuals with chronic infection, particularly those with active inflammation and/or cirrhosis, are at increased risk of developing hepatocellular carcinoma.

Perinatal transmission occurs at or near the time of birth because of exposure to cervical secretions and maternal blood. To a minor degree, transplacental transmission might be responsible for perinatal infections, depending on risk factors that include maternal HBeAg positivity, HBsAg titre, and HBV DNA level [6]. Mothers positive for HBeAg and mothers with very high serum DNA levels (e.g. 10^9 copies/mL) have the greatest risk of transmitting HBV to their offspring. Approximately 70–90% of mothers who are HBeAg positive will transmit the infection to the baby. The rate of transmission is approximately 10% in women with antibody to e antigen (anti-HBe). Mode of delivery does not influence the likelihood of HBV transmission. Another possible route of HBV transmission is amniocentesis in HBsAg-positive mothers. Although HBsAg can be detected in the breast milk of HBV-infected mothers, several studies have shown that there is no additional risk of transmission of HBV to breastfed infants of infected mothers, provided that proper active and passive immunoprophylaxis is carried out.

Clinical manifestations

The clinical manifestations of HBV infection depend on the age of acquisition. The risk of chronic infection is greater than 90% in neonates, and observed in only 5% of adults exposed to HBV. Approximately 6% of infants born to mothers who are positive for anti-hepatitis B early antibody develop acute hepatitis at 2 months of age. Infants are ill with fever, jaundice and hepatic tenderness. Serum aminotransferases are elevated, and there is active inflammation in the liver biopsy specimen. About one-third of older children and adolescents with acute HBV develop these classic symptoms. Most infants, children and adolescents have chronic infection (lasting longer than 6 months) of the asymptomatic immunotolerant type. Inactive carriers are characterized by HBsAg positivity, seroconversion of HBeAg to anti-hepatitis B early antibody, undetectable HBV DNA, and normal serum aminotransferases. Individuals with active hepatitis are at greatest risk for developing cirrhosis and hepatocellular carcinoma.

Diagnosis

The diagnosis of HBV is most commonly made by the presence of HBsAg in the serum. UK guidelines recommend that all pregnant women should be offered screening for hepatitis B infection during each pregnancy. Confirmatory testing and testing for HBeAg of those mothers shown to be infected should follow. Where an unbooked mother presents in labour, an urgent HBsAg test should be performed to ensure that vaccine can be given to babies born to positive mothers within 24 hours of birth. Management of the infant should be based on the results of these markers and, if available, HBV viral load testing of the mother.

Management

If a woman is screen-positive for HBV, she should be referred to an appropriate specialist (hepatologist, gastroenterologist or infectious disease specialist) within 6 weeks of a positive result. There, she should be fully evaluated in terms of any acute management and arrangements made for appropriate postnatal vaccination of the baby. All babies born to these mothers should receive a complete course of vaccine on time. Babies born to highly infectious mothers (e.g. mother HBeAg positive; mother HBeAg positive and anti-HBeAg negative; HBeAg unknown; acute hepatitis B during pregnancy; HBV DNA level $\geq 1 \times 10^6$ IU/mL) should receive hepatitis B immunoglobulin (HBIG) as well as active immunization. HBIG should preferably be given within 24 hours of delivery, and should be ordered well in advance of the birth. HBIG may be given simultaneously with vaccine but at a different site. There should also be discussion about testing of other family members. Notification of hepatitis B is a legal requirement.

Summary box 13.2

- Women who are HBV surface-antigen positive but e-antigen negative should be offered postnatal vaccination of the baby to prevent vertical transmission.
- Women who are e-antigen positive are offered both vaccination and HBIG.

Rubella

Rubella, although usually causing a minor maternal illness, is one of the most teratogenic infections known. Fortunately, since the introduction of the rubella vaccine, the incidence of rubella and congenital rubella syndrome has decreased substantially. Universal immunization against rubella, using the measles, mumps and rubella (MMR) vaccine, was introduced in the UK in the October 1988. The aim of this policy was to interrupt circulation of rubella among young children, thereby protecting susceptible adult women from exposure. This led to a considerable decline in rubella in young children following the introduction of MMR, with a concomitant fall in rubella infections in pregnant women, from 167 in 1987 to one in 2003 [8]. However, recent data from Health Protection Agency national surveillance systems in the UK have reported a national increase in the number of women susceptible to rubella [3].

Pathogenesis and transmission

Rubella is caused by a togavirus and spread by droplet transmission. Following exposure to the virus via nasopharyngeal secretions, almost 80% of susceptible individuals become infected. Replication occurs in the nasopharynx and regional lymph nodes, and viraemia develops 5–7 days after exposure. Viraemia usually results in placental and fetal infection. The incubation period is 14–21 days, and in most cases a rash develops 14–17 days after exposure. Individuals with rubella are infectious from 1 week before symptoms appear to 4 days after the onset of the rash.

Clinical manifestations

Rubella is a mild disease. There may be a mild prodromal illness involving a low-grade fever, malaise, coryza and mild conjunctivitis. Lymphadenopathy may precede the rash and usually involves post-auricular and suboccipital glands. The rash is usually transitory, erythematous and mostly located behind the ears and on the face and neck. Clinical diagnosis is unreliable as the rash may be fleeting and is not specific to rubella. Complications include thrombocytopenia and post-infectious encephalitis. In adults, arthritis and arthralgia may occasionally be seen after rubella infection.

Maternal rubella infection in pregnancy may result in fetal loss or in congenital rubella syndrome (CRS). CRS presents with one or more of the following:

- cataracts and other eye defects;
- deafness;
- cardiac abnormalities;
- microcephaly;
- retardation of intrauterine growth;
- inflammatory lesions of brain, liver, lungs and bone marrow.

Deafness is the most common and sometimes the only manifestation, especially when infection occurs after 16 weeks' gestation. Cardiac defects include patent ductus arteriosus, pulmonary stenosis, septal defects and coarctation of the aorta. Eye defects include cataracts, microphthalmia, pigmentary retinopathy and glaucoma. Neurological problems include encephalitis, microcephaly, mental handicap and behavioural problems. Other abnormalities include hepatitis, splenomegaly, thrombocytopoenia and growth retardation. Diabetes mellitus occurs frequently in later childhood in those with CRS.

Infection from 8 to 10 weeks of pregnancy results in damage in up to 90% of surviving infants. The risk of damage declines to about 10–20% when infection develops between 11 and 16 weeks' gestation [9]. The risk of fetal damage is small when infection happens after 16 weeks of pregnancy: only deafness has been reported following infections up to 20 weeks of pregnancy. Some infected infants may appear normal at birth but perceptive deafness may be detected later.

Diagnosis

The diagnosis of rubella infection is usually based on serological analysis. Detection of rubella IgM indicates recent infection, although re-exposure to rubella may induce a reappearance of low-titre IgM. Following a primary rubella infection, IgM can be detected within 5–7 days and may persist up to 2 months. Specific IgG develops by 2 weeks and persists for life; re-exposure may increase IgG titres temporarily. A history of exposure to, or possible recent infection with, rubella in early pregnancy is actively sought, particularly in recent immigrants, and the laboratory is informed of a suspicious history so that the appropriate tests for primary rubella infection (IgM and IgG avidity) are performed [10]. If the first specimen has detectable antibody and was obtained within 7–10 days of exposure, there is no risk of infection and further evaluation is unnecessary. Diagnosis of subclinical infection is straightforward if the woman is known to be susceptible, the exposure is recognized, and a serum sample is obtained

approximately 28 days after exposure. The diagnosis of subclinical infection is more difficult if the immune status of the woman is unknown. It can be facilitated, however, if the acute-phase serum specimen is obtained as soon as possible after a recognized exposure that did not occur more than 5 weeks earlier. Testing is considered unnecessary if there is documented evidence of two tests on different blood samples both confirming the presence of rubella-specific IgG. Rubella immune status should be assessed at first prenatal care visit. Susceptible women should be counselled regarding prevention strategies and be vaccinated post partum.

Management

The management of the pregnant woman exposed to rubella needs to be individualized and depends on when during gestation she was exposed and on her state of immunity. Confirming the diagnosis, counselling about the risks of infection of and damage to the fetus, and discussing all the available options, including the use of immunoglobulin and consideration of termination of pregnancy, require an understanding of the natural history and consequences of rubella in pregnancy. In the case of congenital infection, emphasis is on diagnosis and acute and long-term management. Isolation may also be important to reduce spread of infection. There is no treatment for rubella and supportive care should be offered. Droplet precautions are recommended for 7 days after the onset of the rash. Human immunoglobulin is not routinely used for post-protection from rubella since there is no evidence that it is effective. It is not recommended for the protection of pregnant women exposed to rubella, and should only be considered when termination of pregnancy is unacceptable.

There is no evidence that rubella-containing vaccines are teratogenic. However, as a precaution, MMR vaccine should not be given to pregnant women. If MMR vaccine is given to adult women, they should be advised to guard against pregnancy for 1 month. Termination of pregnancy following inadvertent immunization should not be recommended. Pregnant women who are found to be susceptible to rubella should be immunized with MMR after delivery. Breastfeeding is not a contraindication to MMR immunization, and MMR vaccine can be given to breastfeeding mothers without any risk to their baby [8].

Summary box 13.3

- Pregnant women who are found to be susceptible to rubella should be immunized with MMR after delivery.
- Rubella antibody testing should be offered at least in a first pregnancy irrespective of a single previous report of rubella-specific IgG and immunization history.

Syphilis

Despite the description of syphilitic infection for more than 500 years and availability of adequate therapy for more than 50 years, syphilis in the adult and neonate still represents a relevant issue for public health providers. The elimination of congenital syphilis from the UK was considered within the framework of the 2013 WHO guidelines for validating the elimination of mother-to-child transmission of syphilis. Diagnoses of infectious syphilis in reproductive-age women fell from 268 in 2010 to 206 in 2013. The uptake of antenatal screening in England rose from 96.6% in 2010 to 97.9% in 2013. Despite the high antenatal screening coverage, concerns have been raised about the effectiveness of case management and control strategies [11].

Pathogenesis and transmission

Treponema pallidum, the causative agent of syphilis, is a Gram-negative bacterium. Syphilis can be passed horizontally from person to person through direct contact, such as during sexual activity, resulting in acquired syphilis, or vertically from mother to baby, resulting in congenital syphilis. Because sexual contact is the most common mode of transmission for acquired disease, the sites of inoculation are usually the genital organs, but lips, tongue and abraded areas of the skin have been described as well. Such an entry point is identified as the site of the initial ulcerating sore, or chancre. The cervical changes associated with pregnancy, including ectropion, hyperaemia and friability, increase the risk of spirochaete entry. Local replication then occurs and lymphatic dissemination leads to the systemic findings of secondary syphilis. The incubation period averages 3 weeks (3–90 days) depending on inoculum load and host factors. Although transmission of syphilis to the fetus can occur throughout pregnancy, the likelihood of vertical transmission increases with advancing gestation. A newborn occasionally may be infected perinatally, by contact at delivery with an infectious lesion present in the birth canal or perineum. Postnatal transmission from mother to child is rare. The likelihood of vertical transmission is directly related to the maternal stage of syphilis, with early primary syphilis resulting in significantly higher transmission rates than late latent infection. Among pregnant women with untreated primary or secondary early syphilis, the rate of transmission is 60–100% but decreases with later stages of maternal infection to approximately 40% with early latent infection and 8% with late latent infection.

Clinical manifestations

Maternal syphilis infection is staged according to duration and clinical features. Primary syphilis is the initial stage and its characteristic lesion is an erosion called a chancre. It is a typical, indolent, well-circumscribed, flat ulcer with a yellow-coated base and an indurated non-undermined wall. As it causes no symptoms and because of its location on the labia minora, within the vagina or on the cervix or perineum, it is often unrecognized. Two to ten weeks after the primary lesions, an infected woman may experience secondary disease: the time of systemic dissemination with involvement of many major organ systems. Of women with secondary syphilis, 90% have dermatological manifestations. The rash of secondary syphilis appears as rough, red or reddish-brown spots mostly occurring on the palms, soles and trunk, where they tend to follow skin lines. Plantar and palmar maculopapular target-like lesions are commonly seen. Patchy alopecia may result when hair follicles are involved. Mucosal lesions called mucous patches will develop in 35% of women. Systemic symptoms are commonly seen in secondary syphilis (70%), with generalized lymphadenopathy, fever, fatigue, weight loss, anorexia, pharyngitis, splenomegaly, sore throat, headache, myalgia and arthralgia (with a noticeable nocturnal pattern). The signs and symptoms of secondary syphilis usually resolve with or without treatment. However, without treatment the infection will progress to the latent stages of disease.

Latent syphilis is defined as the period after infection when patients are seroreactive but demonstrate no clinical manifestations of disease. Early latent syphilis is latent syphilis of less than 12 months' duration. During this stage, 20–25% of women will relapse. Late latent syphilis is diagnosed after being asymptomatic for more than 12 months. The woman is still infectious during latent stages. Of untreated women, 20–30% will progress to tertiary syphilis. After 15 years, three-quarters of infected subjects show evidence of tertiary syphilis, 50–80% of whom have cardiovascular complications. In 9% of untreated subjects the gummata of tertiary disease can be found: localized nodules that can have central necrosis. Approximately 15% of untreated infected subjects develop neurosyphilis in the tertiary stage. Mortality from untreated syphilis has been described to be about 8–14% [12].

Clinicians caring for pregnant women should be aware that any ulcer, regardless of location, that is painless, indurated and indolent and which fails to heal within 2 weeks needs exclusion of syphilis. Similarly, any generalized skin eruption, regardless of its morphology, should be viewed as secondary (disseminated) syphilis until proven otherwise.

The extent of damage to a fetus affected by congenital syphilis depends on the stage of development when infection occurs and the elapsed time before treatment. With infection early in pregnancy and in the absence of therapy, fetal demise or late-term stillbirth occurs, but premature delivery or neonatal death may also occur. In liveborn infants, infection can be clinically recognizable or silent. When symptoms are present, congenital syphilis is characterized by the presence of hepatosplenomegaly, lymphadenopathy, rash, mucocutaneous lesions, haemolytic anaemia or thrombocytopenia, osteochondritis and pseudoparalysis, periostitis, rhinitis and central nervous system (CNS) involvement, all of which usually appear within the first 2–8 weeks of life.

Late congenital syphilis lesions represent the scars induced by initial lesions of early congenital syphilis or reactions to persistent and ongoing inflammation. They usually present after 2 years of life and often in early adolescence, and include Hutchinson teeth, mulberry molars, interstitial keratitis, healed chorioretinitis, secondary glaucoma (uveitis), corneal scarring, eighth nerve deafness, 'saddle nose', protuberant mandible, rhagades, mental retardation, arrested hydrocephalus, convulsive disorders, optic nerve atrophy, juvenile general paresis, cranial nerve palsies and sabre shins. Congenital syphilis can be prevented or treated *in utero*.

Diagnosis

All pregnant women should have serological screening for syphilis at their first antenatal assessment. Tests should be repeated later in pregnancy if a woman has been at risk of infection after a negative initial screen. Diagnosis of syphilis in pregnant women is usually performed by a non-treponemal serological screening test, with a treponemal serological test for confirmation. Non-treponemal antibody tests consist of the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) assay. Treponemal antibody tests are represented by treponemal enzyme immunoassay (EIA), treponemal chemiluminescent assay (CLIA), *T. pallidum* haemagglutination assay (TPHA) and fluorescent treponemal antibody absorption test (FTA-abs).

An EIA/CLIA, preferably detecting both IgM and IgG, is the screening test of choice. Positive screening tests should be confirmed with a different treponemal test (not the FTA-abs) and a second specimen for confirmatory testing obtained. A quantitative RPR or VDRL should be performed when screening tests are positive as it is recommended for monitoring the serological response to treatment. An initial RPR/VDRL titre above 16 usually indicates active disease and the need for treatment.

The diagnosis of congenital syphilis prenatally is difficult. Sonographic findings may include hydrops fetalis, hepatomegaly, placental thickening and hydramnios, but often the infected fetus will have a normal sonogram. Polymerase chain reaction (PCR) can be performed on amniotic fluid.

Management

Treatment of pregnant women with congenitally transmissible syphilis can significantly reduce the risk of congenital syphilis, stillbirths, premature births, neonatal deaths and severe illness in infancy and beyond. The pregnant woman can also be treated to prevent progression of disease, as well as giving the opportunity of treatment for their sexual partners. Once a screen-positive result is confirmed, the woman and her family should be referred to a specialist in genitourinary medicine for assessment, counselling and possible treatment.

Where syphilis is treated in the current pregnancy, particularly when this is early infection, maternal referral to fetal medicine is recommended when 26 weeks' gestation has been reached prior to treatment. Fetal syphilis infection may be suggested by ultrasound detection of non-immune hydrops or hepatosplenomegaly. Fetal assessment will help planning of antepartum care as well as neonatal treatment.

A single dose of benzathine penicillin G 2.4 million units is effective in most cases. Physiological changes in pregnancy alter drug pharmacokinetics and may cause reduced plasma penicillin concentrations. For this reason, when treatment is initiated in the third trimester, a second dose of benzathine penicillin is recommended 1 week after the first, with careful assessment of the neonate at birth. Up to 50% of women treated for early-stage syphilis will have a systemic reaction called the Jarisch–Herxheimer reaction. Although transient with only mild constitutional symptoms, preterm labour and fetal distress may complicate treatment. The uterine contractions appear to occur secondary to the development of fever. Fetal heart rate decelerations are also reported, occurring in about 40%, concomitant with maternal fever, and resolve within 24 hours of maternal penicillin treatment.

After treatment, it may take several months to observe a fourfold drop in RPR/VDRL titre and in many pregnancies labour will occur before this period has elapsed. Hence, serological cure may not be demonstrable before birth of the neonate [13].

Summary box 13.4

- All pregnant women should have syphilis serology at their first antenatal clinic visit, and if risk of syphilis is recognized, re-screening later in pregnancy should be offered.
- Retreatment in pregnancy is indicated where there is uncertainty of treatment or serological cure is in doubt.
- When treatment of early syphilis is initiated in the third trimester, a second dose of benzathine penicillin 1 week after the first is recommended.

Toxoplasmosis

Toxoplasma gondii is an intracellular parasite that can infect humans and almost all warm-blooded animals. The infection is transmitted through infected cat faeces, undercooked raw meat, and transplacentally. It is common worldwide, including in the UK, but it is rarely reported because there are often no symptoms. Around 350 cases are reported in England and Wales each year, but it is thought the actual number of infections could be as high as 350 000. Congenital toxoplasmosis is rare in the UK, with estimates suggesting that only around 1 in 10 000–30 000 babies are born with this condition. Routine antenatal serological screening for toxoplasmosis should not be offered because the risks of screening may outweigh the potential benefits.

Pathogenesis and transmission

Toxoplasma gondii has a complex life cycle with asexual reproduction taking place in mammals and birds (secondary hosts) and sexual reproduction taking place in the digestive epithelium of cats (primary host). Cats mainly become contaminated by ingesting animal flesh encysted with *T. gondii*. Infected cats excrete millions oocytes a day; these oocytes then sporulate and become infectious. The three main routes of transmission are ingestion of raw or undercooked meats, exposure to oocyst-infected cat faeces, and vertical transmission. In pregnancy, the most common mechanisms of infection are through consuming raw or very undercooked meats or contaminated water, or exposure to soil (gardening without gloves) or cat litter [14]. Transplacental passage of toxoplasmosis occurs when a woman becomes infected during pregnancy. The risk of developing congenital toxoplasmosis increases with advancing gestational age. The incidence of transmission is 3–9% if infection occurs in the first trimester and highest (60–81%) if it occurs in the third trimester. Conversely, the severity of disease is worse if infection occurs in the first trimester, with a risk of development of clinical signs in the infected fetus of 60%. Infection prior to pregnancy confers immunity with minimal risk of vertical transmission [15].

Clinical manifestations

Toxoplasmosis is asymptomatic in more than 90% of cases. Only a small proportion of women will develop clinical signs of the disease, which often occurs as a flu-like illness, with lymphadenopathy and fatigue being the most common manifestations. The incubation period is 5–18 days following exposure. The symptoms are usually self-limiting, resolving within a few weeks or months.

Immunocompromised pregnant women are at higher risk of developing serious complications like severe encephalitis, myocarditis, pneumonitis or hepatitis.

Congenital toxoplasmosis is characterized by the tetrad of chorioretinitis, hydrocephalus, intracranial calcification and convulsion. Ultrasound evidence of intracranial calcification, microcephaly, hydrocephalus and intrauterine growth restriction suggests *in utero* infection when maternal infection is documented.

Diagnosis

Serological tests for the detection of specific anti-*Toxoplasma* IgG and IgM antibodies are the most widely used. Anti-*Toxoplasma* IgG can be identified 2–4 weeks after infection, reaches a peak after 2 or 3 months, and then stabilizes at a plateau for several months before decreasing to very low levels persisting throughout life. A positive IgG test before pregnancy means that the fetus is not at risk. Anti-*Toxoplasma* IgM is traditionally tested in parallel with IgG. IgM antibodies are the first to appear after an acute infection (1 or 2 weeks before IgG). Therefore, in a susceptible patient, IgM alerts to a possible acute infection before IgG antibodies are detected. After increasing for 1 month, IgM antibodies persist for a variable period. Absence of IgM when IgG antibodies are detected helps to exclude a recent infection. However, IgM can remain positive for months and even years, and interpretation of a positive result requires great caution. For this reason the measurement of IgG avidity is often useful in pregnant women who present with antibodies in their first sample. IgG avidity measures the strength of antigen–antibody binding, which increases with the time elapsed since infection. In the first month after primary infection IgG antibodies are of low avidity, while the ones produced months or years after infection show high avidity. High avidity allows the exclusion of an infection acquired in the last 12–20 weeks, and if a test was performed in the first trimester, a high-avidity index will exclude that infection took place during pregnancy.

The prenatal diagnosis of fetal infection is based on ultrasound scanning and PCR testing of amniotic fluid or blood. Ultrasound evidence of hydrocephaly, intracranial calcifications in the parenchyma or in a periventricular position, placental thickening, liver calcifications, hyperechoic bowel, ascites and growth restriction have been reported in fetuses affected by *T. gondii* infection *in utero*.

Management

Routine antenatal serological screening for toxoplasmosis should not be offered because the risks of screening may outweigh the potential benefits. Prevention of toxoplasmosis in pregnant women is paramount. Pregnant women should be informed of primary prevention measures to avoid toxoplasmosis infection, such as washing hands before handling food, thoroughly washing all fruit and vegetables, thoroughly cooking raw meats and ready-made meals, wearing gloves and washing hands after handling soil/gardening, and avoiding cat faeces in cat litter or in soil.

Treatment of toxoplasmosis in the infected pregnant women is variable, depending on maternal immune status, gestational age and presence of fetal infection. Primary maternal infection is usually a mild disease and is self-limiting, with symptoms disappearing within a few weeks or months without any treatment. However, treatment is thought to decrease the rate of congenital infection and reduce the severity of the disease in the neonate and therefore it is usually started in pregnant women. Drug regimens most commonly used rely primarily on spiramycin and a pyrimethamine/sulfadiazine combination. In countries with a monthly prenatal serological testing programme, such as France and Italy, the first-line drug for prevention of fetal infection is spiramycin, which is started as soon as maternal infection is suspected. When analysis of amniotic fluid confirms the presence of fetal infection, spiramycin is stopped and treatment switched to the combination of pyrimethamine and sulfadiazine.

Women should be counselled on the option of termination of pregnancy in the case of severe morphological lesions. Over 90% of neonates with congenital infection show no clinical signs of infection at birth. In the absence of any treatment neonates are at risk of developing long-term sequelae: chorioretinal disease (up to 85% of infected children), major neurological abnormalities, and psychomotor and mental impairments.

Summary box 13.5

- Routine antenatal serological screening for toxoplasmosis should not be offered because the risks of screening may outweigh the potential benefits.
- *Toxoplasma gondii* infection should be suspected and screening should be offered to pregnant women with suspicious ultrasound findings, including intracranial calcification, microcephaly, hydrocephalus, ascites, hepatosplenomegaly or intrauterine growth restriction.

Cytomegalovirus

Cytomegalovirus (CMV) is the most common congenital infection in the UK, affecting around 3 per 1000 births, and can cause neurological impairment such as hearing loss. CMV seroprevalence is generally around 40–50%

among white populations but is as high as 80–100% in some non-white populations [16]. In the UK, it is estimated that one to two babies in every 200 will be born with congenital CMV. Of these, about 13% will have problems at birth, such as hearing loss and learning difficulties, with a similar number developing problems later.

Pathogenesis and transmission

CMV is a ubiquitous, double-stranded DNA herpesvirus that is transmitted by sexual contact or direct contact with infected blood, urine, nasopharyngeal secretions or saliva. The incubation period is 28–60 days and viraemia can be detected for 2–3 weeks after primary infection. After the primary infection, CMV remains latent in host cells and recurrent, or secondary, infection can occur. Vertical transmission of CMV mostly occurs by transplacental infection after primary or secondary infection, but can also follow exposure to contaminated genital tract secretions at delivery, or breastfeeding. The evidence of intrauterine transmission in the presence of maternal immunity has been attributed to reactivation of endogenous virus in some cases and to reinfection with different strains of CMV in others. With primary maternal CMV infection, the overall risk of transmission to the fetus is approximately 30–40%. In contrast, only 0.15–1% of women with recurrent infection will transmit the virus to the fetus. Among fetuses infected after a primary infection, 12–18% will have signs and symptoms of CMV at birth and up to 25% will develop sequelae. Fetuses infected after maternal CMV reactivation are usually asymptomatic at birth. As with other congenital infections, the risk of transmission is greatest in the third trimester (40–72%), compared with a lower risk in the first trimester (30%). However, fetal damage is more serious the earlier in gestation transmission occurs.

Clinical manifestations

The majority of adults infected with CMV experience few or no symptoms and no long-term sequelae. Some experience a mononucleosis-like syndrome with symptoms including malaise, headache, fever, myalgia, cervical lymphadenopathy and, less commonly, pneumonia and hepatitis. Secondary infections are usually asymptomatic.

Of congenitally infected infants, 10–15% will have symptoms at birth due to the involvement of multiple organs, in particular the reticuloendothelial system and the CNS, with or without ocular and auditory damage. The abnormalities most frequently present in infants with symptomatic congenital infection are hepatomegaly, splenomegaly, microcephaly, jaundice and petechiae. Hydrocephalus, haemolytic anaemia and pneumonitis can occasionally be present. Among the most severely affected infants 10–30% will die, mostly of disseminated intravascular coagulation, hepatic dysfunction or bacterial superinfection.

Nearly 90% of infants with congenital CMV infection have no signs or symptoms at birth, but at least 10–15% of them are at risk of developing a number of developmental abnormalities, including sensorineural hearing loss, microcephaly, motor defects, mental retardation, chorioretinitis, dental defects and others that were once thought to be limited to infants with symptomatic congenital infections. These abnormalities usually become apparent within the first 2 years of life.

Diagnosis

Primary maternal CMV infection in pregnancy is diagnosed on the basis of *de novo* appearance of specific IgG in the serum of a woman who was previously seronegative, or on identification of specific IgM associated with low IgG avidity. CMV IgM is detected within a few days of infection and may remain positive for 4–8 months and re-emerge with recurrent infection. A secondary infection should be diagnosed when a significant rise of IgG antibody titre is documented independently of the presence of IgM and high IgG avidity. In cases of proven secondary infection, amniocentesis may be considered.

Congenital CMV may be suspected prenatally on the basis of ultrasound findings suggestive of infection. The most frequently reported include abdominal and liver calcifications, hepatosplenomegaly, echogenic bowel or kidneys, ascites, cerebral ventriculomegaly, intracranial calcifications, microcephaly, hydrops fetalis, pleural effusion, oligohydramnios and growth restriction. The severity of the detected abnormalities can help in defining the prognosis of the fetus, but the absence of sonographic findings does not guarantee a normal outcome.

The prenatal diagnosis of CMV is possible by testing amniotic fluid obtained by amniocentesis, where sensitivity of PCR can reach 100% if the test is performed after 21 weeks of gestation and at least 7 weeks after presumed time of maternal infection. Unfortunately, a positive PCR result does not discriminate between infants who will have symptoms and those who will not. It has been suggested that when the viral load in the amniotic fluid is greater than or equal to 10^5 genome equivalents of CMV DNA, the risk of symptomatic congenital CMV infection is significantly high.

Management

Currently, no therapies are available for the treatment of maternal or fetal CMV infection. Use of antiviral medications in routine clinical care of pregnant women is not recommended. Similarly, passive immunization with CMV-specific hyperimmune globulin is not recommended outside of a research protocol [17]. The

principal source of CMV infection among women of childbearing age is exposure to children excreting CMV. Education of susceptible pregnant women has been shown to significantly reduce the incidence of infection. Preventive measures, like hand washing and minimizing exposure from high-risk areas such as nurseries, must be recommended.

Screening in pregnancy is not recommended because there is uncertainty regarding the natural history of primary and recurrent CMV as it relates to the risk to the fetus. Furthermore, the screening test for susceptibility lacks sufficient sensitivity and there is uncertainty regarding the further investigations needed to refine the risk to the fetus in women with primary infection. Finally, interventions have not been shown to be effective in preventing maternal infection or reducing the risk of transmission to the fetus.

When a recent primary infection is diagnosed, invasive testing can be offered to identify infected fetuses. In the counselling process it is important to consider the stage of infection and gestational age, and to stress that the majority (90–95%) of children with congenital CMV infection will not suffer significant CNS sequelae, and that only about 10% will experience some degree of hearing loss. When a primary maternal infection is documented, parents should be informed of a 30–40% risk for fetal infection, and a 20–25% risk for development of sequelae postnatally in infected fetuses.

As no specific antiviral treatment for prenatal therapy is available, the only options following a prenatal diagnosis of CMV infection are termination of pregnancy or observation. The presence or absence of fetal abnormalities diagnosed at ultrasound represent an important factor in the decision-making process. Fetal MRI may improve the prognostic evaluation, especially when brain abnormalities are seen on ultrasound.

Summary box 13.6

- Congenital CMV infection is the leading infection causing mental retardation and sensorineural deafness.
- Routine serological screening in pregnancy is not recommended, and testing should be reserved for pregnant women who develop flu-like illness or following detection of ultrasound evidence suggestive of CMV infection.

Parvovirus B19

Human parvovirus B19 is a single-stranded DNA virus with a predilection for infecting rapidly dividing cell lines, such as bone marrow erythroid progenitor cells, leading to severe anaemia in the fetus. Approximately 50–70% of women of reproductive age have immunity to parvovirus B19. About 1–3% of susceptible pregnant women will develop serological evidence of infection in pregnancy. Women at increased risk of infection include mothers of preschool and school-age children and school teachers. The reported number of infections in the UK is 1 in 512 pregnancies per year, while seroconversion occurs in 1–13% of susceptible pregnant women [18].

Pathogenesis and transmission

Transmission of parvovirus B19 from person to person is probably by droplets from oral or nasal secretions. Viral DNA is present in saliva at levels similar to those in blood. As the main mode of transmission is respiratory, epidemics of parvovirus B19 infection can occur. The virus can also be transmitted parenterally through blood or blood product transfusion, or vertically from mother to fetus. The incubation period is 4–20 days. Patients are infectious 10 days before the onset of the rash and remain contagious for only 1–2 days after the rash appears. Risk of intrauterine infection rise with increasing gestational age, ranging from 15% when infection occurs before 16 weeks of gestation, to 25–70% thereafter.

Clinical manifestations

The clinical expression of parvovirus infection is variable. Infection can be asymptomatic in up to 50% of cases, and in up to 70% of infected pregnant women. Children with parvovirus infection most commonly develop erythema infectiosum, characterized by the presence of flu-like symptoms, fever and headache, followed by a 'slapped cheek' rash (fifth disease) that usually spreads to the trunk and limbs after about 1 week. Adults with parvovirus B19 infection usually do not have an extensive rash, but may suffer from symmetrical polyarthralgias and arthritis.

Parvovirus has been associated with hydrops fetalis, with an overall incidence of 2.9%. Spontaneous miscarriage and stillbirth have also been reported. Possible mechanisms for hydrops include fetal anaemia following transplacental infection which, combined with the shorter half-life of fetal red blood cells, leads to severe anaemia, hypoxia and high-output cardiac failure. Another mechanism can be the development of a viral myocarditis leading to cardiac failure. Parvovirus infection is the most common infectious cause of non-immune hydrops.

Diagnosis

A pregnant woman suspected of having parvovirus because of symptoms or, more commonly, secondary to exposure to an infected child should have serological testing. In patients with a rash, recent parvovirus

infection should be confirmed or excluded by testing for parvovirus B19-specific IgM on the first serum obtained. Women who are IgM negative and IgG positive have evidence of previous exposure and immunity and are not at risk. Absence of parvovirus B19-specific IgM excludes infection in the 4 weeks prior to collection of the serum. Therefore infection cannot be excluded if testing is carried out more than 4 weeks after onset of rash illness. If parvovirus B19-specific IgM is detected in the first 20 weeks of pregnancy, confirmation is required. If IgM and IgG are both present, they indicate recent infection 1 week to 6 months previously. Infection can also be investigated by testing the antenatal booking sample in parallel with the sample at presentation to show seroconversion. Fetal parvovirus infection should be considered if non-immune hydrops is detected on ultrasound. Fetal infection can be diagnosed using PCR to detect parvovirus B19 DNA in amniotic fluid or fetal blood samples [19].

Management

Women with acute parvovirus B19 infection should be monitored for the development of fetal anaemia using serial ultrasonography every 1–2 weeks, up to 12 weeks after infection. Ultrasound monitoring for the features of fetal anaemia should include assessment for ascites, placentomegaly, cardiomegaly, hydrops and intrauterine growth restriction. Above all, Doppler assessment of peak systolic velocity of the fetal middle cerebral artery should be performed as an accurate predictor of fetal anaemia. If hydrops fetalis is present or severe fetal anaemia is suspected, fetal blood sampling should be performed to determine the need for a fetal transfusion. If a transfusion is performed and the fetus survives, 94% will recover within 6–12 weeks. Most fetuses require only one transfusion as fetal haematopoiesis resumes as the parvovirus infection resolves. No significant delay was noted on standard neurodevelopmental testing in the assessment of long-term neurodevelopmental outcomes of children treated with intrauterine transfusion for parvovirus infection.

Summary box 13.7

- In pregnant women exposed to, or who develop symptoms of, parvovirus B19, recent parvovirus infection should be confirmed or excluded by determining parvovirus B19 IgG and IgM.
- If a recent parvovirus B19 infection has been diagnosed in the woman, she should be referred to a fetal medicine specialist and serial ultrasound should be performed every 2 weeks, up to 12 weeks after infection, to allow timely detection of fetal anaemia and arrangements for *in utero* fetal transfusion.

Herpesvirus

Genital herpesvirus infection has been rising in prevalence in the developed world and in the UK, and neonatal infection still represents a tremendous consequence of genital herpes. Neonatal herpes is rare in the UK. Active surveillance by the British Paediatric Surveillance Unit (BPSU) between 1986 and 1991 found an annual incidence of 1.65 per 100 000 live births. Subsequent surveillance from 2004 to 2006 showed an approximate doubling of incidence over the 3-year surveillance period. This might be mostly due to the rise in the prevalence of sexually transmitted infections, demographic and social changes within the general population and improvements in diagnostic techniques [20].

Pathogenesis and transmission

Herpes simplex virus (HSV) types 1 and 2 are members of the large family of herpesviruses. A common characteristic of all members of the herpesvirus family is the ability to establish latency, to persist in this latent state in cranial nerves or dorsal spinal ganglia for various intervals of time, and to reactivate and cause active infection (with or without disease) and viral transmission. Transmission of HSV most often occurs by person-to-person contact. Virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated. The incubation period is 3–6 days. Genital herpes and neonatal herpes may be caused by HSV-1 or HSV-2. HSV-1 was originally localized to orolabial areas, but recent data show that approximately 50% of neonatal herpes is due to HSV-1 and 50% to HSV-2. Recurrent genital herpes is mostly secondary to HSV-2 (>90%).

The risk of neonatal HSV depends on multiple factors: the type of maternal infection (primary or recurrent), the presence of maternal antibodies, the duration of rupture of membranes before delivery, the use of fetal scalp electrodes and the mode of delivery. The risks are greatest for a primary infection occurring in the third trimester, particularly within 6 weeks of delivery, as viral shedding may persist and the baby is likely to be born before the development of protective maternal antibodies. Rarely, congenital herpes may occur as a result of transplacental intrauterine infection. Neonates born from mothers suffering recurrent herpes at the time of delivery, which is commonly asymptomatic or unrecognized, have a modest risk of developing the localized forms of neonatal herpes, both local CNS disease and skin, eye and mouth infection. Most infants who develop neonatal disease are born to women who are completely asymptomatic for genital HSV infection during the pregnancy and at the time of delivery.

Clinical manifestations

Maternal HSV infection can be described by either stage of infection (first clinical episode of infection or recurrence) or prior immune status (primary or non-primary). Typical clinical manifestations include vesicular lesions, with an erythematous base, located on the genital skin or adjacent areas. They often evolve into pustules, then ulcerations and finally, if on keratinized skin, crusted lesions. Atypical presentations are common, including minor erythema, fissures, pruritus, and pain with minimal detectable signs.

Recurrent infection has a variable clinical presentation, from completely asymptomatic viral shedding to overt clinical recurrences. Of pregnant women with a history of HSV, 5–10% will present with a symptomatic recurrence. Finally, asymptomatic viral shedding may occur in the absence of any signs and symptoms.

The manifestations of neonatal or congenital HSV infection have been classified into three levels of disease: (i) skin, eye and mouth infection; (ii) CNS disease (manifested as encephalitis); and (iii) disseminated disease (the most serious form of infection, with a 90% mortality rate if untreated). A typical clinical presentation and/or the presence of a positive culture from the neonate more than 48 hours after delivery allow a diagnosis of neonatal HSV infection.

Diagnosis

Patient history and clinical examination can help in the diagnosis of HSV infection. However, it can be difficult to distinguish clinically between primary and recurrent genital HSV infections, as in up to 15% of cases reported as a first episode of clinical HSV infection it will actually be a recurrent infection. All the lesions identified should be unroofed and the fluid cultured. For women presenting with first episode of genital herpes in the third trimester, particularly within 6 weeks of expected delivery, specific HSV antibody testing (IgG to HSV-1 and HSV-2) is advisable. The presence of antibodies of the same type as the HSV isolated from genital swabs would confirm this episode to be a recurrence rather than a primary infection. For these women, characterizing the infection will influence the management and the counselling regarding mode of delivery and risk of neonatal HSV infection.

Management

Women with suspected genital herpes should be referred to a genitourinary medicine physician, who will confirm or refute the diagnosis, advise on management of genital herpes and arrange a screen for other sexually transmitted infections. Management of the woman usually involves the use of oral aciclovir in standard doses (400 mg three times daily, usually for 5 days) as it reduces the duration and severity of symptoms and decreases the duration of viral shedding. Aciclovir is not licensed for use in pregnancy but has not been associated with increased incidence of birth defects. Following primary first- or second-trimester acquisition, providing that delivery does not ensue within the following 6 weeks, the pregnancy should be managed expectantly and vaginal delivery anticipated. Daily suppressive aciclovir 400 mg three times daily from 36 weeks of gestation reduces HSV lesions at term and hence the need for delivery by caesarean section. In the third trimester, treatment will usually continue with daily suppressive aciclovir 400 mg three times daily until delivery. Caesarean section should be the recommended mode of delivery for all women developing first-episode genital herpes in the third trimester, particularly those developing symptoms within 6 weeks of expected delivery, as the risk of neonatal transmission of HSV is very high at 41%. In the case of a recurrent infection, women should be informed that the risk of neonatal herpes is low, even if lesions are present at the time of delivery (up to 3% for vaginal delivery).

Summary box 13.8

- Following primary HSV infection, providing that delivery does not ensue within the following 6 weeks, the pregnancy should be managed expectantly and vaginal delivery anticipated. Daily suppressive aciclovir 400 mg three times daily from 36 weeks of gestation should be given.
- Women with primary genital herpes in the third trimester of pregnancy have a high risk of transmitting HSV to their neonates and should be offered a caesarean section to decrease this risk.
- In the case of a recurrent infection, women should be informed that the risk of neonatal herpes is low.

At the time of admission to the labour ward, a woman with a history of HSV infection should be questioned about prodromal symptoms (vulvar itching, burning) and recent HSV lesions. A careful examination of the vulva, vagina and cervix should be performed. Suspicious lesions should be cultured. Women with any evidence of prodromal or active HSV infection should be offered a caesarean delivery. Caesarean section should be recommended to all women presenting with primary-episode genital herpes lesions at the time of delivery, or within 6 weeks of the expected date of delivery. Counselling should stress a decreased risk of HSV transmission with a caesarean delivery but not a negated risk, as 10–15% of

infants with HSV are born to women undergoing a caesarean delivery.

Varicella-zoster virus

Varicella-zoster virus (VZV) is the causative agent of one of the most communicable of human diseases: chickenpox (or primary VZV infection), a common childhood disease. Over 90% of individuals over 15 years of age in England and Wales are seropositive for VZV IgG antibody. For this reason, although contact with chickenpox is common in pregnancy, especially in women with young children, primary VZV infection in pregnancy is uncommon, estimated to complicate only 3 in 1000 pregnancies.

Pathogenesis and transmission

VZV is a double-stranded DNA virus of the *Herpesviridae* family. It is transmitted by respiratory droplets and by direct personal contact with vesicular fluid. The incubation period lasts 10–21 days, with a mean of 15 days, and an infected person is contagious 24–48 hours before the rash appears and continues to be infectious until the vesicles crust over. Following the primary infection (e.g. chickenpox) the virus remains latent in sensory ganglia and can be reactivated causing a vesicular rash known as herpes zoster, or shingles.

Transplacental passage of the virus may occur, causing fetal varicella syndrome (FVS) or congenital varicella. FVS has been reported to complicate maternal chickenpox, occurring as early as 3 weeks and as late as 28 weeks of gestation. The incidence has been reported to be 0.91% before 20 weeks, while the risk appears to be lower in the first trimester (0.55%). Neonatal infection can occur after exposure of the fetus or newborn a week before to a week after delivery before protective maternal antibodies develop.

Clinical manifestations

The primary infection (chickenpox) is characterized by fever, malaise and a pruritic rash that develops into crops of maculopapules, which become vesicular and crust over before healing. The head and trunk are affected first, then spreading sporadically to the lower abdomen and extremities. The vesicles are intensely pruritic. Although varicella infection is much less common in adults than in children, it is associated with a higher risk of complications such as pneumonia, hepatitis, encephalitis and even death. The incidence of pneumonia complicating varicella in pregnancy has been quoted at 10–14%. The reported mortality rate in pregnancy is 0–14%.

FVS is characterized by one or more of the following: skin scarring in a dermatomal distribution; eye defects (microphthalmia, chorioretinitis or cataracts); hypoplasia of the limbs; and neurological abnormalities (microcephaly, cortical atrophy, mental retardation or dysfunction of bowel and bladder sphincters). Neonatal varicella that occurs following exposure near or around delivery carries a mortality rate approaching 25%. Clinical manifestations include pneumonia, disseminated mucocutaneous lesions and visceral infection.

Diagnosis

The diagnosis of varicella is usually made on the basis of clinical signs. When the diagnosis is not readily evident, VZV can be isolated from an unroofed skin lesion or vesicular fluid can be tested using a qualitative varicella PCR assay. Seroconversion can be documented by antibody assay with the use of varicella IgG serology.

Prenatal diagnosis of FVS is possible using ultrasound by identification of the following findings: limb deformity, microcephaly, hydrocephalus, soft tissue calcification and fetal growth restriction. Fetal MRI may provide additional information in cases where ultrasound has identified morphological abnormalities. VZV DNA can be detected in amniotic fluid by PCR. However, the presence of VZV DNA has a high sensitivity but low specificity for the development of FVS and women should be counselled about this limitation.

Management

Symptomatic treatment and hygiene are advised to prevent secondary bacterial infection of the lesions. Oral aciclovir should be prescribed for pregnant women with chickenpox if they present within 24 hours of the onset of the rash. Women should avoid contact with potentially susceptible individuals. A hospital assessment should be considered in a woman at high risk of severe or complicated chickenpox. The timing and mode of delivery of the pregnant woman with chickenpox must be individualized.

Prophylaxis using VZV immunoglobulin (VZIG) is an important objective for susceptible, exposed pregnant women. VZIG is recommended for VZV antibody-negative pregnant contacts exposed at any stage of pregnancy, within 10 days of contact. When supplies of VZIG are short, clinicians are advised to check availability of VZIG before offering it to pregnant women. Pregnant contacts with a positive history of chickenpox do not require VZIG. Those with a negative history must be tested for VZV antibody before VZIG is given.

Women who develop chickenpox in pregnancy should be referred to a fetal medicine specialist, at 16–20 weeks

or 5 weeks after infection, for discussion and detailed ultrasound examination. If varicella or serological conversion develops in the first 28 weeks of pregnancy, the woman has a small risk of FVS and should be informed of the implications.

If maternal infection occurs in the last 4 weeks of pregnancy, there is a significant risk of varicella infection of the newborn. A planned delivery should normally be avoided for at least 7 days after the onset of the maternal rash to allow for the passive transfer of antibodies from mother to child.

Breastfeeding is not contraindicated in women with chickenpox. An attenuated live-virus vaccine is available, and varicella vaccination before pregnancy or post partum is an option that should be considered for women who are found to be seronegative for VZV IgG [21].

Summary box 13.9

- Pregnant women with an uncertain or no previous history of chickenpox who have been exposed to infection should have a blood test to determine VZV immunity.
- If the pregnant woman is not immune to VZV and has had a significant exposure, she should be offered VZIG as soon as possible. VZIG is effective when given up to 10 days after contact.

Zika virus

Zika virus (ZIKV) infection is rapidly emerging on a global scale. The last epidemic began in Brazil in 2015 and has now spread rapidly to more than 30 countries in the Americas and the Caribbean, infecting more than 2 million inhabitants. Recent outbreaks and concerning links to Guillain–Barrè syndrome and microcephaly are incompletely understood. The limited understanding of ZIKV presents an enormous challenge for responses to this rapidly emerging threat to human health.

Pathogenesis and transmission

ZIKV is a flavivirus, a single serotype has been described, and infection is thought to lead to lifelong immunity. The incubation period ranges between approximately 3 and 12 days. It is spread through the bite of mosquitoes, and multiple mosquito species are capable vectors. Sexual transmission of ZIKV is possible, with virus detectable in semen for at least 2 months after infection. The association of ZIKV with birth defects suggests transplacental transmission. The risk window for fetal exposure to ZIKV, the rate of vertical transmission and the incidence of birth defects with maternal infection are unknown.

Clinical manifestations

Up to 80% of ZIKV infections may be subclinical [22]. The remainder are typically mild, self-limited illnesses lasting 5–7 days. A pruritic maculopapular rash, conjunctival injection, headache and fever are dominant features, although none are universally present. Arthralgia, particularly of the hands, wrists and ankles, is common and is frequently associated with periarticular swelling. ZIKV infection has been associated with development of Guillain–Barré syndrome, typically a self-limiting neurological disease that may be severe if associated with respiratory failure, profound or persistent paralysis or autonomic instability.

Maternal infection with ZIKV at any stage of pregnancy may be associated with a range of serious and adverse fetal outcomes: fetal death, placental insufficiency, intrauterine growth restriction and CNS abnormalities, including microcephaly and cerebral calcifications (Fig. 13.1). Microcephaly is manifested as incomplete brain development in the setting of an abnormally small head circumference. Recent studies report fetal abnormalities detected by ultrasonography in 30% of ZIKV-positive women.

Diagnosis

Several diagnostic RT-PCR-based assays have been used to identify ZIKV from the body fluids and tissues of infected individuals. The virus may be detectable in serum for only 2–3 days after the onset of illness and this would challenge the identification of suspected cases and confirmation of infection by serum PCR. ZIKV is detectable by PCR in urine samples for longer than in serum samples. From 5 days after the onset of disease, serological investigations can be performed to detect ZIKV-specific IgM antibodies. ZIKV serological testing will be most informative when ZIKV occurs as a primary flavivirus infection and less helpful, even misleading, in the common setting of prior flavivirus exposure or vaccination.

Management

Treatment of ZIKV infection is supportive: rest, oral hydration and treatment of symptoms with acetaminophen-based products are appropriate. No specific antiviral or vaccine is available for ZIKV, although vaccines are in development. Providers should maintain a high level of suspicion for ZIKV infection in any patient

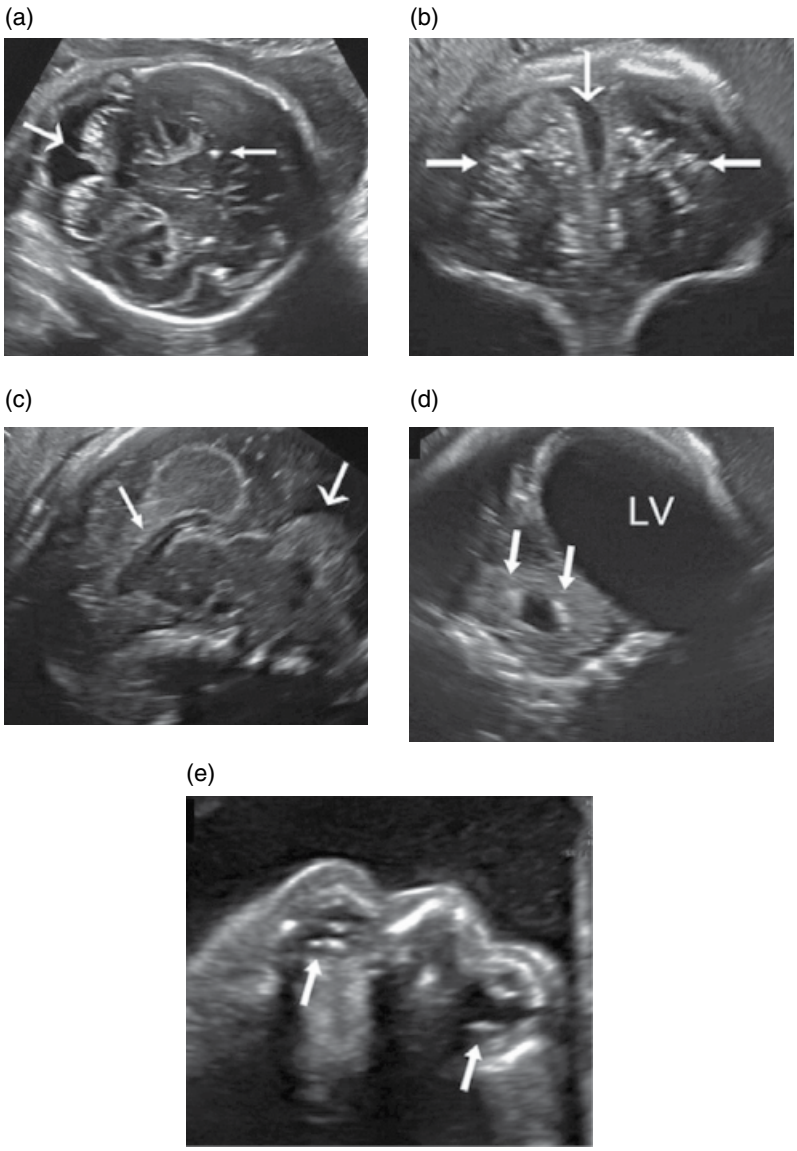

Fig. 13.1 Ultrasound images showing fetal brain malformations seen in common for toxoplasmosis, CMV and ZIKV infections. (a) Transabdominal axial ultrasound image shows cerebral calcifications with failure of visualization of a normal cerebellar vermis (large arrow). Calcifications are also present in the brain parenchyma. (b) Coronal plane shows a wide interhemispheric fissure (large arrow) due to brain atrophy and bilateral parenchymal coarse calcifications (small arrows). (c) Transvaginal sagittal image shows dysgenesis of the corpus callosum (small arrow) and cerebellar vermis (large arrow). (d) Evidence of ventriculomegaly (LV) and calcifications in the fourth ventricle (arrows). (e) Axial view shows calcifications in both eyes (arrows). Note that the proximal eye is very small and lacks normal anatomic landmarks. *Source:* Oliveira Melo *et al*. Zika virus intrauterine infection causes fetal brain abnormality and microcephaly: tip of the iceberg? *Ultrasound Obstet Gynecol* 2016;47:6–7. Reproduced with permission of Wiley Publishers.

presenting with rash and either a personal history of recent travel to an area with active ZIKV transmission or a similar travel history for a sexual partner. Women with suspected or confirmed ZIKV infection should be monitored closely with serial ultrasonography to evaluate for signs of placental insufficiency, given the risks of fetal death and intrauterine growth restriction.

The Centers for Disease Control and Prevention has recommended the use of condoms for at least 1 month after returning for men who reside in or have travelled to an area of active ZIKV transmission to prevent transmission of ZIKV via sexual activity with pregnant or non-pregnant partners. Pregnant women in unaffected areas are currently advised to postpone travel to ZIKV-endemic regions if possible, to practice strict measures for mosquito bite avoidance if travel cannot be postponed, and to avoid sex with male partners who have visited endemic regions.

Summary box 13.10

- Despite mild clinical symptoms, ZIKV infection during pregnancy appears to be associated with adverse outcomes, including fetal death, placental insufficiency, fetal growth restriction and CNS abnormalities.
- Pregnant women are advised to postpone travel to areas with ZIKV transmission and to avoid sex with male partners who have visited endemic regions.
- Men who reside in or have travelled to an area of active ZIKV transmission are advised to practise safer sex for at least 1 month after returning in order to reduce the potential risk of onward sexual transmission.

Effects of untreated prenatal depression, anxiety and stress

It is important to identify prenatal mood and anxiety disorders in the mother since untreated disorders can have negative effects on fetal development, birth outcome and child development. As such, it is important for clinicians to have an understanding of identification and treatment options for the most common disorders. It is difficult to distinguish the effects of untreated prenatal depression, anxiety and stress since so many studies examine them together. Depression, anxiety and stress during pregnancy can lead to poor health behaviours including inadequate prenatal care, poor nutrition, lack of exercise, poor compliance with prenatal vitamins and prescribed medications, and increased alcohol, smoking and drug abuse. A recent systematic review and meta-analysis reported that untreated depression was associated with a 1.56 odds ratio (OR) of preterm birth (PTB) and a 1.96 OR of low birthweight (LBW) [1]. Given the high infant morbidity and mortality associated with PTB and LBW, these increased risks with untreated prenatal depression have large public significance. Untreated prenatal depression, anxiety and stress have also been linked to increased maternal cortisol levels, spontaneous miscarriage, pre-eclampsia, caesarean section, lower Apgar scores and placental abruption. Studies have reported associations between untreated depression and anxiety and adverse outcomes on child development, such as decreased grey matter density, disrupted sleep, developmental delay and autism, cognitive impairment, internalizing and externalizing behaviours (such as attention deficit disorder, conduct disorders, antisocial behaviour), depression, anxiety and psychotic disorders, as well as obesity and metabolic dysfunction [2]. It is difficult to separate the prenatal exposure from the postnatal exposure to maternal depression, as well as other postnatal environmental factors.

Proposed mechanisms underlying maternal prenatal stress and child outcomes include the direct and indirect effect on health behaviours, maternal physiology, placenta and the postnatal environment [2]. Psychosocial stress in pregnancy can negatively impact maternal behaviours, such as smoking, substance use, unhealthy eating, sleep disturbances and physical activity, which may increase adverse pregnancy and child outcomes. Maternal exposure to stress activates the hypothalamic–pituitary–adrenal (HPA) axis and subsequent release of cortisol. Cortisol may enter the fetal circulation through direct transport across the placenta. It can also increase production of placental corticotrophin releasing hormone (CRH), which stimulates the fetal HPA axis. High cortisol concentration *in utero* influences fetal behavioural, immunological and brain development, and placental CRH concentration has been associated with decreased fetal growth and size at birth. The role of placental 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) is to convert cortisol to inactive cortisone, a built-in protection against heightened maternal cortisol concentrations. However, maternal prenatal anxiety may downregulate the 11β-HSD2 enzyme and allow more cortisol to cross into fetal blood.

Catecholamines may also play a role in maternal stress, influencing infant outcomes. For example, catecholamines in maternal blood result in constriction of placental blood vessels, which can decrease the supply of nutrients and oxygen to the fetus and increase fetal catecholamine release. Chronic prenatal stress may negatively impact maternal immunity, resulting in increased risk of infections, increased proinflammatory cytokines (which may affect the developing fetal brain) or immune alterations in the offspring. The postnatal environment

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

also plays a central role in child development and can be difficult to control for when assessing the impact of prenatal stress. Often, prenatal psychosocial stress is a predictor for the postnatal environment. It has been suggested that the fetal programming that occurs as a result of prenatal stress may be protective, equipping the child for the postnatal environment, and it is only when there is a mismatch between the prenatal and postnatal environments that problems in health and behaviour may be anticipated [2].

Summary box 14.1

- Antenatal mood and anxiety disorders in the mother can have negative effects on fetal development, birth outcome and child development.
- Proposed mechanisms include the direct and indirect effects on health behaviours, maternal physiology, placenta and the postnatal environment.

Depression during pregnancy

Depression has been reported in up to 10–15% of pregnant women. This prevalence reflects major depressive disorder (MDD) and less severe depression. MDD is defined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) by at least 2 weeks of low mood, or loss of interest or pleasure, associated with at least five other symptoms such as change in appetite or weight, insomnia or hypersomnia, psychomotor agitation or retardation, decreased energy or fatigue, sense of worthlessness or guilt, difficulty concentrating or making decisions, and recurrent thoughts of death, dying or suicide [3]. The prevalence of MDD in perinatal women is similar to that in women of reproductive age outside the perinatal period, but some women may be at risk during pregnancy. Risk factors for having MDD during pregnancy include being adolescent, poor socioeconomic status, having a prior MDD, current anxiety, comorbid medical problems, life stress, intimate partner violence, poor social support and unintended pregnancy.

Screening guidelines for depression in adults were updated in early 2016, which included screening recommendations for pregnant and postpartum women [4]. Screening pregnant and postpartum women was reported to have 'small to none' harms, and the process of screening could reduce depressive symptoms. It is recommended that screening takes place in healthcare settings with 'adequate systems in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up'. The most widely used screening measure utilized in perinatal women is the Edinburgh Postnatal Depression Scale (EPDS), where a score greater than 10 suggests a possible depression. The Patient Health Questionnaire (PHQ-9) is a widely used screening measure for depression that can be applied to perinatal women [4].

Postpartum blues

Postpartum 'blues' occur in up to 80% of newly postpartum women. Common symptoms include mood lability, low mood, tearfulness, irritability, interpersonal sensitivity, anxiety, fatigue and confusion. The incidence of symptoms peaks in the first 3–5 days after delivery, and symptoms generally resolve spontaneously by 2 weeks. Support and reassurance are generally helpful. Although the expression of the symptoms is presumed to be related to the rapid decrease in hormone levels after delivery, this association has not been unequivocally demonstrated. The clinical significance of postpartum blues is that in up to 25% of women the symptoms do not resolve spontaneously and a full depressive episode may develop.

Postpartum depression

Postpartum depression (PPD) occurs in 10–15% of new mothers. As mentioned in the section about depression during pregnancy, the prevalence of PPD is similar to that in women of reproductive age outside the perinatal period, but some women may be at particular risk during the postpartum period. Risk factors for PPD are similar to the risk factors for developing MDD during pregnancy, and include prior MDD, current depression or anxiety, poor partner and other social support, preterm infant or complicated delivery, being adolescent, poor socioeconomic status, psychosocial stressors and marital conflict. The EPDS and other depression rating scales can screen for the presence of PPD. Ruling out thyroid dysfunction and anaemia is indicated.

As with postpartum blues, studies have failed to unequivocally find an association between hormone concentrations and PPD. It has been postulated that there may be multiple PPD phenotypes. Within the 'hormone-sensitive' phenotype, the normal perinatal fluctuations of reproductive hormones potentially lead to abnormal responses in neurotransmitters (serotonin, monoamine oxidase), HPA axis function, allopregnanolone responsivity, thyroid function, immune function, oxytocin function and genetic expression [5]. In this group of sensitive women, hormonal fluctuations trigger affective dysregulation with the expression of depressive and anxiety symptoms.

The DSM-5 definition of PPD is MDD that has onset within 1 month of childbirth [3]. In reality, many women who are depressed in the postpartum period had

depression during pregnancy, or develop it beyond the first postpartum month. A large-scale study administered the EPDS to 10 000 postpartum women 4–6 weeks following delivery and identified that 14% of them had an EPDS score above 10. Of these women, the onset of the MDD was prior to pregnancy in 27%, during pregnancy in 33%, and developed after delivery in 40% [6]. This study also demonstrated the high psychiatric comorbidity with PPD. Approximately two-thirds of the women who had an EPDS score above 10 had a comorbid anxiety disorder, 23% had bipolar disorder, and 19% endorsed self-harm ideation [6]. Maternal suicide is a leading cause of death in postpartum women in some countries and is often by violent means. Severe PPD can also be a risk factor for infanticide. Suicidal and infanticidal ideation should be inquired about at postnatal visits.

It is important to treat PPD due to the well-established negative effects on infant and child development, in addition to negative effects on the mother and family. PPD can lead to decreased mother–infant attachment and decreased initiation and maintenance of breastfeeding. Children of depressed mothers have been reported to have temperament difficulties, sleep problems and poor self-regulation. Young children may have delayed motor development, behavioural inhibition, externalizing disorders (such as conduct problems), poor emotion regulation and altered cognitive function. Older children and adolescents exposed to PPD have increased prevalence of depressive disorders, anxiety disorders, attention deficit disorder, conduct disorders and medical illnesses.

Eight randomized controlled trials have been published involving antidepressant medications for PPD, including a total of 715 postpartum women. In a pooled analysis of three of these studies, sertraline and paroxetine were found to be more effective than placebo for reducing depressive symptoms in women with PPD [7]. More studies are needed to compare the efficacy of antidepressant medications with psychotherapy, to examine the efficacy of combined antidepressants and psychotherapy, and to confirm that improvement of symptoms after treatment with antidepressant medications also leads to improvement in maternal functioning and infant and child development.

Summary box 14.2

- Postpartum blues occur in up to 80% of newly postpartum women, with symptoms including mood lability, low mood, tearfulness, irritability, interpersonal sensitivity, anxiety, fatigue and confusion.
- PPD has been reported in up to 10–15% of pregnant women and is defined by at least 2 weeks of low mood, or loss of interest or pleasure, associated with at least five other symptoms such as change in appetite or weight, insomnia or hypersomnia, psychomotor agitation or retardation, decreased energy or fatigue, sense of worthlessness or guilt, difficulty concentrating or making decisions, and recurrent thoughts of death, dying or suicide.
- Maternal suicide is a leading cause of death in postpartum women in some countries and is often by violent means, and PPD can also be a risk factor for infanticide.
- It is important to treat PPD due to the well-established negative effects on infant and child development, the mother and the family.

Anxiety disorders

Anxiety disorders are defined in DSM-5 as disorders of excessive fear, which is an emotional response to a perceived or real threat, and anxiety, which is anticipation of future threat [3]. While anxiety disorders are often comorbid with one another, they differ with regard to the stimulus or scenario that induces the fear or anxiety, as well as the associated belief. With all the disorders, a defining feature is that the fear or anxiety is excessive, out of proportion or persisting beyond the appropriate periods, taking cultural contextual factors into consideration. The symptoms may not be attributable to the physiological effects of a substance, medication, another medical condition or mental disorder. Approximately 30% of women experience an anxiety disorder during their lifetime. As anxiety disorders often have a relatively early and chronic course, many women will experience symptoms during the peripartum period, with prevalence estimates for any anxiety disorder ranging from 4.4 to 39% [8].

Generalized anxiety disorder

Generalized anxiety disorder (GAD) is the most common perinatal anxiety disorder, diagnosed by having excessive anxiety and worry that occurs more days than not and can cause functional impairment. DSM-5 criteria for GAD requires symptoms for at least 6 months, so if the onset occurs during pregnancy it may exclude those with excessive worries for less than 6 months and may be difficult to differentiate new-onset GAD from an adjustment disorder with anxious mood. The worries include a number of events or activities, and feel difficult to control. Associated symptoms include restlessness, easy fatiguability, difficulty concentrating, irritability, muscle tension and sleep disturbance, often symptoms that may be considered normal in pregnancy and post

partum. In the general population, prevalence ranges from 1.2 to 6.4%, with higher rates in pregnancy ranging from 8.5 to 10.5% [9]. The worries often involve pregnancy complications and fetal well-being, maternal wellness and partner illness. A previous history of GAD is the strongest predictor of GAD in pregnancy, with additional risk factors including personal or family history of anxiety disorder, lower social support, childhood abuse and lower education. Postpartum, the anxious thoughts often involve mothering skills and the transition to motherhood, breastfeeding, finances, and change in partner relationship, with prevalence rates between 4.4 and 10.8% [9]. GAD is highly comorbid with MDD, often resulting in a more severe and protracted course of illness. GAD can also predict an increase in the development of PPD. In one study, pregnancy anxiety was the strongest predictor of alcohol consumption in the prenatal period.

Maternal anxiety during pregnancy has been associated with an increased risk of PTB and LBW. Research has suggested that GAD and recurrent negative thinking has resulted in less responsive and engaged maternal interactions with their infants. These infants were withdrawn with lowered emotional tone. As a result of excessive maternal worry, mothers may be less able to identify happy infant faces. Maternal GAD during pregnancy was found to result in lower levels of fetal brain-derived neurotrophic factor in cord blood of newborns, suggesting a potential negative impact on the neurodevelopment of the fetus [9].

The mainstays of treatment are individual psychotherapy and selective serotonin reuptake inhibitors (SSRIs) or serotonin–noradrenaline reuptake inhibitors (SNRIs). Cognitive behavioural therapies (CBT) are the first-line choice for mild to moderate perinatal GAD, with the goal of reducing worries to a more reasonable level, lessen the mothers concern over her worries, and reducing autonomic arousal. Additional therapeutic techniques include mindfulness training, relaxation techniques and psychoeducation. SSRIs/SNRIs should be considered in moderate to severe cases, weighing the risk of untreated maternal anxiety and its consequences for the developing infant against the potential risks of medication treatment [9].

Panic disorder

Panic disorder is diagnosed when an individual experiences recurrent unexpected panic attacks, and persistent worry about additional panic attacks or their consequences. A panic attack is defined by an abrupt surge of intense fear or discomfort, along with at least four other symptoms such as accelerated heart rate, sweating, sensation of shortness of breath, chest pain, nausea, feeling dizzy or light-headed, paraesthesias, fear of dying or losing control, and derealization or depersonalization. Agoraphobia, defined as excessive fear or anxiety about being in a situation where escape may be difficult or help not available in the event of developing panic-like or embarrassing symptoms, is often comorbid with panic disorder [3]. In the general population, the 1-year prevalence rate for panic disorder is 2–3%, with a 0.2–5.7% prevalence during pregnancy, decreasing to 0.5–2.9% prevalence at 6–10 weeks post partum. The onset of panic disorder during pregnancy ranges between zero and 54%, with unpredictable courses (worsening, improving or staying the same) that vary widely among studies. There is a risk of onset of panic disorder post partum and after weaning, which is hypothesized to occur due to fall in progesterone levels. Panic disorder in pregnancy may have 4.2 times greater risk of PPD (during the first year postpartum) than those without [8]. Medical conditions that should be considered in the differential for new-onset perinatal panic attacks include thyroid dysfunction, anaemia, pre-eclampsia and phaeochromocytoma.

Case–control studies have reported that untreated panic disorder during pregnancy has been associated with PTB, LBW, shorter gestational age, small for gestational age, anaemia, isolated cleft lip with or without cleft palate and other congenital abnormalities [10].

CBT is the treatment of choice for panic disorder, and has been demonstrated to decrease panic symptoms. Antidepressant medications are considered the first-line pharmacotherapy option, with the goal of reducing panic symptoms and number of attacks. Benzodiazepines are also effective, but have an increased risk of abuse and dependence.

Obsessive compulsive disorder

Obsessions are recurrent persistent thoughts, urges or images that are experienced as unwanted and intrusive, causing marked anxiety or distress. Compulsions are repetitive behaviours or mental acts that one feels driven to complete. The behaviours or acts are clearly excessive, and are not connected in a realistic way to their goal of preventing a dreaded event or situation. The obsessions or compulsions must be time-consuming or cause clinically significant distress or impairment, which helps differentiate the disorder from occasional intrusive thoughts or behaviours that may be common during the perinatal period [3]. In pregnancy, the prevalence of obsessive compulsive disorder (OCD) ranges from zero to 5.2%, and studies show that the course of illness is variable. One meta-analysis showed that prevalence increases as women progress from pregnancy to the postpartum period, and that pregnant or postpartum women are approximately 1.5–2 times more likely to experience OCD compared with the general population [11]. Up to 47% of women retrospectively date their first onset of

OCD in the peripartum period. During pregnancy, the obsessions or compulsions often involve contamination fears and cleaning rituals. During the postpartum period there are often intrusive ego-dystonic obsessional thoughts of intentionally or accidentally harming the infant, fears of contaminating the infant resulting in repetitive washing, fears of infant death, compulsive checking, compulsive ordering and avoidance of being alone with the infant. Postpartum OCD appears to be characterized by the rapid onset of obsessional symptoms after the birth, with onset as early as the second postpartum day [12]. It is important to recognize that most postpartum women, greater than 65%, experience intrusive thoughts of harm coming to their infants, but it is unlikely they will act on those thoughts or develop OCD. Aggressive thoughts related to the child are perceived as distressing to mothers, and women with OCD are not at increased risk of harming their infants [11]. This is important to differentiate from postpartum psychosis, in which the thoughts are not distressing to the mother and the risk of actual harm is increased.

OCD in pregnancy has been associated with lower quality of life in pregnant women, and increased likelihood of PPD [8]. Maternal OCD may have negative impacts on the infant's development. A mother's fear of harming her infant and subsequent avoidance may hinder a secure mother–child relationship, and may also cause the infant to receive inadequate care. Increasing data show that a poor early interaction between the mother and infant can have long-term detrimental effects on the child, such as increased vulnerability to stress and increasing risk for later development of psychiatric disorders [12].

Non-pharmacological options that are effective for treating OCD include CBT and the specific behavioural therapy technique, exposure and response prevention. SSRIs and the tricyclic antidepressant (TCA) clomipramine are the first-line pharmacological treatments, often requiring dosages higher than those used for MDD.

Fear of childbirth

As many as 78% of women experience some fear of childbirth, such as pain, health complications, death of fetus or loss of control. In a subset of women (5–6%), this fear is persistent and causes significant distress, often associated with previous traumatic delivery, anxiety and depressive symptoms during pregnancy, lack of support, dissatisfaction with partners, advanced maternal age and previous caesarean section. The fear may result in less tolerance of pain during childbirth, increased elective and emergency caesarean section rates and increased intrusive memories of childbirth [13].

Post-traumatic stress disorder

Post-traumatic stress disorder (PTSD) follows exposure to actual or threat of death, serious injury or sexual violence, accompanied by recurrent intrusive symptoms for over a month that include avoidance of stimuli associated with the event, negative alterations in cognitions and mood associated with the event, and marked alterations in arousal and reactivity. There is high comorbidity with MDD, GAD and substance misuse [3]. Prevalence rates among women are around 5% for current PTSD and range from 10 to 20% for lifetime PTSD. During pregnancy, the prevalence may be as high as 24% for women at high risk (racial minorities, teens, less educated, or poor) [14]. Women who have experienced a previous trauma, especially childhood or reproductive trauma, may be at increased risk for exacerbation of symptoms during the peripartum period. Prevalence rates of PTSD during the first year post partum range from 0.9 to 4.6%, with PTSD symptoms found in up to 24% [15]. Risk factors associated with postpartum PTSD include previous traumatic life events, sexual abuse, previous depression or psychiatric treatment, previous traumatic births, pregnancy complications, labour anxiety and traumatic experiences during the birth process [15]. Preventive strategies may include providing psychoeducation, extra support, improving coping strategies and increasing the woman's sense of control. One example could include establishing a care plan for delivery, which is shared with the care team, and includes her desires for pain control and medications and immediate post-birth wishes.

Perinatal PTSD increases adverse pregnancy and birthing outcomes, including poor prenatal care, high-risk health behaviours, miscarriage, ectopic pregnancy, PTB and LBW [14]. Perinatal PTSD has been associated with postpartum depression and bonding impairment with the infant, impaired relationship with partner, sexual dysfunction, as well as negatively impacting future reproductive choices [14].

Psychotherapeutic treatment options for PTSD include CBT, exposure therapy and eye movement desensitization.

Summary box 14.3

- Anxiety disorders involve excessive fear out of proportion or persisting beyond the appropriate periods.
- They may not be attributable to the physiological effects of a substance, medication, another medical condition or mental disorder.
- They occur almost twice as often in women than men, with approximately 30% of women experiencing an anxiety disorder during their lifetime.
- Prenatal maternal stress and anxiety have been linked to adverse obstetric, fetal and neonatal outcomes.

SSRIs are considered first-line pharmacotherapy. Prazosin has an off-label role in treating nightmares.

Antidepressant medications during pregnancy

Up to 10% of women take antidepressants at some point during pregnancy. SSRIs are the most widely used; there are fewer data with SNRIs and TCAs. Studies suggest that discontinuation of an antidepressant after conception, in a woman who is doing well, may be associated with an increased risk of relapse. This may be particularly true in women with a multiple past recurrent episodes of MDD or a recent episode. Given the potential adverse effects of untreated prenatal depression, it is important to treat depression to remission, if possible. Adverse effects from SSRIs have been reported, so the minimum effective dose should be used. The recent screening guidelines reported that the harms to the fetus from maternal use of SSRIs/SNRIs are considered 'small to moderate' and the likelihood of serious harms is rated 'low' [4].

The prevalence of most of the adverse effects discussed in this section is low. When there is a potential increased risk from exposure to antidepressant medications during pregnancy, the absolute value of the increased risk is also generally low. Most of the hazard ratios of increased risk range from 1.5 to 2. For many of the adverse effects, underlying disease in the mother (treated or not) may itself be associated with the adverse effect. It is difficult to interpret studies of antidepressant exposure during pregnancy: 'because these are observational studies, causality cannot be determined; it is not possible to control for all possible confounders related to depression, particularly the fact that women with more severe depression may be more likely to take antidepressants during pregnancy' [4].

Miscarriage and birth outcome

Studies of the risk of miscarriage with antidepressant use in the first half of pregnancy have reported mixed results. An increased spontaneous abortion rate may exist in women with depression who do not take an antidepressant. Thus, in studies that do report an increased risk of spontaneous abortion with SSRI use, the increased risk may be due to the underlying depression. Several meta-analyses have reported that antidepressant use during pregnancy is associated with an increased risk of PTB; however, a recent systematic review of studies reported that antidepressant use during pregnancy was not significantly associated with PTB [16]. Studies are also mixed on the association of antidepressants and LBW. It is important to note that the risks of PTB and LBW with antidepressants is similar in magnitude to risks of PTB and LBW with untreated prenatal depression [1].

Congenital malformations

Most recent studies report that prenatal exposure to antidepressants does not increase the risk of major congenital malformations. Although paroxetine has been associated with cardiac malformations, the data have been mixed [16]. A recent study reported that the small increased risk of cardiac malformations with SSRIs became non-significant when the data were adjusted for underlying depression [17]. If there is a small increased risk of cardiac anomalies with an SSRI, it is presumed to be due to serotonergic influence on cardiac development.

Persistent pulmonary hypertension of the newborn

Persistent pulmonary hypertension of the newborn (PPHN) occurs in one to two infants per 1000 live births with a 10–20% mortality risk that can vary with aetiology. A meta-analysis reported that exposure to SSRIs in late pregnancy was associated with a 2.5 times increased risk ratio of PPHN while exposure to SSRIs in early pregnancy was not associated with PPHN [18]. The absolute risk difference for development of PPHN after SSRI exposure in late pregnancy was 2.9–3.5 per 1000 live births. A more recent cohort study suggested that the odds ratio for SSRI use and PPHN was 1.51, which decreased, but remained significant, with adjustment for potential confounders [19]. SSRIs may increase circulating levels of serotonin in the fetus which might increase vasoconstriction and smooth muscle cell proliferation [19]. PPHN may represent the severe end of a spectrum of respiratory difficulties with SSRI exposure.

Neonatal symptoms

One of the most consistent findings with prenatal use of antidepressants is an increased risk of neonatal symptoms that include respiratory distress [16], temperature instability, jitteriness, poor feeding, hypotonia and hypertonia, tremors, cyanosis and seizures. There is no evidence that tapering the antidepressant prior to expected delivery lessens the neonatal symptoms, which can occur in 30% of neonates. The neonatal symptoms are generally mild, require minimal treatment and resolve within the first month. The symptoms may be discontinuation symptoms from abrupt withdrawal of the antidepressant or serotonergic toxicity due to accumulation of the antidepressant in the neonate. Neonatal symptoms, sometime termed poor neonatal adaptation syndrome, have particularly been reported with paroxetine, fluoxetine, venlafaxine and TCAs.

Long-term effects

A recent systematic review of prenatal exposure to antidepressants and developmental outcomes reported inconsistent findings [20]. Some studies suggest delayed motor development and motor control, and possibly delayed language, but no studies have reported a significant association with cognitive problems [21]. When adverse effects are noted, they appear to be within normal limits and resolve with age. It is difficult to separate the effects of prenatal exposure to antidepressants from exposure to the underlying prenatal illness and the influence of postpartum factors such as untreated maternal depression. Studies in older children report some behavioural or emotional problems with prenatal exposure to antidepressants, but the literature is mixed.

A potential long-term consequence of exposure to antidepressant medication during pregnancy is autism or autism spectrum disorders (ASD). Several studies have been published in the past decade, and the results have been contradictory. Untreated maternal depression may be a risk factor for the development of ASD, and many of the studies examining the risk of ASD with SSRI exposure have not taken into account maternal psychiatric diagnosis during pregnancy. Studies that do report an association between SSRI use and ASD generally report a 2–3% increased risk, with the absolute value of the increased risk remaining small. Causality cannot be concluded from these studies. A recent study comparing SSRI exposure during pregnancy to prenatal depression without SSRI exposure did not report an increased risk of ASD, attention deficit disorder or anxiety disorders in offspring [22]. However, this study did report a significant adjusted hazard ratio of 1.78 of depression in adolescence with SSRI exposure during pregnancy compared with exposure to maternal psychiatric disorder without medication [22].

Other effects

Recent studies have reported an increased risk of hypertension and pre-eclampsia with prenatal exposure to antidepressants. The risk of gestational hypertension and pre-eclampsia may be higher with SNRIs compared to SSRIs. Recent reports have suggested a small increased risk of postpartum haemorrhage with SSRIs. Case reports have identified prolonged QTc interval in neonates that resolve after a few days. Positive effects with SSRI exposure has included accelerated infant speech perception and enhanced attention measures. Adverse effects reported with TCAs are similar to those reported with the SSRIs, including increased risks of PTB, LBW and neonatal symptoms. Clomipramine, in particular, has been associated with a possible increased risk of cardiovascular malformations and more severe and prolonged neonatal symptoms.

Summary box 14.4

Antenatal exposure to antidepressants

- Studies often do not control for underlying illness, comorbidities and associated behaviours.
- Untreated antenatal depression is associated with PTB and LBW.
- Although some studies suggest statistically significant increased risks with exposure to SSRIs, SNRIs and TCAs, the increase in absolute risks are small and may not be of clinical significance.
- Possible increased risk of spontaneous miscarriage.
- Possible increased risk of PTB and LBW.
- Possible increase in congenital malformations, but no consistent organ system implicated.
- Possible increased risk of cardiac malformations with paroxetine.
- Increased risk of PPHN with SSRI exposure after week 20.
- Increased risk of neonatal adaptation symptoms.
- Possible increased risk of autism or ASD.
- Long-term effects on child development may be transient, difficult to disentangle from continued maternal depression and other childhood environmental factors.

Breastfeeding and antidepressants

The antidepressant exposure risk with breastfeeding is considerably lower than the exposure risk during pregnancy. A relative infant dose of 10% or less of the maternal dose of psychotropic medications is generally considered low risk, and most studies of antidepressant levels report a relative infant dose of 10% or less [23]. Sertraline, paroxetine and nortriptyline have been reported to have low-to-undetectable infant serum levels in breastfeeding infants, and sertraline is generally considered the first-line choice during breastfeeding. Fluoxetine and citalopram are more likely to have relative infant doses above 10% and have been associated with negative effects in case reports. Adverse effects that may occur include poor feeding, irritability, colic, sedation and sleeping difficulties [24]. Premature infants may be more vulnerable to adverse effects due to decreased capacity to metabolize the antidepressants.

Summary box 14.5

Breastfeeding and antidepressants

- Compatible with most antidepressants.
- Sertraline, paroxetine and nortriptyline are the preferred choices due to very low infant levels.
- Case reports of elevated infant levels with fluoxetine and citalopram.

Benzodiazepines

Many women with mood and anxiety symptoms during pregnancy take benzodiazepines as sole agents or in addition to antidepressants. Cohort studies of prevalence rates of major malformations with benzodiazepine exposure do not suggest an increased risk, but case–control studies have suggested an increased risk of oral cleft with benzodiazepines as a class, and anal atresia with lorazepam. Benzodiazepines have been associated with an increased risk of PTB and LBW. Third-trimester exposure has been associated with the 'floppy infant' syndrome, which includes low APGAR scores, muscle hypotonia and hypothermia. Lorazepam is often utilized during pregnancy due to lower accumulation in fetal tissue [9]. The concurrent use of SSRIs with a benzodiazepine particularly increases the risk of neonatal discontinuation symptoms. The concern with maternal benzodiazepine use and breastfeeding is sedation in infants; this is not commonly reported as an issue.

Non-pharmacological treatments

Non-pharmacological strategies may be the treatment of choice for depression and anxiety disorders in peripartum women who want to minimize fetal exposure to psychotropic medications, and can also be adjunctive treatments. However, systematic studies of whether non-pharmacological therapies for prenatal depression and anxiety disorders reduce the risks from untreated disorders have not been done [1]. Meta-analyses of psychotherapy modalities in pregnant and postpartum women have suggested that psychotherapy is moderately effective compared with usual care [25]. The recently published screening guidelines recommended CBT as effective treatment with 'small to none' harms, noting that most studies have been conducted in postpartum versus pregnant samples [4]. Interpersonal psychotherapy is particularly applicable to pregnancy, with its attention to role transition, interpersonal issues and building social support [25]. Less well studied but promising treatments include exercise, yoga, massage and repetitive transcranial magnetic stimulation. Results with omega-3-fatty acids, folate, St John's Wort, light therapy and acupuncture have been mixed. Pregnant women with severe symptoms who are not responsive to medications or non-pharmacological treatments may need electroconvulsive therapy (ECT). Although ECT has been used safely in pregnancy, there are specific maternal precautions. Reduction in fetal heart rate, uterine contractions, premature labour and fetal demise have been reported [26].

Bipolar disorder

Bipolar I disorder is defined by experiencing at least one lifetime manic episode, which is a distinct period of abnormally and persistently elevated, expansive or irritable mood and abnormally and persistently increased goal-directed activity or energy. The symptoms must last at least 1 week or any duration of time if hospitalization is necessary. The presence of three or more additional symptoms, such as grandiosity, decreased need for sleep, pressured or increased speech, racing thoughts, distractibility or high-risk behaviour must be present, and cause marked impairment in functioning [3]. A diagnosis of bipolar II disorder requires meeting criteria for at least one hypomanic episode (similar symptoms as a manic episode, but only required to be present for four consecutive days with change in functioning, without marked impairment in functioning or necessitating hospitalization) and at least one major depressive episode [3]. The risk of having a recurrence of a bipolar disorder is increased during pregnancy, and particularly during the postpartum period. The risk of relapse is further increased both during pregnancy and after delivery if mood stabilizers are discontinued. Untreated bipolar illness carries many of the risks evident with depressive episodes: poor prenatal care, poor nutrition and health behaviours, substance abuse and suicidal ideation. In addition, impulsive and poor judgement behaviours can complicate the pregnancy. Untreated bipolar disorder has been associated with PTB, microcephaly and neonatal hypoglycaemia.

In the postpartum period, a recent meta-analysis concluded that the risk of relapse in women with bipolar disorders was 37% [27]. Postpartum relapse rates were lower in patients using pharmacotherapy, particularly lithium, during pregnancy (23%) compared with women who discontinued pharmacotherapy (66%) [27]. Risk factors for relapse are medication discontinuation, a previous postpartum mood episode or psychosis, unstable mood in pregnancy, younger age at onset of bipolar disorder and primiparity.

Psychotic disorders and postpartum psychosis

Schizophrenia spectrum and other psychotic disorders are defined by abnormalities in one or more of five domains, which include delusions, hallucinations, disorganized thinking (speech), grossly disorganized or abnormal motor behaviour and negative symptoms [3]. Almost 50% of women with schizophrenia become pregnant, and active psychotic symptoms in pregnancy and

the postpartum period have been associated with adverse outcomes, such as maternal self-harm and physical harm to the infant, negative impact on attachment and poorer developmental trajectories for the child. There are limited data on the course of schizophrenia in pregnancy. According to a recent population study, women with schizophrenia are at lower risk of hospitalization during pregnancy and the first year post partum when compared with the year prior to pregnancy, with the exception being an increased risk in the first 9 days post partum [28]. While psychotic disorders were previously treated with typical or first-generation antipsychotics (FGAs), in recent years atypical or second-generation antipsychotics (SGAs) have become first-line treatments, mainly due to lower rates of extrapyramidal side effects. SGAs have minimal impact on prolactin levels, which is thought to be contributing to the increased fertility rates among women with schizophrenia.

In DSM-5, postpartum psychosis is not recognized as a distinct disorder, but as with mood and anxiety disorders, the specifier 'with peripartum onset' is used if onset of symptoms occurs during pregnancy or within 4 weeks from delivery. Postpartum psychosis has a prevalence of 1–2 per 1000 births in the general population. It can occur as a relapse of a chronic disorder such as schizophrenia or bipolar disorder, or as an initial onset of symptoms postpartum, most commonly taking the form of mania, mixed episodes (with features of both high and low mood) or severe psychotic depression. Patients with bipolar disorder have the highest risk of experiencing a postpartum psychosis. There is a proportion of women with first-onset postpartum psychosis who do not go on to experience a bipolar illness, but have symptoms isolated to the postpartum period. Postpartum psychosis is considered a psychiatric emergency as a result of the rapid onset of severe symptoms and the high potential for devastating outcomes, such as infanticide or suicide. Approximately 4% of women with postpartum psychosis commit infanticide and approximately 5% commit suicide. A recent study reported a greatly elevated 1-year risk of suicide (mortality rate ratio of 289) in mothers with the onset of severe psychiatric illness within 90 days post partum relative to healthy mothers [29].

In the majority of cases, postpartum psychosis has an acute onset within 2 weeks after delivery, with clinical features including mood lability, confusion, insomnia, bizarre behaviour, agitation and disorganization. The content of psychotic symptoms is frequently related to the infant, and delusions are ego-syntonic, or experienced as reasonable or appropriate. There is a loss of reality testing, with a compulsion to act on beliefs and an inability to recognize the consequences of their action, resulting in the increased risk of harm. This is important to differentiate from the ego-dystonic intrusive thoughts that are often present in postpartum depression and anxiety disorders. Treatment often includes inpatient hospitalization and medication management similar to that for psychosis or mood disorders outside of the peripartum period, such as antipsychotics, mood stabilizers, benzodiazepines, sleep regulation, supportive psychotherapy and ECT. It is crucial to rule out other cerebral or systemic conditions, such as delirium, infection, thyroid disorders, drug toxicity or withdrawal, among others.

In the postpartum period, a recent meta-analysis concluded that the risk of relapse in women with a previous postpartum psychosis was 31% [27]. Severe postpartum episodes were more likely in women with previous postpartum psychosis compared to women with bipolar disorder (17%). Additional risk factors for postpartum relapse include relapse during pregnancy, family history of bipolar disorder or postpartum psychosis, primiparity and obstetric complications. In those with isolated postpartum psychosis, initiation of medication immediately after delivery, rather than maintenance during pregnancy, may effectively prevent recurrence of postpartum psychosis [27].

Mood stabilizers

Lithium

An association between lithium exposure and Ebstein's cardiac malformation was reported in the 1970s, but more recent studies have not found lithium to be teratogenic. However, due to the possible increased risk of cardiac malformations, fetal echocardiography and high-resolution ultrasound are recommended at 16–18 weeks. Lithium levels and renal function need to be monitored throughout pregnancy due to increased fluid volume and lithium excretion in the second and third trimesters. Lithium levels generally need to be increased over the course of pregnancy [30]. Thyroid function tests and fetal growth also need to be monitored through pregnancy [31].

Lithium dose can be reduced 24–48 hours prior to delivery or at delivery, but the dose can be maintained if a recent level is normal [30]. Adequate hydration through labour and delivery is important. Following delivery, lithium dosing should be resumed at pre-conception levels and serum levels measured often to rule out toxicity. Neonatal complications have included 'floppy baby' syndrome, nephrogenic diabetes insipidus, hypothyroidism, low muscle tone, lethargy, tachycardia, cyanosis and respiratory difficulties. Few studies have examined the long-term effects of lithium on neurodevelopment, but to date no significant adverse effects have been reported [30].

Valproate

Valproate should be avoided in pregnancy, if possible, due to several adverse effects. Exposure to valproate is

associated with up to 10% increased rates of congenital malformations, including neural tube defects, craniofacial anomalies, cardiac defects, hypospadias and oral clefts [31]. The risks of malformations increase with higher doses and the use of multiple antiepileptic medications. Neonatal symptoms include hypertonia, irritability, poor feeding, hepatic toxicity and hypoglycaemia. The neurodevelopmental teratogenicity is of concern. Neurocognitive impairment has been documented in children through age 6 exposed to valproate *in utero*. There has also been an increased risk of the development of autism and ASD with valproate exposure [30].

Complete blood count, thyroid function tests, liver function tests and antiepileptic serum level should be regular monitored when using valproate (and carbamazepine) during pregnancy [31]. Folic acid supplementation before and during pregnancy is recommended for women on any antiepileptic medication to possibly reduce the risk of a neural tube defect. An α-fetoprotein test can assess a neural tube defect, and high-resolution ultrasound of the face, heart and neuraxis during the beginning of the second trimester is recommended. A careful morphological examination of the neonate and monitoring for withdrawal symptoms, sedation, abnormal clotting, hypoglycaemia or hyperglycaemia are recommended [31].

Lamotrigine

Recent studies do not demonstrate an increased rate of congenital malformations with prenatal lamotrigine exposure, although early studies suggested an increased risk of oral clefts. The increasing oestrogen levels as pregnancy progresses leads to increased glucuronidation, which results in increasing lamotrigine clearance. Lamotrigine doses can be prophylactically increased through pregnancy, or increased when mood symptoms worsen [30]. After delivery, lamotrigine levels increase and the dose should be decreased to the pre-conception dose over the first 2–3 weeks [30]. Neonatal symptoms with maternal lamotrigine use are not common. As yet, there have been no reports of neurodevelopmental impairment after prenatal exposure.

Other antiepileptics

Carbamazepine exposure has been associated with an increased risk of PTB, LBW, spina bifida, other neural tube defects, renal tract abnormalities and other malformations. Studies examining the effect of carbamazepine on cognitive and motor development have reported mixed results. Exposure to topiramate is associated with an increased risk of oral clefts and possibly LBW. Gabapentin has been associated with an increased risk of PTB and LBW. Most of the literature about effects of exposure to antiepileptics comes from studies of women with epilepsy, not with psychiatric disorders.

Antipsychotics

Most of the literature about the effects of prenatal exposure to antipsychotics has not adjusted for underlying psychosis or bipolar illness, both of which can be major confounds. A recent meta-analysis reported a 2.12 OR of increased risk of major malformations with FGAs and SGAs, most commonly cardiac malformations compared to no exposure [32]. There was a 1.86 OR of increased risk of PTB and a lower mean birthweight. There was no increased rate of spontaneous abortions or stillbirths [32]. Third-trimester exposure to both FGAs and SGAs has been associated with abnormal muscle movements and withdrawal symptoms after delivery. There are few studies examining neuromotor development in children, but lower neuromotor performance has been reported in 6-month-old infants with prenatal exposure to both FGAs and SGAs. International registries are available for pregnant women on antipsychotics [30].

Summary box 14.6

Antenatal exposure to mood stabilizers and antipsychotics

- Lithium has a possible increased risk of Ebstein's anomaly or other cardiac anomaly.
- Monitor lithium level and thyroid and renal function through pregnancy.
- Lithium dose needs to be increased during pregnancy, but decreased after delivery.
- Carbamazepine is associated with spina bifida and renal tract anomalies.
- Valproate is contraindicated during pregnancy due to high teratogenicity and neonatal symptoms.
- Valproate is associated with lower IQ and delayed neurocognitive development in children.
- Monitor valproate and carbamazepine levels, hepatic function, complete blood count and thyroid function through pregnancy and supplement with folate before and during pregnancy.
- Lamotrigine does not have an increased rate of congenital malformations.
- Lamotrigine dose often needs to be increased during pregnancy, but should be decreased after delivery.
- Antipsychotics have possible increased risk of congenital malformations, particularly cardiac, possible increased risk of PTB and LBW, possible extrapyramidal symptoms and withdrawal symptoms after delivery, and possible delayed neuromotor development in infants at 6 months.

Breastfeeding and mood stabilizers and antipsychotics

Both valproate and carbamazepine are considered compatible with lactation [23]. Breastfeeding requires close infant observation since serum lithium levels in the infant have been reported to be as high as 50% of the maternal serum level. The infant should be monitored for hypotonia, poor feeding, sustained behavioural change and slow growth. Lithium level, renal function and thyroid status in the infant should be monitored [23]. Lamotrigine levels in breast milk have also been reported to be up to 50% of maternal level, but adverse effects are few, and lamotrigine is considered compatible with breastfeeding. Transient rashes in infants have been reported with maternal lamotrigine use [30]. Lamotrigine could lead to apnoea, sedation and weakness in premature infants [23]. Infant serum levels of topiramate above 10% of maternal level have been reported, but topiramate is considered compatible with breastfeeding. There have been few published reports about maternal antipsychotic use and adverse effects on breastfed infants. To date, there are only a few case reports without consistent patterns. Clozapine is contraindicated during breastfeeding.

Summary box 14.7

Breastfeeding and mood stabilizers and antipsychotics

- Lithium levels in infants may be up to 50% of maternal levels: watch for hypotonia, slow growth and poor feeding. Monitor lithium level, blood urea nitrogen, creatinine and thyroid stimulating hormone in infant.
- Compatible with valproate and carbamazepine.
- Lamotrigine levels in infants may be up to 50% of maternal levels, but minimal adverse effects reported to date.
- Minimal data on topiramate, gabapentin and levetiracetam.
- Compatible with antipsychotics, but minimal data.
- Clozapine not recommended.

Conclusion

There are no risk-free decisions for the pregnant woman with psychiatric illness. It is important for obstetricians to have an understanding of the diagnosis, course and treatment options for the most common mental disorders, as perinatal illness has been associated with adverse obstetric, fetal and neonatal outcomes. There is also potential for adverse effects on the fetus, neonate and child from exposure to psychotropic medication during pregnancy and while nursing. The management of women during the perinatal period needs to be individualized, with a thorough risk–benefit analysis that takes into account the woman's psychiatric course and response to treatments, potential adverse effects of untreated illness, exposure to psychotropic medications and availability of non-pharmacological treatment options. The National Institute for Health and Care Excellence (NICE) has created an antenatal and postnatal mental health clinical management and service guidance that covers recognition, assessment and treatment of mental health problems in women who are planning to have a baby, are pregnant, or have had a baby or been pregnant in the past year (Table 14.1), with recommendations relevant to all healthcare professionals who recognize, assess and refer for or provide interventions for mental health problems in pregnancy and the postnatal period.

Table 14.1 Key recommendations from the National Institute for Health and Care Excellence Clinical Guideline CG192: *Antenatal and postnatal mental health: clinical management and service guidance*.

- Discuss with all women of childbearing potential and a past or current mental health problem use of contraception, how pregnancy and childbirth might affect the mental health problem, and how the mental health problem or treatment might affect the woman, fetus or baby as well as parenting
- Avoid valproate in women of childbearing potential
- Coordinate care by establishing an integrated care plan with all healthcare professionals treating the woman
- Provide detailed information around treatment decisions, advice and monitoring for women, as well as guidance around starting, using and stopping treatment taking into account the risk–benefit ratio for psychotropic medication
- Recognize mental health problems in pregnancy and the postnatal period through screening for depression and anxiety and referring to providers with appropriate knowledge base
- Be aware of considerations for women and their babies in the postnatal period, particularly traumatic birth, stillbirth and miscarriage with interventions facilitated by experienced practitioners
- Establish clinical networks for perinatal mental health services, managed by a coordinating board of healthcare professionals, commissioners, managers, and service users and carers

*The complete list of recommendations can be viewed at https://www.nice.org.uk/guidance/cg192/chapter/1-Recommendations

Autoimmune Rheumatic Diseases and Other Medical Disorders in Pregnancy

Andrew McCarthy[1] *and May Ching Soh*[1,2,3]

Background

The 2009–2012 MBRRACE (Mothers and Babies: Reducing Risk through Audits and Confidential Enquiries across the UK) report has shown a 48% decrease in direct maternal deaths, yet there has not been a significant decrease in indirect maternal deaths [1]. The rate of indirect maternal deaths is now twice that of death from direct causes (6.87 per 100 000 vs. 3.25 per 100 000). Two-thirds of women died from medical or mental health problems in pregnancy, of whom 74% had pre-existing medical (or mental health) problems prior to pregnancy.

With more successsful artificial reproductive therapies, a woman's childbearing years have been greatly extended; some women are facing motherhood at a much older age, thereby increasing the risk of the pregnancy being complicated by coincidental medical conditions. In the UK the latest figures collected through 2009–2012 reveals there were 3 182 873 deliveries of which 3.9% were to women aged 40 years and older; 27% of women who died were obese (body mass index ≥30 kg/m^2) and one-quarter of them smoked. This reflects a major shift, thereby increasing risk of morbidity from medical disorders, and possibly introducing a contributory factor towards indirect deaths in the maternal mortality enquiry.

While many medical conditions in this age group do not result in serious morbidity, others have the potential to do so (e.g. epilepsy, asthma, autoimmune rheumatic diseases and infections). It is important that women receive good advice prior to pregnancy about the potential implications of their medical condition, and enter pregnancy with appropriate confidence about their medication or have specific management plans to alter treatment in early pregnancy. This necessitates that they have ready access to specialist advice once they become pregnant. With more data emerging on the safety of drugs in pregnancy, clinicians no longer have to compromise the effectiveness of medical treatment for long-term conditions. However, changing the mindset of women and other clinicians who are less familiar with pregnancy remains a challenge. It would be ideal if these issues were addressed prior to pregnancy; examples include the continuation of pregnancy-friendly immunosuppressants or biologics in pregnancy and the safety profile of most antiepileptic drugs in pregnancy. This is so that women will be appropriately reassured and will not abruptly discontinue their medications in early pregnancy. Hence the importance of pre-conception counselling cannot be sufficiently emphasized, and was further highlighted in the 2014 report on Saving Lives, Improving Mothers' Care [1].

Management of women with medical disorders is often best coordinated within clinics, with obstetric, medical and midwifery input available. Such clinics make outpatient management much more convenient for the woman, and facilitate good communication between the relevant medical teams. They also serve as a focal point with which the woman may make contact in early pregnancy when treatment changes may need to take place without delay or in later pregnancy if there are problems. Integrated care plans for women with medical disorders should be made. Within units, consideration needs to be given to how such cross-specialty communication occurs if there is no formal multidisciplinary meeting where high-risk cases are discussed. The role of the midwife and support workers cannot be emphasized enough in ensuring that there is a more holistic approach to the care provided.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is the commonest multisystem autoimmune rheumatic disorder affecting women of childbearing age. Prevalence depends on ethnicity, with more severe phenotypes seen in people of African, Far East (Chinese, Korean) and Hispanic extraction. Approximately 30% will have overlap with antiphospholipid syndrome (APS) and are classified as secondary APS.

Fertility is unimpaired in women with SLE unless they have had prior significant cyclophosphamide exposure, secondary APS or have current severe flare. Pregnancy outcomes are worse if conception occurs within 4–6 months of a flare, so planning pregnancy is of paramount importance. Contraception should be discussed with these women. The combined oral contraceptive pill is not associated with an increased risk of flares or SLE disease activity, but is contraindicated in those with secondary APS.

Pre-conception counselling enables any potentially teratogenic drugs (e.g. cyclophosphamide and mycophenolate mofetil) to be switched to more pregnancy-compatible substitutes while the woman's disease is in remission. Folic acid 5 mg should be commenced at least 3 months prior, vitamin D sufficiency confirmed, and hydroxychloroquine (HCQ) must be continued as observational studies have shown improved obstetric outcomes with reduction of flares when there is uninterrupted HCQ use in pregnancy. Aspirin 75 mg and calcium carbonate 2.5 g daily could be considered in women with SLE as their risk of pre-eclampsia is significantly higher than the normal population.

Effect of SLE on pregnancy

Good obstetric outcomes are associated with disease that is in sustained remission for at least 4–6 months prior to conception, ongoing HCQ use in pregnancy and lack of major organ involvement (e.g. lupus nephritis, neuropsychiatric lupus) [2].

Flares of SLE are not more common in pregnancy. The flares that occur in pregnancy generally follow a similar pattern to previously: those with predominantly mucocutaneous disease before pregnancy will flare in a similar fashion, whereas those with lupus nephritis will experience renal involvement. *De novo* presentation with lupus nephritis can occur and may be mistaken for pre-eclampsia if it occurs after 20 weeks' gestation.

Women with SLE have an increased risk of adverse pregnancy outcomes from placental insufficiency. Up to one-quarter of women with SLE develop pre-eclampsia or eclampsia, and 20–31% have preterm delivery. Rates of fetal growth restriction (FGR) range from 5 to 23% in women with SLE.

The risk of deterioration of renal function in pregnancy from a flare of lupus nephritis or pre-eclampsia is higher if the patient is hypertensive or has pre-existing heavy proteinuria or an elevated serum creatinine at baseline. A meta-analysis reported that the incidence of renal lupus flares during pregnancy was 11–69% and renal impairment occurred in 3–27%, which was permanent in up to 10% [3]. One case–control study showed that 28% of patients with class III or IV lupus nephritis developed pre-eclampsia, of whom 35% had a preterm delivery and a significantly lower birthweight compared to the women with SLE without nephritis [4].

Early studies in pregnant women with SLE have demonstrated high circulating levels of soluble fms-like tyrosine kinase-1 (sFlt-1). Similar to the general population, higher circulating levels of sFlt-1 and soluble endoglin (sEng), lower placental growth factor (PGF) and a high sFlt-1/PGF ratio assist in the prediction of pre-eclampsia in SLE pregnancies. In the multicentre Predictors of Pregnancy Outcome: Biomarkers in Anti-phospholipid Syndrome and SLE (PROMISSE) study, low sFlt levels (<1872 pg/mL) and elevated PGF (>70.3 pg/mL) have a negative predictive value in women with SLE, with less than 5% of the cohort developing adverse pregnancy outcomes [5].

Differentiating a flare of SLE from pre-eclampsia

Markers for SLE disease activity are less useful in pregnancy as levels of complement C3 and C4 and erythrocyte sedimentation rate (ESR) all rise in a normal pregnancy; therefore, a relative drop of C3 and C4 from the baseline established in early pregnancy could be a useful marker if previously quantified. Table 15.1 includes helpful tips to differentiate a flare of SLE (especially lupus nephritis) from pre-eclampsia.

Managing a flare of SLE in pregnancy

The management of a flare of SLE depends on the organ systems involved. Prevention is best, and therefore HCQ should be continued in pregnancy. Steroids remain the mainstay of treatment of a flare, but should never be empirically started for the prevention of a flare. Infusions of immunoglobulins which 'mop up' circulating antibodies can be useful for the treatment of a moderate to severe flare; their use must be accompanied by thromboprophylaxis as they increase the risk of thrombosis. Non-steroidal anti-inflammatory drugs (NSAIDs) are safe and non-teratogenic but should only be used up to 32 weeks' gestation (and not within 48 hours of imminent delivery) due to a reversible effect on the neonate's patent ductus arteriosus, resulting in neonatal pulmonary hypertension.

Table 15.1 Useful features for differentiating pre-eclampsia from a flare of SLE or lupus nephritis.

	SLE flare/lupus nephritis	Pre-eclampsia
Hypertension	+	++
Other manifestations of SLE (e.g. rash or oral ulcers)	+	–
Complement (C3, C4)	↓ from baseline (in early pregnancy)	Unchanged
ESR	↑	Unchanged
Double-stranded DNA titres	↑	Unchanged
Proteinuria ≥0.3 g per 24 hours	++	+
Casts	May be present	–
Serum urate	May be ↑	↑↑
Liver function tests	Unchanged	ALT may be ↑
sFlt-1/PGF* ratio	↑	↑

*PGF can be raised in a flare of SLE.
+, present; –, absent; ↑, raised; ↓, decreased; ALT, alanine aminotransferase; ESR, erythrocyte sedimentation rate; PGF, placental growth factor.

Azathioprine has a good safety record in pregnancy. There is increasing evidence for the efficacy of tacrolimus for the treatment of lupus nephritis in pregnancy. On the other hand, mycophenolate mofetil and cyclophosphamide are teratogenic and should never be used in the first 12 weeks of pregnancy. However, if the maternal flare is severe enough to necessitate the use of cytotoxics, cyclophosphamide has been used after the initial period of organogenesis. Long-term follow-up studies of the offspring exposed to cyclophosphamide have shown normal growth and neurodevelopment when followed up until their adolescent years [6]. Rituximab (a B-cell-depleting agent) is not teratogenic but it has a very long half-life and will suppress the neonate's B-cell production for 6–8 months after exposure. Nevertheless, there have not been any adverse effects seen in the exposed offspring, who were able to mount a normal immunological response to vaccination, nor did they have an increased rate of infections. Nevertheless, the number of children exposed to rituximab *in utero* remains small, and there are more cumulative long-term data on cyclophosphamide in pregnancy compared with rituximab.

Congenital heart block and neonatal lupus syndromes

Up to 30% of patients with SLE have Ro antibodies. Ro and La antibodies are part of the extractable nuclear antigens that cross the placenta and potentially damage the neonate's cardiac conduction system resulting in irreversible fibrosis. Ro antibodies are present in 90–100% of mothers of affected offspring, and 68–91% have La antibodies. The risk of congenital heart block is approximately 2% in Ro-positive mothers and is strongly correlated to the titre of Ro antibodies present in the mother. If affected, the overall mortality is around 20%, with deaths usually occurring *in utero* (after developing hydrops and pleural and pericardial effusions). Most infants who survive the neonatal period do well, although two-thirds require pacemakers. The risk of congenital heart block increases exponentially to 15–50% in subsequent pregnancies if there have been previously affected offspring.

Detection of heart block can occur from 18 weeks onwards. However, once in second-degree heart block, the process is almost invariably irreversible, and the treatment would be delivery – if viable – with the implantation of a permanent pacemaker in the neonate. Heart block rarely develops after 28 weeks' gestation, though there are rare instances of heart block developing up to 3 years post partum. Hence most screening programmes for mothers who are Ro or La antibody positive start at 18 weeks and if the second echocardiogram (to determine the PR interval of the neonate) is normal at 28–32 weeks, then no further screening is needed until an ECG at delivery.

The treatment of heart block remains controversial, since none of the therapies previously tried have been effective in reversing second-degree heart block. HCQ has been shown to reduce the incidence of heart block and could be considered even in asymptomatic women who have Ro or La antibodies [7]. High-dose dexamethasone and repeated infusions of immunoglobulins have not been efficacious in reversing established second-degree heart block.

Neonatal cutaneous lupus is an erythematous annular rash, and develops soon after exposure to sun or ultraviolet light. It affects approximately 5% of offspring born to mothers who are Ro or La positive. The rash typically resolves within 6–8 months, with clearance of maternal Ro and La antibodies. Treatment with topical corticosteroids is reserved for severe cases as the rash usually clears spontaneously with only residual hypopigmentation or telangiectasias persisting for up to 2 years.

Summary box 15.1

Women on SLE should remain on HCQ as it affects pregnancy outcomes positively and reduces the risk of fetal congenital heart block in mothers who are Ro and La antibody positive.

Secondary antiphospholipid syndrome

In the normal population, antiphospholipid antibodies are often transient and can be induced by a variety of factors. Medium-to-high titres of antiphospholipid antibodies do not correlate with adverse obstetric outcomes in the absence of accompanying clinical features of recurrent (and consecutive) spontaneous miscarriages under 10 weeks, unexplained mid-trimester losses, preterm delivery before 34 weeks as a result of placental insufficiency or previous thrombotic phenomena [8]. Up to 50% of women with SLE will have circulating antiphospholipid antibodies. Lupus anticoagulant is a much stronger predictor of poor outcomes than anticardiolipin antibodies.

Women with secondary APS who have experienced thrombosis, late losses and features of placental insufficiency should be offered prophylactic low-molecular-weight heparin (LMWH), which should be continued for at least 6 weeks post partum. The use of LMWH to prevent recurrent early pregnancy losses remains controversial; a meta-analysis concluded that LMWH has not demonstrated additional benefit compared with low-dose aspirin [9].

Long-term maternal health and cardiovascular disease

Women with SLE have a much higher risk of premature cardiovascular disease and death compared with the normal population, even in the relative absence of any cardiovascular risk factors. Women with SLE who have had their pregnancies complicated by placental insufficiency are at greater risk of death from cardiovascular causes and accelerated development of cardiovascular disease. Preterm delivery before 34 weeks, which could be a surrogate marker for active SLE in pregnancy, has also been associated with accelerated cardiovascular events in this cohort [10].

Rheumatoid arthritis and other inflammatory arthritides

The adage that rheumatoid arthritis (RA) improves in pregnancy no longer holds true since prospective population-based studies have indicated active disease in at least 40% of women. Those with more severe disease (erosive disease or joint deformities) and anti-cyclic citrullinated peptide (anti-CCP) antibodies often flare more severely than those with seronegative RA.

Seronegative spondyloarthropathies, such as psoriatic arthritis, enteropathic arthritis and ankylosing spondylitis, are less responsive to conventional disease-modifying antirheumatic drugs (DMARDs, e.g. HCQ, methotrexate and sulfasalazine) or prednisolone to treat flares.

Precautions and special considerations in women with inflammatory arthritides

Though women with RA are less fertile, they have similar obstetric outcomes to the normal population, unless they experience active disease in pregnancy. A nationwide prospective study in the Netherlands has shown that active disease in pregnancy is associated with a lower gestational age at delivery and a lower birthweight. Studies from the USA indicate that women with RA have an increased risk of FGR, particularly if they have severe erosive disease. There was also a trend towards an increased risk of developing pre-eclampsia, though the absolute risk remains small when compared to women with SLE.

There is a higher rate of elective caesarean section in women with RA compared to the normal population, which is most likely iatrogenic. Limitation in hip abduction is rarely severe enough to impede vaginal delivery. Additional care is necessary in women with juvenile idiopathic arthritis who may have had hip joint replacements.

Women with inflammatory arthritides should be reviewed by an obstetric anaesthetist to assess cervical spine involvement and degree of jaw excursion in order to anticipate any problems should they require a general anaesthetic in labour. Atlantoaxial subluxation and subsequent paralysis is a rare complication that can occur if a general anaesthetic is administered without due precautions in a woman with erosive disease affecting her cervical spine.

DMARDs and other drugs in pregnancy and breastfeeding

DMARDs are likely to have contributed to the reduced fecundity seen in women with inflammatory arthritides. Methotrexate, previously used as first-line therapy in all patients with RA, is a well-known teratogen. It must be discontinued at least 3 months prior to any attempt at conception and high-dose (5 mg) folic acid should be prescribed. Leflunomide, a pyrimidine synthesis inhibitor, is another commonly used DMARD that has teratogenic potential. Cholestyramine 8 mg for at least 11 days 'washout' should be given prior to pregnancy, but this can also be commenced in very early pregnancy if necessary. There should be confirmation of successful cholestyramine washout with undetectable drug levels (<0.03 μg/mL) taken 2 weeks apart. However, if this is not possible, then ongoing washout with cholestyramine should continue until organogenesis is completed.

Table 15.2 lists a number of DMARDs and other drugs and their suitability in pregnancy and lactation.

Use of anti-TNF and other biologics

'Biologics' are modified part murine and human monoclonal antibodies that act on targeted receptors to reduce the production of various inflammatory molecules. They are increasingly used in women with RA, seronegative spondyloarthropathies and inflammatory bowel disease. At present, they are reserved for patients who have had refractory disease and 'failed' conventional therapy. Therefore, by default, these women have more severe disease. The most commonly used drugs at present are the anti-tumour necrosis factor (TNF) agents, usually infliximab, etanercept, adalimumab, golimumab and certolizumab, and the B-cell depleting agents rituximab and belimumab.

Multiple registries dedicated to studying the effects of these drugs in pregnancy have not demonstrated an increased teratogenic risk. The cases of fetal malformations are sporadic and not part of a syndrome that would suggest interference with organogenesis. Therefore, it is no longer recommended that anti-TNF agents be discontinued prior to pregnancy.

As monoclonal antibodies, these drugs do not cross the placenta (except by slow diffusion in early pregnancy) until after 16 weeks' gestation when syncytiotrophoblasts develop receptors that will bind with the Fc portion of these modified monoclonal antibodies. Transplacental transfer of these drugs increases exponentially from around 22 weeks to its maximal efficiency around 28 weeks' gestation. The efficiency of transfer depends on the half-life of the drug and its Fc portion. Cord blood levels of biologics with a long half-life and an Fc receptor that is conducive to transplacental transfer (e.g. adalimumab and infliximab) are often higher than maternal serum levels if the drug is administered towards the end of pregnancy [11].

There is significant debate surrounding the timing of drug cessation to avoid transplacental transfer, with the European League Against Rheumatisim (EULAR) [12] suggesting that infliximab and adalimumab be discontinued at 20 weeks, whereas etanercept (with its modified Fc portion and short half-life) be discontinued at 30–32 weeks; on the other hand, the British Society of Rheumatology [13] recommends that adalimumab and etanercept can be continued until the end of the second trimester and infliximab stopped at 16 weeks' gestation. However, experts are unanimous that certolizumab, with its large pegylated molecule, only crosses the placenta via slow diffusion and therefore can be continued throughout pregnancy.

The predominant concern with anti-TNF use in pregnancy beyond the recommended gestation is the risk of significant immunosuppression in the newborn. The immature reticuloendothelial system may take 6–8 months to clear the drug, and is dependent on the gestation at which the anti-TNF was discontinued. Therefore, neonates who are exposed *in utero* beyond the recommended gestation should be promptly assessed if there is a suspicion of infection. Live vaccinations (usually rotavirus and BCG) should be avoided for the first 6–7 months of life. The woman, her primary caregiver and paediatric teams should be informed prior to delivery so that the necessary precautions can be undertaken.

Rituximab has an exceedingly long half-life but is not associated with any teratogenesis. However, it is associated with a high rate of miscarriage that is most likely due to underlying maternal disease for which this drug (and likely other drugs as well) is prescribed. EULAR guidelines suggest that, if clinically indicated, it could be continued throughout pregnancy. Transient cytopenias (from B-cell depletion) may occur in the offspring exposed *in utero*; however, neonatal infections or inability to mount a response to vaccination has not been a problem.

The decision to continue any biologic needs to be individualized to the woman, bearing in mind the refractory nature of the underlying disease that has not been amenable to other therapies. If there is a significant risk of flares, with associated maternal (and fetal) morbidity from a flare, then the option to continue these drugs can be discussed, given the caveats that suspected infections in the newborn are promptly assessed and the avoidance of live vaccinations for the first 6–7 months of life.

The obstetrician should be aware that women on biologics are significantly immunosuppressed and they should also be carefully screened for infections at each visit.

Table 15.2 Commonly used drugs used for the treatment of rheumatic diseases and their effect on pregnancy and breastfeeding.

Drug	Effects on organogenesis	Effects on fetus/neonate	Breastfeeding	Authors' recommendations on use in pregnancy
NSAIDs	None	Reversible constriction of ductus arteriosus after 27/40; oligohydramnios; transient anuria and renal failure if used <48hours prior to delivery	✓	Likely a class effect for all NSAIDs. Use if indicated at lowest dose possible till 32 weeks' gestation and stop if delivery is imminent (within 48 hours)
Cyclooxygenase (COX)-2 inhibitors	Likely no increase in anomalies in humans	Oligohydramnios is less profound and preterm closure of the ductus arteriosus is delayed compared with NSAID use	✓ for celecoxib	As more data are available on NSAIDs, it would be safer to change to an NSAID in early pregnancy. However, there could be a role for selective COX-2 inhibitor use in women requiring NSAIDs >32 weeks
Prednisone/prednisolone	None	More than 80% metabolized by placenta and fetus inactivates steroids by hepatic conjugation, and therefore receives <10% of non-fluorinated steroid dose. Theoretical effects in doses in excess of 80 mg: possible cataracts, adrenal insufficiency and infection	✓	The effects are predominantly maternal with immunosuppression with ascending infections, preterm rupture of membranes, increasing risk of gestational diabetes and hypertension. Use lowest dose possible; ensure there is a plan to taper the dose. If disease persistently active, then consider addition of DMARD/biologic to ensure woman does not remain on prolonged courses of high-dose steroids
Hydroxychloroquine	None	None	✓	Continue in pregnancy and breastfeeding
Sulfasalazine (and other 5-aminosalicylic acid compounds)	None	None	✓ except in very preterm jaundiced neonates	Commence folic acid supplementation 5 mg/day 3 months prior to pregnancy. In men with fertility problems, it may need to be swapped with another agent as it affects spermatogenesis and motility
Methotrexate (MTX)	Aminopterin syndrome; high rate of pregnancy loss; 15% rate of congenital anomalies	If no congenital anomalies, long-term follow-up of children exposed to MTX did not reveal any problems	×	Reliable contraception advised. Discontinue ≥3 months prior to pregnancy with daily 5-mg folic acid supplementation. Exposed fetuses should be scanned at 16/40 to determine if there are any congenital anomalies to facilitate elective termination if the mother wishes. No effect if paternal MTX use
Leflunomide	In animal studies, malformations of the head, rump, vertebral column and limb defects. Increased rate of miscarriage	If pregnancy continues, no major structural anomalies noted especialy after cholestyramine washout in very early pregnancy	×	Reliable contraception advised. Wash out with cholestyramine 8 g t.d.s. for 11 days; repeat until drug levels <0.03 μg/mL taken 2 weeks apart (or continue until 12 weeks' gestation). If exposed in early pregnancy, offer washout and reassure woman that, to date, birth outcomes of exposed women no different from disease-matched controls

Azathioprine*	None	None	✓	Continue in pregnancy and lactation
Cyclosporin	None	Transient immune alterations in the neonate	✓	Continue in pregnancy; probably safe in breastfeeding though wide range of concentrations excreted in breast milk
Tacrolimus	None	None	✓	Continue in pregnancy and safe in breastfeeding
Intravenous immunoglobulin	None	None	✓	Concurrent thromboprophylaxis is advised
Cyclophosphamide	Cyclophosphamide embryopathy with high rate of miscarriage	Transient cytopenias. No long-term effect on the neonate if survives pregnancy	×	Use only if there is life-threatening maternal disease after the first trimester. If maternal disease necessitates cyclophosphamide in first trimester, discuss termination
Mycophenolate mofetil	OMENS† and congenital cardiac defects. Phenotype is not dose dependent	Neonates described in the literature, had also been exposed in the period of organogenesis	×	Discontinue for at least 3 months prior to pregnancy

*OMENS: O, orbital distortion; M, mandibular hypoplasia; E, ear anomalies; N, seventh cranial nerve root involvement; S, soft tissue deficiency.
†Azathioprine is converted to the active metabolite 6-thioguanine nucleotides in 15 min but the half-life of the active metabolite in erythrocytes is weeks to months.
✓, safe for breastfeeding; ×, unsafe or not recommended for breastfeeding.
Source: adapted from Soh & Nelson-Piercy [13].

Infections may present atypically (i.e. absence of fever or tachycardia) as these women are unable to mount an adequate immunological response to pathogens. Atypical infections should also be considered. In the longer term, patients on biologics have an increased risk of malignancy, a differential that should be considered if a woman presents unwell [11].

Summary Box 15.2

Anti-TNF agents and rituximab do not appear to be teratogenic but have potent immunosuppressive effects on both the mother and exposed fetus. Fetuses exposed beyond the late second trimester should not receive live vaccinations (rotavirus and BCG) for the first 6–7 months of life.

Scleroderma and other connective tissue diseases

Scleroderma, or systemic sclerosis, is less common than SLE and other inflammatory arthritides, and its inclusion in this chapter is due to its potentially devastating effects in pregnancy. The peak incidence is between 30 and 50 years of age, with a female preponderance of 3 : 1.

Ideally, pregnancy should be planned and the extent of cutaneous disease and systemic involvement carefully quantified. Those with early diffuse disease (<5 years from onset), significant renal impairment, severe restrictive lung disease, pulmonary hypertension or severe cardiomyopathy should be strongly advised against pregnancy. Pulmonary hypertension occurs in 8–12% of patients with scleroderma and is now the main cause of disease-related mortality.

Risk factors associated with poor obstetric outcomes in scleroderma

Women with early (<5 years) or diffuse cutaneous disease, systemic involvement (particularly lung, cardiac or renal) or anti-topoisomerase (anti-Scl-70) antibodies are at greater risk of having more active aggressive disease than those with long-standing disease and anti-centromere antibodies. Up to 40% will have Ro or La antibodies and these should be screened for at booking.

Diffuse cutaneous involvement is associated with twice the risk of miscarriage (24% vs. 12%) and preterm delivery occurs in about 9%. The live birth rate is 77% in those with diffuse disease compared to 84% in women with limited disease.

Pregnancy should be deferred for at least 5 years after diagnosis to ensure that early disease can be aggressively treated with potent and sometimes teratogenic immunosuppressants. Moreover, most renal crises occur in early disease [14].

Scleroderma renal crisis

Scleroderma renal crisis has an almost identical clinical picture to accelerated pre-eclampsia or HELLP (haemolysis, elevated liver function tests, and low platelets) syndrome. Renal histological changes may aid in differentiating the two pathologies. However, as scleroderma renal crisis tends to occur in the third trimester, its management is prompt delivery, prior to initiation of an angiotensin-converting enzyme (ACE) inhibitor. Pregnancy following scleroderma renal crisis is not advised as the risks of recurrence following the cessation of ACE inhibitors (which are contraindicated in pregnancy) cannot be quantified.

Historically, observational studies have linked high doses of corticosteroids (prednisone >30 mg/day or equivalent) with a risk of precipitating a renal crisis. While these data remain contentious, many experts advocate avoidance of high doses of steroids (note that 4 mg betamethasone or dexamethasone for fetal lung maturation is approximately equivalent to 30 mg prednisolone). Presence of anti-RNA polymerase III antibody may be useful in prognosticating the risk of renal crisis, but the strongest predictor remains new-onset diffuse disease (<5 years) with rapidly progressive cutaneous involvement [15]. Therefore, the benefits of antenatal steroids for fetal lung maturation should be very carefully weighed against the risk of precipitating a maternal renal crisis, and they may have to be withheld at gestations for which they are normally prescribed.

Other considerations in pregnant women with scleroderma

Venepuncture, venous access, oxygen saturation and blood pressure measurements may be complicated by the cutaneous involvement. Endotracheal intubation is often difficult as a result of microstomia. There is an increased risk of aspiration and trauma to telangiectatic areas in the nasopharynx. Regional anaesthesia (especially epidural) is usually the preferred option.

Calcium channel antagonists are often used for the treatment of Raynaud's phenomenon. Gastro-oesophageal reflux worsens in pregnancy and proton-pump inhibitors may be added to histamine H_2-receptor antagonists.

Close observation must continue in the immediate postnatal period, particularly in those with cardiac, pulmonary or renal involvement. They are also more vulnerable to pressure sores.

Summary box 15.3

Scleroderma is a multisystem connective tissue disease that has potentially catastrophic effects on the woman's lungs (pulmonary hypertension), heart (cardiomyopathy and arrhythmias) and kidneys (scleroderma renal crisis). These complications are more common with early disease, so women with recently diagnosed (<5 years) scleroderma should be advised to avoid pregnancy.

Ehlers–Danlos syndrome types III and IV

Ehlers–Danlos syndrome (EDS) is a group of disorders characterized by a spectrum of clinical presentations ranging from skin fragility, easy bruising, hypermobility and large joint subluxation to vascular and visceral rupture as a result of (usually) an autosomally dominant inherited defect in collagen metabolism.

EDS type III or benign hypermobility syndrome is the commonest type in young women, presenting typically with generalized hypermobility, recurrent (often spontaneous) joint dislocations and early-onset osteoarthritis with resultant chronic pain and fibromyalgia. There is often an overlap with functional bowel disorders and autonomic dysfunction, such as orthostatic intolerance and postural orthostatic tachycardia syndrome. Aortic root dilatation is typically of a mild degree with no increased risk of dissection in the absence of significant dilation. In labour, precautions are needed to avoid hip dislocations.

EDS type IV (vascular form) is characterized by hypermobility of the small joints, tendon and muscle rupture, arteriovenous fistulae, acrogeria and combined vascular (arterial), visceral and uterine fragility or rupture due to a defect in type III procollagen. In pregnancy, there is an increased risk of preterm rupture of membranes, malpresentation of the fetus, FGR, uterine rupture and postpartum haemorrhage [16]. Because of the high rate of preterm rupture of membranes, prophylactic administration of steroids for fetal lung maturation should be considered, though timing may be difficult. Hence, those with EDS IV require the involvement of the multidisciplinary team for careful monitoring of the aorta for any dilatation. Experts recommend planned lower segment caesarean section before 36 weeks (often at 34 weeks' gestation) to avoid the risk of labour and uterine rupture. Postpartum deaths from aortic rupture can occur.

Summary box 15.4

Women with EDS type IV (vascular) need close multidisciplinary follow-up due to the high risk of complications incuding visceral and vascular rupture, which can extend into the postpartum interval.

Vasculitides in pregnancy

Most vasculitides are more common in elderly males, with the exception of Takayasu's arteritis and Behçet's disease.

Takayasu's arteritis

Takayasu's arteritis is the 'pulseless disease' that occurs in women of the Far East (Japan and Korea). Pregnancy tends to have a positive effect, with lower C-reactive protein levels and improved digital plethysmography up to a year following delivery. However, if there is pre-existing hypertension and involvement of the aortic valve and abdominal aorta, then superimposed pre-eclampsia and FGR are common, with up to 62% and 11–52% of pregnancies affected, respectively. Pulmonary hypertension should be excluded before pregnancy.

Obstetric outcomes are likely dependent on the extent of vessel involvement. FGR is likely due to a combination of impaired placental perfusion as a result of both hypertension and vascular compromise of the abdominal aorta and its branches. There is a correlation between disease severity and poor obstetric outcomes [17].

Behçet's disease

Behçet's disease does not adversely affect maternal and fetal outcomes. Pregnancy results in a threefold reduction in flares; flares were more common in those off their medications, usually mucocutaneous and in the third trimester. However, previous thromboses and vascular complications were associated with poorer outcomes. Thrombotic complications are more likely to recur in pregnancy. Colchicine, the mainstay of treatment, is not teratogenic. However, thalidomide is still used for Behçet's disease and women of childbearing age on this teratogen should be using reliable contraception.

Respiratory disorders

Respiratory disorders in pregnancy constitute a frequent cause of morbidity and occasional mortality. Given the potential difficulties in defining the roles of respiratory

sepsis, bronchospasm and underlying cardiovascular morbidity, it is recommended that women presenting with acute respiratory compromise require prompt assessment by a physician and an anaesthetist or intensive care specialist [1].

Women with respiratory disorders require careful and multidisciplinary assessment when they present for antenatal care. All women with known severe lung disease should be screened for pulmonary hypertension prior to conception [1]. An anaesthetic opinion prior to the third trimester is valuable for those with possible respiratory compromise.

Breathlessness can arise during the course of a normal pregnancy. However, the same complaint can be a manifestation of life-threatening complications such as thromboembolism, cardiac disease or deterioration of background respiratory disease. Patients should have a careful clinical assessment; oxygen saturation, arterial blood gases and chest X-ray (CXR) may assist in differentiating physiological breathlessness from true pathology. In pregnancy there is elevation of the diaphragm and increased tidal volume, although measures of airway flow such as forced expiratory volume in 1 s (FEV_1) and peak expiratory flow rate (PEFR) are unchanged and still valuable in the assessment of respiratory compromise. Women with recurrent admissions have been identified in the maternal mortality enquiry as a high-risk group, and should be assessed by experienced clinicians.

Management of acute respiratory compromise may require delivery. While the physiological adaptation to pregnancy is not critically dependent on any respiratory change, in the presence of pathology the negative impact of pregnancy, including splinting of the diaphragm, may mean that delivery is an important part of the treatment plan for recovery. This may mandate caesarean delivery in difficult circumstances and experienced obstetric, medical and anaesthetic input is required. These women may require general anaesthesia and intensive care after delivery.

Asthma

Asthma is the most common respiratory disorder, with a prevalence of approximately 4% in pregnancy, but was disproportionately represented (prevalence 15%) in those who died. Asthma remains the most common respiratory cause of maternal death [1]. Most women with asthma do not suffer adverse obstetric outcomes, though 'brittle' asthma is always challenging and associated with greater perinatal complications, with a need for fetal monitoring. It is important that women with asthma are given the reassurance that all medications commonly used to control and treat an exacerbation of asthma are safe in pregnancy, and that optimal control is paramount for good obstetric outcomes (see British guideline on the management of asthma at https://www.brit-thoracic.org.uk/document-library/clinical-information/asthma/btssign-asthma-guideline-2014/). Patient education early in pregnancy should include advice on smoking cessation and flu vaccination.

Generally, a short course of oral steroid therapy (prednisolone 0.5 mg/kg daily for 5 days) will achieve control of symptoms where conventional inhalers are failing. As these women may present directly to delivery suites, treatment protocols for an acute exacerbation of asthma and medical back-up should be available. National guidelines emphasize that there should be a lower threshold to refer and admit pregnant women with an acute severe exacerbation of asthma to critical care units [1]. Ideally, women should have optimal control of their asthma prior to childbirth. Those with brittle asthma may require serial visits for stepwise escalation in treatment. Acute exacerbations in labour are rare and are treated in the normal way, with the added precaution of anaesthetic support, supplemental oxygen, intravenous steroids and fetal monitoring.

Summary box 15.5

With the exception of lower thresholds for admission and the involvement of intensive care specialists, asthma should be managed in the same way during pregnancy as when the woman is not pregnant.

Pneumonia

The incidence of pneumonia in pregnancy is similar that in the non-pregnant state. Productive cough and pleuritic chest pain are the most common complaints in addition to breathlessness. Acute pneumonia should be managed by experienced clinicians, and clinically appropriate imaging should not be withheld. Threshold for admission to critical care should be lower in pregnancy, and the focus should be on oxygenation, antimicrobial treatment (including antiviral agents) and thromboprophylaxis. Many will have background respiratory disease, and in one series 24% of patients also had asthma. Infections should be treated vigorously. Most antibiotics (with the exception of tetracyclines) can be used to treat pneumonia in pregnant women; aminoglycosides could be added in severe cases. Preventing progression of underlying infection to sepsis syndrome with associated haemodynamic instability is paramount. Adverse outcomes include a high risk of preterm delivery and abruption. Urgent anaesthetic input is required as delivery may be required.

Varicella pneumonia is a particular cause for concern and can occur in 5% of pregnant women with varicella. It typically arises some days after onset of the rash and is most likely to occur in the third trimester. Women with respiratory symptoms, concurrent encephalitis and hepatitis in the presence of primary varicella infection should be managed with intravenous aciclovir and supportive care. There do not appear to be adverse sequelae for the fetus from aciclovir. Case fatality rates have reduced markedly with aciclovir treatment.

Viral influenzas in pregnancy

The impact of an influenza outbreak on maternal mortality is clear from the 2014 maternal mortality report, and caution regarding influenza vulnerability should be extended into the postpartum period [1]. H1N1 influenza A was the predominant circulating strain then and remains the most widely studied form of all viral influenzas in pregnant women. Antiviral agents (e.g. oseltamivir 75 mg twice daily for 5 days and zanamivir two puffs of 5-mg inhalations twice daily for 5 days) are safe in pregnancy. If the index of suspicion for a viral influenza is high, treatment should be started immediately pending confirmation with nasopharyngeal swabs or aspirates. Poor prognostic factors are presentation in the third trimester with evidence of respiratory compromise at presentation, infiltrates on CXR, obesity and lymphopenia.

Two highly contagious coronavirus respiratory infections are severe acute respiratory syndrome (SARS) from Hong Kong in 2003, and Middle East respiratory syndrome coronavirus (MERS-CoV), which was first described in 2012 in Saudi Arabia. They resulted in severe hypoxaemia necessitating intubation, particularly in women in late gestation, and were associated with a high mortality rate. Fortunately, the number of pregnant women affected remains small, with limited case reports or small case series in the literature. Treatment regimens include ribavirin, interferon alfa 2a, glucocorticoids and antibiotic cover for superimposed bacterial infections. Treatment should not be modified for pregnant women. To date, vertical transmission has not been reported for these coronaviruses in pregnancy.

There appears to be a high rate of spontaneous miscarriage in women with influenza in early pregnancy, but problems with respiratory embarrassment tend to occur in the third trimester. If close to term, delivery should be considered to improve maternal ventilation and markedly reduce oxygen requirements by removal of the fetoplacental unit.

Overarching principles of care are the need for careful isolation of these women to prevent the spread among other vulnerable pregnant women. Women suspected of highly contagious coronaviruses should be placed in a negative pressure isolation room on arrival in triage/hospital. Staff caring for these women should be appropriately protected from airborne infections with N95 (or higher standard) masks in addition to standard isolation gear.

As pregnant women are particularly vulnerable to influenzas, and these vaccinations are safe in pregnancy, women must be strongly encouraged to seek seasonal influenza vaccinations, preferably before 30 weeks' gestation to ensure adequate transplacental transfer of maternal antibodies to the fetus.

Tuberculosis

Tuberculosis can present *de novo* during pregnancy. Symptoms of cough, malaise or weight loss in high-risk groups should be treated with a high index of suspicion. Pregnancy poses a diagnostic difficulty as it is more difficult to interpret non-specific symptoms such as malaise. In the UK, the immigrant population, particularly those who have recently relocated (<5 years), are most at risk, with Somali and Asian women representing nearly all cases [18]. It is associated with a high risk of preterm delivery and intrauterine growth retardation. Delay in diagnosis is greatest for those with extrapulmonary disease. Most treatment options – ethambutol, rifampicin, isoniazid (co-prescribed with pyridoxine) and pyrazinamide – are safe in pregnancy. Streptomycin carries risks of eighth nerve damage and should be avoided. Extrapulmonary disease is as common as pulmonary disease in the UK, and co-infection with HIV significantly increases the risk [18].

Cystic fibrosis

While men with cystic fibrosis are often infertile, fertility is preserved in women. Prenatal diagnosis of this autosomal recessive condition should be discussed before pregnancy. Pregnancy is inadvisable when there is hypoxaemia, poor nutritional status and pulmonary hypertension. Added concerns include liver disease, cystic fibrosis-related diabetes, and the ability of the woman to cope with the demands of a newborn baby, especially in the context of limited life expectancy (late thirties). Pulmonary function tests, echocardiography to exclude pulmonary hypertension, and arterial gases may all guide the decision as to whether pregnancy is advisable. Chest infections require prompt and expert treatment. Early involvement of the anaesthetic staff is advisable, and regional analgesia in labour is preferable. Most women with cystic fibrosis will have a good outcome to their pregnancy, though the most recent confidential enquiry emphasizes that maternal death may occur despite optimal care [1]. There are now an increasing

number of reports of successful outcome to pregnancy following lung transplantation for cystic fibrosis, though there remains a high risk of subsequent rejection, progressive decline in pulmonary function and eventual demise from infection.

Respiratory failure post partum

Respiratory failure is a medical emergency and can arise for the first time in the postpartum period. The differential diagnosis includes adult respiratory distress syndrome, amniotic fluid embolism, pulmonary embolism, infection, side effect of tocolysis and pulmonary oedema secondary to pre-eclampsia, peripartum cardiomyopathy, other undiagnosed cardiac disease or nephrotic syndrome. In the first instance, care is supportive prior to reaching a definitive diagnosis.

Neurological conditions

Epilepsy

Deaths from neurological causes including epilepsy are the third most frequent cause of indirect maternal death. In the 2014 maternal mortality report, there were seven deaths from epilepsy and 17 from other neurological causes. Most women with epilepsy who died did not have pre-conception counselling, and often had poorly controlled epilepsy even prior to pregnancy. Unsurprisingly, the report concluded that many could have had improvements to care which would have influenced outcome. It was also recommended that an identified epilepsy nurse should be part of the care team.

Deaths from epilepsy arise directly from seizures, or SUDEP (sudden unexpected death in epilepsy). The latter category is ill-defined, usually unwitnessed, and may or may not occur during a seizure.

Women of childbearing age who suffer from epilepsy must have their treatment designed to maximize safety and compliance in pregnancy. Ideally, these women are jointly managed by a neurologist (or an epilepsy nurse specialist) with a special interest in pregnancy and an obstetrician specializing in maternal medicine. Pre-conception counselling should discuss the woman's past history (including drug history), the choice of antiepileptic drug (AED) and its effects on organogenesis, the importance of seizure control and SUDEP [1]. Folic acid 5 mg should be started at least 3 months prior to conception due to the relative folate deficiency in this cohort and its beneficial effects on fetal neurocognitive development.

Seizures not only represent a direct threat to maternal health (e.g. drowning, physical injury), but recurrent seizures also put the fetus at risk from hypoxia. Approximately one-fifth of women may experience a deterioration in seizure control during pregnancy [19]. Its causes include poor adherence to medications and falling drug levels (especially with the newer AEDs such as lamotrigine and levetiracetam) with the alteration in protein binding, expansion of intravascular volume and increased renal clearance in pregnancy. The negative effect on seizure control is further compounded by lack of sleep and anxiety.

Some AEDs increase the risk of congenital malformations and women may stop treatment in view of this unless counselled otherwise. The risk of major congenital malformations varies with AEDs, with the lowest rates being found with monotherapy: 2.2% with carbamazepine, 3.2% with lamotrigine, 3.7% with phenytoin and 6.2% with valproate. A higher risk of congenital malformation is associated with higher doses and polytherapy, especially if this includes valproate.

Sodium valproate not only causes congenital malformation (10%) but affects subsequent neurocognitive development (30–40%) [20]. Hence, lamotrigine and levetiracetam are now first-line choices for women of childbearing age. A careful anomaly scan at 20 weeks can exclude specific abnormalities in women on AEDs, but will not achieve 100% detection.

In pregnancy, women must be followed up to ensure doses are titrated, and that they are maintained on as few drugs as possible. Approximately 3% have a seizure during labour, and women should be strongly advised against pool deliveries.

If lamotrigine and levetiracetam doses have been increased in pregnancy, they should be appropriately decreased within 2 weeks of delivery due to the return of maternal physiology to pre-pregnancy levels. Specific advice on childcare, such as not bathing the baby on their own and changing the baby on the floor (not on an elevated changing table), should be provided to the new mother. Patient organizations often have useful information on their websites (see https://www.epilepsy.org.uk/info/caring-children).

Summary box 15.6

Epilepsy in pregnancy has to be well controlled due to the high risk of SUDEP, but control should be maintained on a minimum of AEDs to avoid fetal toxicity.

Headache and migraine

Pregnant women may suffer from headaches that may resolve spontaneously in the second trimester. Migraine is also common in pregnancy. The natural history of migraine in pregnancy suggests a reduction in incidence

throughout the trimesters. Focal migraine can arise in pregnancy and requires an experienced opinion to exclude serious underlying causes. Treatment strategies include low-dose aspirin as prophylaxis, paracetamol, NSAIDs (used intermittently up to 32 weeks) and codeine as pain relief during an acute attack. Propranolol can be added if attacks are persistent. Triptans are safe in pregnancy and a reasonable option for those with troublesome migraine.

Focal transient neurological symptoms can arise in pregnancy and usually have a benign course. One study which assessed women presenting with first occurrence of dysphasia or hemisensory and hemimotor syndromes found a very low incidence of cerebral ischaemia on cerebral imaging [21]. In most cases, it was concluded that these were migrainous attacks, despite the lack of prior history. Subsequently, only 29% demonstrated recurrent migraine on follow-up, suggesting that pregnancy can lower the threshold for a migraine. It is very important that patients presenting with headache are assessed by fundoscopy, and have neck stiffness excluded [1].

Cerebral vascular disease

Strokes in pregnant women are often the result of haemorrhage [1], the main risk factor being poor blood pressure control. Investigation of neurological signs, including cerebral imaging, in pregnancy are the same as in the non-pregnant state.

The incidence of maternal mortality from a cerebral haemorrhage was 0.75 per 100 000 deaths in the 2014 MBRRACE report; 13 of 26 cases were due to subarachnoid haemorrhage and the rest were due to intracerebral bleeds. Risk factors for cerebral haemorrhage include advanced maternal age, African American race, hypertensive disorders with poor blood pressure control, coagulopathy and drug abuse. The period of greatest risk is during the postpartum interval, and this risk is heightened by increasing maternal age. Blood pressure can often be most difficult to control postnatally.

Several UK maternal deaths from cerebral haemorrhages occurred during labour, raising the spectre that labour is a potential risk factor. Defining any increased risk of vascular rupture during labour is not possible from the literature. Decisions on mode of delivery for those with a previous cerebral haemorrhage must be individualized and reflect the patient's wishes, parity and recommendations from the neurosurgeon.

When cerebral aneurysms are detected in pregnancy, management decisions regarding embolization (and the degree of radiation exposure) should be jointly made by obstetricians and neurosurgeons. Pregnancy should not alter the management of an acute stroke; pregnant women should be referred to stroke units and thrombolysis considered as with a non-pregnant patient [1].

Any woman presenting with a severe incapacitating headache should have a full neurological examination and neuroimaging considered.

Summary box 15.7

Strokes in pregnancy are usually haemorrhagic; risk factors include advancing maternal age, hypertension, coagulopathy and drug abuse. An acute stroke should be managed in exactly the same way in a pregnant woman as in a non-pregnant patient.

Cerebral vein thrombosis

Cerebral vein thromboses are more common in pregnancy. Presenting features include a very severe headache, seizures, photophobia and signs of raised intracranial pressure. An experienced opinion should be sought to determine if magnetic resonance angiography is warranted. The treatment involves anticoagulation that should be continued until the postpartum period. Thrombophilias are common in this group. Anticoagulation with LMWH is also needed in subsequent pregnancies.

Summary box 15.8

Cerebral vein thromboses are more common in pregnancy and the woman is likely to have an underlying thrombophilia that will necessitate anticoagulation in the cuurent pregnancy and future pregnancies.

Acute abdominal complications

Up to 2% of all pregnant women will require general surgery, with appendectomy and cholecystectomy being the most common procedures. These problems must be managed aggressively to minimize any risk of associated peritonitis, which can result in premature labour and associated sepsis. The estimated risk of fetal loss is 20% with a perforated appendix as opposed to 5% if uncomplicated. Diagnosis of such complications can be difficult and requires an experienced opinion. The data on route of surgery for appendectomy and cholecystectomy is quite limited, with conflicting data on miscarriage and preterm birth rates. There is a suggestion of a higher rate of fetal loss with laparoscopic approaches, though timing of surgery – with implications for the level of inflammatory insult – is more important than the route of surgery [22]. Caution is

required during the procedure and afterwards, given the risks of preterm delivery and the risk that contractions may be masked by perioperative analgesia.

Half of all cases of newly diagnosed inflammatory bowel disease (IBD) are under 35 years of age. Women with IBD are at increased risk of spontaneous miscarriage, preterm birth and FGR, particularly if active disease is present. Quiescent disease at conception is always a good prognostic sign, with up to 80% remaining in remission. Relapse is often related to discontinuation of medications.

Women with IBD need multidisciplinary care in pregnancy and to deliver at a unit with supportive care for the neonate in the event of prematurity. IBD is treated in the same way in pregnancy as in the non-pregnant state; steroids and 5-aminosalicylic acid compounds (e.g. sulfasalazine, mesalazine, olsalazine) are the mainstays of treatment. Supplementation with haematinics and vitamin D may be required. Anti-TNF drugs may be used in more severe cases (see section on biologics).

Mode of delivery will need to be discussed if there are intra-abdominal adhesions or active disease in the perineal and perianal regions. The 2015 European consensus group lists ileorectal anastomosis or ileoanal pouch as a relative indication for caesarean section; nevertheless the decision still has to be individualized to each woman [23].

Malignant disease

The overall incidence of malignant disease in pregnancy is between 1 in 1000 and 1 in 5000. In the past decade there has been an increasing preparedness to investigate and treat malignant disease in much the same way as in the non-pregnant state. This reflects increasing evidence of safety of chemotherapy in different contexts beyond the first trimester [24]. Not all chemotherapeutic agents are safe, examples including selective oestrogen receptor modulators, tamoxifen and angiogenesis inhibitors. A judgement needs to be made in relation to each agent, the gestation at which it is used, and the underlying malignancy and staging. Antiemetic treatment, steroids and thromboprophylaxis will all need to be considered as part of the treatment profile in view of the nausea associated with chemotherapy and the increased risk of thrombosis in this group.

The MBRRACE 2015 report [25] included a total of 180 maternal deaths between 2009 and 2013, and showed that the range of organ involvement (major categories were breast, brain, haematological, melanoma, lung and gastrointestinal) was similar to that in the non-pregnant group. Older mothers were at greater risk of malignancy and also of dying as a result of it. The report emphasized the need for full investigation of possible malignancy, treatment in the same manner as in the non-pregnant state unless there was specific evidence that this would do harm, and multidisciplinary input but with a named person to coordinate care.

Delayed diagnosis can be a problem in pregnancy as symptoms may be attributed to pregnancy, or signs masked by the abdominal and breast changes of pregnancy. Treatment options may be more limited in view of greater vascularity with pregnancy, more difficult surgical access and greater thromboembolic risk. Chemotherapy and radiotherapy can be considered in pregnancy, based on the increasing volume of reassuring evidence for chemotherapy. There is a modest but generally reassuring level of data looking at development of children exposed to maternal malignancy and chemotherapy *in utero* [26]. The most significant predictor of impairment of neonatal development is prematurity. Therefore, the 2015 maternal mortality report recommends avoiding preterm delivery whenever possible.

Pregnancy may exacerbate the growth of hormone-dependent tumours such as breast cancers. The incidence of pregnancy-related breast cancer is approximately 1 in 1000, and is likely to increase with advancing maternal age. Breast cancer is more likely to present late in pregnancy and prognosis is similar to that of the non-pregnant state when allowance is made for staging. Termination of pregnancy is most likely to be considered if breast cancer is diagnosed in the first trimester, but treatment strategies that allow continuation of the pregnancy may be considered. Treatment can involve surgery, as in the non-pregnant patient. Radiotherapy has been used, but requires careful counselling dependent on the gestational age, the dose required and the potential to shield the fetus. Chemotherapeutic protocols can be used that do not pose a significant risk to the fetus, but are generally avoided in the weeks preceding delivery to minimize the risk of coincident neutropenia or thrombocytopenia [27].

Current advice is that women should defer pregnancy for at least 2 years after a diagnosis of breast cancer, and longer with advanced stages of disease. Similar principles will apply to other tumours. A pragmatic approach has to be taken following a diagnosis of cancer in pregnancy that allows for the individual's wishes, the gestational age, and the feasibility of most forms of cancer treatment in pregnancy with reasonable success rates.

In rare instances, tumours may metastasize to the placenta and fetus. Histological examination of the placenta should be carried out if there is suspected metastatic disease or when maternal death from malignancy occurs. If placental metastatic disease is identified, neonatal follow-up needs to be arranged.

Table 15.3 Ionizing radiation for clinical imaging in pregnancy: doses to mother and baby.

Procedure	Typical effective dose (mSv)*	Average dose absorbed by breast tissue (mGy)	Average dose absorbed by uterus/fetus (mGy)
Chest X-ray	0.02		
CT pulmonary angiogram	2.2–7.0 (max. 21.0)	44.35	0.46
Ventilation–perfusion (*V*/*Q*) scan	1.3–4.4	0.37	0.40
Q-scan	1.0–2.4	0.28	0.25
CT chest	7.0		
CT head	2.0		
CT abdomen	8.0–10.0		

*A range of values are provided because doses will depend on the machine, older machines having higher doses of radiation.
Source: Astani SA, Davis LC, Harkness BA, Supanich MP, Dalal I. Detection of pulmonary embolism during pregnancy: comparing radiation doses of CTPA and pulmonary scintigraphy. *Nucl Med Commun* 2014;35:704–711.

Summary box 15.9

Maligancy can occur in pregnancy and should be investigated in the same way as in the non-pregnant state. Chemotherapy is possible in pregnancy; deliveries should be planned to avoid extreme prematurity.

Imaging in pregnancy

Pregnancy must not preclude effective imaging where clinically indicated. Irradiation from a CXR is minimal and should constitute first-line imaging for any breathless woman. A normal CXR is essential before further ventilation–perfusion (*V*/*Q*) scans are considered. On the other hand, a CT abdomen delivers a substantial dose of irradiation to the abdomen and fetus (8–10 mSv) and alternative forms of imaging should be preferentially considered (Table 15.3).

There have been long-standing concerns about the risks of imaging on the fetus. The International Commission for Radiological Protection has issued some guidance regarding such risks [28]. The risks are low and there is no increased risk of congenital malformations at doses below 100 mGy (equivalent to 100 CT abdomens). These levels could be achieved during fluoroscopically guided interventional procedures or if the woman is undergoing radiotherapy. The risk of childhood leukaemia is trivial, with 10 mGy resulting in one additional case in 1700 exposed individuals. If there has been early exposure (<16 weeks) to doses of radiation exceeding 100 mGy, then there is a risk of reduction in IQ. At doses more than 1000 mGy, there is a risk of microcephaly and severe learning difficulties. However, most of the imaging performed (non-interventional radiological procedures) will not result in such high levels of irradiation to the fetus.

Of greater concern is the exposure of active maternal breast tissue to ionizing radiation in the form of CT pulmonary angiograms when investigating a woman for breathlessness. Hence, the imaging of choice for a pregnant or postpartum woman with a suspected pulmonary embolus is a half-dose *V*/*Q* or *Q*-scan, which has sufficient negative predictive value if the preceding CXR is normal.

Summary box 15.10

Extremely high doses of radiation – beyond the doses for conventional non-interventional imaging – are necessary before there are any deleterious effects on the fetus. On the other hand, maternal breast tissue is vulnerable. Imaging should not be withheld due to an unfounded fear of ionizing radiation in pregnancy.

Obesity and Pregnancy

Mary Higgins and Fionnuala McAuliffe

UCD Perinatal Research Centre, University College Dublin, National Maternity Hospital, Dublin, Ireland

Rates of women with a body mass index (BMI) greater than 30 of reproductive age are rising, with recent estimates of over 25% common in many countries. Therefore obesity in pregnancy is a significant health issue. Obstetricians, when meeting an obese woman in early pregnancy, often focus on the short-term complications of obesity in pregnancy, such as the risk of gestational diabetes mellitus (GDM), pre-eclampsia and thromboembolism, the difficulty of fetal assessment, using ultrasound and fetal heart rate (FHR) monitoring, and the risks of labour. These complications often increase with increasing BMI in a dose–response fashion. Complications need to be considered seriously, as the potential problems may not be minor: obesity has been shown to increase the risk of morbidity and mortality [1].

While the immediate risks may be evident to any clinician in practice, what may not be appreciated are the subtle risks of obesity in pregnancy, how even mild obesity may affect progress in labour, the relative malnutrition of vitamins and minerals, maternal malabsorption and consequent malnutrition as a result of bariatric surgery, as well as the effects of maternal obesity on both fetal programming and long-term risk of cardiovascular disease and the increased risk of childhood obesity. In addition, though many appreciate the risks of morbid obesity (BMI >40, class 3 obesity; Table 16.1) on pregnancy, the clinical team may not fully appreciate the risks of even 'mild' obesity on pregnancy and the effect of pregnancy on the associated complications of obesity. Adipose tissue is an endocrine organ, synthesizing and secreting a variety of hormones and inflammatory markers, including cytokines, leptin and adiponectin. These adipocytokines can have profound effects on pregnancy.

It is well recognized that obesity is increasing in prevalence in both the developed and developing world. Increased sedentary lifestyles, changes in diet and nutrition and a reluctance to implement large-scale public health policies to challenge obesity [2] have resulted in a population very different to that of the 1950s when Friedman first described the 'normal' progress of labour, now known as the Friedman curve [3]. Then, as now, the average BMI of women in labour corresponded to the average BMI of those times, but in the 1950s the median BMI range was 20. Friedman's curve may not apply to the obese, or even overweight, woman.

While all obstetricians appreciate that routine antenatal care needs to be modified in order to provide optimal care to overweight, obese and morbidly obese women, this chapter aims to review the up-to-date evidence that will guide those adaptations.

Contraception, fertility and conception

In adolescence, several studies have shown that obese teenagers may have a higher number of sexual partners, older partners and less use of contraception [4]. This is a worrying pattern that does not continue into adulthood, but does lead to concerns regarding pregnancy risk in a vulnerable group.

For those not wishing to conceive, obesity may be a significant factor when considering contraceptive options. In contrast to adolescents, use of contraceptives does not differ in adult women based on BMI. The following points should be noted when discussing with obese women the most effective contraception. Safety of contraception should also be discussed at length, including the risk of thromboembolism with some forms of contraception.

- Contraceptive implants: no difference in efficacy. Weight gain may be a concern.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 16.1 Classification of maternal BMI (kg/m^2) and cut-off points for defining maternal obesity.

BMI	Class
<19.9	Underweight
20–24.9	Normal weight
25–29.9	Overweight
30–34.9	Obese class I ('mild')
35–39.9	Obese class II ('moderate')
40+	Obese class III ('morbid')

- Depot progesterone: no difference in efficacy. Concerns regarding weight gain are reassuring for adult women, with mean weight gain of less than 2 kg. In contrast, adolescents showed increased weight gain, with obese adolescents having more weight gain than normal-weight adolescents.
- Combined oral contraceptives: data are conflicting but overall there is no significant reduction in efficacy in obese women. Risks of thromboembolism need to be balanced against risk of pregnancy.
- Transdermal combined contraception: body weight over 90 kg is a significant risk factor for failure.
- Emergency contraception: both levonorgestrel and ulipristal acetate have reduced efficacy in obese women (efficacy same as placebo for levonorgestrel and BMI >26 kg/m^2, and for ulipristal and BMI >35 kg/m^2). The copper intrauterine device is considered the most effective form of emergency contraception in all women, irrespective of body weight.
- Tubal ligation: no difference in efficacy, though obesity confers additional risks of surgery (access, infection, risk with anaesthesia).
- Intrauterine device/system: overall, no difference in efficacy. Additional benefits may include improvement in menstrual irregularities and reduction in risk of endometrial carcinoma.

It is now well recognized that there is a reduction in fecundity in obese women. Median time to conception in obese women is 5 months, compared with 3 months for normal-weight women. Various theories suggesting a causative mechanism have been proposed, including the following [5].

- Derangements in hypothalamic–pituitary–ovarian axis.
- Decreased sex hormone-binding globulin (SHBG) with increased free estradiol and testosterone.
- Increased hyperinsulinaemia, resulting in stimulation of ovarian androgen production and hypersecretion of lutenizining hormone.
- Increased rate of polycystic ovarian syndrome (PCOS)/disease: obesity may promote the development of the PCOS phenotype in susceptible women.
- Differences in oocyte quality.
- Differences in endometrial receptivity.
- Menstrual irregularity.
- Inflammatory mechanism (e.g. insulin resistance, metabolic syndrome, increased levels of C-reactive protein, interleukin-6, tumour necrosis factor).
- Effect of adiopocytokines (hormones secreted by adipose tissue).

What is known is that the rate of pregnancy decreases by 5% for every unit of BMI over 29 kg/m^2, even when controlled for PCOS, so there is an indirect correlation between higher BMI and fertility.

Given the possible complications of obesity in pregnancy the ethics of providing subfertility treatment to obese women may be hotly debated, with some centres advocating that couples undergo weight loss prior to commencing any treatment. This is also an opportunity for pre-pregnancy consultation, which will be outlined in more detail in the next section. Weight loss has been shown to increase conceptions, pregnancy and live births; in contrast, women desiring fertility treatment may be concerned regarding non-modifiable factors such as age. Temporarily withholding fertility care may feel patriarchal, but may be an incentive to motivate women and their partners to achieve change. Even a weight loss of 10% of body weight can increase the rate of fertility, between 77 and 88%. The rate of spontaneous conception was doubled (to 35%), a figure comparable to the success rates of some *in vitro* fertilization (IVF) programmes; this suggests that weight reduction should be used as a primary tool prior to embarking on other forms of fertility treatment.

When undergoing fertility treatment, women who are obese face additional challenges, including:

- lower oocyte utilization rate;
- more embryos discarded;
- fewer embryos cryopreserved;
- poorer mean embryo grade;
- higher dose of gonadotrophins used;
- lower implantation rates.

Even in those where fertility treatment is successful, there are still increased risks to pregnancy, including increased risk of prematurity following IVF pregnancy in obese women. This risk of prematurity occurs at all ages of gestation, from viability to term. The risk of prematurity is also seen in twin deliveries following IVF; women with increased BMI are twice as likely to delivery twins prior to 28 weeks' gestation when compared with women with a normal BMI and a twin pregnancy.

Summary box 16.1

- Obesity should be considered when making contraceptive choices, though most have no difference in efficacy. Transdermal combined contraception is a notable exception, with a reduction in efficacy in obese women.
- The most effective form of emergency contraception is the copper coil.
- Obesity reduces fertility, and weight loss can improve fecundity.
- The success of fertility treatment is reduced in obese women when compared with normal-weight women.

Pre-pregnancy consultation

Women with pre-existing medical diseases (e.g. diabetes, cardiac disease, chronic autoimmune diseases) are advised that if they are considering a pregnancy to participate actively in multidisciplinary pre-pregnancy counselling. This aims not just to inform the woman and her partner of the possible risks of pregnancy but also to modify behaviour and medical care in order to best prepare her for a pregnancy. Obesity, given the significant risks of maternal and fetal morbidity, should be regarded similarly. Indeed, this may be a more productive consultation, as the risk factor is modifiable in a way that cardiac disease and autoimmune disease may not be. Women who present for pre-pregnancy consultations self-select to inform themselves and make decisions. Empowering women to make changes can influence not just their health but also the risks of obesity to their pregnancies and their children. Most of the studies reviewing the effects of lifestyle intervention focus on pregnancy itself, but expert opinion suggests that pre-pregnancy interventions hold considerable potential to improve maternal metabolic health.

When?

Opportunities for these consultations include general practice review visits, gynaecological reviews and fertility consultations as well as specialist obstetrics visits with multidisciplinary input. Unlike other long-term diseases, obesity is modifiable, with even small differences in weight significantly reducing the risks to both mother and child.

Bariatric surgery

In addition, women who have undergone bariatric surgery (even if their BMI has normalized) should be counselled regarding the requirement for supplementation after surgery, especially in the context of pregnancy. Nutritional support needs to be tailored both to the patient and the type of surgery she had; an appropriately trained dietitian should ideally provide this. As an example, women who have undergone bariatric surgery may require supplemental calcium, iron, vitamin B_{12}, vitamin A, folic acid, iodine and vitamin K [6].

It is advised that pregnancy should be avoided for 1 year after bariatric surgery because of the rapid weight loss and because malabsorption may increase the rate of intrauterine growth restriction, neural tube defects, neonatal hypoglycaemia and low birthweight. Weight loss following bariatric surgery is associated with a reduction in the rate of GDM, hypertension and pre-eclampsia and with reduced pregnancy-related weight gain.

Concerns have been raised regarding mechanical complications during pregnancy as a result of pregnancy-related vomiting, increased intra-abdominal pressure and repositioning of the abdominal organs to facilitate fetal and uterine growth. Band migration, band leakage, dehydration, herniation and rotation as well as electrolyte disturbances have been described [5]. Some women may choose to undergo tubal ligation concurrently to bariatric surgery.

Screening and general advice

Screening for obesity-related comorbidities (such as type 2 diabetes, chronic hypertension, sleep apnoea, proteinuria, non-alcoholic fatty liver disease and cardiac disease) would be valuable. Specific comorbidities such as ischaemic heart disease may be a relative contraindication to pregnancy. Women should be advised not to smoke cigarettes as this is an additional modifiable risk factor for morbidity and mortality. It has been suggested that those with a history of PCOS specifically should have a cardiovascular risk assessment due to the association with metabolic syndrome. Such an assessment could include family history, waist circumference, blood pressure, glycaemic control (e.g. oral glucose tolerance test) as well as a lipid profile [5]. Weight and height should be measured accurately in order to assess BMI and appropriately advise risks. Special bariatric equipment may be required, for example blood pressure should be measured with an appropriately sized cuff in order to most accurately measure a baseline and assess risk. Bariatric scales may be appropriate.

Because of the relative malnutrition associated with obesity – where the maternal diet may comprise mostly of carbohydrates and fat, high in calories, with minimal minerals and vitamins – it is generally recommended that obese and overweight women should take a higher dose of folic acid than normal-weight women. A dose of 4–5 mg, similar to that for women with diabetes,

epilepsy or a family history of neural tube defects, should be encouraged.

Women should be encouraged to enter pregnancy with a BMI below 30, ideally below 25. Weight is a very personal issue: being labelled 'obese' or 'morbidly obese' may upset women. They are much more than just their weight. At all times care and communication should be conducted sensitively and respectfully.

Summary box 16.2

- Obesity should be considered a medical disease on a par with any other chronic illness.
- Pre-pregnancy planning should be offered to all women with a BMI over 30 with a view to reduction of BMI.
- Pre-pregnancy consultation presents an opportunity to screen for obesity-related comorbidities such as diabetes, hypertension, cardiac disease and sleep apnoea.

Maternal complications: gestational diabetes, pre-eclampsia and pregnancy-induced hypertension

For many women, especially those with a BMI just over the obese range, the booking visit may be the first opportunity for education regarding the impact of obesity on pregnancy, delivery and their children. Because of sensitivities regarding the personal nature of weight and self-image, clinicians may shy away from the challenge of counselling women of the risks of obesity. Some may believe that little can be gained from it as the pregnancy has already started and significant weight loss will not be achievable. Advice regarding exercise, weight gain, nutritional choices and screening for complications such as GDM are appropriate, as pregnancy is a window of opportunity where women are motivated to adopt lifestyle changes.

It is important that this advice is repeated, and from multiple angles from different clinicians. An *honest* discussion means that all members of the team caring for a pregnant woman with obesity approach the pregnancy openly and give the woman information on what may happen in her pregnancy.

Similar to the pre-pregnancy consultation, the first booking visit can be an opportunity to screen for pre-existing disease in order to be able to accurately discuss prognosis. Weight and height should be measured to assess BMI. Self-reporting of weight is unreliable. Blood pressure should be measured with an appropriately sized cuff to establish pregnancy baseline.

Pregnant obese women have been shown to have a diet high in saturated fats and inadequate in carbohydrates, calcium, iron, folate and vitamin D [7]. These micronutrients are crucial for pregnancy. If not already started, consideration should be given to prescribing high-dose folic acid in order to reduce the risk of neural tube defects (it is obviously best to commence this before conception). Depending on the location, consideration can also be given to supplementation with vitamin D (e.g. 400 IU) as obesity predicts poor vitamin D status in both mother and neonate. This will depend on maternal exposure to sunlight of appropriate wavelength and clothing (e.g. those living in cooler climates as well as those with more restrictive clothing). It is also recommended that obese pregnant women lower their intake of processed high-fat foods and confectionary, with a concomitant increase in complex carbohydrates (wholegrain rice, pasta, bread and cereals) in order to be able to improve macronutrient intake by diet. A specific referral to a dietitian for individualized advice may be required, especially for women with a BMI over 40.

Women who have lost weight since a previous pregnancy or a pre-pregnancy consultation should be congratulated: even a small loss of weight can reduce the morbidity associated with a pregnancy affected by obesity. Advice regarding gestational weight gain can be gently but assertively given; the Institute of Medicine recommends a total weight gain in pregnancy of 5–8 kg in obese women [8] (Table 16.2). This is not just for the pregnancy but also for long-term health, since the strongest predictor of weight retention at 1 year post partum is weight gain in pregnancy.

Table 16.2 Institute of Medicine recommendations for total weight gain and rate of weight gain in pregnancy, based on pre-pregnancy BMI (kg/m^2)

Pre-pregnancy BMI	Total weight gain range (lbs)	Rate of weight gain in second and third trimester (mean range, pounds per week)
<19.9 (underweight)	28–40 *(12.7–18.2)**	1 (1–1.3) *0.45 (0.45–0.6)**
20–24.9 (normal weight)	25–35 *(11.4–15.9)*	1 (0.8–1) *0.45 (0.36–0.45)*
25–29.9 (overweight)	15–25 *(6.8–11.4)*	0.6 (0.5–0.7) *0.27 (0.23–0.32)*
30+ (obese, all classes)	11–20 *(5.0–9.1)*	0.5 (0.4–0.6) *0.23 (0.18–0.27)*

*Ranges in italic represent kilogram equivalents.
Source: Institute of Medicine and National Research Council. *Weight Gain During Pregnancy: Reexamining the Guidelines*. Washington, DC: National Academies Press, 2009.

Provided there are no obstetric or medical contraindications, obese women should be encouraged to exercise during and after pregnancy, just as with normal-weight women. Self-reporting shows that one-third of obese pregnant women are compliant with exercise in pregnancy guidelines; this may be reviewed with caution as a consistent finding is that obese women will over-report activity and under-report dietary intake [7].

Written comments in the medical notes should be factual and non-judgemental.

Dedicated clinics

There is no current evidence that one model of antenatal care is superior to any other for obese pregnant women. A dedicated obesity clinic may stigmatize women. Depending on the population demographics, the services may be overwhelmed if the 'bar' for admission is set too low. In contrast, however, a dedicated clinic may not only send a message that obesity is being taken seriously by all members of the multidisciplinary team, but also allow for a package of care to be provided that is consistent to all participants.

Pregnancy following bariatric treatment

Women who have undergone bariatric surgery prior to pregnancy have specific needs to maximize the health of the pregnancy. Those with gastric banding may need bands to be loosened during pregnancy. Dietetic input is essential in order to ensure adequate nutritional intake. This advice may also apply to women who have achieved a normal BMI after surgery, given the nature of the surgery to cause malabsorption.

There are several case reports of internal bowel rotation during pregnancy following gastric bariatric surgery. Women presenting with severe upper abdominal pain should have urgent surgical assessment as they may require emergency laparotomy and bowel excision. Some of these case reports have also described emergency caesarean delivery at the time of laparotomy; others have described preterm delivery or intrauterine demise in the postoperative period in pregnancies at gestations of very early viability.

Gestational diabetes

Although the association between obesity and GDM is well described, it is interesting that a universal theme amongst women with a new diagnosis of GDM is their shock at the diagnosis. This experience was independent of BMI: even those with morbid obesity were surprised and upset at a diagnosis of GDM. Whether the local guidelines suggest risk factor-based or universal screening, women should be screened between 24 and 28 weeks' gestation.

Consideration should be given to screening earlier in women with significant risk factors, such as morbid obesity, as discussed in the sections on booking visit and pre-pregnancy consultations. Where the screening test and diagnostic tests are positive for GDM in obese and morbidly obese women, strong consideration should be given to repeating the test in the postnatal period due to the heterogeneity of GDM, with some women having underlying undiagnosed type 2 diabetes.

It is equally important to gently inform women with GDM, especially those with obesity and morbid obesity, that pregnancy can be considered a 'treadmill test' for future health, and that a diagnosis of GDM is a prognostic indicator for increased risk of diabetes later in life. Modification of risk factors may affect the prognosis.

Hypertension and hypertensive disorders

Obesity is a risk factor for essential hypertension, pregnancy-induced hypertension and pre-eclampsia. This is why it is crucially important to accurately measure blood pressure at both booking visits (to establish baseline) and at subsequent visits in order to screen for both pregnancy-induced hypertension and pre-eclampsia. Nulliparous morbidly obese women (BMI >40) have a 30% chance of developing pre-eclampsia. The risk of both early and late-onset pre-eclampsia is increased in obesity.

Stages in the pathogenesis of pre-eclampsia (cytotrophoblast migration, placental ischaemia, release of placental factors into the maternal circulation, maternal endothelial and vascular dysfunction) are increased as a result of obesity-related metabolic factors [9].

Summary box 16.3

- The first antenatal visit can be an opportunity to inform and plan.
- Consider both calcium and high-dose folic acid supplementation.
- Antenatal anaesthetic consultation should be considered due to the potential difficulties with venous access and regional or general anaesthesia.
- Antenatal visits are opportunities for screening, especially for GDM, pregnancy-induced hypertension and pre-eclampsia.

Fetal complications: ultrasound, anomalies and intrauterine demise

Miscarriage

The risk of miscarriage is increased in obese women, irrespective of the form of conception. In addition, the risk of recurrent miscarriage and intrauterine death is also increased. Given the difficulty of adequate visualization in obesity, it is suggested that a transvaginal probe should be used to scan in early pregnancy in obese women, especially when making the diagnosis of miscarriage.

Fetal anomalies

Obesity confers an increased risk of fetal anomalies, in particular an increased rate of neural tube defects and congenital heart disease. This may be due to a difference in oocyte quality, increased need for artificial reproductive technologies, relative malnutrition or other yet unidentified factors.

Ultrasound assessment

Balanced against the increased risks of congenital abnormalities is the difficulty in obtaining high-quality ultrasound assessment in obese women, with a substantial number of incomplete anatomical assessments. Many centres offer a first anatomy ultrasound at 20 weeks' gestation, allowing both a second attempt at 22 weeks should the assessment be incomplete and the option of termination of pregnancy before 24 weeks should the couple so choose. A recent study analysing the addition of an earlier second-trimester transvaginal ultrasound in obese women (BMI >30) showed an increase in the percentage of 'complete' anatomy scans, from 42 to 51%. Adding a second-trimester transvaginal ultrasound at 14–16 weeks' gestation to the routine anatomy ultrasound at 18–20 weeks' gestation also improved visualization of the head, thorax and abdomen, but not the spine. It is disappointing that the rate of complete anatomy ultrasound was not higher, but this reflects the difficulty of assessing fetal anatomy in obese pregnant women [10].

Growth assessment

Because of the difficulty of assessing fetal growth trajectories by measuring symphysis–fundal height in the obese woman, and the risk of either macrosomia or intrauterine growth restriction, a formal ultrasound assessment of fetal growth in the third trimester is recommended.

Preterm delivery

The rate of premature labour is increased with increasing BMI. This may be iatrogenic (e.g. with a diagnosis of pre-eclampsia, GDM or fetal anomaly) or spontaneous. Spontaneous labour may be the result of polyhydramnios in association with fetal macrosomia, increased maternal inflammation or infection resulting in preterm rupture of the membranes, endometrial factors or increased requirement for IVF (discussed previously) but may also be a result of some other as yet unidentified factors.

Intrauterine death

Obese and morbidly obese women are at increased risk of intrauterine death compared with normal-weight women. Similar to other fetal complications, this may be a result of confounders such as GDM, pre-eclampsia or fetal anomalies, or as a result of a yet unidentified factor. The threshold for investigation should be reduced in obese and morbidly obese women, for example women presenting with reduced fetal movements or with complications in labour.

Summary box 16.4

- Infants of obese women have an increased rate of fetal anomalies, in particular neural tube defects and congenital heart disease.
- Obese women of childbearing age should be advised to take high-dose folic acid.
- There is an increased risk of prematurity and stillbirth in women with BMI over 30.

Delivery issues

Place of delivery

Obese women have a higher incidence of comorbidities and, as such, women with a BMI above 35 may not be suitable for a home birth.

Induction of labour

Obese women have a higher rate of induction of labour. This is due in some to development of complications of pregnancy such as GDM and in others to a postdates pregnancy, which is also increased in pregnancies affected by maternal obesity. The rate of failure of induction increases with increasing BMI, with over half of all inductions of women with a BMI above 40 being unsuccessful. In a nulliparous woman with a BMI over 60, the rate of success of induction may be as low as 20% [11].

So should women with a BMI greater than 40 have an elective caesarean section if the success of induction is not reassuring, and the risks of an emergency caesarean section are high? In a retrospective study of 661 mother–infant pairs with maternal BMI over 40, women having an elective caesarean section had the same morbidity as those with induction of labour. This was despite the fact that 40% of women undergoing induction of labour required an intrapartum caesarean section. Similarly, the risks of neonatal morbidity were equally distributed between the groups [12]. On closer reading, the risks of maternal and neonatal morbidity were highest in those with unsuccessful induction of labour and emergency caesarean section. A composite maternal morbidity score showed a 45% morbidity rate in women with an emergency caesarean birth, compared with 24% in those undergoing elective caesarean birth and 18% in those having a vaginal delivery following induction of labour. Neonatal morbidity followed a similar pattern: 21% with emergency caesarean section, 10% with planned caesarean and 8% following a vaginal delivery after induction. What can be taken from this? That vaginal delivery is an appropriate aim, which means correct selection of women and careful management of labour induction.

Regarding options for induction and augmentation of labour, there are few published studies comparing efficacy of methods in obese women [11]. Those that are available suggest the following.

- Mechanical induction: no data specific to obesity.
- Dinoprostone tampon: obese women are twice as likely to require a second cervical ripening agent compared with non-obese women, and had labour lasting 5 hours longer.
- Misoprostol: obese women receiving misoprostol may have a longer labour than non-obese women (up to 4 hours longer in morbidly obese women) and had a higher rate of caesarean section.
- Dinoprostone tampon compared with misoprostol (oral or vaginal): women receiving dinoprostone had a higher rate of caesarean section after adjusting for confounders.
- Oxytocin: in management of induction and augmentation, obese women require higher doses and longer duration of oxytocin use than non-obese women.

Management of labour

Equipment

There are multiple challenges to managing labour in obese women, not least the logistics of providing the appropriate equipment. Increasingly units are dedicating 'bariatric rooms', where morbidly obese women can labour in a dedicated bed with access to dedicated bariatric equipment, including patient hoists, wheelchairs and seats. Even for obese women who are not morbidly obese, equipment such as longer spinal needles, longer speculums, large blood pressure cuffs and specialized surgical equipment are required to provide safe care [12].

Communication

High-quality communication is a key part of the working of any multidisciplinary team caring for patients, and no less so on the labour ward. BMI can be discreetly noted so that this can be included at staff handover as part of the risk assessment of each woman. Both the consultant obstetrician and anaesthetist should be informed when obese women, at least class 3, present in labour. The remainder of the anaesthetic and obstetric teams, as well as the clinical midwife manager, also need to be aware of obese women in labour due to the increased risk of morbidity, and so early intravenous access and epidural/spinal/combined analgesia should be sited.

Analgesia in labour

Obese and morbidly obese women should undergo a pre-labour anaesthetic review in order to plan options for analgesia in labour and allow more fully informed consent. The BMI at which this should occur would differ between units depending on patient demographics; some suggest all women with a BMI over 40, others a BMI over 50. As well as a focused history and examination, a tactful discussion would include discussion of risks, potential for failure and the mutual goals of both comfort and safety.

It may be difficult for both the staff and the woman for her to be placed adequately to allow safe siting of an epidural catheter or administration of spinal anaesthesia. Appropriate equipment (such as long needles) is very helpful. Consideration should be given to obtaining neuraxial analgesia early in labour, with the most senior anaesthetist performing, or at the very least supervising, placement. Poorly palpable landmarks are associated with placement difficulty, so ultrasound may be useful [13]. Obese women may have a reduced volume of epidural space, so smaller doses of anaesthesia and analgesia may be required. Even if successfully placed, the rates of failure and resiting are higher than in normal-weight women [14].

Difficult regional techniques increase the risk of epidural haematomas, abscesses (1 in 1000) and meningitis (1 in 50 000); however, overall, regional anaesthesia would be considered safer than general anaesthesia. General anaesthesia holds risk of a difficult intubation and the risk of failed intubation (which occurs in 1 in 250 in the general pregnant population but is increased with maternal BMI >30 due to laryngeal oedema and poor airway access) [15].

Fetal monitoring in labour

There are three methods by which fetal heart rate may be monitored in labour: intermittent monitoring, continuous transabdominal and continuous transvaginal with fetal scalp electrode. Because of comorbidities and practicalities, obese women are often unsuitable for intermittent FHR monitoring. External transabdominal monitoring reduces the concerns of introducing infection in an already high-risk group, but is often not practical, especially in women with morbid obesity. Internal monitoring by means of a fetal scalp electrode is sometimes the only method of continuously monitoring FHR patterns in obese and morbidly obese women.

An intriguing recent study has proposed FHR monitoring using transabdominal monitoring of fetal ECG patterns, showing that fetal ECG was more reliable than traditional transabdominal FHR monitoring. The mean BMI in this study was 32 kg/m^2 [16].

Progress in labour

Women who are obese and overweight have statistically significantly longer labours: the average length of labour in normal-weight women is 6.2 hours, in overweight women 7.5 hours and in obese women 7.9 hours. The main 'delay' point in overweight women is between 4 and 6 cm of cervical dilatation, and in obese women prior to 7 cm dilatation; after this there is no difference in progression of labour.

As maternal BMI increases there is a poorer response to oxytocin and an increased need for intrapartum caesarean section. A recent review of labour progress which reported on a study of 5204 labours that ended in vaginal deliveries aimed to develop a more modern partogram to reflect changing demographics. More than half of the participants (53%, $N = 2791$) had a BMI greater than 30, reflecting the increased BMI in parturiants. There was an increased length of the first stage in women with a BMI greater than 30, with the time it took to progress from 4 to 6 cm ranging from 0.5 to 10 hours. Therefore the labour of obese pregnancies may have to be modified to reflect the longer time to progress to the active stage of labour, especially important in the context of the risks of emergency caesarean section [17].

Mode of delivery

Obese women have a higher rate of delivery by caesarean section. This may be due to multiple factors, including increased comorbidity (e.g. GDM, pre-eclampsia), increased fetal weight and macrosomia, increased dystocia as well as clinician concerns of risk of shoulder dystocia and morbidity associated with emergency caesarean section. As discussed previously, the rate of successful induction is decreased in obese women compared with normal-weight women; the overall risk of delivery by caesarean (whether elective or emergency following spontaneous or induced labour) is up to 50% in women with morbid obesity. The odds ratio of caesarean delivery has been reported as 1.46 among overweight women, 2.05 among obese women and 2.89 among severely obese women [18], although this increase is significant only for emergency caesarean deliveries. The success rate of vaginal delivery after caesarean section is also decreased in women with a higher BMI.

Obese and morbidly obese women have the same rights as normal-weight women to request a caesarean section, but a greater emphasis should be placed on fully informing the woman of the significant risks of maternal and fetal morbidity as a result of the caesarean delivery, including the issue of reduced access and increased risk of infection.

As discussed previously, it may take the anaesthetic team longer to establish effective regional analgesia. Conversion to general anaesthesia is not an easier option, as risk of failure of intubation is increased with both pregnancy and obesity. If a caesarean delivery is being performed as an emergency, the anaesthetic team may need to decide quickly the safest method of anaesthesia for the mother and fetus. Good communication with all members of the multidisciplinary team means that provisional plans should be in place for this eventuality, as well as having immediate senior back-up. Early establishment of a good working epidural anaesthesia and intravenous access in labour can also allow for quicker caesarean delivery in the event of an emergency in labour. If there are any delays in establishing effective anaesthesia, then it is prudent to continue fetal and maternal monitoring, continuously feeding back to the anaesthesia team regarding current maternal and fetal well-being.

Modifications of standard caesarean delivery procedures have been suggested for obese women. These include consideration of vertical or transverse subumbilical or supraumbilical incisions [19], as well as propylactic use of subcutaneous drains or negative pressure wound dressings. The evidence for these procedures is currently limited and, as with any procedure, the potential benefits (reduced wound infection, though some suggest an increased risk of infection with use of drains) need to be balanced against potential risks (increased analgesia use, increased bleeding, aesthetics of scar, increased operative time).

In women with 2 cm or more of subcutaneous fat, suturing the subcutaneous space may reduce risk of wound infection, wound separation and haematoma or seroma formation. There is no clear evidence for the best method of skin closure in obese women undergoing caesarean section.

Macrosomia and shoulder dystocia

Infants of obese and morbidly obese women have a higher birthweight and increased risk of shoulder dystocia. Concerns for these in turn leads to a higher rate of induction that is in turn associated with a higher rate of dystocia in labour and caesarean delivery.

Postpartum haemorrhage

Obese and morbidly obese women have an increased risk of postpartum haemorrhage. This highlights again the continuing theme of early intravenous access, early effective epidural and high-quality multidisciplinary team discussion in the management and care of the obese woman in labour. Obese and morbidly obese women should have active management of the third stage of labour.

Summary box 16.5

- The rate of induction of labour failure is higher in obese women.
- Epidural analgesia may be compromised by difficult access; early siting of epidural may be appropriate.
- Risks of caesarean and instrumental delivery may be higher.
- There are increased rates of postpartum haemorrhage.

Postnatal care

Infection and sepsis

Obese women have a higher susceptibility to infections, both bacterial and viral. In pregnancy there is a shift of T helper cells from type 1 to type 2, suppressing antibody-mediated immune responses and activating the innate immune system. The alterations in the maternal immune system allow the genetically foreign fetus to develop without rejection but a side effect is increased susceptibility to infection, including certain pathogens such as *Listeria*, *Toxoplasma*, malaria, influenza, varicella and measles. In obesity there is suppression of function of CD4 and CD8 cells, impairment of natural killer (NK) cells and decreased production of cytokines. In combination the differences in immune response in both pregnancy and obesity have been shown clinically, with increased susceptibility of obese pregnant women to infection compared with normal-weight controls. Other comorbidities, such as anaemia, diabetes, preterm delivery and instrumental or operative delivery, may further increase the risk.

Postnatal infections such as chorioamnionitis, wound infections, mastitis, breast abscess and urinary tract infections are increased in postnatal obese and morbidly obese women. It has been reported that the rate of endometriosis or surgical site infection in women with a BMI above 45 may be as high as 26%. Obesity and pregnancy are major risk factors for respiratory complications of H1N1 influenza infection, with higher rates of admission and mortality in the pregnant obese population. The association with respiratory compromise may be due to restricted lung volume in association with the additive effects of pregnancy- and obesity-mediated immunological changes.

A high requirement for analgesia after an otherwise routine caesarean section may be an indicator of underlying pathology such as a subclinical surgical site infection or necrotizing fasciitis. Obese and morbidly obese women are at increased risk of hospital-acquired infections, partly due to increased risk and partly due to reduced mobility and longer hospital length of stay. Screening for methicillin-resistant *Staphylococcus aureus* (MRSA) may not be routine for obstetric patients but may become so; in one study in the USA, 1 in 50 postnatal women screened positive for MRSA.

It is now nearly universally recommended that all women undergoing elective or emergency caesarean section should receive prophylactic antibiotics; some also suggest repeating the antibiotics following delivery or even dose adjusting to weight. These suggestions are based on altered pharmacokinetics, poorer vascular perfusion of wounds and decreased local immunological response in obese and morbidly obese women [14]. The physical presence of a pannus (or apron) of fat can physically reduce access to the wound, forming a moist, warm and dark environment that promotes bacterial growth and infection.

Use of a pressure dressing (such as PICO) may reduce the incidence of infection. A high vertical incision or transverse subumbilical or supraumbilical incision as an alternative skin incision in morbidly obese women undergoing caesarean delivery has been suggested to reduce not only wound infection but also the physical pressure of retracting a pannus near to the patient's thorax [19].

Thromboembolic disease

It is also nearly universally recommended that all women undergoing elective or emergency caesarean section, instrumental delivery or other operations during the postnatal period should receive prophylactic thromboprophylaxis. This may take the form of appropriately sized thromboembolic deterrent stockings, positive-pressure leg garments or low-molecular-weight heparin (LMWH). Consideration should always be given to individualization of risk assessment and updating this risk assessment based on recent events

(e.g. unexpected caesarean delivery, postpartum haemorrhage); these decisions should be made at a senior level. It has been suggested that independent of other risk factors that all women with morbid obesity should receive thromboprophylaxis to prevent venous thromboembolism (VTE), with LMWH for at least 10 days following even normal delivery and consideration for a full 6 weeks of the postnatal period if other risk factors are present [20].

With regard to LMWH, dose adjusting for maternal weight is critically important [20]. When using a 'standard' dose (e.g. LMWH 75 IU/kg, depending on the formulation) the dose for a 60-kg woman may be a routine 4500 IU, but for a woman weighing 100 kg would be 7500 IU, and for a woman weighing 120 kg would be 9000 IU (nearly twice the 'routine' dose). For some morbidly obese women the propylactic dose may be similar to the therapeutic dose for other women; some women may require two subcutaneous injections to obtain an adequate prophylactic dose and, as such, may have to be given as divided daily doses.

If women present with symptoms suggestive of VTE, full assessment and investigations should be carried out. Wells' score has not been validated in pregnancy and should not be currently used to decide management.

Neonatal issues

Infants of obese mothers have a higher rate of birth injury, respiratory distress, bacterial sepsis, neonatal hypoglycaemia and admission to the neonatal intensive care unit.

Breastfeeding

Obese and morbidly obese women are less likely to initiate and continue breastfeeding. Given the long-term effects in childhood of maternal obesity and the protective effects of breastfeeding, obese and morbidly obese women should be encouraged to breastfeed and may need extra services to help them to do so successfully. Women who have undergone bariatric surgery may need to continue their dietary supplementation while breastfeeding, following the advice of a trained dietitian.

Postnatal anxiety and depression

There is a positive association between obesity and anxiety disorders, and pregnancy is considered to be a special risk group for this given the baseline level of anxiety during or after pregnancy [21]. Many women undergo transient physiological anxiety due to transition to parenting, but for some this may become pathological and continue for some time after delivery. It is well recognized that anxiety and depression during pregnancy increase the risk of anxiety and depression in the postnatal period. Obese and morbidly obese women have higher anxiety trait levels even before 20 weeks' gestation compared with normal-weight women. The rate of anxiety is significantly increased further in morbidly obese women compared with obese women. This is concerning for a number of reasons. Anxiety is considered a barrier to both the treatment and prevention of obesity. The risk of postnatal depression is also increased. Maternal obesity and consumption of a high-fat diet during pregnancy can increase offspring vulnerability for mental or behavioural disturbances.

So why are obese and morbidly obese women more anxious? The perinatal risks of obesity in pregnancy are well described, and we have already mentioned the importance of a full discussion with the pregnant woman at the start of her pregnancy (ideally prior to considering pregnancy) in order to fully inform her of potential risks. Stigmatization of pregnancy obesity may be a factor. Socioeconomic disadvantage and behavioural and neurophysiological changes may all be associated with obesity and anxiety disorders.

Long-term effects

Fetal growth and development is a complex process under the influence of multiple conditions including genetics, maternal environment, uterine environment and hormonal status. Obstetricians are familiar with the Barker hypothesis, which states that the influence of the fetal environment persists into later life. While the most common example of this is the effect of intrauterine growth restriction, there is increasing evidence that maternal obesity alters glucose metabolism and maternal factors that in turn induce changes in developmental trajectories. The effects are numerous, including increased risk in humans of offspring obesity, diabetes, cardiovascular disease, schizophrenia and asthma. In comparison, infants of mothers who have successfully undergone bariatric surgery have

Summary box 16.6

- Increased risk of infection and venous thromboembolism.
- Increased risk of postnatal depression.
- Infants have higher neonatal morbidity compared with infants of normal-weight women.
- Children of obese women have higher rates of childhood obesity and cardiac disease; these effects may be transgenerational.

sustained improvements in cardiovascular markers. This 'diabesity' phenotype has been described as a chronic self-perpetuating cycle [22].

Interventions

There have been calls for educational, environmental and commercial changes to influence people's dietary and lifestyle habits, but without clear leadership and changes in regulations these may not be effective. For the local unit, unable to effectively change national policies with ease, lifestyle advice for obese and morbidly obese women has been proposed with the aim of reducing the morbidity associated with obesity in pregnancy. A number of antenatal interventions in pregnancy have produced differing impacts on pregnancy outcome. The ROLO study (randomized controlled trial of a low glycaemic index diet to reduce macrosomia) resulted in less gestational weight gain and improved maternal glucose tolerance [23]. The LIMIT trial (randomized controlled trial of lifestyle advice with standard care for BMI >25) resulted in less large-for-gestational-age infants with no impact on gestational diabetes [24] and the UPBEAT trial (randomized controlled trial of lifestyle intervention in obese pregnancy) showed less gestational weight gain but no impact on birthweight nor gestational diabetes [25]. While some success has been achieved with pregnancy interventions in terms of improved diet quality and less gestational weight gain, additional focus is required for periods before and after pregnancy as opportunities to improve maternal metabolic health in preparation for subsequent pregnancy.

Summary

Obesity has a significant risk for both maternal and fetal morbidity and mortality in pregnancy. These effects can persist in the children of obese and morbidly obese women, and perhaps even across generations to the children of these children. Interventions in pregnancy have been hindered by lack of interest and compliance and to date have failed to show any real difference. The main challenge reverts back to the reduction in population levels of obesity, so that women enter their pregnancies at a healthier BMI.

One thought of interest on obesity guidelines: while the increased rate of obesity and its corresponding risks in obstetrics and gynaecology is well recognized, it is interesting to note that in a review of national guidelines, only 13 of 31 countries studies had a guideline specific to obesity. In addition, no one guideline reviewed all the aspects that the reviewers had considered relevant to management of obesity in pregnancy. Many discussed screening for GDM or risk of fetal macrosomia. In contrast, the least commonly mentioned components included referral to a local initiative to manage obesity, review by a specialized midwife, monitoring of blood pressure (with an appropriate cuff), utilization of a fetal scalp electrode for monitoring in labour, providing thromboprophylaxis (weight adjusted) and providing prophylactic antibiotics for caesarean section [26].

If women wish to maximize their chances of a healthy pregnancy, and healthy children, then a healthy normal weight should be given as a target prior to their next pregnancy. If their family is complete, aiming for a healthy BMI can act as a target for future health and well-being.

Fetal Growth Restriction

Thomas R. Everett[1] *and Christoph C. Lees*[2,3,4]

[3] *Queen Charlotte's and Chelsea Hospital, London, UK*
[4] *KU Leuven, Belgium*

Fetal growth restriction remains a major cause of perinatal mortality and morbidity, with over 30% of stillbirths having suboptimal growth as a contributory factor. The aetiology of growth restriction is multifactorial and there remains no robust means of predicting fetuses at high risk. This is, in part, due to the fact that the underlying causes are diverse. There also remains no single definition and it is becoming increasingly evident that fetal growth trajectory is as important (and in many case more important) than a single measurement. The balance between iatrogenic prematurity and consequent developmental problems and increased maternal interventions must be weighed against the increased risk of stillbirth. At preterm gestations, management protocols using fetal Doppler and computerized cardiotocography (CTG) improve outcomes, whilst at term gestations delivery does not increase poor outcomes; between 32 and 37 weeks' gestation the evidence for optimal management remains to be established. In order to reduce stillbirth rates further, there remains a need to improve detection of growth restriction and further refine current management protocols.

Definition

There is no single definition of a small or growth-restricted fetus. Variably, some have considered the fetus with an abdominal circumference or estimated fetal weight (EFW) below the 10th centile as small for gestational age (SGA), whilst others have used the 5th or 3rd centile or required Doppler abnormalities to also be present. It is clear that not only a single measurement is important, but fetuses that have significant reductions in growth velocity are at increased risk even if the biometry is still within normal limits [1].

A recent multinational expert consensus statement defining placental fetal growth has set out definitions of early (<32 weeks) and late (>32 weeks' gestation) growth restriction [2] (Table 17.1).

Consequences of growth restriction

The most evident consequence of growth restriction in a fetus is stillbirth. Suboptimal fetal growth is thought to be a significant contributor in 30–50% of antepartum stillbirths, of which placental dysfunction is likely the primary cause. SGA fetuses are at risk of premature delivery, both spontaneous and iatrogenic. Prematurity itself carries gestation-dependent risks, particularly below 30 weeks' gestation, and at this point SGA fetuses are at increased risk of these complications, estimated to be equivalent to being born about 2 weeks prematurely to actual birth gestation. Complications of prematurity include neonatal death, intraventricular haemorrhage, necrotizing enterocolitis and lung disease, which may be chronic.

Low birthweight, particularly when associated with prematurity, has long-term consequences for health and effects are seen particularly in neurodevelopmental outcomes and cardiovascular and metabolic changes. The Barker hypothesis was developed from the historical cohort related to the Dutch famine of 1944. It proposes that the *in utero* environment, particularly with low birthweight babies, causes 'fetal programming' to optimize fetal well-being, but has long-term deleterious effects on cardiovascular and metabolic well-being. Whilst compelling, it should be noted that further factors including genetics and postnatal environment are also important in contributing to long-term health outcomes.

Although the phenomenon of shunting blood to the brain in a compromised fetus is sometimes termed

'brain-sparing', it might best be considered as cerebral redistribution as abnormal brain development can be found in these children. Paediatric follow-up of growth-restricted fetuses shows poorer motor and cognitive function and lower IQ in these children. This is particularly the case when there has been fetal Doppler evidence of cerebral redistribution or evidence of significant placental dysfunction such as absent or reversed umbilical artery end-diastolic flow (EDF) [1,3]. There is also evidence of reduced grey matter, reduced myelination, thinner cortex, reduced number of neurones and smaller head circumference in children born with growth restriction. However, other studies have not replicated these findings and the final determination on whether cerebral redistribution is independent of birthweight and gestation and related to abnormal neurodevelopment remains unclear [2,4].

Impaired angiogenesis results in reduced arteriole and capillary formation. As a consequence there is increased vascular resistance and hypertension. Endothelial dysfunction is evident with increased intimal thickness and vascular stiffness. Consequently, as well as hypertension, there is increased risk of earlier onset cardiovascular morbidity in adulthood [2,5]. Low birthweight is associated with an increase in adult type 2 diabetes and increased insulin resistance and dyslipidaemia has been shown in animal models of growth restriction.

Regulation of fetal growth

The regulation of fetal growth is complex. A fetus has genetically predetermined optimal growth, but the actual fetal growth is determined by the influence of maternal health, placental function and environmental factors. Embryonic growth in the first trimester is remarkably constant. As uteroplacental circulation becomes the major determinant of fetal growth, from the early second trimester discrepancies in fetal growth may become apparent. This is even more so the case in the third trimester.

The function of the placenta is to facilitate oxygen and nutrient transfer to the fetus, whilst removing waste products. Early adaptation of the spiral arteries and trophoblast invasion is essential. This process is not fully understood, but involves complex interactions between genetic and epigenetic programming as well as an appropriate maternal immune response. Failure of this process may result in suboptimal fetal growth, though this is not invariable. Abnormal spiral artery transformation may be associated with completely normal outcomes and vice versa.

Unlike children and adults, glucose is the main source of energy to the fetus and over 95% in the fetus is derived from maternal plasma glucose. Placental glucose transfer is primarily mediated by the glucose carrier GLUT-1 via a mechanism of facilitated diffusion [6]. The transfer of cholesterol, fatty acids and amino acids across the placenta is also closely regulated. There is evidence of increased glucose and fatty acid transfer in cases of increased growth, as seen in gestational diabetes. Conversely, in placentas of growth-restricted fetuses there is evidence of deranged amino acid transfer.

Insulin-like growth factor (IGF)-2 plays an important role in the regulation of fetal growth and amino acid transport. Postnatally, IGF-2 is produced by the liver in response to growth hormone (GH). *In utero*, however, IGF-2 is primarily synthesized within the cytotrophoblast layer of the placenta. IGF-2 binds the IGF receptor (IGF-R), of which there are two types, IGF-1R and IGR-2R. Binding of IGF-2 to IGF-1R results in promotion of growth, whilst binding to IGF-2R results in degradation of IGF-2. Notably, whilst the *IGF2* gene is paternally expressed, the *IGF2R* gene is maternally expressed, demonstrating the opposing parental effects of growth promotion and growth restriction [7]. Regulation of growth by IGF-2 is highlighted by two conditions: Beckwith–Wiedemann syndrome (BWS), an overgrowth syndrome, and Russell–Silver syndrome (RSS), a syndrome of growth restriction. In BWS there is gain of methylation resulting in biallelic *IGF2* gene expression and subsequent overgrowth. Conversely, in RSS the loss of methylation results in biallelic loss of *IGF2* gene expression and subsequent reduced growth. In some cases of BWS and RSS, there may be biallelic gain or loss, due to the relevant part of the chromosome carrying these genes being inherited from the same parent; this is referred to as uniparental disomy.

BWS and RSS are examples of genomic imprinting and epigenetics. Epigenetics is the presence of modifications to the genome that affect gene regulation and which are heritable but potentially reversible. DNA methylation is the commonest form of modification, although more complex histone modification may occur. Over 100 genes have been found to be affected by imprinting; many are involved in fetal and placental growth or thyroid, insulin and glycogen metabolism, with variation between those maternally and those paternally expressed. The recognition of epigenetic influences supports the parental conflict hypothesis: maternally expressed genes are involved in resource conservation (i.e. less flow to the fetus) and paternally expressed genes in resource extraction (i.e. more energy to fetus) [8]. This provides a mechanism for the increasingly recognized paternal contribution to fetal growth disorders.

The association between pre-eclampsia and hypertensive disorders of pregnancy is well known. There is increasing evidence for the association of maternal haemodynamic changes, which may be subclinical, and fetal growth restriction. Reduced maternal cardiac output, lower heart rate and increased peripheral vascular resistance is seen in growth restriction and quite possibly predate its development. There is also evidence of increased vascular stiffness and endothelial dysfunction. Whether these effects are a consequence of growth restriction or cause the condition remains to be elucidated.

Assessment and investigation

Symphysis–fundal height

Routinely, symphysis–fundal height (SFH), the distance from the symphysis pubis to the uterine fundus, is measured at each midwife or antenatal attendance from 24 weeks' gestation. As a guide, the SFH in centimetres is equal to the number of weeks of gestation plus or minus 2 cm. After 36 weeks, the acceptable difference increases to 3 cm. However, SFH has poor intra- and inter-observer reproducibility. SFH is also prone to error due to factors unrelated to fetal biometry, such as maternal obesity, fibroids, polyhydramnios and fetal lie.

There has been recent interest in standardizing SFH measurement by introducing training packages, and plotting the measurement on SFH charts that are generated at booking and adjusted for maternal characteristics. The validity and usefulness of this approach remains to be proven.

Ultrasound biometry

Ultrasound is the current gold standard for fetal growth assessment. Measurements are made of the head circumference, abdominal circumference and femur length. In some cases, biparietal diameter may also be measured. These measurements are inputted into an algorithm, the most common being that developed by Hadlock, to calculate EFW, particularly the four-parameter model. This can then be plotted against gestation-specific centiles.

Customized charts

There remains controversy as to whether fetal growth is the same in all healthy populations, or whether specific differences exist. Two recent studies, INTERGROWTH and WHO, both carried out in different centres throughout the world, have reached different conclusions on this matter. INTERGROWTH suggests that fetal growth is no different in optimally healthy women throughout the world, whereas the WHO study has shown small but significant differences in growth. The controversy is sure to continue, and with it the question of whether customizing birthweight percentiles based on maternal characteristics is appropriate.

Causes

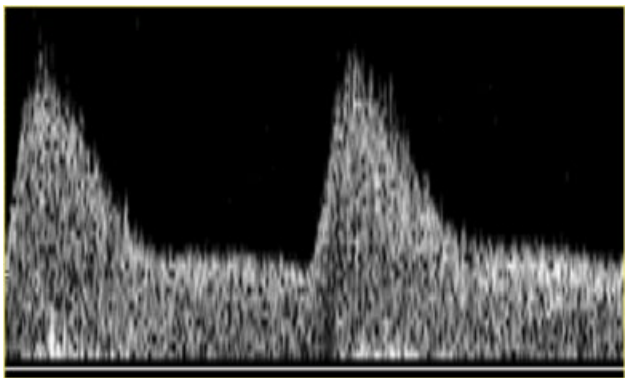
The assessment of the cause of an SGA fetus has important implications for the antenatal management and long-term prognosis. At initial presentation, accuracy of dating of the pregnancy should be assessed and expected date of delivery confirmed. Gestation should be assigned by crown–rump length between 45 and 84 mm (11^{+2} to 13^{+6} weeks' gestation); beyond this gestation, head circumference should be used, although in cases of *in vitro* fertilization (IVF), embryo transfer dates can be used with a correction for day 2 or 5 transfer.

Evidence of poor placentation, failure of adaptation of the spiral arteries and adaptation of the maternal vasculature can be assessed by increased impedance and/or 'notching' in the uterine arteries (Fig. 17.1). Abnormal fetal Doppler indices or oligohydramnios are also suggestive of placental dysfunction as the cause of a small fetus.

A small fetus may have an underlying chromosomal abnormality, particularly when presenting in the second trimester, and invasive testing should be discussed. A detailed anomaly scan should be performed, as any further anomaly would increase this risk further. Serological testing for cytomegalovirus and toxoplasmosis should be performed in severely growth-restricted fetuses. It should be borne in mind, though, that features of placental dysfunction (see above) may also be seen in a poorly functioning placenta secondary to a chromosomal abnormality or infection.

After exclusion of these causes, it should be considered whether a small fetus is constitutionally small. In such cases surveillance is warranted, although these fetuses

(a)



(b)

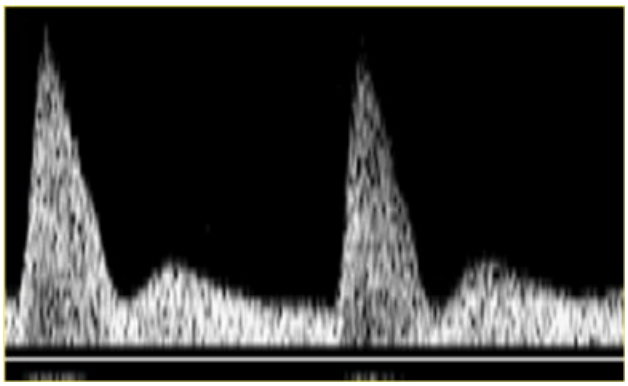


Fig. 17.1 (a) Normal and (b) abnormal uterine artery Doppler waveforms. The waveform in (b) has reduced diastolic flow velocities and an early diastolic notch.

will often follow a normal growth trajectory and have a good prognosis.

Prediction

Because of its heterogeneous aetiology, prediction of growth restriction is complex particularly in first pregnancies. At booking, which usually takes place at 10–13 weeks' gestation, women can be assessed for risk factors. From history alone, these can be subdivided into maternal risk factors, maternal medical conditions and previous pregnancy history (Table 17.2). Paternal SGA should also be noted as this has an odds ratio (OR) of 3.7 for an SGA fetus.

As pregnancy progresses, further risk factors may become evident. In women undergoing combined screening for common trisomies, pregnancy-associated plasma protein A (PAPP-A) is routinely measured. PAPP-A is a placentally derived protease whose main substrate is insulin-like growth factor binding proteins and its serum levels are related to both the function and size of the placenta. There is an association between low PAPP-A levels and low birthweight. Multiple other serum markers have been studied. These include those related to placental mass and function (e.g. ADAM-12, PP-13, IGFBP-1 and IGFBP-3), those related to angiogenesis (e.g. VEGF, endoglin, PGFa and sFlt-1) and those related to endothelial function (e.g. asymmetrical dimethylarginine and homocysteine). None of these has been found to have predictive value that is of clinical use [9].

Ultrasound parameters have been shown to have some utility. The impedance to flow within the uterine arteries can be readily measured. In healthy pregnancy there is normally low resistance and high flow. Abnormalities of uterine artery Doppler waveform include increased impedance and 'notching' (Fig. 17.1). Uterine artery Doppler performed at 24 weeks' gestation has 80% sensitivity for a 5% screen-positive rate for the prediction of a fetus that will require delivery prior to 34 weeks due to growth restriction. The predictive value of uterine artery

Table 17.2 Pre-existing and maternal factors associated with fetal growth restriction.

Risk	OR (95% CI)
Pre-existing maternal factors	
Age >40 years	3.2 (1.9–5.4)
Smoker >11/day	3.21 (2.03–2.4)
Cocaine use	3.23 (2.43–4.3)
Vigorous exercise	3.3 (1.5–72)
Maternal obstetric history	
Previous SGA	3.9 (2.14–7.12)
Previous stillbirth	6.4 (0.78–52.56)
Maternal SGA	2.64 (2.28–3.05)
Maternal disease	
Chronic hypertension	2.5 (2.1–2.9)
Diabetes with vascular disease	6 (1.5–2.3)
Renal impairment	5.3 (2.8–10)
Antiphospholipid syndrome	6.2 (3.47–10.27)
Paternal factors	
Paternal SGA	3.47 (1.17–5.6)
Pregnancy complications	
Heavy bleeding	2.6 (1.2–5.6)
Pregnancy-induced hypertension	2.5 (2.3–2.8)
Pre-eclampsia	2.26 (1.22–4.18)
Echogenic bowel	2.1 (1.5–2.9)
Unexplained APH	5.6 (2.5–12.2)
PAPP-A <0.4 MoM	2.6
Low weight gain	4.9 (1.9–12.6)

APH, antepartum haemorrhage; MoM, multiple of median; SGA, small for gestational age.

Doppler on its own in the first trimester has low sensitivity.

Various algorithms have been developed for the prediction of fetal growth restriction. These commonly use a combination of maternal history, maternal physiological measurements, serum markers and ultrasound parameters. To date, none has had sufficient sensitivity at an acceptable false-positive rate to warrant introduction into routine clinical practice.

Monitoring SGA

There is a clear association between growth restriction and hypertensive disorders of pregnancy, particularly pre-eclampsia. Up to 70% of women with a growth-restricted fetus will develop pre-eclampsia. As such, blood pressure and urine dipstick for proteinuria should be performed at each visit.

Umbilical artery Doppler

The umbilical artery Doppler waveform is the primary Doppler assessment in fetuses with growth restriction. Management protocols based on measurement of the umbilical artery waveform in high-risk pregnancies has been shown to reduce perinatal deaths by up to 29%, though it is not clear on what basis decision-making is improved.

As placental dysfunction increases, there is increasing impedance in placental vessels. This initially presents as raised umbilical artery impedance, detected by increased values in either the resistance index (RI) or pulsatility index (PI). As the uteroplacental circulation is increasingly impaired, absent EDF in the umbilical artery is noted, indicative of loss of normal function in about 60–70% of villi, with progression to reversed EDF as remaining normal placental function is lost (Fig. 17.2). The progression of changes in umbilical artery Doppler waveforms can be rapid and unpredictable, particularly in early-onset fetal growth restriction (FGR). Absent or reversed EDF after 26 weeks of gestation has been shown to have an independent impact on neurodevelopment.

A recent Cochrane systematic review and meta-analysis, including 18 studies and over 10 000 women, demonstrated that women who had Doppler assessment had a significantly lower perinatal mortality (1.2%) compared with those who had not been assessed by Doppler (1.7%; relative risk or RR 0.67; 95% CI 0.46–0.96). Although the data for secondary outcomes showed that there were fewer adverse outcomes in the Doppler group, this did not reach statistical significance [10]. Interestingly, there was a reduction in interventions including induction of labour and lower segment caesarean section in the Doppler group. There was no difference in operative vaginal delivery rates or Apgar scores at 5 min. Notably, though, there is a lack of data on long-term neurological development in the babies in either group.

Middle cerebral artery Doppler

Unlike umbilical artery Doppler, middle cerebral artery (MCA) Doppler can be a proxy for hypoxia and may be abnormal for many weeks in early-onset FGR. The role of the cerebral arteries and the changes that occur in the vessels are important in relation to the concept of 'brain-sparing' in the chronically, or indeed acutely, hypoxic fetus. Although now debated, the concept of 'brain-sparing' involves redistribution of blood by dilatation of the cerebral vessels, thus increasing substrate and oxygen supply to the brain, in response to fetal chemoreceptor or baroreceptor stimulation.

The value of MCA Doppler in the prediction of adverse fetal outcome and assessment of the at-risk fetus has been reported variably. Some studies have suggested that assessment of MCA Doppler is a useful tool, whereas others have found poor predictive value [11–14]. Recently, a meta-analysis of eligible studies (35 in total) including 4025 fetuses has been performed [15]. This found that low MCA PI appears to be associated with fetal well-being assessed by acidosis (pH <7.20) at birth (although this finding is largely biased by a single study in a high-risk population [16]), Apgar score below 7 at 5 min or admission to neonatal intensive care.

It is important to recognize that while these findings do suggest that there is an association between abnormal MCA and adverse outcomes, the association is weak. Overall, this meta-analysis suggests that in clinical practice MCA alone has limited predictive value for compromise of fetal or neonatal well-being.

Cerebroplacental ratio

As discussed in the previous section, the normal physiological response of MCA dilatation in fetuses exposed to acute or chronic hypoxic conditions results in a reduction in fetal MCA PI. Commonly, though not universally, this is associated with increasing impedance in the umbilical artery. Whilst the values obtained on measuring these Doppler parameters individually may be within normal limits, it is possible that the fetus is compensating. By using the ratio of MCA to umbilical artery Doppler PI – the cerebroplacental ratio (CPR, also called the cerebro-umbilical ratio) – it may possible to determine which fetuses may be at risk of compromise, as those with abnormal (i.e. low) CPR may be considered to have failed to reach their growth potential [17,18].

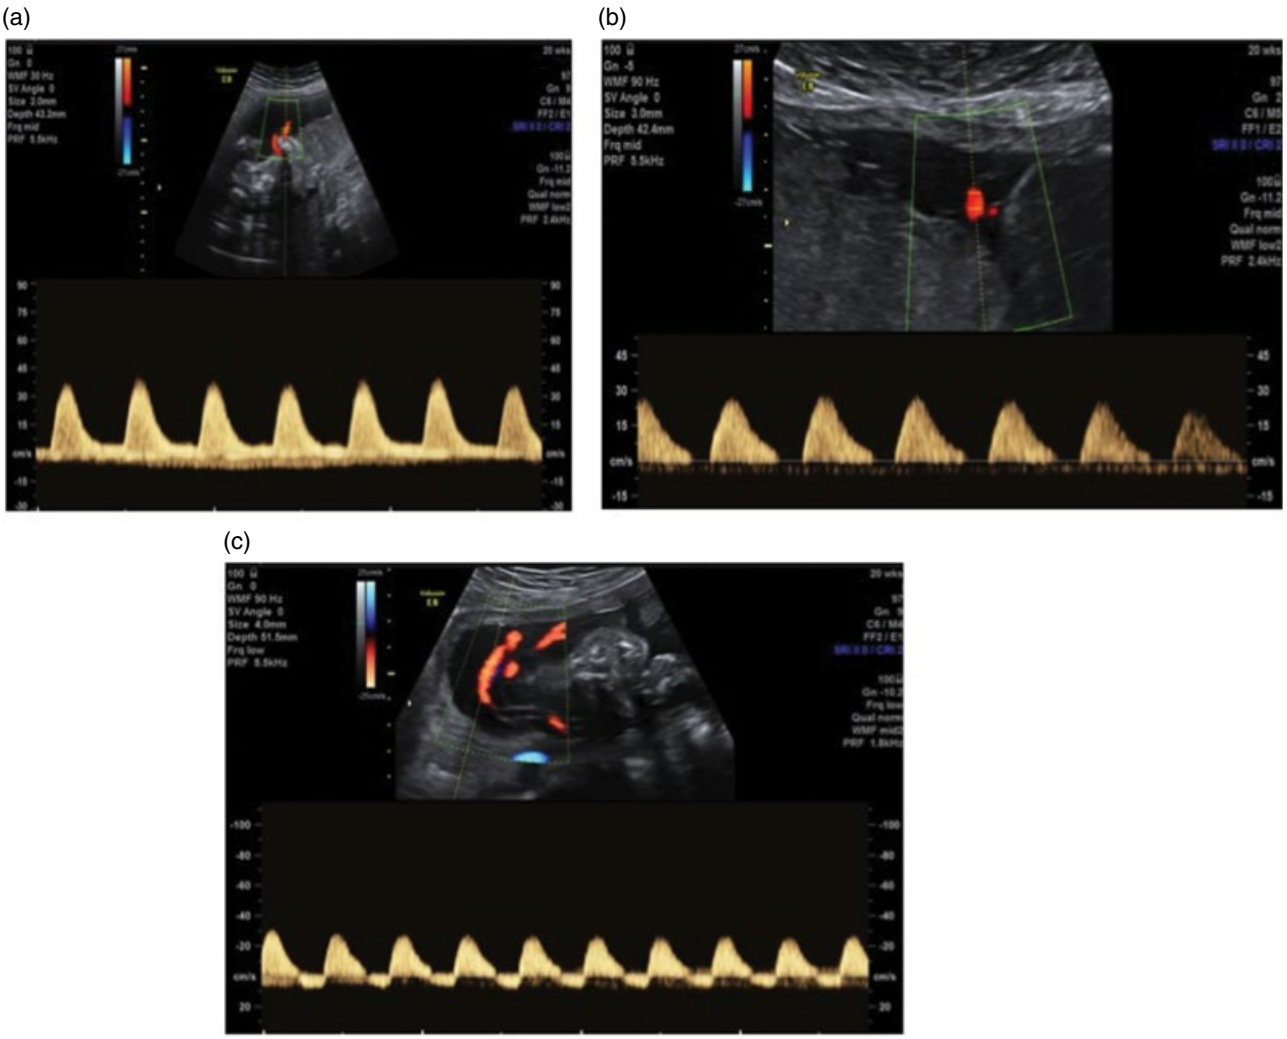

Fig. 17.2 Umbilical artery Doppler waveforms: (a) normal; (b) absent end-diastolic flow; (c) reversed end-diastolic flow. (*See also colour plate 17.2*)

A low CPR [17,19] may be associated with delivery by lower segment caesarean section due to fetal compromise, determined by either abnormal CTG or fetal blood sample below pH 7.20, although no differences in Apgar scores and arterial pH (taken at time of delivery) were found nor is there evidence of adverse neonatal outcomes in the groups with low CPR in either study. However, others [20] have also associated low CPR (PI <1) with adverse perinatal outcome in intrauterine growth restriction (IUGR) and impaired neurodevelopment at 2 years of age.

CPR may be of most use when umbilical artery PI is greater than the 95th centile with a normal waveform, in which situation a low CPR gives an OR for adverse perinatal outcome of 11.7 (95% CI 6.0–22.9). This provides similar predictive value to an abnormal umbilical artery waveform (OR 10.8, 95% CI 3.8–30.5) compared with raised umbilical artery PI alone (OR 6.9, 95% CI 2.9–16.5). It should be remembered that gestation and birthweight remain the most important predictors of morbidity and long-term outcome.

Ductus venosus Doppler

The ductus venosus (DV) is a fetal vessel connecting the intra-abdominal portion of the umbilical vein to the left portion of the inferior vena cava just below the diaphragm [21]. The function of the DV is to shunt the oxygen and substrate-rich blood coming from the placenta via the umbilical vein to the heart. The DV diverts 25% of the blood to the heart, with the remainder being distributed to the liver and joining the circulation via the hepatic portal system. Although entering the heart via the right atrium, this substrate- and oxygen-rich blood is

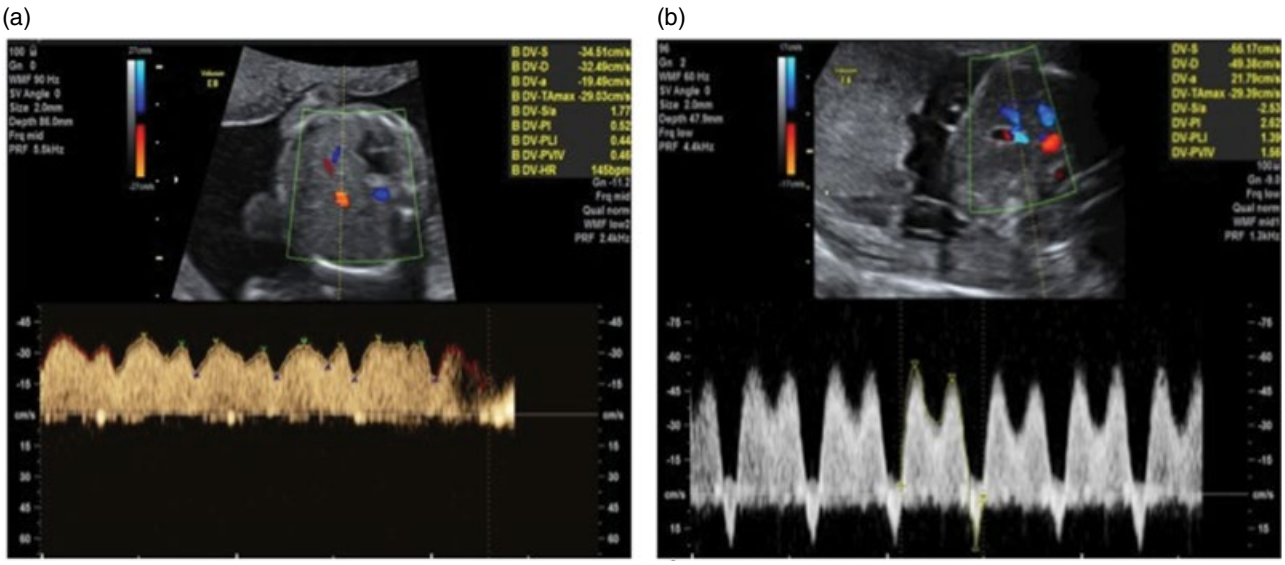

Fig. 17.3 Ductus venosus waveforms: (a) normal; (b) reversed a-wave. (*See also colour plate 17.3*)

preferentially directed to the left atrium and then, via the left ventricle and aorta, to the fetal heart and brain [22,23].

The utility of the DV waveform is primarily in the very premature fetus with IUGR, or the preterm fetus with abnormal umbilical artery waveforms (Fig. 17.3). Reversal or absence of the DV a-wave, particularly in combination with umbilical vein pulsations, has been shown to be closely associated with a pH below 7.20 [24] and perinatal mortality irrespective of gestational age, with a risk of up to 100% in early-onset FGR. It has been shown that DV abnormalities precede changes in computerized CTG in 50% of cases, although it is safe to wait DV PI or waveform changes in cases where computerized CTG remains normal [25].

The TRUFFLE study and the application of its results to the timing of delivery in early-onset IUGR is discussed later.

Cardiotocogram and biophysical profile

CTG monitoring as an assessment of fetal well-being has become a routine part of antenatal care. There is, however, no evidence of benefit in high-risk cases and may in fact result in unnecessary intervention [26].

However, computerized CTG monitoring can provide assessment of short-term variability (STV), which cannot be performed by visual assessment alone. Reduced STV (<3 ms) has been shown to correlate with the fetal metabolic state and significantly reduced STV is closely associated with fetal acidaemia [27–29]. This has been shown to reduce perinatal mortality compared with traditional CTG in the high-risk population (RR 0.20, 95% CI 0.04–0.88) [26], although this effect was not evident once deaths due to congenital anomalies were excluded (OR 0.23, 95% CI 0.04–1.29).

As such, CTG monitoring should not be used as the only form of surveillance in SGA fetuses. If CTG monitoring is used, interpretation should be based on analysis of STV on computerized CTG [30].

The biophysical profile combines the use of CTG with the ultrasound assessment of fetal movement, fetal tone, fetal breathing movements and amniotic fluid. Each parameter is scored 0–2 points, with a maximum total score of 10. A normal score (8 or greater) is reassuring. Biophysical profile has a high false-negative rate and is not a good predictor of fetal acidaemia. It has also been shown to increase caesarean section rates, but not improve perinatal outcome. The use of biophysical profile is not recommended for surveillance of the SGA fetus.

Timing of delivery

Timing of delivery of the small or growth-restricted fetus can be challenging. This is particularly so at very preterm gestations, which are associated with high rates of perinatal complications. Neonatal morbidity and mortality have improved significantly in the past decade, with survival rates of 13% at 24 weeks, 43% at 25 weeks, up to 76% at 26 weeks and up to 90% at 30 weeks' gestation [31]. Timing of delivery must take into account not only survival but also associated significant morbidities such as bronchopulmonary dysplasia, intraventricular haemorrhage, necrotizing enterocolitis and cerebral palsy.

Similarly, neonatal survival without significant morbidity progressively increases with increasing gestational age.

However, both birthweight centile and gestational age are important factors at very preterm gestations and must be considered in combination when considering neonatal outcomes. The PREM scoring system has also been recently validated [32] and it has been suggested that it might be used in combination with the Clinical Risk Index for Babies (CRIB) scoring system for neonatal mortality risk adjustment. Outcomes for growth-restricted neonates below 29 weeks are similar to those of appropriately grown neonates delivering at a gestation 2 weeks earlier [31].

Below 32 weeks, timing of delivery can be based on DV waveforms or computerized CTG analysis of the STV. The TRUFFLE study randomly assigned growth-restricted fetuses between 26 and 32 weeks' gestation to delivery based on one of DV PI above the 95th centile, absent DV a-wave or abnormal STV [33]. The results showed that neonatal survival without neuroimpairment was similar across all groups. However, among survivors at 2 years there were better functional outcomes in those delivered based on waiting for late DV changes rather than CTG abnormality. The earlier GRIT study had shown no difference in outcomes at 2 years between immediate delivery and delayed delivery in compromised fetuses between 24 and 36 weeks' gestation. Based on the fact that these survival rates are good, with low morbidity rates beyond 32 weeks [34,35] and, in light of TRUFFLE data, appear to be improving, delivery of an SGA fetus with absent or reversed EDF in the umbilical artery should be recommended at 32 weeks' gestation.

Beyond 36 weeks, delivery may be informed by the findings of the Disproportionate Intrauterine Growth Intervention Study at Term (DIGITAT) study. This study randomized women between 36^{+0} and 41^{+0} weeks' gestation with fetuses less than the 10th centile to either delivery within 48 hours or expectant management. There were no significant differences in long-term outcomes between the two management strategies [36]. An increased incidence of admission to neonatal care was found in the delivery group [37]. Importantly, there was a higher perinatal mortality in women who did not consent to take part in the study and who in the main opted for conservative management, i.e. waiting, without a clear protocol for monitoring.

In the absence of harm, SGA fetuses beyond 37 weeks can be considered for delivery and delivery should be recommended if there are Doppler abnormalities, including increased umbilical artery PI or decreased MCA PI. However, a pragmatic approach to delay delivery beyond 38^{+0}, if clinically possible, may reduce neonatal admissions.

There remains an absence of high-quality data to guide the timing of delivery between 32 and 36 weeks' gestation. A multicentre European study (TRUFFLE 2) is currently in development to address this. An approach of conservative management with increased surveillance with Doppler and CTG can be adopted in these cases. At 37 weeks, delivery should be considered, as outlined above. Prior to this, if there are any clinical concerns, Doppler waveform abnormalities or reduction in growth velocity, earlier delivery should be advised.

Summary box 17.1

- Fetal growth restriction is a major cause of perinatal morbidity and stillbirth.
- Fetal growth restriction is best defined by both fetal smallness and abnormal Doppler (usually umbilical artery) findings.
- Accurate prediction of growth restriction remains difficult.
- Fetal growth trajectory, as well as absolute fetal size, is important.
- Before 32 weeks, neonatal outcomes can be improved by timing delivery by changes in the ductus venosus Doppler in conjunction with computerized CTG.

Third Trimester Fetal Assessment

Jon Hyett

RPA Women and Babies, Royal Prince Alfred Hospital, Camperdown, New South Wales, Australia

If the first and second trimesters of pregnancy are defined by embryonic and fetal development, the third trimester is defined by consolidation of these processes through maturation, growth and preparation for delivery. Traditional, the term 'third trimester' is used to describe the antenatal period between 28 and 42 weeks' gestation, but it may be more appropriate to subdivide this into parts, based on the potential complications of pregnancy that may occur. Fetal viability now descends to 24 weeks (or earlier) and many of the physiological and pathological processes that impact the 28-week fetus are equally relevant at this earlier gestational point. Phenotypes and underlying aetiologies of intrauterine growth restriction (IUGR) differ before and after 32–34 weeks' gestation and different approaches are needed to recognize complicated pregnancies. Delivery issues at 24–34 weeks focus on prediction, prevention and improvement of outcome of prematurity. In contrast, assessment for delivery at gestations of 37 weeks or more should focus around prediction and prevention of complications of term intrapartum care. Whilst this chapter describes tools and approaches to third-trimester fetal assessment, it is important to recognize that these need to be placed in clinical context, first defining potential risks to an individual pregnancy and then tailoring assessment accordingly.

Stillbirth, broadly defined as death *in utero* during the third trimester of pregnancy (with varied gestational end-points described internationally), continues to present a major problem in obstetric management and should, by necessity, be a focal point of third-trimester fetal assessment. Rates of stillbirth have not changed significantly in the last 30 years, whilst deaths due to congenital abnormality have been significantly reduced through first- and second-trimester screening and rates of neonatal death have fallen through improvements in neonatal care. As a consequence this adverse outcome, which was typically the 'Cinderella' of obstetric complications, is now the subject of major public health and research initiatives. If congenital abnormalities are excluded, the leading causes of stillbirth are very early preterm birth, IUGR, antepartum haemorrhage and infection. A number of tools can be used to assess risks for these complications and their application may help improve fetal outcomes.

Predicting preterm birth

Preterm birth, which affects approximately 10% of pregnancies, is most commonly iatrogenic, following recognition of maternal, placental and/or fetal complications that are likely to result in worse obstetric outcomes through expectant management rather than through delivery [1,2]. Some interventions that may reduce the prevalence of these complications, such as first-trimester prediction and prevention of severe early-onset pre-eclampsia, are making their way in to clinical practice [3,4]. The other major causes of preterm birth are spontaneous onset of preterm labour and delivery after preterm pre-labour rupture of membranes [2]. Less progress has been made in preventing these conditions, but several investigative tools are of value for stratifying risk in the third trimester.

Spontaneous preterm birth can be predicted through transvaginal assessment of cervical length [5,6]. This can be applied as a screening tool in the second trimester, as a component of the 20-week scan. Asymptomatic women who have a short cervix may benefit from progesterone therapy, which has been reported to effect a 45% reduction in rates of preterm birth below 34 weeks' gestation [7–9]. In the third trimester, cervical length is typically used as an assessment tool for women who attend with symptoms (abdominal pain and/or vaginal bleeding) of

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

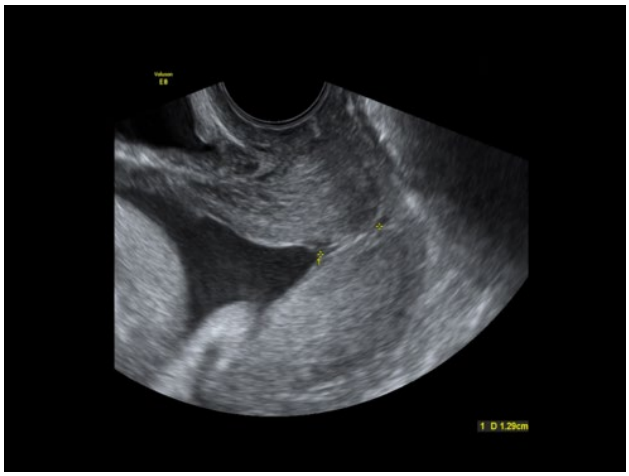

Fig. 18.1 A transvaginal ultrasound image evaluating cervical length. There is partial effacement of the cervix from the internal os (left side of the image) so the cervix appears to be 'funnelled'. The absolute length of the cervix (13 mm) is short, increasing the risk of preterm delivery.

preterm labour (Fig. 18.1). A short cervix, defined by various researchers as closed cervical length less than 15 or 25 mm, is associated with a higher risk of preterm delivery [10,11]. The cervix is measured using a standardized approach [12]. The transvaginal probe is introduced into the vagina and advanced in the midline into the posterior fornix so that the boundaries of the internal and external os can be clearly seen. The probe should be withdrawn a little, taking care to maintain a high-quality image, so that pressure is not put on the cervix that will falsely increase its length. Measurements should be made with good image magnification to improve accuracy and are made in a straight line between the internal and external os. As the cervix is dynamic, three measurements should be made over the course of a 3–5 min period and the shortest of these measures is typically used in most formulas that define risk on the basis of cervical length.

This examination is easy to perform after appropriate training and demonstrates effacement of the lower segment/internal cervical os that is not visible during speculum examination. Many would therefore advocate that women with threatened preterm labour are better served through assessment with a transvaginal scan rather than speculum or digital examination [13]. The sensitivity and specificity of cervical length for prediction of risk of delivery within 7 days have been reported to be 100% and 42%, respectively [10]. This is very similar to the efficacy of vaginal biochemical screening tools such as the vaginal fetal fibronectin test [14]. An ultrasound-based approach is advantageous in so far as the examination is quick, gives an immediate result, is easily repeated (to assess change) and is cheap, but requires the presence of a trained operator. The biochemical tools are less subjective but may not be accurate in some circumstances (e.g. after intercourse/with significant vaginal bleeding) and are more expensive, particularly for use on repeated occasions. Different clinical groups tend to favour one or the other approach to assessment of threatened preterm labour – typically due to local strengths and weaknesses of service provision – but there is also some evidence that a combined approach (using cervical length as a primary screening tool and fetal fibronectin as a second tier screen) is effective in reducing rates of hospital admission and prescription of corticosteroids in circumstances where delivery is not imminent [14].

Identifying placenta praevia, placenta accreta, vasa praevia and uterine scar

Ultrasound, and specifically transvaginal assessment of the cervix, is also useful for third-trimester assessment of placental position and vasa praevia. Up to 20% of placentas may be identified as being low-lying during a transabdominal 18–20 week morphology scan [15]. This cohort are recognized as being at risk of having placenta praevia, with implications for risk of antepartum haemorrhage and mode of delivery. Women who have a low placenta at 20 weeks are typically offered another scan at 34–36 weeks' gestation to confirm placental position [16]. The timing of this assessment is a compromise between allowance of adequate time for development of the lower uterine segment and of performance of the scan before the onset of spontaneous labour. The leading edge of the placenta is often best assessed using a transvaginal approach, particularly if the placenta is posterior, as the leading edge may be masked by the sonographic signal returned from the presenting part, particularly if the fetus is cephalic [17].

Whilst the third-trimester transvaginal scan is being performed, colour Doppler can be used to interrogate the area within the chorionic membrane overlying the internal cervical os. This is a very sensitive means of identifying vasa praevia, with the potential to prevent fetal mortality and morbidity following spontaneous rupture of membranes and rapid exsanguination [18]. There is some debate as to whether all women should be routinely screened for vasa praevia, which has a prevalence of 1 in 1500 to 1 in 2000 pregnancies; whilst routine screening may identify most cases, there is the potential for false positives that may be harmed through a policy of preterm abdominal delivery [19]. The positive predictive value of screening will be low (due to the low disease prevalence), so the prospect of the risk of harm needs careful prospective assessment. An alternative strategy

would involve routine transvaginal assessment for vasa praevia in women deemed to be at high risk; this can be defined through maternal characteristics such as advanced maternal age, *in vitro* fertilization (IVF) pregnancy, known placenta praevia or velamentous cord insertion [20]. Screening for vasa praevia may be performed at 20 weeks rather than in the third trimester but there are few prospective data comparing the efficacy of this screening tool at these two time points.

Cervical length can also be used to predict the potential for success of induction of labour. Induction is commonly offered to some cohorts, for example diabetic women, due to recognized increased risks of perinatal mortality. A transvaginal scan may be used to predict the likely success of induction and could potentially be used to guide the style of induction, although there are currently no prospective data demonstrating that this improves outcomes [21]. The findings of a transvaginal/transperineal assessment can be combined with measures of fetal biometry and other maternal characteristics to predict the likelihood of emergency caesarean section [22]. Some researchers have suggested that this could be used to define a cohort of women that should be offered an elective caesarean section, but others believe that the predictive value of the test is not sufficient to merit such significant intervention.

Women who have had a previous caesarean section, or other uterine surgery, have an increased risk of placenta accreta. The risk of placenta accreta is associated with the number of previous caesarean sections [23]. Transabdominal ultrasound can be used to predict placenta accreta and percreta, and may be used in conjunction with MRI to define the level of risk and extent of extrauterine invasion [24]. Thinning and disruption of the hypoechoic interface between the placenta and myometrium can often be seen using conventional two-dimensional grey-scale imaging. The placenta may include large lacunae and these, together with other aspects of increased and chaotic myometrial/placental blood flow, may be identified using colour Doppler.

There are also some data describing the value of measuring myometrial thickness for the prediction of risk of scar dehiscence in women who have had a previous caesarean section [26,27]. This is a difficult measure to make reliably as there are limitations to approach using both transabdominal and transvaginal methodologies. Various cut-offs for defining a high-risk cohort have been described and there are no data to demonstrate improved perinatal outcomes by screening all women who have had a previous caesarean section during the later part of the third trimester [27]. Although there is continued research interest in screening this cohort of women, it is probably premature to suggest this should be routine clinical practice.

Predicting intrauterine growth restriction and intrapartum fetal hypoxia

The second commonest cause of stillbirth (excluding congenital abnormalities) is IUGR [28]. There appear to be two different phenotypes of IUGR in the third trimester [29]. In the absence of an underlying chromosomal, genetic or structural anomaly or of fetal infection, early-onset IUGR (leading to delivery before 32 weeks) is typically an expression of placental insufficiency and is defined by demonstrating poor growth, with measures of the abdominal circumference and estimated fetal weight lying below an established (3rd, 5th or 10th) centile [30]. The process of fetal compensation then decompensation can be assessed using a number of clinical tools and this process and subsequent management is described in more detail in Chapter 17 [31]. In contrast to this, late-onset IUGR (>34 weeks' gestation) is associated with placental failure rather than insufficiency [32]. Consequently, the fetus may have initially maintained normal growth, and a single measure of biometry may not be sufficient to identify reduced growth velocity. Similarly, tests that are traditionally used to define and manage placental insufficiency (umbilical artery and ductus venosus Doppler) may not be of value, or may have to be used in a different way to be useful in detecting fetal compromise due to placental failure [29].

Stillbirth is a clearly defined, catastrophic but uncommon (in developed societies) end-point. IUGR may have other more insidious impacts. Fetuses that have limited reserve are more likely to be adversely affected by uterine contraction during labour and are at higher risk of hypoxic ischaemic encephalopathy. IUGR is the most significant antenatal risk factor for the development of neonatal encephalopathy and term cerebral palsy [33]. IUGR is also strongly associated with non-communicative cardiovascular and metabolic diseases that affect infants, adolescents and adults and therefore potentially has a lifelong impact on an individual's health and well-being [34,35]. Appropriate identification of IUGR fetuses, through third-trimester fetal assessment, provides the means to intervene to improve outcomes for a significant proportion of pregnancies.

There are conflicting opinions about the most appropriate strategies and methodologies that should be used to define normal fetal growth. Fetuses cannot be repeatedly removed and measured and replaced in the uterus to develop charts based on longitudinal measures and most charts for parameters such as birthweight include populations of fetuses that delivered because of some inherent abnormality. Charts based on data derived from such populations have centiles that are too low, particularly at early gestations, where there is also increased

inaccuracy due to smaller numbers of cases [36]. Other researchers have focused on the issues of population diversity and have suggested that all charts should be customized according to a mother's own characteristics [37]. A third approach, based on the observation that 'perfect' subgroups of women from a range of ethnic groups have similar patterns of growth, suggests that we should use international standardized charts to reduce heterogeneity [38]. There are no data to show whether use of customized or standardized charts improves perinatal mortality, and it is important to recognize that intervention in fetal growth (through premature delivery) may cause harm [39,40].

The simplest approach to identifying babies that are small for gestational age (SGA), and at increased risk of IUGR and its sequelae, involves clinical assessment through abdominal palpation and measurement of symphysis–fundal height. The effectiveness of this assessment has been variously reported but in one large trial involving more than 6000 women had a low sensitivity (28%) at 95% specificity [41]. Whilst single measures have poor predictive value (7% in this trial), this improves with serial measurement and through the use of customized charts, although there are no prospective studies that have proven improvement in perinatal mortality and morbidity [42].

Ultrasound can be used to assess fetal biometry, and measures of the biparietal diameter (BPD), head circumference (HC), abdominal circumference (AC) and femur length (FL) are typically used to estimate fetal weight (Fig. 18.2) [38,43]. Imaging and measuring these structures becomes more difficult as the third trimester advances and the sensitivity, specificity and positive and negative predictive values have been described as 53% (95% CI 49–58%), 81% (95% CI 80–83%), 26% (95% CI 23–29%) and 93% (95% CI 93–94%), respectively [44]. In addition, assessment of single measures of biometry will not identify previously well-grown fetuses that have been exposed to a later insult and are now crossing centiles. In a study involving 4000 pregnancies, Sovio *et al.* [45] showed that the routine application of ultrasound for serial growth assessment improved detection of SGA nearly threefold when compared with routine clinical management (57% vs. 20% in those that had a 'selected' ultrasound). Further improvements might be seen though computerized analysis of growth velocity and a number of groups have developed different methodologies for this process of risk assessment [46,47]. Implementation of a programme of serial ultrasound assessment to monitor fetal growth has not been tested to establish whether it leads to an improvement in perinatal mortality and morbidity. Given the potential for harm through preterm delivery and the significant expense of adding serial scans to routine care, it would be important to demonstrate the added value prior to implementation.

Improvement of the outcomes of fetuses with late-onset IUGR first requires better detection of affected fetuses. Given the difficulties of assessing fetal biometry, other measures that show functional changes in growth-restricted fetuses may be of value in improving screening efficiency. The simplest of these tools involves the mother, by asking her to monitor fetal movement and to report reduced fetal movement in a timely fashion.

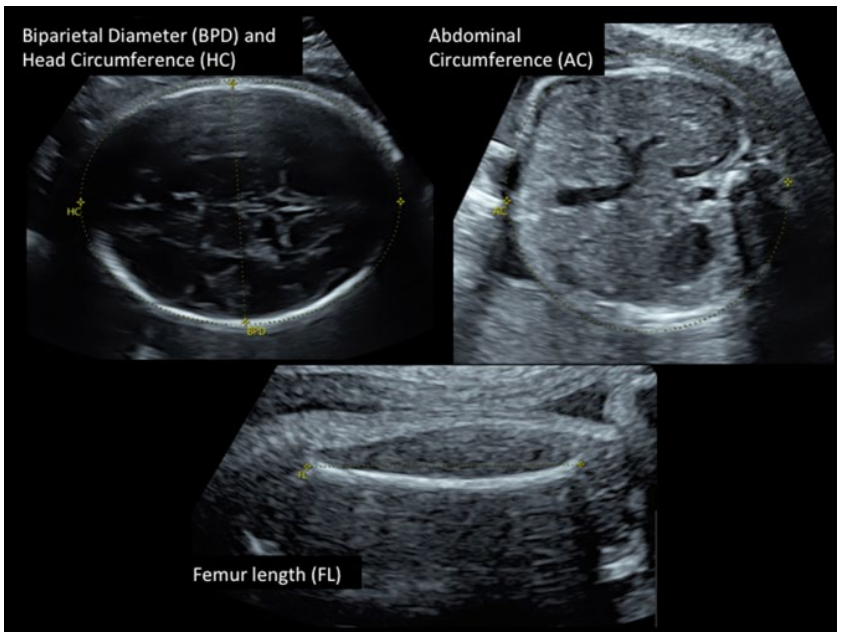

Fig. 18.2 A composite image showing measurement of the biparietal diameter, head circumference and femur length, measures used in most formulas to estimate fetal weight. Measurement accuracy is affected by the plane of assessment: the head should be imaged in an axial section at the level of the cavum septum pellucidum and posterior horn of the lateral ventricle; the abdomen should be imaged in an axial section at the level of the intrahepatic portion of the umbilical vein. Measurement accuracy is also affected by caliper placement; the biparietal diameter measures inner to outer parts of the cranium.

A large randomized controlled trial conducted in the 1980s failed to demonstrate any value in self-reporting of reduced fetal movement, but the quality of these data is disputed as there was (amongst other issues) a significant improvement in outcomes in the non-treatment arm as well as in women randomized to assessment of fetal movement [48]. More recent work has suggested that maternal assessment of fetal movement is important and that perinatal mortality is lower amongst groups that are counselled about self-monitoring [49]. Outcomes may also be improved through protocol-driven management of women who attend with reduced fetal movements, often through inclusion of investigational tools such as cardiotocography (CTG) or targeted ultrasound assessment [50].

The Perinatal Society of Australia and New Zealand (PSANZ) guideline for management of reduced fetal movement recommends that CTG should be performed for all women who present with reduced fetal movements during the third trimester of pregnancy [51]. CTG provides continuous graphical representation of the fetal heart rate together with information about uterine activity. CTG can be used in a variety of circumstances including intrapartum monitoring as well as for antenatal fetal assessment. The interpretation of a CTG depends on clinical circumstance, specifically whether a woman is defined as being in labour. Consequently, it is extremely important that an appropriate history and examination is performed before CTG can be interpreted; our anecdotal experience has shown that inappropriate interpretation of antenatal CTG in women who present with reduced fetal movements and some uterine activity, but who are not in active labour, can lead to false reassurance of clinicians and poor pregnancy outcomes.

There is limited evidence demonstrating that antenatal CTG improves perinatal outcome but the tool is commonly used and is generally freely available within the antenatal assessment environment, so traces are easy to procure [52]. Difficulties in application lie in interpretation. Some aspects, such as measures of baseline heart rate, acceleration, deceleration and short- and long-term variability, can be defined through computer analysis and algorithms for further management can be defined on the basis of these findings [53]. In a series of 305 women presenting with reduced fetal movement during the third trimester, Dutton *et al.* [54] found that an abnormal CTG was the most significant finding associated with adverse pregnancy outcome, reporting an odds ratio (OR) of 7.08 (95% CI 1.31–38.18); the impacts of other clinical findings, such as diastolic blood pressure and a low estimated fetal weight centile, were much less significant.

Whilst an abnormal antenatal CTG is strongly associated with adverse fetal outcome in a woman presenting with reduced fetal movements, this may not prove the best investigation for defining fetal well-being and making decisions about timing of delivery. The antenatal CTG that shows reduced variability, no accelerations and, on some occasions, shallow decelerations may be indicative of a fetus that is compromised by hypoxia, but these findings may be indicative of an irreversible neurological impact so delivery at this stage would be too late to effect the best outcome for this fetus. Alternatively, in some acute situations, the cardiovascular response to a hypoxic insult may be incomplete; the changes seen in baseline heart rate, variability and decelerations may only occur a few hours before death and could be missed through monitoring prior to this time.

CTG monitors fetal heart rate and uterine activity. This information may be valuable and may help define the need for delivery. CTG does not report other maternal parameters (e.g. heart rate, temperature and blood pressure) nor does it provide information about fetal size. It is therefore important to recognize the potential limitations of the technology and to interpret the findings with a good understanding of the clinical circumstances and risks. In a trial of postdates women being randomized to induction or ongoing expectant management, a reassuring CTG was associated with higher perinatal mortality; clinicians need to be aware of the risk of false reassurance that individual tests can provide [55].

In addition to assessing fetal biometry, ultrasound can be used to assess functional parameters that may be impacted by poor fetal growth. The growth-restricted fetus may compensate by reducing renal perfusion, with consequent reduction in urine production that can be assessed through measurement of amniotic fluid levels [56]. The amniotic fluid index (measurement of the liquor in the four quadrants) is used as a surrogate measure of amniotic fluid volume and should be measured in a standardized manner, holding the ultrasound probe perpendicular to the abdomen (an oblique measure will be falsely increased) and measuring the maximal clear (no fetal parts) pool in each quadrant (Fig. 18.3). Normal amniotic fluid indices vary widely across the third trimester, with wide standard deviation [56]. The amniotic fluid index peaks at about 34 weeks' gestation and levels typically reduce towards term. Cut-offs of less than 5 cm and more than 25 cm are typically used to define oligohydramnios and polyhydramnios, respectively. A recent meta-analysis that examined the association between anomalous amniotic fluid indices and adverse perinatal outcome reported that oligohydramios was associated with birthweight below the 10th centile (OR 6.31; 95% CI 4.15–9.58) as well as with perinatal mortality (OR 8.72; 95% CI 2.43–31.26), although the association did not have a strong predictive value for these outcomes [57].

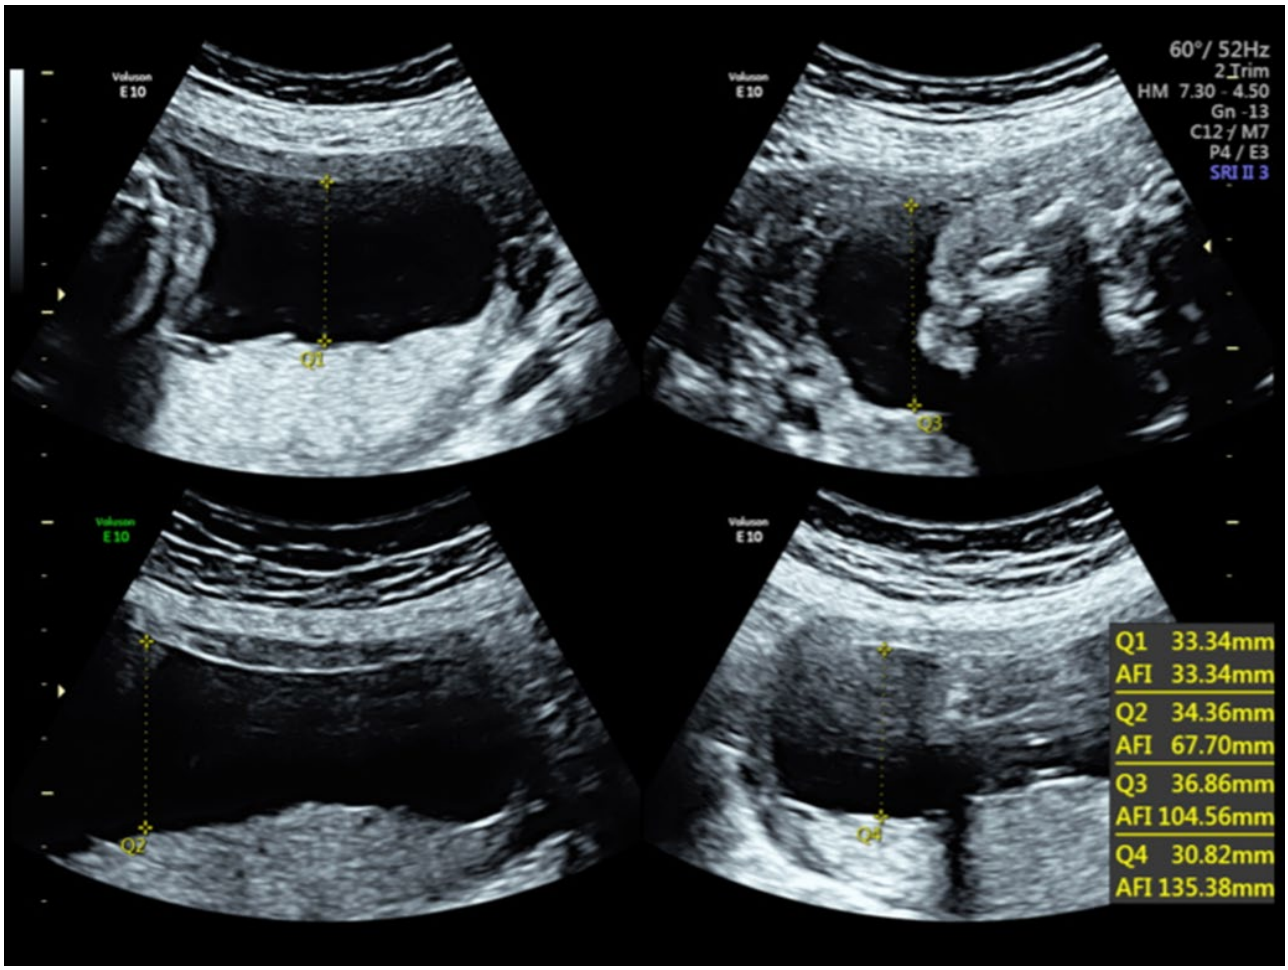

Fig. 18.3 The maximum vertical pool of amniotic fluid is measured in each uterine quadrant to calculate the amniotic fluid index.

A variety of different uteroplacental Doppler measures can also be assessed by ultrasound and may be of value in assessing fetal growth and well-being. The vessel most commonly assessed in the third trimester is the umbilical artery (Fig. 18.4). In early-onset IUGR, associated with placental insufficiency, the umbilical artery Doppler waveform typically changes with reduced forward flow in diastole and an increase in the vessel's pulsatility index (PI). A meta-analysis of studies that reported umbilical artery Doppler parameters in pregnancies defined as having a high risk of fetal growth restriction during the third trimester found that absent or reversed end-diastolic flow was associated with a significant increase in risk of perinatal mortality [58]. In many centres, umbilical artery Doppler parameters are now reported as a matter of routine during a third-trimester scan, but it is important to interpret the findings in the context of the literature, as other studies have shown that this is not a useful marker for fetal well-being in low-risk patient cohorts late in the third trimester [59]. Management of IUGR, placental insufficiency and the finding of an abnormal

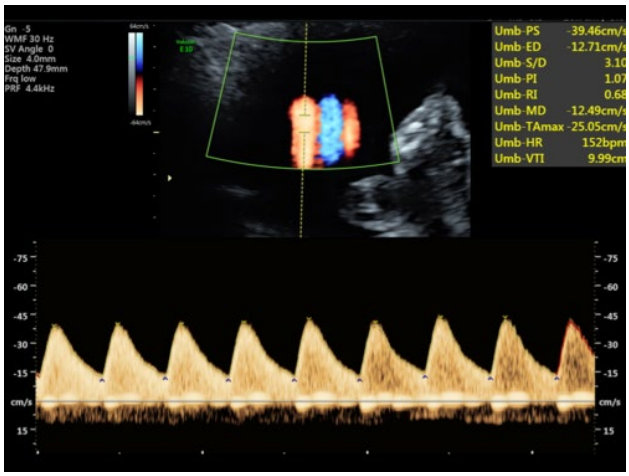

Fig. 18.4 The umbilical artery is typically assessed in a free loop. The vein and arteries can be identified with colour Doppler and pulse wave is used to illustrate the waveform characteristics, which can be measured and compared with standardized charts. In this example there is forward flow in diastole, a normal finding in the third trimester of pregnancy. (*See also colour plate 18.4*)

umbilical artery Doppler is addressed in more detail in Chapter 17.

Later in the third trimester, where the pathology underlying growth failure and ultimately stillbirth is more likely to be due to placental failure rather than placental insufficiency, other Doppler indices become more important in defining fetal welfare. Recent research has shown that, later in the third trimester (i.e. above 32 or 34 weeks) the best marker of fetal compensation for hypoxia is diversion of blood flow, and therefore more oxygen, to the brain. The middle cerebral artery (MCA) can be examined as a marker for this, with demonstration of reduced vascular resistance and a low PI in the fetus that is compromised but compensating effectively (Fig. 18.5) [60,61]. A number of groups have reported that a low MCA PI is associated with low fetal birthweight as well as with fetal distress and the need for emergency caesarean section in labour [62–64]. It has been suggested that presentation of Doppler data as a ratio of middle cerebral and umbilical artery PIs (the cerebroplacental ratio) improves the sensitivity and specificity of this tool in defining high-risk pregnancies [65]. As yet, there are few data that have demonstrated that either routine screening with a cerebroplacental ratio or application to specific high-risk groups (e.g. those with decreased fetal movements) improves pregnancy outcome but there is a lot of interest in the potential value of this tool and further trials of Doppler monitoring late in the third trimester are ongoing [66].

The ultrasound assessment of fetal growth, amniotic fluid index and haemodynamics has, to a large extent, replaced the more formal process of assessing fetal well-being by scoring the biophysical profile. A formal biophysical profile includes four ultrasound-based assessments – fetal breathing, movement and tone and the amniotic fluid index – which are then combined with a CTG 'non-stress' test [67]. Each component of the test is scored two points (if normal) or zero points (if abnormal). Scores below 10 lead to further intensive surveillance or induction of labour depending on the level of the score and the gestation of the pregnancy. Whilst the biophysical profile provides a clear structured method of assessing fetal well-being, it fails to include all parameters that may be of importance (biometry and Doppler) and does not adequately weight the various components of the test in relation to their likely association with pathology. The score has, on occasion, been modified and applied in various high- or low-risk circumstances with various ongoing management strategies [68,69]. Despite this, there is no clear evidence of benefit compared with interpreting ultrasound and/or CTG findings through a less structured approach [70].

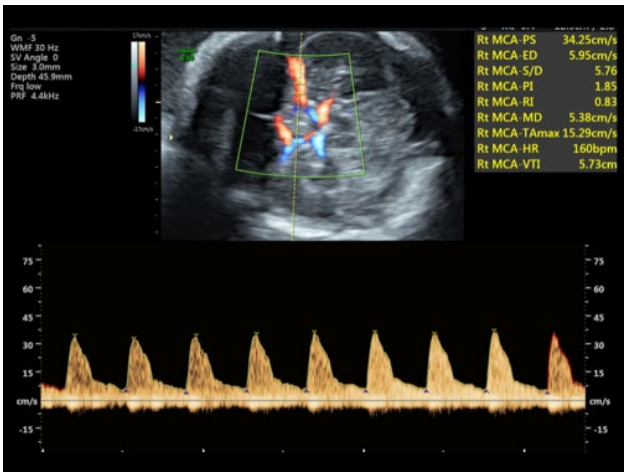

Fig. 18.5 The middle cerebral artery waveform can also be assessed by first identifying the vessels running away from the circle of Willis, then using pulse wave to demonstrate the waveform (sampling approximately 5–10 mm away from midline structures). In this example there is low flow in diastole, a feature of normal perfusion. (*See also colour plate 18.5*)

Predicting fetal macrosomia, risk of failure to progress and shoulder dystocia in labour

Fetal macrosomia also poses a significant risk of adverse pregnancy outcome in the third trimester of pregnancy. Macrosomia is associated with stillbirth and birth injury (shoulder dystocia, brachial plexus injury and limb fracture) as well as increased rates of operative delivery and perineal trauma [71]. Postnatally, macrosomic infants have higher rates of admission to the neonatal unit and are more likely to develop hypoglycaemia and hyperbilirubinaemia [72]. Macrosomic infants have increased rates of diabetes, metabolic syndrome and cardiovascular disease later in childhood and in adult life [73]. Across the world, changes in lifestyle and diet are contributing to increasing rates of gestational diabetes and hyperglycaemia in pregnancy and we face a global epidemic of macrosomia and its sequelae [74].

Despite this, and in comparison with IUGR, macrosomia is poorly defined and under-researched. Macrosomia has traditionally been defined using a fixed birthweight cut-off (commonly 4000 or 4500 g) independent of gestational age of delivery. These thresholds are based on the finding of increased rates of morbidity above these limits, although the reality is that these are continuous variables and it would likely be better to describe risks based on algorithms that define centiles in relation to, rather than being independent of, gestational age, although this adds complexity to categorization [75]. The association with stillbirth, and the underlying mechanism

of death, is also poorly understood, which makes functional assessment of risk to the macrosomic fetus challenging. Many macrosomic infants are born to women who have diabetes in pregnancy and it has been suggested that stillbirth results from metabolic acidosis in these cases [76]. Interestingly, others have suggested that death might occur if the fetal cell mass exceeds placental ability for tissue oxygenation, and it has been proposed that maternal cardiac failure may contribute to fetal death in this circumstance [77].

Clinicians have a poor history for accurate estimation of fetal weight in the later part of the third trimester. In 1992, Chauhan *et al.* [78] reported that women predicted fetal weight more accurately than either clinical or ultrasound examination. The heterogeneity of the literature, using different charts and cut-offs to define macrosomia, make it difficult to determine absolute sensitivity of ultrasound and studies have reported detection rates of 15–79% [79]. Researchers have compared different algorithms for estimation of fetal weight and prediction of macrosomia which have shown significant variation in findings. Predicting risk purely through ultrasound assessment using standard biometric parameters appears unlikely to be useful in defining a macrosomic cohort in routine practice [80]. There is also evidence that different algorithms should be applied to diabetic and non-diabetic populations [81].

Risk assessment may be improved by acknowledging differing maternal characteristics and using a Bayesian multivariate approach to screening [82]. It is not clear whether screening should then be limited to high-risk cohorts (perhaps defined through maternal characteristics and/or medical history), through a contingent process based on findings of screening tests performed at an early stage of pregnancy, or to the whole population [83].

Opinion regarding the management of macrosomic fetuses at term has typically been divided, with few prospective data to inform clinical practice. Some have argued that induction of labour may prevent maternal and neonatal morbidity associated with delivery of an overgrown infant whilst others have maintained that the process of induction carries its own inherent risks. There are now four randomized controlled trials that, in meta-analysis, appear to show that induction of labour may be beneficial and result in reduction in rates of neonatal birth injury (brachial plexus injury and limb fracture) [84]. Some of the trials in this meta-analysis are relatively small and did not report all outcome measures. These are also relatively uncommon outcomes, so 60 inductions need to be performed to prevent one adverse outcome. When this is coupled to the fact that we do not yet have a validated and strongly predictive screening test, it is difficult to advocate a process of routine screening and intervention without further research in this field [85].

In addition to developing algorithms that identify the macrosomic fetus, some groups have focused on the development of algorithms that will predict the likely success of induction of labour or the spontaneous onset of labour. These algorithms variously include maternal demographic factors with ultrasound estimates of fetal size and/or fetal Doppler, cervical length and/or mobility of the pelvic floor [86–89]. There is currently no consensus on the factors that should be included in such a predictive model and no prospective validation or demonstration of improved maternal and perinatal outcomes through application of such a test [90].

Conclusion

Ultrasound is a diverse tool that has many applications in the third trimester. In many settings, a third-trimester scan is not currently part of a routine antenatal screening strategy and there are limited data to support routine population-based screening. It is important, however, to recognize that many contemporary obstetric issues are centred around the third trimester and ultrasound is likely to play a significant role in defining an individual's risk and ensuring that appropriate strategies for maintaining pregnancy and expediting delivery are developed. Ultrasound is often best applied as one component of multivariate risk assessment and this is the subject of much ongoing research, with applications as diverse as the prevention of stillbirth, shoulder dystocia or maternal perineal trauma. Given the current medicolegal environment, it is likely that these methods of risk assessment will become an integral part of management of the third trimester as they will allow clinicians to have better informed conversations about risk with their patients.

Summary box 18.1

- The fetus faces a number of risks that vary through the third trimester and tests for fetal welfare need to be tailored to the issue of surveillance.
- Predictive tools (ultrasound and biochemical testing) for preterm birth improve the chances of preventing or ameliorating outcomes of early birth.
- Ultrasound assessment allows early recognition of invasive placentation and appropriate management at delivery improves maternal outcomes.
- The pathophysiology of IUGR differs before and after 32 weeks and different tests are needed to recognize fetal compromise. Further research is needed to determine whether routine third-trimester ultrasound surveillance reduces the prevalence of stillbirth.

Fetal Medical Conditions

Janet Brennand

The Ian Donald Fetal Medicine Unit, Queen Elizabeth University Hospital, Glasgow, UK

Fetal thyroid function

The advent of fetal blood sampling has allowed direct and accurate quantification of fetal thyroid function. Fetal thyroid hormone synthesis commences at 10–12 weeks' gestation. Prior to this the fetus relies on placental transfer of maternal thyroid hormones. Fetal serum thyroid-stimulating hormone (TSH), thyroxine-binding globulin (TBG), free and total thyroxine (T4) and triiodothyronine (T3) increase with advancing gestation, from 14–16 weeks onwards [1,2]. The concentrations of total and free T4 (FT4) reach adult levels by 36 weeks' gestation. In contrast, T3 concentrations are lower than adult levels throughout pregnancy. There is no relationship between maternal and fetal thyroid hormone levels, confirming that development of the fetal pituitary–thyroid axis is independent of the mother. Fetal TSH concentrations are low until 15–18 weeks' gestation, and the lack of correlation between it and thyroid hormone concentrations indicates that thyroid maturation is independent of TSH. Fetal TSH receptors become responsive to TSH at 20 weeks' gestation.

Thyroid hormones promote normal growth, development and neurological function. Disruption of normal thyroid function, if unrecognized and untreated, can therefore have significant long-term sequelae. Thyroid dysfunction in the fetus can result from a primary problem affecting the fetus. More commonly it occurs secondary to maternal thyroid disease and/or its treatment.

The presence of fetal goitre indicates thyroid dysfunction, provided other differential diagnoses of a fetal neck mass, such as cystic hygroma, cervical teratoma and haemangioma, have been excluded. The goitre may represent fetal hyperthyroidism or hypothyroidism. The serious adverse consequences of fetal hyperthyroidism are miscarriage and intrauterine death, and of hypothyroidism neonatal cretinism.

Fetal hyperthyroidism

Fetal hyperthyroidism is most likely to occur secondary to maternal Graves' disease as a result of placental transfer of autoantibodies. TSH receptor-stimulating antibodies (TRAbs) are of the IgG class and therefore readily able to cross the placenta and stimulate the fetal thyroid gland. TRAbs can stimulate the fetal thyroid from 20 weeks' gestation. TRAbs are increased in at least 80% of women with Graves' disease. It has been estimated that neonatal thyrotoxicosis occurs in 2–10% of babies born to women with Graves' disease [3]. The risk of fetal hyperthyroidism is related to TRAb concentrations. The placenta is more permeable to IgG in the second half of pregnancy and fetal concentrations of TRAbs reach maternal levels at around 30 weeks' gestation. As a result, fetal hyperthyroidism usually develops in the second half of pregnancy

Pregnancies at risk

A pregnant woman with Graves' disease can be categorized as follows [3].

1) Euthyroid, not on medication, but who has previously received antithyroid drugs: the risk of fetal/neonatal hyperthyroidism is negligible and measurement of TRAbs is not necessary.
2) Euthyroid, previously treated with radioactive iodine or surgery: TRAbs should be measured in early pregnancy to detect presence and, if present, their concentration. High concentrations of antibodies identify a pregnancy at risk of fetal hyperthyroidism. TRAbs should be measured again in the third trimester to identify risk of neonatal hyperthyroidism.
3) Requiring antithyroid drugs to achieve normal thyroid function: TRAbs should be measured in the last trimester.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Features

Fetal tachycardia (>160 bpm) is the most common feature of fetal hyperthyroidism, although it is not always present. Other findings include intrauterine growth restriction (IUGR), accelerated bone maturation, cardiomegaly, cardiac failure and hydrops. A large fetal goitre can cause hyperextension of the fetal neck resulting in malpresentation. Oesophageal compression may result in polyhydramnios with its associated risk of preterm labour.

Management

Ultrasound can detect fetal goitre, which is the earliest ultrasound feature of fetal thyroid dysfunction and appears before fetal tachycardia. Fetal goitre is defined as a thyroid circumference equal to or greater than the 95th centile for gestational age and normative fetal thyroid measurements have been defined [4]. Colour flow Doppler may help differentiate between a hyperthyroid and a hypothyroid goitre. Hyperthyroidism is associated with a signal throughout the gland, whereas a signal confined to the periphery of the gland is suggestive of hypothyroidism [5,6]. In at-risk pregnancies monthly ultrasound should be carried out from around 20 weeks' gestation to assess thyroid size.

Cordocentesis is the only direct method of assessing fetal thyroid function. This is an invasive procedure, with a risk of miscarriage, and should be reserved for cases in which it is impossible to distinguish fetal hyperthyroidism from fetal hypothyroidism on clinical grounds, or for cases where the response to fetal therapy is not as anticipated (i.e. deterioration despite treatment).

Treatment

Treatment by maternal administration of antithyroid drugs is both safe and effective in the management of fetal hyperthyroidism. Propylthiouracil is the drug of choice because of the reduced risk of side effects. If the mother is euthyroid she may require thyroxine supplementation. This may also be necessary for women already on antithyroid medication who need to increase the dose.

Fetal hypothyroidism

Worldwide, iodine deficiency is the leading cause of fetal hypothyroidism. Other causes include thyroid dysgenesis, thyroid dyshormonogenesis, TSH receptor mutations and TSH receptor blocking IgG, antithyroid drugs and radioactive iodine after 10–12 weeks' gestation [7]. Maternal thyroid disease associated with thyroid autoantibodies can cause fetal hypothyroidism. Anti-thyroperoxidase antibodies cross the placenta in the third trimester but have little effect on fetal thyroid function. However, although generally stimulatory TRAbs can be inhibitory, resulting in fetal hypothyroidism.

Features

Ultrasound features include IUGR, goitre and decreased fetal movements. There may be tachycardia or bradycardia and in severe cases complete heart block. Cardiomegaly and delayed skeletal maturation may occur. Fetal hypothyroidism is often unrecognized and should be considered in all women with a history of thyroid disease and/or antithyroid medication.

Management

If fetal hypothyroidism is secondary to maternal antithyroid therapy, the dose of the drug should be reduced with the aim of keeping maternal FT4 levels at the upper end of the normal range for gestational age. Ultrasound of the fetal thyroid should be carried out at no greater than fortnightly intervals to ensure reduction in size, which is usually noted within 2 weeks of reducing therapy [8].

Transplacental transfer of T4 is inadequate to treat fetal hypothyroid goitre. The intra-amniotic route is used and 250–500 µg of T4 at 7–10 day intervals is a proposed regimen [9]. The success of treatment can be monitored by ultrasound assessment. If the fetal condition deteriorates despite treatment, cordocentesis is needed to measure fetal TSH and FT4 levels.

Summary box 19.1

- There is a risk of fetal thyroid dysfunction in women who are thyroid receptor antibody positive or who are taking antithyroid medication.
- Fetal goitre, present on ultrasound, indicates fetal thyroid dysfunction if other differential diagnoses have been excluded.
- It should be possible to distinguish fetal hyperthyroidism from hypothyroidism on clinical grounds in most cases.
- Cordocentesis is reserved for those cases in which this distinction on clinical grounds is not possible.
- Fetal thyroid dysfunction can be treated successfully *in utero*.

Congenital adrenal hyperplasia

Congenital adrenal hyperplasia (CAH) occurs when abnormal adrenal steroidogenesis results in androgen excess. Five enzymes are responsible for the conversion of cholesterol to cortisol, and a defect in any one of these will cause precursors to be diverted to the production of androgens. CAH is an autosomal recessive condition and

in 90–95% of cases is due to a deficiency of 21-hydroxylase. Androgen excess *in utero* leads to virilization of a female fetus and in the severe form is associated with salt loss secondary to aldosterone deficiency. Androgen excess does not affect development of fetal male genitalia. Virilized females may be assigned the wrong gender at birth and are likely to require corrective genital surgery.

The aim of therapy is to prevent virilization of a female fetus. The fetal adrenal gland can be suppressed by maternal administration of dexamethasone. A minimum dose of 20 μg per kilogram pre-pregnancy weight in two divided doses is the recommended regimen and therapy must be commenced at 6–7 weeks' gestation when the external genitalia begin to differentiate [10].

Approach to management

- A family with an index case should be offered pre-pregnancy counselling and identification of the genetic mutation.
- The risk of an affected fetus in a subsequent pregnancy is 1 in 4, and of a virilized female fetus 1 in 8.
- Commence dexamethasone treatment at 6–7 weeks' gestation.
- Perform chorionic villous sampling (CVS) at 11–12 weeks' gestation to identify an affected fetus.
- Discontinue dexamethasone in all male fetuses and all unaffected female fetuses.
- If the fetus is an affected female, continue treatment for the remainder of the pregnancy.

This regimen means that seven of eight pregnancies are exposed to unnecessary steroid therapy early in the first trimester. Non-invasive analysis of cell-free fetal DNA from maternal blood can identify the Y chromosome from 7 weeks' gestation and therapy could be discontinued in the pregnancies with a male fetus without waiting for CVS results. If the fetus is female, treatment will have to continue until genetic results from CVS are available, still exposing three of eight fetuses to potentially unnecessary treatment. Future detection of the genetic defect by non-invasive means will be the only way to eliminate this blind approach to early therapy. There are no reported teratogenic effects of antenatal dexamethasone treatment. Information regarding longer-term effects is limited and parents must be made aware of this when discussing the pros and cons of therapy.

Fetal dysrhythmias

These comprise irregular fetal heart rhythm, fetal tachycardias and fetal bradycardias. Rhythm disturbances are encountered in approximately 2% of pregnancies during routine ultrasound. M-mode and pulsed-wave Doppler echocardiography are the main diagnostic techniques. The common dysrhythmias are discussed here. The reader is referred to other literature for a more comprehensive discussion of all dysrhythmias and their diagnosis [11–13].

Irregular fetal heart rate

This is typically described as a 'missed beat' and is usually due to atrial extrasystoles. These extrasystoles are more common in the third trimester and are detected in 1.7% of fetuses after 36 weeks' gestation. Ventricular extrasytoles are much rarer. The extrasystoles are benign and usually resolve prior to delivery. Occasionally (2–3% of cases) a sustained tachycardia develops and it is wise to auscultate the heart regularly to ensure this does not occur.

Tachycardia

A fetal tachycardia is defined as a sustained heart rate above 180 bpm. Fetal tachycardia occurs in 0.5% of pregnancies and is therefore relatively common. Supraventricular tachycardia (SVT) is the most common type (66–90% of cases), followed by atrial flutter (10–30%). Atrial fibrillation and chaotic atrial tachycardia are much less common and ventricular tachycardia is extremely rare during fetal life.

Supraventricular tachycardia

The most common type of SVT is a re-entry phenomenon where an accessory conducting pathway allows rapid retrograde passage of the electrical impulse from ventricle to atrium, establishing a re-entry circuit. This is defined as atrioventricular (AV) re-entrant tachycardia. In this type of SVT the time interval between ventricular and atrial contraction (VA interval) is short. In SVT caused by atrial ectopic tachycardia or permanent junctional reciprocating tachycardia, the VA interval is long. Establishing the length of the VA interval is important when deciding on therapy. In SVT the fetal heart rate is often in the region of 240 bpm with reduced variability. The ratio of atrial to ventricular contractions (AV ratio) is 1 : 1.

Atrial flutter

The atrial rate is very fast at 350–500 bpm. At such a fast rate 1 : 1 AV conduction is not possible. More commonly there is a degree of AV block, usually 2 : 1, but it can be greater.

Management options

The fetus with a sustained tachycardia is at risk of developing cardiac failure, hydrops and ultimately death. Conservative management is an option provided the

fetus is monitored closely to detect early signs of cardiac failure. Delivery, followed by postnatal therapy, is an option if close to term, but it is recognized that pharmacological control of the heart rate in the neonatal period is not always straightforward. *In utero* therapy is effective in restoring sinus rhythm and is the preferred option for treating preterm infants, reserving delivery for those cases that fail to respond to indirect or direct fetal therapy.

The transplacental route is the route of choice for fetal therapy. A number of drugs can be used in the management of fetal tachyardia. Digoxin, flecainide and sotalol are considered first-line treatments for SVT and atrial flutter (AF). Digoxin and flecainide are the best agents for treating SVT, and sotalol is best for AF. Better control is seen for SVT than AF. The presence of fetal hydrops or incessant SVT/AF are independently associated with slower rates of cardioversion. Digoxin can be given as a loading dose, 0.5–1 mg i.v., followed by maintenance therapy, 0.25–0.5 mg t.d.s. Maternal administration is ineffective if fetal hydrops is present. Flecainide is a proarrhythmic drug, given at a dose of 100 mg t.d.s. An effect is generally seen within 72 hours. Sotalol, also proarrhythmic, is given at a dose of 80–160 mg b.d. Owing to their good placental transfer, sotalol and flecainide are the drugs of choice if fetal hydrops is present. Maternal administration of drugs should take place in a hospital setting because of potential proarrhythmic effects (flecainide, sotalol, amiodarone). Baseline ECG and urea and electrolytes should be performed prior to starting medication; these tests should be repeated after starting therapy or increasing drug dosage, looking for prolongation of the QT interval on ECG. Serum drug levels should be monitored if facilities permit.

If there is no response to maternal drug administration or there is severe hydrops, direct fetal therapy is required. This can be intravascularly via cordocentesis, intraperitoneally or intramuscularly. The risks associated with cordocentesis are greater in the presence of hydrops. Digoxin and amiodarone are the preferred drugs for direct fetal therapy.

In the absence of hydrops, success rates of transplacental therapy can be up to 100%. Fetal mortality is 17% if hydrops is present.

Bradycardia

This is defined as a fetal heart rate persistently below 100 bpm.

Atrioventricular block

In AV block there is disturbance of electrical conduction between the atria and ventricles. Three types are described. In first-degree block there is a prolonged AV interval and this cannot be detected on routine ultrasound. Second-degree block is of two types. In type I there is progressive lengthening of AV conduction time until an impulse is blocked; this results in an irregular rhythm but the fetal heart rate may be normal. In type II second-degree block there is conduction of some beats and not others, without lengthening of the AV conduction time. On M-mode the atrial rate may be twice that of the ventricular rate (2 : 1 block) and occasionally 3 : 1 block is seen.

In complete AV block (CAVB) there is complete dissociation of atrial and ventricular contractions. This rare condition (1 in 15 000–22 000 live births) has two important causes: congenital heart disease (CHD) and immune-mediated disease. CHD accounts for 50% of cases of CAVB, the most common defects being left atrial isomerism and congenitally corrected transposition of the great vessels. Immune-mediated disease has been the subject of fetal therapy. Transplacental transfer of maternal anti-Ro and anti-La antibodies results in inflammation and damage to the fetal myocardium and conduction tissue. These antibodies may be present in women with a history of Sjögren's syndrome or systemic lupus erythematosus. The risk of CAVB in a woman with antibodies is approximately 2%, with a recurrence risk of 16%. The risk to the fetus is maximal between 16 and 26 weeks' gestation. Poor prognostic features for CAVB include hydrops, heart rate below 55 bpm and premature delivery. The mortality ranges from 18 to 43%.

There are no treatment options that are clearly effective. Steroids, either dexamethasone or betamethasone, have been administered with variable results. The same is true for beta-sympathomimetics, which are given with the aim of increasing the fetal heart rate. The current lack of evidence confirming efficacy of therapy, and the potential maternal and fetal side effects of medication, must be borne in mind in the evaluation of whether or not to treat.

Summary box 19.2

- Fetal cardiac arrhythmias are common, affecting 1–2% of pregnancies.
- Ectopic beats usually resolve spontaneously.
- Fetal therapy for tachycardias is preferred to premature delivery.
- Detailed fetal echocardiography and testing for maternal anti-Ro and anti-La antibodies should be performed in cases of complete heart block.
- There is currently no therapy of proven benefit for complete heart block.

Fetal and neonatal alloimmune thrombocytopenia

The incidence of fetal and neonatal alloimmune thrombocytopenia (FNAIT) ranges from 1 in 350 to 1 in 1000 pregnancies [14], although it is likely to be underdiagnosed. It occurs when maternal platelets lack antigens that are present on the fetal platelets. An alloimmune response develops whereby maternal antibodies (IgG) are produced that cross the placenta and cause fetal platelet destruction and thrombocytopenia. Fetal platelets express specific antigens from the first trimester. FNAIT is the platelet equivalent of red cell alloimmunization. However, in contrast to red cell alloimmunization, FNAIT can complicate at least 50% of first pregnancies.

To date, 24 human platelet antigens (HPAs) have been described, which are grouped into the following systems: HPA-1, HPA-2, HPA-3, HPA-4, HPA-5 and HPA-15. The distribution of HPA systems is affected by race, and 2% of Caucasian women are HPA-1a negative. HPA-1a antibodies account for 85% of cases of FNAIT. The other antibodies most frequently encountered in Caucasians are HPA-5b and HPA-3a. HPA-5b is associated with milder FNAIT than that induced by HPA-1a. In some cases a responsible antibody cannot be identified, despite a clear clinical diagnosis of FNAIT.

FNAIT is rare, but platelet incompatibility is not infrequent: 1 in 50 pregnancies will be incompatible for HPA-1a. The observed frequency of alloimmunization is much less than this. The development of HPA-1a alloantibodies is related to HLA phenotype. Alloimmunization is rare in the absence of HLA-DRB3*0101 phenotype. The rate of alloimmunization in HPA-1a-negative women exposed to HPA-1a-positive platelets is only 10%, and of these 30% of fetuses will be thrombocytopenic [15].

Most affected infants are asymptomatic or present with signs of minor haemorrhage such as petechiae. In more severe cases there will be internal haemorrhage, and intracranial haemorrhage (ICH) is most frequent. ICH occurs in 7–26% of untreated first pregnancies affected by FNAIT [14]. The sequelae of ICH can be severe, and include perinatal mortality, hydrocephalus and long-term neurological disability. There is at least a similar or increased risk of thrombocytopenia in a subsequent pregnancy when the father is homozygous for the responsible antigen. Obstetric history is relevant. If there was no ICH in the index pregnancy, the risk of ICH in a subsequent affected pregnancy is 7%. If a previous sibling was affected by ICH, the recurrence risk is 75% [16]. The international No IntraCranial Haemorrhage (NOICH) observational cohort study reported that 54% of cases of ICH occurred before 28 weeks' gestation; 63% of cases of ICH affected the first-born child. The catastrophe of ICH is reinforced by the data that 35% died within 4 days of delivery and 53% survived with severe neurological disability [17].

Management

The aim of treatment is to reduce the risk of *in utero* and perinatal ICH. The only method of assessing the fetal platelet count is cordocentesis, and early management strategies for this condition relied on this technique. However, if the fetus is thrombocytopenic, the risk of exsanguination as a result of cordocentesis is greater. Direct transfusion of platelets at the time of cordocentesis will increase the fetal platelet count, but the lifespan of platelets is only 4–5 days, necessitating repeat transfusions at 7–10 day intervals if a normal platelet count is to be maintained. The cumulative fetal loss rate per pregnancy can be up to 8% if cordocentesis and platelet transfusion is the chosen management strategy [18]. An alternative approach is to defer cordocentesis until prior to delivery at which point a single platelet transfusion can be given, if indicated, and the baby delivered a couple of days later. This obviously reduces the risks associated with multiple procedures. However, the fetus may have already been exposed to prolonged thrombocytopenia and suffered an ICH.

Invasive strategies are no longer viewed as primary management options and a non-invasive approach to the management of FNAIT has developed. The use of intravenous immunoglobulin (IVIG) in the management of FNAIT was first reported by Bussel *et al.* [19]. A dose of 1 g/kg per week resulted in a significant increase in fetal platelet count. The mechanism of action of IVIG remains unclear but a number of possible explanations are described [14]. Firstly, anti-HPA antibodies in the maternal circulation will be diluted by the presence of immunoglobulin and therefore less will be transferred across the placenta. Secondly, IVIG may block placental Fc receptors, thus preventing transmission of maternal antibodies. Finally, IVIG may block Fc receptors on fetal macrophages, preventing destruction of antigen–antibody complex-coated cells. IVIG reduces the risk of ICH even in those fetuses that do not show an increase in platelet count, implying some additional protective effect of this therapy.

Several hundred pregnancies have been treated with IVIG, with no occurrence of ICH. There is ongoing discussion about the dose (0.5 vs. 1.0 vs. 2.0 g/kg) and treatment schedules, the gestation at which to start treatment and the role of corticosteroids. Steroids have been efficacious in some cases that are unresponsive to IVIG, and prednisolone is the drug of choice. Antenatal management should be tailored according to disease

severity, recognizing that treatment may be started as early as 12 weeks' gestation for very high risk cases. One of the keys to improving outcomes in the future is to identify factors predictive of severe FNAIT.

Delivery is a time of high risk of ICH in the thrombocytopenic fetus. Elective caesarean section is frequently the chosen mode of delivery, although it must be acknowledged that it does not eliminate the risk of ICH. Vaginal delivery can be considered if the fetal platelet count is above $50–100 \times 10^9$/L prior to delivery. For lower-risk women, namely those whose previous pregnancy was not complicated by ICH, there is evidence from a small series that vaginal delivery is not associated with adverse neonatal outcome [14].

Summary box 19.3

- ICH is the devastating complication of FNAIT.
- ICH occurs in 7–26% of untreated first pregnancies affected by FNAIT.
- Bleeding occurs before 28 weeks' gestation in 50% of cases, and can occur as early as 18–20 weeks' gestation.
- Non-invasive therapy with IVIG is the recommended treatment, acknowledging that the optimal regimen has yet to be established.

Fetal anaemia

This can result from red cell alloimmunization or parvovirus infection. The mechanism of fetal anaemia, its management and treatment are discussed for both aetiologies.

Red cell alloimmunization

If a pregnant woman is exposed to fetal red cells that possess different antigens to her own red cells (i.e. the antigens have been inherited from the father), she will mount an immune response. The initial response is production of IgM antibodies, which do not cross the placenta and therefore the pregnancy in which antibodies are first detected is unlikely to be affected. However, on further exposure to the foreign red cell antigen, IgG antibodies are produced which do cross the placenta and can cause fetal haemolytic anaemia. The antibodies most commonly associated with haemolytic disease of the fetus and newborn (HDFN) are the rhesus system antibodies RhD, Rhc and RhE, and Kell.

Some aspects of the assessment and management of pregnancies at risk of HDFN are discussed in Chapter 12. Figure 19.1 outlines a proposed management strategy for rhesus-sensitized pregnancies. Important points to recognize include the following.

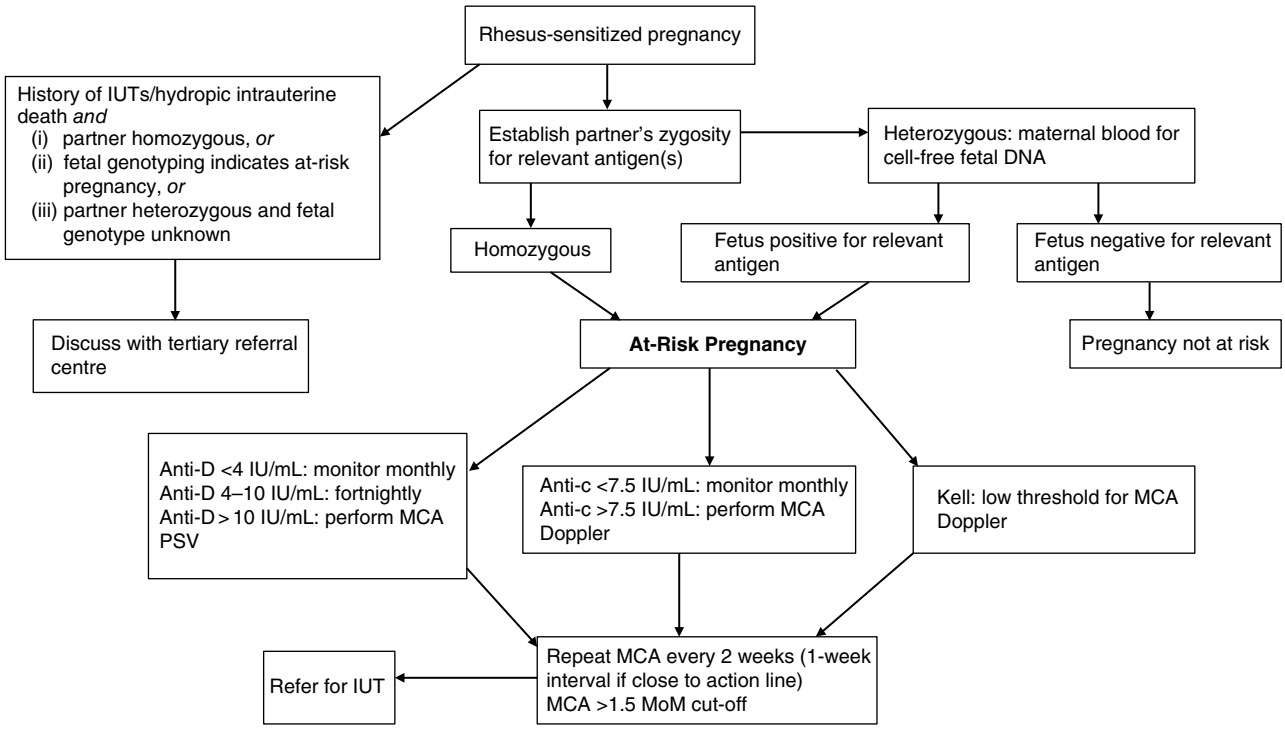

Fig. 19.1 Algorithm for the management of rhesus-sensitized pregnancies. IU, international units; MCA, middle cerebral artery; PSV, peak systolic velocity; IUT, intrauterine transfusion; MoM, multiples of the median. *Source:* Fisher DA. Fetal thyroid function: diagnosis and management of fetal thyroid disorders. *Clin Obstet Gynecol* 1997;40:16–31. Reproduced with permission of Elsevier.

- If the father is heterozygous for the relevant antigen, fetal blood group should be established using the non-invasive technique of assessing cell-free fetal DNA in maternal blood.
- Anti-D and anti-c concentrations can be quantified; this is not possible for anti-E or Kell antibodies.
- The trend of rise in antibody concentration is as important as a particular cut-off level.

Monitoring: middle cerebral artery Doppler

Having established that a pregnancy is at risk of fetal anaemia secondary to red cell alloimmunization, the aim of monitoring is to determine the point at which fetal therapy is indicated, before the fetus becomes severely anaemic. Fetal hydrops indicates the presence of severe anaemia. The early ultrasound features of hydrops are ascites and cardiomegaly, followed by progressive skin oedema, pericardial and pleural effusions and placental oedema. The entire purpose of the monitoring described here is to intervene before hydrops develops (Fig. 19.2).

Doppler is informative in fetal anaemia because of some basic principles of blood flow. If the cross-sectional area of a vessel remains constant, blood velocity is directly proportional to blood flow. In addition, decreased blood viscosity will increase blood flow [20]. The anaemic fetus has a reduced blood viscosity and a hyperdynamic circulation, both of which will increase blood flow and hence blood velocity. In the middle cerebral artery (MCA) this is reflected by an increase in peak systolic velocity (PSV). MCA PSV measurements that are above a cut-off of 1.5 multiples of the median for gestational age identify moderate to severely anaemic fetuses with a sensitivity of 100% and a false-positive rate of 12% [21]. MCA PSV is not a good predictor of mild anaemia, but this is not a concern since this group of fetuses does not require *in utero* therapy. MCA PSV measurement is shown in Fig. 19.3 and the technique is described by Mari *et al.* [21].

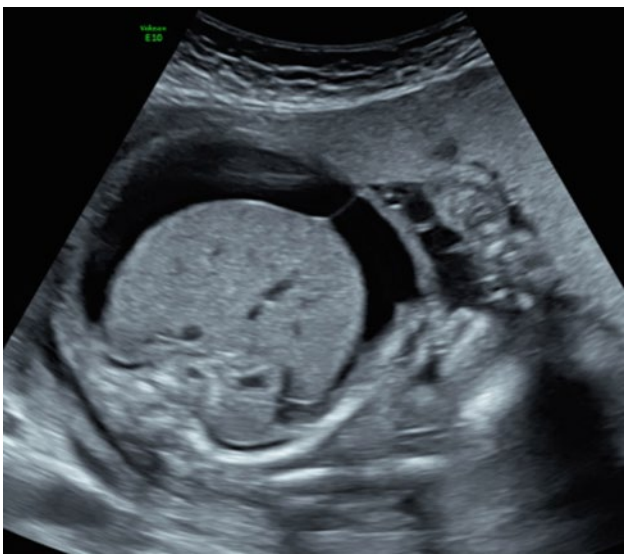

Fig. 19.2 Transverse section through fetal abdomen demonstrating ascites.

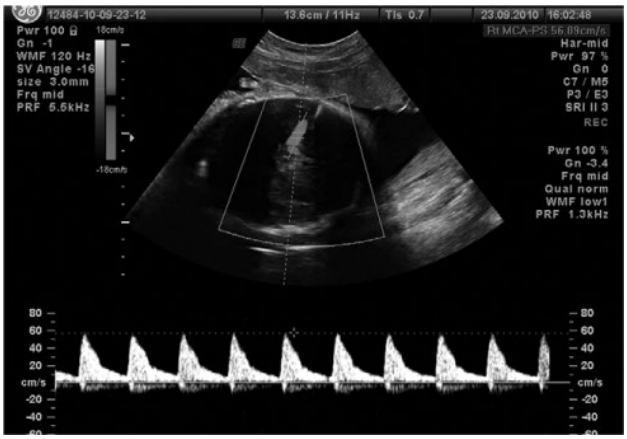

Fig. 19.3 Middle cerebral artery peak systolic velocity measurement.

Non-invasive monitoring using MCA Doppler has replaced serial amniocentesis in the management of at-risk pregnancies. Amniocentesis is an invasive procedure with a procedure-related loss rate of up to 1%. Repeated procedures are usually necessary in the same pregnancy and each procedure carries a risk of fetomaternal haemorrhage, thus exacerbating the degree of fetal anaemia. A multicentre study comparing MCA Doppler with amniocentesis for monitoring at-risk pregnancies has demonstrated that MCA Doppler has a significantly greater accuracy and sensitivity [22]. In addition, 51% of women would have avoided an invasive procedure if MCA Doppler had been solely relied on. It is therefore the monitoring modality of choice in the majority of centres.

Summary box 19.4

- The main antibodies causing fetal anaemia are anti-RhD, anti-Kell and anti-Rhc.
- Parvovirus infection is an important cause of fetal anaemia, and should be considered in all cases of non-immune hydrops.
- Non-invasive testing has replaced invasive testing for the management of fetal anaemia.
- Fetal blood group should be determined on cell-free fetal DNA in maternal blood.
- MCA Doppler has replaced amniocentesis for timing intrauterine transfusion in the majority of centres.
- The need for intrauterine transfusion should be predicted before hydrops develops.

Treatment: intrauterine transfusion

The first intrauterine transfusion (IUT) was performed by Liley in 1963 [23] via the intraperitoneal route. Donor red blood cells are absorbed into the circulation via the diaphragmatic lymphatics. This results in slower restoration of fetal haemoglobin than if blood is given directly into the circulation, and as a result is no longer the route of choice for fetal therapy. It does still have a place in those cases requiring transfusion before 18–20 weeks' gestation, when intravascular access may not be possible. Intraperitoneal transfusion from 16 weeks' gestation has been employed successfully in a small cohort of severe cases of rhesus alloimmunization, until a gestation at which intravascular access could be achieved [24].

The introduction of real-time ultrasound facilitated needle-guided intraperitoneal transfusion in 1977. The first intravascular transfusion was performed fetoscopically by Rodeck *et al.* in 1981 [25]. A variety of techniques for IUT have been employed. Direct intravascular transfusion is the preferred technique in which the additional volume is absorbed by the fetoplacental circulation, thus 'protecting' the fetus from fluid overload. The fetal circulation is accessed via the umbilical cord at its placental insertion (Fig. 19.4) or the intrahepatic portion of the umbilical vein. Intracardiac transfusion is also described. The choice of route will be influenced by placental site and fetal position. Access to the cord insertion is easiest if the placenta is anterior. When accessing the cord insertion the vein is targeted rather than an artery, as the latter is prone to spasm and there is an increased risk of complications.

Technical aspects of the procedure are:

- maternal sedation, antibiotics, single course of steroids at 26 weeks' gestation and above;
- aseptic technique;

Fig. 19.4 Anterior placental cord insertion, with needle guideline.

- needle guide and free-hand approach, using 20 gauge needle;
- cord insertion/intrahepatic vein;
- cross-matched, O, Rh-negative, cytomegalovirus-negative, irradiated blood;
- repeat at 2-week intervals;
- aim for delivery at 34–35 weeks' gestation.

Once the chosen vessel is punctured, a sample of fetal blood is analysed immediately by on-site laboratory staff to obtain the fetal haematocrit. The volume of blood to be transfused is calculated by a formula incorporating fetal haematocrit, donor haematocrit and fetoplacental blood volume. It is important that the donor haematocrit is as high as possible (≥75%) to reduce the risk of volume overload. The aim is for a post-transfusion haematocrit of 40–45%. The estimated post-procedure decline in haematocrit is 1–2% per day, and in general a transfusion interval of 14 days is used, although cases vary individually, as will the policies of different centres. If the fetus is severely anaemic and/or hydropic, a stepwise transfusion is given, aiming for a haematocrit of 30%, with repeat transfusion 1 week later.

Complications of IUT

There are a number of procedure-related complications of IUT. The perinatal mortality rate is 1.6–2% [26]. Complications include vasospasm and fetal bradycardia, chorioamnionitis and preterm labour/delivery, emergency delivery and augmentation of the alloimmunization with implications for future pregnancies.

Outcomes

A review of 19 studies using IUT shows an overall survival rate of 84% [26]. The survival rate is higher for non-hydropic fetuses (94%) compared with hydropic fetuses (74%). There is evidence that infants severely affected by rhesus disease have lower birthweights than matched controls. Infants treated with IUT show evidence of catch-up growth *in utero* and birthweights comparable to controls. Existing data for short-term neurodevelopmental outcome following IUT suggest that this can be expected to be normal in more than 90% of cases, irrespective of a history of hydrops [27,28].

Kell alloimmunization

This can result in profound fetal anaemia, hydrops and intrauterine death. It differs from rhesus alloimmunization for a number of reasons. Past obstetric history is not reliable in predicting outcome in a subsequent pregnancy. Maternal antibody titres do not correlate well with the severity of fetal anaemia; poor outcomes have

been reported with low titres. The type of anaemia is not solely haemolytic, but is also due to erythroid suppression. For these reasons, management of a Kell immunized pregnancy is challenging. Fortunately, the incidence of HDFN due to Kell is low; only 9% of the white population is Kell positive and 0.2% are homozygous [29]. MCA PSV monitoring has been shown to be reliable in the management of Kell alloimmunization. Fortnightly MCA PSV measurements once the antibody titre is 1 : 32 is a reasonable approach to management. However, owing to the unpredictable nature of Kell immunization, earlier implementation of MCA measurements cannot be criticized.

Summary box 19.5

- Ultrasound-guided cordocentesis has revolutionized fetal investigation and therapy.
- Intrauterine transfusion can treat anaemia secondary to alloimmunization or parvovirus infection.
- Intravascular access is obtained at the placental cord insertion or the intrahepatic portion of the umbilical vein.
- The procedure-related loss rate of IUT is 1–2%.
- This risk is higher if fetal hydrops is present.

Parvovirus

Parvovirus infection should be considered in any fetus presenting with non-immune hydrops. Alternatively, a woman contracting parvovirus infection during pregnancy requires appropriate monitoring to detect developing fetal anaemia. The topic has been reviewed extensively by other authors [30–32].

Parvovirus B19 is thought to exclusively infect humans, and it binds to the blood group P-antigen cellular receptor that is present on haematopoietic precursors, endothelial cells, fetal myocytes and placental trophoblast. Its effect on the haematopoietic system results in profound anaemia and non-immune hydrops fetalis (NIHF). In addition, viral particles have been identified in fetal myocardial tissue, and cardiac dysfunction due to myocarditis may also contribute to the development of cardiac failure.

Approximately 50% of pregnant women are susceptible to infection, and outbreaks occur every 3–4 years, most commonly in late winter and spring. The peak incidence of hydrops occurs with infection between 17 and 24 weeks' gestation. The risk of developing hydrops if infection occurs between 13 and 20 weeks' gestation is 7.1%. The virus infects the fetal liver, which in the second trimester is the main source of haematopoietic activity. Haematopoiesis is augmented at this gestation to meet the demands of the growing fetus, and the lifespan of red blood cells is decreased, rendering the fetus particularly susceptible to any arrest in haematopoietic production. Levels of the P-antigen are negligible in the third trimester, and hence the risk of anaemia and hydrops appears to be low. The risk of vertical transmission during pregnancy is 30%, and the mean interval from maternal infection to development of NIHF is 2–6 weeks, although longer intervals have been reported.

Maternal serology will confirm recent infection. If IgM titres exceed IgG titres, the infection took place within the previous month and the fetus remains at risk of complications, even if none are present at initial presentation. Maternal serology can be misleading if checked earlier than 7 days after contact as IgG and IgM could both be negative at this stage. Similarly, by the time of clinically established hydrops, IgM levels may already be low or, rarely, undetectable. Fetal serology is of no help diagnostically as the fetal immune system is too immature to mount a detectable IgG/IgM immune response. Polymerase chain reaction techniques to detect viral DNA are required.

Management

MCA PSV is reliable in predicting fetal anaemia secondary to parvovirus infection. The anaemia can be successfully treated by IUT, which reduces the mortality rate of severe hydrops. Frequently a single transfusion is required. Cordocentesis and IUT are obviously not without risk, and the risks are higher when the fetus is hydropic. Thrombocytopenia is often a feature of parvovirus infection and this will potentially increase the procedure-related risk of exsanguination. In addition to red cell transfusion, consideration should be given to transfusion of platelets in those fetuses with severe thrombocytopenia.

Close fetal surveillance is required following maternal seroconversion prior to 24 weeks' gestation. Weekly MCA PSV should be carried out and IUT considered for results above the cut-off of 1.5 multiples of the median. Serial surveillance for 8–12 weeks after conversion is indicated. Anaemia due to parvovirus has the potential to resolve as the fetus mounts its own immune response. As a result, MCA Doppler monitoring may identify some fetuses that are anaemic at presentation but which are actually in the recovery phase of the infection. If other signs of fetal well-being are present, such as good fetal movements and normal liquor volume, it may be possible to continue conservative management and avoid IUT in these particular cases. A proposed management plan is summarized in Fig. 19.5.

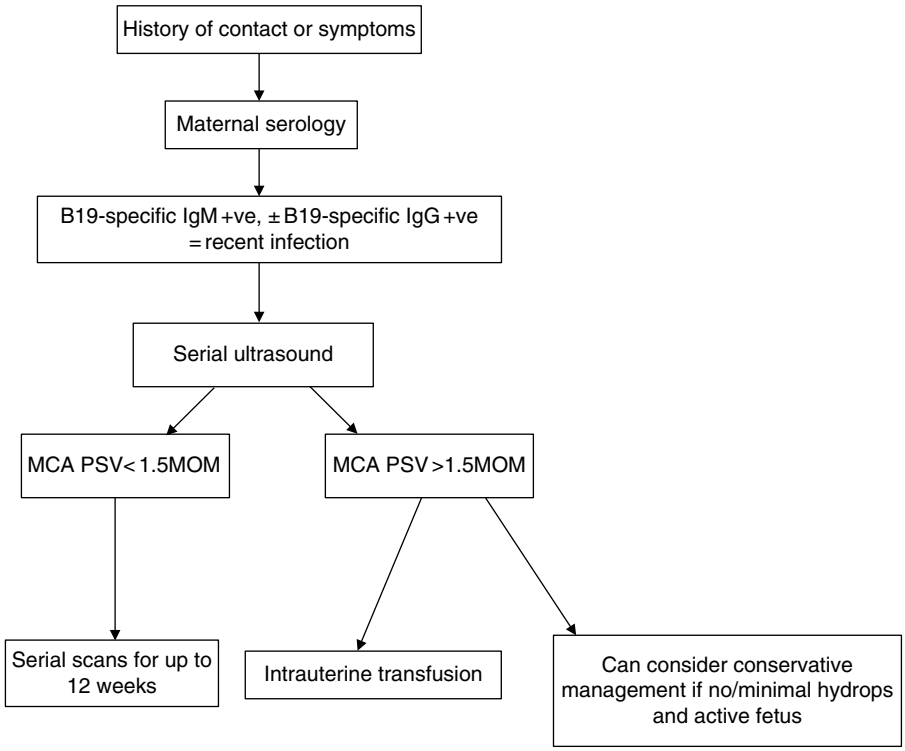

Fig. 19.5 Algorithm for the management of parvovirus infection. MoM, multiples of the median.

Fetal Anomalies

Sailesh Kumar[1,2,3]

[1] *University of Queensland, Queensland, Australia*
[2] *Mater Mothers' Hospital, Brisbane, Australia*
[3] *Imperial College London, London, UK*

Almost 5% of newborns have a congenital malformation. In many cases these malformations are minor and do not impact on either the short- or long-term outcome for the individual. However, major congenital malformations are a significant contributor to both perinatal morbidity and mortality and indeed the detection of such anomalies has been the goal of antenatal screening programmes worldwide. In many countries the antenatal detection of fetal anomalies and the subsequent termination of these fetuses have been responsible for the decline in perinatal mortality rate seen over the last three decades. The detection of fetal structural abnormalities is generally made by ultrasound with additional more sophisticated techniques, such as three/four-dimensional ultrasound, fetal MRI and fetoscopy, reserved for complex cases where standard two-dimensional ultrasound fails to clarify the diagnosis.

The objectives of an antenatal screening programme should be (i) to provide appropriate information for women so that they are able to make an informed choice about their screening options and pregnancy management, (ii) to identify serious fetal abnormalities, either incompatible with life or associated with morbidity, allowing women to make timely decisions about pregnancy outcome, (iii) to identify abnormalities that may benefit from antenatal intervention and (iv) to identify abnormalities that may require early intervention following delivery. Clearly the successful implementation of an antenatal fetal anomaly screening programme depends on many factors including the provision of adequate patient information, the availability of trained sonographers and good ultrasound equipment and clear management pathways for patients once an anomaly has been detected.

The European Surveillance of Congenital Anomalies (EUROCAT) recorded a total prevalence of major congenital anomalies of 23.9 per 1000 births for 2003–2007. Congenital heart defects (CHDs) were the most common non-chromosomal anomalies (6.5 per 1000 births), followed by limb defects (3.8 per 1000), anomalies of the urinary system (3.1 per 1000) and nervous system malformations (2.3 per 1000). It has been estimated that the perinatal mortality rate associated with congenital anomalies is in the region of 0.9–1 per 1000 births.

Although first- and second-trimester aneuploidy screening is widely available in the UK, Europe, North America and many parts of Australasia, for many women the first antenatal ultrasound scan will be the mid-trimester fetal anomaly scan which is generally done at 18–22 weeks' gestation. The majority of fetal structural anomalies will be detected during this examination. With better high-resolution machines and trained sonographers, many structural anomalies are now diagnosed during the late first and early second trimester, which is clearly preferable for women.

Timing and development of fetal malformations

The crucial morphogenetic window during which the fetus is particularly susceptible is the period of blastogenesis, which extends throughout the first 4 weeks of development (from fertilization until the end of the gastrulation stage, days 27–28 post conception). Any insult during this period can result in structural malformations, including patterns of multiple congenital anomalies arising from developmental field defects. Severe damage may cause demise of the fetus or, because of the pluripotent nature of the embryo and early fetus in general, compensatory changes may occur allowing development to continue in a normal or near-normal fashion. Because the fetus is less susceptible to damage when the developmental process of the majority of organs has been

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

completed, the most common anomalies associated with teratogenic exposures during the fetal period are fetal growth restriction (intrauterine growth retardation) and mild abnormalities of phenotype (epicanthic folds, clinodactyly, etc). However, teratogenic drugs can result in a wide variety of effects that range from infertility, prenatal-onset growth restriction, structural defects, and functional central nervous system (CNS) abnormalities to miscarriage or fetal death. Similarly, various perinatal infections (particularly viruses) can have significant teratogenic effects on the developing fetus with an extremely wide spectrum of resulting malformations.

Summary box 20.1

- The fetus is most vulnerable in the first 4 weeks of life.
- Many maternal conditions, drugs and infections can cause structural malformations in specific organ systems.
- Ultrasound is the usual modality of imaging in pregnancy and detects the vast majority of anomalies.

Selected fetal anomalies in specific organ systems

Cardiovascular system anomalies [1]

The fetal heart develops from the splanchnic mesoderm and in its earliest and most rudimentary form is represented by two tubes which subsequently fuse and then canalize. Repeated rotations and septations then occur which ultimately results in a four-chamber organ.

The structural and functional cardiac abnormalities are some of the commonest disorders seen in prenatal life, with the incidence of congenital heart disease estimated at 6–12 per 1000 live births, at least half of which should be detectable before birth. There are many risk factors for fetal cardiac abnormalities, some of which cause structural malformations whilst others perturb function or cause rate and rhythm abnormalities. Common maternal risk factors include pre-gestational diabetes mellitus, phenylketonuria, drug exposure, maternal autoimmune conditions such as systemic lupus erythromatosus (SLE) and infections such as rubella. Other risk factors are a history of maternal or paternal congenital heart disease, aneuploidy, genetic syndromes, twin–twin transfusion syndrome (particularly in the recipient) or in association with other structural malformations or tumours.

Fetal echocardiography should be considered for the following.

- First-degree relative with congenital heart disease: one previous sibling affected, 2–4% risk; two or more previous siblings affected, 10% risk; mother affected, 5–12% risk; father affected, 1–3% risk.
- Maternal insulin-dependent diabetes: 3–4% risk.
- Autoimmune antibodies (anti-Ro and anti-La).
- Drug therapy (lithium, 10% risk) or epilepsy (4–7% risk with monotherapy, 15% risk with polytherapy).
- Monochorionic twins: 4% risk.
- Increased nuchal translucency ≥3.5 mm: 3% risk, rising to 23% risk if >5.5 mm.
- High-risk structural anomalies: tracheo-oesophageal fistula, 15–40% risk; duodenal atresia, 17% risk; omphalocele, 20–30% risk; and diaphragmatic hernia, 10–20% risk.

Detection of any cardiac abnormality should prompt a detailed evaluation for extracardiac anomalies. Karyotyping should be offered (risk 1–50%) depending on the type of lesion. Fetuses with CHD are at increased risk of structural brain abnormalities. The prevalence of prenatal structural brain abnormalities in fetuses with CHD is approximately 28% (95% CI 18–40%). The more common abnormalities include ventriculomegaly, agenesis of the corpus callosum, ventricular bleeding, increased extra-axial space, vermian hypoplasia, white-matter abnormalities and delayed brain development. Fetuses with CHD are also more likely to have reduced brain volume, delay in brain maturation and altered brain circulation identified by Doppler sonography. These changes are usually evident in the third trimester, although have been reported as early as the second trimester. Concomitant 22q deletion testing should be performed for outflow tract abnormalities (1% risk overall but 10% with outflow tract lesions). Delivery should generally take place in a tertiary unit. The mode and timing of delivery is usually decided on standard obstetric criteria.

Aortic stenosis and hypoplastic left heart syndrome

Aortic stenosis accounts for 4–6% of all cardiovascular abnormalities and is four times more common in males. It has an incidence of 3–4 per 10 000 live births. It may be subvalvular, valvular or supravalvular. Stenosis secondary to valve abnormalities is usually due to cusp malformations seen in unicuspid or bicuspid aortic valves. The incidence of bicuspid aortic valves is approximately 1 in 100 newborns. Critical aortic stenosis causes reduced left ventricular output and increased diastolic filling pressure, which then causes hypertrophy followed by dilatation of the left ventricle.

Critical aortic stenosis can cause coronary hypoperfusion, subendocardial ischaemia and significant metabolic acidosis. The development of hydrops fetalis carries a very poor prognosis. Differential diagnoses include hypoplastic left heart syndrome (HLHS), coarctation of

the aorta and cardiomyopathy. HLHS is frequently associated with both aortic and mitral valve atresia.

HLHS is a major congenital heart anomaly and accounts for 1% of congenital cardiac abnormalities. HLHS involves a range of abnormalities, the cardinal feature of which is the inability of the left side of the heart to maintain the systemic circulation. The most severe form involves mitral and aortic valve atresia and an extremely hypoplastic left ventricle, with the degree of hypoplasia determining postnatal outcome. Other causes of HLHS are proximal aortic hypoplasia and left ventricular hypoplasia. Without treatment, newborn babies with HLHS usually die and it is responsible for 25% of all cardiac deaths in the first week of life. Important associated anomalies include pulmonary venous return abnormalities. CNS anomalies, including agenesis of the corpus callosum, microcephaly and holoprosencephaly, have also been reported. HLHS is associated with aneuploidy, genetic syndromes (Holt–Oram, Noonan's) and extracardiac abnormalities.

The majority of cases of HLHS occur too early in gestation for any intervention to be feasible; however, there is a subgroup of fetuses where the initiating insult occurs in mid-gestation or later, rendering some of these fetuses amenable to fetal cardiac intervention. The objective of *in utero* balloon dilatation of the aortic valve is to modify disease progression by opening the aortic valve and promoting prograde flow, thereby allowing growth of left-sided cardiac structures. The ultimate aim is to maintain a heart with two reasonably functioning ventricles and therefore make the fetus a candidate for postnatal biventricular repair. In many congenital heart centres, transcatheter balloon valvuloplasty is the initial procedure of choice in newborns with congenital aortic stenosis that are either duct dependent or have low cardiac output. After delivery, patency of the ductus arteriosus should be maintained with prostaglandin (PG)E_2 and any associated metabolic acidosis corrected. Early neonatal echocardiography should be performed to confirm the cardiac abnormality and treatment then planned.The pregnancy and birth should be managed in a tertiary centre by a multidisciplinary team including fetal medicine specialists, perinatal cardiologists, paediatric intensivists and cardiac surgeons. Karyotyping should be performed and termination of pregnancy should be discussed with parents as the outcome for the majority of cases is very poor.

Pulmonary stenosis and hypoplastic right heart syndrome

This is a fairly common abnormality, with the diagnosis often made after delivery. It has an incidence of approximately 1 in 1500 live births. Pulmonary stenosis may be isolated, occur in association with other abnormalities (Fallot's tetralogy), or occur in association with genetic syndromes (William's syndrome, Noonan's syndrome) or secondary to congenital rubella infection. Narrowing of the pulmonary valve can lead to hypertrophy of the right ventricle and, in severe cases, hypoplasia of the right ventricle. Pulmonary stenosis may progress *in utero*, resulting in tricuspid regurgitation, heart failure and hydrops.

Delivery of the baby should take place in a tertiary unit. The ductus arteriosus should be kept patent with a PGE_2 infusion. Early echocardiography to confirm the diagnosis and to exclude other cardiac malformations should be performed. Cardiac catheterization and balloon valvuloplasty is the treatment of choice, although some cases may require open heart surgery.

Hypoplastic right heart syndrome is ususally due to pulmonary valve atresia with an intact interventricular septum. Occasionally the tricuspid valve is also atretric. The left ventricle thus supplies both the systemic and the pulmonary circulation (by retrograde flow through the ductus arteriosus). The malformation is suspected if there is an obvious discrepancy in size between the two ventricles. Karyotyping may be indicated if additional anomalies are present, although the overall risk for aneuploidy is low. Termination of pregnancy should be discussed, particularly if hydrops is present.

Atrioventricular septal defect

This anomaly covers a spectrum of congenital heart malformations characterized by a common atrioventricular junction coexisting with deficient atrioventricular septation. In ostium primum atrial septal defect there are separate atrioventricular valvular orifices despite a common junction, while in complete atrioventricular septal defect there is a common valve. There is a strong association (30–50%) with Down's syndrome. Additional cardiac malformations are present in more than 70% of cases. The key diagnostic feature on the four-chamber view of the heart is the presence of a common atrioventricular valve. Once the abnormality is detected, referral to a tertiary centre and paediatric cardiologist is advisable. Karyotyping is essential and careful assessment of the fetus for additional anomalies is important. Termination of pregnancy should be offered for large lesions with fetal hydrops, if aneuploidy is detected or if there are other major associated anomalies.

Tetralogy of Fallot

Tetralogy of Fallot occurs in approximately 1 in 3600 live births and accounts for 3.5% of infants born with congenital heart disease. It comprises a ventricular septal defect, right ventricular outflow tract obstruction, the aorta overriding the interventricular septum and right ventricular hypertrophy. The spectrum of severity is wide, ranging from right outflow tract obstruction to

pulmonary atresia; 15% of cases may be associated with DiGeorge's syndrome caused by a deletion on the long arm of chromosome 22 (22q11.2). Once the diagnosis is suspected, referral to a paediatric cardiologist is essential. Karyotyping should be offered (including 22q deletion studies). The development of hydrops is a poor prognostic sign and termination of pregnancy should be discussed.

Central nervous system anomalies

Development of the human CNS involves several complex steps, including neural proliferation, neuroblast migration and neuronal differentiation. This is an extremely complex process influenced by both genetic and environmental factors and continues *ex utero* for several years. Some types of CNS anomalies are associated with an increased incidence of abnormal chromosomal microarray analyses. Pathogenic copy number variants are more common in fetuses with Dandy–Walker syndrome and holoprosencephaly. Chromosomal microarray analyses should be considered as part of the prenatal work-up in fetuses with CNS malformations.

Agenesis of the corpus callosum [2]

Agenesis of the corpus callosum (ACC) is a failure to develop the large bundle of fibres that connect the two cerebral hemispheres. It occurs in 1 in 4000 individuals and has been estimated to have a prevalence of 1.4 per 10 000 live births. ACC can be either complete or partial. It may occur in isolation, associated with aneuploidy, as part of a genetic syndrome (e.g. Aicardi's or Andermann's syndrome) or in association with other brain malformations. Various teratogens (alcohol, antiepileptic medication and cocaine), environmental factors and viral infections (rubella) have also been associated with ACC. If ACC is suspected, a careful search for both intracranial and extracranial anomalies is required. Karyotyping should be offered; the overall rate of aneuploidy is 17–18%. As the association of ACC with other cerebral malformations increases the likelihood of neurological impairment, fetal MRI should be performed in all suspected cases.

Counselling by a paediatric neurologist is essential as the spectrum of potential problems is wide. The prognosis in ACC is dependent on the coexistence of other abnormalities. For complete ACC, normal neurodevelopmental outcome can be expected in almost 84% of cases and severe disability in approximately 8% of affected individuals. There is some evidence to suggest that outcomes in partial ACC may be worse. The outcome for complete and partial ACC is conflicting, the majority of studies showing no difference in behavioural and medical outcomes between the two, with an overall rate of 25–30% of neurodevelopmental delay. Most children with isolated ACC will have mild behavioural problems.

Dandy–Walker malformation [3,4]

Dandy–Walker malformation is the most common congenital malformation of the cerebellum, with an incidence of 1 in 5000 births. Classic Dandy–Walker malformation is characterized by absence of the cerebellar vermis accompanied by dilatation of the fourth ventricle and a posterior fossa cyst. The cerebellum itself may be hypoplastic. In the Dandy–Walker variant, the posterior fossa is minimally enlarged, there is partial agenesis of the vermis, the fourth ventricle communicates with the arachnoid space, and no hydrocephalus is present. Other associated posterior fossa abnormalities include mega cisterna magna, Blake's pouch cyst or isolated vermian hypoplasia. There is an association with a variety of genetic syndromes, chromosomal abnormalities, infections and environmental teratogens. The prevalence of aneuploidy in fetuses with Dandy–Walker malformation and no associated CNS or extra-CNS anomalies is approximately 16%, with chromosomal deletions representing the most common abnormality. Ventriculomegaly is frequently seen. Aneuploidy or other CNS or extra-CNS anomalies are much less common in cases of mega cisterna magna, Blake's pouch cyst or isolated vermian hypoplasia. In contrast, associated CNS malformations are present in up to 68% of cases of Dandy–Walker malformation, the most common of which is agenesis or hypoplasia of the corpus callosum.

Karyotyping should be offered in all cases of Dandy–Walker malformation. Fetal MRI is extremely helpful in both confirming the diagnosis and determining the presence of other CNS malformations. Termination of pregnancy is an option regardless of gestation if classic Dandy–Walker malformation is detected because of the very poor long-term prognosis. The situation is more difficult with isolated Dandy–Walker variant as many of these children may have good long-term outcome. Counselling by a paediatric neurologist is essential.

Holoprosencephaly [5]

Holoprosencephaly (HPE) is a spectrum of congenital malformations involving the brain and face and is characterized by impaired or incomplete midline division of the embryonic forebrain (prosencephalon). Holoprosencephaly has an incidence of 1 in 16 000 live births. Only 3% of fetuses with HPE survive to birth. Facial anomalies associated with HPE include cyclopia, ethmocephaly, cebocephaly, median cleft lip, and less severe facial manifestations. Midline facial defects occur in the majority (>80%) of cases. Approximately 40% of live births with HPE have a chromosomal anomaly and trisomy 13 accounts for over half of these cases.

Alobar HPE is the most severe form. There is incomplete division of the cerebral hemispheres with a single midline forebrain ventricle (monoventricle), which often communicates with a dorsal cyst. The interhemispheric fissure and corpus callosum are completely absent. In semi-lobar HPE, there is failure of separation of the anterior hemispheres, with some separation of the posterior hemispheres. The frontal horns of the lateral ventricle are absent, but posterior horns are present. The corpus callosum is absent anteriorly. In lobar HPE (the mildest form), the cerebral hemispheres are fairly well divided, with fusion of only the most rostral/ventral aspects.

Karyotyping must be offered. Fetal MRI is often very helpful in confirming the diagnosis as well as grading the severity of the HPE. Termination of pregnancy should be discussed and offered. Alobar and most cases of semi-lobar HPE are not compatible with prolonged *ex utero* survival. Lobar HPE can be associated with long-term survival and will need evaluation for endocrine abnormalities and/or craniofacial surgery. Genetic counselling is essential and prenatal diagnosis may be an option in selected cases. HPE due to euploid non-syndromic causes have an empiric recurrence risk of 6%.

Ventriculomegaly [6]

Depending on the gestational age at ascertainment, the prevalence of ventriculomegaly varies between 0.3 and 1.5 per 1000 births. Ventriculomegaly is defined as a measurement of the atrium of the posterior or anterior horns of the lateral ventricles of more than 10 mm at any gestation. A measurement above 15 mm is considered severe. It may be unilateral or bilateral, symmetrical or asymmetrical. In fetuses with apparently isolated unilateral ventriculomegaly, increased dilatation of the ventricles occurs in 5% of cases. Once detected it is important to obtain a detailed history, especially of recent viral illness or significant maternal trauma, family genetic history, previous congenital abnormality or fetal/neonatal thrombocytopenia. Karyotyping should be discussed (7–15% overall risk of aneuploidy), although the risk of chromosome abnormalities for isolated unilateral ventriculomegaly is extremely low. Amniotic fluid should also be sent for viral polymerase chain reaction (PCR) analysis. Maternal blood for infection screening, particularly *Toxoplasma*/cytomegalovirus (CMV) and rubella, should be performed. If the ventriculomegaly is associated with intracerebral haemorrhage, evidence of fetal alloimmune thrombocytopenia should be sought (antiplatelet antibodies/HPA typing).

Fetal MRI should be arranged and further review with a paediatric neurologist is essential, particularly if the prognosis is in doubt. For isolated unilateral ventriculomegaly, additional brain abnormalities are detected by fetal MRI in 5% and 6% of the cases prenatally and postnatally, respectively. Neurodevelopmental outcome for mild isolated ventriculomegaly (<15 mm) appears to be not significantly different from the general population. In general, 6–7% of cases experience some neurodevelopmental delay of variable severity. However, asymmetric bilateral ventriculomegaly may carry a worse prognosis, with these children at significant risk for behavioural abnormalities. Poor prognostic factors include coexistent cerebral anomalies and progression of the ventriculomegaly. In severe ventriculomegaly, the outcome may still be variable but less than 30% of children will develop normally. Termination of pregnancy should be discussed for severe ventriculomegaly (>15 mm), aneuploidy, spina bifida or other associated major malformations. The mode of delivery is on standard obstetric criteria. In the presence of severe macrocephaly, caesarean section or cephalocentesis may be required. Cephalocentesis is associated with a high incidence of procedural/intrapartum demise.

Neural tube defects [7,8]

Most neural tube defects are multifactorial in origin, with a genetic component that interacts with a number of environmental risk factors. The ccommonest forms of neural tube defect are referred to as 'open', where the involved neural tissues are exposed to the body surface. These include anencephaly, craniorachischisis and myelomeningocele. Between 2 and 16% of isolated open neural tube defects occur in association with aneuploidy or a single gene defect. If additional structural anomalies are present, the risk may be as high as 24%. Most cases of neural tube defects are multifactorial in origin. Anticonvulsant use, mutations in the *MTHFR* (methylenetetrahydrofolate reductase) gene, maternal hyperthermia, obesity, diabetes mellitus and a previous family history are all risk factors. Recurrence in any subsequent pregnancy can be significantly reduced by taking high-dose folic acid (4–5 mg) periconceptually. Some neural tube defects are lethal (anencephaly, craniorachischisis) whereas others are compatible with long-term survival. However, there is risk of significant morbidity, including mobility issues and bladder and bowel dysfunction, and counselling by a neurologist is essential.

Prenatal surgical closure of selected cases of myelomeningocele is now an option, with evidence of significant reduction in the need for ventriculo-peritoneal shunting compared with standard postnatal closure. In addition, prenatal surgery improves reversal of hindbrain herniation as well as ambulation by 30 months. However, prenatal surgical intervention is associated with significantly higher rates of oligohydramnios and chorioamniotic separation, as well as spontaneous membrane rupture and preterm delivery.

Gastrointestinal tract anomalies

Duodenal atresia [9]

Duodenal atresia has an incidence of 1 in 5000–10 000 live births. The diagnosis is suspected on ultrasound when polyhydramnios and a double-bubble appearance (due to a dilated stomach and proximal duodenum) are present. Duodenal atresia results from failure of recanalization of the duodenum after the seventh week of gestation, possibly due to an ischaemic event; occasionally, genetic factors may also play a role. Although sometimes seen earlier in gestation, the diagnosis is usually made after 24 weeks. Approximately 50% of cases of duodenal atresia have associated structural anomalies. Almost 30% are associated with Down's syndrome and other anomalies are usually related to the VACTERL group (*V*ertebral, *A*norectal, *C*ardiac, *T*racheo*E*sohageal, *R*enal and *L*imb). If the diagnosis is suspected on antenatal ultrasound, karyotyping must be offered because of the high risk of Down's syndrome. Because of the significant risk of polyhydramnios (50%), regular scans are required and amnioreduction may be necessary if the amniotic fluid index increases substantially or if the patient is symptomatic. Preterm labour occurs in approximately 40% of cases. Delivery should take place in a tertiary centre with neonatal and paediatric surgical facilities. After birth, a nasogastric or orogastric tube is placed to decompress the stomach to minimize aspiration, and routine supportive management usually includes administration of intravenous fluids. Once clinically stable, surgical repair via laparotomy or laparoscopy is performed. Intraoperatively, it is important to exclude any associated malrotations, other small bowel atresia, or an annular pancreas. The long-term prognosis for duodenal atresia is very good, with survival rates of approximately 90%.

Meconium ileus/peritonitis [10,11]

Meconium ileus is impaction of abnormally thick meconium in the distal ileum. Meconium peritonitis occurs when there is perforation of bowel *in utero*, resulting in a sterile chemical peritonitis. Ultrasound features of meconium peritonitis include intra-abdominal calcifications, hyperechogenic bowel, ascites and bowel dilatation. Polyhydramnios may also be present. Serial ultrasound scans should be performed to assess progression of bowel dilatation, development of ascites or intra-abdominal cysts and polyhydramnios, which might indicate complicated meconium peritonitis with a 50% chance of requiring neonatal surgery. If these are present, consideration should be given to delivering the baby in a tertiary centre with neonatal surgical facilities.

Parental cystic fibrosis carrier testing and/or invasive fetal testing should be offered. If cystic fibrosis is diagnosed, appropriate genetic counselling should be offered and termination of pregnancy discussed if the diagnosis is made early in pregnancy. Long-term outcome depends on the underlying cause for the meconium peritonitis. In simple isolated meconium peritonitis the prognosis is usually excellent. In the simple form, thickened meconium begins to form *in utero*, and results in obstruction to the mid-ileum that causes proximal dilatation, bowel wall thickening, and congestion. In complicated cases, thickened meconium and obstruction lead to complications such as segmental volvulus, atresia, necrosis, perforation, meconium peritonitis (generalized) and giant meconium pseudocyst formation. In infants with cystic fibrosis the long-term outlook is guarded because of other extra-abdominal complications that can develop.

Abdominal wall defects

Omphalocele (exomphalos) [12,13]

This is a midline anterior abdominal wall defect of variable size characterized by the absence of abdominal muscles, fascia and skin. It can occur in the upper, mid or lower abdomen. A defect in cranial folding results in a high or epigastric omphalocele, classically seen in pentalogy of Cantrell (epigastric omphalocele, anterior diaphragmatic defect, sternal cleft and pericardial/cardiac defects). Lateral folding defects result in a mid-abdominal omphalocele and caudal defects cause a hypogastric omphalocele seen in bladder or cloacal exstrophy. The herniated viscera are covered by a membrane consisting of peritoneum on the inner surface, amnion on the outer surface and Wharton's jelly between the two layers. The umbilical cord inserts into the sac and not the body wall. It has an incidence of 1.5–3 per 10 000 births. Omphaloceles may be stratified into three groups: small, giant or ruptured. A giant omphalocele is often described as one with an abdominal wall defect of more than 5 cm or with more than 50–75% of the liver within the sac. The larger the defect, the higher the risk of postnatal complications, such as pulmonary hypoplasia and respiratory insufficiency and an increased prevalence of neurodevelopmental delay.

Most cases of omphalocele are sporadic and associated with advanced maternal age. It may occur in isolation or associated with aneuploidy (40%) or as part of a genetic syndrome. If aneuploidy is present, trisomy 18 is the most common chromosome abnormality. Smaller defects are more likely to be associated with chromosome abnormalities. Associated abnormalities are common (50–70%), with cardiac lesions predominating (30–40% of cases). Fetal mortality is strongly associated with the presence of additional structural malformations. The diagnosis can be made in the first trimester,

although most are detected at mid-trimester anomaly scan. Maternal serum α-fetoprotein is usually raised by an average of 4 multiples of the median.

Once the abnormality has been detected, the patient should be referred to a tertiary centre where there are facilities for detailed evaluation of the fetus. Karyotyping and fetal echocardiography should be performed. If macroglossia and other organomegaly are detected, Beckwith–Wiedemann syndrome should be suspected and the cytogenetics laboratory alerted to specifically look for abnormalities in the 11p15.5 region. Beckwith–Wiedemann syndrome is a growth disorder characterized by macroglossia, macrosomia, omphalocele, hypoglycaemia leading to seizures, visceromegaly, hemihyperplasia, renal abnormalities, ear creases and pits, nevus flammeus, and embryonic tumours (e.g. Wilms' tumour, hepatoblastoma, neuroblastoma and rhabdomyosarcoma). Omphalocele may also be part of the OEIS (omphalocele, bladder exstrophy, imperforate anus, spina bifida) complex.

Multidisciplinary counselling with paediatric surgeons, neonatologists, paediatric cardiologists and fetal medicine specialists should take place. The parents should be advised about increased incidence of fetal growth restriction, preterm labour and intrauterine death. Delivery should take place in a tertiary centre. Although vaginal delivery is reasonable and does not appear to influence outcome, elective caesarean section may also be an option in order that delivery takes place in a more controlled environment and timing of neonatal surgery can be better planned. Large omphaloceles are probably best delivered by caesarean section because of the possibility of trauma or soft tissue dystocia during a vaginal delivery.

The aim of surgery is to reduce the herniated viscera into the abdomen and to close the fascia and skin to create a solid abdominal wall with a relatively normal umbilicus. However, treatment can vary depending on the size and type of defect, the size of the baby, and any associated neonatal problems. Many surgeons prefer primary closure whenever possible. However, large defects with significant visceral herniation may require a more gradual or phased approach using silos to achieve reduction over a period of time before the abdominal wall is finally closed.

Gastroschisis [12–14]

This anomaly is believed to result secondary to an ischaemic insult to the developing abdominal wall. A full-thickness defect occurs secondary to incomplete closure of the lateral folds during the sixth week of gestation. The right paraumbilical area is usually affected. The incidence of gastroschisis is between 0.4 and 3 per 10 000 births and appears to be increasing. It has a strong association with young maternal age (<20 years), cigarette smoking, illicit drugs (cocaine), vasoactive over-the-counter drugs (such as pseudoephedrine) and environmental toxins. The diagnosis is usually obvious on ultrasound, often during the first-trimester (11–14 weeks) nuchal translucency scan, with free floating bowel or rarely the liver floating in the amniotic fluid without a covering membrane. Differential diagnoses include ruptured omphalocele sac or limb–body wall complex.

Associated anomalies occur in 10–20% of cases and most of these are in the gastrointestinal tract. It has been proposed that gastroschisis should be classified as simple (if isolated) or as complex (if associated with intestinal atresia, perforation, stenosis or volvulus). Chromosomal abnormalities or genetic syndromes are very rare. There is a slight increase in the incidence of cardiac abnormalities but this is not as high as seen in omphalocele. There is an increased incidence of preterm labour (30%), fetal growth restriction (70%), oligohydramnios (25%) and fetal death (5%). The cause of fetal growth failure is unclear but could be partially due to increased protein loss from the exposed viscera. The herniated bowel is at risk from volvulus and long-segment necrosis and/or more localized atretic and stenotic segments. Increasing bowel dilation, progressive oligohydramnios or decreased growth velocity may all be indicative of a fetus that is at increased risk of intrauterine death or greater neonatal complications. Early referral to a tertiary centre with multidisciplinary management is essential. Fetal echocardiography should be performed due to the increased association with cardiac anomalies. Serial scans should be performed to assess fetal growth and liquor volume, degree of bowel dilatation and bowel wall thickness. There is no contraindication for vaginal delivery but, as for omphalocele, elective caesarean section may also be an option to facilitate neonatal care. Bladder herniation and significant bowel dilatation may be risk factors for intrapartum fetal compromise (fetal distress) requiring operative delivery. Most centres now advocate delivery by 37 weeks given the increased risk of fetal demise after this gestation.

The ideal treatment of gastroschisis is immediate reduction of the herniated bowel back into the abdominal cavity and closure of the abdominal wall (primary reduction and repair). However, if reduction is likely to cause an abdominal compartment syndrome or significant respiratory difficulty, then staged repair is preferred. This involves applying a plastic silo around the bowel to progressively push the herniated viscera into the abdominal cavity over a number of days until definitive closure is possible. Overall survival is good (90–95%), with most deaths occurring in babies who have significant bowel loss, sepsis or long-term complications of short bowel syndrome. There is a 10% risk of hypoperistalsis syndrome, which may require longer hospitalization

and hyperalimentation. Gastrointestinal reflux occurs in 10% of cases and there is a 5–10% risk of obstruction due to adhesions in the longer term. A significant number of cases will also develop inguinal hernias due to increased intra-abdominal pressure post surgery. The risk of recurrence is small but exposure to vasoactive substances should be avoided in any subsequent pregnancy.

Genitourinary tract anomalies [15,16]

Congenital anomalies of the kidney and urinary tract account for one-third of all anomalies detected by routine fetal ultrasonography. In humans, fetal glomeruli develop by 8–9 weeks, tubular function commences after week 14 and nephrogenesis is largely complete by birth. After 20 weeks, the kidneys provide over 90% of the amniotic fluid. Any bilateral renal malformation can be associated with oligohydramnios/anhydramnios, lung hypoplasia, joint contractures and facial abnormalities collectively termed the Potter sequence.

Renal agenesis [17,18]

Unilateral renal agenesis has an incidence of 1 in 500–1000 births compared with bilateral renal agenesis, which occurs in 1 in 5000–10 000 births. Bilateral renal agenesis is not compatible with extrauterine life. It occurs more commonly in males and there is also an increased incidence in twins. Poorly controlled maternal diabetes or ingestion of renotoxic drugs are other aetiological factors. The diagnosis is usually made at the mid-trimester fetal anomaly scan. Although earlier diagnosis is sometimes possible, it is often difficult in the first trimester as the amniotic fluid volume is not significantly reduced at that stage. Anhydramnios is usually present by mid-trimester in bilateral renal agenesis. The liquor volume is usually normal in unilateral agenesis and the normal kidney can be larger due to compensatory hypertrophy.

There is an increased incidence of additional anomalies, particularly in the genital (blind vagina, uterine malformations, seminal vesicle cysts), cardiovascular and gastrointestinal systems in up to 44% of fetuses with renal agenesis. If the diagnosis of bilateral renal agenesis is made antenatally, the parents must be counselled about the dismal outcome and offered termination of pregnancy. Karyotyping and post-mortem is essential to help diagnose aneuploidy or a specific syndrome. Ultrasound of parental kidneys should be considered and genetic counselling offered. The risk of recurrence is low in unilateral renal agenesis (2–4%) but can be as high as 6–10% in bilateral cases.

Multicystic dysplastic kidney [19,20]

Unilateral multicystic dysplastic kidney (MCDK) has an incidence of 1 in 3000–5000 live births compared with 1 in 10 000 for bilateral dysplasia. It is one of the commonest causes of an abdominal mass in the neonatal period. The abnormal kidneys contain undifferentiated cells and metaplastic elements such as cartilage. On ultrasound, large hyperechogenic kidneys containing multiple cysts of varying sizes are present. Contralateral renal abnormalities can occur in 30–50% of cases. The prognosis for the fetus depends on whether there is unilateral or bilateral dysplasia. Bilateral MCDK is often lethal, with fetuses dying from pulmonary hypoplasia after birth. Termination of pregnancy should be offered in these cases.

No specific fetal intervention is required in cases of isolated unilateral MCDK. Serial ultrasound scans to monitor size of the abnormal kidney and liquor volume should be performed. Occasionally, gradual resorption (autonephrectomy) of the abnormal kidney can occur. Karyotyping should be offered to exclude aneuploidy. The mode of delivery is based on standard obstetric criteria. The prognosis is usually good. There is a small risk of long-term hypertension and malignant transformation in the dysplastic kidney. Children with a normal solitary functioning kidney, with evidence of compensatory hypertrophy, have a small risk of future renal insufficiency. In addition, there is an increased risk of hyperfiltration injury, which may be marked by hypertension and proteinuria that warrants long-term surveillance. Children with MCDK have a higher risk of vesico-ureteric reflux compared with the general population, particularly if there are contralateral renal abnormalities. There is also a risk of abnormalities of the internal genitalia for both males and females with MCDK.

Lower urinary tract obstruction [21]

In male fetuses, posterior urethral valves are the most common cause (90%) of bladder outlet obstruction. In female fetuses, urethral atresia accounts for the majority of cases. Less common causes of congenital lower urinary tract obstruction include anterior urethral valves/anterior urethral diverticulum, prune belly syndrome, urethral atresia, prolapsed ureterocoele, syringocoele, megalourethra, megacystis–microcolon–hypoperistalsis syndrome, obstruction by a hydrocolpos in females with cloacal anomalies, or rarely obstruction by a tumour such as a sacrococcygeal teratoma.

Oligohydramnios and a large thick-walled bladder with a keyhole sign and bilateral hydroureters and hydronephrosis are usually evident on ultrasound. The prognosis is worse (95% mortality) in those diagnosed antenatally when mid-trimester oligohydramnios is present. Features that suggest poor prognosis include dilatation of the upper tract, increased bladder wall thickness, oligohydramnios and evidence of renal dysplasia (echogenic renal cortex and cystic renal change), especially before 24 weeks. Obstruction can be complete or partial and the

amount of liquor volume usually gives some idea as to the severity of the obstruction. In complete obstruction anhydramnios rapidly develops. In addition, renal dysplasia can occur from an early gestation if the obstruction is severe. Karyotyping is important as aneuploidy is present in up to 10% of cases. Termination of pregnancy is an option, particularly if there is severe oligohydramnios/anhydramnios, the diagnosis is made early in pregnancy or if there is evidence of renal dysplasia on ultrasound.

Fetal therapy is possible and includes serial vesicocentesis, percutaneous vesico-amniotic shunting (VAS) or cystoscopy. The rationale for VAS is to decompress the urinary tract and therefore relieve the back-pressure on the fetal kidneys and to hopefully prevent the development of renal dysplasia. Shunting also allows restoration of flow of fetal urine into the amniotic cavity and thus prevents pulmonary hypoplasia. Compared with VAS, fetal cystoscopy for cases with posterior urethral valves appears to be more effective in improving both the 6-month survival rate and renal function, while VAS was only associated with improvement in the 6-month survival rate with no effect on renal function. Fetal cystoscopy is more invasive than VAS and carries a 10% urological fistula rate following fetal laser ablation of the bladder outlet obstruction. The risk of requiring dialysis and subsequent renal failure is approximately 30–50% in several series. To date, fetal intervention has not significantly changed the long-term renal outcome for affected individuals. Additional long-term problems include reflux, recurrent infections, bladder compliance and voiding issues and sexual function.

Head and neck anomalies

Cleft lip and palate [22–24]

The incidence of cleft lip and palate varies with ethnicity and geographical region but in a Caucasian population it is approximately 1 in 800–1000 for cleft lip and palate and 1 in 100 for cleft palate alone. Orofacial clefts can be classified as non-syndromic (isolated) or syndromic based on the presence of other congenital anomalies. Approximately 20–50% of all orofacial clefts are believed to be syndromic. The diagnosis is often made following the mid-trimester fetal anomaly scan. Fetal three-dimensional ultrasound and/or fetal MRI may help in determining the extent of palatal involvement. The aetiology of cleft lip/cleft palate is complex and multifactorial, involving both genetic and environmental factors. Many environmental factors are associated with orofacial clefting, including maternal alcohol consumption and cigarette smoking. Folate deficiency is also associated with cleft lip/cleft palate and prenatal folic acid supplementation has been shown to decrease this risk. Maternal corticosteroid use causes a threefold to fourfold increase in orofacial clefting. Anticonvulsants, including phenytoin and valproic acid, also cause cleft lip and palate. Phenytoin causes a nearly 10-fold increase in the incidence of facial clefting.

Associated anomalies include brain, cardiac and limb/spine deformities. There is a high risk of cerebral anomaly with midline clefts. Karyotyping should be offered in all cases. All patients should be referred to a multidisciplinary craniofacial team early following fetal diagnosis, where all aspects of the baby's management including feeding, surgery and cosmetic results can be discussed with parents. It is important to exclude any underlying syndrome after birth and genetic counselling for the risk of recurrence should be offered.

Cystic hygroma/lymphangioma [25,26]

Cystic hygroma is a rare congenital malformation of the lymphatic system and has an incidence of between 1 in 6000 and 1 in 16 000 births. Among aborted fetuses the incidence may be as high as 1 in 300. Approximately 75% occur in the neck, usually in the posterior triangle more commonly on the left side, and 20% occur in the axillary region. Chromosome abnormalities are present in almost 70% of cases, with Turner's syndrome and Down's syndrome particularly common. There is also an association with non-chromosomal conditions (Noonan's syndrome, multiple pterygium syndrome). Once detected, a careful search for additional abnormalities is vital. Karyotyping should always be offered. The presence of hydrops is a poor prognostic feature, with a perinatal mortality rate exceeding 80%. Fetal echocardiography should be performed. There is an increased incidence of preterm labour and polyhydramnios, particularly if the cystic hygroma impairs fetal swallowing. In very large lesions, obstruction of the pharynx and larynx may develop making intubation very difficult. The EXIT procedure (*ex-utero* intrapartum treatment) may be required before the umbilical cord is divided.

Skeletal system anomalies

Skeletal dysplasias are a heterogeneous group of genetic disorders characterized by differences in the size, shape and mineralization of the skeletal system that frequently result in disproportionate short stature. The diagnosis is usually made by clinical features, radiological criteria, family history and, increasingly, by genetic testing. It is estimated that 30–45 per 100 000 newborns have a skeletal dysplasia. Antenatal management depends on identifying the presence of a skeletal dysplasia and making an assessment of the lethality of the condition. Karyotyping should be offered, particularly in the presence of other abnormalities. DNA should be stored for future genetic testing. A precise diagnosis often needs to await postnatal or post-abortal radiology or molecular testing. Most cases of skeletal dysplasias are autosomal

recessive, for which genetic counselling is important. Others may be due to a new dominant mutation. Family history of skeletal dysplasia, malformations and short stature should be obtained. Termination of pregnancy is an option for most cases of skeletal dysplasias as many have a poor outcome. A narrow thorax or significant polyhydramnios in particular indicates a high chance of lethal pulmonary hypoplasia. Specific genetic mutations are known for some skeletal dysplasias – achondroplasia and thanatophoric dysplasia, *FGFR3* mutation; campomelic dysplasia, *SOX9* mutation; diastrophic dysplasia, *DTDST* mutation; and osteogenesis imperfecta, *COL1A* or *COL2A* mutation – and therefore prenatal diagnosis may be possible in selected cases.

Thoracic anomalies

Pulmonary development requires normal fetal breathing movements, an adequate intrathoracic space, sufficient amniotic fluid, normal intra-lung fluid volume and pulmonary blood flow. Maternal health, including nutrition, endocrine factors, smoking and disease, can also adversely influence fetal lung development. There are five stages of lung development: embryonic (0–7 weeks *in utero*), pseudoglandular (7–17 weeks *in utero*), canalicular (17–27 weeks *in utero*), saccular (28–36 weeks *in utero*) and alveolar (36 weeks *in utero* to 2 years postnatal).

Diaphragmatic hernia [27,28]

Congenital diaphragmatic hernia has an incidence of 1 in 3000–5000 births. It occurs more commonly on the left side (75–80%) than on the right side (20–25%). The combination of lung hypoplasia, lung immaturity and pulmonary hypertension and the presence of other malformations can result in high mortality for this condition. The degree of pulmonary hypoplasia depends entirely on the length of time and extent the herniated organs have compressed the fetal lungs. Associated abnormalities may be present in 30–60% of cases and can involve any organ system. Aneuploidy is present in 10–20% of cases and it may also be associated with some genetic syndromes (Fryn's syndrome, Beckwith–Wiedemann syndrome). Congenital diaphragmatic hernia should be suspected if the fetal stomach is not in its usual intra-abdominal position. Liver, mesentery and bowel and spleen may be present in the chest. Differential diagnoses include congenital cystic adenomatoid malformations, bronchogenic cysts, pulmonary sequestration or thoracic teratomas. Polyhydramnios and/or hydrops may sometimes be present. Increased liquor is usually due to impaired swallowing and hydrops may occur if there is significant cardiac compression. Liver herniation is a poor predictive factor for the development of pulmonary hypoplasia.

Management includes detailed assessment of the fetus for additional anomalies, karyotyping and fetal echocardiography. Fetal MRI or three-dimensional ultrasound can sometimes be considered to evaluate lung volume. Parents should be counselled by a paediatric surgeon regarding neonatal management. Termination of pregnancy is an option if significant visceral herniation (particularly liver) is present. The aim is to deliver at term. The mode of delivery is determined on standard obstetric criteria. However, it is essential that delivery takes place in a tertiary centre where the baby can be closely monitored to assess the degree of pulmonary compromise (hypoplasia and vascular hypertension) before surgery is undertaken. Prenatal intervention by fetoscopic endoluminal tracheal occlusion (FETO) is now an option, with the main objective of improving fetal lung growth. There is evidence that treatment *in utero* can increase postnatal survival for both left- and right-sided defects. However, prenatal treatment, only available in select fetal therapy centres, is associated with significant risk of preterm premature rupture of membranes and preterm birth.

Congenital pulmonary airway malformation [29–31]

Congenital pulmonary airway malformations (CPAMs), previously known as congenital cystic adenomatoid malformations, are rare developmental malformations of the lower respiratory tract. CPAMs account for 95% of congenital cystic lung abnormalities and are the most common cystic lung lesions diagnosed by prenatal screening. They are characterized by lack of normal alveoli and excessive proliferation and cystic dilatation of terminal respiratory bronchioles. The incidence of CPAM is between 1 in 11 000 and 1 in 35 000 live births and is slightly more common in males. They are usually unilateral (>85%) and usually involve only one lobe of the lung. Most (60%) are left-sided lesions. The diagnosis is usually made on antenatal ultrasound by the detection of enlarged hyperechogenic lungs sometimes containing cysts of varying sizes. Mediastinal shift, cardiac compression, polyhydramnios and hydrops may also be present. Between 45 and 85% of prenatally identified CPAMs will spontaneously regress. However, large macrocystic or solid lesions can cause hydrops, pulmonary hypoplasia, cardiac dysfunction and perinatal death. The majority of lesions follow a characteristic growth pattern that is highly dependent on gestational age. There is usually an increase in size between 17 and 26 weeks before possible regression after 30 weeks. Large lesions can cause pulmonary hypoplasia, impairment of fetal swallowing and polyhydramnios, cardiac compression and hydrops. Serial scans are essential to monitor the size of the lesion (particularly macrocystic CPAM), the development of cardiac compression and/or hydrops. Prenatal treatment options include the maternal administration of steroids, minimally

invasive procedures or, rarely, open fetal surgery. These interventions aim to alleviate the mass effect, prevent the progression of complications and improve the outcome for these fetuses. In selected macrocystic lesions, fetal therapy (either aspiration of the cyst or insertion of a shunt to drain the cyst) may be an option. Maternal steroid treatment has been reported to have a beneficial effect on large microcystic CPAMs. The mode and timing of delivery is on standard obstetric criteria. Postnatally, the baby will require careful monitoring and a chest X-ray. Surgery may be deferred for up to 24 months.

Pleural effusions [32,33]

Fetal pleural effusions have an incidence of between 1 in 10 000 and 1 in 15 000 pregnancies. Effusions may be primary (due to leak of chyle into the pleural cavity) or secondary (seen in hydrops). Complications include mediastinal shift, cardiac compression, hydrops and pulmonary hypoplasia. Affected fetuses are at significant risk for respiratory distress at birth. Once detected the patient should be referred to a fetal medicine unit for further investigations. The presence of other anomalies should be excluded. Fetal echocardiography should be performed as cardiac abnormalities are present in 5% of cases. Karyotyping should be offered as there is a significant association (10%) with aneuploidy. Maternal serology for infection should be performed. Serial scans should be arranged to assess the size of the effusion and for the development of hydrops or polyhydramnios as these are poor prognostic features. There are several treatment options. Firstly, a period of expectant observation is reasonable if the fetus is not hydropic and the effusion is small or moderate in size. Thoracocentesis or pleuro-amniotic shunting are other options. The risks associated with pleuro-amniotic shunting include miscarriage or preterm labour, rupture of membranes, blockage of the shunt and shunt migration. Survival after pleuro-amniotic shunting is approximately 80%.

Fetal tumours

Teratomas [34–36]

Teratomas are tumours that contain tissue from all three germinal layers (ectodermal, mesodermal and endodermal tissue). Most prenatally diagnosed teratomas are situated in the brain, oropharynx, sacrococcygeal region, mediastinum, abdomen and gonad. Teratomas are the most common perinatal tumour, comprising 37–52% of congenital neoplasms and having a yearly incidence of approximately 1 in 40 000 live births. The majority of teratomas occur in the sacrococcygeal region (60%), followed by the gonads (20%) and thoracoabdominal lesions (15%).

Sacrococcygeal teratomas are the most common neoplasm in the fetus and newborn, with an estimated prevalence of 1 in 30 000–40 000. There is a 3 : 1 female preponderance. The diagnosis is often made when a complex mass is detected at the base of the spine (sacrococcygeal region). It can be either predominantly solid and vascular or predominantly cystic with relatively little vascularity, or mixed with equal amounts of solid and cystic structures. Associated anomalies are present in 10–40% of cases. Arteriovenous shunting through the vascular component of the tumour can result in hydrops, polyhydramnios and high-output cardiac failure. Poor prognostic factors include large solid tumours (>10 cm), hydrops and polyhydramnios. Other complications include gastrointestinal or bladder outlet obstruction. Most sacrococcygeal teratomas are histologically benign, with malignancy more common in solid tumours and in males. Fetuses with large or rapidly growing tumours and polyhydramnios are more likely to experience a complicated outcome after birth.

Tumour dystocia, rupture and haemorrhage during delivery are the main causes of perinatal morbidity and mortality. Additionally, polyhydramnios can precipitate preterm delivery. Maternal complications including pre-eclampsia (mirror syndrome) can occur if there is significant placentomegaly and hydrops. Delivery should take place in a tertiary centre with facilities for immediate surgery. Elective caesarean section should be the mode of delivery, with particular care taken during delivery to avoid trauma to the tumour. Blood should be available in the delivery room in case of tumour haemorrhage. After birth, mortality due to haemorrhagic complications is relatively high and represents the leading cause of mortality in the neonatal period.

Fetal hydrops [37,38]

Hydrops is an end-stage process for a number of fetal diseases resulting in tissue oedema and/or fluid collection (ascites, pleural effusion, pericardial effusion) in various sites. Its aetiology may be either immune or non-immune depending on the presence or absence of red cell alloimmunization. Non-immune causes now account for more than 90% of all cases of hydrops. Congenital heart abnormalities, cardiac arrhythmias (supraventricular tachycardia, complete heart block), twin–twin transfusion syndrome, congenital anomalies, aneuploidy, infections, congenital anaemia and congenital chylothorax are all possible causes for hydrops. Regardless of aetiology, hydrops has a very poor outcome (>80% mortality). Early development of hydrops has a particularly poor prognosis. The mortality rate is highest among neonates with congenital anomalies (60%) and lowest

among neonates with congenital chylothorax (6%). Mortality is significantly higher in premature infants and those delivered in poor condition.

It is important to obtain a detailed family, medical, obstetric and genetic history. A history of prior exposure to possible viral infections (maternal rash, arthralgia/myalgia) is especially important. Detailed ultrasound to detect structural abnormalities, particularly cardiac and thoracic abnormalities, should be performed. The umbilical cord and placenta should be carefully examined to exclude vascular malformations. The fetal heart rate and rhythm should be examined to exclude fetal tachyarrhythmias or bradyarrhythmias. Maternal blood should be taken for full infection screen (CMV, parvovirus, rubella, herpes), *Toxoplasma* serology, blood group and antibody screen, and haemoglobin electrophoresis. Fetal anaemia should be excluded by middle cerebral artery peak systolic velocity monitoring. Fetal echocardiography should be performed in all cases. If anaemia is suspected the most likely cause is parvovirus infection. This is a treatable condition with usually a single fetal transfusion. Karyotyping is mandatory in all cases. Samples should be sent for cytogenetics and infection screen using PCR. If hydrops is secondary to fetal arrhythmia, maternal antiarrhythmic therapy may be of benefit. There is usually a delay in response because of the slow transplacental transfer into the fetal circulation. Occasionally, direct fetal treatment may be required in cases of fetal supraventricular tachycardia unresponsive to maternal treatment. If the hydrops is secondary to a structural anomaly (e.g. pleural effusion), *in utero* therapy (pleuro-amniotic shunting) may be necessary. Termination of pregnancy should be offered if hydrops is severe or if major malformations or aneuploidy are present. Parents should be counselled that untreated hydrops carries a very high (>80%) perinatal mortality rate and that outcome is likely to be poor.

Conclusions

When a fetal structural anomaly is identified, regardless of gestation, there are several key issues that must be considered. Firstly, it is crucial to remember that to the pregnant woman the detection of any anomaly is a source of great anxiety and stress. Women should receive information regarding the abnormal ultrasound findings in a clear, sympathetic and timely fashion, and in a supportive environment that ensures privacy. Whenever appropriate, referral to a tertiary fetal medicine unit should be made. A full and frank discussion with a senior obstetrician or fetal medicine specialist is important for explaining the diagnosis and further management of the pregnancy. Further testing (amniocentesis, chorionic villous sampling or fetal blood sampling) may be required. More complex imaging with fetal MRI may sometimes help delineate anatomy (particularly for CNS anomalies). Additional counselling by a genetic counsellor or geneticist may be necessary. Counselling should always be unbiased and respectful of the patient's choice, culture, religion and beliefs.

In many cases serial scans will be necessary to assess evolution of the abnormality and to attempt to detect other anomalies not previously identified, as this may influence counselling as well as the obstetric or neonatal management. In some cases parental imaging and testing may be required. Referral to an appropriate paediatric or surgical specialist should be considered to enable the woman to receive the most accurate information possible concerning the anomaly and the associated prognosis. It may be important to stress that, not infrequently, both major and minor structural anomalies, whether isolated or multiple, may sometimes be part of a genetic syndrome (despite a normal fetal karyotype) and that long-term prognosis will depend on the final diagnosis. Critically, it is important to stress that antenatal ultrasound is geared towards evaluating anatomy rather than function and that sometimes normal anatomy does not always correlate with normal function and vice versa.

Although fetal therapy is possible for some conditions, it is generally not an option for the majority of fetal structural anomalies. If early or urgent postnatal management is required, delivery at a centre that can provide the appropriate neonatal care should be considered. In cases of termination of pregnancy, stillbirth or neonatal death, the health professional should encourage the performance of a complete post-mortem by a perinatal pathologist to provide maximum information about the fetal anomaly. When a complete post-mortem is refused, at least a partial or external post-mortem (including X-rays and photographs) should be considered.

Summary box 20.2

- When an abnormality is detected consider further investigations, including karyotyping with microarray, parental testing, fetal MRI and fetal echocardiography.
- Counselling should be non-directive, sympathetic and wherever possible should include a paediatric specialist.
- For some conditions termination of pregnancy is an option but it must be broached sensitively.
- The importance of a post-mortem should be explained to parents.
- When appropriate, genetic input should be arranged.
- Pre-pregnancy counselling may be helpful for some parents.

Multiple Pregnancy

Mark D. Kilby[1] and Dick Oepkes[2]

[1] *Centre for Women's and Newborn Health, Institute of Metabolism and Systems Research, College of Medical and Dental Sciences, University of Birmingham, Birmingham, UK*
[2] *Department of Obstetrics, Leiden University Medical Centre, Leiden, The Netherlands*

Multiple pregnancy has a global impact on both maternal and perinatal risk in any pregnancy and impacts on society in terms of both social and economic effects. Improvements in the health of the population, and in particular perinatal care, have led to a reduction in overall total pregnancy complications (both maternal and perinatal). However, the proportion of these attributed to twins and higher-order pregnancies is increasing and of significant importance. Almost every maternal and obstetric problem occurs more frequently in a multiple pregnancy and there are, in addition, a number of potential intrapartum considerations that complicate routine management. The modern management of a multiple pregnancy initially concentrates on the recognition of fetal risk, as mediated primarily by chorionicity, and then the monitoring of fetal growth and well-being using ultrasound. Attempts to reduce the risks of preterm delivery and pre-eclampsia in the mother are equally important and equally as frustrating (as in singleton pregnancy care), with little improvement in overall management of these conditions in the last 20 years. Recognizing the specialized nature of multiple pregnancy management has led to the publication of recommendations by two scientific study groups of the Royal College of Obstetricians and Gynaecologists (RCOG) [1,2] and the commissioning of recommendations of care for multiple pregnancies by the National Institute of Health and Care Excellence (NICE) in 2009 (and published in 2011) [3]. At the heart of care is the recommendation that such pregnancies are managed within specialist multidisciplinary teams and in designated multiple pregnancy clinics so as to organize antenatal, intrapartum and indeed postnatal care.

Incidence

The considerable geographical and temporal variation in the incidence of multiple pregnancy reflects factors including dizygotic twinning as the result of multiple ovulation [4]. The incidence of twinning ranges from 4 per 1000 births in Japan to as frequent as 54 per 1000 in some regions of Nigeria. In addition, this 'complication' is more prevalent in pregnancies with advancing maternal age (presumed to be secondary to the rise in follicle-stimulating hormone concentrations). Familial predisposition to multiple ovulations (usually dizygous twinning) may occur and is presently best explained by an autosomal dominant inheritance pattern. In contrast, monozygous twinning, the result of early cleavage division of a single blastocyst, occurs with a relatively constant incidence of approximately 3.9 per 1000.

Time trends in multiple pregnancy demonstrate a remarkable change in reproductive behaviour and consequence. Some of the first documented records from Scandinavia in the eighteenth century indicate that multiple pregnancy rates may have been higher than they are today, reaching a zenith of 17 per 1000 maternities [5]. However, during the twentieth century, twin pregnancy rates appeared to be in decline until the early 1970s, since when there has been a clear rise in prevalence [6]. Since the early 1980s, the twinning rate in the UK has risen from 9.8 to 13.6 and the triplet rate from 0.14 to 0.44 per 1000 maternities. Such an increase is reflected internationally, with the greatest rise being noted in the USA. Multiple pregnancies accounted for 1.6% of all births in the UK during 2007, with approximately 98% of these being twin births [6]. A considerable proportion of the

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

increase is due to assisted reproductive technologies, such as superovulation (using antioestrogens or gonadotrophins) and *in vitro* fertilization (IVF) with embryo transfer. There is evidence that the number of multiple pregnancies is influenced by the number of embryo transfers and, as such, the number of multiple pregnancies associated with IVF has reduced since the recommendation that embryo transfer numbers be reduced. In addition, epidemiological evidence suggests that both types of assisted reproduction techniques increase the incidence of monozygous twinning by up to eightfold [7]. This is particularly associated with the techniques of 'blastocyst hatching'. Monochorionic twins comprise 20% of spontaneous and 5% of iatrogenic twin gestations. This is important as monochorionic twins have the greatest pregnancy-related complication rates.

However, it is also important to recognize other influences. The association between increasing maternal age (strongest at 30–39 years) and spontaneous dizygous twinning is worthy of note. The combined effects of delayed childbearing and high uptakes of assisted reproductive technologies at advanced maternal age have been responsible for this rise [6].

Perinatal loss

Cumulative fetal loss rate in twins is up to five times higher (and in triplets 10 times higher) than in corresponding singleton pregnancies. Rates of stillbirth and neonatal mortality for a multiple pregnancy are 14.9 and 19.8 per 1000 live births, respectively. This high perinatal fetal loss and morbidity is largely attributed to the increased risk of prematurity and also intrauterine growth restriction (IUGR) with associated iatrogenic prematurity (irrespective of chorionicity, see following section).

Cerebral palsy is approximately three times more common in twins and 10 times more common in triplets compared with singletons. These figures are per fetus, whereas the more relevant figure when counselling parents is the chance of their multiple pregnancies producing any one baby with these complications.

Chorionicity and zygosity

Approximately two-thirds of twins are dizygous and one-third monozygous. However, it is chorionicity rather than zygosity that mediates the degree of perinatal risk in any individual multiple pregnancy. This is most important as it is clinically identifiable. Cumulative fetal loss rates and perinatal mortality are up to five times higher in monochorionic twins compared with dichorionic twins [8]. This study, and a more contemporary one (during a period when modern management was possible including more widespread recognition of feto-fetal transfusion syndrome and its fetoscopically directed treatment [9]), noted that in monochorionic diamniotic twin pregnancies, 85% resulted in double survivors, 7.5% in a single survivor and 7.5% in no surviving baby. These deaths occurred spontaneously or iatrogenically. Perinatal morbidity appears similarly related, with prenatally acquired cerebral lesions evident in the early neonatal period on ultrasound in up to one-third of monochorionic twins compared with 3% of dichorionic twins delivered preterm [10]. Such excess morbidity and mortality is mediated predominantly (but not exclusively) through the inter-twin placental vascular anastomoses that connect the two fetal circulations.

Monozygotic pregnancies assume one of three placental configurations. Division within 3 days of fertilization results in separate dichorionic placentas, which in up to 50% of cases may have the appearance on ultrasound of being adjacent to each other and 'fused'. Splitting after formation of the inner cell mass at 4 days after fertilization results in a single monochorionic diamniotic placenta, whereas splitting after 7 days results in monochorionic monoamniotic twins. Approximately one in five of all twins are monochorionic.

Ultrasonic determination of chorionicity

Chorionicity may be clinically determined during pregnancy using ultrasound, with up to 90–100% accuracy in the first trimester. Ultrasound allows the following features to be ascertained.

- Determination of the number of constituent layers of the dividing membranes (and therefore of membrane thickness).
- Qualitative interpretation of the membrane as 'thick' (dichorionic) or 'thin' (monochorionic) appears as accurate as inter-twin membrane/septal measurement.
- Demonstration of a tongue of placental tissue within the base of the inter-twin membrane, known as the 'twin peak' sign, is diagnostic of a dichorionic pregnancy. In contrast, a thin septum with a single placental mass is suggestive of monochorionicity.
- Presence (or not) of a single placental mass.

Chorionicity should be determined on ultrasound in all multiple pregnancies, as a screening test, ideally within the first trimester between 11 and 14 weeks of gestation (when specificity and sensitivity are greatest). Digital or hardcopy images should be stored demonstrating the signs of chorionicity. This is because chorionicity is relevant to:

- counselling parents in relation to the risk of perinatal morbidity and mortality;

- counselling parents in relation to their risk of genetic and structural abnormalities;
- invasive testing and the management of discordant congenital anomaly;
- feasibility of multiple fetal pregnancy reduction;
- risk of complications that may occur in a multiple pregnancy and potential sequelae that may ensue;
- early detection and management of feto-fetal transfusion syndrome.

Such an examination should be routine and allow the stratification of prospective pregnancy care. In addition, ultrasonic visualization of the inter-twin membrane/septum and genitalia may be difficult later on in pregnancy or when there is significant oligohydramnios complicating the pregnancy. The first ultrasound allocation of chorionicity should be performed in the first trimester between 11 and 14 weeks at a time when increasing numbers of pregnancies are undergoing nuchal translucency screening [11]. Ultrasonic sexing is performed for medical rather than social reasons in multiple pregnancies and, as such, achieves a high degree of accuracy, usually between 16 and 20 weeks.

Zygosity determination

Monochorionic twins by definition are monozygotic, while discordant-sex twins are dizygous. In the remaining 50%, zygosity cannot be determined without DNA fingerprinting, such as the polymerase chain reaction technique that compares parental inheritance patterns of a number of dinucleotide and trinucleotide short tandem repeats which are highly polymorphic in copy number. Such determination is rarely performed prospectively in clinical practice. Just as placental chorionicity is rechecked at birth (usually by clinical or histopathological examination), cord blood zygosity studies may be offered to parents of twins where there is indeterminate zygosity. Not only are parents curious but knowledge of zygosity influences the twins' rearing, their sense of identity, their genetic risks and their transplantation compatibility. However, it is not routine to offer this in current practice within the NHS in the UK. Rarely there may be indications for zygosity testing *in utero* on invasive collection of fetal tissue, such as excluding contamination, deducing genetic risk or demonstrating dichorionicity in the presence of fetal compromise.

Miscarriage

Twins have a high incidence of spontaneous early pregnancy loss. Estimates suggest that approximately 12% of human conceptions start as twins [12]. Studies of ultrasound or miscarriage pathology indicate that twins are found at least twice as commonly in the first trimester as at birth. First-trimester early pregnancy loss and resorption of one previously indefinable twin on ultrasound is known as the 'vanishing twin' phenomenon and is estimated to occur in up to 20% of twin pregnancies [13]. Spontaneous first-trimester loss of one or more fetuses in high-order pregnancies is estimated to occur approximately 50% of the time. When one twin dies *in utero* in mid-trimester, a papyraceous fetus (the squashed paper-like remains of the baby) may be found alongside the placenta after delivery. In some cases, this is only identifiable histopathologically.

Prenatal diagnosis

The widespread use of ultrasound in the first trimester and for routine mid-trimester anomaly scanning to detect structural congenital malformations and Down's syndrome is relevant to all multiple pregnancies. Zygosity determines the risk of congenital abnormality and chorionicity what can be done if it is found to be present.

Zygosity may be deduced definitively in cases of monochorionicity or discordant external genitalia (dizygous), while in dichorionic concordant-sex twins the chance of dizygosity is 75–80%. Monozygous twins have a 50% increase in structural abnormalities per baby. In particular, they have twice the frequency of congenital heart disease (a fourfold increase per pregnancy). Women with dizygous twins can be counselled that the chance of their pregnancy producing a child with Down's syndrome is theoretically double their age-related risk, whereas women with monozygous twins simply have their age-related risk that both twins will be aneuploid. Serum screening is, in general, inapplicable to multiple pregnancies. In contrast, nuchal translucency and first-trimester ultrasound scanning as a fetal-specific screening test is readily applicable and recommended by the National Screening Committee in the UK. At 18–24 weeks, women with multiple pregnancies should be offered a mid-trimester fetal anomaly scan (which includes visualization of the four chambers of the heart and the great vessel outflow tracts) irrespective of chorionicity (as in singleton pregnancies). In countries with a gestational age limit for termination of pregnancy of 24 weeks, the anomaly scan should preferably take place before 22 weeks. In addition, in the first trimester between 11 and 13^{+6} weeks, all women with multiple pregnancies should be offered nuchal translucency screening for the detection of chromosomal anomalies (as well as the formal documentation of chorionicity). In dichorionic twins, the risk of aneuploidy is that of each of the individual fetuses. In monochorionic twin

pregnancies, the risk of aneuploidy is the average between the twins. The use of first-trimester serum screening as an adjunct to nuchal translucency, taking chorionicity into account, may slightly improve detection rates for Down's syndrome in twins, but the results of large prospective studies are awaited [14].

Screening for Down's syndrome using a maternal plasma sample to perform cell-free DNA sequencing, also known as non-invasive prenatal testing (NIPT), in monochorionic twins should be equally reliable as in singletons. However, reliable scientific data are still lacking. NIPT in dichorionic twins has been studied in small series, and appears promising, although with a higher failure rate and lower accuracy compared with singletons [15].

Invasive procedures

Invasive procedures in twins and other higher-order multiple pregnancies are potentially complex techniques and should only be performed in fetal medicine referral centres [15]. The *in utero* topography (placental and membranes) is mapped using ultrasound. The location of the fetuses, the placental site(s) and the plane of the dividing septum in three dimensions should be noted and recorded. Such is a prerequisite for interpretation of discordant results and for selective termination of pregnancy. The operator performing the diagnostic procedure should also undertake any selective termination so as to minimize uncertainty and obviate any need for confirmatory invasive testing.

In monochorionic twins, it is acceptable practice to sample only one fetus by either amniocentesis or chorionic villous sampling (CVS). However, rare cases of heterokaryotypic monochorionic twins may be missed (occurring in <1%). For this reason, amniocentesis on both amniotic sacs is worthy of consideration if monochorionic twins are discordant for structural anomalies, nuchal translucencies or growth.

In dichorionic twins, there has been controversy about whether CVS is less desirable than amniocentesis for performing karyotyping. Because of problems with contamination, some investigators suggest restricting CVS to high-risk cases such as monogenic disease or where there is an aneuploidy risk of greater than 1 in 50. The risk of contamination is likely to be higher than the published figures (2%) since the literature is confined to discordant-sex twins. Any benefits of CVS are outweighed by the potentially disastrous consequences of misdiagnosis due to contamination, with subsequent termination of a diploid fetus or the wrongful birth of a fetus with a chromosome abnormality. For these reasons, the RCOG guidelines [15] discuss potential advantages to amniocentesis as the preferred option for karyotyping in dichorionic twins. Such a decision has to be weighed against the increased risks of selective reduction at increased gestational ages. When performing fetal blood sampling, the intrahepatic vein may be sampled to avoid confusing the cord origins in twins.

There are no randomized controlled trials to indicate procedure-related loss rates in twins. However, background loss rates are appreciably higher. A recent systematic review of the literature relating to the risks of CVS and amniocentesis in twin pregnancies was published in 2012. This study noted that for CVS, nine studies fulfilled the inclusion criteria. The overall pregnancy-loss rate was 3.84% (95% CI 2.48–5.47; $N = 4$). The rate of pregnancy loss before 20 weeks was 2.75% (95% CI 1.28–4.75; $N = 3$) and before 28 weeks was 3.44% (95% CI 1.67–5.81; $N = 3$). For amniocentesis, the overall pregnancy-loss rate was 3.07% (95% CI 1.83–4.61; $N = 4$). The rate of pregnancy loss before 20 weeks was 2.25% (95% CI 1.23–3.57; $N = 2$), before 24 weeks was 2.54% (95% CI 1.43–3.96; $N = 9$) and before 28 weeks was 1.70% (95% CI 0.37–3.97; $N = 5$). Pooled data from four case–control studies showed a higher risk (2.59% vs. 1.53%) of pregnancy loss before 24 weeks following amniocentesis (relative risk, RR 1.81; 95% CI 1.02–3.19) [16].

In dichorionic twins discordant for fetal anomaly, selective termination of pregnancy by the induction of asystole using an abortifacient is associated with an 8% loss rate in the international registry, with lower rates if the procedure is performed before 16 weeks' gestation [17]. Selective termination of monochorionic twins cannot be performed using injection of an abortifacient as this would lead to death of the healthy twin due to sharing of the circulation along vascular anastomoses. However, a variety of cord occlusion techniques has been developed to render selective termination feasible. However, evidence shows that there is an associated increased risk of co-twin demise and co-twin morbidity when these procedures are performed [18]. Survival rates of the co-twin vary between 70 and 80% in reported single-centre series.

Maternal homeostatic responses

All the normal physiological adaptations, such as increased cardiac output, glomerular filtration rate and renal blood flow, are further increased in a multiple pregnancy. Women with twins increase their plasma volume by one-third more than women with singletons. Red cell mass increases approximately 300 mL more than in singleton pregnancies but because this is disproportionately less than the increase in plasma volume, haemoglobin and haematocrit values fall. Maternal iron stores are diminished in 40% of women with twins so

routine haematinic supplementation is recommended (usually as combined iron sulfate and folic acid supplementation).

Hyperemesis gravidarum is more common in multiple pregnancies and is managed as in singleton pregnancies. Severe cases may respond to maternal steroid therapy and require pyroxidine (B_6) supplementation. The majority of minor pregnancy complications such as backache, symphysis pubis dysfunction, oedema, varicose veins, haemorrhoids and stria are all increased as a result of both the physical effects of greater uterine size and greater placental hormone production [19].

Hypertensive disease of pregnancy and pre-eclampsia are up to 10 times more common in multiple compared with singleton pregnancies but are managed once diagnosed on standard principles (as in singletons). Consideration should be given to low-dose aspirin prophylaxis but there are no national/international recommendations to this effect. Maternal pregnancy-related hypertension remains a significant cause of maternal morbidity (and mortality) in multiple pregnancies and a significant cause of iatrogenic preterm delivery, increasing perinatal morbidity and mortality. This occurs in 15–20% of twin pregnancies, 25% of triplets and up to 60% of higher-order multiple pregnancies [20].

Postnatally, the physical difficulties and socioeconomic impact of coping with the demands of two or more babies are considerable. Postnatal depression is more common in women nursing twins than singletons [21]. With the high perinatal loss rates there are often associated problems of postnatal grieving and bereavement. Families of women who give birth to babies after a multiple pregnancy may require additional social support.

Intrauterine growth restriction

Ultrasound is the primary tool for monitoring growth in multiple pregnancies for several reasons. The risk of IUGR (~25%) is higher than in singleton pregnancy, and in two-thirds of cases growth will be discordant (affecting one twin only). In addition, abdominal palpation and symphysis–fundal height measurement are unreliable as indices of growth in individual fetuses as they reflect total intrauterine growth.

There is no proven agreement on the ideal frequency of ultrasound examination. However, it is common policy to scan dichorionic twins at up to 4-weekly intervals from 24 weeks' gestation with or without Doppler measurements as indicated. Monochorionic twins are often scanned more frequently, at 2-weekly intervals, from 16 weeks onwards, as recommended by the International Society of Ultrasound in Obstetrics and Gynecology (ISUOG) practice guideline. At this gestational age, there is significant overlap in diagnosis between early twin–twin transfusion syndrome and selective IUGR. There is controversy as to whether singleton or twin biometric charts should be used. The former appears more sensible, as twins have a higher risk of IUGR with potential morbidity and the use of twin charts thus seems akin to using separate charts for other high-risk groups. Furthermore, increasing emphasis is placed on growth profile and fetal condition (i.e. liquor volume estimation and umbilical artery Doppler velocimetry). Many centres use the measurement of discordancy in estimated fetal weight (EFW, which can be estimated using varied ultrasound parameters) as an index of discordant IUGR:

$$\mathrm{EFW} = 100 \times \left(\mathrm{EFW}_{\mathrm{larger}} - \mathrm{EFW}_{\mathrm{Smaller}}\right) \Big/ \mathrm{EFW}_{\mathrm{larger}}$$

This parameter has some predictive value in monochorionic twins for bad outcome in feto-fetal transfusion syndrome and stillbirth [22], but in dichorionic twins it is a relatively poor predictor of perinatal death [23].

The standard principle of management of IUGR (i.e. delivery when the risks of continued intrauterine life outweigh those of extrauterine existence) needs modification in twin pregnancy to account for the risks to both twins. The latency between absent end-diastolic flow velocity in IUGR in twins is longer before 'pre-terminal' factors precipitate delivery than in singleton pregnancies. In addition, this latency is longest in monochorionic twins. However, careful and specialist surveillance of such pregnancies using cerebral, peripheral and intracardiac arterial and venous Doppler velocimetry is required. For example, cessation of fetal growth with pre-terminal arterial and venous Doppler studies may warrant delivery at 26 weeks in a singleton fetus. However, discordant IUGR at such an early gestation in dichorionic twins might better be managed by allowing the severely affected IUGR fetus to die *in utero*, sparing the healthy fetus the risks of iatrogenic prematurity. Such risks and the balancing of decision-making are always difficult and should be individualized. Decisions should be made in concert with parents and multidisciplinary teams (including neonatologists).

In monochorionic twins, such decisions are even more complex. There is some evidence that the presence or absence of umbilical artery Doppler flow during diastole is indicative of prognosis. Positive end-diastolic velocities indicate the best prognostic group when there is significant discordancy between monochorionic twins in terms of growth. Absent end-diastolic velocity indicates an intermediate risk group and so-called intermittent absent end-diastolic velocity indicates the worst prognostic group and, in particular, the worst outcomes in terms of perinatal morbidity [24]. Indeed, in

monochorionic twin pregnancies complicated by IUGR in one fetus, there is evidence that the 'larger' twin may have the highest morbidity in terms of neurodevelopmental sequelae. In some cases (of early onset) it may be necessary to consider selective cord occlusion rather than delivery of the whole pregnancy (depending on the gestational age of diagnosis). However, these again are difficult decisions evoking clinical complexity and parental anxieties. Management in a tertiary centre is therefore vital and individual discussions relating to procedure-related morbidity and mortality are essential.

Preterm labour

Multiple pregnancies contribute disproportionately to preterm deliveries. Recent data indicate that, overall, 52.2% of multiple births deliver before 37 weeks and 10.7% prior to 32 weeks [25]. This is the major cause of neonatal death in multiple pregnancies: mortality rates are up to seven times higher in twins than singleton pregnancies; in triplets and higher-order pregnancies, rates of nearly 40 per 1000 live births have been recorded [26]. The median gestational ages at delivery in twins and triplets is 37 and 34 weeks, respectively. However, the proportion of these pregnancies delivering before 30 weeks (twins 7%, triplets 15%) is much more concerning because of the associated long-term morbidity. Parents should be informed of the symptoms and signs of threatened preterm labour and the advisability of early presentation. The stimulus to this increased risk is not clearly defined. Certainly (as in polyhydramnios) there is increased uterine distension (i.e. stretch), which may influence autocrine and paracrine intramyometrial processes. There is also focus on the potential maternal–fetal endocrine interaction, which may predispose to this increased risk.

There is little evidence that the screening techniques available are highly predictive of preterm delivery (although some demonstrate promise); however, more reliable identification of twin pregnancies at risk of preterm birth may improve outcome if effective interventions are used. Management of preterm labour in multiple pregnancies differs little from that of singletons, except that the consequences of prematurity affect a greater number of babies. The following discussion concentrates on those aspects which appertain especially to multiple pregnancies.

Prediction

The prediction of preterm labour in twins and multiple pregnancies is as problematic as it is in singletons. One of the most promising methods of prediction of spontaneous labour in twins is the measurement of maternal cervical length using transvaginal ultrasound. A systematic review of 11 studies in the published literature (1436 pregnancies) has indicated the potential efficacy of cervical length in predicting risk of spontaneous preterm delivery in twins. Between 23 and 24 weeks' gestation, the mean maternal cervical length is similar to that of singleton pregnancies (38 mm). At this gestation, a cervical length of 25 mm or less will have a positive summary likelihood ratio of 5.02 (95% CI 3.21–7.61) and a negative summary likelihood ratio of 0.75 (95% CI 0.54–106) for delivery prior to 34 weeks. This correlates with a change from pretest probability of preterm birth of 18.5% to a post-test probability of 14.2% (12.9–15.9) with a negative test and 47.6% (38.9–56.4) with a positive test [27].

The use of home uterine activity monitoring or fetal fibronectin estimation [28] has not been demonstrated conclusively to be useful in prediction and therefore cannot be advocated.

Prevention

Preterm labour in a multiple pregnancy (as in polyhydramnios) is attributed to over-distension ('stretch') of the uterus. Accordingly, there is no specific preventive measure (aside from fetal reduction in higher-order multiple pregnancies as discussed below).

Although hospitalization for bed rest has been widely practised in the past, there is little evidence to support its use. Critical appraisal of the literature and meta-analysis of four randomized controlled trials indicate that bed rest in twins significantly increases the chances of preterm delivery, with a trend to greater perinatal mortality [29]. In contrast, a single randomized controlled trial in triplets demonstrated a non-significant trend to less premature delivery and fewer neonatal deaths but was based on a very small number of cases [30].

Meta-analysis of seven randomized controlled trials demonstrated that prophylactic β_2-sympathomimetic therapy was of no benefit in preventing preterm labour in twin pregnancies [31]. This was not surprising given its lack of efficacy in singleton pregnancies and is presumably due to tachyphylaxis. As in singleton pregnancies, this therapy is no longer used. In addition, cervical cerclage, and most recently vaginal progesterone therapy, has not been shown to be helpful and indeed may actually be harmful [32]. Indeed, an individual patient-level meta-analysis of randomized trials of cervical cerclage in women with a 'short' cervix (on ultrasound at 20–23 weeks) indicated an increased risk of preterm delivery prior to 35 weeks [33].

Most contemporary focus has fallen on the role of maternal administration of progesterone in potentially

reducing the risk of preterm delivery. The Study Of Progesterone for the Prevention of Preterm Birth In Twins (STOPPIT) was a randomized, double-blind, controlled trial to assess the role of daily vaginal progesterone (90 mg) for 10 weeks from 24 weeks' gestation [32]. This study indicated that progesterone did not reduce the composite outcome risk of delivery or intrauterine death before 34 weeks in women with twin pregnancy. This effect was independent of chorionicity (although there was a trend towards worsening of outcome in monochorionic twins). Such findings are in concordance with other studies demonstrating no efficacy [34,35], in which progesterone was administered as intramuscular 17-hydroxyprogesterone caproate (250 mg). Despite these findings, individual patient data analysis has indicated that vaginal progesterone may be effective in the reduction of adverse perinatal outcome in women with a cervical length of 25 mm or less; however, further research is warranted to confirm this finding [36].

Recently, there has been interest as to whether physical interventions, such as the fitting of an Arabin cervical pessary, reduces the risk of preterm birth in twin pregnancies with a short cervix (<25 mm). A recent study, performed under the collaborative umbrella of the Fetal Medicine Foundation found no significant improvement in the risks of preterm birth in the intervention group (compared to the conservative group).

As such, there is no evidence that prophylactic measures, either physical or pharmacological, prevent spontaneous preterm labour in multiple pregnancies.

Management

The use of β_2-sympathomimetic infusions in multiple pregnancy, along with steroids and fluid overload, are known risk factors for the rare but potentially fatal complication of pulmonary oedema. As in singleton pregnancies, such active tocolysis has all but been abandoned. Equally, tocolysis with maternally administered oral nifedipine or intravenous atosiban (an oxytocin receptor antagonist) only leads to a relatively modest prolongation of gestation and studies informing efficacy of use in multiple pregnancies are sparse. Certainly, as in singleton pregnancies, the use of such therapy is usually only advocated to allow prophylaxis with corticosteroids. This is exemplified in a retrospective cohort study of 432 twin pregnancies (1982–1986), which noted that 54% of twins were born after spontaneous preterm delivery; of these, 23% were associated with preterm premature rupture of membranes and a further 23% were iatrogenic [37]. In these iatrogenic indications, 44% were secondary to maternal hypertension, 33% secondary to fetal compromise and/or IUGR, 9% secondary to antepartum haemorrhage and 7% associated with one or more fetal deaths.

Maternal glucocorticoids have been clearly demonstrated to reduce the incidence of respiratory distress syndrome and its perinatal consequences in numerous randomized controlled trials [38]. However, only one uncontrolled study with separate data from multiple pregnancies suggested reduced benefits from antenatal corticosteroid administration in multiple pregnancies compared with singleton pregnancies [39]. The relative 'resistance' of multiple pregnancies to pulmonary surfactant maturation compared with singleton pregnancies has been postulated and has raised the possibility that a larger dose is required in multiple pregnancies but this remains to be objectively tested [40].

A report by Holmes *et al.* [41] has indicated that among 18% of 325 twin pregnancies delivering before 34 weeks' gestation, 70% did so within 24 hours of presentation, the usual interval required for maximal corticosteroid efficacy. It has therefore been proposed that corticosteroids be administered prophylactically. Such a proposal is controversial. It is certainly theoretically possible that this could do more harm than good, as such therapy would potentially need to be administered on a weekly basis and there is no evidence that repeat doses of steroids are of increased value. Furthermore, and not withstanding the safety of steroids in follow-up studies, there remain concerns about the potential adverse fetal effects of repeated steroid courses on glial formation and hippocampal development in children exposed *in utero*.

Complications of monochorionic twinning

Monochorionic twinning, which complicates 20% of all twin pregnancies, may be said to be a congenital anomaly of the placenta where the inter-twin circulations communicate through placental vascular anastomoses. These occur in almost all monochorionic twin pregnancies. Bidirectional superficial arterial–arterial or venous–venous anastomoses may potentially compensate for any haemodynamic imbalance created by deep unidirectional arterial–venous anastomoses. Relatively small inter-twin 'transfusions' are thus likely to be a normal physiological event in monochorionic twins. However, the imbalance of flow between twins may well be pathological and is always a potential risk in such pregnancies (increasing perinatal mortality considerably).

Acute feto-fetal transfusion

When one of a monochorionic twin dies *in utero*, there is a significant risk of ischaemic damage predominantly to

the fetal brain (18% in monochorionic twins), although there are reports of damage to pulmonary and hepatic systems, intestinal atresia, limb reduction and renal necrosis. For twin pregnancies overall, a recent systematic review derived a risk of 9% (95% CI 6–13) for neurological abnormality [42]. Death of one of a monochorionic twin substantially increases the risk of co-twin demise *in utero*. Again, a recent systematic review has reported that surviving monochorionic twin fetuses have a six times greater risk of intrauterine fetal death (12%) following single fetal demise after 20 weeks' gestation than initially surviving dichorionic twins (4%; OR 6, 95% CI 1.8–19.8) [42]. Gestational age at the time of intrauterine fetal death influences the extent and type of fetal brain injury. Single intrauterine fetal death after the second trimester can lead to periventricular leucomalacia, multicystic encephalomalacia or germinal matrix haemorrhage. In the third trimester of pregnancy, subcortical leucomalacia, basal ganglion damage or lenticulostriate vasculopathy may develop. There is debate about whether development of such central nervous system (CNS) anomalies are gestationally dependent. However, the long-term morbidity of such an event prior to 14 weeks is controversial and the association less pronounced.

Unlike dichorionic twins, discordant fetal compromise with risks of intrauterine demise in one twin have to be balanced against the potentially adverse effects of iatrogenic prematurity in the co-twin if delivery needs to be expedited in monochorionic twins. A balanced and sometimes complex discussion may ensue, not only to prevent intrauterine death in the potentially compromised twin but also to prevent sequelae in the co-twin. However, once single intrauterine fetal death has occurred in a monochorionic twin, delivery should not be immediate. The pregnancy should be evaluated for secondary sequelae, initially by the use of ultrasound. Such assessment should be within a tertiary fetal medicine centre. The assessment often includes the use of sequential ultrasound scanning (with increasingly the adjuvant investigation of fetal MRI) to prospectively evaluate the presence of CNS neuropathology that may develop up to 4 weeks after the sentinel event.

Chronic feto-fetal transfusion

Chronic feto-fetal transfusion syndrome (FFTS) occurs in approximately 15% of monochorionic pregnancies (twins and triplets). It is responsible for up to 40% of deaths in monochorionic twins, where it is more commonly known as twin–twin transfusion syndrome (TTTS). The underlying pathophysiology involves chronic shunting of blood from the donor twin to the recipient twin, leading to an inter-twin haemodynamic imbalance. Such a vicious circle of events leads to the 'donor' twin becoming hypoperfused, growth restricted and with associated oliguria and the development of anhydramnios. The co-twin, the 'recipient', becomes polyuric with often severe polyhydramnios and a hyperdynamic circulation that may cause both diastolic and systolic cardiac dysfunction, ending in the development of hydrops fetalis and death (if no treatment ensues). FFTS/TTTS is diagnosed when there is gross discordancy in amniotic fluid volume in monochorionic twins, with polyhydramnios in the recipient and anhydramnios in the donor sac. It constitutes severe disease if the onset is prior to 26 weeks. A staging system has been described and is useful in annotating the condition in a consistent manner but does not always denote a logical order of disease progression (Table 21.1). In general terms, the prognosis is better in early-stage disease (stages I and II) and worse in more advanced disease (stages III and IV). However, cardiac dysfunction may be present in up to 20% of fetuses with stage I disease (by Quintero staging) and as a consequence complicated monochorionic twin pregnancies may progress to the most adverse stages without warning.

Untreated, perinatal loss rates in the mid-trimester approach 95%. The principal clinical problem is severe polyhydramnios, which may be associated with premature rupture of membranes or preterm labour (or a combination of these) usually before 26 weeks' gestation. In addition, differences in inter-twin haemodynamics may be associated with single or double twin demise (with antecedent CNS morbidity). Fetoscopic laser ablation/coagulation of the inter-twin communicating vessels has been demonstrated by critical appraisal of the literature to be the optimal treatment in FFTS/TTTS [43]. This is therefore the treatment of choice in monochorionic twin pregnancies presenting with this complication prior to 26 weeks' gestation. Modification of the fetoscopic laser technique, using the SOLOMON method to ablate across the equatorial plane between arteriovenous anastomoses previously ablated using the selective sequential method, further reduces neonatal morbidity

Table 21.1 Staging system for FFTS/TTTS.

Stage I	Polyhydramnios /oligohydramnios with bladder of the donor still visible
Stage II	Bladder of the donor not visible
Stage III	Presence of absent end-diastolic flow velocity in the umbilical artery, reverse flow in the ductus venosus or pulsatile umbilical venous flow in either twin
Stage IV	Hydrops in either twin
Stage V	Demise of one or both twins

and, in particular, the complication of twin anaemia polycythaemia sequence (TAPS) [44].

Twin anaemia polycythaemia sequence

The incidence of TAPS occurring spontaneously in monochorionic diamniotic twins is up to 5%. However, it may complicate up to 13% of cases of TTTS following laser ablation. TAPS is believed to be due to the presence of miniscule arteriovenous anastomoses (<1 mm) which allow slow transfusion of blood from the donor to the recipient, leading to highly discordant haemoglobin concentrations at birth (Fig. 21.1). The postnatal diagnosis of TAPS is based on the finding of chronic anaemia (including reticulocytosis) in the donor and polycythaemia in the recipient. The criteria for diagnosis include a difference in haemoglobin concentration between the twins of more than 80 g/L and reticulocyte count ratio greater than 1.7 or small vascular anastomoses (<1 mm in diameter) in the placenta. The prenatal diagnosis of TAPS is based on the finding of discordant middle cerebral artery (MCA) Doppler abnormalities, including an MCA peak systolic velocity (PSV) more than 1.5 multiples of the median (MoM) in the donor, suggesting fetal anaemia, and an MCA PSV less than 1.0 MoM in the recipient, suggesting polycythaemia. Additional ultrasound findings in TAPS include differences in placental echogenicity and thickness, with a bright thickened section for the donor twin and an echolucent thin recipient section. The polycythaemic twin might have a 'starry sky' appearance of the liver due to diminished echogenicity of the liver parenchyma and increased brightness of the portal venule walls.

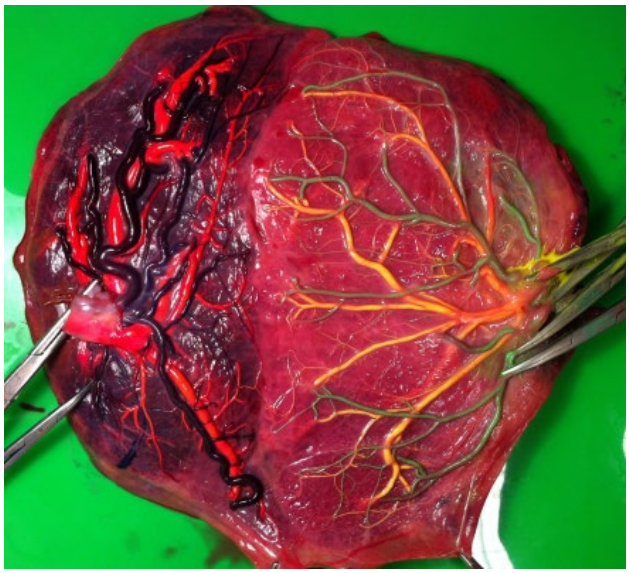

Fig. 21.1 TAPS is believed to be due to the presence of miniscule arteriovenous anastomoses (<1 mm). *Source:* Dr E. Lopriore. Reproduced with permission of Dr E. Lopriore. (*See also colour plate 21.1*)

The outcome of twin pregnancies complicated by TAPS is variable. Severe TAPS may result in intrauterine death of both twins. At the other end of the spectrum, mild TAPS may still allow the birth of two healthy neonates (apart from having a significant haemoglobin difference between the two). It appears that the main neonatal morbidity consists of anaemia (requiring transfusion) and polycythaemia (possibly requiring partial exchange transfusion). However, cases of severe cerebral damage have been reported in neonates with TAPS. Recent evidence suggests that in monochorionic twins complicated by TAPS, the risk of neurodevelopmental delay is increased (20%) Therefore, brain imaging during the third trimester and neurodevelopmental assessment at the age of 2 years are recommended.

The management options depend on the gestational age at assessment, parental choice, the severity of the disease and technical feasibility of intrauterine therapy. Therefore, the management of twin pregnancies complicated by TAPS should be individualized. The commonest options include conservative management, early delivery, laser ablation or intrauterine transfusion (IUT) for the anaemic twin, combined IUT for the anaemic twin and partial exchange transfusion to dilute the blood of the polycythaemic twin. In order to screen for TAPS, the MCA PSV should be measured from 20 weeks onwards in both fetuses, and during the follow-up of treated TTTS cases. Prevention of TAPS by modification of the fetoscopic laser ablation technique remains the best way to prevent morbidity.

Twin reversed arterial perfusion sequence

This rare condition (complicating 1 in 35 000 pregnancies) arises in monochorionic twins with two umbilical cords often linked by large arterio-arterial anastomoses. Flow from one, the 'pump' twin, supplies the other, the 'perfused' twin, in a retrograde fashion. The perfused twin almost always has associated significant congenital malformations, often including a rudimentary heart and aorta. The term 'twin reversed arterial perfusion (TRAP) sequence' is preferred, so named because reversed deoxygenated arterial supply is associated with only rudimentary development of the upper body structures within the fetus. Thus the acardiac twin is perfused by its co-twin (the pump twin) via the intertwin placental anastomoses. Perinatal mortality in the pump twin in untreated cases is approximately 50% due to associated polyhydramnios and cardiac failure that may ensue [45]. Although polyhydramnios may be elevated by amnioreduction, definitive treatments

that cause occlusion of the perfused (acardiac) twin's cord or rudimentary aorta may be achieved by a variety of fetoscopic or ultrasound-guided techniques (intrafetal laser ablation, radiofrequency thermal ablation and fetoscopic cord occlusion). There is still controversy whether to offer intervention electively, or only when signs of cardiac compromise occur, and at what gestational age intervention is best performed. Earlier intervention appears to be associated with a more advanced gestational age at birth. With careful case selection improved outcome for the pump twin is described in up to 85% [46,47]. Most significant complications include co-twin demise or hypoperfusion (with cerebral morbidity) and/or preterm ruptured membranes.

Monoamniotic twins

Of monozygotic twins, 1% lie in the same sac (monoamniotic) exposing them to the risks of cord entanglement. This may prove problematic most commonly (but not exclusively) in the intrapartum period. For this reason most cases are delivered by elective caesarean section. These twins also have higher reported overall perinatal mortality rates of approximately 30%. This appears largely related to the risk of sudden unexplained intrauterine death (often before 34 weeks' gestation). Therefore the timing of delivery of these twins is controversial. Anecdotal and cohort studies have suggested that use of prophylactic maternal sulindac (cyclooxygenase-2 inhibitor) to reduce fetal urine output and thus amniotic fluid volume reduces the risk of cord entanglement [48]. In combination with this, others have advocated hospitalization from 26–28 weeks onwards and elective premature delivery of these twins between 32 and 34 weeks' gestation. The most recent evidence indicates that the risk of these events are relatively low, with close outpatient surveillance being recommended rather than very early elective delivery [49–51]. However, the consensus view suggests a course of prophylactic corticosteroids followed by elective caesarean delivery by 33 weeks in these rare twin pregnancies.

Labour and delivery of twins and multiple pregnancies

Whatever the chorionicity of the twin pregnancy, it is best practice for intrapartum care to be discussed and a multidisplinary plan set out in the early third trimester of pregnancy. The indications for elective caesarean section are relatively few. Congenital anomalies associated with significant risk of cephalopelvic disproportion (including conjoined twins) would be an obvious indication and potentially monoamniotic twins would be another (see below). In addition, monochorionic pregnancies, complicated by placental anomalies associated with increased perinatal mortality (i.e. TTTS or TRAP), are generally delivered at 34–36 weeks and usually by caesarean section [2].

Perinatal mortality increases slightly after 38 weeks' gestation in twins and there are therefore many obstetricians who elect for delivery then. However, there are no data to indicate whether or not this rise in mortality applies to twins whose growth and well-being are known to be normal on ultrasound. Induction of labour is not contraindicated in twin pregnancies. Mode of delivery is decided on standard principles based on presentation of the first twin (cephalic in 70%, breech in 30%) and the documentation of optimal fetal growth and well-being. Those with previous caesarean section scars are probably best delivered by repeat caesarean section because of the greater risk of scar dehiscence/rupture due to both uterine distension and intrauterine manipulation of the second twin. Recent data have indicated that a planned elective caesarean section may achieve an up to 75% reduction in the risk of perinatal death compared with vaginal delivery by reducing risks of acidosis and anoxia (especially to the second twin) [52–55].

Caesarean section has been advised when the first twin is breech, which would obviate the rare risk of interlocking twins and entrapment of the head of a presenting breech above the second cephalic twin. The use of intrapartum ultrasound may allow detection of such problems with early recourse to emergency caesarean section. However, there is no evidence that vaginal delivery of a presenting breech that would otherwise satisfy criteria for vaginal delivery (EFW less than 3.5–4 kg, flexed head and not footling) is inappropriate in selected cases. The presentation of the second twin is of no importance until after birth of the first.

Even in twins where the first twin is cephalic presentation (at term), there may be the need for obstetric delivery of the second twin, with potentially an increased risk of perinatal morbidity. However, a Cochrane review (on delivery of the second twin not presenting cephalically) indicates that caesarean section increases maternal febrile morbidity without improving neonatal outcome [56]. This awaits critical appraisal.

For vaginal delivery, continuous cardiotocography of both twins is best achieved by a combination of internal and external monitoring on a dual-channel recorder. An intravenous line is sited and maternal blood drawn for group and save, in view of the increased incidence of caesarean section and postpartum haemorrhage.

Augmentation of labour with oxytocin may be used as in singletons. An epidural anaesthetic is strongly advised in case of the unexpected need for internal manipulation of the second twin. If one is not sited, an anaesthetist will be required at delivery with early recourse to spinal or even general anaesthesia. The place of delivery is debatable but there is an increasing trend for twins to be delivered in operating theatres so that there is immediate redress to emergency caesarean section if necessary.

Delivery of the first twin proceeds as for a singleton. Its cord is clamped to prevent fetal haemorrhage (from the second twin along any placental anastomoses). An experienced obstetrician discerns the presentation of the second twin, either by abdominal or vaginal examination or, increasingly, by the use of transabdominal ultrasound. Oblique or transverse lies are then converted to a longitudinal lie by external version and held in place by an assistant. Uterine contractions should be monitored and if necessary augmented using oxytocin. The membranes should be left intact to facilitate version. External cephalic version may be used to manipulate the fetal head over the pelvic inlet. Internal cephalic version is preferred as a primary procedure by many experienced obstetricians, as it seems to be associated with a higher success and lower complication rate than external cephalic version. One or preferably both feet are grasped and brought down into the vagina followed by an assisted breech delivery with contractions and maternal effort.

Historical series suggest that the risk to the second twin is increased the greater the delay until delivery. Classically, intervals of greater than 30 min are acceptable providing the cardiotocograph is satisfactory and the presenting part is descending. Uterine inertia with a longitudinal lying second twin is corrected by oxytocin infusion. This is a not uncommon occurrence in the intrapartum management of twins.

Fetal distress may be managed by ventouse delivery, even if the head is high or breech extraction. The already stretched vaginal tissues after the birth of the first twin allow these procedures in circumstances where they would normally be contraindicated. Caesarean section for second twin is occasionally indicated for disproportion, usually where the second twin is much bigger than the first. An oxytocin infusion is given prophylactically in the third stage of labour to minimize the risks of postpartum haemorrhage.

There is some evidence that the risk of perinatal loss is greater at the end of the third trimester in monochorionic twins compared with dichorionic twins. However, there is insufficient evidence that elective delivery before 36 weeks improves outcome. Most current consensus-based guidelines recommend delivery between 36 and 38 weeks' gestation [3].

Higher-order multiples

Perinatal and maternal risk increases exponentially with increasing fetal number. Most higher-order multiple pregnancies are the result of assisted reproductive technologies and thus should be preventable with closer monitoring of follicular response and single (or, at most, two) embryo transfers in IVF therapy. Indeed, there are proven arguments for restricting the number of embryos transferred to one in order to minimize twin and triplet risk, and this course of action appears to have limited adverse effect on live birth rates when more cycles are allowed [57,58].

Every woman/couple with a higher-order multiple pregnancy should have a discussion with a senior obstetrician relating to increased maternal and perinatal risks. This should involve the discussion and option of multiple fetal pregnancy reduction. In addition to perinatal mortality rates, parents should be counselled as to the mean gestational age at delivery (33 weeks for triplets, 31 weeks for quadruplets). In addition, 10% of triplets and 25% of quadruplets deliver before 28 weeks' gestation, with severe neurological sequelae rates of 12% and 25% (respectively) in survivors [59]. The chief perceived disadvantage of multiple fetal pregnancy reduction, usually accomplished by administration of a percutaneous fetal intrathoracic injection of abortifacient (commonly potassium chloride), is complete miscarriage. International registry data demonstrate that this is lowest with reduction to twins, with rates for starting triplets and quadruplets of 7% and 15%, respectively [60]. There is now a consensus that multifetal pregnancy reduction between 10 and 12 weeks should be recommended for quadruplets and higher multiples so as to lower both maternal and fetal risks.

The situation with triplets has been more controversial, with many considering this a social issue for parents. However, recent data indicate that in a fetal reduction group ($N = 482$) compared with an expectantly managed group ($N = 411$), the rate of miscarriage was significantly higher (8.1% vs. 4.4%, RR 1.83, 95% CI 1.08–3.16; $P = 0.036$) and the rate of preterm delivery lower (10.4% vs. 26.7%, RR 0.37, 95% CI 0.27–0.51; $P < 0.0001$) [61].

Higher-order multiple pregnancies should be managed in tertiary perinatal centres with a fetal medicine service. Care is almost always individualized. Management is along standard lines for twins but with greater emphasis on preventing preterm delivery and on monitoring fetal growth and well-being. Although there have been successful reports of triplets and even quadruplets being delivered vaginally, most higher-order pregnancies are now delivered by caesarean section. This alleviates difficulties with electronic fetal monitoring, avoids

unrecognized hypoxaemia (especially given the high incidence of IUGR) and prevents birth trauma from manipulative delivery of non-cephalic presenting fetuses. Given the higher incidence of preterm labour in the midtrimester, the option after delivery of the presenting fetus of conservative management with passive retention of residual fetus to prolong gestational age should be considered [62].

The concept of a multiple pregnancy clinic

Increasingly, there is consensus opinion that the management of multiple pregnancies should be concentrated in a designated 'multiple pregnancy clinic' with experienced midwifery and obstetric discussion and decision-making and with access to immediate diagnostic ultrasound and multidisciplinary opinions (i.e. anaesthetic, neonatal paediatric and psychological services). This care should be holistic in approach (in the widest sense) and could be organized regionally or in subregional centres depending on local population needs and numbers. Such clinics would allow the timely diagnosis of complications of multiple pregnancy along with an individualized plan of care for the prenatal, intrapartum and postnatal periods in women with multiple pregnancies.

Conclusion

The rate of multiple pregnancies appears to be rising, a phenomenon elevated by increased maternal age and the use of assisted reproduction technologies. Even so, the greatest proportion of multiple pregnancies are twins. Obstetric care should be undertaken with specialist teams in a multiples clinic so that prenatal care (influenced by chorionicity), intrapartum care and postnatal well-being may be discussed and planned prospectively. Such developments will hopefully minimize the increased maternal and perinatal risks that exist in such complex pregnancies.

Summary box 21.1

- The prevalence of twin and triplet pregnancies is increasing worldwide. This is associated with a significantly increased risk of maternal and perinatal adverse outcomes in such pregnancies.
- The modification of artificial reproduction techniques with transfer of single embryos reduces significantly (but not completely) the risk of multiple pregnancy.
- Chorionicity is an important factor to determine using ultrasound in the first trimester. Monochorionic twin pregnancies are associated with an increased risk of perinatal mortality and morbidity.
- Multiple pregnancies should be managed in designated multidisciplinary clinics where a holistic approach to pregnancy management can be adopted. This includes the discussion and planning of intrapartum care.
- In the postnatal period, women who have children from multiple pregnancies require increased support as they are at increased risk of emotional/psychological morbidity and this may also lead to socioeconomic stress.

Parturition

The onset of labour is the result of a cascade of intrauterine biochemical events that culminates in cervical softening and dilatation and increased uterine contractility (Fig. 22.1). Alterations in the timing of birth are the leading cause of neonatal mortality and morbidity. The mechanisms involved in the onset of labour in women remain elusive and as a consequence the prediction and management of preterm labour are poor, resulting in potentially severe complications for the newborn, distress to the parents and high medical costs. Spontaneous preterm labour may or may not result from the same endocrine and intracellular pathways as the physiological onset of labour at term. Despite considerable improvements in special care baby units, the perinatal mortality rates for preterm birth remain steady, and there is a wide range of both short-term and long-term complications and handicap in the surviving infants [1,2]. On the other hand, our limited understanding of the physiological mechanisms can make induction of labour difficult. More than 25% of pregnant women will undergo an induction of labour for prolonged gestation (41 or more weeks), hypertensive disorders of pregnancy, pre-labour rupture of membranes, or other indications [3]. A combination of vaginal prostaglandins and intravenous oxytocin is a common method for induction of labour; moreover, oxytocin is used for augmentation of contractions after labour of spontaneous onset. Stimulation of contractility carries the risk of failure and increased chance of delivery by caesarean section: in a study of reasons for caesarean section in labour in nulliparous women, the majority (70%) were due to 'failed induction/dystocia', 29% were indicated for fetal distress and 1% were due to acute clinical emergencies (e.g. cord prolapse, placental abruption) [4]. Studies involving more than two million women in several countries show that the rates of caesarean section in induction of labour at term are 30–40%, contributing to a 50% increase in caesarean section deliveries over the past decade [5]. This compelling epidemiological evidence shows that induction of labour at term is a major contributor to maternal and neonatal morbidity and emphasize the need to improve our understanding of human parturition so that we can develop more efficient ways of inducing and augmenting labour.

Summary box 22.1

The ability of obstetric care providers to predict and prevent preterm labour and birth is poor, resulting in potentially severe complications for the newborn, distress to the parents and high medical costs.

Fetal signals

Fetal surfactant (a mixture of lipids and apoproteins) is a signal for parturition because it provides a link between fetal lung maturation, which is essential for extrauterine life, and the onset of labour through stimulation of prostaglandin production. Amniotic fluid surfactant, which reflects fetal lung maturation, is an important intrauterine source of arachidonic acid, and increases the rate of prostaglandin synthesis in the fetal membranes. This effect is due to the release of fatty acids, including arachidonate, from the lipids of fetal surfactant by the sequential action of phospholipase C and diglyceride lipase activities in amniotic fluid and by the transfer of arachidonate from surfactant phosphatidylcholine to phosphatidylethanolamine and phosphatidylinositol in amnion cells [6]. These lipid pathways provide a link between the process of maturation of the fetus in preparation for birth and the labour-initiating prostaglandin activation.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

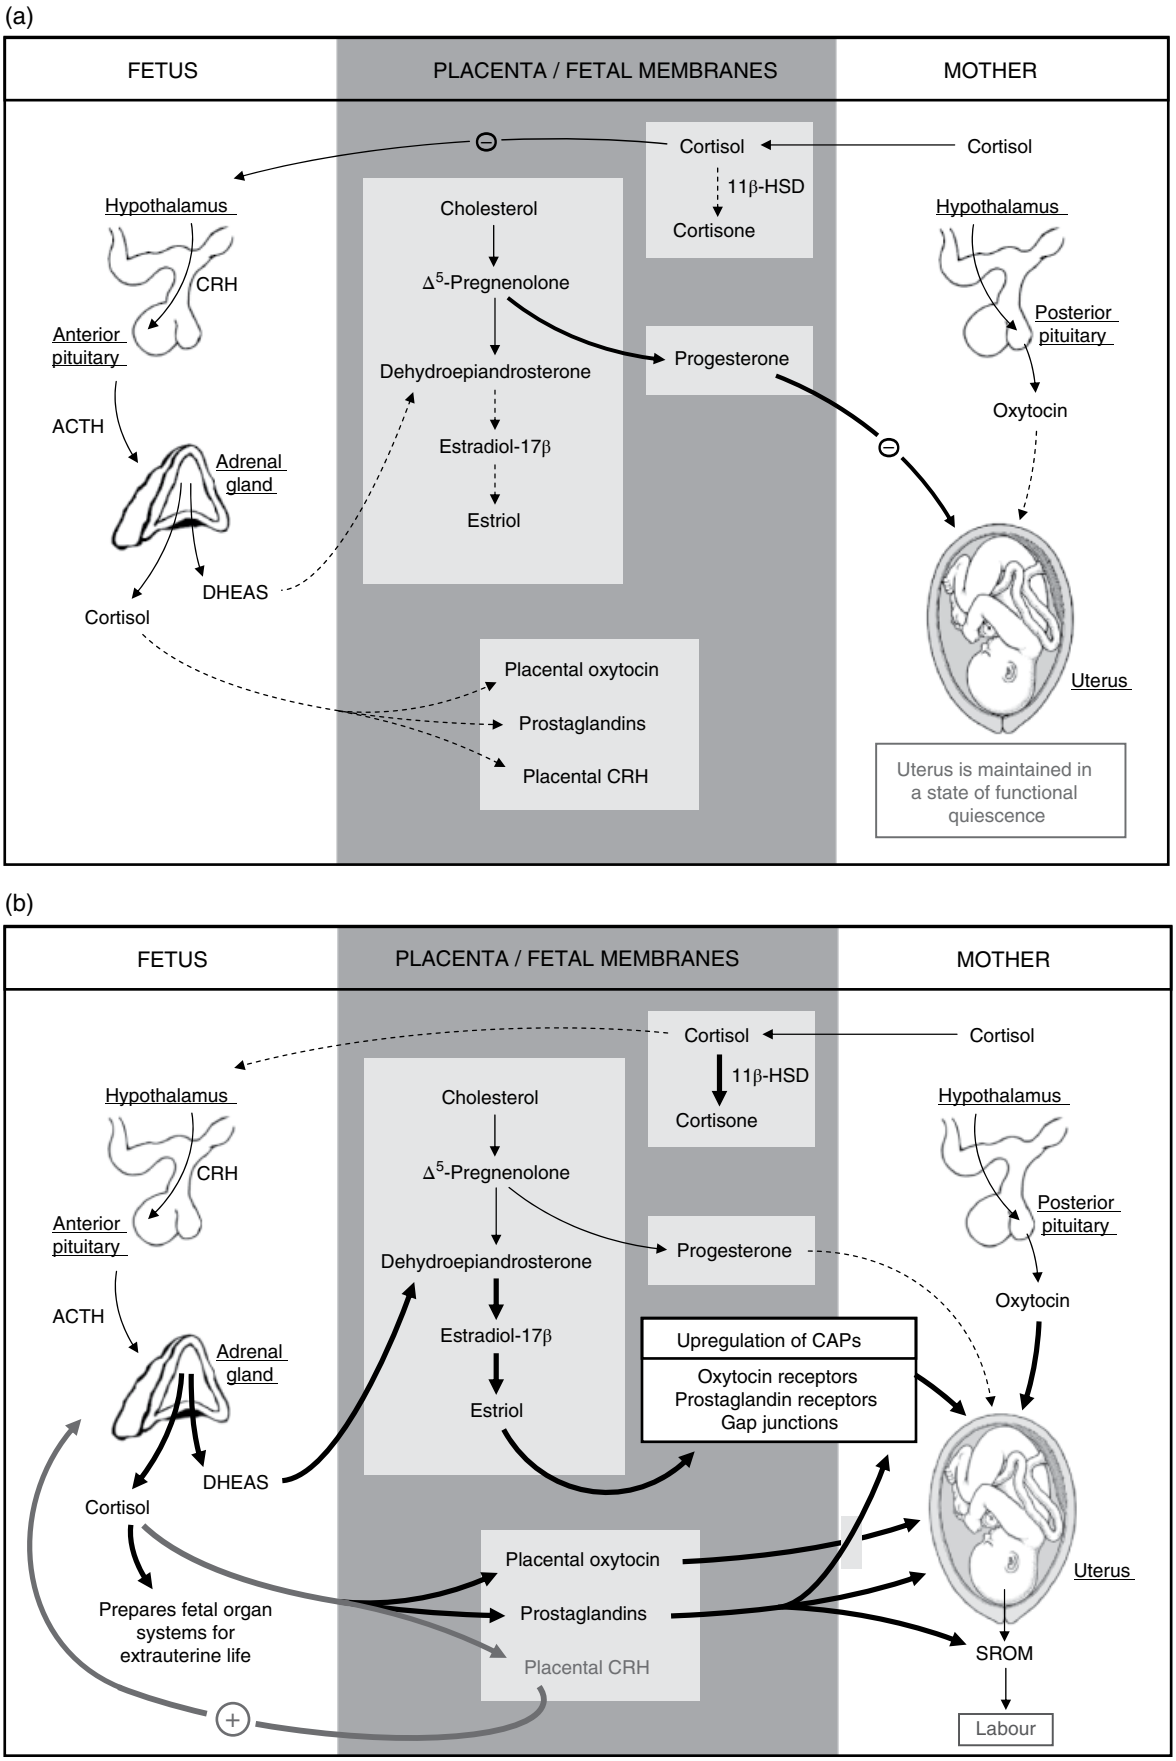

Fig. 22.1 Proposed 'parturition cascade' for the onset of labour at term. The spontaneous onset of labour at term is regulated by a series of paracrine/autocrine hormones acting in an integrated parturition cascade. The factors responsible for maintaining uterine quiescence throughout gestation (a) and for the onset of labour at term (b) are shown. This includes the withdrawal of the inhibitory effects of progesterone on uterine contractility and the recruitment of cascades that promote estriol production and lead to upregulation of the contraction-associated proteins within the uterus. ACTH, adrenocorticotrophic hormone (corticotrophin); CAPs, contraction-associated proteins; CRH, corticotrophin-releasing hormone; DHEAS, dehydroepiandrosterone sulfate; 11β-HSD, 11β-hydroxysteroid dehydrogenase; SROM, spontaneous rupture of membranes.

In addition to the effect of its lipid components, fetal surfactant is likely to be involved in the process of parturition through the effects of the surfactant-associated proteins SP-A and SP-D. These are multimeric molecules containing C-type lectin domains and collagen-like regions. SP-A and SP-D concentrations in amniotic fluid rise sharply from about 26 weeks' gestation to term and the proteins are found in the fetal membranes and decidua [7]. SP-A and SP-D perform innate immune functions in the lungs via macrophage activation, control of inflammation, and clearance of microbes and apoptotic and necrotic cells. These proteins have an important role in non-immune defence mechanisms in the amniotic cavity. SP-A interacts with toll-like receptors TLR-2 and TLR-4 on macrophages and increases the expression of interleukin (IL)-1β and nuclear factor (NF)-κB [8]. In mice, intra-amniotic injection of SP-A provokes premature delivery by a process which involves NF-κB activation [9]. SP-A has direct stimulatory effects on human myometrial cells through activation of NF-κB and mitogen-activated protein (MAP) kinase pathways [10]. On the other hand, SP-A appears to inhibit proinflammatory cytokine expression in the amniotic epithelium [11]. The role of SP-D in pulmonary host defence, particularly in the lungs of premature newborns, is well established. SP-D binds DNA from bacteria and on the surface of dying cells, enhancing the clearance of nucleic acids and limiting inflammatory reactions at sites of infection or apoptosis. SP-D is localized in the endometrium of the secretory phase and in placental villi and may have a role in the prevention of intrauterine infections at the time of implantation and during pregnancy [12].

Steroids

Steroids have complex and versatile metabolic pathways, with complementary distribution of enzyme activities in the different compartments of the human fetoplacental unit [13]. The fetal adrenal glands and liver, the maternal adrenal and liver and the placenta operate as integrated steroidogenic organs in pregnancy [14]. The fetal adrenals produce large amounts of dehydroepiandrosterone (DHA) and DHA-sulfate which, together with 16α-hydroxy metabolites from the fetal liver, are essential precursors for the synthesis of oestrogens in the placenta [15]. Moreover, fetal pregnenolone sulfate contributes significantly to placental progesterone production, complementing progesterone synthesis from maternal cholesterol. The complexity of the steroid metabolome in fetal and maternal blood has been reviewed elsewhere [16]. There are many steroid metabolites in the circulation reflecting fetal organ development and maternal responses for parturition. For example, the levels of conjugated androstenediol and of 16α-hydroxyandrostenedione rise sharply in fetal blood in the last few weeks of pregnancy [15]. On the other hand, several reduced progesterone metabolites including 5β-dihydroprogesterone, which bind to progesterone receptors and may contribute to uterine quiescence, decrease in late pregnancy, providing a functional progesterone withdrawal [17]. The search for steroid signals for parturition is difficult, given the metabolic complexity and the multiplicity of cellular effects on uterine and cervical tissues; however, few areas of physiology offer such clear functional integration among fetal and maternal organs in late pregnancy.

Placental corticotrophin-releasing hormone (CRH) plays a key role in stimulating steroid synthesis in pregnancy, specifically the production of DHA and other steroid sulfates in the fetal zone of the fetal adrenal. Increasing CRH levels in the maternal circulation has been proposed as a predictor of parturition and preterm labour [18], but the performance is poor [19]. The predictive value of measuring multiple steroid compounds simultaneously during late pregnancy and around parturition is likely to be better than measuring CRH alone [16].

Inflammatory responses

Decidual activation

Decidual cells, especially tissue macrophages, may have a role in the mechanism of labour by promoting the synthesis and release of prostaglandins and proinflammatory cytokines [20]. Prostaglandins are the final common pathway for parturition in many species and synchronize uterine activation and cervical ripening through a highly integrated transport system and specific receptor signalling pathways in decidua and myometrium [21,22]. Moreover, the decidua provides a place of immune tolerance and defence to protect the fetus and the placenta from infections. The output of prostaglandin (PG)$F_2\alpha$ by human decidual cells is higher in samples obtained after labour than before the onset of labour, whereas the output of other prostaglandins (PGE_2, PGD_2) and their metabolites remains relatively constant [23]. The release of the PGF isomer 9α,11β-PGF_2 from placenta, amnion and choriodecidua into the amniotic fluid increases at term [24]. $PGF_2\alpha$ and 9α,11β-PGF_2 have direct effects on the myometrial cells of the uterus, increasing intracellular calcium and promoting contractions through the stimulatory FP receptor [25]. The reason for the selective increase in PGF release with labour is not clear, but it appears to involve the action of cytokines produced by macrophages that migrate and settle in the decidua where they have important regulatory roles in pregnancy. Macrophages exhibit remarkable plasticity and their behaviour is influenced by the tissue microenvironment. Proinflammatory cytokines (IL-1; tumour necrosis factor-α, TNF-α) have strong paracrine and autocrine effects on decidual macrophages promoting the upregulation of prostaglandin synthase enzymes [24,26].

In some women, the premature release of prostaglandins provoked by decidual infection or haemorrhage can lead to very early delivery (before 30 weeks' gestation) with devastating consequences for the baby [27,28].

Inflammation and the onset of labour

The cellular disruption of inflammation, especially in the setting of infection, can lead to uterine activation and labour, but it should not be accepted as the general mechanism for the spontaneous onset of labour. In a study of more than 200 pregnant women undergoing caesarean section at term, the intrauterine site most commonly associated with histopathological inflammation was the decidua [29]. When caesarean sections were elective and carried out before the onset of labour, the incidence of deciduitis was low (6%) whereas in women operated on after the onset of labour deciduitis was much more frequent (29%). This could be interpreted as a cause–effect relationship between inflammation and spontaneous labour; however, most of the women with inflammation (86%) were in a group with cervical dilatation of 5 cm or greater. Decidual inflammation may be a consequence or labour, rather than its cause [29]. Inflammation of the fetal membranes is much more common in preterm deliveries than at term. A recent study detected acute chorioamnionic inflammation in 30% of preterm pregnancies but only 5.1 % of term pregnancies [30], confirming previous observations that there is an inverse relationship between gestational age and the frequency of bacteria in the fetal membranes or histological chorioamnionitis [31]. Many acute-phase response genes increase in myometrium due to factors unrelated to labour (e.g. surgical trauma, hypoxia, underlying pathology); these changes are likely to be due to secondary inflammatory responses late in labour, rather than changes required for the onset of labour [32]. Inflammation may be a trigger for spontaneous labour in infection-associated preterm deliveries, but it should not be accepted as the underlying mechanism for the onset of labour at term. The continuing search for the physiological pathways of parturition in women is important. New perspectives into decidual function and the timing of birth have been presented, highlighting the complex interaction of biological factors (prostaglandins, cytokines, growth factors and reactive oxygen species), genetic predisposition and immune defence mechanisms in the regulation of human parturition [33].

Summary box 22.2

Prostaglandins are the final common pathway of the parturition cascade. Prostaglandins given by any route to any species at any stage of gestation will result in pregnancy termination.

Endogenous mediators

Role of oxytocin

There are many genes potentially involved in the regulation of uterine contractility whose expression is modulated by oestrogens, progesterone and other pregnancy hormones. Oxytocin (OXT) is a member of an ancient nonapeptide hormone system and it is widely used in synthetic form for the induction and augmentation of labour because it stimulates uterine contractions. The pulse frequency of OXT secretion increases during human labour [34] and there is general agreement that it is important during the puerperium to facilitate uterine haemostasis after delivery and to initiate lactation. However, the role of OXT in the initiation of parturition is less clear. The high sensitivity of the uterus to OXT in pregnancy is due to a significant increase in the concentration of myometrial oxytocin receptor (OXTR) compared with the non-pregnant uterus [35,36]. The OXT sensitivity of the uterus remains very high at term but there is no clear increase at parturition; labour begins with no preceding warning and no change in the sensitivity of the uterus to circulating levels of OXT [37]. OXT has several roles in human parturition: one promoting uterine contractility to facilitate delivery and to prevent postpartum haemorrhage, and other roles preparing the uterus for the initiation of labour. In addition to stimulating contractility through the phospholipase C/calcium pathway in myometrial cells, OXT activates transcription factors of the NFAT (nuclear factors of activated T cells) family in a calcineurin-dependent manner [38]. The calcineurin–NFAT signalling cascade lies downstream of many cell surface receptors, including G protein-coupled receptors (e.g. receptors for OXT and prostaglandins in myometrium) and receptor tyrosine kinases (e.g. receptors for growth factors and cytokines), providing points of convergence and amplification for hormones, growth factors and other endogenous mediators involved in the preparation of the uterus and the cervix for parturition. NFAT is involved in OXT-mediated stimulation of PTGS2 (prostaglandin-endoperoxide synthase 2, also known as COX2) expression in human myometrial cells, regulating the rate-limiting step in prostaglandin synthesis. Moreover, OXT induces PTGS2 expression and stimulates prostaglandin release in human myometrial and amnion cells through other pathways, including the NF-κB complex, providing a link with the uterine response to cytokines and other inflammatory stimuli [39]. The influence of OXT on calcium homeostasis in human myometrial cells highlights its importance in normal labour [40,41].

Oxytocin receptors

OXT is a potent stimulatory peptide and it has been proposed that an increase in the concentration of OXTR in the uterus may be a trigger for parturition [35]. The implication is that low levels of OXTR expression in myometrium may favour uterine quiescence during ongoing pregnancy. However, the concentration of myometrial OXTR is very high in late pregnancy and there is no evidence that it increases further at the onset of labour [42–44]. It may be argued that uncoupling or blocking of OXTR may be a mechanism to inhibit contractility until parturition. However, the sensitivity of the human uterus to OXT remains relatively unchanged during the last few weeks of pregnancy and does not increase before the spontaneous onset of labour [37]. Both OXT- and OXTR-deficient mice have normal pregnancies and deliveries [45,46]. The accumulated evidence in mice suggests that inhibition of OXTR function is not responsible for uterine relaxation in pregnancy, although OXT retains important roles in luteal function [47], nursing response [46] and social behaviour [45,48]. Nevertheless, the design of OXTR antagonists is seen as a good approach for the management of preterm labour in women, because these drugs have relatively high uterine selectivity and few side effects [41,49,50].

Epidermal growth factor

The concentration of epidermal growth factor (EGF) increases in amniotic fluid during pregnancy [51]. EGF concentrations in maternal blood range from 70 to 800 pg/mL [52], whereas in cord blood the levels are higher (500–3000 pg/mL) [53]. EGF has traditionally been studied as a critical factor in fetal maturation and more recently it has been implicated in the pathogenesis of pre-eclampsia [52]. However, the role of EGF as a physiological mediator in parturition is less well established. EGF stimulates PTGS2 expression in human amnion [54] and myometrial cells [55] and the mechanism has been investigated in some detail. EGF operates through a specific receptor (EGFR, the first member of the ErbB tyrosine kinase family), which is the target of several clinically approved anticancer agents. In human myometrial cells, EGF stimulates PTGS2 expression through interaction of EGFR with members of the mitogen-activated protein kinase family, namely MEK1/2 and ERK1/2. This effect requires activation of protein kinase C [55]. Interestingly, OXT stimulates ERK1/2 in myometrial cells through a mechanisms that may involve transactivation of EGFR by OXTR and the effect of calcium [56]. The effect of EGF, and possibly other growth factors and cytokines, on prostaglandin release and acute-phase responses in the uterus is mediated by steroid receptor co-activator interacting proteins and by transcription factors [57]. OXT and EGF can stimulate PTGS2 expression and prostaglandin release through receptor transactivation and convergence of intracellular signals. These cooperative effects facilitate the preparation for labour in a physiological manner. Moreover, these pathways can be further stimulated by proinflammatory cytokines which amplify PTGS2 transcriptional responses via NF-κB and protein kinase C [39,55]. IL-1β and TNF-α stimulate not only PTGS2, but also the terminal prostaglandin synthases AKR1B1 (prostaglandin F synthase) and PTGES (prostaglandin E synthase) in human myometrial cells [58]. It is likely that the mechanism of labour is set to respond primarily to endogenous hormones and growth factors, with the system retaining the ability to react to inflammatory stimuli in an accelerated or premature manner (Fig. 22.2). Many studies rely on experiments using isolated uterine tissues *in vitro* and may not account for the full biological complexity of interacting maternal and fetal organs during parturition *in vivo*.

The uterus as a smooth muscle organ

The uterus provides a safe environment for the blastocyst to implant. The nutritious endometrial layer becomes receptive and encourages the development of a viable embryo and the trophoblast. Over a period of 40 weeks of gestation, the fetus, placenta and amniotic fluid increase their masses considerably, posing remarkable haemodynamic, metabolic and mechanical demands on the mother. At the same time, the uterus must expand and remain relatively relaxed, with a closed cervix, to allow the growth and differentiation of the fetus to a stage when it is ready to cope with extrauterine life. However, at the onset of labour the uterus is responsible for driving the process of birth through structural, biochemical and electrophysiological changes that result in cervical ripening and dilatation and the establishment of synchronized myometrial contractions. The process ends with the delivery of the newborn and the placenta, followed by an intense period of uterine remodelling and involution.

The myometrial layer contains specialized smooth muscle cells arranged in bundles embedded in a matrix of collagenous connective tissue. The collagen fibres facilitate the transmission of force generated by myometrial bundles. The process of cervical ripening involves changes in the connective tissue with an increase in collagen solubility and alterations in proteoglycans of the ground substance. This process has been regarded as an inflammatory reaction [59], with elevated levels of cytokines [60] and other proinflammatory molecules signalling through toll-like receptors (TLR2, TLR4) implicated in the mechanism of cervical remodelling in spontaneous labour [61].

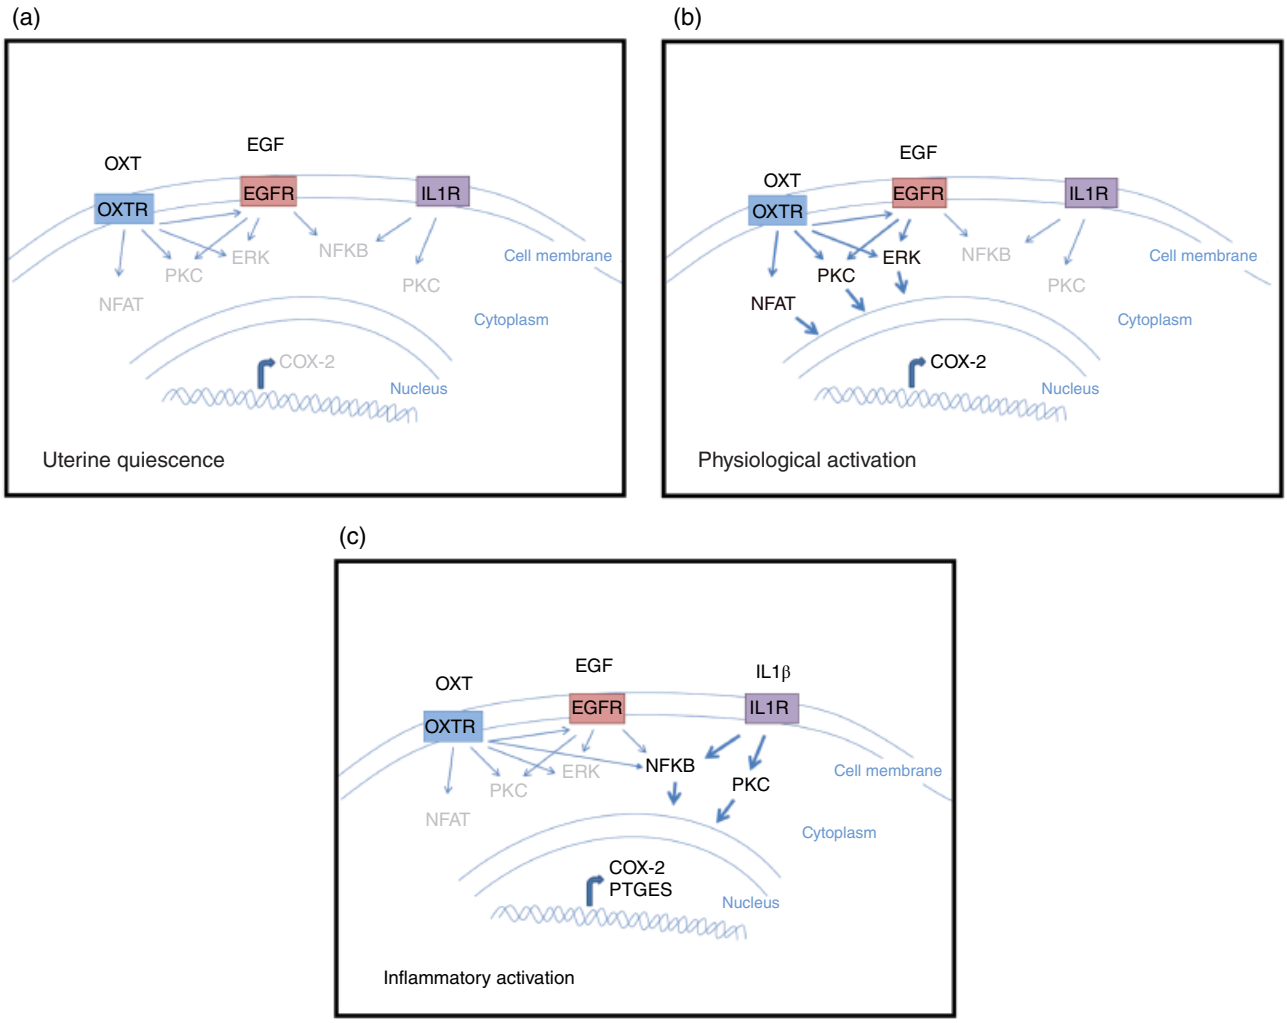

Fig. 22.2 Simplified mechanisms of uterine activation. (a) During pregnancy the uterus remains relatively quiescent with little prostaglandin synthesis because the inducible prostaglandin-endoperoxide synthase 2, also known as COX2, is expressed at low levels. (b) COX2 expression and prostaglandin output can be increased through stimulation of oxytocin receptors (OXTR) and epidermal growth factor receptors (EGFR) which act separately or coordinately via major signalling cascades involving mitogen-activated protein kinases (e.g. ERK), protein kinase C (PKC) and transcription factors such as NFAT (nuclear factor of activated T cells). (c) In the presence of inflammatory stimuli (leucocyte infiltration/macrophage activation following infection or haemorrhage) interleukin 1β receptors (IL1R) can increase prostaglandin release to very high levels through strong stimulation of COX2 and other terminal prostaglandin synthases (e.g. PTGES). The pathways involved include PKC and NFKB (nuclear factor of kappa B) and may involve disruption of OXTR and EGFR signalling.

The basis of uterine contractility

Myometrial smooth muscle cells contain actin (thin filaments) and myosin (thick filaments) in a less organized fashion than in striated muscle, but nevertheless forming efficient contractile units due to their intricate cytoskeletal organization [62]. Mammalian smooth muscle myosin belong to the class II myosins, which are characterized by a hexameric protein structure composed of two heavy chains (about 200 kDa) and two pairs of light chains: the 20-kDa regulatory myosin light chain (MYL_{20}) and the 17-kDa essential light chain. Functionally, myosin consists of three domains: the motor domain which interacts with actin and binds ATP, the neck domain which binds the light chains and is the site of calmodulin interaction, and the tail domain or anchoring domain which helps position the motor domain so that it interacts with actin [63]. Myosin generates contractile force by pulling actin filaments of opposite polarity towards one another (Fig. 22.3).

Myosin is both a structural protein and an enzyme (Mg-ATPase) capable of hydrolysing ATP to generate mechanical energy. The ATPase region of myosin is located in the head and is activated by actin; however, the level of activity is very low when MYL_{20} is unphosphorylated, but increases manifold upon phosphorylation of the regulatory chains. The enzyme responsible for MYL_{20} phosphorylation is the calcium-calmodulin

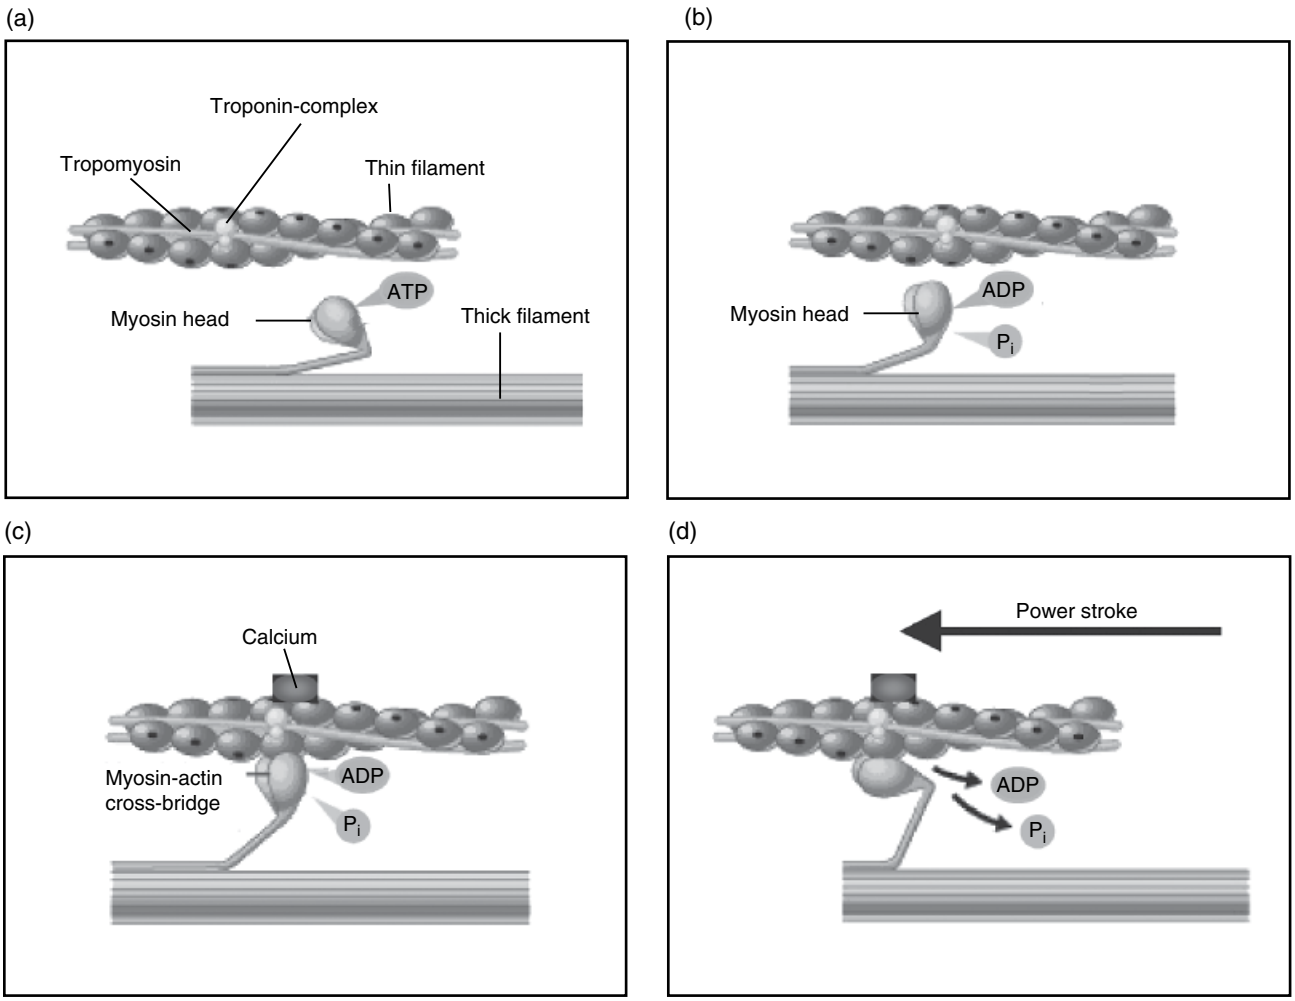

Fig. 22.3 Mechanics of muscle contraction. (a) Appearance of the contractile unit in the resting state. The thick filament refers to myosin; the thin filament is actin. Myosin-binding sites on the actin filaments are covered by a thin filament known as tropomyosin that obscures the myosin-biding sites, therefore preventing the myosin heads from attaching to actin and forming cross-bridges. Adenosine triphosphate (ATP) is hydrolysed into adenosine diphosphate (ADP) and inorganic phosphate (Pi). The troponin complex is attached to the tropomyosin filament. (b) As intracellular calcium concentrations increase, calcium binds to the troponin complex resulting in a conformational change that allows binding sites between actin and myosin to be exposed with the formation of actin–myosin cross-bridges. (c) Formation of actin–myosin cross-bridges results in release of Pi and ADP, causing the myosin heads to bend and slide past the myosin fibres. This 'power stroke' results in shortening of the contractile unit and generation of force within the muscle. (d) At the end of the power stroke, the myosin head releases the actin-binding site, is cocked back to its furthest position, and binds to a new molecule of ATP in preparation for another contraction. The binding of myosin heads occurs asynchronously (i.e. some myosin heads are binding while other heads are releasing the actin filaments), which allows the muscle to generate a continuous smooth force. Cross-bridges must therefore form repeatedly during a single muscle contraction.

dependent myosin light chain kinase (MYLK). There are three types of MYLK, the skeletal, cardiac and smooth muscle enzymes. The three types have a common conserved serine threonine kinase domain, but smooth muscle MYLK has unique immunoglobulin and fibronectin domains [64]. Despite its name, smooth muscle MYLK is expressed in almost all tissues and is involved not only in contractions but in many other cellular activities. Kinases are often portrayed as promiscuous enzymes with multiple substrates; however, despite its ubiquitous expression, the only known substrate of MYLK is myosin. Human myometrium expresses 137-kDa and 218-kDa isoforms of MYLK in both non-pregnant and in term pregnant uterine tissue [65,66]. Interestingly, a small 19-kDa non-catalytic C-terminal fragment of MYLK called telokin is highly expressed in pregnant compared to non-pregnant myometrium, suggesting it may have a regulatory role in gestation [66]. Smooth muscle MYLK has an actin-binding domain at the N-terminus which binds to purified polymeric actin (F-actin); however, the affinity of MYLK for myofilaments, which contain myosin II and many other proteins in addition to F-actin, is much higher. MYLK also has myosin- and calmodulin-binding domains. Purified MYLK can only

bind to calmodulin in the presence of calcium. The protein structure of MYLK suggests that it is a long and flexible molecule capable of attaching itself to actin through its N-terminus, and to the neck region of myosin through the C-terminal telokin domain. In this position the catalytic core of the enzyme is able to phosphorylate MYL_{20} in the thick filaments while being tightly anchored to the thin filaments. MYLK can itself be phosphorylated, modulating its activity during myometrial contractions.

Generation of uterine contractions

Myometrial smooth muscle is myogenic: it can generate contractions spontaneously without the need for external stimulation. Contraction of myometrial cells is initiated by action potentials that depolarize the cell membrane, allowing the rapid entry of calcium through voltage-operated channels (Fig. 22.4). The rise in intracellular calcium concentration ($[Ca^{2+}]_i$) is detected by

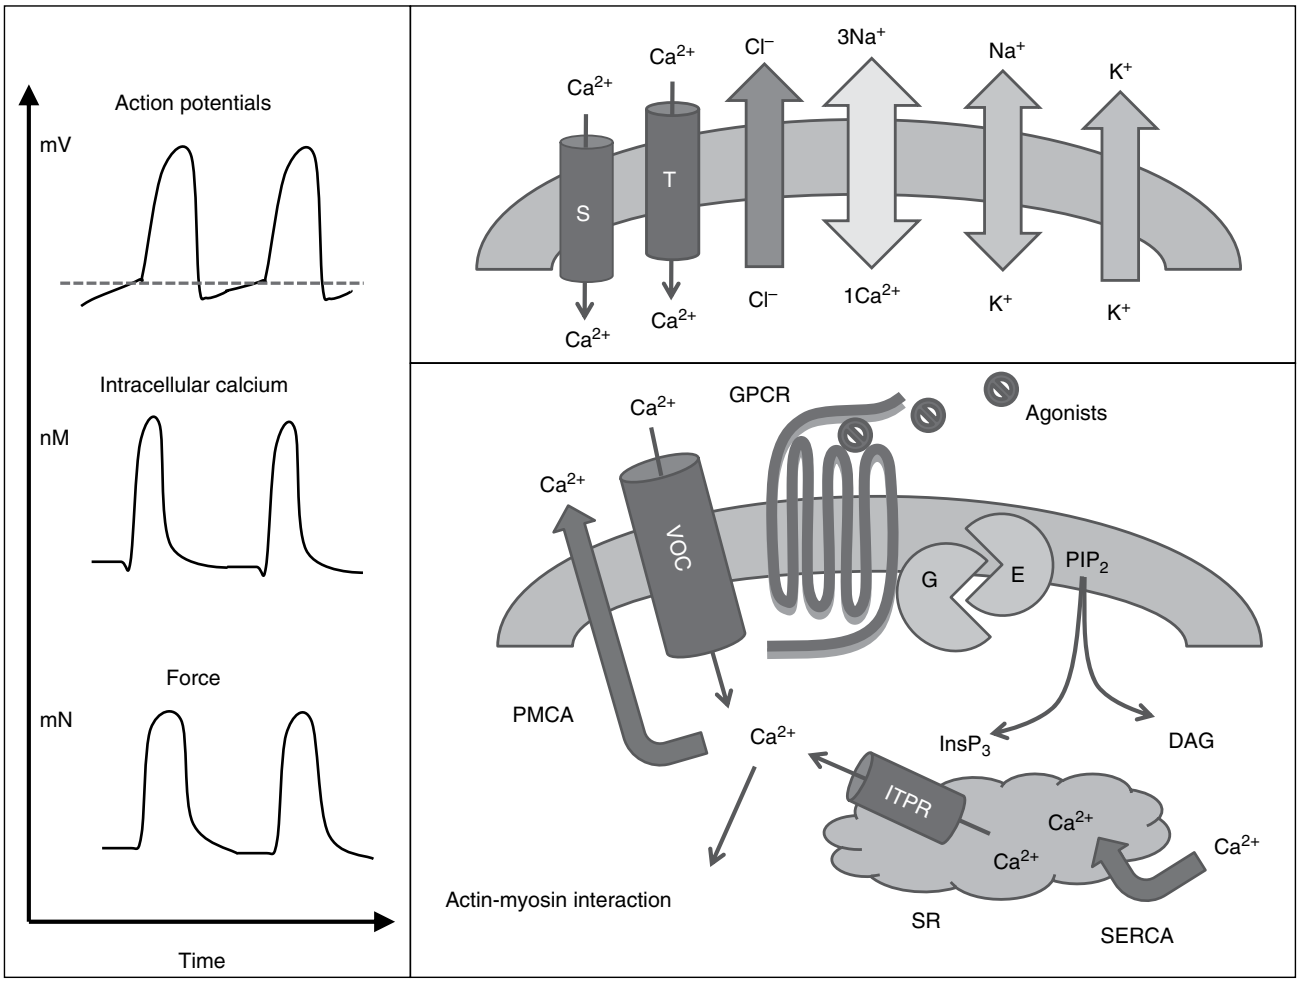

Fig. 22.4 The physiological basis of myometrial contractility. Action potentials are generated by pacemaker depolarization of the cell membrane (top) which is regulated by a complex interaction of several channels and ion pumps. These include store-operated (S) and T-type calcium channels as well as calcium-sensitive chloride (Cl^-) channels, all of which contribute to membrane depolarization. This is balanced by the Na^+/Ca^{2+} exchanger, and the strong hyperpolarizing effect of the Na^+/K^+ pump and the calcium-sensitive K^+ channels. Action potentials (measured in mV) provoke rapid entry of Ca^{2+} into the cell by opening voltage-operated L-type channels (VOC); the increase in intracellular Ca^{2+} levels (typically from 100 to 500 nM) provokes tension (measured in mN) by enhancing actin–myosin interaction. Stimulatory agonists such as oxytocin operate through G protein-coupled receptors (GPCR) which activate G protein effector complexes (G/E). A common G/E interaction involves G_q/phospholipase C which generates two second messengers from membrane phosphatidylinositol 4,5-bisphosphate (PIP_2), namely inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG). $InsP_3$ stimulates contractility by releasing Ca^{2+} from intracellular stores in the sarcoplasmic reticulum (SR) through ITPR channels. DAG stimulates protein kinase C. The phasic nature of myometrial contraction requires rapid Ca^{2+} extrusion mechanisms to lower intracellular Ca^{2+} and decrease tension. Ca^{2+} is transported out of the cell by plasma membrane Ca^{2+}-ATPases (PMCA) and taken up by the SR through smooth endoplasmic reticulum Ca^{2+}-ATPases (SERCA). Phospholamban is a protein that inhibits SERCA, but this inhibition can be blocked by phosphorylation of phospholamban by cyclic AMP-dependent kinases. *Sources:* adapted from Noble *et al.* [83], Berridge [84] and Sanborn [89].

the Ca^{2+} sensor calmodulin, which activates MYLK and provokes the phosphorylation of MYL_{20}. The activity of myometrial MYLK is very sensitive to minor changes in $[Ca^{2+}]_i$ around the 100–200 nM range and it is thought that the enzyme reaches maximal activity at lower Ca^{2+} concentrations than in other types of smooth muscle. Phosphorylation of MYL_{20} stimulates the formation of cross-bridges between actin and myosin filaments and the generation of force [65,67]. The phasic nature of myometrial contractions (recurrent episodes of force separated by intervals of relaxation) at parturition is necessary to allow vascular flow in the placenta and exchange of oxygen and waste products with the fetus during several hours of labour. In order to promote relaxation between contractions, myometrial cells have efficient Ca^{2+} extrusion mechanisms that include Ca^{2+} pumps and Na^+/Ca^{2+} exchangers in the cell membrane, as well as Ca^{2+} entry into intracellular stores, for example sarcoplasmic reticulum (SR) [68,69] (Fig. 22.4).

The increase in steroid hormones and placental-derived growth factors in pregnancy has important effects on the structure of the uterus. Myometrial tissue becomes more vascularized and there is hyperplasia and hypertrophy of myometrial cells. The cellular content of actin and myosin and of the actin-binding proteins caldesmon and calponin increases several fold compared with non-pregnant cells [65]. The increased expression of caldesmon protein in pregnancy has been described as a 'brake' on the myosin motors of the contractile filaments by a mechanism of Ca^{2+} desensitization [70]. Comparisons between pregnant and non-pregnant myometrial strips *in vitro* show that the relationship between the level of MYL phosphorylation and the amount of force is more favourable in pregnant tissue [65].

Calcium homeostasis

The phasic nature of uterine contractions is an intrinsic property of uterine smooth muscle and is related to the capacity of myometrial cells to modify $[Ca^{2+}]_i$ through reversible activation/inhibition of membrane receptors, ion channels and Ca^{2+} pumps. The main source of Ca^{2+} is the extracellular fluid, but intracellular stores such as the SR have important regulatory functions [71].

Myometrial cells are depolarized by action potentials which provoke the influx of Ca^{2+} through voltage-operated channels [72,73]. Interestingly, spontaneous action potentials in pregnant human myometrial cells are inhibited in sodium-deficient or calcium-free solutions [74–76]. This is due to the essential role of extracellular Ca^{2+} and of membrane Na^+/Ca^{2+} exchangers in the generation of action potentials and myogenic contractility. Magnesium sulfate is a natural calcium antagonist and a potent L-type calcium channel inhibitor. Nifedipine is a commonly used pharmacological blocker of external Ca^{2+} entry which also acts on L-type channels. In the presence of nifedipine both spontaneous and OXT-induced contractions in myometrial strips from term pregnant women are virtually abolished, confirming the essential role of external Ca^{2+} in the development of phasic uterine contractions in late pregnancy. L-type calcium channels have been targeted pharmacologically in the management of preterm labour, using magnesium sulfate or nifedipine; these drugs are effective at relaxing the uterus but they lack myometrial selectivity and can cause side effects. The role of T-type channels in the transmission of action potentials and in the regulation of contraction frequency in myometrial cells has been investigated, but the ubiquitous expression of these channels makes them a poor pharmacological target for the control of uterine activity [77,78].

Intracellular calcium stores

The study of calcium stores in smooth muscle has benefited from the development of fluorescent calcium indicator dyes that allow the measurement of transient rises in free Ca^{2+} in discrete cellular compartments. A number of general observations have been made across many tissues [79] which are relevant to human myometrium.

1) Sporadic increases in $[Ca^{2+}]_i$ occur as a consequence of Ca^{2+} release from intracellular stores (e.g. SR) rather than Ca^{2+} entry through the plasma membrane.
2) These increases are usually very transient and are followed by Ca^{2+} entry into the cells through voltage-dependent channels; without Ca^{2+} influx the intracellular stores are rapidly depleted.
3) Two types of intracellular stores can be distinguished by the nature of their regulatory mechanisms: those containing the ryanodine receptors (RYRs), activated by ryanodine or caffeine, and the inositol 1,4,5-trisphosphate receptor (ITPR)-containing stores. The latter are associated with activation of G protein-coupled receptors (GPCRs) in the cell membrane and activation of phospholipase C.
4) Refilling of intracellular stores may be facilitated by their close proximity to the cell membrane and may be linked to the generation of depolarizing currents.

Several isoforms of RYR and ITPR have been described in human myometrium [42,80]. The RYR acts as a Ca^{2+} channel and studies using human myometrial cells have confirmed the presence of functional RYRs in this tissue [81]. Ryanodine and cyclic ADP-ribose (cADPR) promote intracellular Ca^{2+} release in myometrial preparations *in vitro* and potentiate oxytocin-induced $[Ca^{2+}]_i$ increases by facilitating Ca^{2+} entry from the extracellular medium through 'calcium-induced calcium release' [82]. Interestingly, inflammatory mediators such as TNF-α induce CD38 expression in myometrial cells; this

suggests that inflammation may potentiate the parturition cascade by promoting the cADPR system [82].

ITPRs also act as intracellular Ca^{2+} channels and are activated by inositol 1,4,5-trisphosphate ($InsP_3$) generated when endogenous myometrial stimulants such as OXT, endothelin or α-adrenergic agonists bind GPCRs coupled to proteins of the G_q family which activate phospholipase C. $InsP_3$ binds to myometrial ITPRs and promotes Ca^{2+} release [42,71]. Experiments using myometrial strips from late pregnant women [71] and imaging techniques that allow the visualization of discrete Ca^{2+} fluxes in lipid microdomains [69] suggest that ITPR channel activation is an early event in uterine activation by OXT; however, in the absence of extracellular Ca^{2+} the development of force is short-lived because intracellular Ca^{2+} stores are soon exhausted; in other words, the development of phasic uterine contractions is absolutely dependent on the availability of extracellular Ca^{2+} to myometrial cells. Under normal physiological circumstances, for example in the absence of inflammation, ITPR channels in the SR appear to be more important for myometrial function than RYR channels [71]. Experiments using myometrial strips from late pregnant women showed that ryanodine had little effect on spontaneous or OXT-induced contractions [71], suggesting no functional role for RYR in this preparation. Moreover, blocking SR Ca^{2+} uptake with cyclopiazonic acid, an inhibitor of Ca-ATPase in myometrium, increased contractile force and $[Ca^{2+}]_i$.This suggests that the SR may normally contribute to lowering $[Ca^{2+}]_i$ during the relaxation phase of the contractions [71]. The complex role of intracellular Ca^{2+} stores requires further investigation because, in addition to acting as a trigger for agonist-induced Ca^{2+} mobilization, the SR may act as a 'sink' for Ca^{2+} during stimulation and, by enhancing plasma membrane Ca^{2+} efflux, may contribute to homeostatic Ca^{2+} relaxation mechanisms [83].

Electrophysiological mechanisms

A model for the activation of human myometrium based on electrophysiological and receptor mechanisms has been proposed [84], partly based on available experimental evidence [69,85,86]. In this model, activation of uterine contractility during labour is driven by action potentials initiated by slow depolarization of clusters of pacemaker myometrial cells. The action potentials trigger Ca^{2+} entry into the cells through L-type voltage-operated channels and the rise in $[Ca^{2+}]_i$ provokes contractions, thus linking the electrical signal with force (excitation–contraction coupling). This model envisages that the balance of depolarization and hyperpolarization in the cell membrane is controlled by multiple pumps and channels, including a Na^+/Ca^{2+} exchanger; a Na^+/K^+ pump, and Ca^{2+}-activated K^+ channels that contribute to relaxation (hyperpolarization). On the other hand, Ca^{2+}-sensitive chloride channels, T-type channels, and a putative channel that senses whether the level of Ca^{2+} in the SR store is low (store-operated channel, SOC) can tip the balance of the 'pacemaker' towards depolarization [84]. GPCR agonists like OXT can initiate depolarization by generating $InsP_3$ and emptying the SR store through ITPR channels, thus activating SOC, whereas RYR channels would contribute to contraction directly by increasing $[Ca^{2+}]_i$. Further regulatory refinement of myometrial activation can be provided by Ca^{2+}-ATPases that promote Ca^{2+} extrusion through the plasma membrane (PMCA) or Ca^{2+} uptake into the SR (SERCA).

Some aspects of this model have been reinforced by the abundant experimental evidence in favour of a role for L-type Ca^{2+} channels as the major route for Ca^{2+} entry into myometrial cells and the unquestionable involvement of the GPCR/phospholipase C/$InsP_3$ pathway activating ITPR channels in human myometrium [76,87]. However the role of RYR channels in human myometrium is questionable. The presence of Ca^{2+}-activated K^+ channels in this tissue has been demonstrated but their role in phasic myometrial activity during labour is not clear. An interesting interaction between Ca^{2+}-activated K^+ channels and α_2-macroglobulin has been described in myometrial cells whereby in the presence of OXT α_2-macroglobulin induces oscillations in Ca^{2+}-activated K^+ channel activity and promotes Ca^{2+} entry via SOC [88]. A number of endogenous Ca^{2+}-ATPase modulators has been described, including phospholamban, a membrane-associated protein that inhibits SERCA-mediated Ca^{2+} uptake into the SR. Interestingly, phospholamban can be phosphorylated by cAMP-dependent kinases leading to its inactivation and the liberation of SERCA activity [83].

Receptor-regulated myometrial contractility

In addition to the spontaneous uterine activity driven by action potentials, there is strong evidence that receptors and their cell signalling pathways have a physiological influence on the regulation of uterine contractility. The uterus has a rich variety of receptors, many of which are upregulated in pregnancy, and responds to classical hormones and transmitters (e.g. OXT, 5-hydroxytryptamine) as well as local modulators (e.g. prostaglandins and thromboxanes). The link between the myometrial cell membrane receptor and the initiation of a signalling cascade is, in most cases, a regulatory GTP-binding protein. G proteins can activate effector enzymes such as phospholipase Cβ (PLCB), adenylyl cyclase (ADCY) or phosphoinositide 3-kinase. The PLCB pathway is activated by receptors usually coupled to G_q which stimulate myometrial contractility. Endogenous agonists include peptide hormones (OXT, endothelin), prostanoids ($PGF_2\alpha$,

thromboxane A_2), catecholamines, muscarinic agents and inflammatory mediators (bradykinin, serotonin). The response is initiated by the hydrolysis of a receptor-sensitive pool of phosphatidylinositol 4,5-bisphosphate (PIP_2) in the cell membrane. The breakdown of PIP_2 generates two molecules with potent signalling effects: $InsP_3$, which releases calcium form the SR, and 1,2-diacylglycerol (DAG), which activates protein kinase C (PRKC) and stimulates the phosphorylation of many target proteins. Potential substrates of PRKC include ion channels, calcium pumps, and proteins involved in GPCR function and coupling to phospholipase C, ITPR regulation and elements of the contractile machinery [89]. In addition, DAG has PRKC-independent effects, for example in human myometrial cells DAG analogues facilitate store-operated or receptor-operated Ca^{2+} entry through the cell membrane via L-type channels and Na^+/Ca^{2+} exchangers [90].

Some ligands can activate more than one type of myometrial receptor, creating complex responses depending on the relative abundance and affinity of each receptor subtype and the presence of other agonists competing or interacting with related receptors. For each receptor, the effect on myometrial contractility will depend on the integration of these signals and on the physiological state of the organ under different endocrine influences. Changes in myometrial sensitivity to agonists are likely to be important mechanisms for maintaining the balance between uterine quiescence and contractility. The uterus is very sensitive to OXT, which is commonly used for the induction and augmentation of labour; however, many uncertainties remain about its mechanism of action. For instance, analysis of the Ca^{2+}–tension relationship in pregnant myometrial strips reveals a strong component of 'Ca^{2+} sensitization' during OXT-induced contractions [91,92], probably involving inhibition of myosin phosphatase. The pathways involve small GTP-binding proteins of the Rho family and activation of Rho-dependent kinases [93].

Uterine relaxation

The physiological mechanisms responsible for the transition of the pregnant uterus from a long period of relative relaxation to a short period of active contractions in labour remain unknown. Greater understanding of the factors involved in the loss of uterine quiescence may assist in the anticipation and prevention of preterm labour. Therapeutic approaches to inhibit uterine contractility in women in preterm labour remain rudimentary [94], based on the use of drugs that are not effective or have potentially serious side effects. We need to increase our understanding of the endocrine and physiological control of parturition in women.

Role of cyclic nucleotides

The importance of cyclic nucleotides (cGMP and cAMP) in smooth muscle function cannot be over-emphasized. These molecules provide rapid intracellular responses to a variety of signals and have profound effects on regulatory proteins through the activation of specific protein kinases. The role of cyclic GMP as a mediator of nitric oxide (NO) [95] effects in myometrium is a matter of controversy. Initial studies suggested a link between NO production, cGMP generation and uterine relaxation [96]. However, cGMP has a much more potent inhibitory role in tracheal and vascular smooth muscle than in myometrium [97,98]. Intravenous nitroglycerin has been used to relax the uterus during postpartum emergencies [99,100] but the use of NO donors for routine tocolysis is not recommended [101].

Cyclic AMP is produced from ATP in response to activation of GPCRs positively coupled to ADCY, and is known to influence a wide range of physiological events including relaxation of myometrial smooth muscle [102]. The actions of cAMP in myometrial cells, as in other cell types, result from the dynamic interplay of multiple ADCY, phosphodiesterases and protein kinase A (PRKA) isoforms that allow spatial and temporal changes in cAMP levels to be translated into compartmentalized responses within the cell. Most of the effects of cAMP are due to its ability to bind to PRKA. The localization of PRKA activity within cells depends on reversible interactions with 'A kinase anchor proteins' (AKAP). Although the evidence that agonist-mediated increases in cAMP result in uterine relaxation is strong, the mechanism of action of cAMP in myometrium is not well known. PRKA–AKAP complexes have been described in pregnant human myometrium [103–105], but there is little information about the physiological targets that become phosphorylated during cAMP-induced relaxation. New lines of research suggest that cAMP interacts with progesterone receptors to regulate COX2 expression in human myometrial cells [106].

G protein-coupled receptors and their second messenger pathways

The uterus has GPCRs for many endogenous agonists and responds with contraction or relaxation depending on the type of G protein and second messenger pathway activated. In general, receptors coupled to G_q are stimulatory through activation of PLCB and receptors coupled to G_s are inhibitory (promote relaxation) via stimulation of ADCY (Table 22.1). Some ligands can activate more than one type of myometrial receptor, creating complex responses depending on the relative abundance and affinity of each receptor subtype and the presence of other agonists competing or interacting with related receptors. G proteins are heterotrimers ($\alpha\beta\gamma$ subunits)

Table 22.1 Examples of G protein-coupled receptors in myometrium and their signalling pathways.*

Endogenous ligands	Receptors	G protein class	Signalling pathway	Effect on myometrial contractility
Amines				
Catecholamines	ADRA1	$G_{q/11}$	↑PLCB/$InsP_3$–Ca^{2+}/DAG–PRKCB ↑PLCD/ $InsP_3$–Ca^{2+}	Stimulation

*This table is not exhaustive and other receptors require further study in human pregnant myometrium [127–129].
ADCY, adenylyl cyclase; ARF6, ADP-ribosylation factor 6; ARHGEF, RHO guanine nucleotide exchange factor; DAG, 1,2-diacylglycerol; GRK, G protein-coupled receptor kinase; $InsP_3$, inositol 1,4,5-trisphosphate; PLCB, phospholipase Cβ; PLCD, phospholipase Cδ; PRKA, protein kinase A; PRKCB, protein kinase Cβ.

and the effects of Gα subunits on PLCB, ADCY and other effectors are modulated by the interaction of Gβγ subunits, especially those liberated from $G_{i/o}$ or G_{12}, with the same or with other effector proteins including ADCY, ARF6, GRK, PLCB, PLCD, phosphatidylinositol kinases and ion channels. For each receptor, the effect on myometrial contractility will depend on the integration of these signals and on the physiological state of the organ under different endocrine influences. Changes in myometrial sensitivity to agonists may be an important mechanism for maintaining the balance between uterine quiescence and contractility. For example, pregnancy induces an increase in the myometrial response to OXT [35] and histamine [95] and a decrease in the response to tachykinins in women [95]. More research needs to be done on the responses of pregnant and non-pregnant human myometrium to selective GPCR agonists and antagonists to build a complete picture.

Receptor-mediated uterine relaxation

The β_2-adrenoceptor (ADRB2) has been a pharmacological target to relax the uterus for many years, using beta-mimetic drugs. Exposure of human pregnant myometrial strips to the β_2 agonist isoproterenol *in vitro* results in a significant decrease in contractile force and in the frequency of spontaneous contractions. Similar effects have been obtained with ritodrine, a beta-mimetic used as a tocolytic agent in preterm labour [107,108]. Table 22.2 lists a number of endogenous ligands that can relax the uterus. Some of these, for example catecholamines and prostaglandins, have complex stimulatory and inhibitory effects due to the presence of multiple receptors in myometrium. Inhibitory receptors such as ADRB2 or the prostaglandin PTGER2 receptors have in common the coupling through $G\alpha_s$ to ADCY. Receptors coupled to $G_{i/o}$ (e.g. α_2-adrenoceptors, ADRA2) inhibit ADCY and decrease cAMP production, favouring uterine contractions; however, in many systems prolonged stimulation of $G_{i/o}$-coupled receptors provokes sensitization of ADCY to subsequent stimulation by other G_s-coupled receptors (heterologous sensitization) [109].

Changes in the sensitivity to endogenous agonists (catecholamines, prostaglandins) operating through ADRB2, PTGER2 and other receptors coupled to cAMP production may be responsible for the transition from uterine quiescence to the onset of labour. This is an attractive hypothesis, although it requires more evidence to support it. Beta-mimetics (ritodrine, terbutaline, salbutamol) were among the earliest agents used clinically to inhibit uterine contractions, but their efficacy is questionable [110]. ADRB2 receptors are widely expressed in many organs, and consequently the use of beta-mimetics in pregnancy is associated with potentially serious cardiovascular, neuromuscular and metabolic side effects. There is contrasting new information to be considered before the possible clinical use of PTGER2 agonists to relax the uterus [111].

Table 22.2 Endogenous and exogenous factors affecting myometrial contractility during labour.

Uterine stimulants
Endogenous
Oxytocin
Prostaglandins
Endothelin
Epidermal growth factor
Exogenous
Oxytocin
Prostaglandins
Uterine relaxants
Endogenous
Relaxin
Nitric oxide
L-Arginine
Magnesium
Corticotrophin-releasing hormone
Exogenous
β-Adrenergic agonists (ritodrine hydrochloride, terbutaline sulfate, salbutamol, fenoterol)
Oxytocin receptor antagonist (atosiban)
Magnesium sulfate
Calcium channel blockers (nifedipine, diltiazem, verapamil)
Prostaglandin inhibitors (indometacin)
Phosphodiesterase inhibitor (aminophylline)
Nitric oxide donor (nitroglycerin, sodium nitroprusside)

Desensitization of GPCRs

Sustained stimulation of GPCRs typically causes desensitization (a reduction in response in the face of a constant stimulus), which protects cells from overstimulation and involves numerous adaptive mechanisms in characteristic time frames. Within seconds to minutes of stimulation, most GPCRs desensitize as a consequence of receptor phosphorylation by G-protein receptor kinases (GRKs) or second-messenger regulated protein kinases which are very abundant in human myometrium [112]. This phosphorylation can inhibit G-protein activation (i.e. cause receptor desensitization), but the most important effect of GRK-mediated phosphorylation is to facilitate the binding of arrestin proteins [113]. This not only prevents G-protein activation but also targets the desensitized receptor for internalization. The consequent reduction in cell surface receptor number can also underlie desensitization in the intermediate time frame of minutes to hours. Over longer periods (hours to days), numerous adaptive processes serve to either reinforce or reverse the earlier desensitization by changing rates of synthesis and degradation of receptors and downstream effectors. Arrestins have many other roles, including acting as scaffolds to facilitate receptor-stimulated activation of mitogen-activated protein kinases (MAPKs) in discrete cellular compartments. This mechanism has been confirmed for bradykinin B_2 receptors in human myometrial cells [114].

One of the difficulties with the use of agonists for $G\alpha_s$-coupled receptors to promote uterine relaxation is the tendency of GPCRs to desensitize and downregulate. This process has been particularly well studied for the ADRB2 receptor but it has long been known to occur with other utero-relaxing receptors such as PTGER2 and PTGIR [115]. The loss of tocolytic effect of ritodrine in women in preterm labour has been known for many years [116].

Summary box 22.3

G protein-coupled receptors are useful pharmacological targets to manipulate uterine activity but the risk of side effects must be considered.

Gap junction proteins

Uterine relaxation in pregnancy may be due to lack of electrical and metabolic coordination between myometrial smooth-muscle cells. Gap junctions are specialized protein channels that facilitate the propagation of electrical activity and the exchange of small molecules between cells. The appearance of gap junctions in myometrium is thought to herald the onset of labour in animals and humans [117–119]. GJA1 (connexin 43) is one of the main structural proteins in gap junctions; its expression in myometrium is stimulated by estradiol and inhibited by progesterone [120]. Studies of *GJA1* gene regulation indicate that the family of activator protein-1 transcription factors is critical in determining the level of GJA1 expression in myometrial cells [121,122]. Retinoic acid upregulates GJA1 expression in human endometrial and myometrial cells probably through nuclear receptors [123,124]. The function of gap junctions is tightly regulated through phosphorylation of specific serine residues at the C-terminus of GJA1. A number of protein kinases are involved in the functional regulation of GJA1, including PRKA, PRKC and MAPK1. Phosphorylation at Ser-368 seems important for translocation of GJA1 from the cytosol and its assembly on the plasma membrane. On the other hand, phosphorylation of GJA1 and other connexins may also trigger internalization and degradation. Activation of MAPK1 in pregnant rat myometrium leads to phosphorylation of GJA1 at Ser-255 and this causes loss of amplitude and synchronization of uterine contractions [125]. In mice, conditional deletion of the *GJA1* gene causes a dramatic delay in parturition [126]. A better understanding of the pathways that regulate GJA1 expression and phosphorylation in human myometrium will clarify the role of these proteins during pregnancy and labour.

Mechanics of normal labour at term

Labour and delivery are not passive processes in which uterine contractions push a rigid object through a fixed aperture. The ability of the fetus to successfully negotiate the pelvis is dependent on the complex interaction of three variables: the powers, the passenger and the passage.

The powers

The powers refer to the forces generated by the uterine musculature. Uterine activity is characterized by the frequency, amplitude (intensity) and duration of contractions. It can be assessed by observation, palpation, external monitors (such as external tocodynamometry, which measures changes in shape of the abdominal wall as a function of uterine contractions and is therefore more qualitative than quantitative), and direct measurement of intrauterine pressure (which requires insertion of a pressure transducer directly into the uterine cavity usually through the cervix after rupture of the fetal membranes). It is generally believed that the more optimal the powers, the more likely a woman is to have a successful vaginal delivery; however, there are few data to support this statement. Classically, three to five contractions in 10 min has been used to define 'adequate' uterine activity in labour, and is seen in around 95% of women in spontaneous labour at term. Various units have been devised to objectively measure uterine activity using an intrauterine pressure transducer, the most common of which is the *Montevideo unit* (the average strength of contractions in mmHg multiplied by the number of contractions per 10 min), which is a measure of average frequency and amplitude above basal tone; 200–250 Montevideo units defines adequate labour [130,131]. The ultimate measure of uterine activity is a clinical one. If uterine contractions are 'adequate', one of two events will occur: either the cervix will efface, dilate and the fetal head will descend, or there will be worsening caput succedaneum (scalp oedema) and/or moulding (overlapping) of the skull bones. The latter situation suggests a diagnosis of cephalopelvic disproportion.

The passenger

The passenger is the fetus. There are several fetal variables that may influence the course of labour and delivery.

1) Fetal size: can be estimated clinically through the use of the four Leopold manoeuvres or by ultrasound.
2) Fetal lie: refers to the longitudinal axis of the fetus relative to the longitudinal axis of the uterus.
3) Fetal presentation: refers to the fetal part that directly overlies the pelvic inlet.
4) Attitude: refers to the position of the head with regard to the fetal spine (i.e. the degree of flexion and/or extension of the fetal head).
5) Position of the fetus: refers to the orientation of the fetal presenting part relative to the maternal pelvis.
6) Station: a measure of descent of the presenting part of the fetus through the birth canal.

The presence of a multifetal pregnancy increases the probability of abnormal lie and malpresentation in labour.

The passage

The passage consists of the bony pelvis (sacrum, ilium, ischium and pubis) and the resistance provided by the pelvic soft tissues (cervix and muscles of the pelvic

floor). Measurements of the various parameters of the female bony pelvis have been made with great precision, both directly in cadavers and through the use of imaging (CT and MRI) in living women, and four distinct shapes have been defined (gynecoid, anthropoid, android and platypelloid). In practice, however, the use of clinical pelvimetry to assess the pelvic shape and capacity is of limited value. The only way to determine whether a given fetus will be able to pass safely through a given pelvis is for a woman to undergo a trial of labour.

Stages of labour

Although labour is a continuous process, for reasons of study and to assist in clinical management, it has been divided into three stages as described by Friedman (Fig. 22.5) [132,133]. The first stage refers to the interval between the onset of labour and full cervical dilatation (10 cm). It has been subdivided into several phases according to the rate of cervical dilatation. The duration and rate of cervical change during the second stage of labour varies between nulliparous and multiparous women (Table 22.3). The second stage refers to the interval between full cervical dilatation and delivery of the infant. The third stage, which refers to delivery of the placenta and fetal membranes, usually lasts less than 10 min, but up to 30 min may be allowed in the absence of excessive bleeding before active intervention is considered.

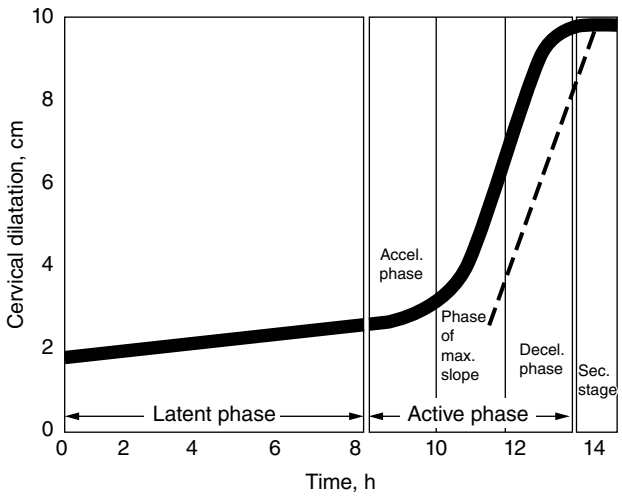

Fig. 22.5 Characteristics of the average cervical dilatation curve for nulliparous labour. The 2-hour 'action line' is shown as a stippled line. *Source:* Friedman EA. *Labor: Clinical Evaluation and Management*, 2nd edn. New York: Appleton-Century-Crofts, 1978. Table 22.3 Progression of spontaneous labour at term.

Parameter	Mean	Fifth percentile
Nulliparas		
Total duration of labour (hours)	10.1 hours	25.8 hours
Duration of first stage of labour	9.7 hours	24.7 hours
Duration of second stage of labour	33.0 min	117.5 min
Duration of latent phase	6.4 hours	20.6 hours
Rate of cervical dilatation during active phase	3.0 cm/hour	1.2 cm/hour
Duration of third stage of labour	5.0 min	30 min
Multiparas		
Total duration of labour (hours)	6.2 hours	19.5 hours
Duration of first stage of labour	8.0 hours	18.8 hours
Duration of second stage of labour	8.5 min	46.5 min
Duration of latent phase	4.8 hours	13.6 hours
Rate of cervical dilatation during active phase	5.7 cm/hour	1.5 cm/hour
Duration of third stage of labour	5.0 min	30.0 min

Cardinal movements in labour

The mechanisms of labour, also known as the cardinal movements, refer to the changes in position of fetal head during its passage through the birth canal. Because of the asymmetry of the shape of both the fetal head and the maternal bony pelvis, such rotations are required for the fetus to successfully negotiate the birth canal. Although labour and birth is a continuous process, seven discrete cardinal movements of the fetus are described: engagement (which refers to passage of the widest diameter of the presenting part to a level below the plane of the pelvic inlet), descent, flexion, internal rotation, extension, external rotation (also known as restitution) and expulsion (Fig. 22.6).

Summary box 22.4

Labour is a clinical diagnosis characterized by regular phasic uterine contractions increasing in frequency and intensity and resulting in effacement and dilatation of the uterine cervix. The ability of the fetus to successfully negotiate the pelvis is dependent on the complex interaction of three variables: the powers, the passenger and the passage.

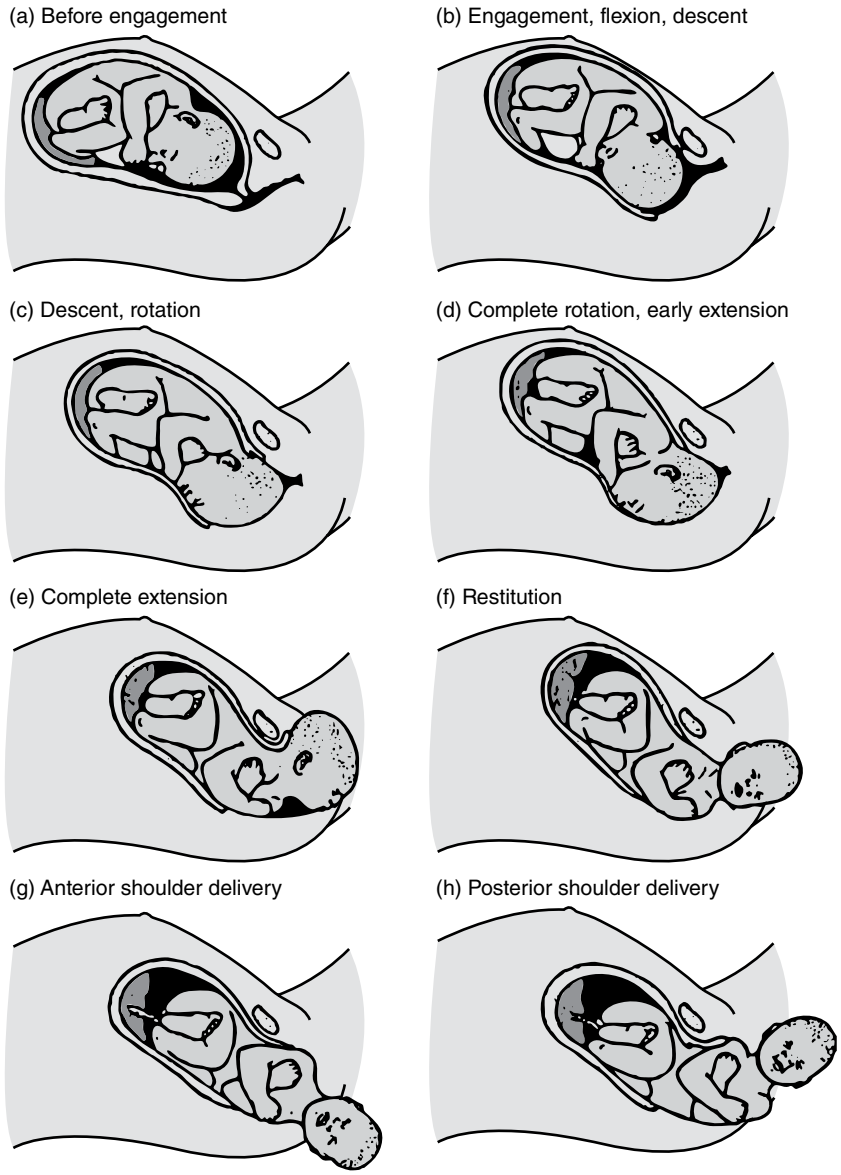

Fig. 22.6 Cardinal movements of the fetus during labour and birth.

Management of uncomplicated labour and delivery

Intrapartum management

Initial assessment in labour should include a focused history (time of onset of contractions, status of the fetal membranes, presence or absence of vaginal bleeding, perception of fetal movement), physical examination and routine necessary laboratory testing (full blood count, blood type). Physical examination should include documentation of the patient's vital signs, notation of fetal position and presentation, an assessment of fetal well-being, and an estimation of the frequency, duration and quality of uterine contractions. The size, lie, presentation and engagement of the fetus should be assessed by abdominal palpation. If there are no contraindications to pelvic examination, the degree of cervical dilatation, effacement, status of the fetal membranes, and the position and station of the presenting part should be noted. If the practitioner is still uncertain about fetal presentation or if the clinical examination suggests an abnormality (such as a multifetal pregnancy, low amniotic fluid volume or intrauterine growth restriction), an ultrasound examination is indicated. Assessment of the quality of uterine contractions and degree of cervical dilatation should be performed at appropriate intervals in order to follow the progress of labour. Vaginal examinations should be kept to a minimum to avoid promoting intra-amniotic infection. Pain management should be

discussed and implemented when desired. The fetal heart rate should be recorded before, during and after a uterine contraction at least every 30 min in the first stage of labour and every 15 min in the second stage.

Clinical assistance at delivery

Preparation for delivery should take into account the patient's parity, presentation of the fetus and the progression of labour. The goals of clinical assistance at delivery are the reduction of maternal trauma, prevention of fetal injury and initial support of the newborn if required. When the fetal head crowns and delivery is imminent, pressure from the practitioner's hand is used to hold the head flexed and to control delivery, thereby preventing precipitous expulsion, which has been associated with perineal tears as well as intracranial trauma. Once the fetal head is delivered, external rotation (restitution) is allowed to occur. If the cord is around the neck, it should be looped over the head or, if not reducible, doubly clamped and transected. Use of suction to clear secretions from the fetal mouth, oropharynx and nares has not been shown to reduce the incidence of meconium aspiration syndrome [134] and, as such, is not routinely recommended. Thereafter, a hand is placed on each parietal eminence and the anterior shoulder of the fetus is delivered with the next contraction by downward traction towards the mother's sacrum in concert with maternal expulsive efforts. The posterior shoulder is then delivered by upwards traction. The infant should be held securely and wiped dry with a sterile towel. The timing of cord clamping is dictated by convenience and is usually performed immediately after delivery.

Delivery of the placenta and fetal membranes

The third stage of labour can be managed either passively or actively. *Passive management* involves waiting for the three classic signs of placental separation (lengthening of the umbilical cord, a gush of blood from the vagina signifying separation of the placenta from the uterine wall, and a change in the shape of the uterine fundus from discoid to globular with elevation of the fundal height) before applying traction to the umbilical cord. *Active management* of the third stage has been shown to reduce total blood loss and the incidence of postpartum haemorrhage [135], but can complicate management in cases involving an undiagnosed second twin or placenta accreta. In active management, uterotonic agents such as OXT are administered at birth to hasten delivery of the placenta. Two techniques of controlled cord traction are described to facilitate separation and delivery of the placenta: (i) the Brandt–Andrews manoeuvre, in which an abdominal hand secures the uterine fundus to prevent uterine inversion while the other hand exerts sustained downward traction on the umbilical cord; or (ii) the Créde manoeuvre, in which the cord is fixed with the lower hand while the uterine fundus is secured and sustained upwards traction applied using the abdominal hand. Care should be taken to avoid avulsion of the cord.

After delivery, the placenta, umbilical cord and fetal membranes should be examined. A missing placental cotyledon or a membrane defect may suggest retention of a portion of the placenta, which can lead to postpartum haemorrhage or infection. In this setting, manual and/or surgical exploration of the uterus may be required to remove the offending tissue. The cervix, vagina and perineum should also be carefully examined for evidence of birth injury. If a laceration is seen, its length and position should be noted and repair initiated. Adequate analgesia (either regional or local) is essential for repair. Special attention should be paid to repair of the perineal body, the external rectal sphincter and the rectal mucosa. Failure to recognize and repair rectal injury can lead to serious long-term morbidity, most notably faecal incontinence.

Conclusions

The timely onset of labour and birth is an important determinant of perinatal outcome. Labour is a physiological and continuous process. The factors responsible for the onset and maintenance of labour at term are not completely understood, and continue to be under active investigation. A better understanding of the mechanisms responsible for the onset of labour will further our knowledge about disorders of parturition, such as preterm and prolonged (post-term) labour, and will improve our ability to secure a successful pregnancy outcome.

Post-term Pregnancy

Aaron B. Caughey

Department of Obstetrics and Gynecology, Oregon Health and Science University, Portland, Oregon, USA

Gestational age is an important determinant of perinatal outcomes. Most attention to this issue has been focused on predicting and preventing preterm births, defined as delivery prior to 37 weeks of gestation. This seems entirely appropriate as preterm birth is the greatest cause of perinatal morbidity, mortality and costs [1,2]. However, post-term births are also associated with increased perinatal morbidity and mortality [3]. Furthermore, post-term pregnancy is easily preventable by delivery of the neonate by induction of labour. Thus this potentially problematic condition of pregnancy deserves further attention, research and careful consideration. This chapter discusses what is known about the existing epidemiology of post-term birth and associated outcomes, the methodological issues related to studying post-term pregnancy, that complications associated with post-term pregnancy rise in a continuous manner as opposed to suddenly at any specific threshold, and the management and prevention of post-term births and future directions for research and clinical care.

Definitions

Post-term pregnancy is currently defined as a pregnancy progressing to 42 weeks (294 days) of gestation or beyond [4]. Other terms such as 'prolonged' or 'post-dates' have also been used but for the sake of nomenclature 'post-term' should be used [5]. Further, although 42 weeks is the current threshold designation for post-term pregnancy, up until the 1980s 43 weeks was the threshold while many clinicians currently use the term to describe pregnancies of 41 weeks' gestation and beyond.

It is sensible that there should be a term to describe the range of 41 to 41^{+6} weeks of gestation, and recently the designation 'late term' was agreed upon and endorsed by the American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal–Fetal Medicine (SMFM) in the USA. This term is in contrast to 'full term', describing pregnancies from 39^{+0} to 40^{+6} weeks of gestation, and 'early term', describing pregnancies from 37^{+0} to 38^{+6} weeks of gestation [6].

Given the wide range of terminology, it is best to always include the gestational age along with the descriptor for clarity, for example 'post-term pregnancy at 42^{+1} weeks gestation' or 'late term pregnancy at 41^{+2} weeks gestation'.

Incidence

In order to accurately determine the 'natural' incidence of post-term pregnancy, there must be meticulous early pregnancy dating, universal follow-up of all pregnancies, and absence of obstetric intervention.

The 14% post-term pregnancy rate quoted for the Hawaiian island Kauai [7] may be regarded as informative because of low rates of obstetric intervention and full follow-up, but lacks correction for potential gestational age dating error. In the UK, the fall in incidence of post-term pregnancy from 11.5% in 1958 [8] to 4.4% in 1970 [9] illustrates the effect of the rise in rates of induction of labour from 13 to 26% over the same period. More recently, in the USA in 2005, 14% of all pregnancies progressed beyond 41 weeks of gestation and just under 6% progressed beyond 42 weeks of gestation [10]. This is lower than the approximately 18% of pregnancies beyond 41 weeks and 10% beyond 42 weeks in 1998, with these changes attributed to increases in the use of induction of labour, but are also partly due to improved early gestational age dating [11,12]. An analysis of 171 527 births in residents of the North-east Thames region in 1989–1991 gave an incidence of 6.2% for post-term pregnancy [13]. In a study of 1514 healthy pregnant women in whom the discrepancy between date of last menstrual period (LMP) and dating based on first-trimester crown–rump

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

length (CRL) was less than –1 to +1 days, the duration of pregnancy was estimated using time-to-event analysis: non-elective delivery was taken to be the event while elective delivery was taken to be censoring [14]. The median time to non-elective delivery was 283 days from LMP. The life-table graph published in this study gives an incidence of post-term pregnancy of about 6%. This study likely underscores the importance of accurate dating in the actual incidence of post-term pregnancy.

As noted earlier, accuracy of gestational age is an important component of determining whether a pregnancy is post-term. This has been demonstrated in several studies of pregnancy dating. For example, one study found that reliance on menstrual dates gave an incidence of post-term pregnancy of 10.7%, whereas the use of basal body temperature (BBT) charts gave a much lower rate of 4.7% [15]. In another study, the routine use of ultrasound to confirm pregnancy dating decreased the overall incidence of post-term pregnancy from 12 to 3% [16]. The impact of BBT or ultrasound dating is likely because women are far more likely to be oligo-ovulatory and have delayed ovulation than polyovulatory with earlier ovulation. Delayed ovulation in any given menstrual cycle would place a pregnancy at an earlier gestational age than that predicted by the first day of the LMP.

Other studies have demonstrated that the use of ultrasound to establish gestational age lowers the incidence of post-term pregnancy. Eik-Nes *et al.* [17] showed that adjustment of dates following measurement of the biparietal diameter at 17 weeks' gestation led to an incidence of post-term pregnancy of 3.9%. Three other studies of routine ultrasound examination for dating have demonstrated a reduction in the rate of false-positive diagnoses of post-term pregnancy, and thereby the overall rate of post-term pregnancy, from 10–15% to approximately 2–5% [18–20]. In a Cochrane review of randomized trials of routine versus selective second-trimester ultrasound, routine second-trimester biometry was found to reduce the number of pregnancies classified as post-term [21].

Moreover, early ultrasound for pregnancy dating may be superior to mid-trimester ultrasound in this regard. In a small prospective randomized trial, Bennett *et al.* [22] demonstrated that routine first-trimester ultrasound for pregnancy dating reduced the incidence of post-term pregnancy from 13% to 5% compared with second-trimester ultrasound dating. In another study, it was demonstrated that not only did first-trimester ultrasound dating lead to lower rates of post-term pregnancy beyond 42 weeks' gestation, but the same was true for diagnosis of pregnancy beyond 41 weeks' gestation [23]. Improved dating also reveals a greater difference in the rate of perinatal complications between term and post-term pregnancies. This is due to the misclassification bias that usually occurs with misdating. Such misclassification of women who are term as post-term and women who are post-term as term both lead to a smaller difference in the rate of complications between term and post-term pregnancies. Thus, older studies of women whose pregnancies did not have dating confirmation by ultrasound underestimate the rates of complications seen in post-term pregnancies. The multicentre First and Second Trimester Evaluation for Aneuploidy Trial (FASTER) studied 3588 women undergoing first-trimester ultrasound [24]. Gestational age determination using CRL as opposed to LMP reduced the apparent incidence of pregnancies greater than 41 weeks' gestation from 22.1 to 8.2% (P <0.001). Of note, ultrasound at 12–14 weeks' gestation, while considered early, can often lead to worse estimates of gestational age than ultrasound at 18–22 weeks. Thus, reliance on standard nuchal translucency ultrasound over an earlier first-trimester ultrasound may be problematic and requires further research.

Summary box 23.1

- Post-term gestation is defined as 42 weeks of gestation and beyond.
- Many other terms, such as 'post-dates' and 'prolonged pregnancy', are used interchangeably with 'post-term'.
- It is likely that many so-called post-term pregnancies are due to misdating.
- Pregnancies with dating confirmed by ultrasound are less likely to become post-term.
- First-trimester ultrasound is even better than second-trimester ultrasound with respect to the prevention of misdiagnosed post-term pregnancy.

Aetiology

It is likely that the majority of post-term pregnancies represent the upper range of a normal distribution. Further, as noted above, the most common 'cause' of post-term pregnancy is inaccurate pregnancy dating. However, it does appear that there are specific associations with a range of predictors that may help point to potential aetiologies of post-term pregnancy.

Rare but classically described causes of post-term pregnancy include placental sulfatase deficiency (an X-linked recessive disorder characterized by low circulating estriol levels), fetal adrenal insufficiency or hypoplasia, and fetal anencephaly (in the absence of polyhydramnios) [25,26].

Genetic factors may also play a role in prolonging pregnancy. In one study, women who were the product of a pregnancy beyond 41 weeks' gestation were more likely themselves to have a pregnancy progress beyond

41 weeks' gestation (relative risk, RR 1.3) [27]. Similarly, women who have had a prior post-term pregnancy are more likely to have another such pregnancy [27,28]. For example, after one pregnancy beyond 41^{+0} weeks of gestation, the risk of a second such pregnancy in the subsequent birth is increased 2.7-fold (from 10 to 27%). If there have been two successive prolonged pregnancies, the incidence rises to 39% [29]. Paternal genes expressed in the fetoplacental unit also appear to influence length of gestation. In a recent Danish case–control study [30] of women with two consecutive births, the risk of a second post-term pregnancy among 21 746 women whose first delivery was post-term was 20% as compared with 7.7% among 7009 women whose first delivery was at term. However, the risk of recurrent post-term delivery was reduced to 15% when the first and second child had different fathers (odds ratio, OR 0.73, 95% CI 0.63–0.84).

Low vaginal levels of fetal fibronectin at 39 weeks are predictive of an increased likelihood of post-term pregnancy [31]. Ramanathan *et al.* [32] showed how transvaginal measurement of cervical length at 37 weeks predicts both post-term pregnancy and failed induction. These observations suggest that a defect or delay in the remodelling of the cervix that takes place prior to successful initiation of labour may cause post-term pregnancy and may also be associated with some of the apparent increase in dystocia associated with post-term pregnancy.

Post-term pregnancy could result from variations in the corticotrophin-releasing hormone (CRH) system during pregnancy, such as alteration in the number or expression of myometrial receptor subtypes, altered signal transduction mechanisms or increase in the capacity of CRH-binding protein to bind and inactivate CRH. Prospective longitudinal studies have shown that women destined to deliver before term tend to have a more rapid exponential rise in CRH in mid-pregnancy while women who go on to deliver post-term babies have a slower rate of rise [33]. Efforts currently directed towards researching the initiation of labour before term may lead to greater understanding of the aetiology of post-term pregnancy.

Epidemiology

There are a number of risk factors associated with post-term pregnancy which may have biological causal association. First among these is nulliparity, with a greater proportion of nulliparas reaching 40, 41 or 42 weeks' gestation and the median duration of pregnancy being 2 days longer in nulliparas compared with multiparas. Recent data have also shown an association with male fetuses [34]. Additionally, it has been described that African-American women have higher rates of preterm delivery [35], raising the possibility that race/ethnicity may be associated with overall gestational age and prolonged pregnancy in particular. One recent study found a decreased risk of post-term pregnancy among African Americans, Asians and Latinas compared with white women [36]. Further, some effects of race/ethnicity have been described to vary between obese and non-obese patients [37]. Obesity has been found to be associated with post-term pregnancy in several studies [38,39]. The association may have actual causality: studies have demonstrated this finding consistently and have shown a dose–response effect, with greater response among women who are obese than those who are overweight.

The theoretical mechanisms for the association between obesity and post-term pregnancy remain unclear. Since adipose tissue is hormonally active [40] and since obese women may have an altered metabolic status, it is possible that endocrine factors involved in the initiation of labour are altered in obese women. The long-noted associations between lower pre-pregnancy body mass index (BMI) and increased spontaneous preterm birth [41,42] are consistent with our findings and may be explained by a common, as yet unknown, mechanism regarding parturition, potentially related to circulating levels of oestrogen or progesterone. Since, evolutionarily, as a species we have evolved to face the environmental pressures of food scarcity, it is likely that the outcomes of a post-term pregnancy rarely served as an evolutionary pressure related to obesity 10 000 years ago when we existed primarily as nomadic tribes with a lower median BMI than today. Thus there is likely little benefit to the fetus for the pregnancy to proceed beyond 42 weeks' gestation, and such post-term pregnancies may be a product of current intrinsic and environmental factors.

Summary box 23.2

Post-term gestation is seen more commonly with:

- anencephaly;
- placental sulfatase deficiency;
- fetal adrenal hypoplasia;
- male fetuses;
- previous post-term pregnancy;
- maternal obesity;
- nulliparity;
- white race.

The aetiology of post-term pregnancy appears to have both a maternal and fetal component. It seems likely that there is some genetic predilection towards post-term pregnancy.

Risks associated with post-term pregnancy

Perinatal mortality

Post-term pregnancy is associated with an increased risk of perinatal mortality, both antepartum stillbirth as well as infant death. There is an important methodological distinction to make when measuring complications by gestational age. Some complications can only happen to women and infants who are delivered at that week of gestation. Other complications can occur to all women who are pregnant at that week of gestation, both those delivering as well as those who remain pregnant. For example, an antepartum stillbirth can occur in anyone who is pregnant at a given gestational age, i.e. in ongoing pregnancies. Alternatively, a neonatal death can only occur to the group that actually delivers at that week of gestation [43]. When considering the outcomes related to post-term pregnancy, we see the association with antepartum stillbirth regardless of how the effect is measured, but when the appropriate denominator of ongoing pregnancies is used, we see the risk of antepartum stillbirth begin to increase earlier at 39 and 40 weeks' gestation. Yudkin *et al.* [44] questioned the validity of using perinatal mortality rates as a means of relating outcome to gestational age, arguing that the population at risk of intrauterine fetal death at a given gestational age is the population of fetuses *in utero* at that gestational week and not those delivered at that week. However, the population at risk of intrapartum and neonatal complications such as cord prolapse or meconium aspiration syndrome is clearly the population of babies delivered at that week of pregnancy [45]. These issues are clearly explained by Smith [45], who related the perinatal risks at each gestational week to the appropriate denominators. Antepartum deaths were related to the number of ongoing pregnancies, intrapartum deaths to all births at that gestational age, excluding antepartum stillbirths, and neonatal deaths were related to the number of live births. Yudkin *et al.* [44] expressed the prospective risk of stillbirth for the next 2 weeks of the pregnancy; Hilder *et al.* [13] expressed the risk as a rate over the next week; Cotzias *et al.* [3] generated considerable controversy [46,47] by expressing the risk of prospective stillbirth for the remainder of the pregnancy. This is a counter-intuitive concept for most obstetricians, whereas many find the concept of the prospective risk of stillbirth over the coming week an accessible concept, particularly in pregnancies of 40–42 weeks' gestation ('If this woman remains undelivered in the next 7 days, what is the chance of a fetal death occurring *in utero*?').

In the broad range of literature, studies which dichotomize gestational age at 42 weeks demonstrate increased perinatal mortality (Table 23.1). The outcomes presented in this table compare pregnancies fulfilling the epidemiological definition of post-term pregnancy with those delivered at 'term'. In modern obstetric practice, women with epidemiological and obstetric risk factors are more likely to be delivered before 42 weeks. Thus women with twin pregnancies, pre-eclampsia, diagnosed intrauterine growth restriction, antepartum haemorrhage or previous perinatal death are likely to be over-represented in the 37–41 week population and under-represented among those delivered at 42 weeks and later, potentially underestimating the increased risks from progressing to the post-term period.

Studies have also examined these outcomes by week of gestation across all term pregnancies by week and demonstrate similar findings (Table 23.2). Specifically, this table addresses the argument that the duration of pregnancy is a continuum and that perinatal risks are unlikely to alter abruptly on day 294 of a pregnancy. Outcomes are presented by week of gestational age from 37 weeks up to and including 43 weeks' gestation. Outcome statistics are presented in a variety of forms as discussed above.

At first sight, it might seem that whether studies have used thresholds like 42 and 43 weeks of gestation or

Table 23.1 Perinatal mortality rates in term versus post-term pregnancies.

Reference	Source	Outcome	37–41 weeks	42 weeks and over

OP, ongoing pregnancies.

examined complications by week was only a matter of whether the strata required increased subgroup sample size due to needs for increased statistical power. However, examining these outcomes by threshold or in a continuous fashion is an important methodological issue. If complication rates increase as gestational age increases, then one would see an increase regardless of what threshold was chosen. And it is true, if one examines stillbirth rates before and after 39, 40, 41, 42 or 43 weeks, there is always a higher rate beyond the threshold. More importantly is how such information can be utilized to inform clinical management. Thus, a comparison of one week to the next is truly what needs to be examined. Are the risks higher of delivering at a given gestational age or of waiting an additional week of gestation? For such comparisons, examining complications week by week is of more use than simply comparing before and after a given threshold.

There are other methodological problems with this literature. Of course, there may be errors or biases in recording of information relating to gestational age. Women with uncertain dates have been repeatedly shown to be at increased risk of perinatal mortality [48,49]. Their inclusion may inflate the apparent perinatal risks of post-term pregnancy. Older studies of perinatal outcome in post-term pregnancy showed that about 25% of the excess mortality risk in post-term pregnancy relates to congenital malformations [25]. Of the studies quoted in Tables 23.1 and 23.2, only that by Smith [45] specifies that cases of lethal congenital malformation have been excluded from the analysis. Hilder *et al.* [46] reanalysed the data presented in their 1998 study [13] after correcting for congenital malformation, showing that the outcomes presented were not biased by fetuses with congenital malformation being preferentially represented among post-term pregnancies. Another potential bias is the interval between intrauterine death and delivery. A fetus that dies *in utero* at 41 weeks and is delivered at 42 weeks will be counted as a perinatal death at 42 weeks' gestation. If this happened regularly, this would suggest that perinatal mortality risks actually increase half a week to a week earlier.

Both tables show that post-term pregnancy is associated with an increased risk of perinatal death. However, there is no consistency between studies as to the timing of that increased risk from fetal death before labour, to antepartum death to early neonatal death or even infant mortality. The studies summarized in Table 23.1 suggest that an increased risk of neonatal death is the main source of the increased perinatal risk. This has been further substantiated by a recent study from California which finds higher rates of infant death in births at

41 weeks and beyond even in a low-risk population [50]. However, Table 23.2 shows that when pregnancies ending at 42 weeks are compared with those delivered at 41 weeks, every adverse outcome is increased with the exception of the 'estimated probability of intrapartum and neonatal death' from the Smith study [45]. When pregnancies ending at 41 weeks are compared with those ending at 40 weeks, this outcome is again unchanged, as is the neonatal mortality rate in multiparas in the Ingemarsson and Kallen series [51] and the infant mortality rate in the Hilder series [13]. All other outcomes deteriorate from 40 weeks to 41 weeks and again from 41 weeks to 42 weeks.

Perinatal morbidity

Epidemiological studies identify birth after 41 weeks or after 42 weeks as a risk factor for a variety of adverse neonatal outcomes. One retrospective cohort study of all low-risk, term, cephalic and singleton births delivered at the University of California, San Francisco, between 1976 and 2001 examined the incidence of adverse neonatal morbidity outcomes at 40, 41 and 42 weeks' gestation and compared these with the rates in pregnancies delivered at 39 weeks' gestation, after controlling for maternal demographics, length of labour, induction, mode of delivery and birthweight (except macrosomia) [52]. Compared with the outcome at 39 weeks' gestation, the relative risk of meconium aspiration increased significantly from 2.18 at 40 weeks to 3.35 at 41 weeks and 4.09 (95% CI 2.07–8.08) at 42 weeks. A composite outcome of 'severe neonatal complications', including skull fracture and brachial plexus injuries, neonatal seizures, intracranial haemorrhage, neonatal sepsis, meconium aspiration syndrome and respiratory distress syndrome, increased from a relative risk of 1.47 at 40 weeks to 2.04 at 41 weeks to 2.37 (95% CI 1.63–3.49) at 42 weeks. Similar findings have been demonstrated in multiple other studies that examined perinatal morbidity including pre-eclampsia, meconium, meconium aspiration syndrome, macrosomia, neonatal acidaemia, need for neonatal mechanical ventilation, caesarean delivery and perinatal infectious morbidity [53–57].

For example, dystocia, shoulder dystocia and obstetric trauma are all increased in post-term pregnancy [58]. Here, the risks increase with increasing fetal weight, but gestational age remains a risk factor independent of birthweight. In a case-matched study of 285 women with uncomplicated singleton post-term pregnancy and spontaneous onset of labour and 855 women with uncomplicated singleton term pregnancy, Luckas *et al.* [59] showed that caesarean delivery was significantly more common in women with post-term pregnancy (RR 1.90, 95% CI 1.29–2.85). The increase was equally distributed between caesarean deliveries performed for failure to progress in labour (RR 0.74, 95% CI 1.02–3.04) and fetal distress (RR 2.00, 95% CI 1.14–3.61). This finding is consistent with the hypothesis that some cases of post-term pregnancy are associated with a defect in the physiology of labour, in addition to any increase in risk of fetal hypoxia. However, the possibility of bias in management arising out of the knowledge that a pregnancy is post-term cannot be excluded as a factor in the increase in caesarean delivery rates.

A strong association between neonatal seizures and delivery at 41 weeks' gestation or more has also been identified in previous case–control studies. Minchom *et al.* [60] found that delivery after 41 weeks' gestation was associated with an odds ratio of 2.7 (95% CI 1.6–4.8). Curtis *et al.* [61] studied 89 babies with early neonatal seizures delivered after 42 weeks' gestation in Dublin; 27 were delivered after 42 weeks' gestation compared with 6 of 89 controls (OR 4.73, 95% CI 2.22–10.05).

Cerebral palsy

Neonatal encephalopathy may be followed by the development of cerebral palsy, while other cases of cerebral palsy may occur following a clinically normal neonatal period. It is accepted that the presence of neonatal encephalopathy indicates that a neurological insult has taken place during labour or the early neonatal period, while its absence is thought to indicate an insult at some earlier time in pregnancy [62]. Gaffney *et al.* [63] examined the obstetric background of 141 children from the Oxford Cerebral Palsy Register; 41 children whose cerebral palsy was preceded by neonatal encephalopathy were compared with 100 who had not suffered from neonatal encephalopathy. The babies with neonatal encephalopathy were more likely to have been delivered at 42 weeks' gestation or more (OR 3.5, 95% CI 1–12.1). Babies born at 42 weeks or more to nulliparous women were at particular risk of this sequence of events (OR 11.0, 95% CI 1.2–102.5).

Effect of parity and birthweight

Whether these outcomes, their rates, peaks and nadirs are affected by other demographics such as maternal age, race/ethnicity, socioeconomic status and medical complications of pregnancy has been minimally studied. However, it has been examined by parity. One series [51] shows that the increasing risks of adverse outcome associated with advancing age of gestation are more marked in nulliparas than in multiparas (Table 23.2). The aetiology for the modification of these outcomes by parity is unclear and could be due to true biological differences or perhaps differences in dating accuracy between the two

groups. Birthweight has also been examined as a modifier of outcomes by gestational age. In an analysis of 181 524 singleton pregnancies with reliable dates delivered at 40 weeks or later in Sweden between 1987 and1992, birthweight of two standard deviations or more below the mean for gestational age was associated with a significantly increased odds ratios for both fetal death (OR 7.1–10.0) and neonatal death (OR 3.4–9.4) [51]. A Norwegian cohort [58] also showed that small-for-gestational age babies were more vulnerable to the risks of post-term pregnancy. In this study, babies weighing less than the 10th centile had a relative risk of 5.68 (95% CI 4.37–7.38) of perinatal death at 42 weeks' gestation or later compared with babies between the 10th and 90th centile at the same gestational age. In this series, birthweight above the 90th centile was associated with the lowest relative risk of perinatal death (RR 0.51, 95% CI 0.26–1.0). These findings make biological sense in that one might suspect that there would be a subgroup of fetuses whose growth is affected due to intrauterine factors that increase the risk for fetal or neonatal demise. The practice pattern of delivering such fetuses at an earlier gestational age is thus supported by such findings.

Summary box 23.3

Post-term gestation is associated with:

- stillbirth;
- caesarean delivery;
- fetal macrosomia;
- meconium-stained amniontic fluid;
- birth trauma;
- neonatal acidaemia;
- cerebral palsy;
- neonatal/infant mortality.

A key methodological point when examining outcomes by gestational age in term and post-term pregnancies is properly determining the population at risk, i.e. *ongoing pregnancies* (all women pregnant at a particular gestational age) or *pregnancies delivered* (just the women who deliver at a particular gestational age). While the outcomes listed are all more frequent in pregnancies at 42 weeks' gestation and beyond, they are also increased (though not as high) in pregnancies at 41 weeks' gestation.

Management

Management of post-term pregnancies actually starts before a pregnancy becomes post-term. The goals of managing such otherwise low-risk pregnancies is to prevent the complications of post-term pregnancy and to prevent post-term pregnancy itself. Thus, the mainstay of management involves the use of antepartum testing to reduce risks of complications from expectantly managing these pregnancies. It also includes reducing the risk of post-term pregnancy through good pregnancy dating, outpatient cervical ripening and induction of labour, all before a pregnancy becomes post-term. These broad topics are discussed next.

Antenatal testing

The evidence of increased perinatal mortality and morbidity in late term and post-term pregnancy compared with delivery at 39 or 40 weeks' gestation inevitably leads to the conclusion that some cases of post-term pregnancy could be prevented by earlier delivery. It would seem logical to use screening tests to identify pregnancies destined to have an adverse outcome and to intervene selectively in these cases.

The ideal test of fetal well-being in post-term pregnancy would allow identification of all fetuses at risk of adverse outcome, at a stage where delivery would result in a universally good outcome. Thus a 'negative' test would indicate that the fetus is safe *in utero* for an interval of a few days until either delivery or a repeat test is performed and that the woman would eventually deliver with a good outcome. At present, no method of monitoring post-term pregnancy is backed up by strong evidence of effectiveness. There is some observational evidence that some pregnancies at risk of adverse outcome can be identified, but less evidence that prediction of the adverse outcome confers prevention.

Fetal movement counting

The least invasive monitoring is maternal assessment of fetal movements, also known as fetal kick counts. This test is used commonly in the supervision of term and post-term pregnancies (Table 23.3) but is not supported by firm evidence of efficacy. Generally, women are asked to count fetal movements once or twice per day and are expected to experience four to six such movements in 20–30 min. Two randomized trials have addressed the question of whether clinical actions taken on the basis of fetal movement improve fetal outcome [64,65]. The larger of these trials involved over 68 000 women [65]. These trials collectively provide evidence that routine formal fetal movement counting does not reduce the incidence of intrauterine fetal death in late pregnancy. Routine counting results in more frequent reports of diminished fetal activity, with a greater use of other techniques of fetal assessment, more frequent admission to hospital and an increased rate of elective delivery. It may be that fetal movement counting in post-term pregnancy will perform more effectively than it does in low-risk

Table 23.3 Randomized trials of routine versus selective induction at 41–42 weeks' gestation.

pregnancies. However, in the end, if this test did demonstrate reduction in perinatal morbidity or mortality, it is likely that such a protocol also leads to maternal anxiety and high rates of false positives.

Cardiotocography

Antenatal cardiotocography (CTG), also known as a non-stress test, has been widely used for more than 20 years to monitor moderate- to high-risk pregnancies. Observational studies have reported very low rates of perinatal loss in high-risk pregnancies monitored in this way [66,67]. Six randomized controlled trials comparing CTG with other methods of antepartum fetal monitoring have been the subject of a Cochrane review [68]. Women with post-term pregnancies were included in these trials. On the basis of the information presented in this review, the antenatal CTG has no significant effect on perinatal outcome or on interventions such as elective delivery. Miyazaki and Miyazaki [69] reported a series of 125 women with post-term pregnancies where a reactive CTG was recorded within 1 week of delivery. Ten adverse outcomes were reported from this group: four antepartum deaths, one neonatal death, one case of neonatal encephalopathy and four cases of fetal distress on admission in early labour. The poor performance of antenatal CTG in this series and in the randomized trials may relate to errors in interpretation or excessive intervals between tests. Numerical analysis using computerized calculations of the baseline rate and variability may reduce the potential for human error [70]. Weiner *et al.* [71] compared the value of antenatal testing with computerized CTG, conventional CTG, biophysical profile scores and umbilical artery Doppler; 337 pregnant women who were delivered after 41 weeks' gestation and who had 610 antenatal tests were included in this study. Of 12 fetuses with reduced fetal heart rate variation on computerized CTG, 10 had a trial of labour. Of these 10 fetuses, nine had fetal distress during labour. Of the 12 fetuses with reduced fetal heart rate variation, seven were acidotic at delivery (umbilical artery pH <7.2).

Overall, there were 10 acidotic fetuses at delivery in the study group. Only two of them had an umbilical systolic/diastolic ratio above the 95th percentile, three had an amniotic fluid index greater than 5, and five had fetal heart rate decelerations before labour. Fetuses who demonstrated an abnormal intrapartum fetal heart rate tracing or who were acidotic at delivery had a significantly higher rate of reduced fetal heart rate variation or decelerations before labour. The authors conclude that computerized CTG may improve fetal surveillance in post-term pregnancy. The obvious criticism of this study is the circular argument of using an antepartum CTG abnormality to predict an intrapartum CTG abnormality.

Ultrasound assessment of amniotic fuid

Ultrasound monitoring of amniotic fluid volume was first described in 1980 when a subjective classification of 'normal', 'reduced' or 'absent' amniotic fluid was described, based on the presence or absence of echo-free space between the fetal limbs and the fetal trunk or the uterine wall [72]. To test the value of the classification, 150 patients with pregnancies of 42 weeks or more underwent ultrasound examination in the 48 hours prior to delivery. The patients classified as having reduced or absent amniotic fluid had a statistically significant excess incidence of meconium-stained liquor, fetal acidosis, and birth asphyxia and meconium aspiration. Manning *et al.* [73] described a semi-quantitative method based on the largest vertical pool of amniotic fluid and used a 1-cm pool depth as the cut-off for intervention in a population of babies with suspected growth restriction. This was subsequently modified to 2 cm to improve detection of the growth-retarded infant [74]. Crowley *et al.* [75] found an increase in adverse outcomes in post-term pregnancies where the maximum pool depth was less than 3 cm. Fischer *et al.* [76] found that a maximum vertical pool of less than 2.7 cm was the best predictor of abnormal perinatal outcome.

Phelan *et al.* [77] described the amniotic fluid index (AFI), the sum of the maximum pool depth in four quadrants. Fischer *et al.* [76] found that maximum pool depth performed better than AFI in predicting adverse outcomes in post-term pregnancies. Alfirevic and Walkinshaw [78] randomly allocated women with post-term pregnancy to monitoring using either maximum pool depth or AFI. Both groups underwent computerized fetal heart rate monitoring every 3 days in addition to amniotic fluid measurements. The threshold for intervention was a maximum pool depth of less than 1.8 cm or an AFI of less than 7.3 cm. These figures had been identified as the third centiles for the local population. The number of women found to have an abnormal AFI was significantly higher than the number found to have an abnormal maximum pool depth and more women underwent induction of labour in the AFI arm of the trial. There were no perinatal deaths and no statistically significant differences in perinatal outcome between the two groups.

Morris *et al.* [79] performed an observational study of 1584 pregnant women at or beyond 40 weeks' gestation in Oxford. Women underwent measurement of amniotic fluid, using both the single deepest pool and AFI. The results of these ultrasound measurements were concealed from caregivers. These authors agreed with Alfirevic and Walkinshaw [78] that more women 'test positive' using AFI than with single deepest pool; 125 women (7.9%) had an AFI of less than 5 cm in contrast to 22 women (1.4%) who had single deepest pool less than 2 cm. There were no perinatal deaths. There were seven cases of severe perinatal morbidity, an incidence of 0.44%. Two of these had an AFI below 5 cm and four had an AFI of less than 6 cm. None of the seven cases had a deepest pool measurement of less than 2 cm, thus emphasizing the trade-off between specificity and sensitivity.

Locatelli *et al.* [80] conducted a similar study, but measured AFI twice weekly from 40 weeks until delivery. A composite adverse outcome of fetal death, 5-min Apgar score less than 7, umbilical artery pH less than 7 and caesarean delivery for fetal distress occurred in 19.8% of those with an AFI below 5 compared with 10.7% of those with an AFI above 5 ($P = 0.001$).

These studies of amniotic fluid after 40 weeks suggest some association between reduction in volume and adverse outcome, but overall it performs with poor sensitivity and specificity. There is no evidence to suggest that it can be relied on as a means of monitoring pregnancies after 41 weeks' gestation. In a meta-analysis of studies on the relationship of amniotic fluid with adverse fetal outcome, Chauhan *et al.* [81] concluded that there was some association between oligohydramnios and an increased risk of caesarean delivery for non-reassuring fetal heart rate patterns and low Apgar scores; however, the data relating to neonatal acidosis were insufficient. Fundamentally, while there is biological plausibility that decreases in amniotic fluid volume may pre-date complications in the term and post-term pregnancy, there are inadequate data to definitively state that such assessment followed by intervention will necessarily affect perinatal outcomes, by how much and with what timing. Furthermore, confidence in ultrasound assessment of amniotic fluid volume is undermined by studies which show a poor correlation between ultrasound AFI and actual amniotic fluid volumes measured by dye-dilution studies [82,83]. Development of a better test to identify the senescent placenta or changing fetal–placental–maternal physiology at term and post-term that will prevent perinatal complications is paramount.

Biophysical profile

Observational studies indicate that low biophysical scores identify babies at higher risk of adverse outcome [84]. However, evidence of ability to predict adverse outcome must not be interpreted as proof of the ability to prevent these outcomes.

A systematic review of four trials, comparing biophysical profile scoring with other forms of antepartum fetal monitoring, yields insufficient data to show that the biophysical profile is better than any other form of fetal monitoring [85]. Only one of these randomized controlled trials deals specifically with post-term pregnancy [78]. This trial compares monitoring of post-term pregnancy using a modified biophysical profile score (consisting of computerized CTG, AFI and the rest of the components of the conventional biophysical profile) with simple monitoring using CTG and measurement of amniotic fluid depth. The more complex method of monitoring post-term pregnancy is more likely to yield an abnormal result, but does not improve pregnancy outcome as evidenced by umbilical cord pH.

An observational study of biophysical profile scoring in the management of post-term pregnancy showed that 32 of 293 women who had abnormal biophysical profiles had significantly higher rates of neonatal morbidity, caesarean delivery for fetal distress and meconium aspiration than the women with reassuring biophysical profiles [86]. A further observational study of 131 post-term pregnancies showed that a normal biophysical profile score was highly predictive of normal outcome, but an abnormal test had only a 14% predictive value of poor neonatal outcome [87].

Doppler velocimetry

Two studies of routine umbilical artery Doppler velocimetry [88,89] in post-term pregnancy indicate that it is of no benefit. In a small observational study comparing the predictive values of CTG, AFI, biophysical profile scoring and the ratio of middle cerebral artery (MCA) Doppler to umbilical artery Doppler, Devine *et al.* [90] found that the ratio of MCA Doppler to umbilical artery Doppler was the best predictor of 'adverse outcome' in this study, defined by meconium aspiration syndrome or caesarean delivery for fetal distress or fetal acidosis.

Prevention of post-term pregnancy

The prevention of post-term pregnancy centres around efforts to ensure that a misdiagnosis is not made from improper pregnancy dating and encouraging the onset of labour prior to post-term pregnancy developing. While the first demands public health action to ensure that all patients have the option to obtain first-trimester ultrasound dating confirmation, widespread adoption of this practice seems limited at this point. However, most women undergo second-trimester ultrasound, which also reduces the risk of being misdiagnosed with a post-term pregnancy, though not as much as first-trimester ultrasound.

Post-term pregnancy can absolutely be prevented by simply inducing all patients before they reach 42 weeks of gestation. This appears to be a reasonable approach, but does carry some costs due to the prolonged admissions to labour and delivery units for induction of labour. A better way of preventing such post-term pregnancies would use techniques to encourage spontaneous labour. Several minimally invasive interventions have been recommended to encourage the onset of labour at term and prevent post-term pregnancy, including membrane stripping, unprotected coitus and acupuncture. *Stripping or sweeping of the fetal membranes* refers to digital separation of the membranes from the wall of the cervix and lower uterine segment. This technique, which likely acts by releasing endogenous prostaglandins from the cervix, requires the cervix to be sufficiently dilated to admit the practitioner's finger. Although stripping of the membranes may be able to reduce the time interval to spontaneous onset of labour, there is no consistent evidence of a reduction in operative vaginal delivery, caesarean delivery rates, or maternal or neonatal morbidity [91–93]. *Unprotected sexual intercourse* causes uterine contractions through the action of prostaglandins in semen and potential release of endogenous prostaglandins similar to stripping of the membranes. Indeed, prostaglandins were originally isolated from extracts of prostate and seminal vesicle glands, hence their name. Despite some conflicting data, it appears that unprotected coitus may lead to the earlier onset of labour, reduction in post-term pregnancy rates, and less induction of labour [94–96]. In one small randomized trial which attempted to address this question, women were randomized to a group advised to have coitus versus a control group which was not. In this study, the women advised to have coitus did so more often (60% vs. 40%), but there was no measurable difference in the rate of spontaneous labour in this underpowered study [97]. Similarly, the efficacy of *acupuncture* for induction of labour cannot be definitively assessed because of the paucity of trial data and requires further examination [98,99].

Ultrasound to establish accurate gestational age

The first step towards managing post-term pregnancy is to reduce the number of cases of post-term pregnancy by providing ultrasound verification of gestational age for all pregnancies. A systematic review shows that routine second-trimester ultrasound reduces the number of cases of post-term pregnancy [21]. A recent randomized controlled trial of first- versus second-trimester ultrasound showed a lower rate of post-term pregnancy in pregnancies dated by first-trimester ultrasound [22].

A secondary analysis of data from the FASTER trial showed that first-trimester ultrasound determination of gestational age by CRL as opposed to LMP reduces the apparent incidence of pregnancies greater than 41 weeks from 22.1% to 8.2% [24]. It does seem that obtaining a first-trimester ultrasound to assess viability and gestational age at the first visit is a good idea and may impact the overall number of diagnosed post-term pregnancies.

Induction of labour for post-term pregnancy

Given that a patient cannot have a stillbirth at 42 weeks if she is induced at 41 weeks, induction of labour has been identified as the principal intervention to reduce perinatal morbidity from post-term pregnancy. However, there is concern that such inductions of labour are in turn driving up the caesarean delivery rate. Thus, obstetric providers have responded in various ways to the apparently increased perinatal mortality and morbidity associated with post-term pregnancy. Such potential clinical options include induction at term to prevent pregnancies reaching 42 weeks, routine induction at 41 or 42 weeks or shortly before, and selective induction at 41 or 42 weeks in cases identified by tests as being at risk of adverse outcome. Fortunately, the benefits and hazards of some of these strategies have been evaluated in randomized controlled trials. Randomized or quasi-random trials comparing elective induction at term versus expectant management, and elective induction after 41 weeks versus monitoring of post-term pregnancies were identified using the search strategy described by the Cochrane Pregnancy and Childbirth Group and formed the basis of a systematic review of management options in post-term pregnancy [100]. The main outcomes of interest are those already identified in the analysis of post-term pregnancy risks: perinatal mortality, neonatal encephalopathy, meconium-stained amniotic fluid, caesarean delivery. In addition, evidence was sought relating to the effect of the various management options on maternal satisfaction. Subsequently, there have been other systematic reviews of randomized trials comparing induction of labour with expectant management in pregnancies of 41 weeks' gestation and more [101] or 41 weeks' gestation or less [102].

One major concern regarding induction of labour has been that of increased risk of caesarean delivery. However, this conclusion has not been universally accepted [103]. One component of the concern regarding induction of labour is the large number of retrospective studies which demonstrate higher rates of caesarean delivery in the induced patients [104,105]. The methodological problem with these studies is that they generally compare women who are induced to those in spontaneous labour [106]. A recent study which compared women who were induced with those who underwent expectant management actually found lower rates of caesarean delivery in the women who were induced [107]. Further, in a recent meta-analysis of three small studies of elective induction of labour prior to 41 weeks' gestation, induction of labour led to lower rates of caesarean delivery [108].

An alternative approach to the prevention of post-term pregnancy is selective or preventive rather than routine induction of labour at an earlier gestational age. In a small preliminary study of active management of risk in pregnancy at term (AMOR-IPAT) in which induction of labour at 41 weeks was recommended for all women with risk factors for cephalopelvic disproportion or intrapartum non-reassuring fetal testing, Nicholson *et al.* [109] were able to decrease the caesarean delivery rate from 17% in the expectantly managed group (induction rate, 26%) to 4% in the risk-factor managed group (induction rate, 63%).In a recent, prospective, randomized controlled trial, there was a trend towards lower caesarean rates in the risk-factor managed group, but the study was underpowered for this outcome [110]. However, it did find lower rates of admission to neonatal intensive care and an improved adverse outcome index in the risk-factor managed group, which was induced in the majority of cases.

Induction of labour at 41 weeks

Sixteen randomized trials comparing 'routine' induction of labour at a specified gestational age with a policy of selective induction of labour in response to an abnormal antepartum test are summarized in Table 23.3. These trials form the basis of a systematic review by Sanchez-Ramos *et al.* [101]. Twelve of them had been previously included in the Cochrane review by Crowley [100]. One trial is larger than all others and contributes considerable weight to both meta-analyses [111]. Both meta-analyses adopt an inclusive approach and include trials of variable size and quality. The gestational age at trial entry varies from 287 to 294 days' gestation. A variety of methods of antepartum fetal testing are used to supervise pregnancies in the expectant arm of the trials.

As noted above, it could be costly to routinely induce all women at 41 weeks' gestation. However, a study found routine induction of labour at 41 weeks' gestation to be cost-effective (i.e. more costly than not, but worth the improved outcomes) when compared with expectant management [112]. Routine induction of labour at 41 weeks' gestation was also included in recent recommendations from ACOG to safely reduce the primary caesarean delivery [113].

Induction at or before 40 weeks

Pre-emptive induction of labour, where women with uncomplicated pregnancies were routinely offered induction at or before 40 weeks, was practised in some

obstetric units in some countries in the 1970s. Six randomized trials compare a policy of 'routine' induction at 39 weeks [114,115] or 40 weeks [116–119], with either 'expectant' management of an indefinite duration or expectant management until 42 weeks' gestation. These trials reveal no evidence of any major benefit or risk to 'routine' induction at 40 weeks. Two perinatal deaths of normally formed babies occurred in the expectant arm of these trials and none in the induction arm. Obviously, this is not a significant difference. There was no effect on rate of caesarean delivery (OR 0.60, 95% CI 0.35–1.03), instrumental delivery or use of analgesia in labour. Not surprisingly, given the relationship between gestational age and meconium staining of the amniotic fluid in labour, induction around 40 weeks reduces the incidence of meconium staining in labour (OR 0.50, 95% CI 0.31–0.86). Unfortunately, the authors of these trials did not address the important question of women's views of induction of labour at this stage of pregnancy. The authors therefore missed a golden opportunity in failing to measure women's satisfaction with their care. 'Routine' induction of labour at 40 weeks would no longer be considered a realistic option for the prevention of post-term pregnancy. The number of inductions at 40 weeks required to prevent an adverse outcome at 41 or 42 weeks would be excessive and intervention at this level would be unlikely to be welcomed by women, obstetricians or midwives. Currently, a large prospective trial of this question – routine induction of labour at 39 or 40 weeks' gestation versus expectant management – is being conducted in the USA.

Induction of labour and perinatal morbidity and mortality

Even the largest trial [111] has insufficient statistical power to detect a significant reduction in the perinatal mortality rate. To have an 80% chance of detecting a 50% reduction in a perinatal mortality rate of 3 per 1000, a sample size of 16 000 is required. Table 23.3 records the 13 perinatal deaths that occurred in the randomized trials, three among 3159 women allocated to induction and 10 among 3067 women allocated to selective induction. One normally formed baby, among those allocated to induction [120], died from asphyxia following emergency caesarean delivery for meconium-stained amniotic fluid and bradycardia 2 hours after induction of labour. The other two deaths among those allocated to routine induction occurred in babies with lethal congenital anomalies. Three further deaths occurred in babies with anomalies among those allocated to selective induction. The other seven deaths occurred in normally formed babies. Two deaths in the Canadian Post-term Pregnancy Trial [111] occurred despite adherence to the monitoring protocol of daily movement counting and three times weekly CTG and ultrasound assessment of amniotic fluid volume. These babies were both small, weighing 2600 and 3175 g. In the trial by Dyson *et al.* [121], a neonatal death from meconium aspiration occurred in a 43-week baby delivered for acute fetal bradycardia following spontaneous labour. Fetal heart rate monitoring and ultrasound assessment of amniotic fluid had been reassuring 48 hours before the spontaneous onset of labour. One of the deaths in the trial by Henry [122] was attributed to gestational diabetes. The second occurred due to meconium aspiration in a woman who refused induction following detection of meconium at amnioscopy. The deaths in the trials by Bergsjo *et al.* [123] and Cardozo *et al.* [124] were due to pneumonia and abruptio placentae, respectively.

The authors of systematic reviews adopt a different approach to the inclusion of perinatal deaths in babies with fetal abnormalities. These are excluded in the Cochrane review [100] and included by Sanchez-Ramos *et al.* [101]. Thus, the Cochrane systematic review shows that induction of labour is associated with a significant reduction in perinatal mortality in normally formed babies (OR 0.23, 95% CI 0.06–0.90), while Sanchez-Ramos *et al.* confirm the reduction in risk of perinatal death (0.9 vs. 0.33%) but with the 95% confidence intervals for the odds ratio of 0.41 crossing unity (95% CI 0.14–1.28).

Both systematic reviews report a significant reduction in the incidence of meconium-stained amniotic fluid but this does not affect the rate of meconium aspiration (0.82, 95% CI 0.49–1.37) [100]. There is no effect on fetal heart rate abnormalities during labour. The odds ratio for neonatal jaundice (3.39, 95% CI 1.42–8.09), based on the small number of trials that reported this outcome, indicate that it is increased by induction. The systematic reviews do not show any beneficial or hazardous effects on Apgar scores, neonatal intensive care admission or neonatal encephalopathy.

Effect of induction of labour on risk of caesarean delivery

Sanchez-Ramos *et al.* [101] report that induction of labour is associated with a reduction in the rate of caesarean delivery (OR 0.88, 95% CI 0.78–0.99). Crowley [100] reported a similar outcome, but interpreted it as evidence that a policy of 'routine' induction of labour does not increase the likelihood of caesarean delivery. She believed that a post-randomization bias in the Hannah trial [111] may have weighted the results towards a spurious reduction in risk of caesarean delivery. Women in the expectant arm of the Hannah trial who required induction because of abnormal antenatal tests were denied vaginal prostaglandins whereas those allocated to 'routine' induction were treated with prostaglandin E_2. This could potentially lead to an increase in dystocia or failed induction in those denied prostaglandins. However, this does

not account for the 8.3% rate of caesarean delivery for fetal distress in the selective induction arm of the Hannah trial compared with 5.7% in the routine induction arm. The effect of a policy of induction of labour on reducing the rate of caesarean delivery for fetal distress is consistent across the trials reviewed. No significant heterogeneity was detected by Sanchez-Ramos *et al.* [101]. These authors also performed funnel plots, which were symmetric, indicating no evidence of publications bias.

Because the reduced rate of caesarean delivery associated with induction of labour is contrary to a traditionally held view among obstetricians that induction of labour increases the likelihood of delivery by caesarean section, a number of secondary analyses were carried out by Crowley [100]. These showed that induction of labour for post-term pregnancy does not increase the caesarean delivery rate, irrespective of parity, cervical ripeness, method of induction or ambient caesarean delivery rates. As noted above, routine induction of labour at 41 weeks' gestation was also included in recent recommendations from ACOG to safely reduce the primary caesarean delivery [113].

Women's views of induction for post-term pregnancy

Regrettably, randomized trials give little information on women's views of induction versus conservative management. Only one trial assessed maternal satisfaction with induction of labour [124]. These authors showed that satisfaction was related to the eventual outcome of labour and delivery, rather than to the mode of onset of labour. Women's views are likely to be influenced by the local culture, by the attitude of their caregivers and by practical considerations such as the duration of paid maternity leave. Few obstetricians, midwives or childbirth educators are capable of giving women unbiased information about the risks of post-term pregnancy and the benefits and hazards of induction of labour. In a prospective questionnaire study of women's attitudes towards induction of labour for post-term pregnancy, Roberts and Young [125] found that despite a stated obstetric preference for conservative management, only 45% of women at 37 weeks' gestation were agreeable to conservative management if undelivered by 41 weeks. Of those undelivered by 41 weeks' gestation, 31% still desired conservative management. This significant decrease was unaffected by parity or certainty of gestational age. In a subsequent study, Roberts *et al.* [126] offered women a choice between induction and conservative management at 42 weeks; 45% of women opted for conservative management. Certainly, an intervention that is common practice in more than 20–25% of pregnancies in most developed countries deserves more study with respect to its impact on women as well as the neonates who are the product of these pregnancies.

Post-term pregnancy and home birth

There is a lack of good-quality epidemiological evidence on the outcome of post-term pregnancy when delivery occurs at home. Bastian *et al.* [127] used multiple methods of case identification and follow-up to assemble a population-based cohort of 7002 home births in Australia; 50 perinatal deaths occurred, giving a perinatal mortality rate of 7.1 per 1000. Of 44 perinatal deaths in women of known gestational age, seven (15.9%) occurred post-term (≥42 weeks). A study conducted among Native Americans examined an increase in perinatal mortality in home births attended by midwives compared with those attended by doctors and identified post-dates pregnancies, breech deliveries and twins as the source of the difference in mortality rates between the two groups [128]. Given these relatively weak findings combined with the overall evidence regarding post-term pregnancy and intrapartum complications and perinatal morbidity and mortality, many home birth providers will refer such patients to an in-hospital practice.

Summary box 23.4

Antenatal testing

The following tests are often started at 40–41 weeks of gestation:

- fetal movement or 'kick' counts;
- CTG or non-stress test;
- assessment of amniotic fluid volume;
- biophysical profile.

Post-term pregnancy

Post-term pregnancy may be prevented by:

- induction of labour;
- stripping/sweeping the membranes;
- vaginal intercourse;
- accupuncture.

While induction of labour has been asociated with caesarean deliveries in previous retrospective literature, current prospective literature supports the premise that caesarean delivery is lower among those induced at 41 or 42 weeks' gestation compared with those managed expectantly beyond these thresholds.

Clinical guidelines for management of post-term pregnancy

Following the publication of the Canadian Post-term Pregnancy Trial [111] and the Cochrane review on post-term pregnancy management [114], the Society of Obstetricians and Gynaecologists of Canada (SOGC) issued a clinical practice guideline [129] that recommended the following.

1) After 41 weeks' gestation, if the dates are certain, women should be offered elective delivery.
2) If the cervix is unfavourable, cervical ripening should be undertaken.
3) If expectant management is chosen, assessment of fetal health should be initiated.

The Royal College of Obstetricians and Gynaecologists (RCOG) issued a clinical guideline on induction of labour in 2001 that included recommendations on management of post-term pregnancy [130].

1) Ultrasound to confirm gestation should be offered prior to 20 weeks, as this reduces the need for induction for perceived post-term pregnancy.
2) Women with uncomplicated pregnancies should be offered induction of labour beyond 41 weeks.
3) From 42 weeks, women who decline induction of labour should be offered increased antenatal monitoring, consisting of twice-weekly CTG and ultrasound estimation of maximum amniotic pool depth.

The ACOG Practice Guidelines [5] are somewhat similar, but specifically include the following.

1) The definition of post-term pregnancy should remain at 42 weeks of gestation and beyond.
2) Women with post-term pregnancies who have unfavourable cervices can either undergo labour induction or be managed expectantly.
3) Prostaglandins can be used in post-term pregnancies to promote cervical ripening and induce labour.
4) Delivery should be effected if there is evidence of fetal compromise or oligohydramnios.
5) Despite a lack of evidence that monitoring improves perinatal outcome, it is reasonable to initiate antenatal surveillance of post-term pregnancies between 41 weeks and 42 weeks' gestation because of evidence that perinatal morbidity and mortality increase as gestational age advances.
6) Recent ACOG guidelines regarding reducing the caesarean delivery rate suggest that routine induction of labour at 41 weeks' gestation is indicated.

The SOGC guidelines provoked an impassioned response [103]. These authors challenged the evidence of increased morbidity and mortality as pregnancy advances and the evidence from randomized trials that induction of labour post-term does not increase caesarean delivery rates and may reduce perinatal mortality rates. In particular, they were concerned that the recommendation from SOGC and RCOG that induction should be 'offered' at 41 weeks' gestation would be interpreted as a policy of mandatory induction at 41 weeks' gestation.

Thus, these three professional organizations, each with presumably capable and thoughtful members, arrived at a range of varied conclusions. Certainly this suggests, at the very least, there is a need for further research in this area, both on the effects of induction of labour, but also in ways to screen and prevent complications in late term and post-term pregnancies.

Practical management of post-term pregnancy

The RCOG recommendations are an excellent guide to practice. Every effort should be made to ensure that dates are as accurate as possible. When a woman reaches 41 weeks she should meet with a consultant obstetrician. Women have a right to be informed of the small increase in risk associated with continuing the pregnancy after 41 weeks. Thornton and Lilford [131] showed that pregnant women are much more risk averse than their caregivers. Following a vaginal examination, induction of labour should be offered on a date after 41 weeks that is acceptable to both the woman's wishes and the hospital resources. The vaginal examination could be accompanied by sweeping of the membranes, provided women are warned about the discomfort associated with this and are agreeable to proceed. Membrane sweeping reduces the need for 'formal' induction of labour [93]. The vaginal examination allows the obstetrician to inform the woman of the likely ease and success of induction of labour. For women who have previously delivered vaginally and for women with a favourable cervix, induction of labour is unlikely to be a difficult process. Women who wish to avoid induction of labour should be supported but should be made aware of the lack of reliability of antenatal tests and the lack of evidence that avoiding induction of labour reduces the risk of caesarean delivery. As induction of labour with prostaglandins is associated with an increased risk of uterine scar dehiscence compared with spontaneous onset of labour [132], women who have had a previous caesarean delivery, especially those with no vaginal deliveries, require carefully individualized management at 41 weeks' gestation.

Induction and Augmentation of Labour

Jane E. Norman and Sarah J. Stock

MRC Centre for Reproductive Health, University of Edinburgh Queen's Medical Research Institute, Edinburgh, UK

Definition

Induction of labour is defined as the artificial initiation of labour [1]. It is performed when it is considered that there are benefits to the baby and/or mother if the baby is delivered, compared with the alternative of the baby remaining *in utero*. Rates of induction of labour have increased over a 10-year per period in the UK, from 15.4% in 2003–2004 to 21.2% in 2013–2014 [1]. Rates of induction of labour for singleton pregnancy were 23.3% in the USA in 2010, but with modest declines in the following two years [2].

Indications for induction of labour

The UK, the USA and the World Health Organization (WHO) have produced guidelines on the indications and methods for this common clinical procedure [3–5]. Possible indications for induction of labour include a range of conditions associated with maternal or fetal compromise (Table 24.1), although the risks and benefits of induction in many of these particular scenarios have not been fully evaluated in randomized trials. In practice, the timing of induction requires careful clinical judgement, and it is not always obvious at which point in these disease or physiological processes that the interests of the mother or baby, or both, will be better served by ending the pregnancy by induction of labour.

In practice, clinical conditions are not the only factors affecting induction rates, with one recent study suggesting that over 25% of the variation in induction rates is unexplained by such factors [6]. This variation may reflect differences in physicians' willingness to induce labour for maternal or caregiver convenience, greater or lesser demand from women for induction of labour in different areas, or uncertainties about the benefits and risks of induction across a range of scenarios.

Contraindications to induction of labour

There is greater consensus about the contraindications to induction of labour. Contraindications relate either to factors which make labour or vaginal delivery unsuitable or to indications for immediate delivery (these latter include complete placenta praevia, vasa praevia, transverse fetal lie, umbilical cord prolapse and previous classical caesarean section). The American College of Obstetricians and Gynecologists (ACOG) also includes 'previous myomectomy entering the endometrial cavity' as a contraindication to labour induction [4]. These contraindications are absolute and are fairly uncontroversial. In clinical practice, however, a frequent but challenging scenario is the woman with a previous caesarean section; such women commonly present with recognized indications for induction but are at increased risk of uterine rupture. Their management is discussed further in the section on induction of labour in the presence of previous caesarean section.

Predicting success of induction of labour

Induction of labour is most successful when the cervix is 'ripe' at the time of labour induction [7,8]. Ripening is the process by which the cervix changes in consistency prior to the onset of labour: collagen content and cross-linking decline and water content increases [9]. Physiologically, this facilitates the cervix being progressively dilated by contractions of the myometrium once labour starts. Prior to the onset of labour, ripeness can be measured by using a strain gauge to determine the force required to dilate the cervix. In clinical practice, however, the most commonly used assessment of cervical ripening is the Calder modification of the Bishop score [8] (Table 24.2). This score comprises five components of the cervix, all

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 24.1 Potential indications for induction of labour.

assessed on vaginal examination: cervical length, dilation, position, consistency and its station relative to the ischial spines. Labour induction with an unripe cervix will require more uterine activity to effect cervical dilation, potentially causing a longer labour, more pain and stress for both mother and baby, a higher risk of uterine rupture and evidence of an increased odds ratio (OR) of delivery by caesarean section (2.29, 95% CI 1.53–3.41) [10]. Despite this, one systematic review has suggested that the Bishop score is a poor predictor of the outcome of induction of labour at term and should not be used [11].

Given the deficiencies of the Bishop score, ultrasound measurement of cervical length is a superficially more attractive option to predict success of induction of labour. A variety of cervical lengths, ranging from 16 to 32 mm, have been used to indicate cervical ripeness. When these varying cervical lengths are assessed together, a 'short' cervical length predicts success and a 'long' cervical length predicts failure of labour induction, with a likelihood ratio (LR) of success after a positive test of 1.66 (95% CI 1.20–2.31) and after a negative test of 0.51 (95% CI 0.39–0.67) [12]. These data are based on results from 19 trials and 3065 women, with 'success' in labour induction being defined variously as achieving vaginal delivery, achieving delivery with 24 hours of labour induction, or achieving the active stage of labour. Although there is a statistically significant association between an ultrasound measurement of short cervical length and the success of induction, the predictive value of these measurements do not support the clinical use of this test in practice. It is widely considered that a diagnostic test should have a positive LR of 5 or greater or a negative LR of 0.2 or less to be clinically useful; ultrasound measurement of cervical length for predicting success of induction of labour is clearly suboptimal when measured against this standard [13].

A systematic review of randomized controlled trials to compare Bishop score with any other method for assessing pre-induction cervical ripening in women admitted for induction of labour identified only two trials (both comparing transvaginal ultrasound with Bishop score) [14]. The total number of women recruited was less than 250. No superiority of one test over the other was demonstrated in total.

Analysis of cervico-vaginal fluid insulin-like growth factor-binding protein (IGFBP)-1 has also been used to predict the success of induction of labour in a population of 193 nulliparous women. IGFBP-1 is associated with an adjusted OR of 5.5 (95% CI 2.3–12.9) in predicting vaginal delivery, after adjustement for cervical length on ultrasound and Bishop score [15]. More studies need to be done to determine any potential role in clinical practice.

To summarize, neither the Bishop score nor (currently) transvaginal ultrasound are effective as tools to predict success of induction of labour. This does not mean that the Bishop score should be abandoned, as it may be useful in determining whether the cervix is ripe or whether further doses of prostaglandins are required to achieve ripeness. However, alternative, more effective tests to predict the outcome of induction of labour would undoubtedly be helpful.

Pharmacological and mechanical methods of induction of labour

In order to reduce the risk of adverse events associated with labour induction with an unripe cervix, induction is often preceded by strategies to induce cervical ripening. In the UK, this is most commonly achieved with prostaglandins, normally intravaginal prostaglandin (PG)E_2. There has been increasing use of prostaglandins in association with induction of labour in Scotland over the last three decades [16].

In the USA, a wider variety and routes of administration of prostaglandins are endorsed, including

Table 24.3 Pharmacological agents for cervical ripening.

Agent	Route of administration	Dose	Maximum dose
PGE_2 tablets	Intravaginal	3 mg every 6 hours	6 mg
PGE_2 gel (dinoprostone)	Intravaginal	1 mg every 6 hours	3 mg (4 mg in unfavourable primigravidae)
PGE_2 controlled-release pessary (dinoprostone)	Intravaginal	Pessary releases 10 mg in 24 hours	One
PGE_1 (misoprostol) tablets*	Intravaginal	25 μg every 3–5 hours	None stated
PGE_1 (misoprostol) vaginal delivery system	Intravaginal	200 μg released at rate of about 7 μg/hour over 24 hours	One
PGE_2 (dinoprostone)*	Intracervical	0.5 mg every 6–12 hours	1.5 mg

*US practice.

intracervical and intravaginal PGE_2 and intravaginal misoprostol tablets. Oral administration of prostaglandins is not normally recommended for labour induction at term because it is associated with gastrointestinal side effects. Commonly used dose regimens in the UK and USA are shown in Table 24.3.

Prostaglandins for cervical ripening and induction of labour

The efficacy of prostaglandins for cervical ripening was shown in a seminal paper by Calder *et al.* [17]. Although highly effective in this regard, the cervical ripening effects of prostaglandins cannot easily be separated from their stimulatory effect on uterine contractions and it is largely this that causes the potential adverse effects of induction of labour with prostaglandins. Excessive uterine contractions are termed 'hyperstimulation' and can be associated with abnormalities of fetal heart rate (FHR). In some women, an abnormal FHR may require immediate delivery by caesarean section.

There are now extensive trial data on the use of prostaglandins for induction of labour. Demonstrated benefits of PGE_2 for cervical ripening compared with placebo or no treatment include a 'probable' reduced risk of vaginal delivery not being achieved within 24 hours, a 'probable' reduced risk of caesarean section and an increased risk of uterine hyperstimulation with FHR changes (4.8% vs. 1.0%; risk ratio, RR 3.16, 95% CI 1.67–5.98] [18].

Summary box 24.1

Prostaglandins for induction of labour reduce the risk of the woman not being delivered within 24 hours of the start of induction and reduce the requirement for caesarean section, but increase the risk of uterine hyperstimulation with FHR changes.

When formulations of vaginal PGE_2 are compared, the latest Cochrane review suggests that 'tablets, gels and pessaries appear to be as effective as each other, any differences between formulations are marginal but may be important' [18].

In another Cochrane review, intracervical PGE_2 has been shown to be superior to placebo for cervical ripening, but inferior to vaginal prostaglandin in terms of the risk of not achieving vaginal delivery within 24 hours (RR 1.26, 95% CI 1.12–1.41) [14], leading the National Institute for Health and Care Excellence (NICE) to conclude that 'intracervical PGE_2 should not be used for induction of labour'.

The effects of vaginal or oral PGE_1 (commonly administered as misoprostol) are similar to those of PGE_2 when placebo is used as the direct comparator of each; in other words PGE_1 also reduces the risk of vaginal delivery not occurring within 24 hours compared with placebo [19,20]. However, direct comparison between vaginal PGE_2 and vaginal misoprostol shows that labour induction with vaginal misoprostol is associated with a lower likelihood of vaginal birth not occuring within 24 hours (RR 0.77, 95% CI 0.66–0.89) and a trend to a greater risk of uterine hyperstimulation with FHR changes (RR 1.43, 95% CI 0.97–2.09) [21]. A systematic review of randomized comparisons demonstrated lower caesearean section rates with oral misoprostol compared with vaginal PGE_2 (RR 0.88, 95% CI 0.78–0.99) [20]. This same systematic review suggested that trials comparing vaginal misoprostol with oral misoprostol showed fewer babies with a low Apgar score and lower rates of postpartum haemorrhage in the oral group, but heterogeneous results for vaginal delivery within 24 hours and caesearan section rates [20]. In a sytematic review and network meta-analysis comparing prostaglandins, the odds of failing to achieve a vaginal delivery were lowest with vaginal misoprostol and the odds of caesarean section were lowest with titrated oral misoprostol [22]. A newly marketed slow-release formulation

of misoprostol [23] now has licencing approval in the UK and some other European countries, but has not yet been comprehensively compared with other formulations of vaginal prostaglandin for labour induction.

Authorities in the UK and USA have come to different conclusions about the benefits of misoprostol over and above those of PGE_2. In the UK, NICE currently recommend that misoprostol not be used routinely except in the situation of intrauterine fetal death. In contrast, ACOG endorses the use of misoprostol for induction of labour in a woman with an unfavourable cervix (assuming there has been no previous uterine surgery) [4]. Cochrane suggests that if misoprostol is being used, that oral is 'safer' than vaginal, and a dose of 20–25 μg in solution is most appropriate [20].

Other methods of cervical ripening and induction of labour

Various alternative induction strategies have been investigated in order to avoid the stimulatory effects of prostaglandins on uterine contractions and hence avoid the adverse effects of prostaglandins in labour induction. Mechanical methods commonly involve extra-amniotic saline solution infusion and laminaria, the hygroscopic dilator or extra-amniotic Foley catheter placement or cervical ripening balloon. Enthusiasm for the Foley catheter as a cervical ripening/pre-induction agent has increased following the publication of a large randomized trial demonstrating similar section rates to those observed with PGE_2, but with fewer maternal side effects [24]. A subsequent randomized trial compared the Foley catheter to oral misoprostol for labour induction, and again showed similar rates of adverse effects [25]. Importantly, a network meta-analysis comparing the Foley catheter, misoprostol and dinoprostone for induction of labour showed the lowest rates of uterine hyperstimulation accompanied by FHR changes in association with Foley catheter use, although vaginal misoprostol was the most effective agent for achieving vaginal delivery within 24 hours [26].

Membrane sweeping is recommended on routine antenatal visits post-term as an adjunct to labour induction as it reduces the risk of pregnancy prolongation beyond 41 weeks [27]. Of the pharmacological methods, nitric oxide donors [28] and intracervical hyaluronidase [29] both appear to ripen the cervix without inducing myometrial contractility, but there is insufficient evidence as yet to recommend their use in clinical practice. Mifepristone, a progesterone antagonist, has less stimulatory effects on myometrial contractions than prostaglandins but insufficient evidence about safety currently precludes use with a live baby [3,30].

Once the cervix is ripe, continuation of labour induction may involve forewater amniotomy (artificial rupture of the membranes) with or without augmentation of labour with oxytocin. Forewater amniotomy for induction of labour (without PGE_2 but sometimes with oxytocin) is commonly used as a primary method of induction in women with a ripe cervix, but is not routinely advised because of the increased requirement for oxytocin augmentation [31] if used alone, and because of lower acceptability compared with prostaglandin if used in combination with oxytocin [3]. It is probably for these reasons that use of artificial rupture of membranes with or without oxytocin is now much less commonly used as the primary method of induction of labour in the UK.

Augmentation of labour

Augmentation of labour is the process of speeding up the first stage of labour. For decades, amniotomy with or without oxytocin has been the standard intervention in this scenario, but recent systematic reviews suggest that these practices may not be evidence based.

Amniotomy

A meta-analysis of 14 trials in nearly 5000 women indicated that routine amniotomy had no effect on the duration of the first stage of labour, maternal satisfaction or Apgar scores at delivery, but that there was a trend to increased risk of caesarean section (RR 1.26, 95% CI 0.98–1.62) [32]. These facts support the authors' conclusion that 'we cannot recommend that amniotomy should be introduced routinely as part of standard labour management and care'.

There is a little more evidence in support of the use of amniotomy with oxytocin for augmentation of labour. As with prostaglandins, oxytocin has to be used carefully because the myometrial contractions it induces cause a reduction in blood flow to the uterus. This reduction in blood flow can lead to fetal distress, especially if the fetus is already compromised. A Cochrane systematic review and meta-analysis showed that early amniotomy and oxytocin augmentation applied prior to any delay in labour being identified reduced the risk of caesarean section (RR 0.87, 95% CI 0.77–0.99) and shortened the duration of labour (average mean difference 1.28 hours, 95% CI –1.97 to –0.59) [33]. There were no differences in any neonatal outcomes or in maternal satisfaction rates.

Summary box 24.2

The use of oxytocin for augmentation of labour reduces the total duration of labour by about 75 min and the risk of caesarean section by just over 10%.

There is great variability in uterine response to oxytocin, both between different women and, during the course of labour, within individual women. Thus, if oxytocin is used, it should be started in a low dose initially, with increasing doses titrated against the clinical response, and the dose reduced in the presence of frequent contractions. Possible benefits of higher doses of oxytocin more rapidly escalated (compared with lower doses) include a faster labour and a reduced risk of caesarean section, at the expense of increased rates of hyperstimulation, but the evidence for this is weak [3,34]. Commonly suggested starting doses range from 0.0005–0.006 units/min to a maximum of 0.004–0.042 units/min. The British National Formulary (BNF) suggests a starting regimen of oxytocin of 0.001–0.002 units/min and notes that although the maximum licensed dose in the UK is 0.02 units/min, in clinical practice it is reasonable to administer oxytocin in doses up to a maximum of 0.032 units/min. Both the BNF and the NICE intrapartum care guideline [35] indicate that oxytocin should be increased at intervals not less than every 30 min. Regardless of the regimen used, the target frequency of uterine contractions is three to five every 10 min.

Complications of induction of labour

The most common complication of induction of labour is the risk that the procedure is not successful and that labour does not ensue, which occurs in around 15% of primigravidae with an unfavourable cervix, but less commonly in multiparous women or those with a higher Bishop score at the start of the induction process [36].

Caesarean section is considered by many clinicians a complication of induction of labour, although there is now good evidence that this is incorrect. Indeed, in the clinical scenario for which there is most evidence, that of post-term pregnancy, meta-analyses indicate that induction reduces the risk of caesarean section compared with expectant management [37,38]. A similar reduction in the risk of caesarean section was observed in a systematic review of randomized trials of induction compared with expectant management (OR 0.83, 95% CI 0.76–0.92) [39] and in our own large population-based observational study comparing elective induction with expectant management [16].

Hyperstimulation

The contractile response to prostaglandins varies from woman to woman and is not easily predictable. Thus it is not surprising that some women contract excessively after administration of standard doses of prostaglandins. Uterine hyperstimulation is defined as a contraction frequency of more than five in 10 min or contractions exceeding 2 min in duration; tachysystole occurs when uterine hyperstimulation is accompanied by an abnormal FHR pattern. NICE quotes a rate of hyperstimulation across a range of induction agents of 1–5% [3], although this may be less common with the low-dose PGE_2 regimens in use in the UK.

Profound alterations in FHR pattern may require immediate delivery by caesarean section. In the presence of less severe FHR alterations, tocolysis (e.g. with terbutaline 250 μg i.v. or s.c.) may be sufficient to treat hyperstimulation in the majority of women.

Monitoring and setting during induction of labour

Monitoring

The evidence base for monitoring of maternal and fetal well-being during induction of labour is sparse. Most authorities suggest that a cardiotocograph should be performed to confirm that the FHR is normal prior to prostaglandin insertion. Thereafter, the onset of labour can be identified by the presence of uterine contractions. If contractions do not ensue spontaneously, digital cervical assessment should be performed at intervals no more frequently than every 6 hours to determine if there has been any change in the Bishop score. The cardiotocographic assessement should be repeated when contractions begin, normally 2–6 hours after prostaglandin administration.

Setting

There is increasing interest in carrying out induction on an outpatient basis, with the induction agent being administered at home or being administered in hospital and the woman then going home to await the onset of labour. Indeed, a recent survey has suggested that 18% of UK obstetric units offer this option [40]. Although there is some evidence that outpatient cervical ripening is somewhat preferred by women [41], and that outpatient cervical ripening increases maternal satisfaction during the induction process [42], there is currently insufficient evidence to determine whether outpatient cervical ripening is safe to recommend in routine use. Additionally, one randomized trial has shown that more than 50% of women randomized to outpatient induction, and who needed cervical ripening, did not go home because of abnormalities in FHR monitoring [43], and a large observational study showed similar durations of hospital stay prior to delivery in both the home and the hospital cervical ripening groups [44].

Induction of labour at term (>37 weeks' gestation): risks and benefits

Post-term pregnancy

The highest-quality evidence on the risks and benefits of induction of labour relates to the scenario of post-term pregnancy. The cumulative risk of perinatal death rises progressively after 38 weeks of gestation [45] and many authorities have suggested that induction of labour might reduce perinatal death. A recent meta-analysis for the Cochrane collaboration, reporting on 17 randomized trials incorporating 7407 women, compared a policy of labour induction for women who were 'post dates' to a policy of awaiting spontaneous onset of labour [38]. The babies of women in the induction arm were significantly less likely to have either perinatal death or meconium aspiration syndrome or to be delivered by caesarean section (Table 24.4). There were no significant interactions by gestational age subgroups. Translating the above data into numbers needed to treat (NNT), 410 (95% CI 322–1492) women would have to be induced for post-dates pregnancy to prevent one perinatal death. However, these data should perhaps be interpreted with caution, as the total number of fetal or neonatal deaths was small, one in the induction group and 13 in the actively managed group in this most recent meta-analysis [38].

Taken together, these data suggest that induction of labour at or beyond 41 weeks reduces perinatal death without increasing the risk of caesarean section. For these reasons, many authorities (including NICE) suggest that induction of labour should be routinely offered at 41 weeks' gestation and beyond in order to improve neonatal outcome. Additionally, there is some evidence that the majority of women at this gestation prefer induction of labour to conservative management [46].

Summary box 24.3

Post-term induction of labour reduces perinatal death (estimated NNT, 410) and reduces the need for caesarean section.

Pre-labour membrane rupture

Another common indication for induction of labour is when the fetal membranes rupture at term prior to the onset of labour, but labour fails to start. If the pregnancy continues without the baby being delivered, there is a risk of ascending infection which could lead to chorioamnionitis and attendant fetal and maternal compromise. However, 95% of women will labour spontaneously within 24 hours of membrane rupture, and thus early recourse to induction of labour might involve the adverse consequences of induction of labour in a woman who would have laboured spontaneously with conservative management. Again, this issue has been subject to randomized trials. At 37 weeks of gestation or more, compared with expectant management (no active management for at least 24 hours), induction within 24 hours reduces the risk of chorioamnionitis (RR 0.74, 95% CI 0.56–0.97), endometritis (RR 0.30, 95% CI 0.12–0.74) and (for the baby) neonatal intensive care admission (RR 0.72, 95% CI 0.57–0.92) without increasing rates of caesarean section (RR 0.94, 95% CI 0.82–1.08) [47]. Importantly, women undergoing induction of labour were happier with their treatment than those managed expectantly. However, a conservative approach in order to await the onset of labour is justifiable if the woman wishes, given that induction does not significantly reduce rates of neonatal infection (RR 0.83, 95% CI 0.61–1.12). Current advice from NICE is that women with pre-labour rupture of the membranes at term (≥37 weeks' gestation) should be offered a choice of induction of labour or expectant management, and that if labour has not commenced approximately 24 hours after rupture of membranes, then induction of labour is appropriate [3]. In practice, management decisions are likely to be based on local organization of care and the individual woman's request.

For women who are preterm, at least for those who are 'late' preterm, a recent randomized trial has shown no difference in rates of neonatal sepsis (the primary outcome) in women at 34–36 weeks' gestation with pre-labour rupture of the membranes, suggesting that conservative management is probably most appropriate in this group [48].

Table 24.4 Effect of induction of labour for post-dates pregnancy.

Outcome	RR	95% CI	Amount of evidence
Perinatal death	0.31	0.12–0.81	17 trials, 7407 women
Meconium aspiration syndrome	0.50	0.34–0.73	8 trials, 2371 women
Caesarean section	0.89	0.81–0.97	21 trials, 8749 women

Source: data from Gulmezoglu *et al.* [38].

Maternal request

The most controversial area, and the issue for which there is little evidence from randomized trials, relates to induction of labour in the absence of any medical indications, i.e. induction of labour on maternal request. Women and their partners are increasingly able to control many aspects of their lives, and this wish to plan their lives extends (for many women) into where, when

and how they have their baby. Although maternal choice is promoted in the UK, at least in regard to place of delivery and more 'natural' childbirth (such as delivery under water), there is less support for women who opt for delivery by elective caesarean section or who wish to have their labour induced before 41 weeks' gestation unless there are 'medical' indications to do this. Elective caesarean section on request can increase the rate of some maternal complications and may also have resource implications for the health service; these issues have been comprehensively debated elsewhere.

Induction of labour on request (elective induction) might be a suitable compromise for women who wish to choose the date of delivery of their baby but who hope for a vaginal delivery. Popular mythology is that elective induction is associated with an increased risk of caesarean section. However, only three randomized trials, none of optimal quality, have assessed the effects of induction of labour prior to 41 weeks' gestation for this indication. Although the relative risk of caesarean section was 1.73 when data from these trials was combined, the confidence intervals cross unity and thus this apparent increase in caesarean section rate is not statistically significant (95% CI 0.67–4.50) [49]. Caughey *et al.* reviewed the observational data around elective induction of labour and found no significant increase in caesarean section rates from observational data when women having elective induction were compared with women undergoing expectant management. We subsequently completed a retrospective cohort study of over 300 000 women undergoing induction in Scotland between 1981 and 2007 and showed either no increase or a very modest increase in caesarean section rates in association with elective induction of labour after adjustment for confounding variables of age at delivery, parity, period of birth, deprivation quintile and birthweight [16]. Additionally, we showed a reduction in perinatal mortality, with NNT at 40 weeks' gestation of 1040 inductions for every one perinatal death prevented. This beneficial effect on perinatal death reduction was achieved at the expense of one extra admission to the neonatal intensive care unit for every 131 women induced. We believe that these data provide support for a policy of agreeing to an individual woman's request for elective induction of labour, and for extending choice to the timing of delivery.

Summary box 24.4

There is no evidence that induction of labour 'on request' for women with an uncomplicated pregnancy and without a previous caesarean section increases the risk of caesarean section compared with a policy of expectant management.

Prevention of shoulder dystocia

In the scenario where birthweight is expected to be high (e.g. babies already diagnosed with macrosomia or babies of diabetic mothers), a strategy of induction has been hypothesized to prevent further intrauterine growth, thus reducing the risk of both fetal macrosomia and shoulder dystocia and increasing the chance of vaginal delivery. A recent systematic review (1190 women, four trials) has shown that induction of labour near term for babies with a suspected birthweight of more than 4000 g reduces the risk of shoulder dystocia (RR 0.60, 95% CI 0.37–0.98) and any fracture (RR 0.20, 95% CI 0.05–0.79) but not brachial plexus injury nor caesarean section [50]. These results are different from previous systematic reviews on this topic, and are not yet reflected in national guidelines. If women are being offered induction of labour because of macrosomia, they should be informed of the increased rate of pelvic floor damage seen in the induction group.

Advanced maternal age

As described above, induction of labour at term reduces the risk of perinatal mortality, with no significant difference in this effect for women induced at 39–40 weeks compared with 41+ weeks' gestation. The risk of stillbirth rises progressively with age and, taken together, these data have prompted the Royal College of Obstetricians and Gynaecologists (RCOG) to issue a Scientific Impact Paper stating that 'there is therefore an argument for offering induction of labour at 39–40 weeks of gestation to women ≥40 years of age', with NNT of 550 to prevent one stillbirth [51]. A subsequent randomized trial of the effect of elective induction at 39 weeks' gestation to women aged 35 years or more, and powered to evaluate the effect on caesarean section rather than perinatal mortality or stillbirth, showed that a policy of elective induction in women aged 35 years or more does not increase the risk of caesarean section, and there were no differences in women's experience of childbirth between the two groups [52].

Intrauterine fetal death

In the absence of induction of labour, 90% of women will spontaneously deliver within 3 weeks of intrauterine fetal death. The risks of conservative management include disseminated intravascular coagulation and (particularly in the presence of ruptured membranes) ascending infection. Additionally, many women with a diagnosis of intrauterine fetal death will wish to deliver the baby as soon as possible. There are no randomized trials comparing a policy of induction with

conservative management in this situation, and NICE recommends that conservative management is reasonable if 'the woman appears to be physically well, her membranes are intact and there is no evidence of infection or bleeding' [3].

In the presence of intrauterine fetal death, mifepristone 200 mg three times daily significantly reduces the induction to delivery interval [53]. In practice, a single dose of mifepristone (200 mg) followed by either low-dose vaginal misoprostol (e.g. 25–50 μg 4-hourly up to six doses) or vaginal PGE_2 is commonly used for induction of labour with intrauterine fetal death at 24 weeks or greater; higher doses of prostaglandin may be needed at earlier gestations and lower doses should be used if the woman has had a previous caesarean section.

Induction of labour in the presence of previous caesarean section

Women with a previous caesarean section who undergo induction of labour are considered to have an increased risk of repeat caesarean section and uterine rupture compared with those who labour spontaneously. There is some evidence for this: one systematic review showed that women with a previous caesarean have a risk of caesarean delivery of 24% (range 18–51%) during a spontaneous labour but a risk of 48% (range 28–51%) following induction of labour with PGE_2 [54]. One large cohort study indicated increased odds of uterine rupture when labour was induced with prostaglandins compared with spontaneous labour (OR 2.9, 95% CI 2.0–4.3) [55]. In 14% of women with uterine rupture the baby suffered a perinatal death. In another large cohort study, we analysed outcomes in women with one previous caesarean section [56]. We compared outcomes for women undergoing induction of labour with those having expectant management and those having elective repeat caesarean section. Compared with expectant management, induction of labour was associated with lower odds of caesarean delivery (adjusted OR 0.81, 95% CI 0.71–0.91), higher odds of neonatal unit admission (adjusted OR 1.29, 95% CI 1.08–1.55), and no impact on perinatal morality. In contrast, elective repeat caesarean section was associated with lower perinatal mortality than induction of labour (adjusted OR 0.23, 95% CI 0.07–0.75).

In view of these data, induction of labour in women with a previous caesarean section should be undertaken with caution and in an environment where uterine rupture can be rapidly diagnosed and treated if necessary. Some clinicians may feel that the possible risks of induction of labour in the presence of a previous caesarean section are too great, and that such women are best delivered by elective caesarean section if immediate delivery is indicated. Such decisions need to be made on an individual patient basis, given the lack of randomized trials in this area [57]. Although there are insufficient randomized trials to help decision-making on the best induction agent [58], the Foley catheter deserves investigation as the method of choice, given the reduced risk of hyperstimulation.

Pre-eclampsia

The final indication for induction of labour is the scenario of mild pre-eclampsia. Severe pre-eclampsia at term is an absolute indication for delivery, either by caesarean section or attempting to expedite vaginal delivery by induction of labour. Mild pre-eclampsia is often managed conservatively, but there is evidence from a recent paper that liberal induction of labour after 36 weeks' gestation in women with mild pre-eclampsia or gestational hypertension improves maternal outcomes expressed as a composite of maternal mortality, maternal morbidity, progression to severe hypertension or proteinuria, and major postpartum haemorrhage (RR 0.71, 95% CI 0.59–0.86) [59]. In contrast, for women with mild hypertension at 34–37 weeks' gestation, expectant management appears to be a better strategy [60].

Summary

Induction of labour is one of the most commonly undertaken procedures in obstetric practice. Prostaglandins are the agents most commonly used, with good evidence that they speed up the process of induction of labour. Further randomized trials are required to determine the effects of induction in a variety of clinical scenarios. Meanwhile, clinicians should discuss the current literature and its implications with pregnant women prior to making decisions about their management.

Obstetric Emergencies

Sara Paterson-Brown[1] and Timothy J. Draycott[2]

[1] *Queen Charlotte's Hospital Imperial NHS Trust, London, UK*
[2] *Department of Women's Health, Southmead Hospital, Bristol, UK*

This chapter details how to minimize the risks as well as the consequences of an obsteric emergency and how to manage various scenarios. We then discuss aspects of emergency skills training before including some algorithms: these are consistent with other more succinct algorithms but contain more detail as this is a reference textbook and additional information can be assimilated rather than just reproducing the 'checklist' type flow diagrams.

General principles for minimizing the risk of an emergency occurring

Promote good antenatal health

Good general health and a supportive home environment promote good health during pregnancy. The UK Confidential Enquiries into Maternal Deaths over many triennia [1–3] remind us of the increased risks not only of those with pre-existing disease, including mental illness and obesity, but also of socially excluded and vulnerable women including immigrant women, those abusing substances, and those in abusive relationships. Good antenatal care is paramount in promoting health: women should be screened for a variety of risk factors and any problems that are identified should be acted on [4]. We know from the confidential enquiries over the years that we sometimes fail to recognize, communicate or act on risk factors which are apparent in the antenatal period. This makes it even more important, when considering intrapartum care, to make every effort to review a woman's antenatal health to identify any such risks, and pay heed to any instructions made in the antenatal period.

Organized intrapartum care

Poor teamwork is directly associated with preventable morbidity and mortality for mothers and babies. The senior sister in charge and the senior obstetrician on the delivery suite should work together as a team to coordinate clinical activity. It is worthy of mention that when some people are in charge of a delivery suite, no matter how busy it is, things are calm and in control, while at other times even a quiet day can feel hectic. The skills required to coordinate workload and staffing are multiple and often acquired over years, but if you recognize either of the above characteristics in those you work with, take a moment or two to try to define what they are doing differently and try to emulate the one and avoid features of the other.

Triage

The principles behind effective triage have hinged on the ABC approach to prioritizing casualties according to whether they have an airway (A) problem (which can lead to death within minutes if left untreated) through difficulties with breathing (B) to circulatory disorders (C). Although this can also be useful in obstetrics, it does not address the fact that obstetricians have to prioritize between two patients: the mother and the baby. Indeed there is little written about obstetric triage [5,6] and how to fit the fetus (F) into the equation. Clearly it is not as easy as ABCF and emergency care to save a baby may take priority over a less than life-threatening maternal condition. However, it is true to say that in most societies the life of the mother is given priority over that of an unborn baby and, most importantly, the fetus is best treated by adequate, rapid and effective resuscitation or stabilization of the mother anyway [5].

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Summary box 25.1

Hints for keeping the workload under control

- Keep your mind open to all the activity going on.
- Try to coordinate activity so that things happen in sequence and not all at the same time.
- Listen to your midwives' and doctors' concerns and address them.
- Prioritize according to risk (triage).
- Get simple things done quickly, as once resolved they relieve staff.
- Do not defer decisions unnecessarily (work just builds up).
- Give each woman a carer with the appropriate skills to match the complexity of the clinical problem.
- Recognize if a doctor or midwife is out of their depth: support them and encourage them to call for help.
- Regularly revisit women with risk factors to check the situation is not deteriorating (do not assume you will be called).

General principles for minimizing adverse consequences resulting from an emergency

If risk factors have been identified, preparations can be made to deal with the anticipated problem and staff should be informed, briefed and their roles defined. It is not uncommon that when such problems are prepared for, everything goes smoothly: this does not mean that staff are over-cautious; it means they did their job well. Sadly, things do not always go smoothly, or an unexpected emergency occurs, and in such situations there are some features of general care which are important:

Communication and team working

A recent review of teamworking in maternity care [7] identified that good team communication, coordination and leadership were all evident in the best functioning teams. In one study of simulated eclampsia [8], more efficient teams were likely to have stated (recognized and verbally declared) the emergency (eclampsia) earlier, using closed-loop communication (task clearly and loudly delegated, accepted, executed and completion acknowledged).

Integrating and teaching these simple team behaviours in clinical drills appears to be clinically effective [9]. This has been reiterated in a US study, which reported a statistically significant and persistent improvement of 37% in perinatal morbidity for the hospital exposed to a programme combining team training and clinical drills, whereas there were no improvements in the hospital exposed to team training only, or the control.

Good leadership is often invoked by reports, but can be nebulous in practice. Recent studies have demonstrated that leadership may best be established by the person who has the most experience of the emergency [10] and leadership may be more effective when the leader knows all the members of the multiprofessional maternity team and their relevant roles – before the emergency happens – from previous training together or from handover. Once again the leader should be mindful of the same three components of the situation as the rest of the team (team, situation, patient focus): establish the setting (using SBAR, i.e. situation, background, assessment, recommendation), allocate critical tasks with closed loops (directed–acknowledged–confirmed) and, if necessary, pass leadership to team members who are more experienced for the specific emergency at hand [11].

Women and their families also want similar information in an emergency. In recounted experiences, companions often informed women of the situation and the aims of treatment because they had heard loud and clear messages about the cause of the emergency, the condition of the baby, and the aims of immediate and ultimate management [11].

Local multiprofessional training for all staff annually, with teamwork training integrated into the clinical training, appears to be the most effective method of improving teamwork.

Summary box 25.2

Aids to good communication

- Someone needs to take the lead role and coordinate activity in a systematic way such that staff work together as a team.
- Establish the situation and voice it to the team.
- The skills of any unknown staff need to be clarified.
- Roles need to be allocated which match the skills of the staff concerned.
- Specific jobs need to be given to specific people to avoid duplications and omissions.
- When someone is asked to do something, it is worth checking that they understand and are happy with what is being asked of them, and then they should confirm when it has been completed.
- Someone needs to document timings and actions.
- Someone needs to talk to the patient (and her partner) even if only briefly to keep them calm and informed and help them feel confident and supported.

Documentation

This has already been mentioned briefly, but in all emergencies it helps to have someone looking at the clock, holding pen and paper, who is responsible for documenting the important facts as they happen. Remember that if, as is often the case, this person is fairly junior, he or she may not understand exactly what is going on and may fail to document key activity, and therefore it is imperative that senior members of the team ensure that all essential information is communicated. Once the emergency is over, notes should be written carefully and comprehensively and signed legibly. This is the best time to account for what has happened, and any relevant diagnosis, follow-up care plan and prognosis for future pregnancies should be spelt out clearly whenever possible at this stage.

Risk management

After the emergency is over, reviewing the event with staff is hugely appreciated and very important: this is usually multidisciplinary but will sometimes be in small groups. Healthcare assistants and porters may need this support too and should not be forgotten. If everything went well, everyone should be congratulated; if some things were less than perfect, discussing why the difficulties were encountered and what might make things easier/work better another time is often helpful. This is a time for positive critical reflection; any negative feedback can wait and be dealt with privately.

Duty of candour

If the event has resulted in harm to the patients (woman/baby), then even if care was exemplary a senior doctor should speak personally to her and/or her partner/relative to express regret that the incident occurred and empathy for the current situation or outcome, and explain that such cases are reviewed to check everything was done that should have been and in a timely manor. Such dialogue should be recorded together with an offer to provide feedback to the patient/family should they so wish. This transparency and heightened communication and caring approach is directly driven from the NHS Litigation Authority and the Care Quality Commission with a statutory duty of candour for healthcare providers to comply since 2015 [12].

Emergency training

Over the last two decades the reduced duration of junior doctors' training, combined with the dramatic cuts in their working hours, it is unsurprising that their clinical experience of obstetric emergencies is much less than that of their predecessors. They rely increasingly on training away from the bedside and there is no doubt that improving training for intrapartum emergencies is at least part of the potential solution to improving outcomes in the UK and further afield.

A review of effective training for obstetric emergencies published in 2009 [13] concluded that many of the courses then reviewed had common features: institution-level incentives to train; multiprofessional training of all staff in their units; teamwork training integrated with clinical teaching and use of high-fidelity simulation models. These themes have been echoed in a more recent review for obstetric training [14] that concluded that all maternity and neonatal health professionals should participate in in-service training sessions. Furthermore, on-site 'in-house' training with low-tech, highly realistic models is more readily implementable than offsite training at simulation centres and training integrated into institutional clinical-governance and quality-improvement initiatives is likely to have better results.

The various regional and national multidisciplinary training courses have different emphases, complement each other and supplement local training. A few illustrations of these specialist courses are listed here.

- ALSO (Advanced Life Support in Obstetrics). This course is geared to midwives, obstetric senior house officers and junior specialist registrars and deals with the main obstetric emergencies in a structured systematic fashion. Candidates should gain a sound understanding of the problems and the structured approaches in how to manage them (www.also.org.uk).
- mMOET (Managing Medical and Obstetric Emergencies and Trauma). This course is geared to a more senior and multidisciplinary group: obstetric consultant and senior specialist registrars (post MRCOG and at least specialty training year 5), anaesthetic consultant and senior specialist registrars, and senior accident and emergency doctors. These courses can also include midwives and obstetric physicians whose presence emphasizes and promotes the team approach that is so important in the obstetric emergency. This course runs candidates through approximately 25 emergency scenarios and skills and deals with more advanced and complex aspects of emergency obstetrics and emergency behaviour (www.moet.org.uk).
- MOSES (Multidisciplinary Obstetric Simulated Emergency Scenarios). This course focuses on emergency behaviour and team-working dynamics

as they apply to the obstetric patient, rather than training on knowledge or techniques. It involves midwives, anaesthetists and obstetricians who often attend together from the same department. This course is very different from, and complements, MOET or ALSO (blsimcentre@bartsandth-elondon.nhs.uk).

- PROMPT (PRactical Obstetric Multi-Professional Training). A training programme for maternity units, it was developed in Bristol, UK and can be purchased by maternity units, who then deliver the teaching locally.

Effects of emergency training

Whilst we increasingly rely on these training programmes, the current evidence supports an annual, local unit-based, multiprofessional approach as these are most likely to translate into improved clinical outcomes. Not all training is productive and even the same teaching material delivered in different settings can have opposite results [15] but the best improvements to date have been reported from the PROMPT group, where there is evidence of significantly reduced preventable birth injury [16–19] and an associated 90% reduction in litigation costs [20]. These reductions have been replicated in pilot sites across the world, including developing world settings.

Collapse

Collapse as it presents to the obstetrician can be due to a variety of causes, from the sometimes innocent vasovagal faint through to cardiac arrest, but the initial assessment and management of the patient is remarkably similar and requires a systematic disciplined ABC approach combined with manual uterine displacement of the uterus or lateral tilting of the pregnant patient to minimize aortocaval compression. The essential steps of how to approach the apparently lifeless patient are summarized in Fig. 25.1, and aim to make the crucial diagnosis of cardiac arrest (as opposed to reduced consciousness due to another cause) so that cardiopulmonary resuscitation (CPR) can be commenced early. Most other conditions require basic resuscitation with attention to airway and breathing combined with intravenous access and circulatory support while the cause of the problem is diagnosed and then treated (Table 25.1).

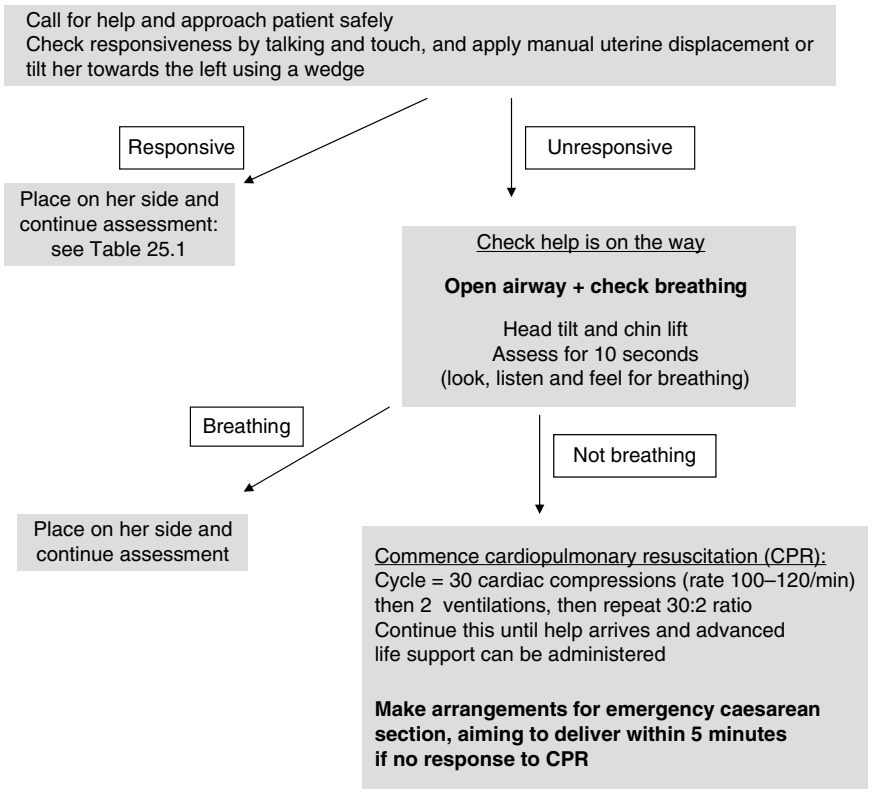

Fig. 25.1 Basic life support: approaching and treating the apparently lifeless patient.

Table 25.1 Causes, features and initial treatment of collapse in the obstetric patient (distinguishing features in bold).

	Cause/risk factors	Specific clinical features	Specific treatment points: all need ABC + lateral tilt if undelivered
Adrenal insufficiency	Inadequate or absent steroid cover in someone previously taking steroids	Drug history can be sought Hypotensive collapse Metabolic imbalance	Supportive with intravenous fluids (check electrolytes, especially sodium may be low) Hydrocortisone (200 mg i.v. stat) Check BM: may need glucose
Amniotic fluid embolism	Uterine tachysystole Syntocinon hyperstimulation Previous uterine surgery Multiparity Polyhydramnios	Restless, shortness of breath and cyanosis **Vaginal bleeding follows within 30 min due to disseminated intravascular coagulation** [2]	Oxygen + ventilate Deliver the baby as soon as possible Hydrocortisone (200 mg i.v. stat) (Aminophylline, diuretics, adrenaline, morphine)*
Anaphylaxis	Drug administration, e.g. antibiotics, Voltarol, anaesthetic agents, Haemaccel, latex	History of drugs/latex Rash Stridor Oedema	Adrenaline (1 mL of 1 in 1000 i.m. or 1 mL of 1 in 10 000 i.v. repeated as needed) with intravenous fluids Hydrocortisone (200 mg i.v. stat) Chlorpheniramine (20 mg i.v.)
Aspiration (Mendelson's syndrome)	Inhalation after vomiting/ passive regurgitation (reduced consciousness with unprotected airway)	Shortness of breath, restlessness, cyanosis **Bronchospasm**	Oxygen + ventilate (Aminophylline, steroids, diuretics, and antibiotics)*
Bacteraemic shock	Overwhelming sepsis due to especially Gram-negative rods or streptococci	Hypotensive **Warm/fever/blotchy**	Sepsis care bundle: replenish circulation, systems support Antibiotics intravenously (e.g. imipenem)
Cardiogenic shock	Congenital or acquired disease Cardiomyopathy	History Restless, **shortness of breath, chest pain**	**Sit up** Oxygen + frusemide
Eclampsia	Associated with cerebrovascular events or pulmonary oedema or magnesium toxicity	Hypertensive Proteinuria	Magnesium sulfate (antidote is calcium gluconate) Control blood pressure with hypotensives
Hyperglycaemia	Diabetes	Hyperventilation and **ketosis**	Intravenous fluids, insulin (and potassium)
Hypoglycaemia	Diabetes, Addison's disease, hypopituitary, hypothyroid	**Sweating/clammy** Loss of consciousness	Intravenous glucose
Intracerebral bleed	Arteriovenous malformation	Fits, CNS signs and **neck stiffness**	Supportive and urgent neuro-imaging
Massive pulmonary embolism	Usually deep pelvic thrombosis	Restless, cyanosis, **elevated jugular venous pressure**	Lie down, oxygen, IV fluids, anticoagulation/thrombolysis
Neurogenic	Vasovagal (uterine inversion)	**Vaginal examination**	Intravenous fluids ± atropine Reduce uterine inversion
Oligaemic	Haemorrhage (can be concealed)	**Tachycardia, pale and cold**	Restore circulation and turn off the tap [24]
Pneumothorax Pneumomediastinum	Previous history of labour/ pushing	Chest pain, shortness of breath	Aspirate/drain

*These treatments should be undertaken under anaesthetic supervision in a high-dependency or intensive care unit.

Cardiac arrest (Fig. 25.1)

CPR is not only difficult to administer but is particularly inefficient in the pregnant patient due to the following:

- Difficulties in performing CPR in pregnancy: the uterus needs to be manually displaced; if there are insufficient pairs of hands, the patient must be tilted.
- Increased oxygen requirements in pregnancy (20% increase in resting oxygen consumption).
- Decreased chest compliance due to splinting of the diaphragm (20% decrease in functional residual capacity).
- Reduced venous return due to caval compression limits cardiac output from chest compressions (stroke volume 30% at term compared with non-pregnant state).
- Risk of gastric regurgitation and aspiration (relaxation of cardiac sphincter).

For these reasons and to improve the chance of maternal survival it is considered appropriate to empty the uterus by performing a peri-mortem caesarean section within 4–5 mins if CPR (performed with uterine displacement or lateral tilt) is ineffective [5]. To achieve this the obstetrician at such an arrest should be preparing for caesarean section almost immediately. It is reiterated that the point of emptying the uterus is to aid in the resuscitation of the mother and is not for fetal reasons. Fetal viability issues should not delay this procedure, which is worthwhile when the pregnancy is of sufficient size to compromise resuscitation; as a guide, if the uterus has reached the level of the umbilicus it should be considered.

To perform a peri-mortem caesarean section rapidly, the skin incision should be that with which the operator is most familiar, and the uterine incision will be influenced by the gestation of pregnancy. These details matter little compared with the pressing need to evacuate the uterus and render the mother more receptive to life-saving resuscitation techniques. A large caesarean section pack is unnecessary and *in extremis* all the obstetrician needs is a scalpel to commence the procedure whilst other instruments are being collected.

It is stressed again that this is not done for fetal reasons but there is no doubt that at more advanced gestations fetal viability is more likely the more quickly the baby is delivered: 70% survive intact if delivered within 5 min, falling to 13% after 10 min [21].

To detail the management of each possible condition that can cause maternal collapse is beyond the scope of this chapter, but Table 25.1 summarizes the different possibilities and those features specific to them in terms of risk factors, clinically distinguishing features and specific points of treatment. More detailed accounts can be found in references in the MOET manual [5] but a few summary points are highlighted here.

Airway problems

The airway of an obstetric patient is more vulnerable than in the non-pregnant state. Not only is there more likely to be swelling and oedema, but the progestogenic effects that reduce gastric emptying and relax the cardiac sphincter increase the chance of regurgitation and subsequent aspiration of gastric contents. For these reasons the management of any obstetric patient with reduced consciousness requires careful attention to maintaining and protecting the airway, and this should involve an anaesthetist. In simple circumstances, the patient should at the very least be nursed on her side, and a jaw thrust and chin lift can aid in bringing the tongue forward to open the airway. Severe laryngeal oedema due to pre-eclampsia or anaphylaxis are examples of situations that can critically compromise the airway in the obstetric patient, and in these circumstances an anaesthetist is needed extremely urgently to establish and maintain the airway (usually by a cuffed endotracheal tube).

Breathing problems

If the airway is patent but breathing is laboured or consciousness impaired, then supplementary oxygen is vital. This should be given by face-mask with a reservoir bag, and the oxygen should be turned up to maximum at the wall in the emergency situation. Raised respiratory rate, restlessness and confusion are all signs of hypoxaemia, can precede collapse and should be taken extremely seriously. Oxygen saturation should be measured in air by a pulse oximeter, and arterial blood taken for gas analysis if there is any concern, and results of these should be reviewed with the anaesthetist on duty.

Circulatory problems

Circulatory problems can be due to cardiac disease (where the resulting pathology is usually pulmonary oedema and low-output failure), inadequate venous return with resultant low-output failure (massive pulmonary embolus) or an underfilled circulation (hypovolaemia, due to haemorrhage or sepsis). Early intravenous access with large-bore cannulae is vital, but treatment needs to be specific to the cause. Cardiac failure patients do not require (and indeed may be killed by) volume expansion, but are helped by being sat up and given diuretics, and may need inotropic support. On the other hand, a woman with a pulmonary embolus or one who is hypovolaemic needs volume expansion and to be lain down flat. Distinguishing between these conditions is vital as the management of

each would clearly be dangerous to the other. Hypovolaemia, which can be due to loss from the intravascular compartment (e.g. haemorrhage) or due to relative underfilling caused by vasodilatation (e.g. sepsis), is managed by volume expansion. Fluid replacement strategies with crystalloid or colloid remain controversial but the use of crystalloids in critically ill patients is supported by a Cochrane review [22] and Hartmann's solution is preferable to dextrose [23].

Haemorrhage

Obstetric haemorrhage is one of the most common causes of major maternal morbidity and mortality [24,25] and successive confidential reports in the UK show that it accounts for approximately 0.5 deaths per 100 000 maternities [3]. Over the years these confidential enquiries have highlighted a variety of substandard care issues and emphasis is placed on the importance of clear local procedures and policies to trigger rapid and appropriate responses which should be rehearsed regularly. Furthermore, there should be senior input in high-risk cases, especially women with a previous caesarean section and a low-lying placenta, as their risk of a morbidly adherent placenta is increased. In such cases antenatal and intrapartum multidisciplinary consultant input is advocated, with clear plans for surgery and with conservative options for treatment considered in advance [26].

Summary box 25.3

Care bundle components for women with suspected placenta accreta

- Consultant obstetrician involved in antenatal plan and present at delivery.
- Consultant anaesthetist involved in antenatal plan and present at delivery.
- Blood and blood products available on site.
- Multidisciplinary involvement in preoperative planning.
- Consent to include possible interventions.
- Level 2 critical care bed available.

Clinical care should concentrate on identifying risk factors for haemorrhage in all women to enable preparations and avoiding action to be taken. However, once massive haemorrhage occurs management should follow a logical sequence of diagnostic and therapeutic options as illustrated in Figs 25.2 and 25.3.

Summary box 25.4

Hints to minimize morbidity from haemorrhage

- Antepartum haemorrhage: if it is due to severe abruption with an accompanying bradycardia, the urgency of delivery is clear and an interval from decision to delivery of 20 min or less is associated with reduced neonatal adverse outcome [27].
- The descriptions 'heavy lochia' or 'she's trickling' are dangerous and should not be accepted: the woman should be reviewed and the problem resolved before it develops into a bigger problem.
- A bedside haemoglobin assessment in the acute phase of haemorrhage can be falsely reassuring (as dilution does not occur until there has been fluid resuscitation) and circulatory volume and blood replacement should be based on the amount of blood lost, the vital signs and the likely ongoing clinical scenario, *not* the haemoglobin [24].
- Continued vaginal bleeding with a contracted uterus is due to either retained placenta/membrane/clot or trauma and needs to be managed actively and not ignored. The problem will only get worse, so the woman should undergo examination under anaesthesia while she is well.
- Hypotension is a very late sign: blood pressure is maintained until very late in the obstetric patient who is bleeding, and tachycardia, peripheral perfusion, skin colour and urine output should be heeded early.
- Small women have relatively smaller circulating blood volumes and so allowance for body habitus should be made when estimating the significance of the estimated loss [24].
- If the lower segment of the uterus or the cervix fills up with blood or clot, it can cause vagal stimulation producing a bradycardia that can mislead. Vaginal examination should be done if in doubt.
- Bleeding can be concealed:
  - A uterus filling up is suggested by a rising fundus.
  - Intra-abdominal bleeding: massive volumes of blood can be accommodated within the peritoneal cavity without affecting girth measurements, which are unhelpful and can be falsely reassuring.
  - The uterus that is not central but shifted to one side should raise alarm bells: it suggests a broad ligament haematoma.
  - Whilst a tachycardia can aid in the recognition of concealed haemorrhage this can be inhibited by beta-blockers, and also sometimes by the intraperitoneal blood stimulating a vagal response.
- Petechiae suggest disseminated intravascular coagulation [28].

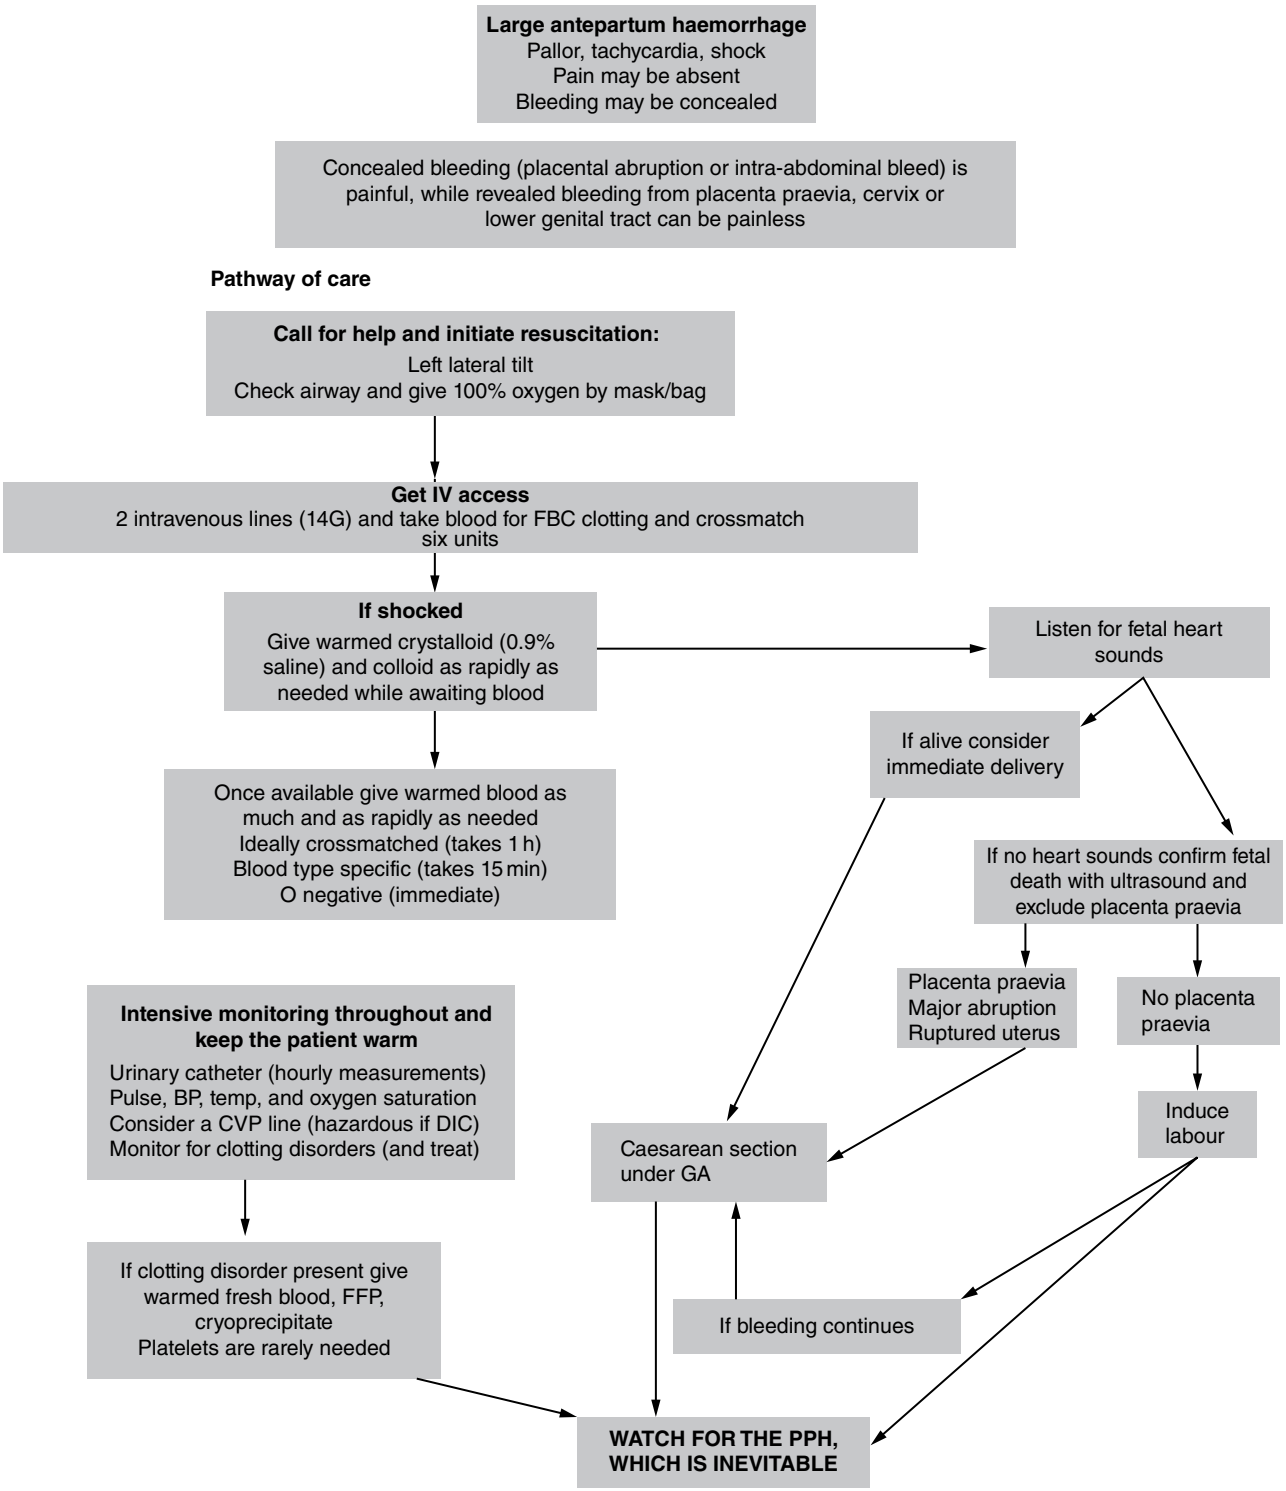

Fig. 25.2 Large antepartum haemorrhage. BP, blood pressure; CVP, central venous pressure; DIC, disseminated intravascular coagulation; FBC, full blood count; FFP, fresh frozen plasma; GA, general anaesthesia; PPH, postpartum haemorrhage.

Life-saving measures and advanced techniques for massive postpartum haemorrhage

Resuscitation with volume, blood and clotting factor replacement

Rapid replacement of circulating volume with *warmed* crystalloid and colloid while awating blood will maintain the circulation temporarily, but blood together with clotting products are needed urgently and should be given in anticipation of, and should attempt to minimize, the coagulopathy that is almost inevitable in the face of massive haemorrhage. To this purpose a ratio of 1 : 1 blood/fresh frozen plasma (FFP) is needed; if bleeding continues, cryoprecipitate should be given empirically while awaiting clotting studies [24,29]. Platelets should be given if levels fall below 50×10^9/L.

Tranexamic acid reduces death from PPH and early treatment optimises the benefits. Ig should be given intravenously and repeated, if bleeding continues or restarts (from 30 mins to 24 hrs later) [30].

Aortic compression

If bleeding is out of control and the anaesthetist needs to stabilize the patient, it is worth trying aortic compression while waiting for senior or specialist help to arrive. In the woman who has been delivered vaginally tilt the uterus forward and press a closed fist down onto the abdomen just

below the umbilicus. If the abdomen is already open, sweep the small bowel mesentery up towards the liver and with a swab on a stick or with finger and thumb squeeze the aorta. The effect is dramatic and can be life-saving.

Uterine packing

This is useful for placental bed bleeding but can also be used with uterine atony when there is an element of uterine tone present. The technique is not new, but rather than using a gauze pack an inflatable balloon has the advantage of being quick and expandable. Various balloon catheters have been reported for this technique including the Sengstaken–Blakemore and specifically designed ones, but the urological Rusch balloon catheter is cheaper and effective [31]. Some have used a condom attached to the end of a urinary catheter, but the balloon of a normal urinary catheter itself is not suitable as its capacity is far too small. The volume needed is very dependent on the individual and the key is to insert the balloon catheter and gently fill it whilst keeping the uterus as contracted as possible. As a rough guide approximately 200–400 mL or so is usually required, and as the balloon is inflated resistance is met and bleeding is seen to reduce. If bleeding is controlled, the balloon is usually left in for approximately 24 hours and then – again an advantage over the traditional uterine pack – it can be deflated in stages. If bleeding continues despite the balloon being inflated, then further steps need to be taken to turn off the tap. Whatever is used to pack the uterus, antibiotic cover should be given for the procedure and until the pack/balloon is removed; similarly the bladder should be catheterized until the pack is removed.

Brace suture

The B-Lynch brace suture, first described in 1997 [32], can avoid hysterectomy in cases of bleeding from uterine atony. It aims to exert longitudinal lateral compression on the uterus combined with a tamponade effect and is performed by means of one long suture placed as illustrated in Fig. 25.4. The key to this technique is to check the hypothesis that it works by exteriorizing the uterus and compressing it (bleeding should be controlled) before continuing. Since its first description there have been many reports of its successful use but there have been modifications suggested that have confused the understanding of the principles behind it, and some of these have been associated with problems [33–36]. Longer-term complications have also been reported [37,38] and it is worth reiterating that the suture should be of a rapidly absorbable material to avoid the prolonged presence of free loops of suture material in the abdomen after the uterus involutes [37].

Interventional radiology

Arterial embolization is increasingly reported in the management of postpartum haemorrhage [39,40]. It is especially effective in achieving haemostasis in cases of genital tract trauma where surgical control has failed or the injury is inaccessible. However, it can also help in more non-specific haemorrhage such as uterine atony, when the internal iliac and uterine arteries can be cannulated and their tributaries can be embolized. Developing links with, and knowing contact details of, an interventional radiology department in advance of the emergency scenario makes the urgent referral all the easier. There is a report suggesting that morbidity is better if embolization is carried out before rather than after hysterectomy [41], but this will clearly depend on local facilities and arrangements and the stability of the patient. Embolization is extremely difficult if the internal iliac arteries have been tied off and therefore this technique, which also threatens trauma to the internal iliac vein (a vascular surgeon's nightmare), should rarely be attempted by the obstetrician. Complications from embolization have been reported, including necrosis of uterus and bladder [42], but long-term follow-up has demonstrated that fertility can be maintained but pregnancy outcomes are complicated by a 32% risk of recurrent severe postpartum haemorrhage [43].

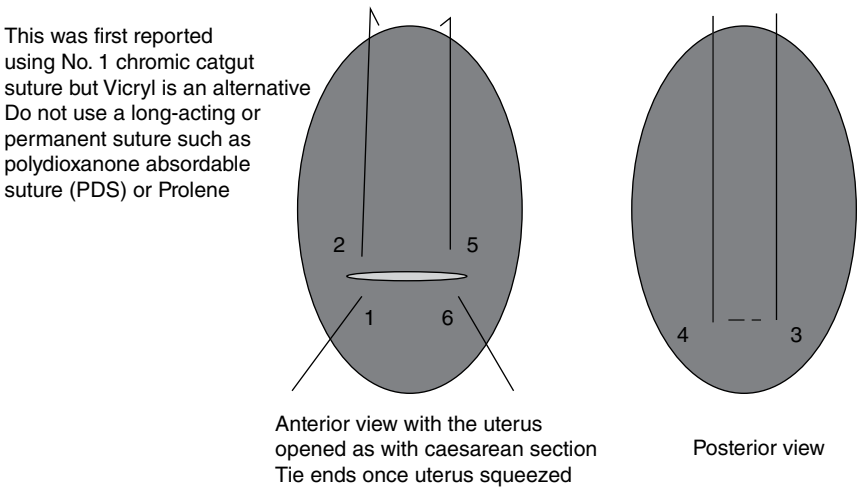

Fig. 25.4 B-Lynch 'brace' suture for treatment of bleeding due to uterine atony, but some uterine tone is needed.

Cell salvage

This technique of contemporary perioperative autologous blood salvage and retransfusion for use in obstetrics has been supported by the National Institute for Health and Care Excellence (NICE) [44], the Obstetric Anaesthetists Association [45] and the Royal College of Obstetricians and Gynaecologists (RCOG) [29,46]. A review confirmed its value and safety [47] and it is acceptable to Jehovah's witnesses [48,49].

Recombinant activated factor VII

There have been a few case reports of the value of giving this in the presence of severe clotting disorders in obstetric haemorrhage [50] but these treatments are still largely research based. It is expensive and only works if the patient has been given other clotting factors on which this can work. Practically speaking, this tends to be within research or on a named patient basis after discussion at consultant level between haematologist and obstetrician, whilst further evidence is collected. Initial reports were encouraging and the subject has been well reviewed [51] and is mentioned in the RCOG guidelines on blood transfusion in obstetrics [29] and postpartum haemorrhage [46].

Obstetric causes of collapse

Eclampsia

Eclampsia can present with collapse due to the fitting and post-ictal phase of the disease, an intracerebral catastrophe, magnesium toxicity or pulmonary oedema. The principles of treatment are as for any collapse and, in addition, blood pressure control, magnesium sulfate and strict fluid balance to avoid fluid overload provide the basis of good care. If the patient is antenatal then the mother must be stabilized before delivery (see Chapter 7). A summary flow chart of acute management of this condition is shown in Fig. 25.5.

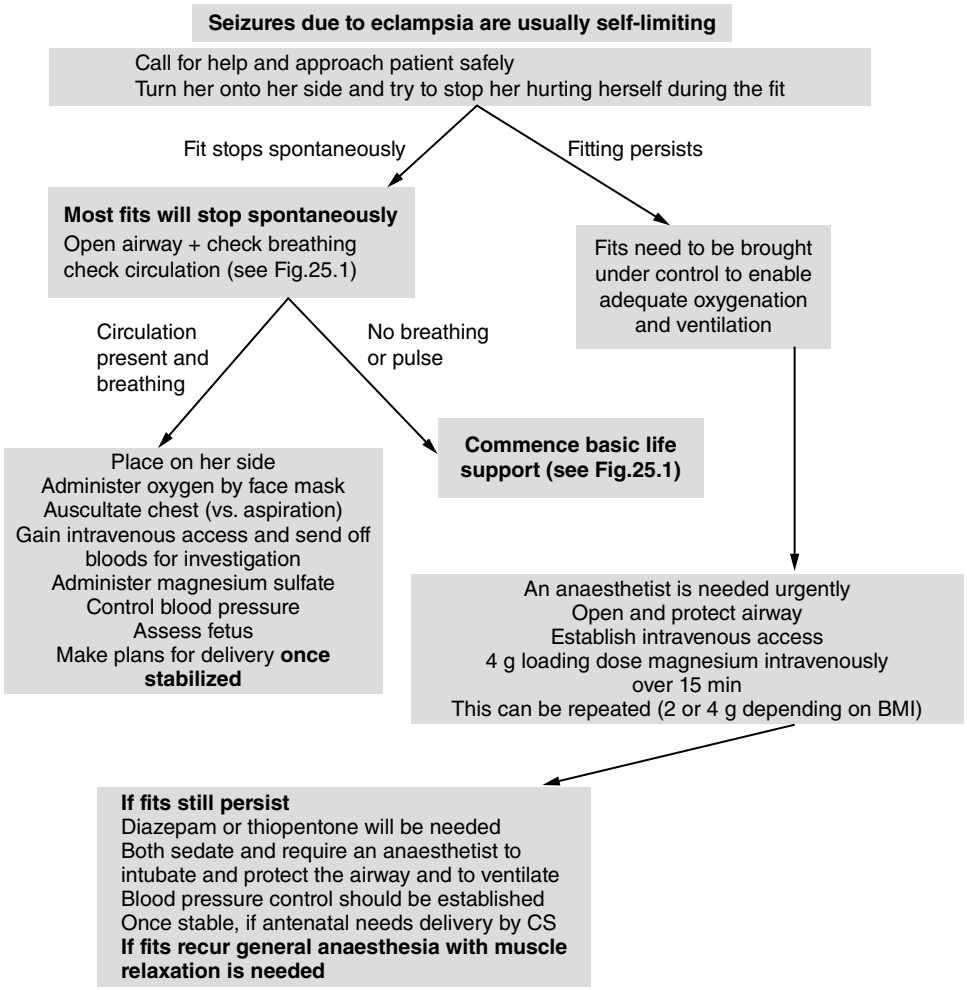

Fig. 25.5 Eclampsia. BMI, body mass index; CS, caesarean section.

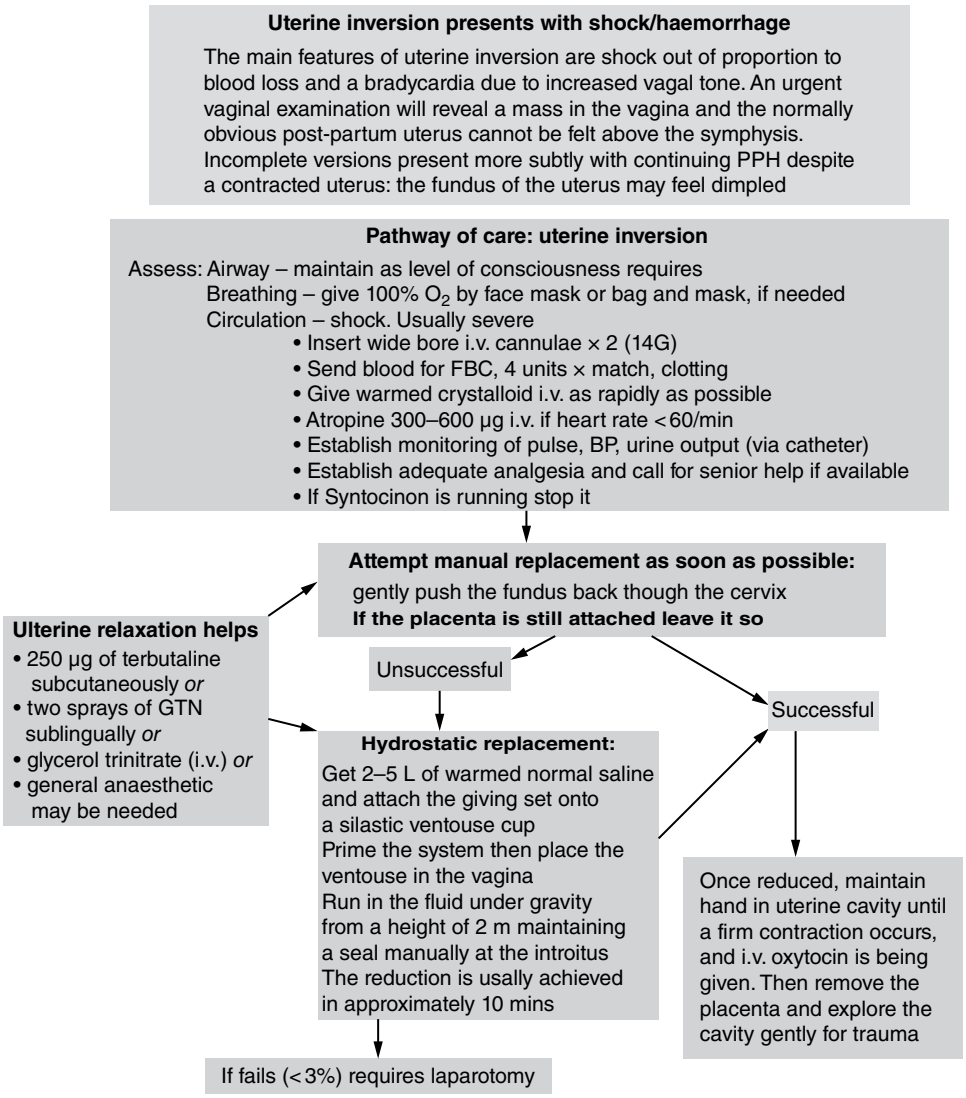

Fig. 25.6 Uterine inversion. BP, blood pressure; FBC, full blood count; GTN, glyceryl trinitrate; PPH, postpartum haemorrhage.

Uterine inversion and uterine rupture

Uterine inversion and uterine rupture can both contribute to maternal collapse and their management is illustrated in Figs 25.6 and 25.7. It is worth noting that 18 of the 42 cases of uterine rupture in the CESDI report had a laparotomy before a diagnosis was made [52]. Signs can be subtle and fetal heart abnormalities in the presence of a uterine scar should be taken extremely seriously and rarely, if ever, justify fetal blood sampling. Similarly, a multiparous patient with secondary arrest should arouse suspicion, and Syntocinon augmentation should only be decided after careful clinical assessment of the patient by the obstetrician to exclude obstructed labour.

Emergency obstetric deliveries

Most emergency operative deliveries (caesarean section, instrumental delivery, breech and twin deliveries and interventions for fetal distress) together with neonatal resuscitation are mentioned in the relevant chapters, but the management of shoulder dystocia and cord prolapse is illustrated in Figs 25.8 and 25.9 and discussed here.

Shoulder dystocia

Shoulder dystocia is every obstetrician's and midwife's nightmare, and rightly so. A lot of effort is now focused

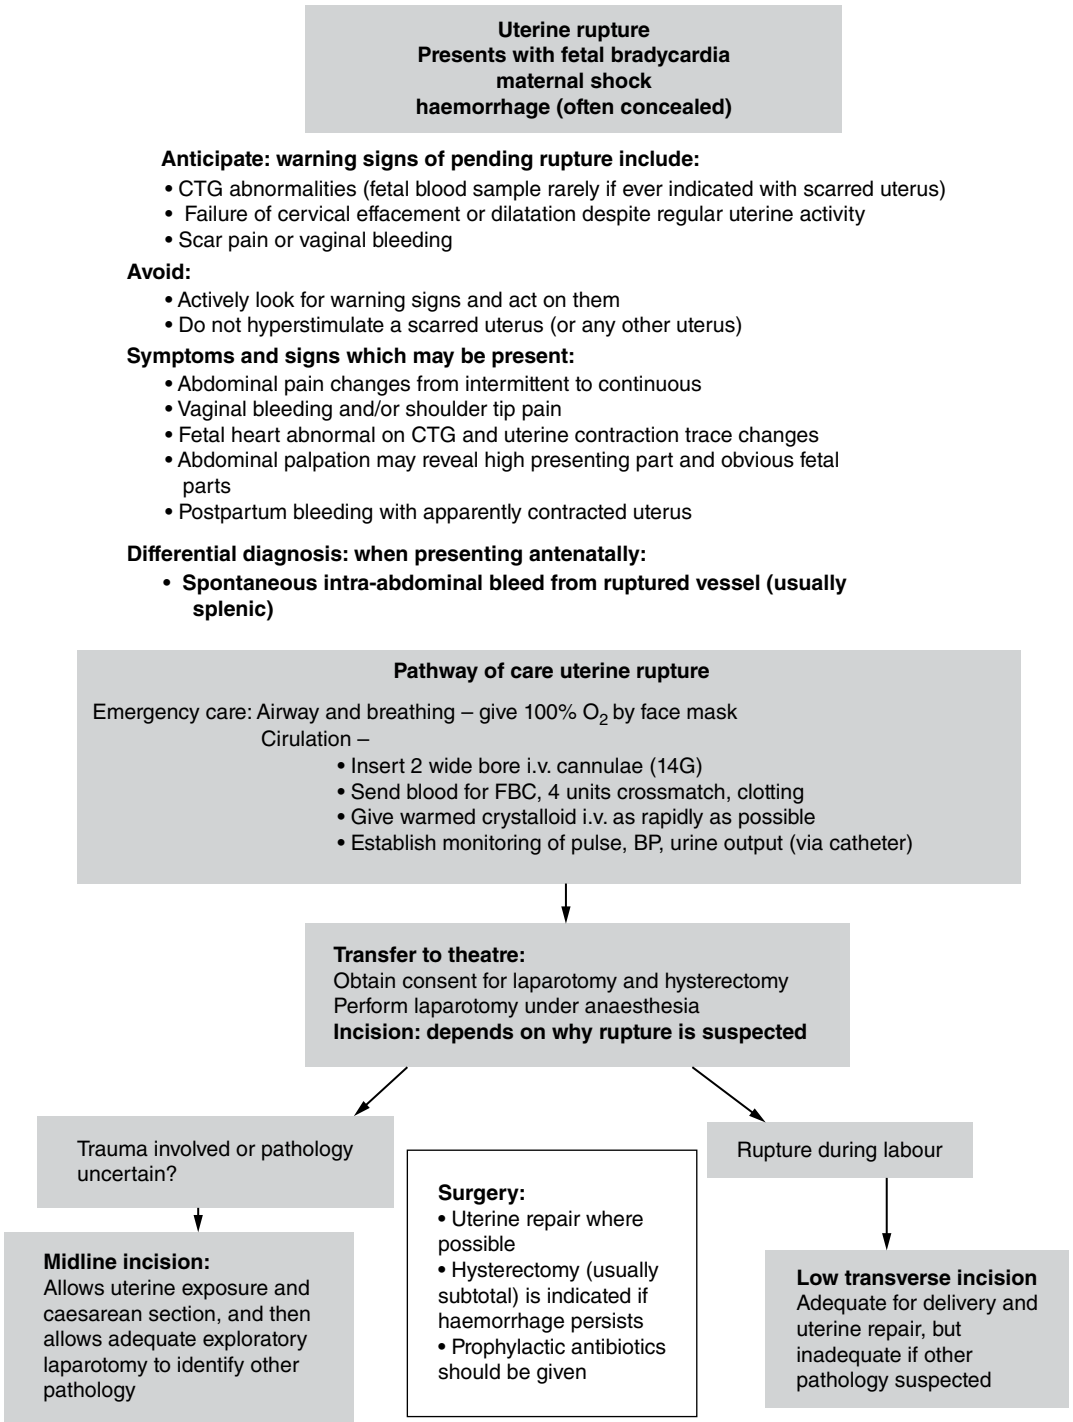

Fig. 25.7 Uterine rupture. BP, blood pressure; CTG, cardiotocography; FBC, full blood count.

on practical training using sophisticated mannequins [53] and this has resulted in improved clinical outcomes [17]. The flow chart in Fig. **25.8** highlights the processes and sequences of its management, but additional points to note include the following.

- Always remember that the problem is at the pelvic brim and pulling on the baby or pushing down on the fundus are both unhelpful and dangerous.
- Time is deceptive and what feels like a lifetime is only a few minutes (try to glance at a clock or get someone to note timings).

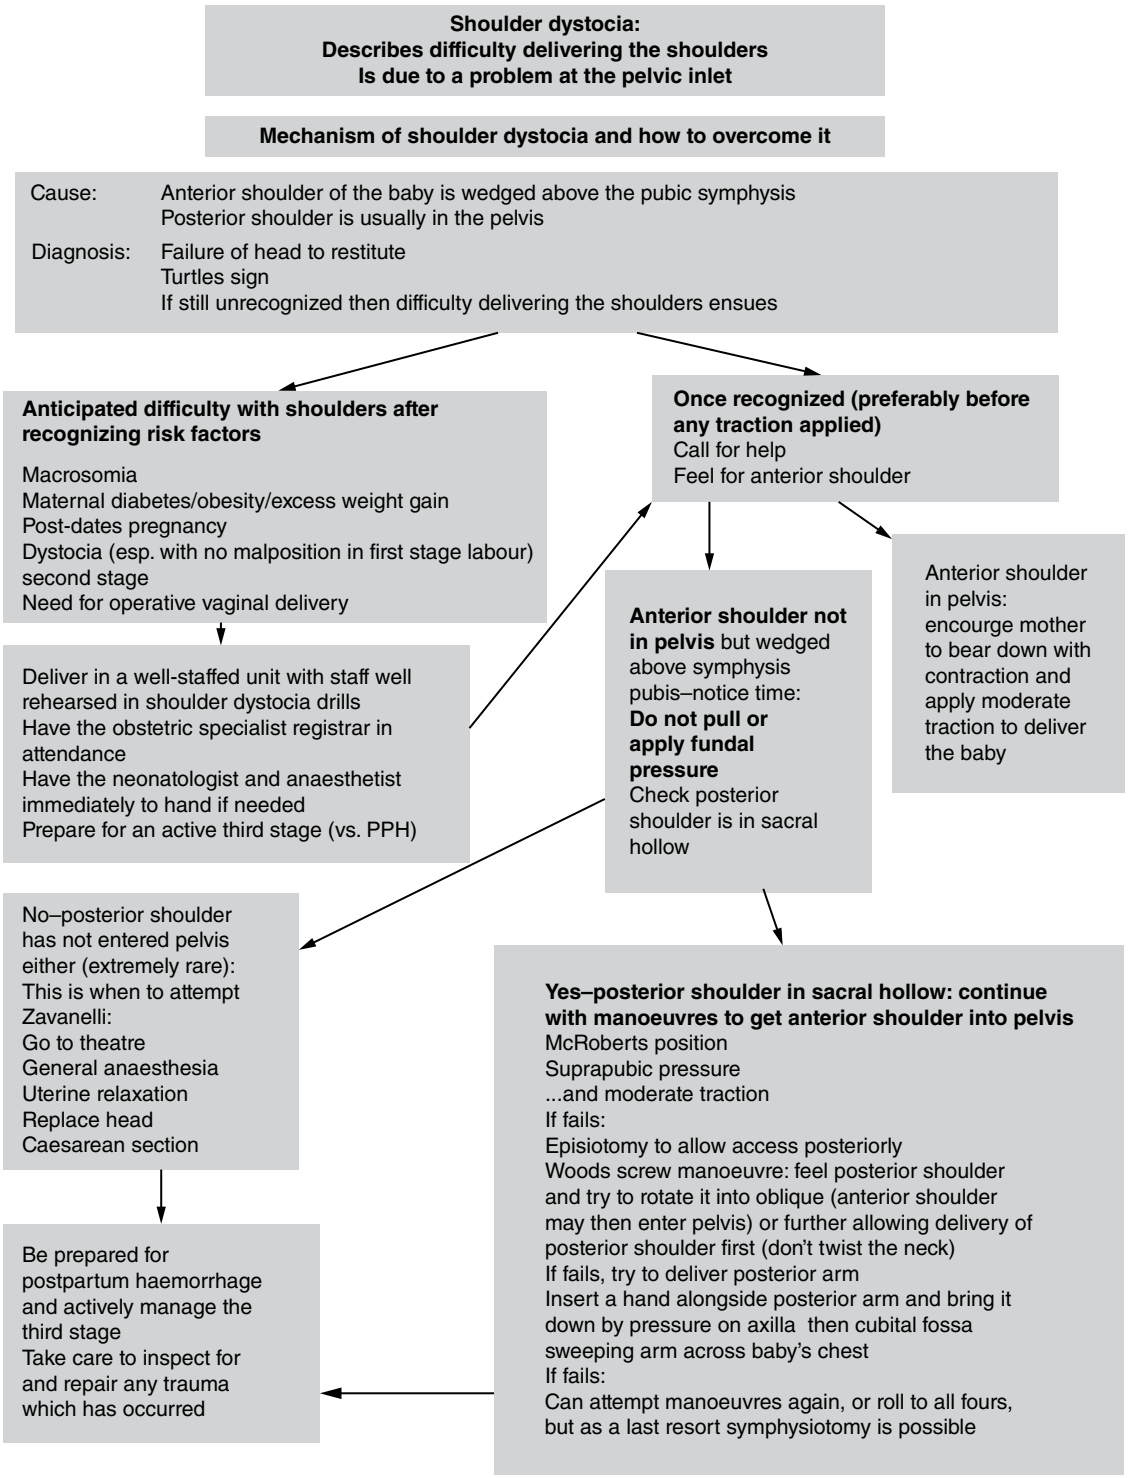

Fig. 25.8 Shoulder dystocia. PPH, postpartum haemorrhage.

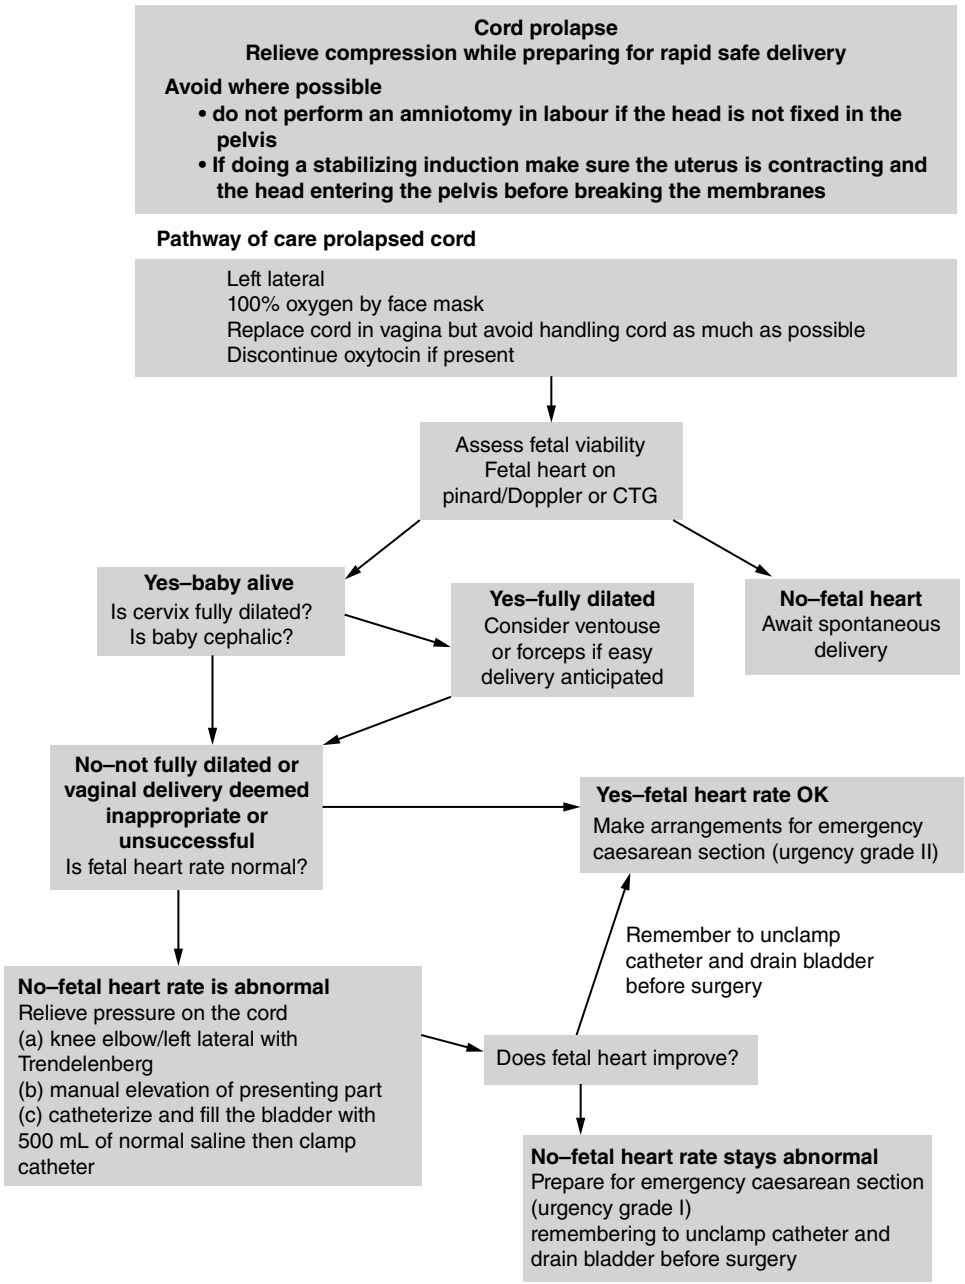

Fig. 25.9 Cord prolapse. CTG, cardiotocography.

- There remains a place for cephalic replacement [54] and occasionally symphysiotomy can be life-saving [55]. Check if the posterior shoulder is still above the pelvic brim or has entered into the pelvis and can be felt in the sacral hollow to help decide which of these manoeuvres would best suit.
- Careful and precise documentation is essential after the event.

Cord prolapse

Figure 25.9 highlights the main features of this emergency. The principles of treatment are as follows.

- Handle the cord as little as possible.
- If an operative vaginal delivery is proposed, it should be simple and achieved quickly; if it is not, it should be abandoned early.

- If there is no fetal bradycardia this need not be a panic delivery under general anaesthesia, and regional block administered with the patient lying on her side may be appropriate.
- If the bladder has been filled with saline, remember to empty it before surgery (just removing the spigot from the Foley catheter is not sufficient).

Summary

Good antenatal care, anticipating possible problems and preparing for them, and running a well-coordinated delivery suite are the mainstays of coping with obstetric emergencies. Training and drills help to focus on teamwork and provide a supportive system to reduce adverse consequences. Keep things simple and focus on the problem to hand. The ABC principle is a good one for dealing with any ill patient, but is particularly useful in the apparently lifeless patient and those who require resuscitation, although it is crucial to remember to manually displace the uterus or apply lateral tilt in anyone still pregnant. In any obstetric emergency keep the basic pathology in mind: why has this happened, what is the problem and how can it be treated?

[3] *St George's University of London, London, UK*

Malpresentation, malposition and cephalopelvic disproportion

Definitions

The *vertex* is a diamond-shaped area on the fetal skull bounded by the anterior and posterior fontanelles and laterally by the parietal eminences. Vertex presentation is found in 95% of labours at term and is associated with flexion of the fetal head. Breech, brow, face and shoulder presentations constitute the remaining 5% and are collectively known as *malpresentations*. Their aetiology is usually unknown, but associations include macrosomia, multiparity, polyhydramnios, multiple pregnancy, placenta praevia, preterm labour, and anomalies of the uterus or pelvis (congenital or acquired, e.g. lower segment fibroids) and more rarely the fetus.

The *denominator* is a laterally sited bony eminence on the presenting part ('occiput' for vertex presentation, 'mentum' for face, 'acromium' for shoulder and 'sacrum' for breech). The *position* of the presenting part is defined by the relationship of the denominator to the maternal bony pelvis. The vertex enters the pelvis in the occipito-transverse (OT) position and during descent rotates to an occipito-anterior (OA) position in 90% of cases. This position is associated with a well-flexed head, allowing the smallest anteroposterior (suboccipito-bregmatic) and lateral (biparietal) diameters to pass through the pelvis (both 9.5 cm). *Malposition* occurs when the occiput remains in a tranverse or posterior position as labour progresses. Persistent malposition results in *deflexion* with a larger anteroposterior diameter presenting (occipito-frontal 11.5 cm). It is associated with increasing degrees of anterior or posterior *asynclitism*, with one of the parietal bones preceding the sagittal suture (in posterior asynclitism, the posterior parietal bone leads; Fig. 26.1). Significant degrees of asynclitism can result in labour dystocia and a higher risk of operative delivery [1].

In most cases, flexion occurs as the vertex descends onto the pelvic floor, leading to correction of the malposition and a high chance of spontaneous delivery. The *level* of the presenting part should be critically assessed as labour progresses. On abdominal examination, the head should descend until it is no more than 1/5 palpable in the late first stage. On vaginal examination the presenting part is assessed relative to the level of the ischial spines. Care must be taken to assess the level using the *lowest bony part*. Malposition is associated with increased moulding of the fetal skull and a large caput succedaneum, which may give false reassurance about the true degree of descent. In modern obstetric practice, operative vaginal delivery is not attempted if the leading edge of the skull is above the ischial spines (i.e. above '0' station; Fig. 26.2).

Malpresentations

Breech presentation

The incidence of breech presentation varies according to gestation: 20% at 30 weeks falling to 4% by term. The aetiology of most breech presentations at term is unclear but known factors to consider include placenta praevia, polyhydramnios, bicornuate uterus, fibroids and, rarely, spina bifida or hydrocephaly.

Types of breech presentation

Between 50 and 70% of breech presentations manifest with hips flexed and knees extended (extended breech) Complete (or flexed) breech is more common in multiparous women and constitutes 5–10% at term (hips and knees flexed; Fig. 26.3). Incomplete or footling breech (10–30%) presents with one or both hips extended, or

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

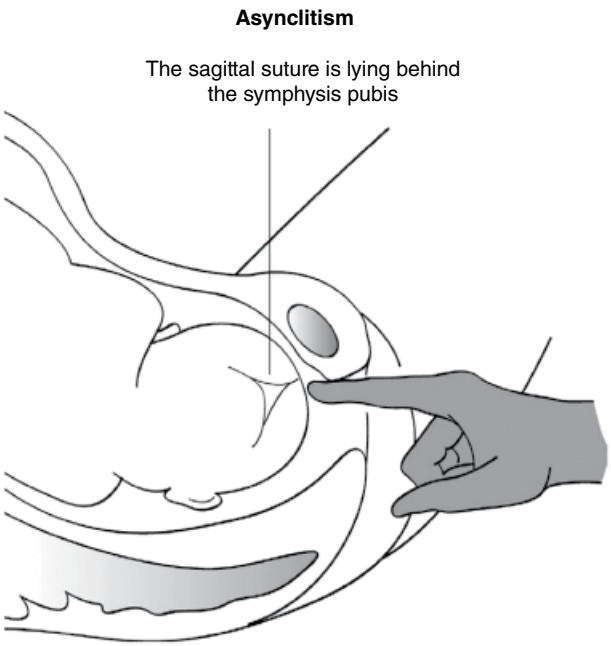

Fig. 26.1 Posterior asynclitism of the vertex: posterior parietal bone presenting below the sagittal suture.

one or both feet presenting and is most strongly assoiated with cord prolapse (5–10%). Knee presentation is rare.

Clinical diagnosis may miss up to 20% of breech presentations, relying on identifying the head as a distinct hard spherical hard mass to one or other side under the hypochondrium which distinctly 'ballots'. In such cases the breech is said to feel broader and an old adage reminds us: 'Beware the deeply engaged head – it is probably a breech!' Auscultation may locate the fetal heart above the maternal umbilicus and ultrasound confirmation should be considered.

Antenatal management

If breech presentation is suspected at 36 weeks, ultrasound assessment is recommended as it allows a comprehensive assessment of the type of breech, placental site, estimated fetal weight, confirmation of normality and exclusion of nuchal cord or hyperextension of the fetal neck.

External cephalic version (ECV) is encouraged after 36 or more weeks as the chance of spontaneous version to

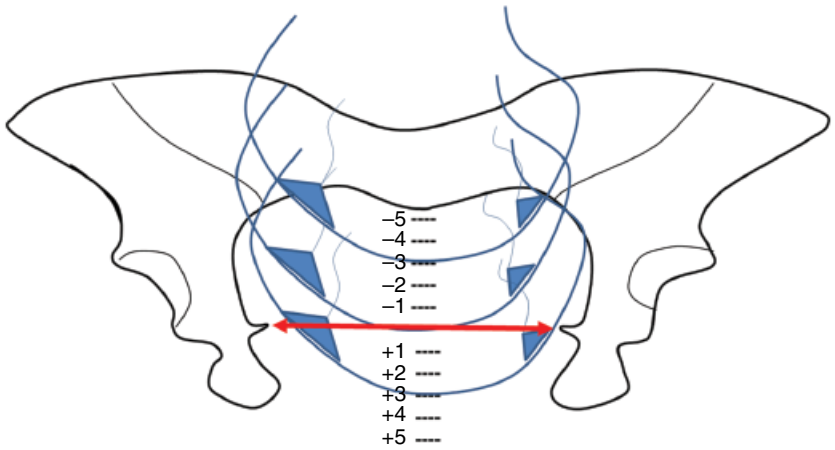

Fig. 26.2 Level of the presenting part relative to the ischial spines.

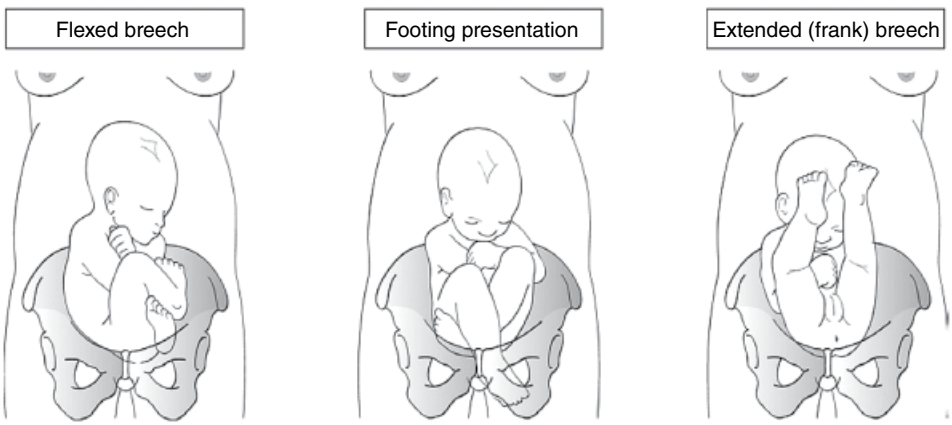

Fig. 26.3 The common types of breech presentation.

cephalic presentation after 37 weeks is only 8%. Absolute contraindications are relatively few but include placenta praevia, bleeding within the last 7 days, abnormal cardiotocography (CTG), major uterine anomaly, ruptured membranes and multiple pregnancy [2]. Couples should receive counselling about the procedure and its success rates and complications, and the subsequent management of persistent breech presentation. Tocolysis increases the likelihood of success, with average rates of 50% (range 30–80%). Women should be made aware that even with a cephalic presentation following ECV, labour is still associated with a higher rate of obstetric intervention than when ECV has not been required. ECV should be performed in a setting where urgent caesarean section (CS) is available in case of fetal compromise during or soon after ECV. CTG for 30–40 min prior to and after ECV should provide confirmation of fetal health. The chance of success is greater with multiparity, flexed breech presentation and an adequate liquor volume. The use of moxibustion at 33–35 weeks, in combination with acupuncture, may reduce the numbers of births by CS. Training specialist midwives is potentially cost-efficient with success rates comparable to consultant-led services (51–66%) [3].

The first step in ECV involves disengaging the breech by moving the fetus up and away from the pelvis, shifting it to a sideways position, followed by a forward somersault to move the head to the lower pole; if this fails a backward somersault can be tried. The need for emergency delivery by CS because of suspected fetal compromise is estimated to be 0.5%. Mothers who are rhesus-negative should have a Kleihauer–Betke test after the procedure and receive anti-D. If ECV is unsuccessful, women who are keen to avoid CS may be offered a repeat attempt under neuraxial blockade. This increases the chances of success (58.4% vs. 43.1%; relative risk, RR 1.44, 95% CI 1.27–1.64) and reduces the incidence of CS (46.0% vs. 55.3%; RR 0.83, 95% CI 0.71–0.97) [4]. Otherwise appropriate counselling about the options of elective CS or assisted vaginal breech delivery should be offered.

Deciding mode of delivery

Despite increasing evidence supporting elective CS for breech delivery at term, controversy and debate continue among professional groups.

1) *Breech presentation at term diagnosed antenatally*. The Term Breech Trial is the largest published randomized controlled trial where the primary outcome (serious perinatal morbidity and mortality) favoured planned CS over planned vaginal birth: 17/1039 (1.6%) versus 50/1039 (5.0%; RR 0.33, 95% CI 0.19–0.56; P <0.0001) [5]. The trial concluded that 'planned CS is better than planned VB for the term fetus in the breech presentation; serious maternal complications are similar between the groups'. This has significantly changed practice in many countries despite continuing debate and criticism about the trial design and intepretation of outcomes. However, the latest systematic review has confirmed a significant increased perinatal risk associated with planned vaginal birth [6].
2) *Breech at term diagnosed in labour and preterm breech delivery*. Observational trials of term breech 'undiagnosed' until presentation in labour confirm that this group has a high vaginal delivery rate with relatively low perinatal morbidity. In a similar vein, the evidence to guide best practice for delivery of the preterm breech remains equivocal, decisions often being based on individual interpretation of the data and local custom and practice.

Conducting a vaginal breech delivery

For women who wish to deliver vaginally, antenatal selection aims to ensure optimal outcome for mother and baby but remains relatively subjective. Women with frank and complete breech presentations (fetal weight <4000 g) encounter minimal problems, while those with footling breech are advised elective CS because of the increased risk of cord prolapse. CT or X-ray pelvimetry do not appear to improve outcome. Spontaneous onset of labour is preferred and labour management is similar to vertex presentation. Successful outcome depends on a normal rate of cervical dilatation, descent of the breech and a normal fetal heart rate (FHR) pattern. Where progress of labour is poor and uterine contractions are inadequate, oxytocin augmentation can be used juidiciously with early resort to emergency CS if progress remains slow (<0.5 cm/hour), particularly in the late first stage.

Epidural anaesthesia prevents bearing down before the cervix is fully dilated and is particularly important for labour with a preterm breech, when there is a real risk of head entrapment in the incompletely dilated cervix if pushing commences too early. For all breech labours, the mother should be encouraged to avoid bearing down for as long as possible. It is best to wait until the anterior buttock and anus of the baby are in view over the mother's perineum, with no retraction between contractions. Classically, the mother's legs are supported in the lithotomy position (the alternative upright breech technique is described later). Primigravidae will usually require an episiotomy with appropriate analgesia, although multigravidae can be assessed as the perineum stretches up.

The buttocks deliver in the sacro-tranverse position. The mother should be encouraged to push with contractions, aiming for an unassisted delivery up to and beyond the level of the umbilicus. There is no need to pull down

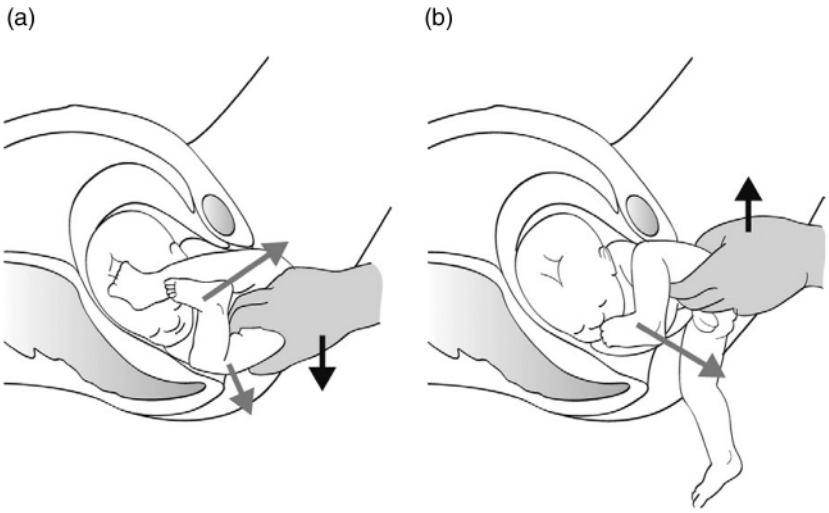

Fig. 26.4 Delivery of extended legs by gentle abduction of the thigh with hyperflexion at the hip, followed by flexion at the knee: (a) right leg; (b) left leg.

a loop of cord. The accoucheur should sit with hands ready, but resting on their own legs. Assistance is only required if the legs do not deliver. Gentle abduction of the fetal thigh whilst hyperflexing the hip, followed by flexing the lower leg at the knee will release the foot and leg (Fig. 26.4).

When the scapulae are visible with the arms flexed in front of the chest, sweep each arm around the side of the fetal chest to deliver using a finger placed along the length of the humerus. If the scapulae are not easily seen or if the arms are not easily reached, they may be extended above the shoulders. This can be resolved using the Løvset manoeuvre.

1) Hold the baby by wrapping both hands around the bony pelvis, taking care not to apply pressure to the soft fetal abdomen.
2) Rotate the baby 180° to bring the posterior shoulder to the front, i.e. to lie anteriorly (Fig. 26.5a).
3) Complete delivery of the anterior arm by gently flexing the baby laterally downwards towards the floor; the arm will deliver easily from under the pubic ramus (Fig. 26.5b).
4) Repeat the 180° rotation in the opposite direction, bringing the posterior shoulder to the front, then flex the baby laterally downwards to deliver the second arm.

Nuchal displacement (an arm trapped behind the fetal neck) is rare. If the left arm is trapped, the baby will need to be rotated in a clockwise direction to 'unwrap' the arm so that it can be reached. If the right arm is involved, anticlockwise rotation is needed.

Allow the head to descend into the pelvis, assisted by the weight of the fetus until the nape of the neck is visible under the symphysis pubis. Ensure slow controlled delivery of the head using one of four methods.

1) Mauriceau–Smellie–Veit manoeuvre: two fingers are placed on the maxilla, lying the baby along the forearm. Hook index and fourth fingers of the other hand over the shoulders with the middle finger on the occiput to aid flexion. Apply traction to the shoulders with an assistant applying suprapubic pressure if needed (Fig. 26.6).
2) Burns–Marshall method: grasp the feet, apply gentle traction and swing the baby gently up and over the maternal abdomen until the mouth and nose appear.
3) Forceps are applied to the head from below, with an assistant supporting the baby's body in the horizontal plane avoiding hyperextension. Kielland's forceps can be useful as they lack a pelvic curve. Apply traction, bringing the forceps upwards as the mouth and nose appear.
4) The upright breech technique is increasingly popular in midwifery deliveries. Mobility is encouraged with delivery on all fours, sitting (on a birth stool), kneeling, standing or lying in a lateral position. Delivery is spontaneous with no manual assistance in 70% of cases and a reduced incidence of perineal trauma (14.9%).

Entrapment of the aftercoming head

This rare complication occurs in two situations.

1) If the fetal back is allowed to rotate posteriorly, the chin may be trapped behind the symphysis pubis. Correction requires difficult internal manipulation to free the chin by pushing it laterally. McRoberts' manoeuvre and suprapubic pressure may help. Symphysiotomy is a last resort that can increase the available pelvic diameters.
2) In preterm delivery, the body can slip through an incompletely dilated cervix, with resulting head entrapment. If the cervix cannot be 'stretched up'

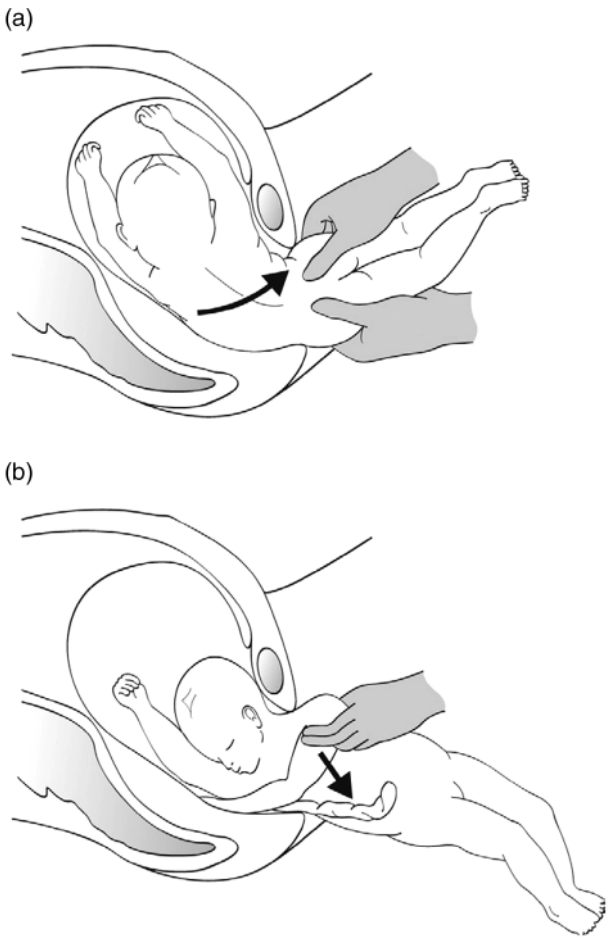

Fig. 26.5 Løvset's manoeuvre for extended arms: (a) rotation to bring the posterior (left) arm to the front followed by (b) delivery of the left arm (now anterior) from under the pubic ramus.

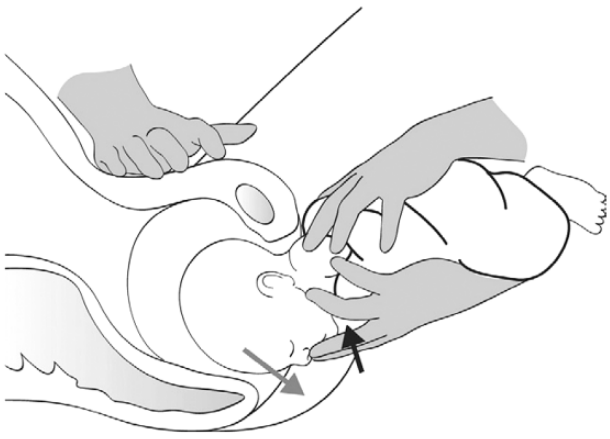

Fig. 26.6 Delivery of the head using the Mauriceau–Smellie–Veit manoeuvre assisted by suprapubic pressure.

digitally, surgical incisions are made in the cervical ring at 2, 6 and 10 o'clock (Dührssen incisions). Head entrapment in the contractile upper segment can occur at CS. Acute tocolysis and/or extension of the uterine incision may be required to release the head.

Women should be intimately involved in decisions about mode of breech delivery and the available evidence presented appropriately. A senior midwife or a doctor experienced in assisted breech delivery must be present. As vaginal breech deliveries decline, developing expertise in breech delivery now relies on simulation training and experience of breech delivery at CS.

Summary box 26.1

- ECV has a high success rate (51–66%) and should be encouraged.
- Ensure the fetal back does not rotate posteriorly during breech delivery.
- The most experienced accoucheur available should directly supervise vaginal breech delivery.

Brow presentation

Brow presentation occurs in 1 in 1500–3000 deliveries. The head is partially deflexed (extended), with the largest diameter of the head presenting (mento-vertical, 13.5 cm). The forehead is the lowest presenting part but diagnosis relies on identifying the prominent orbital ridges lying laterally. The eyeballs and nasal bridge may just be palpated lateral to the orbital ridges. Position is defined using the frontal bone as the denominator (i.e. 'fronto-'). Persistent brow presentation results in true disproportion, but when diagnosed in early labour careful assessment of progress is appropriate. Flexion to vertex or further extension to face presentation occurs in 50% and vaginal delivery is possible. Cautious augmentation with oxytocin should only be considered in nulliparous patients for delay in the early active phase of labour. If brow presentation persists, emergency CS is recommended. Vaginal delivery of a brow presentation is possible in extreme prematurity. Preterm labour is best managed in the same way as term labour, with delivery by CS if progress slows or arrests. Cord prolapse is more common and, though rare, uterine rupture can occur in neglected labour or with injudicious use of oxytocin. For this reason labour should not be augmented in multigravid patients with a confirmed brow presentation if progress is inadequate.

Face presentation

Face presentation occurs in 1 in 500–800 labours. The general causes of malpresentation apply for face presentation, but fetal anomalies (neck or thyroid masses,

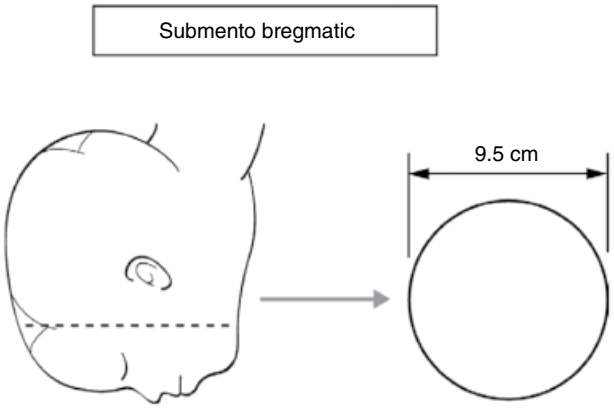

Fig. 26.7 The anteroposterior submento-bregmatic diameter of face presentation.

hydrocephalus and anencephaly) should be excluded. The fetal head is hyperextended and the occiput may be felt higher and more prominently on the same side as the fetal spine. However, face presentation is rarely diagnosed antenatally. On vaginal examination in labour, diagnosis relies on feeling the mouth, malar bones, nose and orbital ridges. Position is defined using the chin or mentum as the denominator. The mouth and malar bones form a triangle which can help differentiate face presentation from breech, where the anus lies in a straight line between the prominent ischial tuberosities. Face presentation is often first diagnosed in late labour. The submento-bregmatic diameter (9.5 cm) is compatible with normal delivery but only with the fetus in a mento-anterior position (60%) (Fig. 26.7). The same diameter presents with a persistent mento-posterior position (25%) but this cannot deliver vaginally as the fetal neck is maximally extended. Fetal scalp clips, blood sampling and vacuum extraction are absolutely contraindicated. Forceps delivery from low cavity can be undertaken for mento-anterior or mento-lateral positions by an experienced accoucheur but CS may still be required when descent is poor.

Shoulder presentation

The incidence of shoulder presentation at term is 1 in 200 and is found with a transverse or oblique lie. Multiparity (uterine laxity) and prematurity are common associations and placenta praevia must be excluded. The lie will usually correct spontaneously before labour as uterine tone increases, although prolapse of the cord or arm is a significant risk if membranes rupture early. For this reason, hospital admission from 38 weeks is recommended for persistent transverse lie. External version can be offered (and may also be considered for transverse lie presenting in very early labour). On vaginal examination, the denominator is the acromium but defining position can be difficult. If membrane rupture occurs at term with the uterus actively contracting, delivery by CS should be undertaken promptly to avoid an impacted transverse lie. If the uterus is found to be moulded around the fetus, a classical CS is recommended to avoid both fetal and maternal trauma. In cases of intrauterine death with a transverse lie, spontaneous vaginal delivery is possible for early preterm fetuses by extreme flexion of the body (spontaneous evolution). However, CS will usually be required beyond mid-trimester, although a lower segment approach may be used.

Malposition and cephalopelvic disproportion

In higher-income countries, cephalopelvic disproportion is usually 'relative' and due to persistent malposition or relative fetal size (macrosomia). Classically we consider these problems with regard to the passage, the passenger or the powers, either alone or in combination.

The passage

Absolute disproportion due to a contracted pelvis is now rare in higher-income countries unless caused by severe pelvic trauma and this should be known before the onset of labour. Caldwell and Moloy described four types of pelvis: gynaecoid (ovoid inlet, widest transversely, 50%), anthropoid (ovoid inlet, widest anteroposterior, 25%), android (heart-shaped inlet, funnel-shaped, 20%) and platypelloid (flattened gynaecoid, 3%). These can influence labour outcome but as pelvimetry is rarely used and clinical assessment of pelvic shape is inaccurate, this rarely influences clinical mangement in labour. The anthropoid pelvis is associated with a higher risk of persistent occipito-posterior (OP) position and relative disproportion.

The passenger and OP malposition

Fetal anomalies (e.g. hydrocephalus, ascites) where disproportion may be a problem in labour are usually assessed antenatally and delivery by elective CS considered. Fetal macrosomia is increasing, related to the rising body mass index (BMI) in many pregnant populations. The evidence for inducing non-diabetic women with an estimated fetal weight above the 90th centile (or >4000 g) in order to reduce cephalopelvic disproportion remains equivocal. Malposition is an increasingly common cause of disproportion and may be related to a sedentary lifestyle. OP position is associated with deflexion and/or asynclitism with a larger diameter presenting. Optimal uterine activity will correct the malposition in 75% of cases. Flexion occurs as the occiput reaches the pelvic floor with long rotation through 135° to an OA position and a high chance of normal delivery. Moulding of the

fetal skull and pelvic elasticity (related to changes at the symphysis pubis) are dynamic changes that facilitate progress in labour and delivery. Short rotation through 45° to direct OP can result in spontaneous 'face to pubes' delivery, although episiotomy may be required to allow the occiput to deliver. Persistent OP position occurs in up to 25% of cases and is associated with further deflexion. The risk of assisted delivery is high because of relative disproportion as the presenting skull diameters increase. Delivery in the OP position from mid-cavity (0 to +2 station) requires critical assessment to decide whether delivery should be attempted vaginally or abdominally and is discussed in later sections.

The powers

Disproportion is intimately related to dystocia and failure to progress in labour. National Institute for Health and Care Excellence (NICE) guidelines recommend that first stage delay is suspected with cervical dilatation of less than 2 cm in 4 hours when forewater amniotomy should be offered. Delay is confirmed if progress is less than 1 cm 2 hours later and oxytocin augmentation should be offered [6]. This shortens labour but does not affect operative delivery rates. High-dose oxytocin may reduce CS rates but larger trials are required before these regimens are used routinely. The decision to use oxytocin in labour arrest in multigravid patients must only be made by the most senior obstetrician and should always be approached with extreme caution as uterine rupture is a possible consequence.

In the second stage, particularly with epidural analgesia, passive descent for at least 1 hour is recommended, and possibly longer if the woman wishes, before encouraging active pushing. With regional analgesia and a normal FHR pattern, birth should occur within 4 hours of full dilatation regardless of parity [7]. Oxytocin may be commenced in nulliparous patients in the passive phase if contractions are felt to be inadequate and particularly with the persistent OP position. Failure of second-stage descent combined with excessive caput or moulding suggests disproportion and requires critical assessment to decide the appropriate mode of delivery.

Summary box 26.2

- OP position with deflexion of the head and asynclitism results in relative disproportion compounded by inadequate uterine activity.
- With epidural analgesia in place, passive descent should be encouraged for at least 1 hour.
- Augmentation with oxytocin should be used with extreme caution in multigravid patients with labour arrest.

Instrumental vaginal deliveries

Background

The incidence of instrumental vaginal delivery (IVD) varies widely and in Europe ranges from 0.5% (Romania) to 16.4% (Ireland), although there is no direct relationship with CS rates [8,9]. Epidural analgesia is associated with higher IVD rates. Allowing a longer passive second stage for descent results in less rotational deliveries and possibly a reduction in second-stage CS [10,11]. Common indications for IVD include delay in the second stage of labour due to inadequate uterine activity, malposition with relative disproportion, maternal exhaustion and fetal compromise. Women with severe cardiac, respiratory or hypertensive disease or intracranial pathology may require IVD to shorten the second stage (when forceps may be preferred).

Assessment and preparation for IVD

The condition of the mother and fetus and the progress of labour should be assessed prior to performing IVD. Personal introductions to the woman and her partner are essential, explaining the reason for IVD and ensuring a chaperone and enough support are available. The findings, plan of action and the procedure itself should be explained and the discussions carefully recorded. Verbal or written consent is obtained. The mother and her partner may be physically and emotionally exhausted and great care should be exercised in terms of behaviour, communication and medical action.

On abdominal examination, the fetal head should be no more than 1/5 palpable (preferably 0/5). A scaphoid shape to the lower abdomen may indicate an OP position. The FHR pattern should be assessed, noting any clinical signs of fetal compromise (e.g. fresh meconium). With acute fetal compromise (e.g. profound bradycardia, cord prolapse) delivery must be expedited urgently and this may only allow a brief explanation to be given to the patient and her partner at the time.

If contractions are felt to be infrequent or short-lasting, an oxytocin infusion should be considered in the absence of signs of fetal compromise. Both vacuum and forceps deliveries are associated with an almost threefold increased risk of shoulder dystocia compared with spontaneous delivery and this should be anticipated. However, it remains unclear whether this increased incidence is a cause or effect phenomenon [12].

On vaginal examination the cervix should be fully dilated with membranes absent. The colour and amount of amniotic fluid is recorded. Excessive caput or moulding may suggest the possibility of disproportion. Inability to reduce overlapping skull bones with gentle pressure is

designated 'moulding +++'; overlapping that reduces by gentle digital pressure is 'moulding ++', and meeting of the bones without overlap is 'moulding +'. Identification of position, station, degree of deflexion and asynclitism will help decide whether IVD is appropriate, where it should be undertaken and who should undertake the procedure.

Successful IVD is associated with station below the spines and progressive descent with pushing. If the head is 1/5 palpable abdominally, the leading bony part of the head is at the level of the ischial spines (mid-cavity). When the head is more than 1/5 palpable and/or when station is above the spines, delivery by CS is recommended.

Position is determined by identification of suture lines and fontanelles. The small posterior fontanelle (PF) lies at the Y-shaped junction of the sagittal and lambdoidal sutures but may be difficult to feel when there is marked caput. The anterior fontanelle (AF) is a larger diamond-shaped depression at the junction of the two parietal and two frontal bones. It can be differentiated from the PF by identifying the four sutures leading into the fontanelle. In deflexion (particularly OP positions) the AF lies centrally and is easily felt. Position can be confirmed by reaching for the pinna of the fetal ear, which can be flicked forwards indicating that the occiput lies in the opposite direction. Reaching the ear suggests descent below the mid-pelvic strait. The degree of asynclitism should be assessed (see Fig. 26.1), with increasing degrees suggesting disproportion and a potentially more difficult IVD. Assessment of level and position can be difficult with OP position and in obesity. If there is any doubt after careful clinical examination, ultrasound assessment is recommended. The fetal orbits are sought and the position of the spine is noted. This is simple to do and can reduce the incorrect diagnosis of fetal position without delaying delivery, although on its own may not reduce morbidity associated with IVD [13].

IVD is normally performed with the mother in the dorsal semi-upright position with legs flexed and abducted, supported by lithotomy poles or similar. The procedure is performed with good light and ideally aseptic conditions. The vulva and perineum should be cleansed and the bladder catheterized if the woman is unable to void.

Adequate analgesia is essential and requires careful individualized assessment. Epidural anaesthesia is advisable for mid-cavity IVD (i.e. station 0 to +2 cm below the ischial spines; see Fig. 26.2). In the absence of a pre-existing epidural, spinal anaesthesia may be considered. IVD at station +2 cm or below is termed 'low-cavity' and regional or pudendal block with local perineal infiltration (20 mL 1% plain lidocaine) can be used. Outlet IVD is performed when the head is on or near the perineum with the scalp visible without separating the labia. Descent to this level is associated with an OA position requiring minimal or no rotation and perineal infiltration with pudendal anaesthesia is effective.

When the vertex is below the spines, IVD is carried out with different types of forceps or vacuum equipment, depending on the position and station of the vertex and the familiarity and experience of the doctor. Overall, comparing outcomes is easier if designation is by station and position at the time of instrumentation (e.g. left OP at +3) rather than simply mid, low or outlet IVD [11,14].

Choice of instruments: forceps or ventouse

The choice of instrument depends on the operator's experience, familiarity with the instrument, station and position of the vertex. Therefore, knowledge of the station and the position of the vertex is essential. The fetus in an OA position in the mid/low cavity can be delivered using non-rotational, long or short-handled forceps or a vacuum device: silicone, plastic or anterior metal cups (with suction tubing arising from the dorsum of the cup) are all suitable. For the fetus lying OT at mid- or low-cavity, or lying OP position mid-cavity, Kielland's forceps or vacuum devices can be used to correct the malposition. Manual rotation is another technique to consider.

Low-cavity direct OP positions can be delivered 'face to pubis' but this may cause signifcant perineal trauma as the occiput delivers. For this reason, an OP vacuum cup (with the suction tubing arising from the edge of the cup) may be preferred. The cup will promote flexion and late rotation to OA often occurs on the perineum just prior to delivery. The Kiwi OmniCup® is an all-purpose disposable vacuum delivery system with a plastic cup and in-built PalmPump™ suitable for use in all positions of the vertex. Later models also display force traction to help the accoucheur avoid cup slippage (http://clinicalinnovations.com/portfolio-items/kiwi-complete-vacuum-delivery-system/)

Forceps delivery

Forceps come in pairs and most have fenestrated blades with a cephalic and pelvic curve between the heel and toe (distal end) of each blade. The heel continues as a shank which ends in the handle. The handles of the two blades sit together and meet at the lock. The cephalic curve fits along either side of the fetal head with the blades lying on the maxilla or malar eminences in the line of the mento-vertical diameter (Fig. 26.8a). When correctly attached, uniform pressure is applied to the head, with the main traction force applied over the malar eminences. The shanks are over the flexion point,

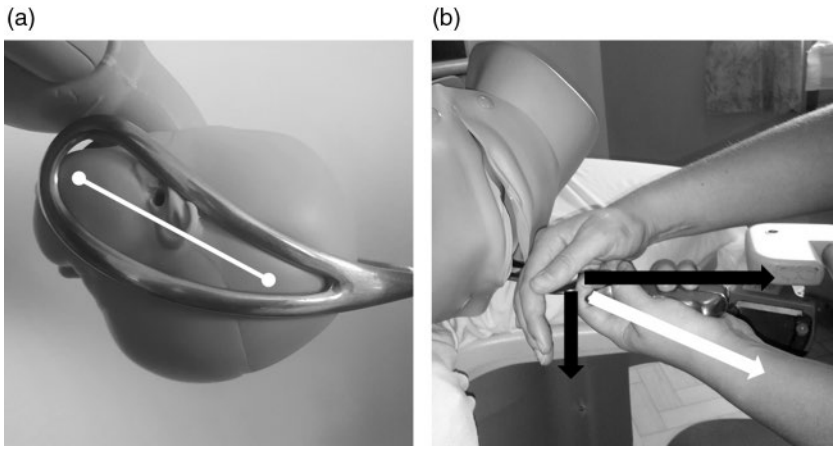

Fig. 26.8 (a) Malar forceps application showing mento-vertical diameter; (b) forceps traction (Pajot's manoeuvre).

allowing effective traction in the correct direction. Non-rotational forceps (the longer-handled Neville Barnes or Simpson, and the shorter-handled Wrigley's) have a distinct pelvic curve that allows the blades to lie in the line of the pelvic axis whilst the handles remain horizontal. Kielland's forceps have a minimal pelvic curve to allow rotation within the pelvis to correct malposition.

Prior to applying forceps, the blades should be assembled to check whether they fit together as a pair. All forceps have matching numbers imprinted on the handles or shanks and these should also be checked.

Non-rotational forceps can be applied when the vertex is no more than 45° either side of the direct OA position (i.e. right OA to left OA). Application and delivery in a direct OP position is also possible but not routinely recommended because of increased perineal trauma. The left blade is inserted first using a light 'pencil grip', negotiating the pelvic and cephalic curves with a curved movement of the blade between the fetal head and the operator's right hand, which is kept along the left vaginal wall for protection. Hands are swapped to insert the right blade using the same technique. Correct application results in the handles lying horizontally, right on top of left, and locking should be easy. Before applying traction, correct application must be confirmed: (i) the sagittal suture is lying midline, equidistant from and parallel to the blades; (ii) the occiput is no more than 2–3 cm above the level of the shanks (i.e. head well-flexed); and (iii) no more than a fingertip passes into the fenestration at the heel of the blade.

From mid- and low-cavity, Pajot's maneouvre should be used, balancing outward traction with one hand with downward pressure on the shanks with the other (Fig. 26.8b, white arrow). The handles are kept horizontal to avoid trauma to the anterior vaginal wall from the toes of the blades. Traction is synchronized with contractions and maternal effort, and the resultant movement is outwards down the line of the pelvic axis until the head is crowning. An episiotomy is usually needed as the perineum stretches up. The direction of traction is now upwards once the biparietal eminences emerge under the pubic arch and the head is born by extension. The mother will usually ask to have her baby handed to her immediately (unless active resuscitation is required). After completing the third stage, any perineal trauma is repaired and a full surgical count completed. The procedure, including plans for analgesia and bladder care, should be fully documented.

Rotational forceps

Kielland's forceps have a minimal pelvic curve allowing rotation of the head at mid-cavity. They are powerful forceps requiring a skilled accoucheur who is willing to abandon the procedure if progress is not as expected. The number of units able to teach use of Kielland's forceps to the point of independent practice is declining in the UK.

The forceps should match and are applied so that the knobs on the handles face the fetal occiput. Kielland's are used to correct both OT and OP positions using two methods of application.

1) Direct application involves sliding each blade along the side of the head if space permits, and is more easily achieved with OP positions.
2) Wandering application is useful in OT positions. The first blade is applied in front of the fetal face, from where it is gently 'wandered' around to lie in the usual position alongside the malar bone. The posterior blade is applied directly using the space in the pelvic sacral curve.

If application is difficult or the blades do not easily lock, the procedure should be abandoned. Correct application should be confirmed. Once locked, it is essential to hold the handles at a relatively steep angle

downwards in the line of the mid-pelvic axis in order to achieve easy rotation.

Asynclitism is corrected using the sliding lock, moving the shanks over each other until the knobs are aligned. Rotation should take place between contractions, using only gentle force. Rotation may require the fetal head to be gently disimpacted, either upwards or downwards but no more than 1-cm displacement is needed. Correct application should be checked again after rotation. Traction should result in progressive descent and an episiotomy is usually required. At the point of delivery, the handles of Kielland's are only just above the horizontal because of the lack of pelvic curve. If there is no descent with traction during three contractions with maternal effort, the procedure should be abandoned. Whether Kielland's delivery takes place in the delivery room or in obstetric theatre requires careful assessment of fetal and maternal condition, analgesia and labour progress. If there is any doubt, a formal trial of forceps should be arranged.

Vacuum delivery

Ventouse or vacuum delivery is increasingly favoured over forceps delivery for similar indications in the second stage of labour. The prerequisites to be satisfied before vacuum delivery are the same as for all forms of IVD. Vacuum delivery is contraindicated below 34^{+0} weeks and should be used with caution between 34^{+0} to 36^{+0} weeks [11]. Overall it is contraindicated for fetuses with possible haemorrhagic tendencies (risk of subgaleal haemorrhage) and before full dilatation [11]. Experienced practitioners may consider vacuum after 8 cm in a multigravid patient in some circumstances.

There are many types of vacuum cup in regular use, made of different materials and of differing shapes. Whichever cup is used, the aim is to ensure that the centre of the cup is directly over the flexion point. The flexion point is 3 cm in front of the occiput in the midline and is the point where the mento-vertical diameter exits the fetal skull [15]. Traction on this point promotes flexion, presenting the smallest diameters for descent through the pelvis: this is the optimum flexing median application (Fig. 26.9a). Other applications increase the risk of cup detachment, failed vacuum delivery and scalp trauma. In decreasing order of effectiveness, these are the flexing paramedian application (Fig. 26.9b), the deflexing median application (Fig. 26.9c) and the deflexing paramedian application (Fig. 26.9d).

It is vitally important to select the correct cup and this will vary depending on both the position and attitude of the fetus. The soft Silc, Silastic or anterior metal cups (where the tubing is attached on the dorsum of the cup) are not suitable for OT or OP positions, as their shape and configuration do not allow application over the flexion point. They are suitable for OA positions where the flexion point is accessible in the midline.

Metal cups come in different sizes, usually 4, 5 or 6 cm in diameter. In a systematic review they were more likely to result in successful vaginal birth than soft cups (RR 1.63, 95% CI 1.17–2.28), but with more cases of scalp injury (RR 0.67, 95% CI 0.53–0.86) and cephalhaematoma (RR 0.61, 95% CI 0.39–0.95) [16]. A specially designed cup should be used for OT and OP positions: metal OP cups have tubing emerging from the lateral aspect of the cup and the Kiwi OmniCup has a groove in the dorsum of the cup to accommodate the flexible stem. These cups can be manoeuvred more laterally or posteriorly to reach the flexion point. Hand-held vacuum is associated with more failures than metal ventouse [16], although a larger study suggested that the OmniCup has an overall failure rate of 12.9% [11].

Aldo Vacca (1941–2014) was the doyen of vacuum delivery and (with reference to the flexion point and cup application) his favourite quote was 'It's always more posterior than you think'. After ensuring flexion point application, the cup must be held firmly on the fetal scalp, and a finger should be run around the rim to ensure that no maternal tissue is entrapped. A vacuum of 0.2 bar (150 mmHg or 0.2 kg/cm^2 negative pressure) is created using a hand-held or mechanical pump, before

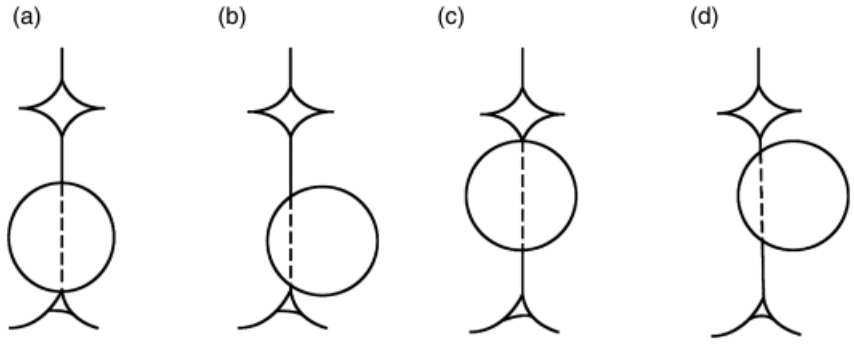

Fig. 26.9 Placement of the vacuum cup, from most favourable (a) to unfavourable (d). (a) Flexing median; (b) flexing paramedian; (c) deflexing median; (d) deflexing paramedian.

rechecking the position over the flexion point and confirming maternal tissue is not trapped. The vacuum is increased to 0.7–0.8 bar (500–600 mmHg or 0.8 kg/cm^2) in one step, waiting 2 min where possible to develop the 'chignon' within the cup. Axial traction in the line of the pelvic axis should be timed with uterine contractions and maternal pushing. A thumb should be placed on the cup, with the index finger on the scalp at the edge of the cup allowing the operator to feel any potential detachment before it is heard (by which point it is often too late to prevent detachment). Descent promotes autorotation of the head to the OA position and episiotomy is often not required. Parents should be reassured that the 'chignon' will settle over 2–3 days.

Manual rotation

Manual rotation for persistent OP position is an alternative to IVD. The procedure requires insertion of one hand into the posterior vagina to encourage flexion and rotation. Careful patient selection is essential and the operator must ensure that effective analgesia is in place. The right hand is inserted for a left OP position (insert left hand for right OP). Four fingers are placed behind the fetal occiput to act as the 'gutter' on which the head will rotate, with the thumb placed alongside the anterior fontanelle. When the mother pushes with a contraction, the thumb applies pressure to flex the head and rotation to an OA position should occur with minimal effort. In a series ($N = 61$) where OP position was managed in two groups, the spontaneous delivery rate increased from 27% to 77% in the group offered digital rotation ($P < 0.0001$) [17].

Complications of IVD

In a Cochrane review of 32 studies ($N = 6597$), forceps were less likely to fail to achieve a vaginal birth compared with ventouse (RR 0.65, 95% CI 0.45–0.94) [16]. Vaginal and perineal lacerations, including third- and fourth-degree tears, are more common with forceps than with vacuum. Infra-levator haematomas may occur occasionally and these should be drained if large or symptomatic. The risk of flatus incontinence or altered continence is also higher.

Follow-up of women who have had low or outlet IVD confirms normal physical and neourological outcomes for the vast majority of the newborn. In terms of neonatal outcome, cephalhaematoma is more common with vacuum but risk of facial injury is less. Facial and scalp abrasions are usually minor and heal in a few days. Unilateral facial nerve palsy is rare and resolves within days or weeks and is not usually related to poor technique. Skull fracture is rare and most need no treatment unless depressed, when surgical elevation may be indicated. Vacuum delivery may result in retinal haemorrhages, haematoma confined to one of the skull bones and neonatal jaundice. Severe scalp lacerations imply poor technique and are fortunately rare. Subgaleal haemorrhage may cause minor or severe morbidity and rarely mortality [18]. In reviewing morbidity associated with IVD, it is important to remember that the alternative option of second-stage CS is also associated with increased morbidity for both mother and baby.

Safe practice: sequential intrumentation and trial of instrumental delivery

For all IVDs, the procedure should be abandoned if there is 'no evidence of progressive descent with moderate traction during each contraction, or where delivery is not imminent following three contractions of a correctly applied instrument by an experienced operator' [11]. Sequential instrumentation is associated with increased neonatal morbidity and the decision to proceed must take into account the relative risks of delivery by second-stage CS from deep in the pelvis. It can be difficult to judge whether to proceed with IVD, especially in cases with mid-cavity malposition at the level of the ischial spines. In such cases a trial of instrumental delivery should be undertaken in theatre under regional anaesthesia, with the full theatre team and neonatal practitioner present. The estimated incidence of trial of instrumental delivery is 2–5%. It is vital to maintain awareness of the situation, with a clear willingness to abandon the attempt if progress is not as expected, proceeding immediately to CS. The couple should be advised of this strategy and appropriate consent obtained prior to the procedure, which should be undertaken by the most senior obstetrician available. In the presence of fetal compromise, it is prudent to consider delivery by emergency CS, rather than proceeding with a potentially difficult IVD. Paired cord blood samples should be taken and results recorded after every attempted IVD.

Contemporary developments in IVD

New methods are being developed to achieve IVD and include disposable plastic forceps with the ability to measure traction force (see http://www.medipex.co.uk/success-stories/pro-nata-yorkshire-obstetric-forceps/ and Fig. 26.10) and the Odon device where traction is applied using a plastic bag placed around the fetal head and neck. This device is undergoing trials led by the World Health Organization (see http://www.who.int/reproductivehealth/topics/maternal_perinatal/odon_device/en/).

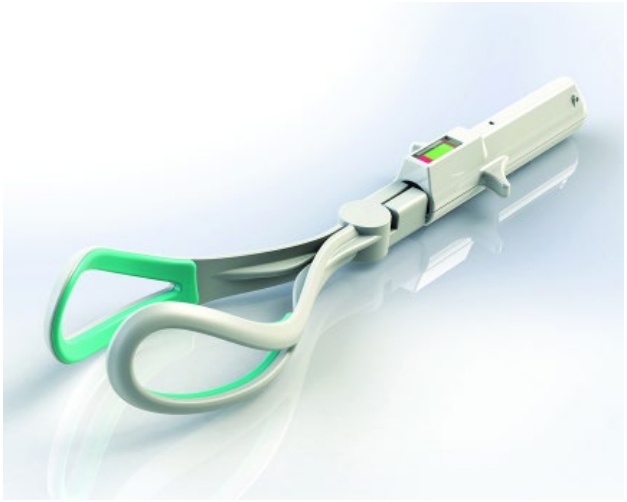

Fig. 26.10 Pro-Nata Yorkshire obstetric forceps. Reproduced with permission of Mark Jessup.

Summary box 26.3

- Level and position must be critically assessed before proceeding with IVD and ultrasound is a useful adjunct.
- Successful vaginal delivery is more likely when the correct vacuum cup is applied directly over the flexion point.
- Safe practice with IVD requires the operator to maintain a willngness to abandon the procedure at all times.

Caesarean section

CS rates vary widely across Europe, ranging from 14.8% in Iceland to 52.2% in Cyprus [8,9]. In 2015, the World Health Organization confirmed that CS rates higher than 10% are not associated with reductions in maternal and newborn mortality rates but acknowledged that the effects of CS rates on other outcomes (maternal and perinatal morbidity, paediatric outcomes, and psychological or social well-being) are still unclear and require further research [19]. This is very pertinent to obstetrics in the twenty-first century at a time when CS rates for non-obstetric indications are rising. This includes elective CS where the primary indication is maternal request, often reflected in significantly higher rates in the private sector.

Indications

The indications for CS are grouped into four categories depending on the urgency of the procedure [20,21].

- *Category 1*. There is immediate threat to the life of mother or fetus. Examples include abruption, cord prolapse, scar rupture, scalp blood pH below 7.20, and prolonged fetal bradycardia. Although a decision-to-delivery interval of 30 min is a useful audit tool to help review local practice, it does not correlate directly with poor perinatal outcome. Timing should be individualized and depends on the clinical urgency in each case. Those cases of utmost urgency require clear and timely communication between all members of the team. Team performance may benefit by practising rapid transfer to theatre using 'hot drill' simulation techniques [21].
- *Category 2*. There is no immediate risk to the life of mother or fetus. Delivery should be expedited in a timely manner but individual assessment remains critical. Examples include those with deteriorating CTG and a borderline scalp pH (especially in the early active phase of labour) or with slow progress in labour and poor maternal pain control. It is accepted that clinicians will categorize cases differently based on their interpretation of the clinical situation.
- *Category 3*. Requires early delivery but with no current maternal or fetal compromise. This group has a wide range of indications, including planned CS with ruptured membranes at term, not contracting or a growth-restricted fetus in the preterm period with abnormal venous Doppler but a normal FHR tracing.
- *Category 4*. The delivery is timed to suit the mother and maternity staff. This replaces the term 'elective CS' and should normally be delayed until 39 weeks to minimize the incidence of transient tachypnoea of the newborn.

Types of caesarean section

Lower uterine segment incision

The commonest CS procedure uses a transverse incision in the lower uterine segment (LUS). The abdomen is usually opened with a Pfannenstiel (transverse suprapubic) incision. The Joel-Cohen technique involves blunt digital stretching and separation of tissues using the natural tissue planes, with minimal sharp dissection and non-closure of both peritoneal layers. This has advantages over Pfannenstiel and traditional (lower vertical incision) techniques with improved short-term outcomes including shorter operating time, reduction in estimated blood loss and less pyrexia. Disposable double-ring retractors provide 360° circumferential atraumatic wound retraction and reduce superficial surgical site infection in gastrointestinal surgery by 45%. They give excellent access at CS and can be particularly useful in patients with a high BMI to support the panniculus during delivery and uterine repair. One of the flexible rings is inserted

Fig. 26.11 Disposable retractor for caesarean section.

through the incision to lie under the abdominal wall and the surgeon and assistants roll up a thin polythene cylinder onto the second ring which lies outside the abdomen (Fig. 26.11).

Ensure that the uterus is not significantly dextrorotated. The utero-vesical peritoneum is divided, the bladder reflected caudally and a transverse incision is made in the LUS taking care to avoid injury to the fetus. Enlarging the uterine incision with scissors increases the risk of unintended extension compared with digital expansion. A recent systematic review confirmed that digital expansion in the cephalad–caudad direction rather than transversely further reduces the incidence of unintended extension, uterine vessel injury and major blood loss over 1500 mL [22]. In the later stages of labour, care should be taken to avoid making the incision too low, which can result in inadvertent delivery through the anterior vaginal wall below the level of the cervix.

A hand is inserted to guide delivery of the presenting part through the lower segment. Wrigley's forceps may be used to assist delivery in cephalic presentation. After delivery of the placenta, the uterine cavity should be checked to ensure it is empty. There is no advantage in inserting a finger through the cervix to facilitate drainage of lochia, even at elective CS. The CAESAR trial confirmed that single versus double closure of the uterus and non-closure versus closure of the peritoneum did not influence short-term morbidity, including infection [23]. However, it remains difficult to give definitive guidance because of the paucity of long-term morbidity data. At present, traditional two-layer repair is recommended based on observational data showing a fourfold increase in uterine rupture with single-layer closure, particularly if a locking suture technique is used. Whichever closure method is used, it is vital to ensure optimum alignment of all layers: decidua to decidua, myometrium to myometrium, and serosa to serosa. Blood loss is much less with lower-segment compared with upper-segment CS.

Before abdominal closure, undertake careful peritoneal toilet to remove excess blood and liquor and inspect both adnexa. Remember that handling the peritoneal layer may cause discomfort even under effective neuraxial blockade. The rectus sheath may be closed with a No. 1 polyglactin suture. In repeat CS or with BMI 30 and above, a delayed absorbable (polydioxanone) or non-absorbable polypropylene suture is recommended because it significantly reduces the risk of late wound dehiscence. The subcutaneous fat layer should be closed if it is more than 2 cm thick as this further reduces the risk of wound breakdown. Finally, subcuticular skin closure reduces the risk of superficial dehiscence compared with use of staples or clips. Prophylactic antibiotics and low-molecular-weight heparin to prevent thromboembolism are routinely administered. Enhanced recovery programmes provide an evidence-based approach to surgical recovery and include early mobilization and feeding. Removal of the urinary catheter and venous cannulae should be considered at 4–6 hours after surgery in uncomplicated cases.

Upper segment uterine incision

Classical CS involves a high midline vertical incision through the upper uterine segment (UUS). The vertical DeLee incision is sited one-third in the lower segment and two-thirds in the upper. UUS incisions have a higher risk of rupture in labour and elective CS is recommended in future pregnancies. There is also a small risk of spontaneous rupture in the antenatal period and elective CS is undertaken at 37–38 weeks (with prior steroid administration to promote fetal lung maturity). There are several indications for using the UUS approach, including impacted transverse lie with ruptured membranes, preterm CS with a narrow poorly formed LUS, large fibroids in the LUS, and in some cases of anterior placenta praevia with large vessels in the LUS. In the presence of an invasive placenta, it is vitally important to incise the uterus away from the placental site as this can lead to torrential life-threatening haemorrhage. A classical incision may be used if the invasive placenta involves the LUS, but a transverse incision at the fundus or even delivery via a posterior uterine incision may be required.

The UUS is often 2–3 cm thick and care must be taken on entering the cavity. However, the incision gives excellent access and delivery of the fetus is generally easy. Closure requires three layers of sutures and No. 1 or 0 polyglactin is recommended. An assistant holds the walls of the UUS together whilst individual sutures are inserted and tied. Interrupted figure-of-eight or Z stiches are

used for the first layer as these are more haemostatic. Subsequent layers may require interrupted sutures depending on the amount of bleeding. A non-suction tube drain can be left *in situ*. Postoperative morbidity (including paralytic ileus) is more common after UUS section and close observation is required.

Peri-mortem caesarean section (PMCS) or resuscitative hysterotomy

Cardiac arrest occurs in only 1 in 12 500 pregnancies. Peri-mortem CS is recommended if the gestation is greater than 20 weeks and return of spontaneous circulation does not occur after 4 min of effective cardiopulmonary resuscitation (CPR). The primary aim is to save the mother's life, as emptying the uterus improves venous return and facilitates resuscitation. Ideally, delivery should be completed within a further minute. This is rarely achieved in practice, but expediting delivery can be helped by following these simple steps: minimal skin preparation, avoiding full surgical 'scrub up' (i.e. a pair of gloves is all that is required) and a scalpel is the only instrument required. For clinicians unfamiliar with the Pfannenstiel incision and lower segment CS technique, a midline lower abdominal incision and vertical uterine incision approach is recommended. Bleeding will be minimal and the placenta can be left *in situ*. If resuscitation is successful, the patient will be anaesthetized and moved to theatre to complete surgery. Sadly in most cases, resuscitation is unsuccessful. In the UK, the appropriate legal entity must be informed (the coroner in England) and a post-mortem is likely to be required. For this reason, all tubes and cannulae present at the time of death must be left in place, the uterus left unsutured and the abdomen covered but not surgically closed. Appropriate support is essential for all family, relatives and staff involved.

Complications associated with caesarean section

Morbidity and mortality associated with CS cannot be totally avoided. Complications include haemorrhage, urinary tract damage, anaesthetic-related complications, infection and venous thrombosis. Simple bladder injury can be repaired in two layers with 2/0 polyglactin. The bladder should be left on free drainage via an indwelling urethral catheter which can be removed after 7–10 days. Ogilvie's sydrome (pseudo-colonic obstruction) is a rare complication following CS and presents with signs of intestinal obstruction (increasing pain and marked distension). A high index of clinical suspicion is required as vomiting is not a prominent feature. An urgent surgical opinion should be sought if abdominal X-ray confirms significant caecal dilatation. Caecal perforation is more likely with diameters over 10 cm and carries a mortality of 30–72%. Vesico-vaginal or uretero-vaginal fistulae are extremely rare. Maternal mortality with CS is estimated to be less than 0.33 per 1000 and is usually related to the reason the CS was done, major haemorrhage or more rarely anaesthetic complications.

Delivery of the deeply impacted head

The incidence of second-stage CS is increasing. It is a potentially complex and difficult procedure with significant maternal and fetal morbidity, including extension of the uterine incision and major postpartum haemorrhage. This is particularly so if the head is deeply impacted in the pelvis after an unsuccessful attempt at IVD. The surgeon may need to extend the uterine incision into the UUS using either a J-shaped extension from the lateral end, or an inverted-T starting at the middle of the incision. The latter results in a definite weak point in the uterine scar but in both situations elective CS will likely be recommended for future deliveries. Two main approaches have been used to help deliver the deeply impacted head, categorized as the push or pull techniques [24]. Routine or selective use of tocolytics has been recommended but there are insufficient data to confirm that uterine relaxation is effective [16].

The push technique

Some practitioners prefer to disimpact the head from below before proceeding with emergency CS. Others will ask an assistant to insert a hand into the vagina aiming to push up on the head after the uterine incision is made. It is important to await uterine relaxation. Rather than pushing up blindly, the assistant should confirm the position of the occiput, aiming to gently flex the head during disimpaction. This will allow smaller diameters to present as the head rises up through the pelvis. With flexion, the head will naturally rotate into an OT position as it rises through the mid/upper pelvis towards the pelvic inlet. Extension of the incision more often occurs on the same side as the occiput. This is probably because of the combined bulk of the fetal occiput lying in the surgeon's hand during manipulation, rotation and disimpaction.

The pull technique

This is also known as reverse breech extraction. The surgeon passes a hand into the upper segment and grasps both feet before gently pulling the fetus up to deliver the breech first. The chest and shoulders follow and the head is lifted out of the pelvis. In a systematic review comparing the push and pull methods, the pull technique was associated with a significant reduction in extension of the uterine incision, mean blood loss, operating time and infection [24].

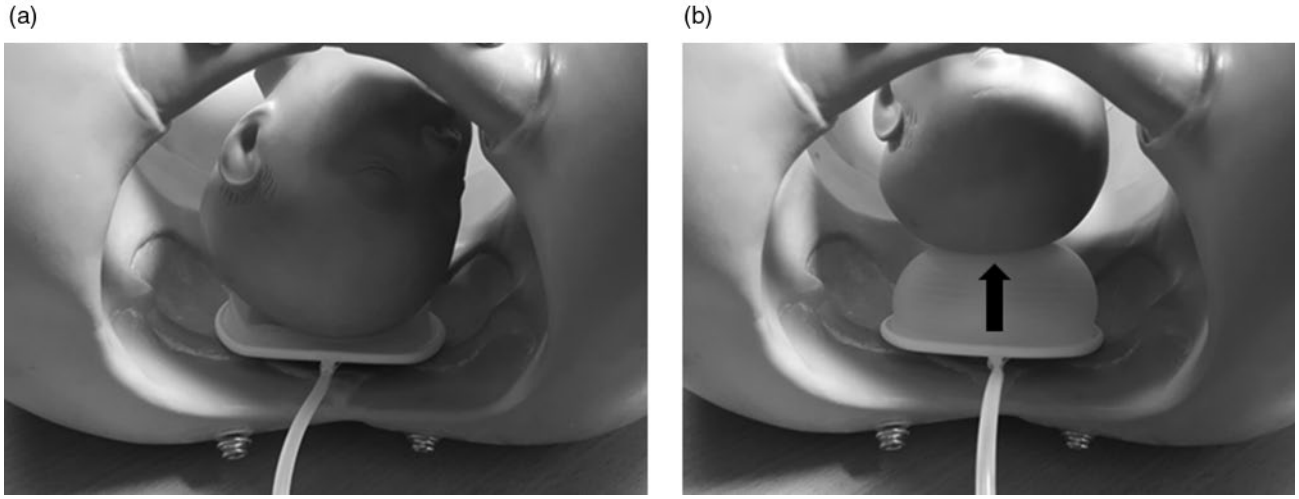

Fig. 26.12 Fetal Pillow to elevate the impacted fetal head: (a) deflated and (b) inflated.

Alternative techniques

The Patwardhan method was described in 1957 and relies on delivery of one or both shoulders first. It has traditionally been used on the Indian subcontinent. With the back anterior or lateral the uterine incision is made over the anterior shoulder and the order of delivery is as follows: shoulders (anterior then posterior, plus arms), trunk by flexion (with fundal pressure), legs, and finally the head is lifted out of the pelvis. This is modified when the back is posterior: anterior shoulder/arm, both legs, trunk by flexion, posterior shoulder/arm, head. It may have some advantages over the push method but there is insufficient evidence to offer definitive guidance.

Various fetal head-lifting devices are being developed and evaluated. The Fetal Pillow® has a soft foldable base plate with a balloon attached to one surface. It is inserted to lie beneath the fetal head and the balloon is filled with 180 mL of saline prior to incising the uterus. The fetal head is elevated by 3–4 cm (Fig. 26.12). In a non-blinded randomized trial ($N = 240$), use of the Fetal Pillow resulted in a significant fall in the number of major uterine wound extensions: 6 (5.0%) versus 39 (32.5%) (RR 0.23, 95% CI 0.11–0.48) [25].

Summary box 26.4

- CS rates vary widely but rates above 10% are not associated with improved maternal or neonatal outcomes.
- The primary aim of peri-mortem CS is to improve maternal survival when circulation is not re-established after 4 min of effective CPR (gestation >20 weeks).
- In the presence of an invasive placenta, incise the uterus away from the placenta to avoid life-threatening haemorrhage.
- In second-stage CS, pull techniques reduce the incidence of extension of the uterine incision.

Episiotomy and perineal lacerations

Perineal lacerations occur with normal delivery and IVD. Perineal tears are classified based on the involvement of the perineum.

1) First-degree tears involve the skin only.
2) Second-degree tears involve the skin and perineal muscle.
3) Injury to the anal sphincter is classified as a third-degree tear and is subdivided into 3a, involving less than 50% of the external anal sphincter (EAS); 3b, involving more than 50% of the EAS; and 3c, involving both EAS and internal anal sphincter (IAS). When the tear damages the sphincter and involves the anal epithelium, it is termed a fourth-degree tear. Collectively the group of injuries are referred to as obstetric anal sphincter injuries (OASI) [26].

Episiotomy

Episiotomy is a surgical incision of the perineum made after informed consent with the aim of increasing the soft-tissue outlet dimensions to help childbirth. Liberal use is not associated with reduction in OASI. Surprisingly, rates in Europe for women who deliver vaginally vary from 4.9% (Denmark) to 72.9% (Portugal), confirming that local custom rather than evidence guides most practice [9].

Episiotomy is used selectively in the UK. Midwives will consider episiotomy when (i) there is significant delay in delivery through a rigid perineum, (ii) in the presence of acute fetal compromise to expedite delivery, or (iii) to avoid significant perineal trauma. This is an individual decision based on clinical experience. Episiotomy facilitates IVD, although the need for an episiotomy is less with ventouse deliveries and with a distensible perineum. Judicious use of mediolateral episiotomy with IVD is associated with a sixfold decreased risk of OASI. When internal vaginal access is needed, as in some cases of assisted breech delivery and shoulder dystocia, episiotomy can improve access.

In the USA, a midline episiotomy starting from the fourchette and extending towards the anus is popular. This is associated with minimal bleeding, is easier to align for repair and requires less postoperative analgesia. However, the risk of OASI is higher and many countries prefer the mediolateral approach. Local anaesthetic infiltration of the perineum is effective for episiotomy with normal delivery and with outlet vacuum delivery but otherwise regional analgesia should be considered. It is important to check that analgesia is effective prior to episiotomy and additional local infiltration can be used when necessary. A single incision is made but the length is variable and depends on the size of the perineum and type of delivery. Blood loss is minimized by performing the episiotomy when the head crowns and the perineum is stretching up. The incision should be angled at 60° to the midline, in the direction of the ischial tuberosity. This is associated with a lower incidence of OASI, anal incontinence and perineal pain compared with the classical description at an angle of 45° [27]. Early repair after completion of the third stage prevents unnecessary blood loss; any profusely bleeding vessels are initially clipped then ligated.

Perineal repair

Effective analgesia should be checked again prior to repair. Additional tears requiring suturing may need further local infiltration. A thorough systematic examination should be undertaken before proceeding to ensure there is no occult sphincter damage and this may require a combined rectal and vaginal examination. Good light and optimal exposure are essential to achieve a good repair. Uterine bleeding may cause difficulty in visualizing the edges of the wound but this can be overcome by insertion of a tampon or vaginal swab with a tail.

Traditional repair is described in three layers, including a locking layer for the vagina, interrupted sutures for the perineal muscles and interrupted sutures for the skin. The two-stage technique is similar but skin edges are apposed but left unsutured (edges ≤0.5 cm apart). In contemporary practice the three-stage, continuous non-locking technique is recommended [28]. This is associated with the least short-term pain, is easily performed by the inexperienced operator and has economic advantages as only one suture is used. A rapidly absorbing polyglactin suture is recommended (2/0 gauge, 36-mm tapercut needle) although standard polyglactin may also be used. It is important to ensure that the initial anchoring stitch is placed above the apex of the incision. If there is an extension, placing a traction suture halfway up the vaginal tear can help to bring the apex into view. The vaginal mucosa and underlying tissue are approximated using a single continuous non-locking stitch. The hymenal ring acts as a useful marker to help align tissues as oedema results in asymmetry of the opposite sides of the incision. The perineal muscles are approximated with the same suture, which is also used to bring the skin into alignment by placing the suture below the skin surface in the subcutaneous fascia. A single knot is tied behind the hymenal ring. If the muscle layer is vascular, interrupted sutures may be required.

When the repair is complete, rectal examination should be performed to exclude accidental suture involvement of the rectum or anal canal (which if found should be removed and resuturing performed if necessary). A full count of instruments, needles and swabs is mandatory and must be recorded. Retention of vaginal swabs is a common cause of litigation and vaginal examination is essential to exclude inadvertent retention. The operative note should include full details of the repair, blood loss and plans for postoperative care. Pain relief should be prescribed and this may include administration of rectal diclofenac with consent. Observations should be continued, watching for excessive bleeding, pain or haematoma formation that may necessitate additional medical or surgical intervention. Later complications include infection, wound breakdown, pain, scarring or dyspareunia.

Obstetric anal sphincter injury

Reported rates of OASI in Europe vary from 0.1% (Poland and Romania) to 4.2% (Denmark and Iceland), although quality of reporting varies [9]. Unrecognized or inadequately repaired OASI can lead to long-term incontinence of faeces with or without flatus. OASI is best repaired in the operating theatre under regional anaesthesia. Good lighting, appropriate instruments, and an experienced surgeon and assistant are essential for successful repair. Thorough inspection is required to confirm the degree of sphincter and/or mucosal damage. It is important to exclude separate button-hole injuries of the rectal mucosa lying at a higher level. Anal

epithelium is repaired with continuous or interrupted 3/0 polyglactin sutures. The sphincter is repaired using monofilament 3/0 polydioxanone or braided 2/0 polyglactin with equivalent results [26]. An end-to-end technique should be used for all IAS repairs and for partial-thickness tears of the EAS (i.e. 3a and some 3b). Either end-to-end or the overlapping technique can be used for full-thickness EAS tears and these have equivalent outcomes [26].

Postoperative care should include antibiotics and physiotherapy support can be helpful. Routine use of laxatives is recommended to reduce the risk of wound dehiscence, but bulking agents should be avoided. At follow-up it is vital to enquire about incontinence of faeces or flatus, faecal urgency, pain and dyspareunia. Where facilities exist and when indicated, endo-anal ultrasound and/or anal manometry may be offered. If symptoms persist and cannot be improved by conservative measures, referral to a specialist gynaecologist and/or colorectal surgeon should be arranged.

Jango *et al.* [29] reviewed the effect of subsequent vaginal delivery on women who had suffered OASI. Those with faecal incontinence following OASI were recommended elective CS for future delivery. In those with no faecal incontinence, vaginal delivery carried a higher risk of deterioration of anal incontinence symptoms, although the risk of long-term faecal incontinence was not significantly increased.

Summary box 26.5

- Routine or liberal use of episiotomy is not recommended.
- Mediolateral episiotomies should be angled at 60° to the midline to reduce the risk of OASI.
- Exclude OASI by performing a systematic rectal and vaginal examination prior to all repairs.
- The continuous non-locking technique should be used for routine perineal repair.
- Isolated button-hole injuries should be sought and excluded during OASI repair.

Conclusion

The obstetrician in contemporary practice must be knowledgable about the various malpresentations and malpositions that arise and how they should be managed. We have emphasized the importance of accurate assessment of the position, attitude and station of the fetus within the maternal pelvis, a critical skill for the trainee to develop and the experienced clinician to maintain. These skills are brought to a focus in the management of malposition and second-stage arrest at the level of the ischial spines (i.e. at mid-pelvis). In this situation, ultrasound can be a useful adjunct to clinical skills. The operative techniques available to facilitate safe assisted delivery have been described (IVD, manual rotation and CS) and we encourage obstetricians to consider carefully the advantages and disadvantages of each method, selecting the safest and most appropriate to use in each case.

NICE intrapartum care guidance provides useful information about the management of abnormal labour [7] but there are still many controversies and unanswered questions that require further rigorous randomized trials. Simulation training can help to teach the technical skills required to perform intrapartum procedures safely, supported by direct supervision from senior clinicians and objective assessment of competence before moving on to independent practice. Intrapartum procedures can be stressful for the couple, the fetus and the clinician. Adequate knowledge, training, communication skills (before and after the procedure) and accurate record-keeping are essential to help alleviate the stress. Maintaining situation awareness, critical decision-making, clear communication and functional team-working are human factors and are the non-technical skills that must be embraced to ensure safe obstetric practice [30].

Fetal Monitoring During Labour

Sara Paterson-Brown[1] *and Tracey A. Johnston*[2]

[1] *Queen Charlotte's Hospital Imperial NHS Trust, London, UK*
[2] *Birmingham Women's and Children's NHS Foundation Trust, Birmingham, UK*

What this chapter cannot do is provide a comprehensive manual of fetal physiology, fetal heart rate interpretation and fetal monitoring techniques. While the main principles of these are discussed here, the reader is referred to other learning tools for fetal monitoring, including standard textbooks, the Royal College of Obstetricians and Gynaecologists (RCOG) e-learning program [1] and the online K2 fetal monitoring training system [2]. These e-learning systems are divided into sections which cover maternal and fetal physiology and pathophysiology, fetal heart rate and cardiotocography, and include a wealth of cases that can be worked through, asking the reader to interpret and make decisions which can be compared with those of experts.

Fetal physiology

Normal

The fetus is sustained by the uteroplacental unit and under normal circumstances provision is surplus to requirements, enabling the fetus to thrive, grow and build up energy reserves. Aerobic metabolism of glucose provides the fetus with its energy, and the oxygen which is vital for this process is usually plentiful. In normal pregnancy there is therefore more oxygen supplied by the uteroplacental unit than needed by the fetus and energy reserves in the form of glycogen are stored by the fetus.

Fetal compromise

The fetus can be compromised by a reduction in oxygen supply, an increase in oxygen requirements (e.g. in sepsis) or a reduced capacity to transport oxygen (severe fetal anaemia, e.g. rhesus disease, fetomaternal haemorrhage or some intrauterine infections such as parvovirus). The severity and duration of the insult will vary according to the cause, and similarly the effects on the fetus are equally wide-ranging, but the principal fetal responses are described below.

- *Acute*. If oxygen delivery falls, there is reduced oxygen in the fetal circulation (hypoxaemia); if levels fall further, hypoxia occurs (reduced oxygen in the fetal tissues). Two things occur in response to hypoxaemia and hypoxia: the circulation adapts to maintain supplies to vital organs (brain and heart) and anaerobic metabolism utilizing glucose released from the stored glycogen reserves provides continued energy supplies. The main consequences of anaerobic metabolism, which is almost 20 times less efficient than aerobic metabolism, are that fetal reserves are used up relatively quickly and the lactic acid, which is the waste product of this metabolism, results in a metabolic acidosis that can be harmful.
- *Chronic*. If there is uteroplacental disease and fetal supplies are limited, then glycogen stores may not accumulate and fetal reserves will be lacking. In chronic cases of reduced supply, the fetal circulation adapts as mentioned above with cranial sparing, and the peripheral circulation is effectively reduced. Depending on the severity and duration of this compromise, the pathophysiology results in decreased renal perfusion which in turn produces oligohydramnios (and, when more severe, anhydramnios) and reduced fetal growth. If there is further deterioration, anaerobic metabolism occurs and a metabolic acidosis develops.
- *Acute on chronic*. If an acute insult occurs in a fetus already compromised, it can withstand less hypoxia than a well-nourished fetus because it has less reserve and may have already made adaptations to conserve vital cerebral perfusion.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Thus the response and vulnerability of any fetus to a hypoxic insult will be largely dictated by (i) the condition of the fetus at the onset of that insult, (ii) the severity of that insult, and (iii) the duration of that insult. The fetal condition can deteriorate extremely quickly and defining the period of time beyond which damage will be sustained is impossible due to the individual circumstances of each fetus and each insult, but a normal well-grown and mature fetus that has good reserves can tolerate a short period of severe hypoxia, whereas the same insult can be catastrophic for a growth-restricted fetus.

Summary box 27.1

Progressive hypoxia with metabolic acidosis is accelerative. Hypoxia that has led to metabolic acidaemia indicates that:

- fetal reserves are spent;
- tissue hypoxia and acidaemia will be rapidly progressive;
- fetal damage becomes increasingly likely.

Metabolic acidaemia

Paired umbilical cord blood samples at delivery enable direct measurements of uteroplacental function (umbilical vein) and fetal acid–base status (umbilical artery). There are now a number of published series of routine paired cord samples [2–5] and results largely conform and are approximated in Table 27.1. The base deficit in the umbilical artery indicates the degree of fetal metabolic acidosis and values above 12 mmol/L suggest that there has been significant hypoxia and subsequent fetal damage may occur [6]. If venous pH and base deficit are normal, this rules out chronic hypoxia. The mean pH difference between artery and vein is 0.08 and if this difference is less than 0.03, it is likely that both samples have been taken from the umbilical vein. Timing of cord clamping after delivery can also influence cord samples [7].

Fetal and neonatal consequences of hypoxia

The damage that results from hypoxic insults varies according to the vulnerability of the fetus and the nature and duration of the insult, ranging from minimal clinical signs through brain damage to death. While neonatal complications tend to increase as cord arterial pH falls [8], especially at values below 7.0 [9–11], many born with such values do well [9,10,12] while approximately one-quarter suffer neurological morbidity or mortality [13].

Death

Intrapartum deaths do occur as a result of hypoxia, with an incidence in the UK of approximately 0.22 per 1000 [14], and intrapartum-related deaths (both stillbirths and neonatal deaths) account for 1 in 12 perinatal deaths [15]. While scrutiny of these cases has identified elements of substandard care, many cases are managed well and yet death still results. Confidential enquiries have shown that approximately half of intrapartum stillbirths are considered to be avoidable [16,17], with errors in care extending from a failure to recognize problems in the antenatal period and/or in labour to recognizing but failing to act on signs of fetal compromise [17].

Neonatal pathology

The paired umbilical cord gas results provide an objective measure of *in utero* fetal metabolism, reflecting the presence or absence of intrauterine hypoxia, but although they are associated with neonatal outcomes they are not predictive and do not indicate neonatal resuscitative needs. Indeed many babies born with low cord gases are vigorous at birth. On the other hand, the Apgar score is a subjective assessment of the need for neonatal resuscitation but does not indicate the cause of the problem. Resuscitation therefore occurs according to clinical need and the possible cause may then be clarified by the cord gases. A variety of neonatal problems can follow on from intrauterine hypoxia, including hypoglycaemia, disturbed thermoregulation and necrotizing enterocolitis, but the main worry is that of hypoxic brain injury due to the long-term morbidity associated with it.

Hypoxic–ischaemic encephalopathy

Neonatal encephalopathy is associated with a multitude of causes but hypoxic–ischaemic encephalopathy (HIE) is neonatal encephalopathy specifically caused by peripartum hypoxia. The centiles listed in Table 27.1 demonstrate that 2.5% of neonates are born with a cord arterial pH below 7.05. The incidence of more severe acidaemia (cord arterial pH <7.0) is approximately 3.7 per 1000 live births, while that of HIE at term is approximately 2.5 per 1000 live births [13]. The diagnosis of HIE requires evidence of intrapartum hypoxia and although there are various definitions [18–20], in essence there needs to be evidence of all of the following:

- an intrapartum insult (e.g. a sentinel event in labour or a pathological fetal heart recording);
- a metabolic acidosis at birth (pH <7.0 and base excess >12 mmol/L);
- moderate or severe neonatal encephalopathy;
- specific features on imaging in the neonatal period.

A spectrum of permanent brain injury can occur as a result of HIE [21] ranging from spastic quadriplegic

Table 27.1 Routine paired umbilical cord values.

	pH (median)	pH (2.5–97.5 centile)	Median base deficit (mmol/L)	Base deficit (mmol/L) (2.5–97.5 centile)
Umbilical vein	7.35	7.17–7.48	3.7	9.0–0.5
Umbilical artery	7.25	7.05–7.38	4.3	11.1–0.5

or dyskinetic cerebral palsy [18,20] to learning difficulties without motor impairment [22]. The incidence of cerebral palsy is 1–2 per 1000 deliveries and although the majority of these are due to antenatal complications, at least 10–15% result from events in labour [13].

Treatment and outcome of HIE

Severe acidaemia at birth (pH <7.0) does not always result in HIE, which in turn does not automatically result in cerebral palsy, but the more severe the metabolic acidosis at delivery and the more severe the HIE, the worse the prognosis for the baby. Individual clinical features and responses of the baby help inform the likely outcome as does cerebral imaging.

The greatest advance in this field is that of controlled total body cooling of term neonates with HIE. The cooling needs to start within 6 hours of birth and has been shown to improve intact neonatal survival (relative risk of cerebral palsy 0.67, 95% CI 0.47–0.96) with number needed to treat of 8 (95% CI 5–17) [23,24]. The obstetrician's role in this process is one of early communication and frank discussion with neonatal colleagues to help clarify the obstetric history and the likely diagnosis, which should help to promote early cooling or referral to a centre that provides this treatment if it is not available locally (see Chapter 32).

Summary box 27.2

Factors that reduce oxygen delivery to the fetus

Uteroplacental pathology
- Maternal demographics (age, smoking).
- Maternal diseases (hypertension, diabetes, sickle cell disease).
- Intrauterine growth restriction.
- Placental separation (marginal bleeds and abruptions).
- Post maturity.

Fetal pathology
- Fetal anaemia: rhesus isoimmunization, parvovirus infection, fetomaternal haemorrhage.

Labour
- Uterine contractions (especially if hypertonic or with prolonged labour).
- Cord compression.
- Maternal hypotension (aortocaval compression).
- Obstetric emergencies (maternal collapse, uterine rupture, abruptions, cord prolapse).

Midwives and obstetricians
- Injudicious use of prostaglandins or Syntocinon.

Labour

The rest of this chapter focuses on the normal physiology of labour and the fetal responses to labour, before highlighting abnormal labour patterns that increase fetal challenges and the problems which can arise from them. Without knowledge of the physiology and pathophysiology of labour, the anticipation and recognition of early signs of hypoxia may be missed. Failure to recognize the fetus at risk on entry to labour or failure to look for and then recognize early signs of hypoxia in labour can compromise the opportunity for prompt and timely action that may be crucial in avoiding irreversible damage.

The challenges of normal labour

Uterine contractions

In normal labour, the fetus is 'stressed' due to uterine contractions. The uteroplacental circulation is a low-pressure system and its perfusion ceases at the height of a uterine contraction in the first stage of labour (where intrauterine pressures reach about 90 mmHg) and throughout practically all of a contraction when the woman is pushing in the second stage of labour (intrauterine pressures up to 250 mmHg). Oxygen delivery to the fetus therefore effectively ceases during these periods.

A fetus in a normal pregnancy has adequate reserves of oxygen and can cope with this brief, temporary insult as long as the uterus relaxes enough between contractions for gas transfer to occur thus replenishing the supply of oxygen. The interval between the contractions is *crucial*

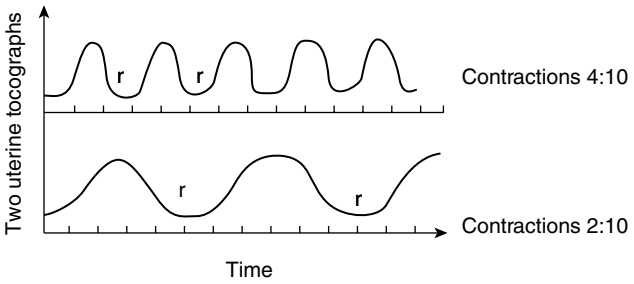

Fig. 27.1 Number of uterine contractions versus their duration in each 10-min period and how this influences the period of fetal recovery during uterine relaxation (r), both similar at approximately 4 min.

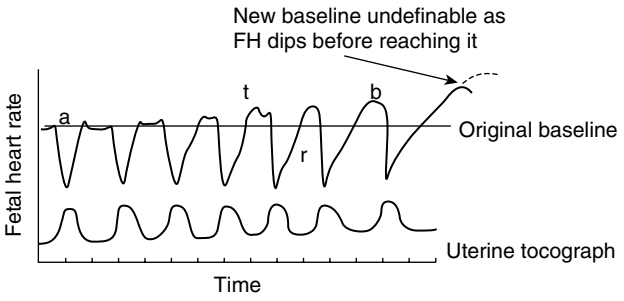

Fig. 27.2 Variable decelerations associated with cord compression demonstrating a typical dip (a). A rising baseline (b), a rebound tachycardia (t) and delayed recovery (r) are all suspicious signs.

to allow this recovery (Fig. 27.1), with 60–90 seconds of uterine relaxation needed between contractions [1].

A less well-nourished fetus does not have the same oxygen reserves even when the uterus is relaxed, and may have reduced or minimal energy reserves, so may not manage the episodic oxygen deprivation associated with each uterine contraction.

Head compression

The fetal head is subjected to pressure as it is compressed onto the cervix and through the pelvis by uterine contractions, and latterly this is exacerbated by maternal expulsive efforts. Head compression can produce a reflex bradycardia due to changes in intracranial pressure. This is a normal autonomic response, but clearly during any bradycardic episode the fetal circulation is reduced, so once again a baby already compromised will be more affected by this temporary reduction in oxygen delivery to the tissues due to the slower heart rate.

Cord compression

The umbilical cord lies in random fashion around the fetus *in utero* and can wrap around or lie in close proximity to any part of the fetus so that during a contraction it can become squashed. This is increasingly likely once the membranes have ruptured. The normal autonomic responses of a healthy fetus to an episode of cord compression is the result of baroreceptor and chemoreceptor stimulation and proceed as follows.

- Initially, the larger, less muscular, umbilical vein obstructs resulting in decreased cardiac return, which stimulates baroreceptors that cause a tachycardia.
- Hypoxia secondary to the umbilical vein obstruction stimulates chemoreceptors to trigger a parasympathetic response which produces a bradycardia.
- With further compression, umbilical artery obstruction raises peripheral resistance, exacerbating the bradycardia.
- As the contractions wear off, the process is reversed.

Cord compression, which is common, therefore produces a fairly classic pattern of fetal heart rate (FHR) decelerations as a normal autonomic response in a healthy fetus (Fig. 27.2, pattern 'a'). However, as mentioned above, every time a deceleration occurs the fetal circulation is reduced and therefore adequate uterine relaxation between contractions is vital to allow recovery of the fetal circulation with subsequent tissue perfusion. Prolonged or repetitive decelerations can have a cumulative effect over time: firstly the shouldering disappears, then there is a rebound tachycardia, delayed recovery from the decelerations and a rising baseline (Fig. 27.2). In the most severe type the baseline is undefined because the next contraction occurs before it is reached and the fetal heart decelerates again. Moreover, cord compression is more common when there is reduced Wharton's jelly to protect the umbilical vessels, as with a premature or growth-restricted fetus, and these are therefore more likely to suffer cord compression as well as being already compromised.

The challenges of abnormal labour

Infection

Pyrexia in labour is associated with an increased risk of fetal hypoxic damage and cerebral palsy [25,26]. The two processes of hypoxia and sepsis seem to potentiate each other rather than being simply additive, and this process can escalate quickly needing early recognition and appropriate action. One problem is that epidural anaesthesia is associated with a rise in core temperature and therefore mild pyrexias in labour are relatively common. This risks causing a rather relaxed attitude to fevers in labour rather than raising alarm bells. Clinical vigilance is needed, with proper assessment and appropriate treatment.

- If there are clinical signs of infection, even a mild pyrexia is significant.
- If there is no regional blockade, pyrexia of 37.5 °C is significant.

- Pyrexia of 38 °C with regional blockade is significant.
- Paracetamol alone is not a treatment for infection: it may lower the temperature by nature of its antipyretic effect and this is useful, but it does not mean that the infection is treated. 'Hiding' one of the signs of infection in this way can be dangerous.

In all these situations appropriate microbiology cultures should be taken and antibiotic treatment started. Clinical awareness of the infection and what it might mean to fetal condition, fetal reserve and the likely tolerance of the fetus to the remaining labour will all play a part in timing the delivery.

Prolonged labour

A fetus has to tolerate more uterine contractions during prolonged labour. This is common with fetal malpositions and, as such, is also associated with induced labour for post-term pregnancies or prolonged rupture of membranes, both of which increase the risks to the fetus (added risk of uteroplacental insufficiency or infection, respectively).

Excessive uterine activity

This comprises either tachysystole (more than five contractions in 10 min) or hypertonus (prolonged contraction or increased basal tone) and both can occur spontaneously or be iatrogenic. When excessive uterine activity occurs spontaneously, it can be extremely concerning because it is likely to be associated with pathology such as infection (additional risks and vulnerability already discussed) or bleeding. In the case of bleeding (which may be concealed retroplacental separation) there is the added insult of placental separation as well as failure of adequate uterine relaxation for the fetus to contend with. This situation is very dangerous and fetal deterioration is likely to be rapid.

Conversely, iatrogenic tachysystole and hypertonus are reversible if recognized and acted upon. These can result from prostaglandin sensitivity or overdose as well as oxytocin overdose. A common obstetric and midwifery aim when stimulating labour with oxytocin is for a certain number of contractions every 10 min but as this focuses attention on the contraction and not the relaxation, it is easy to see why excessive uterine activity is a relatively common problem [27–29]. If contractions last for 1 min, then aiming for four contractions in 10 min is reasonable, but if they last 2 min squeezing four into 10 min will cause fetal hypoxia (see Fig. 27.1). The added problem here is that oxytocin tends to be used in abnormal labour (e.g. prolonged rupture of membranes, post-term inductions, prolonged labour) so there are many other risk factors for fetal compromise. Tachysystole often goes unrecognized, with the Syntocinon infusion continuing or even being increased further until FHR abnormalities and thus hyperstimulation (tachysystole with FHR abnormalities) develops.

Uterine rupture

This results in catastrophic interruption to fetal oxygenation and delivery needs to be effected within minutes. However, even with this dramatic pathology, signs other than abnormal FHR monitoring may be subtle and the diagnosis is often not made until laparotomy [30]. Keeping the possibility in mind during problems with progress in labour or in those at increased risk may help to anticipate the diagnosis and lead to rapid action if needed.

Placental abruption

This may also be missed clinically as bleeding may be concealed and pain can be difficult to distinguish from labour, especially with a posterior placenta. Tachysystole and hypertonus are signs that are often missed because the focus of attention tends to be on the fetal heart and not the clinical signs and the tocograph. Therefore, again, the relatively later sign of an abnormal FHR pattern is often the only indication that there is something wrong.

Cord prolapse

Cord prolapse can also cause severe catastrophic cessation of fetal oxygenation requiring urgent delivery and is usually confirmed on vaginal examination after fetal heart abnormalities have been detected.

Cord compression becoming cord occlusion

Whilst an element of cord compression is relatively common in labour (and often self-corrects with alteration in maternal position, or rotation and descent of the fetal parts) it can deteriorate and lead to prolonged cord occlusion. This is a particular risk in the second stage of labour when the woman commences pushing and the head descends. In the presence of an FHR pattern in keeping with cord compression, it is therefore sensible to have made preparations for rapid delivery should the need arise, before commencing pushing.

Detecting the fetus with hypoxia

Recognizing fetal risk

As the ability of any fetus to cope with labour depends on its condition on entry into labour, antenatal recognition of risk is vital in planning safe delivery. Any woman identified as high risk for fetal compromise in labour can then be cared for accordingly, while those of low risk can be

monitored less intensively. Whichever technique is used, the aim of intrapartum monitoring of the fetus is to 'screen' for early signs of hypoxia in order to allow timely intervention and safe delivery before irreversible damage has been sustained. The priority with a low-risk pregnancy would be to have a detection system with a low false-positive rate so that unnecessary intervention is kept to a minimum; conversely, the priority for an at-risk fetus would be to have a detection system with a low false-negative rate and good sensitivity to identify the problem early.

The different techniques available for monitoring the fetus in labour are discussed in the following sections but it is worth pointing out that inevitably not all high-risk cases are detected antenatally and the unknown 'high-risk' fetus is especially vulnerable in labour because the index of suspicion is reduced. It is therefore important that with every woman and fetus admitted in labour, there is a deliberate effort to re-screen using history and examination to confirm normality before proceeding with the planned birth.

Summary box 27.3

Clinical scrutiny on admission in labour: be alert to clues for risk

- Antenatal risk factors may have been missed (revisit antenatal history).
- Risk factors may have developed since last seen (prolonged latent phase/rupture of membranes or bleeding).
- Examine carefully: fetal growth, liquor volume and colour, pyrexia.
- Labour characteristics: pattern of uterine contractions, fetal presentation and position.

Liquor and the passage of meconium

A good liquor volume is a reassuring sign that the fetus has not been subjected to chronic hypoxia in the antenatal period (discussed above). If no liquor is seen in labour after amniotomy (spontaneous or artificial), the safe assumption must be that there is oligohydramnios/anhydramnios and the case in question is an unrecognized growth-restricted fetus. All practising midwives and obstetricians will have seen the thick 'green-pea soup' meconium following the delivery of a baby who had not previously been recognized as being compromised. The clinical secret is to think about this possibility and be clear that absence of liquor indicates oligohydramnios/anhydramnios/growth restriction until proved otherwise (e.g. in the labour ward setting this can be assessed by an ultrasound scan).

The other sign in labour is that of the colour of the liquor. The National Institute for Health and Care Excellence (NICE) guidelines on intrapartum care discusses whether the presence of particulate meconium is significant or not [31,32], but working from pathophysiological principles seems a more logical way to interpret the signs.

- A term fetus may have passed meconium by nature of its maturity, but if this is 'innocent' the meconium should be diluted by adequate liquor.
- If the fetus is preterm, the passage of meconium is not normal and may suggest infection or hypoxia.
- If the meconium is thick, then by definition the liquor volume is reduced and reflects uteroplacental insufficiency and possible fetal compromise.
- If the liquor has been clear and then becomes meconium stained during labour, it suggests that the fetus may be compromised and this could be due to either hypoxia or infection.

Fetal monitoring in labour

Searching for signs and understanding the condition of the fetus and the normal stresses or pathophysiological insults it is exposed to is the single most important part of fetal monitoring in labour. Omitting this fundamental process on admission in labour and proceeding directly to FHR monitoring assumes that all babies have the same reserves and vulnerabilities. Our earlier discussions demonstrate how wrong such assumptions are: having an informed index of suspicion for a particular fetus and an understanding of any likely pathophysiology from the antenatal period and during labour increases the chance that signs of compromise will be detected early. Waiting until events are obvious is unthinking and dangerous as it may be too late to correct. To expect any monitoring system to dictate clinical decisions is unrealistic, illogical and hazardous.

The other point worth making before exploring the different techniques for monitoring the fetus in labour is that of the margin of error between the extremes of failing to recognize a fetus in difficulty (which will therefore sustain damage/death) and mistakenly identifying a healthy fetus as being in difficulty and subjecting it and the mother to an unnecessary operative delivery. When reviewing the different techniques of monitoring it is interesting to note that the trade-off is usually between increased operative delivery versus increased neonatal morbidity, and the relative risks of these will depend on the background prevalences of pathology; hence the recommendation from NICE that low-risk women be monitored differently to high-risk

women [31,32]. This does not remove an obligation to discuss the advantages and disadvantages with the pregnant woman in the antenatal period, so that she is informed and involved in the decisions surrounding her care in labour, particularly the fetal monitoring plan. The long-term outcomes of cerebral palsy and death are rare, and statistically significant differences have yet to be shown from the different monitoring modalities in low-risk pregnancies, although neonatal seizures are a significant concern and should not be ignored.

Historically, listening to the fetal heart has been the main method of monitoring the fetus in labour, but this is a step removed from the important information, which is whether oxygen supply is adequate for fetal tissue metabolism. If not and anaerobic metabolism has commenced, then by definition fetal hypoxia exists and is likely to get worse. The problem is that there is no direct continuous measure of fetal tissue pH, and even if there were it would be invasive and as such likely to be impractical for routine monitoring. Periodic fetal blood sampling (FBS) can be done in those showing signs of possible compromise, and to date this has been used when FHR pattern abnormalities have been found (discussed in more detail later). Fetal pulse oximetry has been explored as a means of measuring fetal oxygen saturation and is used in combination with FHR monitoring but randomized trials have failed to provide convincing evidence that it is helpful [33–35]. Near-infrared spectroscopy has also been explored [36,37] but has not yet been subjected to randomized clinical trials [38].

Fetal heart rate

FHR monitoring is the main technique used to supplement clinical scrutiny in intrapartum fetal monitoring. FHR is influenced by numerous factors that act largely through the two opposing divisions of the autonomic nervous system: the sympathetic nervous system, stimulation of which speeds up the rate, and the parasympathetic nervous system, stimulation of which slows it down. As such the heart rate is in a constant state of variation as these two influences oppose each other to maintain homeostasis. Both are responsive to the many stresses of labour, including changes in oxygen levels (via chemoreceptors), changes in fetal circulation (via baroreceptors) and infection, and these stresses are indirectly reflected in the FHR pattern. In addition, myocardial ischaemia also produces a fetal bradycardia. It is for these reasons that the FHR provides a reasonable indicator of fetal condition. This subject is well covered in the online RCOG and K2 teaching programmes [1,2].

Summary box 27.4

Fetal heart rate characteristics

- Baseline variability is the single most helpful parameter in screening for fetal hypoxia.
- Baseline heart rate rises with chronic stresses, including infection and hypoxia.
- Baseline heart rate should not fall during labour unless in response to treated infection; if it does, this reflects hypoxia.
- Accelerations are a healthy sign.
- Decelerations occur owing to:
  - head compression (uniform and should be in synchrony with uterine contractions, i.e. early);
  - cord compression (variable and should also be early; see Fig. 27.2); and
  - hypoxia (late and either uniform or exist as a delayed recovery or extension of the above decelerations).
- What happens to the right-hand side of the deceleration shows how the fetus is coping with the stress (Fig. 27.3).

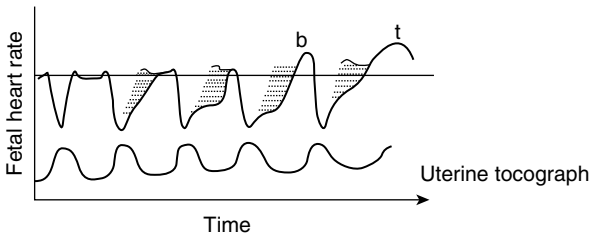

Fig. 27.3 Suspiscious signs that the fetus is becoming compromised. The recovery phase from each deceleration (right-hand side of each dip) takes longer with successive contractions (shaded areas) and the baseline rises (b) with a rebound tachycardia (t).

There are different classification systems to aid interpretation of FHR. The one most commonly used in the UK was the one described in the NICE intrapartum care guideline [31], which was updated in December 2014 [32]. In October 2015, the International Federation of Gynecology and Obstetrics (FIGO) also published guidelines for fetal monitoring [39–43]. Although virtually the same evidence base was reviewed for both, there are some differences between the two classification systems which has led to confusion, and some units in the UK have now opted to use the updated NICE guideline while others use the FIGO guidelines. The RCOG requested that NICE review their recommendations and further revisions were made in February 2017 which are illustrated in Table 27.2. Both systems classify features of the heart rate to assist with interpretation

of fetal well-being and give guidance on management (Tables 27.2 and 27.3). Although these systems differ slightly, the real issues are that one must understand fetal cardiac physiology and that the fetal heart trace is interpreted thoughtfully in the context of the full clinical picture, and changes over time are analysed carefully.

For example, the normal baseline values are taken from *populations* of healthy babies; it does not mean that the baseline of one fetus remains normal if it changes from, for example, 110 to 160 bpm or from 160 to 110 bpm over the course of labour. A small rise in the baseline (~20 bpm) during the course of labour is common due to sympathetic stimulation (via adrenaline) but more than

Table 27.2 Revised 2017 NICE classification of fetal heart features [32].

Feature	Normal	Non-reassuring	Abnormal
Baseline*	110–160	100–109 and 161–180	>180, <100
Variability*	5–25 bpm	<5 bpm for 30–50 mins or >25 bpm for 15–25 BPM	<5 bpm for >50 minutes or >25 bpm for >25 minutes, or sinusoidal
Decelerations*	None, early, or variable with no concerning features for <90 mins	Variable with no concerning features for >90 mins Variable with any concerning features in <50% of contractions for >30 mins Variable with any concerning features in >50% of contractions for <30 mins Late decelerations in >50% contractions for <30 mins with no other risk factors	Variable decelerations with any concerning features >50% contractions for 30 mins (less with risk factors) Late decelerations for 30 mins (less with risk factors) Acute bradycardia or single prolonged deceleration for >3 mins
Category*	All normal = normal/ reassuring	One non-reassuring with two normal features = non-reassuring	One abnormal or two non-reassuring features = abnormal
Management*		Consider the full clinical picture: explain/ escalate/conservative measures (position, contractions, fluids, paracetamol, antibiotics)	Escalate, conservative measures and further action such as FBS or delivery based on clinical picture Urgent delivery if prolonged bradycardia persists (if recovered by 9 min may reconsider)

*Concerning features include: decelerations lasting >1 minute, reduced variability, failure to return to baseline, biphasic shape and no shouldering.

Table 27.3 Summary of the FIGO classification of fetal heart features [42]: cardiotocography classification criteria, interpretation and recommended management.*

	Normal	Suspicious	Pathological
Baseline	110 – 160 bpm	Lacking at least one characteristic of normality, but with no pathological features	<100 bpm
Variability	5 – 25 bpm	Lacking at least one characteristic of normality, but with no pathological features	Reduced variability, increased variability, or sinusoidal pattern
Decelerations	No repetitive† decelerations	Lacking at least one characteristic of normality, but with no pathological features	Repetitive† late or prolonged decelerations during >30 min or 20 min if reduced variability, or one prolonged deceleration with >5 min
Interpretation	Fetus with no hypoxia/acidosis	Fetus with a low probability of having hypoxia/acidosis	Fetus with a high probability of having hypoxia/ acidosis
Clinical management	No intervention necessary to improve fetal oxygenation state	Action to correct reversible causes if identified, close monitoring or additional methods to evaluate fetal oxygenation‡	Immediate action to correct reversible causes, additional methods to evaluate fetal oxygenationc, or if this is not possible expedite delivery. In acute situations (cord prolapse, uterine rupture or placental abruption) immediate delivery should be accomplished

*The presence of accelerations denotes a fetus that does not have hypoxia/acidosis, but their absence during labour is of uncertain significance.
†Decelerations are repetitive in nature when they are associated with more than 50% of uterine contractions.
‡Fetal blood sampling.

this suggests it is secondary to stresses such as hypoxia or infection; baselines rarely fall in labour (unless sepsis is treated for example) and hypoxia should be suspected.

These baseline changes are important and worthy of a word of caution: paper cardiotocograph traces are usually folded up as they print and then are neatly tucked away, while computerized traces only display a short section of the heart rate pattern at any one time. In both situations proper review of a trace requires deliberate unfolding or scrolling back to the preceding trace in order to evaluate it fully. The consequence of failure to do this is that important signs of deterioration may be overlooked.

Heart rate monitoring techniques

How is it best to monitor the fetal heart? The options are between intermittent auscultation (directly using a Pinard stethoscope or a hand-held Doppler device) or continuous electronic recording via an abdominal Doppler transducer or fetal scalp electrode.

Intermittent auscultation

Listening directly to the fetal heart with a Pinard has been useful in the past, but although the device is small and cheap it has the disadvantage of only being heard by the person using it and the rate needs to be calculated by the listener. The hand-held Doppler machine is also small and portable but has the added advantages of magnifying the sound so that the woman and any other attendants can also hear the heart beat and it can also digitally display the heart rate. The only recording of these heart rates is done manually in the case notes. There is insufficient evidence to support one technique over the other, but one trial in Zimbabwe found more obstetric interventions and fewer neonatal complications when using the Doppler device compared with the Pinard stethoscope [44].

According to NICE [31,32], listening should be after a contraction for a full minute on each occasion: every 15 min in the first stage of labour and at least every 5 min in the second stage. FIGO also recommends auscultating the fetal heart every 15 min during the first stage of labour and every 5 min during the second stage, but recommends listening for at least 60 seconds 'during and for at least 30 seconds after a contraction' [41]. This approach will detect the benign early decelerations of head compression commonly present in the late first stage and second stage of labour, and may miss late decelerations. Both recommend commencement of continuous electronic fetal monitoring (EFM) in the presence of abnormality, but FIGO recommends auscultating over three consecutive contractions to confirm ongoing abnormality before commencing continuous EFM [41]. There are problems with intermittent auscultation: firstly, in clinical practice listening is often performed for less than 1 min [45] and, secondly, because the heart rate varies during the course of the minute, the recommendation is that the rate is averaged [31,32,41]. This latter point is worthy of comment: baseline variability and changes in the baseline are of paramount importance in assessing fetal well-being and thus averaging the heart rate removes both. Recording a range is common practice (e.g. 120–150 with accelerations and no decelerations) but a range without defining a baseline is not ideal; even on a trace it is difficult to distinguish accelerations and decelerations and it is much more difficult when just listening. This may explain why randomized controlled trials have consistently shown an increase in neonatal seizures in low-risk pregnancies monitored using intermittent auscultation compared with continuous EFM [31,46] (Table 27.4). However, as there is no statistically significant difference in rates of cerebral palsy or infant mortality, this disadvantage has to be weighed against the decreased risk of operative delivery associated with intermittent auscultation.

Admission cardiotocography

Because of the importance of assessment and risk stratification on admission in labour, and the potential disadvantages of intermittent auscultation, the concept of 'snapshot' cardiotocography (CTG) on admission to help differentiate the high-risk from the low-risk fetus is logical. Unfortunately, admission CTG in clinically low-risk pregnancies is not beneficial because it is associated with increased interventions without improved outcomes [47], and its use in the low-risk population is therefore not recommended [32,41].

Table 27.4 Randomized controlled trials that have compared electronic fetal monitoring and intermittent auscultation (values are relative risk with 95% confidence interval in parentheses).

	All women*	Low-risk pregnancies†
Neonatal fits	0.5 (0.31–0.80)	0.36 (0.16–0.81)
Perinatal mortality	0.85 (0.59–1.23)	1.02 (0.31–3.31)
Instrumental vaginal delivery	1.16 (1.01–1.32)	
Caesarean section	1.66 (1.30–2.13)	
Total operative deliveries		1.35 (1.09–1.67)

*In over 37 000 pregnancies (12 trials) [46].
†NICE subset of three trials of lo--risk pregnancies [31].

Cardiotocography

Electronic recording of the FHR with printout allows contemporaneous continuous recordings of the heart rate and a permanent record. The baseline and its variability are fairly easy to define and accelerations or decelerations from the baseline can be studied. As such it is a sensitive tool to document heart rate changes. Compared with intermittent auscultation its use improves fetal outcomes, with fewer neonatal seizures [45], but it impedes maternal mobility (unless telemetry transducers are used) and it tends to distract care from the woman to the monitor [44] and is associated with increased obstetric interventions (all forms of operative delivery).

The advantage of EFM is that it is very sensitive and detects the fetus at possible risk, but its poor specificity means that an abnormal trace does not mean the fetus is necessarily hypoxic. The need to improve the predictive value of EFM and reduce the disadvantage of increased operative delivery rates has focused research on additional techniques to supplement EFM when the trace is not normal. Pulse oximetry and near-infrared spectroscopy have already been mentioned briefly as not yet being clinically useful [33–37]. Whilst vibroacoustic stimulation for fetal assessment in the antenatal period looks promising, further research is still needed, including intrapartum studies to explore any potential benefits in labour [48]. The more invasive technique of intermittent FBS from the fetal scalp during labour is well integrated into intrapartum care as an adjunct to EFM and has been subject to clinical trials.

Fetal blood sampling

The value of FBS has been hotly debated in recent years [49,50] but currently remains an integral part of intrapartum fetal monitoring and is still recommended by NICE [32] and FIGO [42,43] except in acute fetal compromise (where emergency delivery is needed), maternal infection (e.g. HIV and hepatitis), fetal bleeding disorders and prematurity (<34 weeks).

Most FBS measurements examine pH and gas values, but more recently fetal lactate has been measured. This needs a smaller blood volume and so has potential advantages to pH estimation. This comparison between pH and lactate measurements using fetal blood has now been the subject of randomized controlled trials and while there were no differences in fetal outcomes or operative delivery rates, the success of FBS was greater in the lactate group due to the smaller volume of blood needed for analysis [51]. All FBS samples should be taken with the woman in the left lateral position to avoid aortocaval compression during the technique [31].

Interpretation of FBS results

The interpretation of the FBS result must include the clinical condition and the risk factors affecting the mother and fetus, and must allow for the fact that one result only reflects the pH/lactate at that moment. An isolated reading, even if normal, must not be taken as meaning there is no problem as the process of metabolic acidosis might only be starting (after hypoxaemia has proceeded to hypoxia, as described in detail earlier) and could yet accelerate quickly, depending on the cause. A pathological CTG requires repeat FBS even if the previous result was normal, to help assess the trend of fetal deterioration, and the timing of the repeat sample will depend on the nature of the CTG, the original result and, most importantly, the clinical features of the case. The NICE intrapartum guideline describes FBS classification and actions [31] (Table 27.5). The FIGO guideline [43] includes lactate measurements (Table 27.6).

The aim is to achieve delivery before irreversible fetal damage, and to wait until severe acidaemia occurs in order to justify intervention is illogical if the chance of vaginal delivery is remote and the fetal condition is already deteriorating. Hence two successive fetal blood samples, an hour apart, with pH of 7.35 and 7.25 should not be reassuring: this fetus is deteriorating rapidly and in another hour it is likely that the next pH value will be below 7.20. The clinical decision here will be largely determined by whether the woman is 9 cm dilated and progressing quickly (in which case repeat

Table 27.5 NICE classification of fetal blood samples [31].

pH	Interpretation	Action suggested by NICE [31]	Appropriate clinical action
≥7.25	Normal	Repeat within 1 hour if trace stays pathological or sooner depending on trace	Clinical features should also influence this timing and falling results indicate compromise (see text)
7.21–7.24	Borderline	Repeat within 30 min or sooner depending on trace	Clinical features will determine whether this repeat sample is sensible or whether delivery should be expedited (see text)
≤7.20	Abnormal	Ask for consultant obstetric advice	Delivery is needed and consultant should be informed but this should not delay delivery

Table 27.6 FIGO classification of fetal blood samples [43].

pH	Lactate (mmol/L)	Interpretation	Action
>7.25	<4.2	Normal	Repeat in 60 min if CTG still abnormal
7.20–7.25	4.2–4.8	Intermediate	Conservative measures; repeat in 20–30 min if not normalized
<7.20	>4.8	Abnormal	Conservative measures/rapid delivery

FBS within the next 30 min might allow progress to full dilatation and vaginal delivery) or whether she is still 4 cm dilated despite Syntocinon for the last 4 hours (in which case expediting delivery by caesarean section is likely to be more appropriate). This is why clinical judgement has to complement the basic rules suggested for guidance: such rules should not be followed unthinkingly.

Fetal blood sampling dilemmas

FHR abnormalities in the presence of oxytocin infusions cause enormous problems, and practice varies between stopping the oxytocin infusion to halt the FHR anomalies, stopping oxytocin until FBS is performed and found normal, or continuing the infusion and performing FBS. It should be remembered that contractions are needed for labour to progress, so the key decision is assessing the uterine contractions. The oxytocin infusion should continue if uterine contractions and relaxations are appropriate (see above) but if the fetal heart requires FBS, then proceed with it. NICE recommends stopping oxytocin if the trace is non-reassuring or abnormal until the FBS result is known; if it is normal, the oxytocin infusion can be restarted [32]. It needs to be remembered that FBS will need repeating to check that the fetus is not deteriorating with the augmented contractions.

FBS is rarely indicated at full dilatation as delivery is usually more appropriate for a pathological CTG, but a normal result can allow time for descent and rotation to convert what would have been a more complex operative delivery into a more straightforward one. If this is the plan, however, it should be remembered that the fetal condition deteriorates more quickly in second stage than in first stage (because of maternal expulsive effort) and such a policy is fairly high risk so the obstetrician should be on hand to effect delivery if the CTG deteriorates.

There is controversy regarding FBS in the presence of a uterine scar, because fetal heart anomalies are often the first sign of problems with scar integrity and FBS can be falsely reassuring prior to what might be very rapid fetal demise. On the other hand, scar rupture is a much rarer event than FHR abnormalities and not performing FBS and proceeding straight to caesarean section will inevitably lead to an increase in 'unnecessary' intervention. For these reasons, the decision to perform FBS in cases of vaginal birth after previous caesarean delivery should be taken at consultant level.

Decisions to perform FBS in early labour (≤3 cm dilated) or repeating the procedure on multiple occasions (≥3 cm) should be taken carefully and at a senior level, but may be appropriate and achieve safe vaginal delivery [52].

The dilemma faced when failing to obtain an adequate sample on attempting FBS (less of a problem when sampling for lactate) is whether to continue labour (unsafe if the FHR pattern is pathological) versus proceeding straight to delivery, but recent suggestions of scalp stimulation can help guide practice: if the scalp stimulation from the procedure produces accelerations and the trace normalizes, then this is reassuring [43].

Fetal ECG

ST analysis

Over the last couple of decades the use of computerized analysis of the fetal ECG, particularly the ST segment, has been introduced into clinical practice. The fetal ECG is detected by means of an internal electrode (attached to the fetal scalp) and the printout highlights when there is an ST event, namely elevation of the ST segment suggesting myocardial hypoxia. The original randomized trials [53–55] supporting this supplement to CTG monitoring suggested better neonatal outcomes with fewer operative deliveries, but the reality has been disappointing with a number of reports of problems when using this technique in routine clinical practice [56–58]. The eagerly awaited large randomized controlled trial from the USA showed that fetal ECG ST-segment analysis used as an adjunct to conventional intrapartum electronic FHR monitoring did not improve perinatal outcomes or decrease operative delivery rates [59]. These data are included in the most up-to-date Cochrane review, which is similarly unsupportive of ST analysis [60].

The difficulties with this method of monitoring arise because of the following:

- ST events are frequent among controls (50%) with normal CTG and normal cord gas values [58];
- ST events, together with abnormal CTG patterns, appear late in the hypoxic process and are inconsistent

(50% in moderate metabolic acidaemia, 67% in severe acidaemia) [58];
- if the ST event precedes the start of monitoring, it may not register [57].

A review of the first 1502 cases monitored in a teaching hospital in the UK showed no improvement in emergency operative delivery or neonatal encephalopathy rates [56]. The crux of the argument is that clinical decision-making when using this tool should include accurate CTG interpretation as well as registering the ST event, but the problem is that ST analysis has been marketed as reducing intervention because it is 'better' than CTG and it is therefore unsurprising that users have a tendency to disregard a pathological CTG if the ST event does not trigger [61].

Non-invasive fetal ECG

The other disadvantage of ST analysis is the internal spiral scalp electrode, which risks scalp trauma and transmission of infection. The signal pick-up and feasibility of external electrodes placed on the maternal abdomen has been explored [62] but is still in the research arena. This would avoid the spiral electrode problem, but difficulties remain with ST analysis and how to relate it to CTG interpretations in clinical practice and therefore further developing this technology is questionable.

Computerized CTG analysis

There is some evidence that computerized CTG analysis reduces perinatal mortality in the antenatal period [63], but the same is not so for intrapartum monitoring. Preliminary trials looking at adding an expert system to aid in the interpretation of the fetal heart trace and improve intervention rates and neonatal outcomes were underpowered [64] but a definitive, large, multicentre UK trial which randomized over 47 000 women to intrapartum CTG monitoring either with or without decision support [65] showed that there was no difference in outcomes for either mother or baby, except for a slightly increased incidence of FBS in the decision support group. The authors concluded that their hypothesis that substandard care is largely related to failure to identify pathological FHR patterns was not supported and that most adverse outcomes associated with preventable substandard care involved a failure to take appropriate management decisions once the CTG abnormality had been recognized.

The future

The conflict between the need to detect the fetus in danger and to expedite delivery while avoiding unnecessary intervention remains. The following suggestions or research examples demonstrate where further developments may improve this inexact science.

- Antenatal detection of growth restriction can be improved by the systematic use of growth charts to plot the symphysis–fundal height routinely and appropriate use of ultrasound and thorough antenatal care and admission assessments in labour will further help stratify women and their babies into lower- or higher-risk groups.
- Intermittent auscultation techniques for low-risk pregnancies could be further explored to establish whether neonatal outcomes can be improved by critically specifying the baseline (and variability from that baseline) rather than just recording an average rate or a range for FHR.
- Computerized CTG analysis is well established in, and has improved the accuracy of, antenatal EFM (where failing to fulfil the Dawes–Redman criteria is associated with acidaemia and intrauterine deaths) [63,66,67]. Development of this tool for intrapartum CTG application has had promising results [68], but results from the definitive INFANT trial [65] did not confirm any benefit. However, further development to include clinical parameters and not just pattern recognition designs may help return the focus to treating the baby not the CTG.
- Clinical flags that alert the clinician in real time during EFM and which take into account clinical factors as well as CTG parameters may all improve the detection of fetal compromise, but will never replace clinical acumen. Maintaining an alert, enquiring, critical review of the whole clinical picture will always be needed and highly valued. There is no place for complacency and the hope that machines will tell clinicians what to do is unrealistic.

Summary

Intrapartum fetal monitoring must start from a clinically inquisitive stance where all antenatal factors are assimilated and added to observations on presentation in labour. Distinguishing between low- and high-risk pregnancies will then tend towards one particular approach to fetal monitoring but it should be remembered that whichever technique is chosen, none is foolproof, and continued vigilance and awareness of clinical developments in labour are needed. This anticipation of hypoxia should help early recognition of problems so that appropriate action can avoid both unnecessary intervention and inappropriate inactivity which could lead to irreversible damage to the fetus.

Preterm Labour

Phillip Bennett

Imperial College Faculty of Medicine, Institute for Reproductive and Developmental Biology, Hammersmith Hospital Campus, London, UK

Epidemiology

Definitions

Preterm birth is defined as delivery of a baby before 37 completed weeks of pregnancy. Legally, in the UK, the 1992 Amendment to the Infant Life Preservation Act defined the limit of viability as 24 weeks. However, a small number of infants born at 23 weeks will survive. Mortality in preterm babies born after 32 weeks' gestation is similar to that of babies born at term. The risk of neonatal mortality or survival with handicap becomes significant in very preterm infants (defined as those born between 28 and 32 weeks) but is most significant in extremely preterm infants (defined as those born before 28 weeks) (Fig. 28.1). In modern obstetric practice assessment of gestational age is based principally on fetal biometry measured by first- or second-trimester ultrasound rather than the date of the last menstrual period. However, in the past, assessment of gestational age was not always accurate and paediatric statistics were based on birthweight rather than gestational age data. Low birthweight is defined as less than 2.25 kg, very low birthweight as less than 1.5 kg and extremely low birthweight as less than 1 kg. Using these definitions to describe outcome data leads to blurring of the distinction between preterm babies and small-for-gestational-age babies, particularly in the low birthweight category, and also fails to differentiate the normally grown preterm neonate from the neonate who is both preterm and small for gestational age.

Incidence

Globally, about 15 million babies are born preterm each year. The incidence of preterm birth varies significantly across the globe. In most developed nations the rate of preterm birth is below 10%, the UK rate is around 7% and in the USA the rate fluctuates between 9 and 12% with huge geographical or interstate variation. Countries with preterm birth rates exceeding 15% include Malawi, Congo, Comoros, Zimbabwe, Equatorial Guinea, Mozambique, Gabon, Pakistan, Indonesia, Mauritania and Botswana. The greatest numbers of preterm births occur in India, China, Nigeria, Pakistan, Indonesia and the USA [1].

Preterm birth rates are increasing in almost all countries with reliable data. Especially in the developed world, this is associated with assisted reproduction increasing the rates of multiple pregnancy and an increased tendency to obstetric intervention. Strategies in the USA to encourage obstetricians to reduce their reliance on elective preterm delivery to manage conditions such as growth restriction and pre-eclampsia have been associated with a significant local reduction in the preterm birth rate, although this applies largely to late preterm births.

The proportion of preterm births in each gestation or age week époque increases almost exponentially from about 32 weeks. This means that the great majority of preterm births occur at later gestations. In England some 15% of all preterm births occur before 32 weeks, whilst 70% occur between 35 and 37 weeks (Fig. 28.2). The UK rate of preterm birth prior to 32 weeks has remained relatively stable at 1–2%. About one-quarter of preterm births are elective deliveries, usually for pre-eclampsia, intrauterine growth restriction or maternal disease. The remainder are due to preterm labour and delivery.

The incidence of spontaneous preterm labour is at its lowest in women in their twenties. The risk is increased in teenagers and in women aged over 30. There is a higher incidence of preterm labour in first pregnancies. Higher parity alone is not a risk factor for preterm labour. Indeed there is a progressively lower risk with each successive term birth. Marital status, cigarette smoking, environmental stress, poor nutrition and use of alcohol, coffee and street drugs (especially cocaine) have all been

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

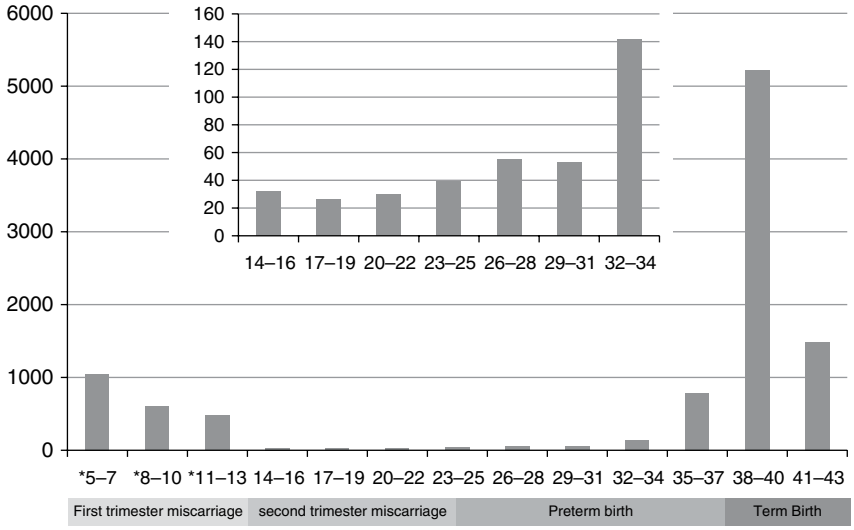

Fig. 28.1 Anticipated pregnancy outcome from 10 000 conceptions. The rate and timing of losses in the first trimester are derived from the CONCEIVE study (Foo FL, Collins A, McEniery CM, Bennett PR, Wilkinson IB, Lees CC. Preconception and early pregnancy maternal haemodynamic changes in healthy women in relation to pregnancy viability. *Hum Reprod* 2017;32:985–992). The outcomes in the second and third trimester are from the UK Office for National Statistics.

linked to an increased risk of preterm birth. However, many of these factors are interlinked and all are factors associated with social disadvantage. There does appear to be an association between race and risk of preterm delivery. In the UK the risk of preterm birth is 6% in white Europeans but 10% in Africans or Afro-Caribbeans, although it is difficult to differentiate genetic variation from social deprivation. In studies of populations where black and white women have similar lifestyles, levels of income and access to medical care (e.g. in US Army personnel), preterm delivery rates show a less marked ethnic variation. However, the identification of specific genetic polymorphisms that increase the risk of preterm labour does suggest that genetic as well as environmental factors may be involved, which explains the increased risk of preterm labour in certain ethnic populations. Intervention studies have shown that antenatal smoking cessation programmes reduce the risk of preterm birth, although there is no evidence currently that other interventions, such as increased frequency of antenatal care, dietary advice or an increase in social support, reduces the risk of preterm labour.

Summary box 28.1

- Preterm birth is defined as delivery of a baby before 37 completed weeks of pregnancy.
- Globally, about 15 million babies are born preterm each year.
- Risk factors include primigravida, older maternal age, smoking, illicit drug use and cervical surgery.

Neonatal outcomes after preterm birth

As of 2014, preterm births became the single largest cause of death of children under the age of 5 throughout the world [2]. Of the 6.3 million children who died before the age of 5 years in 2013, 52% died from infection and 44% died in the neonatal period. The three leading causes of death were complications of preterm birth (15.4%), pneumonia (14.9%) and complications of labour and delivery (10.5%). Previously infection had been the largest cause of death in this age group but global improvements in the management of pneumonia, diarrhoea and measles since the turn of the century has substantially reduced the impact of these diseases on childhood mortality.

Globally, there are dramatic differences in survival rates for preterm infants depending on where they are born. Over 90% of extremely preterm babies (<28 weeks) born in low-income countries die within the first few days of life, while less than 10% of babies born at this gestation die in high-income settings, a 10 : 90 survival gap. The risk of a neonatal death due to complications of preterm birth is more than 12-fold higher for an African baby than for a European baby.

In developed nations, and in particular the UK, survival rates for preterm babies have improved steadily over the past three decades principally due to the introduction of surfactant therapy, improvements in neonatal respiratory management and more widespread use of antenatal steroids (Fig. 28.3). The Epicure study, which examined extremely preterm infants born in 1995, reported mortality rates of 100%, 90% and 80% for preterm infants admitted to neonatal units at 21, 22 and 23 weeks' gestation, respectively. The subsequent Epicure II study repeated this exercise in a similar cohort born in 2006 and found that although rates of survival of babies born between 22 and 25 weeks' gestation has increased since 1995, the pattern of major neonatal morbidity and the proportion of survivors affected are unchanged. Therefore improved survival for very preterm infants has been associated with an increase in the proportion of children with cerebral palsy who were born preterm. Neonatal mortality rises gradually between 32 and 28 weeks, from 2 to 8%, and then more dramatically and exponentially to 80% at 23 weeks (Table 28.1).

In the past, surfactant deficiency leading to neonatal respiratory distress syndrome (RDS) was the major cause of morbidity and mortality in preterm infants. Alveolar surfactant production begins at 30–32 weeks' gestation. Therefore preterm infants born prior to 30 weeks are at highest risk. The impact of RDS on neonatal morbidity and mortality has been dramatically reduced in the past three decades through use of antenatal corticosteroids and exogenous surfactant replacement. The risk of chronic lung disease, defined as a need for ventilation or oxygen supplementation at 36 weeks after conception, has however continued to rise because of the increased survival of extremely preterm infants. The fetal and neonatal brain is especially susceptible to injury between 20 and 34 weeks. The greatest risk of long-term neurodevelopmental problems is in infants born before 28 weeks or at birthweights of less than 1000 g. The Epicure study showed that in infants born before 26 weeks' gestation, approximately half had some disability at 30 months and approximately one-quarter had severe disability [3]. Cerebral palsy may be related to periventricular haemorrhage, post-haemorrhagic hydrocephalus

and periventricular leucomalacia. Hypoxia–ischaemia is a major risk factor for neonatal cerebral damage. However, there is growing evidence for a strong link between chorioamnionitis, fetal inflammation and the risk of periventricular leucomalacia.

The overall risk of cerebral palsy associated with preterm birth at any gestational age (i.e. 23–36 weeks) is increased sevenfold over that of babies born at term; however, with decreasing gestational age this risk increases dramatically, with relative risks of 14, 46 and 70-fold, in infants born before 34, 31 and 28 weeks, respectively. The risk of visual impairment due to retinopathy of prematurity is inversely related to gestational age at birth and directly related to the concentration and duration of oxygen treatment. The risk of retinopathy of prematurity rises dramatically from less than 10% at 26 weeks to above 50% in infants born at 24 weeks. About 3% of infants born before 28 weeks' gestation will require a hearing aid and 50% will be found to have learning difficulties at school requiring additional educational support.

Preterm birth is associated with an increased prevalence of other medical disabilities, learning difficulties, and behavioural and psychological problems even in those without cerebral palsy. The risks of autism and mental retardation are increased 10-fold in preterm infants born before 28 weeks, and that of schizophrenia is increased fivefold. Difficulty with cognitive processes contributes to an increased risk of school problems in children born preterm. Only half of children born before 28 weeks are able to enter preschool with their peer group. The proportion of children born preterm who experience academic difficulties increases with age as the complexity of the schoolwork increases. Even in adults born preterm and who have no apparent medical problems, there are lower rates of high-level education and higher rates of low income and dependence on social security benefits.

Mothers of infants born preterm are at increased risk of experiencing depressive symptoms. The length of time that the newborn preterm infant must stay in the hospital also affects the ability of the mother to fulfil her role in the family. Families caring for a child born preterm face long-term and multiple challenges. The impact on families is long term, with parents, siblings, finances and family functioning all affected. Families will need to continue to manage the effects of prematurity when the children are toddlers, reach school age, become adolescents and, in some cases, into adulthood. The parent's marital relationship is likely to become stressed, often leading to divorce and consequent worsening of parenting difficulties. Parents will experience higher stress levels through difficulties in supervision of the child, the child's peer relationships and self-esteem, the impact of the child's difficulties on family routines, and worrying about the child's future. Siblings are affected because of the decreased attention that they receive from their parents. The family as a unit is affected by the greater likelihood of not having additional children, the financial burden, limits on family social life, high levels of family stress and dysfunction, and parents' difficulty in maintaining employment.

Summary box 28.2

- Preterm birth is the single largest cause of death of children under the age of 5 throughout the world.
- The overall risk of cerebral palsy associated with preterm birth at any gestational age is increased sevenfold over that of babes born at term. It is 70-fold higher in infants born before 28 weeks.
- Over 90% of extremely preterm babies (<28 weeks) born in low-income countries die within the first few days of life while less than 10% of babies born at this gestation die in high-income settings, a 10 : 90 survival gap.

Endocrinology and biochemistry of labour

To effectively predict and prevent labour requires a good understanding of the endocrinology and biochemistry underlying the onset of labour in humans, both at term and preterm [4,5] (Fig. 28.4). Our understanding of the mechanisms leading to the onset of labour in the human remains incomplete, in part because the mechanisms of the onset of parturition in different species appear to have evolved differently, making the direct extrapolation of data from animal models to the human not necessarily valid.

Labour as an inflammatory process

Throughout pregnancy the uterine cervix needs to remain firm and closed whilst the body of the uterus grows by hypertrophy and hyperplasia but without significant fundal dominant contractions. For labour to be successful the cervix needs to be converted into a soft and pliable structure that can efface and dilate and the uterus needs to become a powerful contractile organ. There is no single endocrine or biochemical switch in the human that changes the uterus from its not-in-labour state to its in-labour state. The onset of labour is a gradual process which begins several weeks before delivery itself with changes in the lower pole of the uterus which cause cervical ripening and effacement. The onset of clinically identifiable contractions is a relatively late event in this process. Cervical ripening occurs through breakdown of collagen, changes in proteoglycan concentrations and an increase in water content. The lower segment of the uterus also stretches and relaxes and behaves physiologically more like the cervix than like the contractile upper segment of the uterus. These changes in the lower segment of the uterus are associated with an increase in the production of inflammatory cytokines, particularly interleukin (IL)-8 and prostaglandins from the overlying fetal membranes and decidua and from the cervix itself. Cervical ripening is associated with an influx of inflammatory cells into the cervix which release matrix metalloproteins that contribute to the anatomical changes associated with ripening. The later increase in fundally dominant contractility in the upper segment of the uterus is associated with an increase in the expression of receptors for oxytocin and prostaglandins, in gap junction proteins, which mediate electrical connectivity between myocytes, and in more complex changes in the intracellular signalling pathways which increase the contractility of the myocytes.

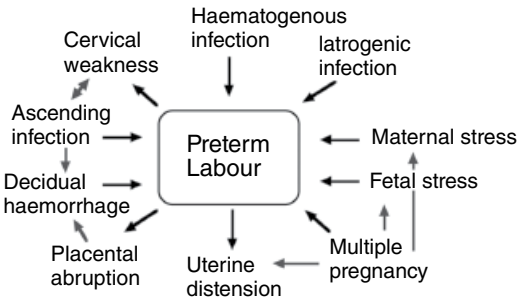

Fig. 28.4 The interplay of the causes of the preterm labour syndrome.

Roles of progesterone, corticotrophin-releasing hormone and oxytocin

In many species progesterone is thought to play an important role in suppressing the onset of labour [6]. Progesterone has a generally anti-inflammatory action within the uterus. As discussed above, many of the biochemical events associated with cervical ripening and the onset of labour are similar to those seen at sites of inflammation. In most species the onset of labour is heralded by withdrawal of progesterone.

So, for example, in the rodent, prostaglandin-mediated regression of the corpus luteum leads to a fall in progesterone concentrations immediately prior to the onset of labour. In the sheep increased production of cortisol from the fetal adrenal signals fetal maturation and induces placental 17α-hydroxylase, which increases synthesis of oestrogen at the expense of progesterone, again leading to progesterone withdrawal immediately prior to the onset of labour. There is no systemic withdrawal of progesterone in the human prior to the onset of labour, although there is an increase in the expression of genes formerly repressed by progesterone, which has led to the hypothesis of a 'functional progesterone withdrawal' mediated by changes in the expression or function of progesterone receptors or of cofactors needed for the function of the progesterone receptor. Another hypothesis is that inflammatory events seen within the uterus at

the time of labour are associated with increased activity of the transcription factors nuclear factor (NF)-κB and AP-1 (transcription factors strongly associated with inflammation in other contexts such as asthma, inflammatory bowel disease or arthritis). NF-κB and AP-1 repress the function of the progesterone receptor and so could mediate functional progesterone withdrawal. Although in the mouse progesterone concentrations fall due to luteolysis just prior to labour, there is still sufficient circulating progesterone concentrations to activate progesterone receptors. In the mouse it appears that the final event leading to parturition is the increased production of surfactant protein A from the fetal lung, which stimulates the activity of NF-κB within the uterus leading to an influx of inflammatory cells, an increase in inflammatory cytokine synthesis and depression of the residual function of the progesterone receptor. It is an attractive hypothesis that pulmonary maturation in the human may signal the final phase of the onset of labour but there is at present no direct evidence that this mechanism applies in the human.

Circulating levels of corticotrophin-releasing hormone (CRH), synthesized in the placenta, increase progressively throughout pregnancy and especially during the weeks prior to the onset of labour. CRH-binding protein concentrations fall with advancing gestational age such that, approximately 3 weeks prior to the onset of labour, the concentration of CRH exceeds that of its binding protein. Unlike in the hypothalamus, placental CRH is upregulated by cortisol. Several studies have linked placental production of CRH with the timing of birth and have demonstrated that a premature rise in CRH is associated with preterm delivery. The upregulation of CRH by cortisol suggests a mechanism by which the fetus, through increased adrenal cortisol production, may signal its maturation and control the timing of birth [7]. For much of pregnancy the CRH receptor expressed by the myometrium is linked to second messenger systems that promote relaxation. Near to term, however, CRH may enhance the contractile response to oxytocin and may stimulate the production of prostaglandins from the fetal membranes and the placenta.

In the monkey, uterine contractions occur only at night. In the days preceding labour and delivery there are nocturnal non-fundal dominant contractions which have been termed 'contractures'. The conversion from contractures to contractions is mediated by an increase in the production of oxytocin from the maternal posterior pituitary gland [8]. In the monkey, therefore, while the fetus might signal its general readiness to be born through increased cortisol production from the adrenal, the precise timing of birth is signalled by the mother. This may be a mechanism of defence against predators which ensures that delivery is always at night. Contrary to the experience of many obstetricians, this phenomenon does not apply to the human. There is no increase in the production of oxytocin associated with the onset or progression of either preterm or term labour. There is, however, an increase in the expression of oxytocin receptors within the uterus and there is local production of oxytocin in the uterus, decidua and fetal membranes. Although oxytocin probably does not play an important role in the precise timing of parturition in the human, increases in the density of oxytocin receptors suggests that oxytocin does play a role in mediating contractility. Recent studies have shown that oxytocin acts not only to stimulate the uterus to contract, but also to upregulate inflammatory mediators within the uterus, therefore adding an additional 'pre-labour' mechanism of action for the hormone. Oxytocin also plays important postnatal functions in mediating the milk-let down reflex, contracting the uterus to prevent postpartum haemorrhage and having a effect on maternal bonding with the baby.

Causes of preterm labour

Preterm labour is not a single disease entity but is a syndrome that may have one or more causes [9,10]. Research into the prediction and prevention of preterm labour has to some extent been made more difficult because many investigators have treated the syndrome as if it is a single disease. With the exception of studies specifically in multiple pregnancy and in populations of women with a short cervix, most clinical studies of interventions to prevent or delay preterm labour have not attempted to differentiate subjects on the basis of the underlying cause. Similarly, many studies which have attempted to identify biomarkers for preterm labour have not taken into account its multiple aetiology.

Preterm labour has been linked to cervical incompetence, abnormalities of haemostasis, infection within the uterus, placental abruption or decidual haemorrhage, fetal or maternal stress and multiple pregnancy. These various factors may act together to increase the likelihood of preterm delivery or to affect the gestational age at which preterm delivery occurs. Multiple pregnancy probably leads to preterm delivery through at least three mechanisms. Over-distension of the uterus leads to premature upregulation of contraction-associated proteins and of factors which mediate cervical ripening, all of which have been shown to be sensitive to mechanical stretch. Multiple pregnancy is associated with multiple placentas and therefore with an earlier rise in placental CRH concentrations in the circulation. The development of multiple corpora lutea may lead to increased production of relaxin and to premature cervical ripening. The incidence of multiple pregnancy has increased due to the trend of delayed

childbirth, since multiple births occur with a greater frequency amongst older mothers. However, the principal contributing factor has been the linked increase in the use of assisted reproductive technologies. This has been controlled to some extent in the UK by restricting the number of embryos transferred at *in vitro* fertilization, although poorly controlled ovulation induction therapies may continue to contribute to the problem.

Cervical function

With improved survival at early gestational ages, there is now overlap between second-trimester pregnancy loss and early preterm delivery. Historically, cervical incompetence was diagnosed in women who experienced persistent, often rapid and painless, late second-trimester pregnancy loss. More recently, the concept of cervical competence as a continuum has evolved. It is probable that cervical length and strength, together with the quality of the cervical mucus, contribute towards cervical function, both to retain the pregnancy within the uterus and to exclude potential bacterial pathogens from ascending from the vagina. Numerous studies have demonstrated a strong relationship between cervical length and the risk of preterm delivery. The cervix may be damaged (or completely removed) by surgery in the treatment of cervical cancer or, rarely, during a difficult instrumental vaginal delivery, or caesarean section at full dilatation. Historically, there were associations between diethylstilbestrol exposure *in utero* and developmental anomalies in the genital tract and cervical weakness. This ceased to be a problem in modern obstetric practice since the cohort of women exposed to the drug in the 1960s are now beyond reproductive age. A short or partially dilated cervix may allow bacteria to ascend into the lower pole of the uterus where, acting through the Toll-like receptors of the innate immune system which recognize bacterial components, they stimulate production of inflammatory cytokines, prostaglandins and the inflammatory response. This then leads to cervical ripening and shortening, which in turn decreases the ability of the cervix to act as either a mechanical or microbiological barrier and, ultimately, leads to the development of either localized or generalized chorioamnionitis and to preterm delivery. A short or weak cervix may therefore contribute to preterm delivery not only by leading to simple second-trimester miscarriage but also by contributing to a risk of ascending infection leading to a more classical spontaneous preterm labour. Delivery by caesarean section at or close to full dilatation of the cervix is now recognized as a risk factor for preterm birth. The probability is that difficult delivery leads to mechanical damage to the cervix, through the trauma from failed instrumental delivery, through a uterine incision made within cervical rather than lower segment tissue, or through damage to the cervix caused by the need to disimpact a deeply engaged fetal head.

There is an association between risk of preterm delivery and cervical intraepithelial neoplasia (CIN) [11]. The greatest risk is in those women with CIN who have had a particularly deep large loop excision of the transformation zone (LLETZ) or a cold knife cone biopsy. In women who have had a deep LLETZ or a cold knife cone biopsy, mechanical damage to the integrity of the cervix is probably a major aetiological factor in their risk of preterm labour. However, there is a smaller underlying risk associated with CIN alone. It may be that human papillomavirus (HPV) infection is an independent risk factor for preterm birth. It is also possible that the underlying factors associated with the development of CIN following HPV infection in an individual woman may also be factors which increase her risk of preterm birth.

Genital tract infection

There is a strong correlation between infection within the uterus and the onset of spontaneous preterm labour. As discussed, activation of inflammatory mediators is a central part of the normal biology of parturition. Therefore infection within the uterus has the potential to activate all the biochemical pathways, ultimately leading to cervical ripening and uterine contractions. It has been estimated that approximately 40% of all preterm births are associated with bacterial infection. The most likely source of infection is bacteria ascending from the vagina through the cervix into the lower part of the uterus. However, bacteria may also gain access to the amniotic cavity through haematogenous spread or by introduction at the time of invasive procedures. Following preterm delivery histological chorioamnionitis is usually more common and severe at the site of membrane rupture than elsewhere, such as overlying the placenta or umbilical cord. In virtually all cases of congenital pneumonia, inflammation of the fetal membranes is also present. Bacteria identified in the majority of cases of congenital infection are often also found in the maternal lower genital tract and, following twin preterm delivery, chorioamnionitis is more common and severe in the presenting twin than in the second twin (although this is not always the case). These factors all suggest that ascending infection from the lower genital tract is the commonest mechanism for chorioamnionitis.

The most common microbes isolated from the amniotic cavity of women in preterm labour are *Ureaplasma urealyticum*, *Fusobacterium* and *Mycoplasma hominis*. More than 50% of patients in preterm labour will have more than one microorganism isolated from the amniotic cavity. Microorganisms can be identified in the fetal membranes of the majority of women delivering both

preterm and at term. It is probable that some cases of spontaneous preterm delivery are due to an excessive inflammatory response to a lesser degree of bacterial invasion of the amniotic cavity. So, for example, bacterial vaginosis (see below) may be a greater risk factor for preterm labour in women who carry a high secretory form of the tumour necrosis factor (TNF)-α gene.

There is now considerable interest in the role of the microbial communities in the vagina in the aetiology of preterm birth. The collective term for the range of bacterial species in the vagina is 'vaginal microbiota'. The collective term for all the bacterial genes present is 'vaginal microbiome' (although the term 'microbiome' is often used interchangeably with 'microbiota' to define a microbial community occupying a reasonably well defined habitat which has distinct physicochemical properties). The study of the bacterial genes present in the vaginal microbiome is described as metagenomics.

In reproductive life the vaginal microbiota is usually dominated by the presence of lactobacilli, representing more than 90% of bacterial species present. Lactobacilli secrete lactic acid, which maintains a low pH hostile to other microorganisms and which has anti-inflammatory actions. Lactobacilli also excrete specific antimicrobial proteins. A minority of women will have a *Lactobacillus*-depleted vaginal microbiota, and this may allow overgrowth of bacterial vaginosis (BV)-associated anaerobic organisms such as *Gardnerella vaginalis*, which creates a biofilm that allows other opportunistic bacteria to thrive. The increased oestrogen concentrations of pregnancy increase the availability of vaginal mucosal glycogen, a source of energy for lactobacilli. Therefore, in general, the proportion of lactobacilli increases in the vagina during pregnancy. The relationship between the structure of the vaginal microbiota and the risk of preterm birth varies from population to population. In some but not all populations in the USA, where *Lactobacillus* depletion is common, a dysbiotic *Lactobacillus*-depleted BV-like vaginal microbiota is a risk factor for preterm birth. In the UK, prevalence of a dysbiotic vaginal microbiota in pregnancy is low but is probably still a risk factor. However, the dominance of one particular species, *Lactobacillus iners*, appears to be a risk factor for both cervical shortening and preterm birth. *Lactobacillus iners* has less ability to excrete anti-inflammatory isomers of lactic acid or antimicrobial proteins, and may represent a transitional organism between healthy vaginal microbiota and vaginal dysbiosis or bacterial vaginosis.

Haemorrhage

Placental abruption may lead to the onset of preterm labour. This is thought to be through release of thrombin, which stimulates myometrial contractions by protease-activated receptors but independently of prostaglandin synthesis. This may explain the clinical impression that preterm labour associated with chorioamnionitis is often rapid whereas that associated with placental abruption is less so because there is no pre-ripening of the uterine cervix. Generation of thrombin may also play a role in preterm labour associated with chorioamnionitis when it is released as a consequence of decidual haemorrhage.

Fetal and maternal stress

There is evidence that both fetal and maternal stress may be risk factors for preterm labour. Fetal stress may arise in association with abnormal placentation and growth restriction. Maternal stress could be due to environmental factors. In both cases it is postulated that over-secretion of cortisol leads to upregulation of CRH production in the placenta.

Summary box 28.3

- Preterm labour has been linked to cervical incompetence, abnormalities of haemostasis, infection within the uterus, placental abruption or decidual haemorrhage, fetal or maternal stress and multiple pregnancy.
- There is an association between risk of preterm delivery and deep LLETZ or cold knife cone biopsy.
- Colonization of the vagina with *Lactobacillus iners* or with a *Lactobacillus*-depleted high-diversity community structure are risk factors for preterm pre-labour rupture of membranes and preterm birth.

Prediction of preterm labour

In the majority of cases of preterm labour obstetric management consists principally of attempting to suppress contractions in women who are already in established labour. As discussed in more detail later, this strategy is essentially ineffective. Obstetric strategies to reduce perinatal morbidity and mortality associated with preterm labour should ideally involve the early identification of women at risk and the use of prophylactic therapies. Prediction of preterm labour can be considered in two broad scenarios. Firstly, there is prediction at a time removed from the labour event itself, intended to direct possible prophylactic therapy. Secondly, there is the prediction of delivery in women who are symptomatic, essentially intended to differentiate those who are genuinely in preterm labour from those who have preterm contractions but are not at risk of imminent delivery.

Attempts have been made to devise risk scoring systems based on socio-demographic characteristics,

anthropomorphic characteristics, past history, patient behaviour and habits and factors in the current pregnancy. None of these systems has been found to have positive predictive values or sensitivities which make them clinically useful in identification of individual women at risk. Most systems rely heavily on past obstetric history and are therefore irrelevant to women having their first baby. At present there are no screening tests which are routinely applied to primigravid women, or to multigravid women who are not at high risk for preterm labour. Women at high risk of preterm labour will initially be detected based solely on past obstetric history. Having had a single previous preterm delivery increases the risk of preterm delivery in a subsequent pregnancy four times when compared to a woman whose previous delivery was at term. A past obstetric history which consists of a term delivery followed by a preterm delivery confers a higher risk of preterm delivery in the third pregnancy than a past obstetric history that consists of a preterm delivery followed by a term delivery. This may be because the latter group contains a disproportionate number of women whose preterm delivery was for 'non-recurring' causes such as placental abruption, whereas in the former group the preterm delivery following the term delivery may be due to damage to the cervix during the original term delivery.

Ultrasound measurement of cervical length

There is very good evidence that transvaginal sonographic measurement of cervical length can be used to identify women at risk of preterm labour in both low- and high-risk pregnancies and in women who are symptomatic [12] (Fig. 28.5). Transabdominal measurement of cervical length is unreliable because of the need for a full bladder, which may compress the cervix leading to an overestimate of its length, and because it is more difficult to obtain adequate views of the cervix with this technique. Transvaginal ultrasound should be performed with the bladder empty. The probe is placed in the anterior fornix of the vagina without undue pressure on the cervix and optimally the internal and external os and the echogenic endocervical mucosa should be identified along the length of the canal. For identification of risk in asymptomatic women (those who do not have symptoms of labour) two broad strategies are currently in common use: a single measurement in the mid-second trimester, or serial measurement of cervical length throughout the second and early third trimester of pregnancy.

A single measurement of cervical length, usually at the time of a routine ultrasound scan between 18 and 22 weeks, has been widely used to identify subjects at high risk of preterm birth for inclusion into intervention trials. If a screening strategy using a single ultrasound

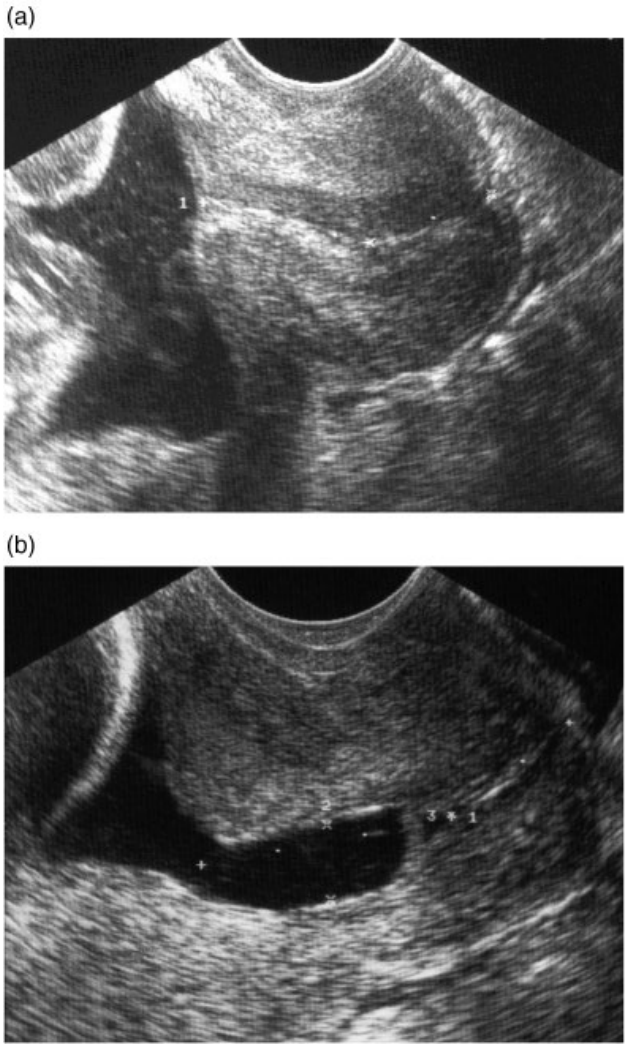

Fig. 28.5 Appearance of the cervix on transvaginal ultrasound: (a) normal cervix; (b) funnelling leading to a short cervix.

measurement of cervical length is used, then assessment between 21 and 24 weeks' gestation appears to be better than assessment prior to 20 weeks' gestation in predicting the risk of preterm labour. However, this is to a certain extent a self-fulfilling prophesy since clearly the closer to the actual onset of preterm labour the assessment of cervical length is made, the more likely it is that the cervix will be found to be short. It is arguable that identification of a risk of preterm labour as late as 23 weeks may be too late for any potential prophylactic therapies to be fully effective. In addition, such a strategy is unable to detect any of the women whose pregnancy loss or preterm delivery occurs prior to 23 weeks. A large number of studies have examined the relationship between gestational age, cervical length and the risk of preterm delivery (Fig. 28.6). Many studies have used single cut-off values. So, for example, a cervical length of

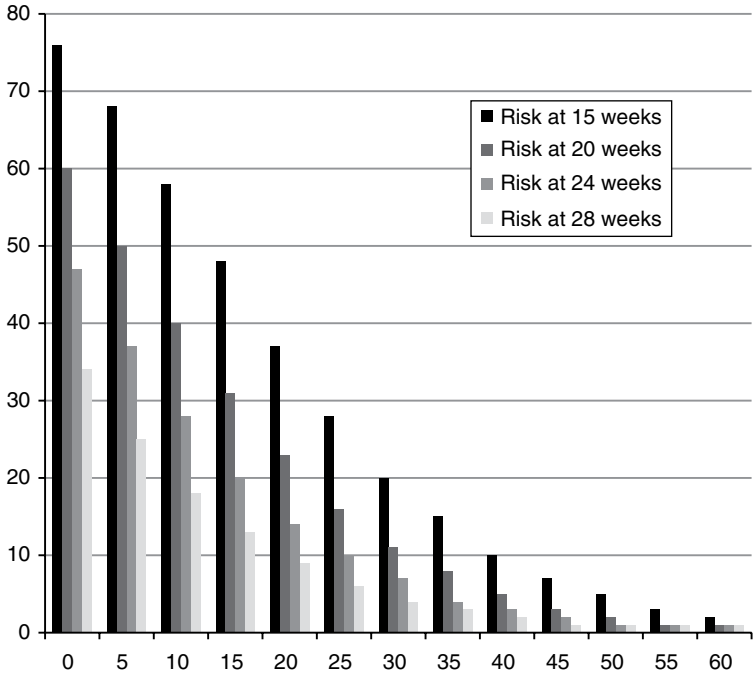

Fig. 28.6 Risk of preterm birth (<32 weeks) by cervical length and gestational age of measurement. *Source:* adapted using data from Iams JD, Berghella V. Care for women with prior preterm birth. *Am J Obstet Gynecol* 2010;203:89–100.

15 mm or less at 20–24 weeks predicts a risk of preterm delivery prior to 34 weeks' gestation of approximately 50% in a low-risk population. It is absolute cervical length rather than the presence or absence of funnelling which is the principal predictor of spontaneous preterm birth (although clearly the presence of funnelling will lead to a shorter cervical length).

It has been suggested that the introduction of routine measurement of cervical length at the time of the second-trimester anomaly ultrasound scan would enable screening of low-risk populations. This concept is greatly predicated on the assumption that an effective intervention is available (see section on progesterone and cervical cerclage). The value of routine measurement of cervical length also depends on the prevalence of a short cervix and the incidence of preterm birth in the background population. In UK populations this approach will only detect about 15% of all preterm births, a reflection of the multi-aetiological nature of the syndrome.

Women at high risk of preterm birth may be offered serial measurement of cervical length to assess their risk of preterm labour. This approach appears to be superior to a single measurement in assessing the risk of preterm delivery. It has been widely advocated as an approach for the detection of women who would benefit from progesterone prophylaxis during pregnancy. It is also a particularly useful approach in women with a history of a previous preterm birth or second-trimester pregnancy loss in whom a diagnosis of cervical insufficiency or incompetence is not clear and can be used to reduce the number of unnecessary cervical cerclage procedures performed. In this management strategy, cervical cerclage would be indicated either when cervical length reduces to a fixed cut-off, commonly 25 mm, or falls below the 10th or 3rd centile for cervical length at that gestational age. In continental Europe it is common practice to perform a vaginal assessment of cervical length at each antenatal consultation, although multicentre trials have shown that this policy is of no benefit in predicting the risk of preterm delivery.

Bacterial vaginosis

As alreadt discussed, BV is a risk factor for preterm birth, although most studies have shown that treating BV with antibiotics does not change the risk. Studies of the risk of preterm labour associated with BV have reported widely varying results. However, it seems that, overall, BV approximately doubles the risk of preterm delivery. It also appears that there is a relationship between the gestational age at diagnosis of BV and the risk of preterm delivery, in that if BV is diagnosed earlier in pregnancy this appears to be associated with a higher risk of preterm delivery. Routine screening for BV is not therefore undertaken in low-risk populations. Some obstetricians do include screening for BV in the management of high-risk populations, and this is currently undertaken by non-genetic techniques, although the future introduction

of DNA sequence-based bacteriology may change this situation. Currently, diagnosis of BV can be made on Gram staining of vaginal fluid using either Nugent's or Spiegel's criteria, by gas–liquid chromatography of vaginal fluid (finding a high ratio of succinate to lactate) or on clinical grounds based on a high vaginal pH, a fishy odour in a thin homogeneous vaginal discharge and the presence of clue cells in the discharge on a wet mount. There is no significant difference in the ability of each of these diagnostic tests to predict preterm birth.

Although there is reasonably good evidence that BV is a risk factor for preterm delivery, it is less clear that treating it with antibiotics is beneficial. This may be in part because various studies of BV have used different antibiotics in different regimens and at different times, but it may also reflect the fact that antibiotics may not necessarily result in the re-establishment of normal bacterial flora. The two antibiotics commonly used in the treatment of BV are metronidazole administered orally or clindamycin, which may be given either orally or vaginally. Clindamycin may have advantages over metronidazole since it has better activity against anaerobic bacteria and *Mycoplasma hominis* and *Ureaplasma urealyticum* which are often associated with BV. While screening of pregnant women who are at high risk for preterm delivery based on their past obstetric history or other factors might be justified, there is currently no strong evidence to recommend the routine screening and treatment of the general obstetric population.

Summary box 28.4

Preterm labour may be predicted by:

- transvaginal sonographic measurement of cervical length in the second trimester;
- measurement of fetal fibronectin in cervical vaginal fluid in the second trimester.

Fetal fibronectin

Fetal fibronectin is a glycoprotein variant of the fibronectin family present in amniotic fluid, placenta and the extracellular substance of the decidua. Its synthesis and release is increased by the mechanical and inflammatory events which occur prior to the onset of labour. Fibronectin is often described as 'leaking' from disruption to the fetal membranes and decidua in the lower pole of the uterus associated with the early biochemical events of parturition. However, it is also an inflammatory response gene, and therefore concentrations of fibronectin in vaginal fluid can be considered to also be a marker of inflammation (which may be pathological or a normal part of the onset of labour at term).

Fetal fibronectin may normally be detected in vaginal secretions at levels in excess of 50 ng/mL up to 20 weeks' gestation and again after 36 weeks' gestation. Detection up to 20 weeks is possible because the amniochorion is not fully fused with the decidua until that time. Detection closer to term is a feature of the normal mechanical and biochemical events leading to normal term labour. The presence of fibronectin in vaginal secretions at levels above 50 ng/mL between 20 and 36 weeks is therefore not normal and may be used to predict a risk of preterm labour [13,14]. When originally introduced as a commercial test, fibronectin analysis was principally intended to be used in women who present with preterm contractions to differentiate those with a risk of imminent delivery. However, it is now being increasingly used to predict risk in women who are asymptomatic but at risk for other reasons, in particular cervical shortening. The currently available bedside testing kits allow quantification of the concentration of fibronectin in the vaginal fluid, which has improved the predictive performance of the test. So, for example, women with a cervical length below 25 mm between 22 and 28 weeks, but with a fetal fibronectin concentration of less than 10 ng/mL, will have a risk of preterm birth before 34 weeks of less than 10%; this rises to over 50% if the fibronectin concentration is greater than 200 ng/mL.

Predictive algorithms (e.g. QUIPP, Apple Store) have now become available that combine the information of past obstetric history, gestational age, cervical length and fibronectin concentration to produce an estimate of risk delivery within a defined time period (e.g. 7 days) or prior to a defined gestational age (e.g. 34 weeks). These algorithms have been developed based on populations who had interventions if they were identified as being at high risk and therefore their general applicability, particularly to low-risk populations, is uncertain. Nevertheless, they act as a useful guide to enable clinicians to take into account all the risk factors for preterm birth and to direct therapy and counsel patients about the risks and benefits of interventions.

Prevention of preterm labour

In primigravid women with no other significant risk factors for preterm delivery there is currently no effective method for the prediction of preterm labour and therefore management can only be instituted at the time of acute presentation with contractions. However, it is possible to identify a group of women in the antenatal period who are at risk of preterm delivery based on their past obstetric history, the presence of abnormalities of the genital tract, and use of screening tests such as transvaginal ultrasonic measurement of cervical length and detection of fetal fibronectin in vaginal secretions [15].

A continuing problem in the direction of therapies intended to reduce the risk of preterm birth is a lack of suitable tools to stratify women at risk into different aetiological groups. Most studies of interventions have either had no classification or have selected subgroups of women, for example those with a multiple pregnancy or those with a short cervix. Even in those subgroups, however, the underlying aetiology may be different. So, for example, it is possible that damage to the cervix caused by an excisional treatment for CIN, may result in both cervical incompetence and a physically shorter cervix. Such women may benefit from cervical cerclage. However, the cervix may have its structural integrity compromised without necessarily being rendered any shorter and would nevertheless still benefit from cerclage. Cervical shortening may be due to activation of inflammation within the vagina and cervix, in which case cerclage might be detrimental. It is possible that some of the dramatic differences in the effectiveness of interventions that are seen in different clinical trials may arise from enrolment of women whose underlying aetiology of their risks of preterm birth are different, despite the apparent presentation, for example with a short cervix, being similar.

At present, no prophylactic therapy has been demonstrated to be unequivocally beneficial in preventing the onset of preterm labour in a high-risk population. Commonly used therapies include cervical cerclage and progesterone. Previously, non-steroidal anti-inflammatory drugs and oral beta-sympathomimetics have been used. Vaginal pessaries are being studied.

Cervical cerclage

The objective of the MRC/RCOG multicentre randomized trial of cervical cerclage, published in 1993, was to assess whether cervical cerclage in women deemed to be at increased risk of cervical incompetence prolongs pregnancy and thereby improves fetal and neonatal outcome. However, women were randomized only if their obstetrician was uncertain whether to recommend cervical cerclage. Therefore cervical cerclage was compared with a policy of withholding the operation unless it was considered to be clearly indicated. In this study, the largest ever conducted of this question, the overall preterm delivery rate was 28% and there were fewer deliveries before 33 weeks in the cerclage group (13% vs. 17%). This difference was reported to be reflected in deliveries characterized by features of cervical incompetence: painless cervical dilatation and pre-labour rupture of the membranes. The use of cervical cerclage was associated with a doubling of the risk of puerperal pyrexia.

Based largely on these data, current UK guidelines suggest that history-indicated cerclage should be offered to women with three or more previous preterm births and/or second-trimester losses [16,17]. Various tests, including assessment of cervical resistance index, hysterography or insertion of cervical dilators, have been found to have no benefit in predicting cervical weakness. Nevertheless a clinical examination of the cervix of a woman considered at risk is beneficial. It will highlight any congenital or acquired abnormalities and will identify the women in whom cerclage may be a more challenging procedure than expected before discovery on the operating table.

Many obstetricians currently use transvaginal ultrasound measurement of cervical length to assess risk of preterm birth and target intervention by cervical cerclage in women where there is uncertainty about the possible benefit. If ultrasound-indicated cervical cerclage is to be used, the appropriate threshold has not yet been universally agreed, although a length below 25 mm is a commonly used cut-off. The presence of visible fetal membranes at the time of cervical cerclage is a strong prognostic indicator for the risk of preterm delivery. Visible fetal membranes are never seen at a cervical length greater than 15 mm.

An individual patient data meta-analysis of four large studies of targeted cervical cerclage in women with a short cervix taken from a general obstetric population with no increased background risk of preterm birth showed that cervical cerclage was not beneficial. It has therefore generally been concluded that cervical cerclage is of no benefit in a woman with a short cervix but no other risk factors for preterm labour. However, in the analysis the selected cut-off cervical length for cerclage varied between less than 15 mm and less than 25 mm, and the ultrasound examinations were performed relatively late in pregnancy at 22–24 weeks. The results of this meta-analysis also stands in stark contrast to a much smaller earlier study which showed a marked benefit of cervical cerclage undertaken by a single senior skilled obstetrician. As discussed later, there are various aspects of the technical performance of the operation that will affect the outcome. It is possible that the failure to demonstrate benefit of cervical cerclage in a large general population of women with short cervix is partly due to the short cervical length cut-off, late gestational age at screening, variable skill and experience of the operators and technique of the procedure. It is also probably the case that a population of women at risk of preterm birth with a short cervix at the end of the second trimester of pregnancy represents a mixture of women with genuine mechanical cervical problems, who would probably benefit from cervical cerclage, and women whose cervix is short for other reasons, who would probably not benefit and may even be harmed (see discussion on effects of suture material).

Whilst the current evidence is that cervical cerclage is not beneficial in women whose only risk of preterm birth is a short cervix in the late second trimester, there is good evidence to suggest that women with a history of spontaneous second-trimester loss or preterm delivery who have cervical shortening are at an increased risk of subsequent second-trimester loss/preterm birth and may benefit from ultrasound-indicated cerclage while those whose cervix remains long are at low risk. A meta-analysis of four randomized controlled trials of cervical length-indicated cerclage in women with a prior second-trimester loss or birth before 36 weeks showed an almost 50% reduction in deliveries prior to 35 weeks in the cerclage group. Women with a prior LLETZ represent another group who may benefit from cervical cerclage and are becoming an increasingly large cohort in the obstetric population. This group is now often managed in a similar way, with a cut-off cervical length of 25 mm being used to indicate cervical cerclage. Although there are no randomized controlled trials in this group of patients, current observational data suggest that this policy reduces their risk of preterm birth to that of the background population. A cervical length of 38 mm at 12 weeks or 36 mm at 16 weeks can be used as a screen to discharge women in this cohort from further surveillance.

Cervical cerclage technique

Various different techniques have been described for cervical cerclage. The operation was originally popularized in the 1950s by Shirodkar as a transvaginal pursestring suture placed following bladder mobilization and posterior dissection to allow insertion at the level of the internal os. In the 1960s the simpler McDonald procedure of a transvaginal pursestring suture without bladder mobilization become popular. Some exponents of the McDonald procedure deliberately place the suture midway along the cervix to reduce the risk of bladder injury and to facilitate removal. It is now clear that the success of cervical cerclage depends on placing the suture as close to the internal os as possible. In my experience this will require dissection of the bladder off the cervix in more than 50% of cases.

Cervical cerclage is most commonly performed using a braided Mersilene tape suture with needles on each end. However, there is evidence that use of Mersilene may be associated with higher rates of pregnancy loss and preterm birth than use of the more inert material nylon. Mersilene, when used for cervical cerclage and in other forms of surgery, may encourage bacterial biofilm formation, and has a detrimental effect on the vaginal microbiota leading to activation of vaginal/cervical inflammation [18]. Some operators who use Mersilene tape completely bury the suture. This is associated with better outcomes but with much greater difficulty in removing the stitch at the end of the pregnancy. Similarly, leaving large amounts of Mersilene tape in the vagina after cerclage to facilitate removal probably increases the risk of adverse outcome. The use of Mersilene tape for cervical cerclage may explain the higher puerperal sepsis rates seen in the large trials, but also the dramatically improved outcomes seen in women who undergo abdominal cerclage, in which accurate placement of the stitch at the isthmus is made easier, whilst the stitch itself is in an anatomical location unexposed to the vaginal microbiota.

The current evidence, although based on small numbers, is that insertion of a cervical cerclage where the only risk of preterm birth is multiple pregnancy is not beneficial; indeed it may be associated with an increase in the risk of preterm delivery and pregnancy loss. Similarly, cerclage does not appear to be of benefit in women with multiple pregnancy and a short cervix but no other risk factors for preterm birth. This underlines the aetiological differences in the risk of preterm birth between singleton and multiple pregnancy. There are no large studies of the role of cerclage in women with twins who have a past history of second-trimester pregnancy loss or preterm delivery. However, it would be illogical to deny a woman who had previously benefited from cervical cerclage, a cerclage in a subsequent pregnancy because she was carrying twins.

Emergency 'rescue' cerclage

Rescue cervical cerclage may be performed when a woman is admitted with silent cervical dilatation and bulging of the membranes into the vagina but without the onset of uterine contractions. Characteristically, such women present with slight vaginal bleeding, a watery vaginal discharge, or vague pelvic or vaginal pain. The available literature, mostly composed of case reports and small case series, suggests that rescue cerclage may delay delivery by a further 5–7 weeks on average compared with expectant management/bed rest alone, associated with a twofold reduction in the risk of delivery before 34 weeks. However, there are concerns that emergency or rescue cerclage might convert a second-trimester pregnancy loss into an early preterm delivery with its associated handicap risk, particulary in the context of chorioamnionitis. Adverse features which should contraindicate rescue cervical cerclage include evidence of chorioamnionitis: maternal pyrexia, abdominal pain, contractions, raised white blood cell count or C reactive protein levels. Whether antibiotics are beneficial in such cases has not been established.

Non-steroidal anti-inflammatory drugs

The central role for prostaglandins and inflammatory cytokines in the onset of labour at term and in the aetiology of preterm labour suggests that non-steroidal

anti-inflammatory drugs (NSAIDs) may be beneficial in preventing preterm delivery. NSAIDs work largely by inhibition of the cyclooxygenase enzymes which catalyse the synthesis of prostaglandins. However, various NSAIDs also have other mechanisms of action, including effects on intracellular signalling pathways and on inflammatory transcription factors such as NF-κB and AP-1. Whilst there are several studies of the use of NSAIDs in the acute management of preterm labour, there are few good randomized trials of their use as prophylaxis. NSAIDs are associated with significant fetal side effects, in particular oligohydramnios and constriction of the ductus arteriosus. Oligohydramnios occurs in up to 30% of fetuses exposed to indometacin. The effect is dose dependent and may occur with both short-term and long-term exposure. Discontinuation of therapy usually results in a rapid return of normal fetal urine output and resolution of the oligohydramnios.

Constriction of the ductus arteriosus occurs in up to 50% of fetuses exposed to indometacin at gestational ages greater than 32 weeks. There is a relationship between dose and duration of therapy and gestational age. Ductal constriction is seen less commonly below 32 weeks and rarely below 28 weeks. Long-term indometacin therapy, particularly after 32 weeks, is therefore associated with a significant risk of persistent pulmonary hypertension. More detailed ultrasound studies have shown that administration of indometacin is associated with a rapid reduction in hourly fetal urine production but that oligohydramnios may develop more slowly and become significant at between 15 and 28 days.

There are two major isoforms of the cyclooxygenase enzyme, COX1 and COX2. COX1 is constitutively expressed in the majority of cells whereas COX2 is inducible and catalyses the synthesis of prostaglandins at the sites of inflammation. Since it is probable that it is COX1 whose function is important for fetal renal function and ductal patency, it was hoped that the use of NSAIDs selective or specific for COX2 might be associated with a lower risk of fetal side effects. However, nimesulide, which is approximately 100-fold more effective in inhibition of COX2 than COX1, is associated with an incidence of fetal oligohydramnios similar to that seen in fetuses exposed to indometacin and there have been isolated case reports of fatal fetal renal failure. Prophylactic use of the COX2-specific rofecoxib, although associated with weaker effects on both fetal renal function and the ductus arteriosus than indometacin or nimesulide, is associated with an increased rate of preterm delivery. The reasons for this are unclear but probably represent an effect on anti-inflammatory as well as proinflammatory prostaglandins [19].

At present therefore there is no good evidence that NSAIDs confer benefit when used as prophylaxis for preterm labour. They are associated with a significant risk of potentially life-threatening side effects. If NSAIDs such as indometacin are to be used, perhaps as short-term therapies in association with cervical cerclage, and particularly for more than a few days after 28 weeks, then it is essential that there should be ultrasound surveillance of fetal urine production or amniotic fluid index and of the ductus arteriosus and that therapy should be stopped when fetal side effects become evident.

Progesterone

Progesterone is probably the most widely used intervention to prevent preterm labour worldwide. Currently, two different progestin preparations are in common use. The synthetic 17α-hydroxyprogesterone caproate, which is chemically similar to testosterone and is not a natural progesterone metabolite, has been shown to reduce the risk of preterm birth in women at high risk based on past history but who do not have a short cervix. Current evidence suggests that 17α-hydroxyprogesterone caproate is not effective in the group of women whose risk of preterm birth is predicted by a short cervix, nor is it effective in women at risk of preterm birth because of multiple pregnancy.

The mechanism of action of 17α-hydroxyprogesterone caproate is unclear. Concentrations of progesterone in the circulation during normal pregnancy are substantially above the K_d for the progesterone receptor. As discussed, unlike in other species, in the human progesterone concentrations in the circulation do not fall at the time of either term or preterm labour. There is no evidence for lower progesterone concentrations either in the circulation or in tissues in women at risk of preterm birth. The relative binding affinity of 17α-hydroxyprogesterone caproate for nuclear progesterone receptors is only about 30% that of natural progesterone. 17α-hydroxyprogesterone caproate does not inhibit myometrial contractions *in vitro*.

Several large randomized trials in multiple gestations have identified harm related to exposure to 17α-hydroxyprogesterone caproate, and the synthetic drug is therefore contraindicated in this population. In addition, 17α-hydroxyprogesterone caproate is given as a weekly intramuscular injection, which itself is very painful and therefore patient compliance may not be good. For these reasons 17α-hydroxyprogesterone caproate has not found great popularity outside the USA.

Probably the most widely used progesterone for prevention of preterm birth is natural progesterone administered as a vaginal pessary. Vaginal progesterone appears to be principally effective in patients identified as at risk of preterm labour because of a short cervix. It is not effective in women at risk who have a normal cervical

length, nor has it been proven to be of benefit in multiple pregnancy, although there is some evidence that it may be beneficial in women with twins who also have a short cervix. Unlike 17α-hydroxyprogesterone caproate, natural progesterone has not been associated with any harm to either mother or fetus.

Both an individual patient data meta-analysis of five randomized controlled trials and a systematic review of 36 randomized controlled trials support the use of vaginal progesterone to reduce preterm birth in women with singleton pregnancies at risk of preterm birth associated with a short cervix. The results of both systematic reviews are mainly driven by the 2011 international PREGNANT trial, a randomized controlled trial in which pregnant women at low risk for preterm birth were screened for cervical length with transvaginal ultrasound and progesterone given if the cervix measured 10–20 mm [20]. Overall, the study showed a clear benefit for progesterone in reducing risk of preterm birth in this group, although the trial also showed substantial heterogeneity across study sites. Progesterone appeared to be highly effective in several studies outside the USA, but to have no significant effect on preterm birth rates in US populations. Vaginal progesterone was declined FDA approval for use in the USA partly because of a lack of significant effect on preterm birth rates in the US study centres. The largest randomized controlled trial of vaginal progesterone, OPPTIMUM, was undertaken in the UK and published in 2016 [21,22]. This included women at risk of preterm birth for a variety of reasons and was powered to include three primary outcomes: preterm birth, a composite of neonatal death or severe morbidity, or childhood neurodevelopment. It showed that vaginal progesterone did not reduce any of the primary outcomes but that there was no harm associated with progesterone use. The study did show a non-statistically significant reduction in the risk of preterm birth in women randomized to progesterone because of a short cervix and has been criticized because of a lower compliance rate than seen in other studies, and because the study was not powered to specifically study the patient with a short cervix. A meta-analysis performed after publication of OPPTIMUM continues to show a significant benefit of vaginal progesterone in women with a short cervix.

The potential mechanism of action of natural progesterone is also unclear. The concentrations of progesterone in the circulation during normal pregnancy are substantially above the K_d for the nuclear progesterone receptor. There is no evidence for lower progesterone concentrations in the circulation of women at risk of preterm birth, and administration of vaginal progesterone to women at risk does not elevate circulating progesterone concentrations. It seems likely that the mechanism of action of natural progesterone is local rather than systemic, and it is possible that it may act both through the parent hormone and through metabolites. Progesterone may act to increase the volume and quality of cervical mucus, hence improving physical and biochemical barriers to ascending infection. One widely excepted hypothesis is that progesterone may act as an anti-inflammatory. In cell culture model studies, progesterone inhibits cytokine- or lipopolysaccharide-stimulated activation of inflammatory transcription factors, prostaglandin synthetic enzymes, and the synthesis of prostaglandins and cytokines. However, clinical studies have shown that progesterone does not inhibit cervical–vaginal inflammatory mediators, nor does it have any effect on the vaginal microbiota.

Summary box 28.5

- Current evidence shows that cervical cerclage is not beneficial in women whose only risk of preterm birth is a short cervix in the late second trimester.
- There is good evidence that women with a history of spontaneous second-trimester loss or preterm delivery who have cervical shortening will benefit from ultrasound-indicated cerclage.
- A cervical cerclage should be placed as near to the internal as as possible.
- Vaginally administered progesterone does not reduce the risk of preterm birth in women at risk because of their past history who have a normal cervical length. It may reduce the risk in women with a short cervix in the second trimester.

Preterm pre-labour rupture of membranes

Preterm pre-labour rupture of membranes (PPROM) occurs in approximately 2% of all pregnancies and accounts for up to one-third of preterm deliveries. The most frequent consequence of PPROM is preterm delivery, with some 50% of cases delivering within a week, 75% within 2 weeks and 85% within a month. There is an inverse relationship between gestational age and latency, with a shorter interval between membrane rupture and preterm labour at later gestational ages. As with preterm labour, postnatal survival following PPROM is directly related to gestational age at delivery and birthweight. However, there is the additional complication that where PPROM occurs prior to 23 weeks' gestation there may be neonatal pulmonary hyperplasia leading to an increased risk of neonatal death, even if delivery occurs at gestational ages at which the outcome would usually be good.

The risk of pulmonary hyperplasia following PPROM is approximately 50% at 19 weeks falling to about 10% at 25 weeks. The retention of amniotic fluid within the uterus is associated with better outcome. A pool of amniotic fluid greater than 2 cm is associated with a low incidence of pulmonary hypoplasia.

Although many women with preterm rupture of the fetal membranes go into labour fairly quickly thereafter, those women who do not establish in preterm labour shortly after PPROM are at risk of chorioamnionitis. This may represent infection ascending into the uterine cavity, although in some cases PPROM may follow established chorioamnionitis. In either case such infection can be harmful and potentially fatal to both mother and baby and so PPROM requires careful clinical monitoring to allow early detection and treatment of *in utero* infection and chorioamnionitis.

Accurate diagnosis of PPROM is therefore important. This may be based on history, identification of a pool of liquor in the vagina and of oligohydramnios on ultrasound. Biochemical tests of PPROM are available that depend on detection of nitrazine (pH), placental α-microglobulin (PAMG)-1 or insulin-like growth factor binding protein (IGFBP)-1 in vaginal fluid. Nitrazine (pH) testing does not appear to be useful in diagnosis of PPROM, having a clinically useless positive predictive value. Tests for PAMG-1 or IGFBP-1 have clinically useful positive predictive values and so could be used where clinical assessment of PPROM is equivocal but if clear pooling of amniotic fluid is seen are probably unnecessary.

Once PPROM has been confirmed the management is a balance between the risks of prematurity if delivery is encouraged versus the risks of maternal and fetal infection if there is conservative management. It is important to recognize, especially in the context of PPROM, that increasing gestational age at delivery by increasing the latency period is not necessarily associated with improvements in neonatal and childhood outcomes. The links between chorioamnionitis, and particularly funisitis, and lung disease and cerebral palsy imply that to deliberately retain the fetus in an adverse uterine environment could potentially worsen early neonatal outcomes and thus the risk of cerebral palsy.

The ORACLE II study [23] from 2001 showed that prophylactic use of erythromycin improves neonatal morbidity, reduces the risk of sepsis and is associated with a longer latency period, whereas co-amoxiclav increases the risk of necrotizing enterocolitis and should therefore be avoided. Antibiotics of any type, given prophylactically, do not reduce the incidence of perinatal death or neonatal encephalopathy and do not affect the rates of maternal sepsis or maternal death. These findings have been confirmed by meta-analysis of subsequent studies [24,25]. Follow-up of the babies in the ORACLE I study showed no differences in serious childhood morbidity at 7 years, and in particular no differences in cerebral palsy rates between babies whose mothers were or were not given antibiotics following PPROM. Erythromycin has a number of potential advantages over other antibiotics in PPROM. It can be administered orally and is effective against group B *Streptococcus*, other streptococcal and staphylococcal infections and *Mycoplasma*, all of which may be implicated in chorioamnionitis. Its use is therefore currently recommended in the UK as prophylaxis for up to 10 days following a diagnosis of PPROM. However, this is not based on any stratification of the causes of PPROM. Recent studies have demonstrated that there is a more complex relationship between the vaginal microbiota, PPROM and erythromycin. In cases where the vaginal microbiota is largely *Lactobacillus* dominated, erythromycin may lead to the elimination of potentially protective *Lactobacillus* and allow a dysbiotic BV-like microbiota to become established. A dysbiotic vaginal microbiota correlates with the development of chorioamnionitis and funisitis and is therefore a risk factor for later neurodevelopmental problems. It is probable that the role of erythromycin will need to be re-evaluated when diagnostic tools to assess the vaginal microbiota within clinically useful time scales become available.

Management of PPROM continues to be controversial. There is currently no consensus on how to manage women whose membranes rupture between 34 and 37 weeks' gestation. Most obstetricians will institute conservative management in uncomplicated PPROM before 34 weeks and many would induce labour relatively early in women whose membrane rupture occurs subsequent to 37 weeks. In any woman labour should be induced if there is good evidence of infection, although making a diagnosis of chorioamnionitis may be challenging (discussed below).

A large randomized controlled trial from the Netherlands, PRROMEXIL (PPROM Expectant Management versus Induction of Labor) published in 2012 compared immediate induction of labour or expectant management in women with PPROM between 34 and 37 weeks' gestation [26]. This found that the risk of chorioamnionitis was slightly reduced in the induction of labour group compared with the expectant management group but there were no differences in rates of neonatal sepsis, RDS or caesarean section. Because fewer babies than expected born to the women in the expectant management group developed neonatal sepsis, the trial was underpowered for this outcome; however, a subsequent meta-analysis of eight trials confirmed all

these findings. In 2016, the PPROMT trial, a multicentre randomized controlled trial performed at 65 centres across 11 countries, showed that expectant management does not increase the risk of neonatal sepsis whilst early delivery was associated with increased risk of RDS [27]. Mothers in the expectant management group were more likely to have evidence of sepsis at the time of delivery, but less likely to require caesarean section. From these studies it is reasonable to conclude that, in the absence of signs of infection or fetal compromise, a policy of expectant management with appropriate surveillance of maternal and fetal well-being should be followed in pregnant women who present with PPROM up to 37 weeks. It is probably the case that the later the PPROM, the lower should be the index of suspicion for chorioamnionitis leading to induction of labour.

Lower genital tract swabs are routinely taken in women with PPROM. Positive cultures for potential pathogens do not correlate well with the risk, or development, of chorioamnionitis; however, they are useful in determining the causative organisms once chorioamnionitis develops and in directing antibiotic therapy for both the mother and the preterm neonate. Conservative management should include clinical surveillance for signs of chorioamnionitis, including regular recording of maternal temperature and maternal and fetal heart rate. The roles of white cell count (WCC) and C-reactive protein (CRP) are frequently misunderstood. Neither WCC or CRP are highly specific for chorioamnionitis. There is wide overlap, at the lower ends of the value ranges, between cases with and without histologically proven chorioamnionitis. Chorioamnionitis is often associated with a 'normal' WCC or CRP value. WCC may be normally elevated in pregnancy, will rise in response to antenatal corticosteroid therapy and has a relatively narrow range, rarely being less than 10×10^6/L and rarely exceeding 20×10^6/L,whether there is chorioamnionitis or not. CRP is a better indicator of chorioamnionitis, but is not good for screening for the development of chorioamnionitis because of its low specificity at the cut-off values needed to give high sensitivity, and its inability to 'predict' chorioamnionitis (in other words CRP remains low until chorioamnionitis actually develops) [28]. Most studies have used CRP cut-off values of 5, 12 or 20 mg/L. Where low cut-off values are used the sensitivity improves (i.e. most true cases of chorioamnionitis are correctly identified) but this is at the expense of specificity (i.e. many women who test positive do not in fact have chorioamnionitis). As cut-off values are increased the number of false positives is reduced but at the expense of failing to identify many genuine cases of chorioamnionitis. When upper limits of CRP are set at 30, 35 or 40 mg/L, the last CRP before delivery is 90, 95 and 100% specific for chorioamnionitis. Therefore whilst a low CRP value is not reassuring, a high value (>50 mg/mL) has a very high association with chorioamnionitis, particularly if it has risen rapidly. Chorioamnionitis should therefore be strongly suspected if there is clinical evidence (tenderness, pyrexia, maternal and/or fetal tachycardia), if there is a rapid rise in CRP values, or if a single CRP value is very high in the absence of any other clinical explanation such as pneumonia, pyelonephritis, deep vein thrombosis or pulmonary embolism. The absence of fetal movements or fetal breathing movements is also an adverse sign.

The use of ultrasound measurement of cervical length in women with PPROM is uncertain. Some studies have shown that cervical length is predictive of latency, others have not. Ultrasound assessment is probably preferable to digital assessment since it appears to be associated with little risk of the introduction of infection. However, at present the technique is not generally used in the management of PPROM.

The current evidence is that tocolytic therapy for women with preterm contractions following PPROM leads to an increase in maternal chorioamnionitis without significant benefits to the infant. The potential benefits of tocolytic drugs do not apply in the majority of cases of PPROM since there is usually time for administration of corticosteroids and *in utero* transfer before the onset of preterm labour itself. The dilemma about when to induce labour in cases of PPROM often does not materialize since 50% of women being managed conservatively will deliver within 7 days. The development of chorioamnionitis will stimulate the mechanisms leading to the onset of labour. Labour itself is therefore a marker of potential chorioamnionitis and so should not be inhibited.

Summary box 28.6

- PPROM occurs in 2% of all pregnancies and accounts for up to one-third of preterm deliveries.
- Preterm delivery follows PPROM within a week in 50% of cases.
- Management of PPROM is a balance between the risks of prematurity and the risks of maternal and fetal infection.
- Increasing gestational age at delivery by increasing the latency period is not necessarily associated with improvements in neonatal and childhood outcomes in the context of chorioamnionitis.
- In the absence of chorioamnionitis, current evidence supports conservative management up to 37 weeks.

Management of symptomatic preterm labour

Prediction of delivery risk in symptomatic preterm labour

Of women who present to hospital with preterm contractions and are thought to be in threatened preterm labour, over 70% will remain pregnant for the following 14 days or more. As discussed in more detail later, there is little evidence to suggest that use of tocolytics, namely drugs intended to suppress uterine contractions, confer any significant benefit in cases of preterm labour. The improvement in neonatal morbidity and mortality seen with advancing gestational age is often used as an argument for the potential benefit of delaying preterm labour using tocolytic agents. However, there is no evidence that tocolytic drugs confer this benefit and there is a real risk that to deliberately prolong a pregnancy, particularly in the context of chorioamnionitis, might lead to harm through retaining the fetus in an adverse intrauterine environment.

There are clear benefits to the timely administration of magnesium sulfate ($MgSO_4$) and corticosteroids to reduce the risk of neonatal morbidity (see below), and to *in utero* transfer to a perinatal centre with suitable neonatal intensive care facilities. Inappropriate administration of multiple courses of corticosteroids is associated with harm to the fetus, whilst unnecessary *in utero* transfer is expensive and blocks both obstetric beds and neonatology intensive care cots, to the detriment of other mothers and babies who might benefit from transfer. There is therefore a clear need for predictive tests that can determine which women who present with preterm contractions are genuinely at risk of delivery within the next 7 days and which are not. As with prediction in asymptomatic women, at present the two modalities in common use are transvaginal measurement of cervical length and fetal fibronectin concentrations in the vaginal fluid.

Ultrasound measurement of cervical length

The use of ultrasound measurement of cervical length in women symptomatic of threatened preterm labour varies geographically. In the USA almost all obstetric residents are skilled in ultrasound measurement of cervical length and suitable ultrasound machines are available in the delivery suites. In the UK and most of the rest of world, most delivery suites do not have ultrasound machines equipped with suitable transvaginal probes, and most obstetric registrars do not have the necessary skills. Studies have used various cervical length cut-off values to define risk, commonly 15, 20 or 25 mm. The negative predictive value is generally stable at each defined length whilst the positive predictive value improves at 15 mm. A cervical length of 15 mm, in a woman symptomatic of preterm labour, has positive predictive values of 28 and 44% for delivery within 48 hours or 7 days with negative predictive values of 97 and 94%, respectively. A cervical length of 15 mm could therefore be reasonably used as a cut-off value at which to offer corticosteroids and *in utero* transfer. Studies in the USA have shown that using this strategy no babies in the group considered to be at low risk of preterm birth are born prematurely without a full course of antenatal corticosteroid therapy, and overall babies in this group had significantly lower rates of exposure to steroids and tocolytics.

Biomarkers: fetal fibronectin, phosphorylated IGFBP-1 and PAMG-1

In the UK, the lack of availability of transvaginal ultrasound machines on labour wards and of an appropriately qualified or experienced clinician to perform the ultrasound, together with the ready availability of bedside testing, means that vaginal biomarker testing is probably the optimal diagnostic test at present. Of the three available methods, detection of fetal fibronectin is the most studied and probably most widely used test (Table 28.2). When first introduced these tests were established as being 'test positive' at a concentration that conferred a high negative predictive value at the expense of the positive predictive value. In other words, if the test was 'negative' the risk of preterm delivery within the next 48 hours or 7–14 days was sufficiently low that in most cases it would be reasonable to withhold steroids or *in utero* transfer. The commonly used 'qualitative' fetal fibronectin test uses a 'test-positive' cut-off of 50 ng/mL. Here, a positive fibronectin test in a symptomatic woman predicts a risk of preterm delivery within the next 7 days of approximately 40%, but a negative fetal fibronectin test reduces the risk to less than 1%. Quantitative fetal fibronectin testing has now become available and this has improved the test. Test results can now be interpreted either by using a range of different cut-off values or by direct interpretation of the quantified results. So, for example, as screen-positive cut-off values are increased from the original 50 ng/mL to 200 and 500 ng/mL, the positive predictive value for delivery within 14 days increases from 20% to 37% and 46%, respectively, whilst the negative predictive value only decreases from 98% to 97% and 96%. Using a lower cut-off of 10 ng/mL decreases the positive predictive value to 10% with no effect on the negative predictive value.

It is possible to combine the results of transvaginal measurement of cervical length and vaginal fluid fibronectin concentrations to improve risk stratification, provided that facilities for both tests are available. It is essential that the fibronectin test be performed before transvaginal ultrasound examination. Most studies have

Table 28.2 Performance of quantitative fetal fibronectin test in predicting preterm birth in symptomatic women.

Fetal fibronectin concentration (ng/mL)	No. of subjects	Delivery within 7 days (%)	Delivery within 14 days (%)	Delivery by 34 weeks (%)
<10	170 (57%)	1	1.8	1.5
10–49	62 (21%)	0	1.6	8.2
50–199	41 (14%)	0	7.7	11.5
200–499	14 (5%)	14	29	33
>499	13 (4%)	38	46	75

combined measures of cervical length with catagoric fibronectin results based on a cut-off of 50 ng/mL and have demonstrated higher sensitivity and positive predictive value while maintaining high negative predictive value. Where qualitative fibronectin testing is used, it appears that a high fibronectin concentration has a better predictive value than a short cervical length alone. So, for example, a women with a cervical length below 10 mm but a fibronectin concentration of 10 ng/mL has a very low risk of delivery within 7 days, whereas a woman with a cervical length of 30 mm but a fibronectin concentration above 500 ng/mL is at very high risk. However, either of these two scenarios is likely to be quite rare. The improved predictive value of quantitative fibronectin compared with cervical length is probably a reflection of where on the biochemical pathway to preterm labour the individual woman is. In most cases cervical shortening will precede release of fibronectin into vaginal fluid by several weeks. Fibronectin testing is therefore most useful in identifying the woman at imminent risk of preterm delivery. Measurement of cervical length is probably of better value in identifying women whose risk is more remote. Some studies of interventions to prevent preterm birth which have recruited patients based on fibronectin positivity have been, probably justifiably, criticized for enrolling patients who are too late in the processes of parturition to be helped by the intervention. The development of computed algorithms (e.g. QUIPP, Apple Store) is now allowing fetal fibronetcin concentrations to be interpreted as a continuous variable and to provide individualized risk assessment taking into account the patient's history and cervical length measurements if available.

Acute tocolysis [29]

Sympathomimetics

The maximum benefit to the preterm neonate from antenatal corticosteroid administration is from 24 hours to 7 days after the first dose of the course. *In utero* transfer has also been shown to improve neonatal morbidity and mortality and clearly time would be required to move a mother in preterm labour from one hospital to another. Suppression of uterine contractions has therefore been seen as an obvious solution to the problem of preterm labour. The use of tocolytic drugs intended to inhibit uterine contractions began with the introduction of alcohol and then beta-sympathomimetics into obstetric practice in the 1970s. Early clinical trials suggested that beta-sympathomimetics had great efficacy in inhibiting preterm contractions; there was widespread advertising by the manufacturers and most obstetricians developed the impression that tocolysis (specifically with beta-sympathomimetic drugs such as ritodrine and salbutamol) was an effective therapy for acute preterm labour. This impression was strengthened because of the very high placebo response rate, which implied mistakenly that the drug was being effective. More modern studies have shown that ritodrine will delay preterm delivery in a minority of patients for 24 and 48 hours but that its use is not associated with any improvement in any marker of neonatal morbidity or in neonatal mortality rates. Ritodrine and salbutamol are associated with significant, potentially life-threatening maternal side effects (particularly if given in combination with corticosteroids) that include fluid overload, pulmonary oedema, myocardial ischaemia, hyperglycaemia and hypocalcaemia. Numerous maternal deaths have been reported in which tocolysis using beta-sympathomimetic drugs has played a role. Beta-sympathomimetics as tocolytics are therefore now rarely used in the context of preterm labour, since safer, though not necessarily more efficacious, tocolytic drugs are now available, and their use should probably be completely abandoned. Beta-sympathomimetics continue to have a role in the suppression of excessively frequent or strong contractions stimulated by prostaglandins in the context of induction of labour at term, where short-term use poses few risks.

Non-steroidal anti-inflammatory drugs

The NSAID most widely studied as an acute tocolytic is indometacin. Earlier relatively small randomized placebo-controlled studies suggested that indometacin may delay preterm delivery in the short term but the total number of women enrolled in these trials was small. As discussed in previous sections, indometacin has a major effect on fetal renal function and on the fetal cardiovascular system, in particular on the fetal ductus arteriosus. Use of indometacin for tocolysis has also been associated with higher incidences of necrotizing enterocolitis, intraventricular haemorrhage and abnormalities in neonatal haemostasis. A series of later studies have all generally been small and of low overall quality. In some network meta-analyses and indirect comparisons indometacin has appeared to have some benefit in postponement of birth compared with placebo and beta-mimetics and in maternal adverse effects compared with beta-mimetics and $MgSO_4$. However, these types of indirect comparisons (e.g. where indometacin is compared with salbutamol, salbutamol is compared with $MgSO_4$ and therefore indometacin can be indirectly compared with $MgSO_4$) are heavily affected by the entry criteria and high placebo response rates in the original studies. There is a lack of longer-term childhood outcomes, limitations of small numbers, and minimal data on safety. At present there is no evidence that indometacin or any other NSAID has any advantage as a first-line tocolytic over calcium channel blockers or oxytocin antagonists, each of which has a much better maternal and fetal side-effect profile.

Oxytocin antagonists

Although there is no good evidence for an increase in circulating concentrations of oxytocin in either term or preterm labour, both term and preterm labour are associated with an increase in the expression of the oxytocin receptor in the myometrium and oxytocin is synthesized within the uterus itself, in the myometrium and the decidua. This has led to the exploration of drugs which antagonize the oxytocin receptor as tocolytics. At present no specific oxytocin antagonists are available for clinical use, although atosiban, a mixed arginine vasopressin (AVP) and oxytocin receptor antagonist, has a European Medicines Agency licence for the treatment of preterm labour. Atosiban has been the subject of both placebo comparison trials and comparisons with beta-sympathomimetic drugs. The 2000 placebo-controlled trial undertaken in the USA [30] was, to a certain extent, flawed in that randomization at early gestational ages was skewed, resulting in an increase in neonatal deaths amongst very preterm babies whose mothers were treated with atosiban when compared with placebo (Figure 28.7). Atosiban crosses the placenta, but the drug does not accumulate in the fetus with longer infusion rates. Despite its action at the AVP receptor, atosiban does not affect maternal or fetal cardiovascular parameters or fetal oxygenation. The majority of the infant deaths associated with exposure to atosiban were newborns with birthweights below 650 g, suggesting that extreme prematurity not an effect of atosiban was the cause.

The primary outcome of the placebo-controlled trial (i.e. the time between the initiation of treatment and therapeutic failure, defined as either preterm delivery or need for an alternate tocolytic) showed that atosiban was no different to placebo. For this reason, and because of failure to show overall morbidity or mortality benefit, an FDA licence was denied. There were statistically significant differences in the number of women who remained undelivered and did not require an alternative tocolytic at the specific 24- and 48-hour and 7-day time points, although this applied only in women who were beyond 28 weeks' gestation. As with all previous trials of tocolytic drugs, this trial was complicated by a very high placebo response rate. Analysis of the data shows that, for example, at 48 hours post randomization, although 70% of women randomized to receive atosiban appeared to respond to it, in reality the majority of these represented placebo responders. It can be calculated that only 11% had a genuine clinical response. This represents one-quarter of those women who were genuinely in preterm labour and had potential for a genuine clinical response.

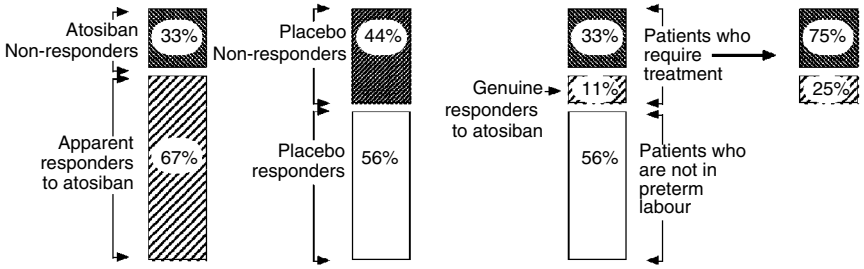

Fig. 28.7 Analysis of the 48-hour outcome data from the placebo-controlled trial of atosiban. Of all patients allocated to atosiban treatment, only 11% showed a genuine clinical response (rather than a placebo response) which represents one-quarter of those with the potential to benefit. This effect applied only in women at 28 weeks' gestational age or greater. *Source:* Romero *et al.* [30].

The trials comparing atosiban with beta-sympathomimetic drugs showed that atosiban was clinically of equal efficacy to beta-sympathomimetics but with a dramatically improved maternal side-effect profile. However, the clinical response rate to either atosiban or beta-sympathomimetic drugs in these trials was so high (>90%) that it is probable that the majority of patients enrolled in the study were not genuinely in preterm labour. Neither the placebo-controlled trial nor the beta-sympathomimetic comparison trials demonstrated any improvement in any aspect of neonatal morbidity or neonatal mortality associated with the use of atosiban.

More recently, it has been found that oxytocin mediates at least two pathways through its receptor, one to stimulate contractions, the other to activate inflammatory pathways and to increase prostaglandin and cytokine synthesis. Atosiban acts as an inhibitor of contractions but as a partial activator of inflammation. A proinflammatory action in a tocolytic is not ideal and may explain the limited efficacy of atosiban. At present, second-generation oxytocin receptor antagonists are in development that are specific to the oxytocin receptor and which do not activate inflammation.

Calcium channel blockers

The central role of calcium in the biochemistry of myometrial contractions led to the exploration of the use of calcium channel blockers, specifically nifedipine, as a tocolytic drug. Because there has been no interest from the pharmaceutical industry in promoting nifedipine for this indication, most of the randomized controlled studies have been comparison trials of nifedipine versus sympathomimetics and other tocolytics. Two small trials comparing nifedipine with placebo or no treatment showed a significant reduction in the risk of birth within 48 hours associated with an increase in maternal adverse effects.

The largest number of trials compare nifedipine with beta-mimetics. Meta-analysis of these trials shows that there were fewer maternal adverse effects, an increase in the interval between trial entry and birth, and a decrease in rates of preterm and very preterm birth, RDS, necrotizing enterocolitis, intraventricular haemorrhage, neonatal jaundice and admissions to neonatal intensive care unit.

There have been three small and one substantial (APOSTEL III) randomized trials comparing nifedipine with atosiban. The three small trials showed contradictory results. Unlike earlier trials of tocolytic agents, APOSTEL III took advantage of cervical length and fibronectin to better define a population in threatened preterm labour. The study showed that tocolysis for 48 hours with nifedipine or atosiban resulted in similar prolongation of pregnancy and perinatal outcome rates. Discontinuation of either nifedipine or atosiban because of side effects was rare, but rates of discontinuation were no different between the two drugs.

At present, the obstetrician (other than in the USA where $MgSO_4$ is still used for its tocolytic action despite evidence that it is ineffecive) has a choice between atosiban or nifedipine and it is probably reasonable, in our current state of knowledge, not to use tocolytic therapy at all. More specific oxytocin antagonists are in development, as are drugs which target other receptors, such as prostaglandin receptors. It is probable that the disappointing results of tocolytics in most trials to date is because of poor trial design and, in particular, the high placebo response rates when contractions alone have been used to diagnose preterm labour. In future trials which are able to target tocolytic drugs more specifically at women genuinely in preterm labour, for example by taking advantage of cervical length measurement or fetal fibronectin testing, may more properly define the potential value of tocolytic therapy.

Antenatal corticosteroid therapy

The potential for antenatally administered corticosteroids to accelerate lung maturity was discovered by Professor Sir Graham ('Mont') Liggins in experiments in which sheep were induced into preterm labour by injection of corticosteroids. Unlike preterm sheep delivered by caesarean section, the sheep in these experiments did not develop fatal RDS. A large number of (human) randomized trials took place during the 1970s and 1980s which, taken together, have shown that a single course of either betamethasone or dexamethasone administered to pregnant women between 24 and 34 weeks' gestation who are at risk of preterm delivery within 7 days has a beneficial significant effect on neonatal morbidity and mortality. Although the paediatric use of surfactant has had a major impact on the incidence and consequence of RDS, nevertheless antenatal corticosteroid therapy is still associated with a reduction in neonatal mortality, principally due to a significant reduction in rates of RDS and intraventricular haemorrhage. Antenatal corticosteroids have a receptor-mediated effect on all the components of the surfactant system in type 2 pneumocytes. They also have effects on the structural development of the lungs, lead to accelerated maturation of the fetal intestine and have effects on the myocardium and on catecholamine responsiveness, which may explain the reduced incidence of necrotizing entocolitis and intraventricular haemorrhage seen in extremely preterm infants that appear to be independent of the effect on RDS (Table 28.3).

Women who are considered to be at risk of preterm delivery at between 24 and 35 weeks of gestation should

Table 28.3 Effects of antenatal corticosteroids on neonatal outcomes (World Health Organization analysis).

Interval	Death	RDS	CV haemorrhage

be targeted for a single course of antenatal corticosteroids. Antenatal corticosteroids should also be considered for women from 23 weeks onwards, based on estimated fetal weight and parental wishes. Whilst antenatal corticosteroids are most effective in reducing RDS in pregnancies that deliver from 24 hours and up to 7 days after administration of the second dose of antenatal corticosteroids, there is an effect on neonatal death rates even if delivery is within the first 24 hours so steroid should still be given even if delivery is expected in less than 24 hours.

A single course of corticosteroids does not appear to be associated with any short-term maternal or fetal adverse effects, with the exception of the destabilization of blood sugar control in diabetics or impaired glucose tolerance in pregnancy. Diabetes mellitus should not be considered a contraindication to antenatal corticosteroid treatment for fetal lung maturation, particularly because RDS is more common in the babies of diabetic mothers. Women with impaired glucose tolerance or diabetes who are receiving steroids should have additional insulin according to an agreed protocol and be closely monitored.

The dramatic effects of a single course of corticosteroids unfortunately led to the routine prescription of multiple courses of steroids, often at weekly intervals, in women deemed to be at risk of preterm delivery, especially those with multiple pregnancies. Concerns about the long-term consequences of recurrent exposure to high-dose steroids, namely the adverse effects on development and behaviour, has generally led to an abandonment of this policy. Although one or more repeat courses of corticosteroids is associated with reduced severe lung disease and serious infant morbidity, repeated courses of steroid are associated with an increased risk of intrauterine growth restriction. The challenge for the obstetrician is therefore to use a combination of the clinical history, markers of infection or inflammation, the results of cervical length measurements and fetal fibronectin or other biomarkers to refine the estimate of risk of preterm delivery in any individual woman to correctly target a course of corticosteroids prior to delivery, and to reduce the number of repeat courses ideally to one or none.

Both dexamethasone and betamethasone have been explored in randomized trials, with each having similar effects on RDS rates. Studies in France suggested that betamethasone reduced the incidence of periventricular leucomalacia whereas dexamethasone had no such protective effect; however, this may be explained by the presence of sulfating agents used as preservatives in French preparations of dexamethasone. A historical cohort study used multivariate logistic regression analysis to compare the two steroid-treated groups with each other, finding that the risk of neonatal death was lower with betamethasone than with dexamethasone. In other studies dexamethasone has been associated with a decreased incidence of intraventricular haemorrhage compared with betamethasone. At present, there is no clear evidence of benefit of dexamethasone over betamethasone or vice versa. Therefore either betamethasone 12 mg i.m. in two doses or dexamethasone 6 mg i.m. in four doses are the steroids of choice to enhance lung maturation.

Magnesium sulfate

Prior to the 1980s, $MgSO_4$ was widely used in the USA in the intrapartum management of pre-eclampsia and eclampsia and the clinical impression that $MgSO_4$ made induction of labour more difficult led to its evaluation as a tocolytic agent. With the withdrawal of beta-sympathomimetic drugs from the American market and the failure of atosiban to obtain FDA approval, there are no licensed tocolytic drugs available for the American obstetrician to use and $MgSO_4$ is therefore in common use. However, randomized placebo-controlled trials of $MgSO_4$ show no significant short-term delay of delivery, increase in birthweight or difference in perinatal mortality when compared with placebo. $MgSO_4$ is

ineffective at delaying birth or preventing preterm birth, and has no apparent advantages for neonatal and maternal outcomes when used as a tocolytic agent [31]. However, studies where $MgSO_4$ has been compared with sympathomimetics or indometacin have suggested equal efficacy. These two apparently contradictory findings can probably be explained by the lack of power of the studies to detect a significant difference between drugs with little or no efficacy but a high placebo response rate.

In the late 1990s it began to become apparent that infants born to mothers given $MgSO_4$ either to prevent eclampsia or for tocolysis appeared to have a reduced risk of cystic periventricular leucomalacia and cerebral palsy. Since that time a series of randomized controlled trials has been conducted which confirm that the risks of both cerebral palsy and substantial gross motor dysfunction are reduced in the infants of women given $MgSO_4$ just prior to preterm delivery [32]. The beneficial effects of $MgSO_4$ appear to be greatest in women at early gestations, particularly between 24 and 30 weeks. There is probably little or no effect in women beyond 34 weeks. Every effort should therefore be made to offer intravenous $MgSO_4$ to women at risk of preterm delivery before 30 weeks, and if possible to those up to 32 weeks.

The mechanism of action of $MgSO_4$ in the neonatal brain is not clearly established. It may act by blocking *N*-methyl-D-aspartate (NMDA) receptors which mediate glial injury processes in hypoxia–ischaemia. $MgSO_4$ may also act to block calcium influx into damaged cells, to inhibit vasoconstriction, to reduce cytokine-mediated cell damage, and to interact with a wide range of cellular functions through its complex with ATP. $MgSO_4$ has the advantage over corticosteroids of being effective when administered close to the time of preterm delivery. As with its use in the context of pre-eclampisa, $MgSO_4$ has the potential for toxicity in the mother, leading to nausea and vomiting, lethargy, cardiac dysrhythmia, hypotension, urine retention, and respiratory and cardiac arrest. It is therefore essential that the same safeguards are put in place when it is used for cerebral palsy prophylaxis.

The optimal dosing regimen for $MgSO_4$ has not been determined. Different studies have used different protocols, although these were commonly based on the protocols that would be used in pre-eclampsia, or where the drug is used as a tocolytic. A typical protocol would be a 4-g bolus followed by 1 g/hour i.v.

Antibiotics

Analysis of the use of antibiotics in symptomatic preterm labour with intact membranes in women with no clinically defined infection is dominated by the 2001 ORACLE I trial [33]. This showed that administration of antibiotics to women in spontaneous preterm labour with intact membranes does not delay delivery or improve any aspect of neonatal morbidity or mortality. The only short-term positive health benefit is a reduction in maternal infection rates. However, a follow-up study which examined the effect of antibiotics given during pregnancy to mothers in threatened preterm labour on childhood outcomes at 7 years showed an increase in the risk of cerebral palsy associated with antibiotic use. Surprisingly, this was principally in babies who were actually born at term. Taken together these data show that antibiotics should not be prescribed to women in uncomplicated preterm labour with no evidence of infection. However, it is important to emphasize that there are associations between preterm labour, chorioamnionitis, pneumonia, pyelonephritis and lower urinary tract infection. Care needs to be taken to exclude these diagnoses which do require antibiotic therapy to reduce the risk of complications of puerperal sepsis.

Summary box 28.7

- Of women who present to hospital with preterm contractions, 70% will remain pregnant for the next 14 days or more.
- Risk of preterm delivery in women with symptoms can be assessed using either fetal fibronectin or ultrasound measurement of cervical length, but low fibronectin concentration has a better negative predictive value.
- The is little evidence for the benefit of tocolysis.
- Tocolysis may have value in allowing *in utero* transfer and/or steroid therapy, but this is unproven.
- At present the obstetrician (other than in the USA where $MgSO_4$ is still used for its tocolytic action despite evidence that it is ineffecive) has a choice between atosiban or nifedipine. In our current state of knowledge, it is probably reasonable not to use tocolytic therapy at all.
- Women who are considered to be at risk of preterm delivery at 24–35 weeks of gestation should be targeted for a single course of antenatal corticosteroids.
- Every effort should be made to offer intravenous $MgSO_4$ to women at risk of preterm delivery before 30 weeks, and if possible to those up to 32 weeks.
- Antibiotics should not be prescribed to women in uncomplicated preterm labour with no evidence of infection.

Management of inevitable preterm delivery

Rates of neonatal morbidity and mortality are higher in babies transferred *ex utero* to neonatal intensive care units compared with those born in the tertiary referral

centre. Every effort should therefore be made to transfer a woman to an obstetric unit linked to a neonatal intensive care unit prior to a preterm delivery. The introduction of fetal fibronectin testing has reduced the numbers of unnecessary *in utero* transfers.

Cardiotocography monitoring

Except at the extremes of prematurity (perhaps below 26 weeks) there should be continuous electronic fetal heart rate monitoring once preterm labour is clearly established in most cases. The value of cardiotocography (CTG) in preterm labour is less well established than at term. Physiological control of fetal heart rate differs in the preterm fetus compared with the fetus at term, making CTG interpretation difficult. The fetal heart rate baseline is higher, averaging 155 bpm before 24 weeks compared with 140 bpm in a term fetus. Prematurity may normally be associated with a reduction in fetal heart rate baseline variability and be decreased secondary to the effect of fetal tachycardia but without significant hypoxia. The normal sleep–wake cycles seen at term may be absent or less common. Before 30 weeks the frequency and amplitude of accelerations are reduced, whereas fetal heart rate decelerations without contractions often occur in the healthy preterm fetus between 20 and 30 weeks' gestation. Fetal monitoring in labour should be individualized, taking into account the context of preterm delivery, gestational age and estimated fetal weight, the likelihood of chorioamnionitis and any other complications, the overall prognosis for the neonate, and the wishes of the parents. Modern ultrasound-based CTG machines have rendered the use of fetal scalp electrodes largely redundant but they should particularly be avoided in babies below 34 weeks' gestational age.

Vaginal or caesarean section delivery

There is no evidence of benefit for routine delivery by caesarean section where the presentation is cephalic. However, hypoxia is a major risk factor for the development of cerebral damage and there should therefore be a relatively low threshold for delivery by caesarean section in the presence of abnormal fetal heart rate patterns. Nevertheless, preterm labour is usually rapid. The fetal head will be small, and therefore there will be a complete absence of the relative cephalopelvic disproportion seen at term, meaning that there is no need for moulding of the fetal head. In many cases the cervix is already ripe and effaced before the onset of contractions.

The preterm delivery of a breech continues to be an obstetric dilemma. Although it is now established that elective caesarean section is preferable for the term breech, it has proved impossible to undertake randomized trials of caesarean section for the preterm breech. One potential disadvantage of planning to deliver the preterm breech (or indeed cephalic presentation preterm) by elective caesarean section is the high incidence of 'threatened' preterm labour which does not lead to preterm delivery. An aggressive policy of delivering preterm babies by caesarean section has the potential to lead to iatrogenic preterm deliveries. At the other end of the spectrum, caesarean section before term where the breech is already in the vagina may be more traumatic than a vaginal delivery. At present, until further evidence becomes available the mode of delivery of the preterm breech will need to be made on a case-by-case basis by the obstetrician at the time. There is no evidence of benefit from the old practice of elective forceps delivery to protect the fetal head during preterm delivery and episiotomy is rarely required. If instrumental delivery is required for the preterm infant below 34 weeks, ventouse should be avoided. It is usually easy to rotate a preterm fetal head to an occipito-anterior position manually, or it can be done using Kielland's forceps by those who still have the skill. There is now good evidence for the benefit of delayed cord clamping and in waiting at least 30 seconds but no longer than 3 min if the mother and baby are stable. If the preterm baby needs to be resuscitated or there is significant maternal bleeding, the umbilical cord can be briefly milked in the direction of the neonate and then clamped more quickly. If delivery by caesarean section is required, there may be a need to perform a classical caesarean section through a vertical incision in the uterus, particularly at very preterm gestational ages when the lower segment of the uterus is poorly formed. Occasionally, an incision initially made in the lower segment proves to be insufficient for delivery. In these cases the incision can be converted to a J-shaped incision. Particularly at the limits of viability, delivery should be performed has atraumatically as possible, ideally delivering the baby *en caul* in intact membranes. This greatly minimizes the risk of fetal trauma, and nautical folklore has it that a child born *en caul* will never drown at sea.

Summary box 28.8

- There is no evidence of benefit for routine delivery in preterm labour by caesarean section where the presentation is cephalic.
- Except at the extremes of prematurity, there should be continuous electronic fetal heart rate monitoring once preterm labour is clearly established.

Stillbirth

Bryony Jones[1,2]

[1] *Queen Charlotte's and Chelsea Hospital, Imperial College Healthcare NHS Trust, London, UK*
[2] *Imperial College London, London, UK*

Stillbirth is defined in the UK as the birth of a baby on or after 24 weeks of gestation who does not show any signs of life [1]. The definition recommended by the World Health Organization (WHO) for international comparison is a baby born with no signs of life at or after 28 weeks' gestation. [2] Stillbirth may be further divided into antepartum and intrapartum. In the UK, *antepartum stillbirth* is defined as the birth of baby on or after 24 weeks of gestational age, showing no signs of life and known to have died before the onset of labour. *Intrapartum stillbirth* is defined in the UK as a baby born at or after 24 weeks of gestational age, showing no signs of life and known to be alive at the onset of labour.

The incidence of stillbirth varies between countries but in the UK affects up to 1 in 200 pregnancies [3]. Despite the many advances in women's health over the past decades, there has been no significant change in the UK incidence of stillbirth, nor has the worldwide incidence of stillbirth changed [4]. The stillbirth rate does vary appreciably between regions. As no one factor leads to stillbirth, the stillbirth rate is considered to be a measure of the general health of women as well as the quality of the provision of antenatal and intrapartum care and as such it has been used as a regional comparator [5].

Stillbirth is a devastating pregnancy outcome. Each stillbirth is a tragedy and brings with it enormous distress and grief, not only for the parents and their extended family and friends but for all the health professionals who care for them. Late-gestation stillbirths are particularly poignant, particularly if not associated with a significant congenital abnormality and if delivery at an earlier gestation would not have been associated with a prohibitive infant mortality or morbidity.

Stillbirth rates

The UK rate of stillbirth is 4.16 per 1000 total births [6]. This mortality rate is higher than that reported by other high-income countries, where worldwide estimates show an average stillbirth rate (at 28 weeks' gestation) of 3.5 per 1000 births (Fig. 29.1). There are 2.6 million stillbirths globally, with more than 7178 deaths daily [2]. The majority of deaths occur in developing countries, with 98% occurring in low- and middle-income countries.

Significant regional differences in the stillbirth rate have been noted [7]. The variation in stillbirth rates may primarily reflect multicultural differences, with women in lower socioeconomic groups having twice the stillbirth risk compared with women from higher socioeconomic groups. Unfortunately, there are significant variations in data collection, definitions (especially gestational age cut-offs) and research methodology that make direct comparisons between countries difficult. Furthermore, variations in access to termination of pregnancy services impact on stillbirth rates that is difficult to account for. Regions with the highest stillbirth rates have some of the most significant limitations in data quality [8]. The number of stillbirths has reduced more slowly than has maternal mortality or mortality in children younger than 5 years, which were explicitly targeted in the Millennium Development Goals [9, 10].

The fact that regional and national differences in stillbirth rate exist and appear to be related to wider factors impacting on women's health suggests that reduction in the rate of stillbirth is possible and potentially a useful indicator of improving socioeconomic and healthcare systems. This is published as the annual rate of reduction,

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Classification of stillbirth by relevant condition at death (ReCoDe): population based cohort study. *BMJ* 2005;331:1113–1117. Reproduced with permission of the BMJ Publishing Group Ltd.

and allows comparison over time of the stillbirth rate within one region or country.

Classification of stillbirth

Broadly, stillbirths may be divided into those associated with intrapartum or antepartum death, with further stratification by gestational age. Globally, about half of all stillbirths occur in the intrapartum period, representing the greatest time of risk. The estimated proportion of stillbirths that are intrapartum varies from 10% in developed regions to 59% in South Asia [2,11].

The aetiology of stillbirth is multifactorial and despite intensive investigation of potential causes, many cases remain unexplained. Another complicating factor is that often more than one condition may contribute to stillbirth in an individual case (e.g. preterm rupture of membranes with infection in a fetus with polyhydramnios secondary to gastrointestinal obstruction). Additionally, conditions may be associated with stillbirth without directly causing them (well-controlled gestational diabetes and a cord event).

Several classification systems for causes of stillbirth have been developed. No single classification system is universally accepted as each has its own strengths and weaknesses. There are additional sources of confusion when considering the challenge of classification. First, the definition of stillbirth varies among investigators, countries, health organizations and classification schemes. Second, many systems are designed to classify perinatal mortality and therefore by definition include both stillbirths and neonatal deaths. It is likely that stillbirth and neonatal death have many similar, overlapping but distinct sets of disease states. However, aetiologies for neonatal death may not be relevant to intrauterine fetal demise, for example at 20 weeks of gestation. Additionally, classification systems can include a single aetiology, which is problematic given the complexity of stillbirth, and means that a single distinct cause cannot be attributed to the majority of cases.

A recent systematic review identified 81 systems for classification of causes of stillbirth [12]. Many of these different systems have been developed for different purposes, for example to attribute the most likely cause as part of counselling for grief and future pregnancies, or to assist clinicians in defining best practice, or to develop strategies for the prevention of

stillbirth through health service organizational changes. Consequently, the different classification systems prioritize information in different ways, which means they are not directly comparable.

There are national and international drivers to reduce the stillbirth rate. One of the key factors that has been highlighted is the importance for healthcare systems of understanding the changes and measures that need to take place to improve stillbirth rates, by studying attributable causes over time. To facilitate this, a uniform system of classification is required. The perfect system does not exist given the complexity of the aetiology of stillbirth. The UK has recently adopted the Frøen–Codac 2009 classification system [13] for use in national perinatal mortality surveillance. This classification system has been shown to record the primary cause of 46–47% of all stillbirths as 'unknown' [14, 15]. This system is designed to be applicable to high and low socioeconomic nations and involves detailed recording and sub-analysis.

Alternative classification systems include Wigglesworth [16] (66.2% of stillbirths remain unexplained) and relevant condition at death or ReCoDe [17] (Table 29.1). The latter classification mentions the coding of primary and secondary 'causes' of stillbirth, the goal being to identify the relevant conditions present at the time of death *in utero*. It is a hierarchical classification where the hierarchy starts from the conditions directly affecting the fetus and moves 'outward' in anatomical groups. These authors emphasize the important contribution of fetal growth restriction, with approximately 50% of stillbirths associated with fetal growth restriction. The ReCoDe classification may be able to assign a cause for 85% of cases of stillbirth.

Aetiology

Stillbirth has multiple associated maternal and fetal risk factors (Table 29.2). In two-thirds of pregnancies that result in stillbirth, more than one factor is known to be associated with stillbirth and so it is often unclear what the actual cause of death is.

Several risk factors for stillbirth are present prior to pregnancy, including parity, ethnicity, socioeconomic status and mental health problems. Interestingly, the risk for stillbirth and parity is bimodal, with both nulliparity and a parity of three or higher being risk factors for stillbirth. It is likely that the root cause of stillbirth with parity is different in the nulliparous and multiparous woman and that different strategies will be required to address them [18]. In the UK, mothers of African, African-Caribbean and South Asian ethnic origins have been shown to have a higher risk of stillbirth than women of Caucasian origin. First-generation migrants, regardless of ethnic origin, also have a higher risk of stillbirth than women born in and brought up in the UK. Maternal age appears to have a bimodal distribution, with pregnancies in women younger than 25 and older than 35 years of age being at greater risk for stillbirth.

Table 29.1 Classification system according to relevant condition at death (ReCoDe).

Group A: Fetus
1) Lethal congenital anomaly
2) Infection
   2.1) Chronic
   2.2) Acute
3) Non-immune hydrops
4) Isoimmunization
5) Fetomaternal haemorrhage
6) Twin-twin transfusion
7) Fetal growth restriction*

Group B: Umbilical cord
1) Prolapse
2) Constricting loop or knot†
3) Velamentous insertion
4) Other

Group C: Placenta
1) Abruptio
2) Praevia
3) Vasa praevia
4) Other 'placental insufficiency'‡
5) Other

Group D: Amniotic fluid
1) Chorioamnionitis
2) Oligohydramnios†
3) Polyhydramnios†
4) Other

Group E: Uterus
1) Rupture
2) Uterine anomalies
3) Other

Group F: Mother
1) Diabetes
2) Thyroid diseases
3) Essential hypertension
4) Hypertensive diseases in pregnancy
5) Lupus or antiphospholipid syndrome
6) Cholestasis
7) Drug misuse
8) Other

Group G: Intrapartum
1) Asphyxia
2) Birth trauma

Group H: Trauma
1) External
2) Iatrogenic

(*Continued*)

Table 29.1 (Continued)

Group I: Unclassified
1) No relevant condition identified
2) No information available

* <10th customized weight for gestational age centile.
† If severe enough to be considered relevant.
‡ Histological diagnosis.

Table 29.2 Conditions associated with stillbirth.

Infection
Severe maternal illness
Placental infection leading to hypoxaemia
Fetal infection leading to congenital deformity
Fetal infection leading to damage of a vital organ
Precipitating preterm labour with the fetus dying in labour
Maternal medical conditions
Hypertensive disorders
Diabetes mellitus
Thyroid disease
Renal disease
Liver disease
Connective tissue disease (systemic lupus erythematosus)
Cholestasis
Antiphospholipid syndrome
Heritable thrombophilias
Red cell alloimmunization
Platelet alloimmunization
Congenital anomaly and malformations
Chromosomal abnormalities including confined placental mosaicism
Fetomaternal haemorrhage
Fetal growth restriction
Placental abnormalities including vasa praevia and placental abruption
Umbilical cord pathology including velamentous insertion, prolapse, occlusion and entanglement
Multifetal gestation including twin–twin transfusion syndrome and twin reverse arterial perfusion
Amniotic band sequence
Central nervous system lesions

Executive summary of a National Institute of Child Health and Human Development Workshop. *Obstet Gynecol* 2009;114:901–914. Reproduced with permission of Wolters Kluwer Health, Inc.

One of the main risks for stillbirth is presumed placental dysfunction, which commonly results in impaired fetal growth [3] Very low birthweight (less than 3rd centile) is associated with a 10-fold increased risk of stillbirth [19]. Although placental dysfunction is not currently modifiable, recognition of the association between fetal growth rates and stillbirth allows risk stratification of pregnancies, with greater surveillance of pregnancies with intrauterine growth retardation and consideration of elective delivery timed to allow an appropriate balance between the risk of stillbirth and infant mortality [20].

Specific population attributable risk (PAR) factors for stillbirth have also been defined. The PAR factor score indicates the relative increase in risk of stillbirth associated with specific risk factors when applied to women in higher income countries. PAR factors are particularly important as many of them are potentially modifiable and the score indicates the increased risk of stillbirth related to the risk factor [10] (Fig. 29.1). Key risks include maternal infection, hypertension, diabetes mellitus, underlying chronic diseases as well as nutrition, obesity and smoking. Cigarette smoking is strongly associated with increased risk of stillbirth, with a PAR factor score of 7%. Smoking is known to result in fetal growth restriction, and although the mechanism is uncertain it may be due to an impact on placental function. Cessation of smoking during early pregnancy has been demonstrated to reduce the incidence of intrauterine growth restriction, premature birth and stillbirth [21]. Early pregnancy smoking cessation programmes are therefore important for the health of both mother and child.

Maternal obesity is a particularly important modifiable risk factor. Obesity is associated with a PAR score of 8–18%. Conversely, maternal age over 35 and maternal smoking both had PAR scores of around 7%. The risk of stillbirth is doubled among women with the highest body mass index (BMI) category (2.19, 2.03–2.36) compared with women with a normal BMI. Several pregnancy complications associated with maternal obesity, notably gestational diabetes and pre-eclampsia, have been implicated in fetal death and stillbirth [22]. The method by which obesity leads to stillbirth is unclear, although there are a number of potential mechanisms and it is likely that obesity has its effects via multiple pathways simultaneously [23]. It is well described that obesity during pregnancy increases the risk of gestational diabetes mellitus as well as hypertensive disorders, both pre-existing and gestational. Both gestational diabetes and hypertension are established risk factors for stillbirth [24]. A recent publication from MBRRACE suggests that some cases of stillbirth could have been avoided if gestational diabetes had been diagnosed early at the screening stage and managed appropriately. In some cases of stillbirth, had the pregnancy been screened adequately for gestational

diabetes, the stillbirth might have been avoided [15]. Obesity also increases the risk of hyperlipidaemia during pregnancy. Hyperlipidaemia reduces prostacyclin secretion and enhances peroxidase production. This in turn results in vasoconstriction and platelet aggregation and may contribute to pre-eclampsia through this mechanism [24]. Other conditions such as sleep apnoea are more common in obesity and obese pregnant women have more extended periods of snoring, more apnoea–hypoxia events, and more episodes of oxygen desaturation during sleep than non-obese pregnant women. It is possible that this greater tendency towards sleep apnoea and its consequent hypoxia reduces oxygen delivery to the fetus, thereby increasing the risk of stillbirth [25]. Women with obesity may be less able to perceive changes in fetal movement than women with a normal BMI and it has been suggested that this may lead to delayed presentation with a fetus at risk of antepartum death. Obese women may also experience more difficulty with labour and delivery, and monitoring during labour can be technically challenging in obese women.

Socioeconomic factors are also important in the aetiology of stillbirth. In the UK, pregnancies in women living in areas with the highest levels of social deprivation are over 50% more likely to end in stillbirth or neonatal death compared with births from the least deprived areas [5]. For women who are first-generation immigrants living in socially deprived conditions, the risk of stillbirth is more than twice the rate of stillbirth in women born in the UK, even from the same socioeconomic class and ethnic background [26]. The reasons for this difference are likely multifactorial. There is a greater incidence of obesity, poor nutrition and smoking in the population of women from deprived economic backgrounds and women who are socially disadvantaged are less likely to receive adequate antenatal care. A common factor underlying many stillbirths – the absence or low quality of antepartum and intrapartum care – means that referral for increased supervision is less likely to occur [27].

Finally, domestic abuse is an important aetiological factor. The mechanisms by which domestic abuse contributes to increased perinatal mortality are not fully understood. One possible pathway is a direct effect of blunt physical trauma causing disruption to the placenta and fetal death. A second possible mechanism is elevated maternal stress levels and poor nutrition, both of which are associated with low birthweight or preterm delivery and are well-known risk factors for perinatal and infant mortality. Thirdly, and probably most importantly, a woman who is experiencing domestic abuse may have particular difficulties accessing and using antenatal care services. Ensuring that women who suffer from domestic abuse are able to access antenatal care is a key consideration when designing antenatal care pathways [28].

Diagnosis of intrauterine fetal demise and antepartum stillbirth

Women with intrapartum stillbirth may present with diminished sensation of fetal movements, although it is more common for women to present with a condition associated with intrapartum stillbirth such as pre-eclampsia, chorioamnionitis and placental abruption. Diagnosis of intrapartum fetal death cannot be made clinically or on the basis of cardiotocography. The diagnosis of intrapartum fetal death should only be made by real-time ultrasonography. Ultrasound is required to demonstrate absent fetal cardiac activity [29]. Ultrasound may additionally demonstrate Spalding's sign (collapse of the fetal skull with overlapping bones) or fetal hydrops. Ultrasound is less reliable at detection of occult placental abruption.

Once the diagnosis has been confirmed, the parents can be told prior to delivery, which allows them to be prepared for the stillbirth. It is important to acknowledge emotional responses for all the caregivers following a diagnosis of stillbirth [30]. Telling parents about the diagnosis must be made in a clear and empathic manner. The manner in which the diagnosis is communicated remains with parents and affects the subsequent grief response. One large systematic review demonstrated that responses from parents and staff were often related: the behaviours and actions of staff have a memorable impact on parents while staff described emotional, knowledge and system-based barriers to providing effective care [31].

Management of antepartum stillbirth

In the absence of issues regarding maternal well-being, the choice of induced delivery or waiting for spontaneous labour must be given to couples following the diagnosis of intrauterine fetal demise. Waiting for spontaneous labour carries risks, including maternal disseminated intravascular coagulation (DIC) and chorioamnionitis. The risk of DIC is 10% if the intrauterine death occurred within 4 weeks and rises to 30% after 4 weeks. Maternal haematology, including platelet count, fibrinogen and coagulation studies, should be regularly monitored for the development of DIC [32].

Because of the risk of complications, women should be counselled that induction of labour is generally the safest option and that vaginal delivery is likely the best option for those planning subsequent pregnancies. Induction of labour using mifepristone has been shown to reduce the time from the start of induction until delivery for women in the third trimester. For women with a second-trimester intrauterine fetal death and an unripe cervix, vaginal misoprostol has been shown to be more effective than intravenous oxytocin at inducing labour [33]. However, it is important to note that misoprostol remains unlicensed in the UK for the induction of labour for second-trimester intrauterine death. For women with a previous caesarean section, or uterine scar from other surgery, there is limited evidence to help guide the management of induction of labour. Although most of the evidence of significant risks of induction of labour in women with previous uterine surgery relate to adverse fetal outcomes rather than adverse maternal outcomes, induction of labour following fetal demise using prostaglandin is considered reasonable [34]. Although misoprostol is associated with increased risk of uterine rupture, using lower doses (25–50 μg) will reduce this [35]. An alternative to pharmacological induction of labour is mechanical cervical ripening. This may reduce the risk of uterine rupture from pharmacological agents but the risk of infection and subsequent maternal morbidity may increase [36,37].

Legal considerations following stillbirth

The current law on stillbirth registration is set out in the Births and Deaths Registration Act 1953, amended by the Still-Birth (Definition) Act 1992. The legal definition of stillbirth is 'any child expelled or issued forth from its mother after the 24th week of pregnancy that did not breathe or show any other signs of life'.

A fully registered doctor or midwife must medically certify stillbirth; the doctor or midwife must have been present at the birth or examined the baby after birth. HM Coroner must be contacted if there is doubt about the status of a birth and the police should be contacted if there is suspicion of deliberate action to cause stillbirth. In the UK referrals to the coroner should also occur for an apparently fresh stillbirth not attended by a healthcare professional or should there be any concern regarding potential for criminal act, such as common assault.

Fetal deaths delivered later than 24 weeks that had clearly occurred before the end of the 24th week do not have to be certified or registered. The baby can be registered as indeterminate sex awaiting further tests.

Within the UK, the mother (or father if the couple were married at the time of birth) is responsible for registering the stillbirth, normally within 42 days (21 days in Scotland) but with a final limit of 3 months for exceptional circumstances. Routine birth and parental information is required to register the birth and the birth is entered onto the Stillbirth Register, which is separate from the standard Register of Births. The parents are then issued with a Certificate of Stillbirth and the documentation for burial or cremation. A certificate for cremation cannot be issued before the registration.

Stillbirths are currently not routinely covered by coronial law, except in Northern Ireland. There are examples of parents who have petitioned for the circumstances surrounding the death of their baby to be referred to the coroner (or procurator fiscal in Scotland) when parents have felt that local hospital reviews were inadequate. In some such cases, the coronial reports have highlighted vital gaps in quality of care [38].

Lactation suppression

Suppression of lactation is of psychological importance for some women following the loss of their baby. Simple measures such as a supportive bra, ice packs and analgesics can be used, but up to one-third of women using these measures will experience severe breast pain [39]. It is important to ascertain the mother's wishes: many women desire to suppress lactation, while some women wish to make altruistic donations to breast milk banks.

A single dose of cabergoline (1 mg) seems to be as effective as bromocriptine (2.5 mg twice daily) for 14 days [40] for lactation suppression. Dopamine antagonists may cause transient hypertension and therefore may be contraindicated in patients with hypertension [41].

Psychological aspects

The death of a baby is a profound loss [42]. The grief following the death of a baby may be different from other types of bereavement. From the moment that the pregnancy has been confirmed, the parents envision an entire lifetime for themselves and their baby. These expectations develop during the pregnancy and with the death of their baby, parents lose an entire future [43]. It is important to acknowledge the necessary grief of families and offer appropriate individualized support [44, 45].

There is considerable interpersonal variation in grief and mourning. This is true for different family members and issues can arise between partners when they cannot synchronize their grief and this subsequently may be a source of interpersonal and relationship stress.

Ultimately, this results in a significantly increased risk of relationship breakdown between the parents following stillbirth [46, 47].

Bereavement is also a significant risk factor for development of psychiatric illness. Among mothers, the relative risk of being hospitalized for any psychiatric disorder is highest during the first year after the death of the child but remains significantly elevated 5 years or more after the death [48].

Multiple pregnancy with loss of one of the babies presents particular emotional challenges for families. Parental attachment to surviving babies is often difficult and approximately one-third of couples experience difficulties coping at home following the birth [49]. Informal and formal support for bereaved couples should be offered [50].

Follow-up investigations

Understanding how or why their baby has died can help the parents in their grieving process. Any findings can be used to inform the parents if there is a risk to future pregnancies and the level of this risk and can help identify any additional treatment or surveillance in any future pregnancy. All parents should be offered investigations to help determine the cause of the stillbirth whilst respecting their wishes.

The Royal College of Obstetricians and Gynaecologists (RCOG) has a suggested list of investigations [29].

- Serological investigations include maternal haematological studies and routine biochemistry (may help diagnose and manage pre-eclampsia and its complications, sepsis and intrahepatic cholestasis of pregnancy and identify diabetes), Kleihauer test (fetal–maternal haemorrhage in addition to dose of anti-RhD gammaglobulin), and maternal infection screen (parvovirus B19, rubella, cytomegalovirus, herpes simplex and *Toxoplasma gondii* and others as indicated). Thrombophilia and antiphospholipid screening is currently recommended, although the association between inherited thrombophilias and intrauterine fetal demise is uncertain.
- Antibody screening and anti-Ro and anti-La antibodies will be indicated if there is concern regarding fetal anaemia or hydrops. Parental screening for fetal/neonatal alloimmune thrombocytopenia will be indicated if there is evidence of otherwise unexplained fetal bleeding.
- Cytogenetic analysis should be offered (especially if there is evidence of dysmorphic features or a congenital anomaly) either from samples taken at the time of postmortem or from the placenta or cord at delivery [51].
- Histopathological examination of the placenta is recommended in all cases of stillbirth. Although some reports find causal or contributory placental abnormalities in up to 60% of stillbirths, the significance of such findings in many cases remains uncertain [52].

Parents should be offered full post-mortem examination to help explain the cause of an intrauterine fetal demise as this can provide more information than other (less invasive) tests and can sometimes be crucial to the management of future pregnancies [53]. Post-mortem may not be acceptable to parents because of individual, cultural or religious beliefs and their decision must be respected. Alternative options to invasive post-mortem may be considered, including post-mortem MRI and tissue diagnostics [54,55]. Written consent must be obtained for any invasive procedure on the baby, including tissues taken for genetic analysis. Consent should be sought or directly supervised by an obstetrician or midwife trained in special consent issues and the nature of perinatal post-mortem.

Large-scale studies involving health economics are needed to determine which investigations are most appropriate after stillbirth [56].

Management of a future pregnancy and prevention

There is limited evidence to help guide the timing of subsequent pregnancy. Historical data suggested that pregnancies occurring within 6 months of a stillbirth were associated with increased risks of preterm birth, low birthweight and small-for-gestational-age babies and outcome. However, couples should be reassured that the absolute risk remains low [29, 57–59].

Two interventions may assist in reducing stillbirth: firstly, smoking cessation advice should be offered if indicated and, secondly, overweight women (BMI >30 kg/m^2) should be advised to lose weight [60, 61]. Further advice on adequate nutrition and a healthy lifestyle may also reduce subsequent stillbirth. Global strategies that have been advocated in addition to the above include screening and treatment of syphilis, presumptive treatment for malaria, insecticide-treated mosquito nets, birth preparedness, access to emergency obstetric care, caesarean section for breech presentation, and elective induction for post-term delivery [62].

In a future pregnancy, couples should be offered pregnancy care in a specialist unit with access to obstetrician-led care. Management of the pregnancy will depend on the history of the loss, for example reducing risk of pre-eclampsia by low-dose aspirin, serial growth scans to assess fetal growth in cases of suspected growth restriction

and/or pre-eclampsia, and cervical length assessment and possible cervical cerclage in cases of preterm labour.

Early term induction of labour may be offered especially in cases of previous pre-eclampsia and where there are placental issues including placental abruption, while acknowledging the limited evidence base for this practice [63].

The management of the subsequent pregnancy is important as there is an increased recurrence risk of pre-eclampsia and placental abruption following a stillbirth [64,65]. Additional psychological support is often required [50]. There may also be a delayed grief reaction and an effect on mother–baby bonding [66].

Internationally, there is a focus on reducing the stillbirth rate. The Every Newborn Action Plan has the target of 12 or fewer stillbirths per 1000 births in every country by 2030; 94 mainly high-income countries and upper middle-income countries have already met this target, although with noticeable disparities [9, 67].

Whilst the social and societal benefits in reduction of stillbirth are obvious, the cost–benefit analysis also shows that there may be a significant return on investment for interventions to reduce the number of stillbirths. Improvements in maternal, newborn and child health services could generate as much as 10-fold to 25-fold returns in economic and social benefits [68]. A *Lancet* series makes the case for a more than triple return on investment for prevention of stillbirths, in reducing maternal deaths, newborn deaths and stillbirths. The economic and social benefits associated with reductions in stillbirths compared with the cost of the interventions to achieve this reduction make a powerful case for healthcare investment into this aspect of maternity care [69].

Summary box 29.1

- Stillbirth rates in the UK have not changed significantly over the past 20 years, although national and international agendas have been set to reduce the rates.
- Many stillbirths have been considered 'unexplained' and therefore unavoidable. In many cases, however, risk factors such as obesity, smoking and fetal growth restriction are found and therefore the risks are potentially modifiable.
- Fetal growth restriction is commonly not detected antenatally and strategies to improve detection are needed.

Analgesia, Anaesthesia and Resuscitation

Felicity Plaat

Queen Charlotte's & Chelsea Hospital, Imperial College Healthcare NHS Trust, London, UK

In consultant-led units more than 70% of obstetric patients require anaesthetic input. This includes labour analgesia, anaesthesia for caesarean delivery and other surgical interventions, input into management of patients requiring critical care, and resuscitation. Because the role of the anaesthetist has expanded, current guidelines suggest that as a minimum there should be dedicated consultant anaesthetic input during the working week, and that elective obstetric work should be separately staffed [1].

Pain

The International Association for the Study of Pain defines pain as 'an unpleasant, subjective, sensory and emotional experience associated with real or potential tissue damage, or described in terms of such damage'. In simple terms, pain is what hurts. More than 95% of women report pain of varying intensity in labour. Melzack [2] measured pain in parturients using the McGill Pain Questionnaire and showed that although scores ranged from mild to excruciating, only pain associated with digit amputation and causalgia was equal to or greater than labour pain, which outscored cancer, post-herpetic neuralgia and pain of fracture.

Although pain may be considered the physiological consequence of normal labour, it may also be the harbinger of pathological processes, such as obstructed labour, fetal malposition, uterine hyperstimulation, uterine rupture or extant pathology such as fibromas or other tumours, haemorrhoids, and adhesions or scarring from previous surgery.

Severe pain stimulates a sympathetic autonomic response the magnitude of which reflects the severity of pain, and is exacerbated by dehydration and exhaustion. It is characterized by hyperventilation, tachycardia, hypertension, increased oxygen and glucose consumption, and vasoconstriction with decreased blood flow across the placenta. Maternal plasma adrenaline and noradrenaline concentrations increase 200% and 600%, respectively, during labour without analgesia. Increased maternal catecholamine levels can be associated with dysfunctional labour [3]. In the presence of maternal disease and/or fetal compromise, such effects are undesirable and under some circumstances may even be life-threatening.

Summary box 30.1

Severe and prolonged pain is associated with sympathetic automomic hyperactivity, increased maternal heart rate and blood pressure, vasoconstriction, increased oxygen consumption and reduced fetal oxygenation.

Non-regional analgesia for labour

Non-pharmacological methods of pain relief include antenatal education, aromatherapy, hypnotherapy ('hypno-birthing'), acupuncture, water injection, water immersion, massage and other relaxation techniques (this list is not exhaustive). A recent review suggests that continous support by a trained support person or 'doula' reduces analgesic requirements, shortens labour, increases satisfaction and improves outcome for the neonate. The effect is greatest if the support is provided by someone who is neither part of the woman's social network nor part of the hospital staff. It is worth noting that the effect is greatest in units where neuraxial analgesia is not routinely available [4]. This bears out the clinical experience that neuraxial analgesia is often requested when one-to-one care is not available. The evidence for other techniques is generally of poor quality, although

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

some, such as water immersion (birthing pools), are very popular and may reduce analgesia requirements.

Entonox (50% N_2O in oxygen) is widely used in the UK. Although 80% of women who use it would do so again, and there is evidence it is effective, it is associated with side effects such as nausea, vomiting and dizziness [5]. Although the use of sevoflurane and other inhalation anaesthetics has been studied, currently they are not part of mainstream clinical practice. Systemic opioids (pethidine and diamorphine) are almost universally available in birthing units in the UK, although evidence suggests that their effect is sedative [6] and that they have no analgesic effect in labour compared with placebo [5]. When offered this form of medication women should be informed of this. Diamorphine may be slightly more effective and may have less effect on the neonate than pethidine and is slowly replacing pethidine in some units in the UK.

Patient-controlled intravenous analgesia (PCA) is an alternative if regional analgesia is contraindicated. The ultrashort-acting opioid remifentanil has theoretical advantages over other opioids owing to its short latency and rapid metabolism. However, respiratory depression occurs in over 30% of women and cases of hypoxic cardiac arrest have been reported. The evidence for analgesic efficacy is modest [7]. If remifentanil PCA is used for labour, pulse oximetry and the continuous presence of trained personnel is mandatory and it should only be used in units where staff are experienced in and regularly care for women with this type of analgesia [1].

Regional analgesia

There is no question that neuraxial blockade (epidural or intrathecal) provides the most effective form of pain relief in labour, and very few women cannot benefit from this form of analgesia (Table 30.1). Based on data from 70% of obstetric units in the UK in 2011, the Obstetric Anaesthetists' Association (www.oaa-anaes.ac.uk) estimated that the average regional analgesia rate in 2007 was 22.7%, although this varied in units that offered the service from 4.1 to 37.6%. Modern regional techniques aim to provide pain relief whilst preserving sensation, minimizing motor blockade (muscle weakness) and reducing the effects on labour. The basis for achieving this is to reduce the dose of local anaesthetic used. Such techniques are frequently referred to as 'low-dose' or 'mobile' epidurals. In 2008, 80% of UK units were using low-dose techniques [8]. Guidance from the National Institute for Health and Care Excellence (NICE) published in 2014 states categorically that low-dose regimens should be used for the initiation and maintainence of analgesia [9]. Methods for reducing local anaesthetic consumption include combining the local anaesthetic with an opioid to achieve a synergistic effect (commonly fentanyl), avoiding conventional test doses (usually high concentrations of local anaesthetics) and using a combined spinal–epidural technique. The latter involves injection of the initial dose into the intrathecal space (a spinal injection) prior to placing an epidural catheter. The intrathecal dose requires one-tenth of the amount of local anaesthetic to be effective and provides almost instantaneous pain relief. The combined spinal–epidural technique is therefore particularly useful in the later stages of labour and in multiparous women in whom rapid labour is anticipated. It may also provide more reliable analgesia throughout labour and the use of combined spinal–epidural analgesia for labour is growing (Table 30.2) [10].

There is growing evidence that the effects of regional analgesia on the progress and outcome of labour are dose related. Systematic review of randomized controlled trials comparing regional and non-regional (opioid) analgesia shows that regional analgesia does not increase the overall risk of caesarean delivery but may be associated with increased caesarean delivery for fetal distress [11]. The effect is the same whether started early or later in labour [12]. Regional analgesia prolongs the second stage of labour (by approximately 15 min) and increases the need for augmentation and the use of instrumental vaginal delivery [11,13]. Evidence from randomized controlled studies suggests that low-dose neuraxial regimens are associated with fewer instrumental deliveries compared with conventional epidural analgesia [14]. Concerns about impaired maternal effort in the second stage of labour have resulted in the widespread habit of discontinuing regional analgesia in late labour [15]. However, a recent review concludes that in the absence of large trials the evidence suggests that all this achieves is poor analgesia in the second stage of labour [16]. Neither is there any evidence to withhold neuraxial analgesia from women in the latent stage of

labour [9]. Other side effects of regional analgesia include increased use of urinary catheterization, maternal fever (non-infective and believed to be a result of the local anaesthetic) and pruritus due to neuraxial opioids.

Ambulation in labour has not been shown to significantly affect the mode of delivery, However, mobility may decrease analgesic requirements and avoids the risks associated with prolonged recumbency. Mobilizing with regional anaesthesia has been shown to be safe and is viewed positively by women who undertake it [17]. To permit safe ambulation, all delivery unit staff must be appropriately trained and certain conditions must be met (Table 30.3). Motor and proprioceptive block must be excluded. Studies have demonstarated that women themselves can reliably tell if they can ambulate safely [18]. Results are currently awaited from a study comparing upright and recumbent positions in the second stage of labour in nulliparous women with neuraxial analgesia (ISRCTN Registry 35706297).

Summary box 30.2

In the UK, 80% of units now use 'low-dose' epidurals. Reduced doses of local anaesthetics decrease the incidence of motor block, allow ambulation and may diminish the effects on progress of labour and need for assisted vaginal delivery.

There are several obstetric and medical indications for neuraxial block in labour in addition to the need for pain relief (Table 30.4). Cases considered at high risk of requiring intervention for delivery benefit from an indwelling epidural catheter (which has been tested and shown to be effective) that can be rapidly replenished (e.g. in the case of an after-coming twin). Maternal disease in which the effects of pain or the Valsalva manoeuvre associated with pushing may be detrimental will also benefit from regional analgesia in labour. Obesity per se may become a major indication for this type of analgesia, since the whole spectrum of obstetric complications are increased in this group. Difficulties in siting neuraxial blocks make its early use advisable.

Table 30.3 Requirements for safe 'mobile epidurals' in labour.

Cooperative understanding parturient
Presenting part of fetus engaged and well applied to cervix
Minimal or no motor and proprioceptive block
No postural hypotension
Continuous fetal monitoring (cardiotocography) when indicated
Suitable conditions
Good epidural catheter fixation
Attending midwife
Disconnection of intravenous line (bung inserted)
No shoes
Safe, even floor without cables, steps or mats

Table 30.5 lists serious complications of regional blockade. A national survey in the UK carried out by the Royal College of Anaesthetists found that serious complications associated with death or permenent sequelae were rarer than previously estimated [19]. Although approximately 50% of all blocks performed are in the obstetric population, the incidence in this population was low compared with other patient populations possibly due to the general level of good health of obstetric patients. There were no deaths. Overall the incidence of

Table 30.4 Indications for regional analgesia for labour.

Pain relief
Avoid the deleterious effects of pain (maternal exhaustion, raised catecholamines, maternal and fetal acidosis)
Reduce premature urge to push
Anaesthesia for manual removal of placenta
Reduce need for emergency general anaesthesia
Multiple pregnancy (rapid anaesthesia for delivery of after-coming twin if required)
Breech
Suspected cephalopelvic disproportion/macrosomia
? Previous caesarean section
? Obesity
Improve uteroplacental flow/fetal condition
Pre-eclampsia
Preterm labour
Impaired uteroplacental function (poor Doppler/non-reassuring CTG)
Improve maternal condition
Reduces oxygen demand, (especially women with cardiac/respiratory disease)
Reduces circulating catecholamines (especially maternal fixed cardiac output states)
Decreases urge to push (Valsalva manoeuvre) in second stage

Table 30.5 Serious complications of regional blockade.

Complication	Incidence
Cardiovascular collapse	Very rare
High total spinal (relative/absolute overdose of local anaesthetic)	
Local anaesthetic toxicity (inadvertent intravenous administration)	
Infection (epidural abscess)	1 in 145 000
Meningitis	
Epidural haematoma	1 in 168 000
Trauma (direct damage to spinal cord/nerve root damage)	
Permanent	1 in 240 000
Transient	1 in 6700

Source: Ruppen W, Derry S, McQuay H, Moore RA. Incidence of epidural hematoma, infection, and neurologic injury in obstetric patients with epidural analgesia/anesthesia. *Anesthesiology* 2006;105:394–399. Reproduced with permission of Wolters Kluwer Health, Inc.

permenent harm in the obstetric population resulting from neuraxial blockade was between 0.3 and 1.24 per 100 000; combined spinal–epidural analgesia was associated with the highest incidence (3.9 per 100 000) and epidurals with the lowest (0.62 per 100 000).

Anaesthesia for caesarean section

The increased use of regional anaesthesia for caesarean section has contributed to the fall in anaesthetic-related maternal mortality. The great majority of anaesthetic-related maternal deaths are due to general anaesthesia, particularly in the emergency situation. General anaesthesia is particularly hazardous in obstetrics because of changes associated with pregnancy that increase the risk of difficult or failed intubation, of hypoxia and of aspiration. General anaesthesia is frequently reserved for the extremely urgent section when the anaesthetist, who may not have previously met the patient, has very little time for assessment. There are concerns that as general anaesthesia is used less and less in obstetrics, skills will dwindle increasing the risks of this type of obstetric anaesthesia. The Royal College of Anaesthetists suggests that more than 95% of elective and more than 85% of emergency cases should be performed under regional anaesthesia [20]. However, in the most urgent cases, up to a 15% rate of conversion to general anaesthesia may be expected. In 2013, only 10% of caesarean sections in the UK were performed under general anaesthesia [21].

The four-grade classification of urgency of caesarean section, endorsed by the Royal College of Obstetricians and Gynaecologists and the Royal College of Anaesthetists and used in the National Sentinel Audit of caesarean sections, should be universally adopted to improve communication especially in the emergency situation [22]. Prior to scheduled surgery, regardless of the type of anaesthetic planned, patients should be fasted (6 hours for solids, 2 hours for clear fluids) and given premedication (oral ranitidine and metoclopramide). Labouring women at risk of caesarean section should be limited to sips of water and given oral ranitidine 150 mg 8-hourly throughout labour. Intravenous ranitidine 50 mg may be given within 30 min of induction whereas sodium citrate, which is only effective for 15–30 min, should be given immediately before induction of general anaesthesia. In the emergency situation, intrauterine resuscitation of the fetus (Table 30.6) should be undertaken during preparation for anaesthesia [23]. Oxygen therapy in the presence of profound fetal distress is still recommended, although the evidence is not compelling [24].

Table 30.6 Intrauterine resuscitation.

Relieve aortocaval compression: left lateral position ≥15° tilt, uterine displacement
Ensure effective analgesia: top up epidural (decreases maternal catecholamine levels and improves uteroplacental blood flow)
Rapid intravenous infusion (transiently decreases uterine activity)
Stop Syntocinon infusion (often overlooked)
Tocolysis (terbutaline/glyceryl trinitrate)
High-flow maternal oxygen (optimize oxygen delivery

Regional anaesthesia is recommended in severe pre-eclampsia as haemodynamic stability is better maintained than in the normotensive patient and because the risks of general anaesthesia are further increased in pre-eclampsia. Abnormal placentation is no longer seen as an absolute indication for general anaesthesia. A combination of general and neuraxial anaesthesia allows the mother to be awake for delivery, after which general anaesthesia can be induced for caesarean hysterectomy or other complicated surgery. Similarly for fetal surgery, or other surgery during pregnancy, combined general anaesthesia and regional blockade is frequently used. The combined spinal–epidural technique allows effective anaesthesia to be prolonged as long as required and the epidural component can be used to provide postoperative analgesia.

Summary box 30.3

The great majority of direct anaesthetic-related maternal deaths are associated with emergency general anaesthesia. The Royal College of Anaesthetists recommends that more than 85% of emergency and more than 95% of elective caesarean sections should be performed under regional anaesthesia.

Cardiopulmonary resuscitation and critical care

Cardiac arrest during pregnancy is rare. The commonly quoted incidence is 1 in 30 000 pregnancies. A recent survey from the USA found the incidence of cardiac arrests during hospitalization for delivery to be much higher than this (1 in 12 000). Nearly 60% of cases survived to hospital discharge [25]. The most common conditions associated with cardiac arrest were mainly obstetric: haemorrhage, amniotic fluid embolism, thromboembolism and sepsis. In a recently completed study in the UK, the single most common cause of cardiac arrest leading to peri-mortem caesarean section was anaesthetic catastrophe (Virginia Beckett, personal communication). The majority of fatal cardiac arrests in the UK are caused by 'indirect' causes, the leading one being cardiac disease. Although the overall maternal mortality in the UK has declined, there has been no change in that from indirect deaths since 2003 [26]. In the obstetric patient, pulseless electrical activity/asystole is more common than ventricular fibrillation arrest. Hypovolaemia due to haemorrhage is probably the commonest cause. Pulmonary embolism is another cause of pulseless electrical activity. Amniotic fluid embolism appears to be causing an increasing number of maternal deaths in the UK, and typically presents with sudden cardiovascular collapse often associated with profound hypoxia. Local anaesthetic toxicity and magnesium overdose also occur in this population. Lack of knowledge of resuscitation (both basic and advanced) among healthcare professionals caring for maternity patients has repeatedly been highlighted [27]. In consecutive reports on maternal mortality in the UK, resuscitation skills were judged to be poor in a significant number of cases. One of the 'top ten' recommendations of the 2003–2005 report was that 'All staff must undertake regular, written, and audited training for the improvement of basic, immediate and advanced life support skills'. A growing number of courses are available. Training should be supplemented by regular team practice of cardiac arrest drills to ensure appropriate care is delivered [28].

Resuscitation in pregnancy is different from resuscitation in the non-pregnant adult. Cardiopulmonary resuscitation is both more difficult to perform and less effective in the obstetric patient. Occlusion of the inferior vena cava is the norm in the supine position at term and results in a more than 60% reduction in venous return. In order to reduce aortocaval compression, uterine displacement or pelvic tilt is required. Because of the importance of uninterrupted cardiac compressions and because effective cardiac compression becomes progressively more difficult the more the patient is tilted, uterine displacement is the preferred method [29]. Hypoxia develops more quickly due to increased oxygen requirements and decreased oxygen reserves. Artificial ventilation becomes more difficult due to enlarged breasts and decreased lung compliance resulting from the enlarging uterus. Reduced lower oesophageal sphincter tone increases the risk of regurgitation, requiring endotracheal intubation as early as possible.

Speed of response is crucial to the outcome for both the woman and her child [30]. Minimizing aortocaval compression, airway protection, normal hand position for cardiac compressions (modified hand position now not recommended by the Resuscitation Council) and early uterine evacuation form the basis for resuscitation of the pregnant patient at term (Table 30.7). It is now

Table 30.7 Cardiopulmonary resuscitation in the pregnant patient.

Basic life support
Left uterine displacement (manual displacement/tilt/wedge)
Hands higher on sternum
Cricoid pressure to prevent regurgitation*
Advanced life support
Secure airway early
Early evacuation of uterus (within 5 min of cardiac arrest)
Remove fetal monitors prior to defibrillation
Avoid lower limb intravenous access
(Drug doses should not be altered)

*Cricoid pressure is recommended by UK authorities but not by those in the USA [29,30].

Table 30.8 Indications for transfer to an intensive care facility.

General
Lack of trained staff/facilities on delivery suite

Mechanical ventilation
Airway protection
Tracheal toilet
Renal
Renal replacement therapy
Neurological
Significantly depressed conscious level
Miscellaneous
Multiorgan failure
Uncorrected severe acidosis
Hypothermia

recommended that early (within 5 min) evacuation of the uterus should be considered, regardless of fetal viability, to improve chances of successful resuscitation, from about 20 weeks [29]. Uterine evacuation in this situation will not require haemostasis until circulation is restored. The delay caused by aseptic precautions may itself be fatal. A scalpel and a pair of forceps plus gloves for the operator's protection may be all that is required [29,30]. A midline incision has been recommended as it is helped by the separation of the recti abdomini muscles that occurs in later pregnancy; however, if staff involved are more familiar with a Pfannenstiel incision, then this should be used.

A report on obstetric admissions to intensive care indicates that the majority of obstetric admissions are post partum (>80%). Of these, much the most common cause was haemorrhage (>30%). In contrast, among antenatal admissions, non-obstetric conditions predominated, with pneumonia being the single most common cause [31]. The early provision of critical care to the sick parturient can reduce morbidity and mortality. The anaesthetist on the delivery suite must identify as early as possible when transfer to intensive care is required (Table 30.8).

The limits to what care can be safely provided on the delivery suite will be determined by local resources. The effects of intensive care management on the fetus must be considered [32]. Maternal oxygen-carrying capacity should be optimized, the effects of pharmacological agents on uteroplacental blood flow considered, adequate maternal nutrition ensured and radiological investigations minimized. Post partum there are obvious advantages to keeping the mother and infant together. Recommendations on the standards for critical care on delivery suites have been defined [32]. The role of the obstetric anaesthetist in neonatal resuscitation is poorly defined. There is general agreement that the first responsibility is to the mother [33,34]. However, since up to one-third of cases where neonatal resuscitation is required occur apparently without warning, there is also consensus that all those likely to be present at delivery, including the obstetric anaesthetist, should have undergone training in neonatal resuscitation.

Summary box 30.4

During cardiopulmonary resuscitation in the pregnant patient, aortocaval compression must be minimized using uterine displacement, the airway protected from aspiration by intubation, and the uterus emptied within 5 min of cessation of circulation to maximize chances of maternal and fetal survival.

Summary

The majority of parturients require anaesthetic input. Regional analgesia has been modified to reduce adverse effects on the progress and outcome of labour. By increasing consultant anaesthetic presence on the delivery suite and by minimizing the use of general anaesthesia for emergencies, anaesthetic-related maternal mortality and morbidity has been reduced. At-risk parturients should be identified and referred for antenatal anaesthetic input. The anaesthetist plays a key role in the provision of critical care for the obstetric patient.

Puerperium and Lactation

D. Keith Edmonds[1,2]

[1] *Imperial College London, London, UK*
[2] *Queen Charlotte's and Chelsea Hospital, London, UK*

The puerperium is the period from delivery of the placenta until 6 weeks after delivery. It is a time of enormous importance to the mother and her baby and yet it is an aspect of maternity care that has received relatively less attention than pregnancy and delivery. During the puerperium the pelvic organs return to the non-gravid state, the metabolic changes of pregnancy are reversed and lactation is established. In the absence of breastfeeding, the reproductive cycle will recommence within a few weeks. The puerperium is a time steeped in myth, cultural dogma and rituals, and indeed many of the medical recommendations about the puerperium have developed as adaptations of socially acceptable traditions rather than science.

The puerperium is also a time of psychological adjustment. While most mothers' elation following the arrival of a newborn baby is obvious, the transition to becoming a responsible parent and anxiety about the child's welfare will influence the mother's ability to cope. These anxieties may be compounded if she has had a difficult labour or if she has any medical complications. However, the majority of women are subject to another problem that new mothers find very difficult to cope with and this is the plethora of well-meaning but conflicting advice from doctors, midwives, relatives and friends. These cultural influences may be in conflict with the mother's own beliefs and so whilst it is understandable that these individuals wish to support the mother, it is extremely important that an atmosphere be created whereby a mother can learn to handle her baby with confidence in her own way. Midwifery and obstetric staff play an important role in supporting this philosophy. In caring for a woman during the early puerperium, the role of the obstetrician and midwife is to monitor the physiological changes of the puerperium, to diagnose and treat any postnatal complications, to establish infant feeding, to give the mother emotional support and to advise about contraception and other measures that will contribute to her continuing health. It is important to bear in mind that maternal morbidity and mortality are an ongoing risk in the puerperium and hence its importance cannot be understated.

Physiology of the puerperium

Two major physiological events occur during the puerperium: the establishment of lactation and the return of the physiological changes of pregnancy to the non-pregnant state. Some changes occur quite rapidly (within 2 weeks) whilst others take 6–12 weeks to complete.

The uterus

The crude weight of the pregnant uterus at term is approximately 1000 g while the weight of the non-pregnant uterus is 50–100 g. From a clinical perspective the uterine fundus is no longer palpable abdominally by 10 days after delivery. By 6 weeks after birth, the uterus has returned to its normal size. The cervix is very flaccid after delivery, due to the reduction in collagen content as a result of cervical remodelling prior to labour, but within a few days returns to its original state. The placental site in the first 3 days after delivery is infiltrated with granulocytes and mononuclear cells and this process extends into the endometrium and the superficial myometrium. By the seventh day, there is evidence of regeneration of endometrial glands and by day 16 the endometrium is fully restored. Decidual necrosis begins on the first day and by the seventh day a well-demarcated zone exists between necrotic and viable tissue. The presence of mononuclear cells and lymphocytes persists for about 10 days and it is presumed that this acts as some form of antibacterial barrier. Haemostasis immediately after birth is accomplished by arterial smooth muscle contraction and compression of vessels by the uterine muscle.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

The vessels in the placental site are characterized during the first 8 days by thrombosis, hyalinization and obliterative fibrinoid endarteritis. Immediately after delivery, bleeding lasts for several hours and then rapidly diminishes to a red-brown discharge by the third or fourth day after birth. This vaginal discharge is known as lochia and after the third or fourth day becomes mucopurulent and sometimes malodorous. This is known as the lochia serosa and it has a mean duration of 22–27 days. However, 10–15% of women will have lochia serosa for at least 6 weeks [1]. Not infrequently, there is a sudden but transient increase in uterine bleeding between 7 and 14 days after delivery. This corresponds to the shedding of the slough over the placental site and as myometrial vessels are still at this stage larger than normal, this accounts for the dramatic bleeding that can occur. However, although some women are alarmed by this event, it is self-limiting and subsides within 1–2 hours. The endometrium will proliferate from the basal layers of the decidua but this is influenced by the method of infant feeding. If lactation is suppressed, the uterine cavity may be covered by new endometrium within 3–4 weeks; however, if lactation is established, endometrial growth in the majority of women may be suppressed for as long as breastfeeding continues. This is because lactation suppresses ovarian function and so a physiological hypo-oestrogenic state is created that prevents endometrial cell growth

Ovarian function

Women who breastfeed their infants will be amenorrhoeic for long periods, often until the child is weaned. However, in non-lactating women, ovulation may occur as early as 27 days after delivery, although the mean time is approximately 70–75 days. Among those women who are breastfeeding, the mean time to ovulation is 6 months. Menstruation resumes by 12 weeks after birth in 70% of women who are not lactating and the mean time to first menstruation is 7–9 weeks. The risk of ovulation within the first 6 months after delivery in women exclusively breastfeeding is between 1 and 5% [2]. The hormonal basis of puerperial ovulation suppression in lactating women appears to be the persistence of elevated serum prolactin levels, which may suppress adipoleptin secretion from adipocytes. Prolactin levels fall to the normal range by the third week after birth in non-lactating women but remain elevated to 6 weeks after birth in lactating women. Prolactin is then only elevated during episodes of suckling.

Cardiovascular and coagulation systems

Changes take place in the cardiovascular and coagulation systems that have practical and clinical implications and these are summarized in Table 31.1. Although both heart rate and cardiac output fall in the early puerperium, there may be an early rise in stroke volume and, together with the rise in blood pressure due to increased peripheral resistance, it is a time of high risk for mothers with cardiac disease and these mothers require extra supervision at this time (see Chapter 8). Although by 6 weeks a woman's body has changed physically back to the non-pregnant state, it can be seen from Table 31.1 that cardiac output may remain elevated for up to 24 weeks after birth. During the immediate postnatal period, fibrinolytic activity is increased for 1–4 days before it returns to normal by 1 week. Platelet counts are normal during pregnancy but there is a sharp rise in platelets after delivery, making it a time of high risk for thromboembolic disease [3].

Urinary tract

During the first few days, the bladder and urethra may show evidence of mild trauma sustained at delivery and these changes are usually associated with localized oedema. These are transient and do not remain in evidence for long. The changes that occur in the urinary tract during pregnancy disappear in a similar manner to other involutional changes and within 2–3 weeks the hydroureter and pelvic dilatation in the kidney are almost eliminated and completely return to normal by 6–8 weeks after birth.

Table 31.1 Changes in the cardiovascular and coagulation systems during the puerperium.

	Early puerperium	Late puerperium
Cardiovascular		
Heart rate	Falls: 14% by 48 hours	Normal by 2 weeks
Stroke volume	Rises over 48 hours	Normal by 2 weeks
Cardiac output	Remains elevated and then falls over 48 hours	Normal by 24 weeks
Blood pressure	Rises over 4 days	Normal by 6 weeks
Plasma volume	Initial increase and then falls	Progressive decline in first week
Coagulation		
Fibrinogen	Rises in first week	Normal by 6 weeks
Clotting factors	Most remain elevated	Normal by 3 weeks
Platelet count	Falls and then rises	Normal by 6 weeks
Fibrinolysis	Rapid reversal of pregnancy inhibition of tissue plasminogen activator	Normal by 3 weeks

Weight loss

There is an immediate loss of 4.5–6 kg following birth due to the baby, the placenta, amniotic fluid and blood loss that occurs at delivery. By 6 weeks after delivery, 28% of women will have returned to their pre-pregnancy weight; those women who did not have excessive weight gain in pregnancy should have returned to their normal pre-pregnancy weight by 6 months after delivery. Women with excessive weight gain in pregnancy (>15 kg) are likely to find that at 6 months they still have net gain of 5 kg, which may persist indefinitely [4]. Breastfeeding has no effect on postpartum weight loss unless lactation continues for 6 months [5]. Diet and exercise have no effect on the growth of infants who are being breastfed and women can therefore be encouraged to return to normal activity and to regain their weight even though they are lactating [6].

Thyroid function

Thyroid volume increases by approximately 30% during pregnancy and this returns to normal over a 12-week period. Thyroxine and triiodothyronine return to normal within 4 weeks after birth.

Hair loss

Hair growth slows in the puerperium and women will often experience hair loss as temporarily more hair is lost than regrown. This is a transient phenomenon but it is important for women to realize that this may take between 6 months and a year to return to normal. The low levels of circulating oestrogen are the aetiology of this phenomenon and so it is more common in breastfeeding mothers.

Management of puerperium

The morbidity associated with the puerperium is underestimated and an important review showed that mothers have high levels of postpartum problems. Nearly one-third (31%) of women felt that they had major problems for up to 8 weeks after birth. In trying to reduce the impact of this morbidity, there are a number of principles which need to be applied in planning postnatal care.

1) *Continuity of care*. An ideal pattern of care is one that offers continuity from the antenatal period through childbirth and into the puerperium involving the smallest team of health professionals with which the mother can empathize.
2) *Mother–infant bonding*. It is now well established that mothers and their partners should be able to hold and touch their babies as soon as possible after delivery. Good postnatal facilities that allow rooming-in, privacy and the opportunity for close contact play an important part in helping parents have a good experience of early parenting.
3) *Flexible discharge policies*. The optimum duration of postnatal stay varies with the needs of the individual mother and her baby. Some mothers will elect to have a home confinement, some will elect to have early discharge at 6 hours postnatally and others may have greater needs, particularly those who have had complicated deliveries and those who wish to establish breastfeeding before going home. The current pressure on maternity services in the Western world means that any length of stay in hospital to respond to maternal needs as opposed to medical necessity has curtailed this flexibility. While this has not had an impact on successful breastfeeding, psychological morbidity may have increased.
4) *Emotional and physical support*. Mothers require help and support after childbirth and this may come from partners, relatives and friends. Good professional support is also important and good communication between hospital staff, community midwives, general practitioner (GP) and health visitor is essential.

Routine observations

During the patient's stay in hospital, regular checks are made of her pulse, temperature, blood pressure, fundal height and lochia and any complaints noted. The perineum should be inspected daily if there has been any trauma and the episiotomy or other wounds checked for signs of infection. It is also important that urinary output is satisfactory and that the bladder is being emptied completely. These observations are necessary to give the earliest warning of any possible complications.

Ambulation in the puerperium

It is now well established that early mobilization after childbirth is extremely important. Once the mother has recovered from the physical rigours of her labour, she should be encouraged to mobilize as soon as possible. The physiotherapist has an important role to play in returning the patient to normal health during the puerperium. Leg exercises will be particularly important to encourage venous blood flow in any mother who has been immobilized in bed for any reason. Exercises to the abdominal and pelvic floor muscles are most valuable in restoring normal tone, which may have been lost during pregnancy.

Complications of the puerperium

Serious and sometimes fatal complications may arise during the puerperium. The most serious complications are thromboembolism, infection and haemorrhage, but mental disorders and breast problems occur also.

Thrombosis and embolism

The MBRRACE-UK 2014 report [7] shows that pulmonary embolism is still the major cause of death in the puerperium. The rate of death has remained unchanged for many years and approximately 50% of deaths occur post partum (Table 31.2). The authors suggest that it is unsurprising that there has been little impact on these figures because of the direct association with obesity. Some 49% of women who died of pulmonary embolism were either overweight or obese and this has become a major international issue. Data from the USA suggest that their maternal mortality rate is rising and one accepted factor is obesity. Over 60% of women falling pregnant in the USA are seriously overweight. Other factors are also contributing to the increased risk, including increased maternal age, changing ethnicity, and increasing medical complications of pregnancy.

All pregnant women should be assessed for venous thromboembolism (VTE) during pregnancy and this should be repeated either during or after birth to determine their suitability for thromboprophylaxis. If thromboprophylaxis is deemed appropriate, moderate-risk women should receive this for 10 days and high-risk women for 42 days.

Table 31.2 Deaths from pulmonary embolism reported by MBRRACE-UK.

Triennium	Total deaths	Rate per 100 000	Postnatal	Rate per 100 000
1985–1987	30	1.3	13	0.6

Puerperal infection

Puerperal pyrexia, which is potentially fatal, may have several causes but is an important clinical sign that merits careful investigation. Infection may occur in several sites and each needs to be investigated in the presence of elevated temperature.

Genital tract infection

Genital tract infection continues to be a life-threatening problem for women and Table 31.3 shows the risk of puerperal sepsis and maternal death over the last years of maternal death reports. The most virulent organism is β-haemolytic *Streptococcus* but more commonly *Chlamydia*, *Escherichia coli* and other Gram-negative bacteria will be the infective agents. Table 31.4 summarizes the main causes of postnatal pyrexia. Early diagnosis and treatment are imperative if the long-term sequelae are to be avoided. Whilst it is encouraging that rates of death have halved in the last 5 years, they have still not returned to those of 1985. Vigilance with diagnosis and rapid administration of antibiotics are important strategies, as is the involvment of infectious disease consultants, especially when a woman fails to respond to the antibiotic of first choice.

Table 31.4 Causes of postnatal pyrexia.

Urinary tract infection
Genital tract infection
Endometritis
Infected episiotomy
Mastitis
Wound infection following caesarean section
Deep venous thrombosis
Other infection, e.g. chest infection, viral infections

Patients may present more acutely ill with what is now known as a systemic inflammatory response. The presence of any two of new onset of confusion, sustained heart rate of more than 90 bpm, respiratory rate of greater than 20 breaths/min and a temperature of more than 38.3°C or less than 36°C confirms the diagnosis. Immediate administration of antibiotics should be commenced without waiting for investigation results. If any one of the following signs is present, a diagnosis of severe sepsis should be made with consideration of transfer to intensive care:

1) systolic blood pressure less than 90 mmHg;
2) heart rate more than 130 bpm;
3) oxygen saturation less than 91%;
4) respiratory rate more than 25 per min;
5) responds only to pain or unresponsive.

Urinary tract infection

This is a common infection in the puerperium following the not infrequent use of catheterization during labour. Some women will also develop urinary retention and require indwelling catheters. *Escherichia coli* is the commonest pathogen and again early treatment is advised.

Respiratory infection

Chest infections are not normally a serious problem in the puerperium, although recent outbreaks of potentially fatal influenza viruses have increased the level of concern. The infrequent use of general anaesthesia has reduced the risk of chest infection in the immediate postpartum period but any woman who presents with signs of a serious chest infection must have the possibility of an underlying pulmonary embolus excluded.

Other causes

Any surgical wound should be examined for evidence of infection and this is obviously important following caesarean section. Wound infection may manifest itself as a reddened tender area around the incision, with associated swelling and induration. Treatment will depend on the extent and severity of the infection. If the infection is well localized, it may discharge spontaneously but an abscess may require incision and drainage. Broad-spectrum antibiotics will be required and bacteriological specimens should be sent for examination. It is occasionally necessary to re-suture wounds after infection but often wounds will granulate from the base and heal spontaneously. The legs should always be inspected if a puerperal pyrexia is present because of the risk of thrombophlebitis and it may also be a sign of deep venous thrombosis. The breasts should be examined for signs of breast infection, although breast abscess formation is very unusual before 14 days after birth.

Urinary complications

Other than infection, urinary retention is the commonest complication following delivery, especially if there has been any trauma to the urethra and resulting oedema round the bladder neck. A painful episiotomy may make it very difficult for women to spontaneously micturate and retention of urine may occur. Following epidural anaesthesia, there may be temporary interruption of the normal sensory stimuli for bladder function and over-distension of the bladder may occur. It is extremely important that in the immediate postnatal period urinary retention is avoided as over-distension may lead to an atonic bladder, which is then unable to empty spontaneously. If the bladder is distended, it is usually palpable abdominally but if this is not the case or the clinician is uncertain of the abdominal findings, an ultrasound scan should be performed to determine the volume of urine retained in the bladder. The treatment of urinary retention is to leave an indwelling catheter on continuous drainage for 48 hours. The patient can be ambulant during this time. After the bladder has been continuously emptied, the catheter can be removed and then the volumes of urine passed can be monitored. If there is any suspicion that further retention is occurring, then a suprapubic catheter should be inserted so that the bladder can undergo a further period of continuous drainage and then intermittent clamping of the catheter can be instituted until normal bladder function returns.

Incontinence of urine

Urinary incontinence will occur in many women immediately following delivery and approximately 15% of women will have urinary incontinence that persists for 3 months after birth [8]. However, a study by Glazener *et al*. [9] showed that three-quarters of women with urinary incontinence 3 months after childbirth still have this 6 years later. A further follow-up study has shown that this does not improve after 12 years, with 75% still experiencing urinary incontinence [10]. Urinary incontinence is more frequently seen following instrumental delivery and least frequently after elective caesarean section. Urinary fistulae are uncommon in obstetric practice today, although direct injury from obstetric forceps may occasionally occur. Complications to the ureter are most commonly seen after a complicated caesarean section, when ureteric injury may either result in a ureteric fistula or ureteric occlusion. Women with this type of urinary problem should not be managed by obstetricians but should be referred to a urological colleague for surgical management.

Incontinence of faeces

It is now recognized that 35% of women undergoing their first vaginal delivery develop anal sphincter injury

[11,12]. Approximately 10% will still have anal symptoms of urgency or incontinence at 3 months after birth. Again, in the 12-year follow-up study by Glazener *et al.* [10], there was no improvement in this anal incontinence rate over time and at 6 years the faecal incontinence rate actually increased to 13%. The aetiology of this type of anal sphincter trauma is complex in the same way that mechanisms which maintain continence are complex, but include instrumental delivery, prolonged second stage of labour, birthwieght over 4.0 kg, occipito-posterior position and episiotomy. Instrumental delivery is a recognized cause of trauma and randomized trials suggest that the use of vacuum extraction is associated with less perineal trauma than forceps delivery [13,14]. The incidence figures confirm this: forceps delivery is associated with a 32% incidence of anal incontinence compared with a 16% incidence for vacuum extraction. The incidence of third- and fourth-degree tears varies enormously from centre to centre, suggesting that the clinical ability to recognize this type of trauma may vary. In those women who have a recognized anal sphincter rupture, 37% continue to have anal incontinence despite primary sphincter repair [15]. A recent Cochrane review of the role of caesarean section in avoiding anal incontinence concluded that there is insufficient evidence to recommend this [16].

Secondary postpartum haemorrhage

Delayed postpartum bleeding occurs in 1–2% of patients. It occurs most frequently between 8 and 14 days after birth and in the majority of these cases it is due to sloughing of the placental site. However, if this bleeding is not self-limiting, further investigation will be required. Ultrasound examination of the uterine cavity will usually determine whether there is a significant amount of retained products, although it can be difficult to distinguish between blood clot and retained placental tissue. Suction evacuation of the uterus is the treatment of choice and, if this is required, it is imperative that antibiotic cover is given. If curettage is not required immediately to arrest bleeding, it is best to start antibiotics at least 12 hours beforehand. This will reduce the risk of endometritis leading to uterine synechae. A combination of metronidazole and co-amoxiclav can be used in those patients who have endometritis without retained products of conception. In those who do have retained products who require curettage, intravenous antibiotics in the form of metronidazole and a cephalosporin, clindamycin or gentamicin are the antibiotics of choice. Great care must be taken at the time of curettage as the infected uterus is soft and easy to perforate. Rarely, these measures do not result in cessation of bleeding, and in life-threatening circumstances embolization of the uterine arteries may be effective in controlling the bleeding, as may the use of uterine tamponade using a Foley catheter balloon. If these techniques fail, then hysterectomy as a life-saving procedure may be needed.

It is important to remember that choriocarcinoma may present in this manner and, if suspected, can be diagnosed by elevated levels of human chorionic gonadotrophin. Rarely, a patient with a coagulopathy may present with a secondary haemorrhage.

Puerperal psychological disorders

Mild pyschological disturbance and transient depression are extremely common in the few days after birth. This transient state of tearfulness, anxiety, irritation and restlessness has been variously described as the 'blues' and it may occur in up to 70% of women. It usually resolves by day 10 after delivery and is probably associated with disruptive sleep patterns and the adaptation and anxiety of having a newborn baby. The changes in steroid hormone levels that occur immediately following delivery are not correlated with this transient depressive state, and because it is transient no therapy is needed. Postpartum depression and psychosis are dealt with in Chapter 14.

Counselling of patients after perinatal death

See Chapter 29.

Drugs during lactation

Drugs taken by a breastfeeding mother may pass to the child, and it is important to consider whether particular drugs will have any effect on the fetus. This is often a difficult problem and the reader is referred to Schaefer *et al.* [17] for more information.

Infant feeding

The major physiological event of the puerperium is the establishment of lactation. Some mothers in developed countries still reject breastfeeding in favour of artificial feeding but there is increasing evidence of the important short- and long-term benefits of breastfeeding. The World Health Organization (WHO) now recommends exclusive breastfeeding for 6 months.

Advantages of breastfeeding

Nutritional aspects of breast milk

Human milk does not have a uniform composition: colostrum differs from mature milk and the milk of the early puerperium differs from the milk of late lactation. Indeed, the content of milk varies at different stages of

the same feed. Nevertheless, there are substantial differences in the constituent concentrations of human milk and cows' milk (Table 31.5), with human milk having less protein but more fat and lactose. Human milk and milk formulas also differ with respect to a number of specific components, for example the long-chain polyunsaturated fatty acids, and this may have important neurodevelopmental consequences for the baby [18]. There is no doubt that breast milk is the ideal nutrition for the human baby.

Protection against infection

One of the most important secondary functions of breastfeeding is to protect the infant against infection. This is particularly important in developing countries, where it has been estimated that in each year there are 500 million cases of diarrhoea in infants and children and about 20 million of these are fatal. However, the extent to which breastfeeding protects against infection in infants in developed countries has been a matter of dispute. In a study from Dundee, Scotland, it was found that babies who had been breastfed for at least 3 months had greatly reduced incidences of vomiting and diarrhoea compared with babies who were either bottle-fed from birth or completely weaned within a short time of delivery [19]. This study also found that the protection against gastrointestinal illness in breastfed babies persisted beyond the period of breastfeeding itself and, in the developed country setting at least, was not undermined by the early introduction of at least some supplements. There was a smaller protection against respiratory tract infections but not against other illnesses.

A number of mechanisms contribute to the anti-infective properties of breast milk. Breast milk contains lactoferrin which binds iron, and because *E. coli* requires iron for growth, the multiplication of this organism is inhibited. Breastfeeding also encourages colonization of the gut by non-pathogenic flora that competitively inhibit pathogenic strains. In addition, bactericidal enzymes such as lysozyme are present in breast milk that contribute to its protective effect.

Table 31.5 Comparison of the constituents of human and cows' milk.

Constituent	Human milk	Cows' milk
Energy (kcal/100 mL)	75	66
Protein (g/100 mL)	1.1	3.5
Fat (g/100 mL)	4.5	3.7
Lactose (g/100 mL)	6.8	4.9
Sodium (mmol/L)	7	2.2

However, the most specific anti-infective mechanism is an immunological one. If a mother ingests a pathogen that she has previously encountered, the gut-associated lymphoid tissue situated in the Peyer's patches of the small intestine will respond by producing specific IgA, which is transferred to the breast milk via the thoracic duct (Fig. 31.1). This immunoglobulin, which is present in large amounts in breast milk, is not absorbed from the infant's gastrointestinal tract but remains in the gut to attach to the specific offending pathogen against which it is directed. In this way the breastfed infant is given protection from the endemic infections in the environment against which the mother will already have immunity [20]. Breast milk also contains living cells, such as polymorphs, lymphocytes and plasma cells, and although their functions are not yet fully understood they may also be active against invading pathogens.

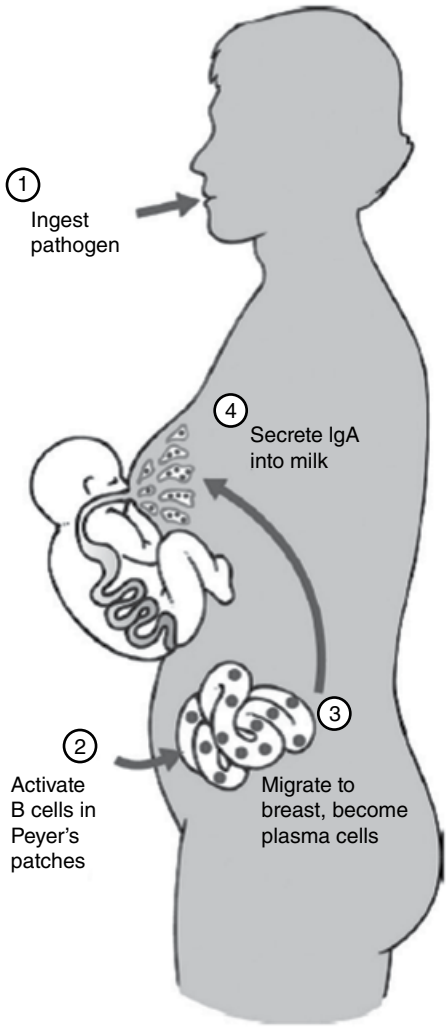

Fig. 31.1 Pathways involved in the secretion of IgA in breast milk by the enteromammary circulation.

Breastfeeding and neurological development

Previous studies have suggested that breastfed infants have a superior neurodevelopmental advantage and for many years this has been part of the campaign to encourage breastfeeding. However, there may not be such a great impact when the confounding variables, including parental IQ and socioeconomic status, are controlled for. In a 10-year follow-up study, Jedrychowski *et al*. [21] suggest that the increase in IQ ranges from 2.1 to 3.8 points depending on the length of breastfeeding. It would seem wise not to overestimate this effect when couselling mothers about the advantages of breastfeeding.

Breastfeeding and atopic illness

There are a number of reports that show a lower incidence of atopic illness, such as eczema and asthma, in breastfed babies. This effect is particularly important when there is a family history of atopic illness [22]. When the atopic illness is present, it is commonly associated with raised levels of IgE, especially to cows' milk protein. Oddy *et al*. [23] suggest that apart from a positive family history, the most important predisposing factor for atopic illness is the early introduction of weaning foods. The protective effect of breastfeeding against atopic illness may therefore be secondary rather than primary, because breastfeeding mothers tend to introduce supplements at a later stage. Nevertheless, mothers with a family history of atopic illness should be informed of the advantages of breastfeeding and of the dangers of introducing supplements too quickly.

Breastfeeding and disease in later life

Breastfeeding may be associated with reduced juvenile-onset diabetes mellitus [24] and neoplastic disease in childhood [25]. It is possible that some of these benefits are related to the avoidance of cows' milk during early life rather than to breastfeeding per se, for example it is possible that early exposure to bovine serum albumin could trigger an autoimmune process leading to juvenile-onset diabetes. Breast milk is a particularly important ingredient in the diet of preterm infants as it appears to help prevent necrotizing enterocolitis among these particularly vulnerable babies.

Breastfeeding and breast cancer

There is an epidemic of breast cancer among women in the developed countries of the Western world. A number of recent studies have shown a reduced risk (~10%) of premenopausal breast cancer among women who have breastfed their babies [26]. Because breastfeeding appears to have no effect on the incidence of postmenopausal breast cancer, its overall protective effect will be relatively small but the protection offered by lactation still represents an important advantage against a much feared and common disease.

Breastfeeding and fertility

The natural contraceptive effect of breastfeeding has received scant attention in the Western world because it is not a reliable method of family planning in all cases. Nevertheless, on a population basis, the antifertility effect of breastfeeding is large and of major importance in the developing world. It has to be remembered that the majority of women in the developing world do not use artificial contraception and rely on natural checks to their fertility. By far the most important of these natural checks is the inhibition of fertility by breastfeeding. In many developing countries, mothers breastfeed for 2 years or more, with the effect that their babies are spaced at intervals of about 3 years. In the developing world, more pregnancies are still prevented by breastfeeding than by all other methods of family planning combined. The current decline in breastfeeding in the developing world is a cause for great concern because, without a sharp rise in contraceptive usage, the loss of its antifertility effect will aggravate the population increase in these countries.

Mechanisms of lactational amenorrhoea

The mechanisms of lactational amenorrhoea are complex and incompletely understood. The key event is a suckling-induced change in the hypothalamic sensitivity to the feedback effects of ovarian steroids. During lactation, the hypothalamus becomes more sensitive to the negative feedback effects and less sensitive to the positive feedback effects of oestrogen. This means that if the pituitary secretes enough follicle-stimulating hormone to initiate the development of an ovarian follicle, the consequent oestrogen and inhibin secretion will inhibit gonadotrophin production and the follicle will fail to mature. During lactation there is inhibition of the normal pulsatile release of luteinizing hormone from the anterior pituitary gland which is consistent with these observations.

From a clinical standpoint, the major factor is the frequency and duration of the suckling stimulus, although other factors such as maternal weight and diet may be important confounding factors. If supplementary food is introduced at an early stage, the suckling stimulus will fall and early ovulation and a return to fertility will be the consequence.

Breastfeeding and obesity

Artificially fed children have twice the risk of childhood obesity compared with breastfed children [27]. Breastfed children also have a significantly reduced blood pressure [28]. These children have a significantly reduced chance

Table 31.6 Prevalence of breastfeeding from birth until 9 months, 1985–2013.

	1985	1990	1995	2000	2005	2013
Birth	63	62	66	69	76	74
6 weeks	41	42	42	42	41	
4 months	26	28	27	28	27	12
6 months	23	22	21	21	22	
9 months	14	14	14	13	12	1

of being obese as adults and dying prematurely from cardiovascular disease. These reports are primarily observational studies, and therefore some caution must be observed as the risks are multifactorial.

Trends in infant feeding in the UK

Because of the many advantages of breastfeeding, it is important that mothers are given accurate information and encouraged to breastfeed successfully whenever possible. Conversely, mothers who choose to bottle-feed should be given proper instructions on best practice and be supported in their decision. In the UK, about 74% of mothers overall start to breastfeed but many discontinue after a short time. The prevalence of breastfeeding in the UK up to 2013 is shown in Table 31.6 and the figures have shown no significant change over the previous 10 years, although a small increase in breastfeeding at birth is noted. Factors associated with a higher breastfeeding prevalence include higher social class, primiparity, older age of mother and place of residence (mothers in the south of the UK have a higher prevalence). In attempting to improve these disappointingly low rates of successful breastfeeding, it is important that health professionals should understand the physiology of lactation.

Physiology of lactation

At puberty, the milk ducts that lead from the nipple to the secretory alveoli are stimulated by oestrogen to sprout, branch and form glandular tissue buds from which milk-secreting glands will develop (Fig. 31.2). During pregnancy, breast tissue is further stimulated so that pre-existing alveolar–lobular structures hypertrophy and new ones are formed. At the same time milk-collecting ducts also undergo branching and proliferation. Both oestrogen and progesterone are necessary for mammary development in pregnancy but prolactin, growth hormone and adrenal steroids may also be involved. During pregnancy only minimal amounts of milk are formed in the breast despite high levels of the

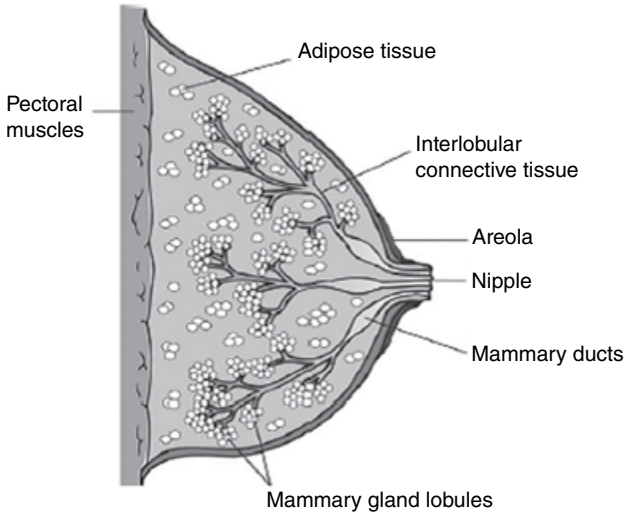

Fig. 31.2 Structure of the lactating breast.

lactogenic hormones prolactin and placental lactogen. This is because the actions of these lactogenic hormones are inhibited by the secretion of high levels of oestrogen and progesterone from the placenta and it is not until after delivery that copious milk production is induced.

Milk production

Two similar but independent mechanisms are involved in the establishment of successful lactation (lactogenesis): the first causes release of prolactin, which acts on the glandular cells of the breast to stimulate milk secretion (Fig. 31.3), and the second induces release of oxytocin, which acts on the myoepithelial cells of the breast to induce the milk ejection reflex (Fig. 31.4). Although these two mechanisms are similar, in that they can both be activated by suckling, they are mediated through two entirely different neuroendocrinological pathways. As can be seen in Figs 31.3 and 31.4, the key event in lactogenesis is suckling and the sensitivity of the breast accommodates itself to this important activity. During pregnancy the skin of the areola is relatively insensitive to tactile stimuli but becomes much more sensitive immediately after delivery. This is an ingenious physiological adaptation which ensures that there is an adequate stream of afferent neurological stimuli from the nipple to the hypothalamus to initiate and maintain the release of prolactin and oxytocin, both of which are required for successful lactation.

Milk ejection reflex

Successful breastfeeding depends as much on effective milk transfer from the breast to the baby as on adequate milk secretion. The milk ejection reflex is mediated by

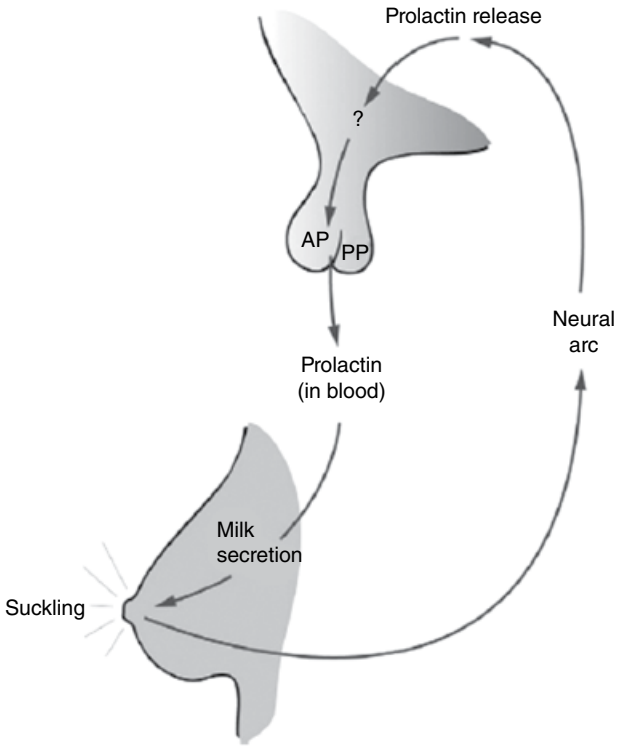

Fig. 31.3 Pathway of prolactin release from the anterior pituitary (AP).

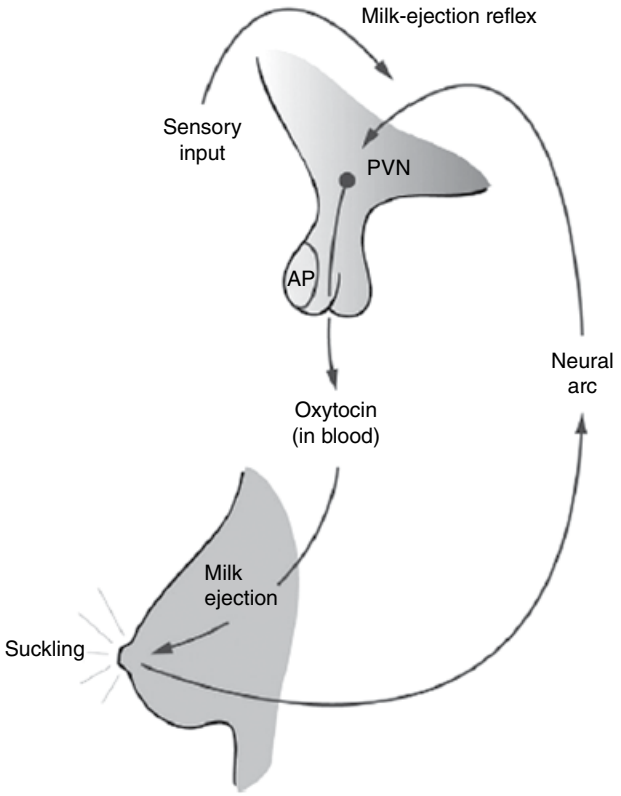

Fig. 31.4 Pathway of oxytocin release from the posterior pituitary. PVN, paraventricular nucleus.

the release of oxytocin from the posterior pituitary gland (see Fig. 31.4). Oxytocin causes contraction of the sensitive myoepithelial cells that are situated around the milk-secreting glands and also dilates the ducts by acting on the muscle cells that lie longitudinally in the duct walls. Contraction of these cells therefore has the dual effect of expelling milk from the glands and of encouraging free flow of milk along dilated ducts. This is recognized by the mother as milk 'let-down' and she may be aware of milk being ejected from the opposite breast from which the baby is suckling. In contrast to prolactin, which is secreted only in response to suckling, oxytocin can be released in response to sensory inputs such as the mother seeing the baby or hearing its cry. Oxytocin has a very short half-life in the circulation and is released from the posterior pituitary in a pulsatile manner. The highest levels of oxytocin may be released prior to suckling in response to the baby's cry, while prolactin is released only after suckling commences. The milk ejection reflex is readily inhibited by emotional stress and this may explain why maternal anxiety frequently leads to failure of lactation. Successful breastfeeding depends on engendering confidence in the mother and ensuring correct fixing and suckling on the nipple.

Another factor is of potential physiological importance as an inhibitor of breast milk: if the milk is not effectively stripped from the breast at each feed, this will inhibit lactopoiesis and lead to a fall in milk production.

Volumes of breast milk

During the first 24 hours of the puerperium the human breast usually secretes small volumes of milk, but with regular suckling milk volumes steadily increase and, by the sixth day of the puerperium, an average volume of 500 mL will be taken by the baby. Once lactation is fully established, an average daily milk volume is about 800 mL. In well-established lactation, it is possible to sustain a baby on breast milk alone for 4–6 months.

Management of breastfeeding

Despite the fact that it is a physiological event, many women experience difficulties in establishing breastfeeding. The greatest asset that a nursing mother can have is the support of an experienced and sympathetic counsellor. This counsellor may be a midwife, a health visitor or a lay person but the creation of a relaxed and confident environment is vital for successful breastfeeding. Babies are individuals, so there is no simple strategy that works in every case; mothers should be

Table 31.7 Ten steps to successful breastfeeding.

1	Have a written breastfeeding policy
2	Train all staff
3	Inform all pregnant women about the benefits and management of breastfeeding
4	Help mothers to initiate breastfeeding within 30 min of birth
5	Show mothers how to breastfeed
6	Foster the establishment of breastfeeding support groups
7	Practice 24-hour rooming-in
8	Encourage breastfeeding on demand
9	Give newborn infants no other food or drink, unless medically indicated
10	Use no artificial teats

encouraged to learn to respond to their own babies but all too often well-meaning but dogmatic and conflicting advice is given. The best approach is to give mothers all the options and let them make their own decisions; they will soon learn by trial and error what is best for their own babies. As an important stimulus to the promotion of effective breastfeeding, the concept of 'baby-friendly' hospitals has been developed, with breastfeeding an important part of that assessment. The Baby-Friendly Initiative has adopted 10 successful steps to breastfeeding as its central strategy and these are outlined in Table 31.7. Support for the breastfeeding mother is both an art and a science and the reader is referred to some of the detailed texts on the subject [29,30].

Suppression of lactation

Those women who do not wish to breastfeed should not be given any medication to suppress lactation routinely. They should be encouraged to use non-pharmacological approaches initially and only if these fail should a pharmacological approach be used. The drug of choice is cabergoline 1 mg stat to prevent lactation or 0.25 mg twice daily for 2 days to suppress established lactation. Bromocriptine is contraindicated due to the risk of heart attack and stroke.

Summary box 31.1

- The physiological changes that occur during pregnancy are reversed after birth and return to their normal pre-pregnancy state over a period that varies from 6 weeks to 6 months.
- Thromboembolism remains a major cause of maternal death, which in the majority of cases is avoidable with prompt and appropriate treatment.
- Puerperal infection remains a major cause of maternal death worldwide and in the majority of cases is avoidable with prompt recognition of the clinical symptoms and signs and subsequent treatment.
- Postpartum monitoring of urinary function is essential to avoid urinary retention and subsequent long-term bladder dysfunction.
- Postnatal suicide is an increasing cause of maternal death and there is therefore a need for antenatal and postnatal vigilance in detecting at-risk mothers and ensuring they receive appropriate psychiatric support.

Neonatal Care for Obstetricians

Simon Hannam

Neonatal Intensive Care Unit, Great Ormond Street Hospital for Children, London, UK

Management decisions during pregnancy and labour require knowledge of neonatal care and outcome. The informed obstetrician will thus more confidently deal with prospective parents' questions and be more engaged in the collaborative planning of perinatal care, particularly in high-risk pregnancies or where the fetus is at high risk of neonatal complications. This chapter therefore focuses on the basic neonatal knowledge required by the practising obstetrician but also provides a personal perspective gained from experience of some of the determinants of success and occasional failure of perinatal care. A neonatal reference text should be consulted for more detail on transitional physiology, neonatal resuscitation, neonatal conditions and management to augment the brief notes included later in this chapter.

Anticipation and levels of neonatal care

After birth, 90% of babies are cared for by their mothers and healthcare professionals should aim to facilitate this natural process. Approximately 8–10% of babies require more than normal care and about 2–3% need intensive care (level 3) following delivery; the majority of these may be anticipated because of impending prematurity, fetal abnormalities or concerns about fetal well-being. Care in complex cases requires multidisciplinary involvement, good planning and handover of respective responsibilities and duties of care from obstetrician and midwife to the neonatal team. Anticipating potential problems during the antenatal period facilitates the achievement of excellent care and helps avoid the unexpected becoming an uncontrolled emergency.

Other care categories are special care (level 1) or high-dependency care (level 2). Levels 1–3 are delivered in the neonatal unit. If the baby's condition allows, a level of care sometimes referred to as 'transitional care' is delivered usually on a postnatal ward and aims to avoid separation of mother and baby and to promote breastfeeding. Healthcare professionals support the mother to deliver medical care that may not be safely provided at home. Promotion of and support for breastfeeding is essential at all levels of neonatal care.

Summary box 32.1

Promoting good neonatal outcome in high-risk deliveries

- Anticipation and management of potential problems requiring specialist neonatal care is facilitated by multidisciplinary communication.
- Explicit, detailed and well-documented explanation of anticipated neonatal scenarios after delivery allows clear pathways of care to be agreed with parents before birth.

Antenatal communication and care plans

Anticipation and management of potential problems requiring specialist neonatal care is facilitated by multidisciplinary communication. The essential role of the neonatologist in antenatal discussions is to ensure that a comprehensive plan for delivery (timing, mode and place) and clear plans for resuscitation and stabilization are in place. The possible scenarios following birth need to be clearly discussed with parents to ensure their views and aspirations are fully taken into account when plans are agreed. The neonatal management plan will include the personnel and expertise of staff required at the delivery and the level of resuscitation deemed appropriate.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

The planning of place of delivery is especially important for infants with an antenatal diagnosis of a surgical condition. Antenatally there should be multidisciplinary discussions between parents, neonatolgists and surgeons as well as obstetricians in order to provide information regarding survival and treatment options.

Documentation

The neonatal plan for complex babies should be clearly documented and copies made available in the maternal case record, the hand-held maternal notes and the neonatal service pending file. These plans will involve resuscitation, specialist management (e.g. cardiac or surgical) and likely scenarios that may require different pathways of care. The plans should also detail the mother's feeding intention, particularly if feeding after birth is anticipated to be problematic (e.g. extreme prematurity and some surgical cases). In some cases where only compassionate care is required, detailed plans should include pain relief and comfort feeds and may also include hospice care plans.

Antenatal counselling and late karyotype

Knowledge of the karyotype can reduce uncertainty when considering the longer-term prognosis of the high-risk fetus. Not always considered is the value to the neonatologist of knowing the karyotype for planning the extent of resuscitation even if parents are unwilling to terminate the pregnancy on the basis of an abnormal karyotype. In such cases, a late karyotype specifically to inform early neonatal management is invaluable and may prevent active resuscitation when a more appropriate plan may be to provide compassionate care and support for the family.

Timing of delivery

Consideration of the multidisciplinary management of the baby after elective delivery facilitates team coordination. It is essential to ensure appropriate members, equipment, investigations and theatres are available if these should be required. In addition, anxious parents should not have their expectations and confidence dashed by unrealistic or non-existent perinatal plans.

Resuscitation plan for high-risk deliveries

Formal resuscitation plans are required for certain high-risk deliveries, such as extreme prematurity at the margins of viability, some serious fetal malformations that may require specialist intervention and stabilization, or if there is uncertainty about survival and long-term outcome. Explicit, detailed and well-documented explanation of anticipated neonatal scenarios after delivery allows clear pathways of care to be agreed with parents before birth. A well-meaning reassurance that the paediatrician or neonatologist will be present at delivery is inadequate and unhelpful. Therefore it is essential that engagement and timely communication between professionals involved antenatally (obstetrician, midwife, fetal medicine specialists, clinical geneticists, fetal cardiologists or surgeons) and a senior neonatologist is required in all cases where neonatal resuscitation and early stabilization may be needed before definitive management can be started. Such engagement will provide full and detailed information to the family and permit a written plan to be agreed with the parents and other professionals. The plans help to avoid confusion, especially if spontaneous labour and delivery occurs after-hours or pre-empts planned delivery.

Resuscitation guidelines

Plans for resuscitation need to take into consideration the various resuscitation guidelines that have been produced by international and national bodies, such as the International Liaison Committee on Resuscitation (ILCOR), the Royal Colleges and the British Association for Perinatal Medicine [1]. The ethical and practical issues of starting, withholding or withdrawing (or redirecting) resuscitation and neonatal intensive care should be explicitly considered and discussed with the family [2,3]. Palliative care may be a positive option but needs to be discussed and planned in detail. These discussions help prepare families and staff for the different outcomes following birth.

In the UK the guidelines are heavily reliant on data obtained by the population-based EPICure studies of 1995 [4] and 2006 [5]. There have been significant advances in health service organization and perinatal management, including use of antenatal steroids, surfactant and ventilation techniques. The outcome data of the EPICure 2 showed that survival increased in babies born between 22 and 25 weeks' gestation from 40% in 1995 to 53% in 2006 (P <0.001) [5]. This improvement in survival demonstrates that guidelines need to be continually reviewed in the light of advances in care.

Compassionate and palliative care

Palliative care after birth may be the preferred option for some babies. There is increasing awareness of the need for palliation, improving management and increasing availability of resources for neonatal palliative care. Planning before birth for such a care pathway helps parents establish links with caring staff and plan visits to palliative care centres if needed and avoids delays in hospital.

Communication following neonatal death

In circumstances where neonatal death is the outcome, family support by neonatal staff should include the antenatal team wherever possible. Continuing engagement by the obstetric staff in the postnatal care of the baby and family is especially helpful when the outcome is death or significant early morbidity. This ongoing communication between the antenatal and postnatal teams improves quality of care for the individual family and for all babies in general, as open dialogue fosters respect and support.

Organization of neonatal services

Providing the appropriate level of care for the mother and/or her baby requires careful planning and well-organized and integrated health services.

Managed neonatal clinical networks

Managed health service networks aim to deliver appropriate healthcare to a defined local population in the most effective and efficient manner. Specialized neonatal care is a high-cost, low-volume service that is increasingly delivered in managed networks. In 2009, the UK Department of Health *Toolkit for High-Quality Neonatal Services* [6] set the standards of care that should be provided for preterm or sick infants. Included in these recommendations was the stipulation that neonatal care should be delivered in managed clinical networks.

Within each network, different hospitals provide a range of care as agreed by that network. The level of care provided by each hospital is based on resources, capacity, geography and the availability of appropriately skilled and trained staff. A network consists of at least one neonatal intensive care (level 3) unit providing intensive care facilities, with specialist staff and facilities. The various network hospitals collaborate to ensure that every infant has access to the most appropriate level of care. The development of coterminous maternity networks are also enhancing the organization of perinatal services.

In the UK, neonatal intensive care (level 3) units provide care for extremely preterm babies and the sickest term babies requiring all levels of advanced respiratory support and parenteral nutrition. These units have 24-hour cover from specialized nursing staff and neonatal specialist doctors. Local neonatal (level 2) units provide respiratory support for babies of 28 weeks' gestation or more and special care (level 1) units provide care for babies that do not require respiratory support for prolonged periods (usually 24–48 hours only).

Neonatal transport

Ensuring that babies receive the appropriate level of care ideally requires delivery in the correct place if delivery is predictable and safe antenatal transfer of mother is possible. Postnatal transfer of babies to the correct level of unit after delivery also needs to be available. Specialist neonatal transfer services are evolving that have the expertise and equipment and thus help to avoid depleting specialist staff from the either the referral unit or the specialist centre. A major role of the neonatal networks is to ensure that pregnant women are transferred to the most appropriate setting if it is predicted that their baby will need a higher level of care than that provided by the admitting hospital. In order to facilitate family involvement, it is also expected that the infant should be cared for within the network rather than being transferred great distances.

Birth and postnatal adaptation: neonatal resuscitation

Only 1% of normal birthweight babies require active resuscitation after birth and only 0.2% require advanced resuscitation including endotracheal intubation. Although the need for resuscitation may be predictable based on risk factors, 30% of babies requiring resuscitation are not predicted. Babies who may be at risk of not making a successful adaptation without assistance include those in the following groups: preterm births (usually <36 weeks), those with known fetal complications, infants of diabetic mothers, fetal distress, fresh meconium-stained liquor, malpresentation and breech, multiple pregnancies, caesarean section under general anaesthesia or for fetal distress, risk of fetal infection and instrumental delivery.

In the UK, the Royal College of Paediatrics and Child Health (RCPCH), the Royal College of Obstetricians and Gynaecologists (RCOG) and the Royal College of Midwives (RCM) have published their recommendation that all professionals present at the time of birth are proficient in resuscitation of the newborn [7]. Basic neonatal resuscitation is now a requirement of training for obstetricians and midwives and advanced resuscitation for neonatal paediatricians and practitioners.

Antenatal and newborn screening

Antenatal screening continues after birth with newborn screening programmes. In the UK, antenatal screening includes the National Health Service (NHS) fetal anomaly,

Table 32.1 NHS Newborn Blood Spot Screening Programme.*

*Blood sample taken at 5–8 days after birth.

infectious diseases in pregnancy and sickle cell and thalassaemia screening programmes. These results influence antenatal management of mother and fetus and, in some cases, postnatal management of the newborn. The NHS National Screening Committee recommendations for systematic neonatal population screening include the following.

- NHS Newborn and Infant Physical Examination (NIPE) Screening Programme carried out within 72 hours and then repeated at 6–8 weeks. The specific areas included are the detection of congenital cataracts (red reflex), congenital heart disease, developmental dislocation of the hip and cryptorchidism in boys.
- Newborn Hearing Screening Programme (NHSP) carried out within 2 weeks by automated otoacoustic emission (AOAE) in well babies and automated auditory brainstem response (AABR) in babies following neonatal intensive or special care.
- NHS Newborn Blood Spot Screening Programme involves taking a blood sample at 5–8 days after birth in term babies. There are currently differences in the tests included in the different countries within the UK (Table 32.1).

Neonatal outcome

Prematurity

Prematurity is the major determinant of neonatal outcome in developed countries. The preterm birth rate (live births occurring before 37 weeks' gestational age) is 5–9% in Europe and 12–13% in the USA and is increasing. In the USA there has been a 31% increase in prematurity since 1981 [8]. In England and Wales, there were 700 000 liveborn babies in 2013, 7% preterm and 1.0% less than 32 weeks' gestation [9].

The infant mortality rate (deaths at less than 1 year of age) in term infants was 3.8 per 1000 live births compared with 21.1 for preterm infants. Of those born at less than 32 weeks of gestation, 15% resulted in an infant death and this accounted for over half of all infant deaths. Variation may be due to methodological differences such as case ascertainment, selection bias, and varying outcome definitions and follow-up duration. Reports from geographically defined population-based studies show lower survival rates than single-centre selective studies that are subject to bias.

Variation in preterm birth rates (all births) also appears to have a major influence on reported neonatal mortality rates between populations. Compared with other European regions, the delivery rate per 1000 births between 22 and 31^{+6} weeks in two regions in England (Trent: 16.8, 95% CI 15.7–17.9; Northern: 17.1, 95% CI 15.6–18.6) was significantly higher compared with a group mean of 13.2 (95% CI 12.9–13.5) [10]. Live birth rates showed similar trends. When comparisons were made between regions after adjustment for prematurity rates, the variation in survival outcomes was reduced.

Perinatal management policies and differences in perinatal healthcare provision as determinants of survival are inadequately quantified. The extent to which obstetricians use antenatal steroids and actively manage delivery and whether neonatologists perform resuscitation and redirection of care during intensive care, all potentially have effects on reported survival and outcome.

At the extremes of viability, biological variation and ethical considerations are important in determining management policies. Policies based simply on gestation at birth are inadequate and prediction of outcome may be more accurate if gender, exposure to antenatal steroids, single or multiple births and birthweight are considered with gestation.

Survival

Advances in perinatal care have resulted in a significant increase in survival of preterm babies. Survival in late preterm babies (32–36 weeks) is 98–99%. There are limited data on longer-term morbidity in this group but recent reports suggest this neglected area should be studied in greater detail. There are five times more late preterm babies born than babies born before 32 weeks' gestation and therefore as a group require considerable healthcare resources.

Babies born before 28 weeks' gestation have shown the greatest increase in survival since the advent of modern perinatal care. Few babies less than 28 weeks' gestation survived until techniques were developed during the

1960s and 1970s to provide respiratory support. Over the following two decades, the use of antenatal corticosteroids, use of surfactant and improvements in respiratory support have resulted in striking improvements in reported survival.

The EPICure study of all births between 22 and 25 weeks' gestation in the UK and the Republic of Ireland during 1995 provided important population-based information on babies born at the borderline of viability [4,11]. During the study regionalized neonatal care was poorly developed. This study was repeated in the UK during 2006 for babies born between 22 and 26 weeks' gestation in England [5]. Survival overall increased from 40 to 53% as well as at each week of gestation. The development of more regionalized neonatal care delivery in the UK, with increasing use of managed neonatal networks during the period between the two studies, may have contributed to the improvement.

Neonatal mortality and early morbidity

Neonatal death in preterm births is largely due to respiratory complications, periventricular haemorrhage and infection. Antenatal steroids, the use of early surfactant and continuous positive airway pressure are all associated with a reduction in death and morbidity.

Childhood morbidity

Neurodevelopmental sequelae of prematurity present during the first 5 years after birth and include cerebral palsy, poor cognitive performance and sensory impairments (visual and auditory deficits). During later years, academic underachievement and behavioural sequelae may occur. The definitions used for neurodevelopmental impairments and disability between studies are not uniform but more rigorous definitions are evolving. Disability reported in studies usually refers to one or more severe functional impairments, including non-ambulatory cerebral palsy, developmental quotient or IQ of less than −2 or −3 standard deviations from the norm, blindness and hearing impairment not improved with aids.

Neuromotor domain

Although cerebral palsy is the most commonly quoted outcome after very preterm birth, developmental and cognitive impairments are more common. The term refers to static injury to the developing brain that affects motor function. Different patterns are described and most commonly after preterm birth spastic diplegia is found. Of infants born between 22 and 26 weeks' gestation who were evaluated at 3 years of age in EPICure 2, 14% had cerebral palsy with increasing proportions at lower gestation [12] and it is more commonly seen in boys. Overall rates do not appear to be changing significantly as survival increases, but there is concern that the absolute prevalence will increase with increased survival of the most immature babies.

Developmental domain

The most common disability at 3 years is developmental or cognitive impairment, affecting up to 45% of extremely preterm babies [12]. As gestational age increases, the percentage of those with developmental impairment decreases. During the school years this domain of impairment is even more significant.

Sensory and communication domain

The prevalence of severe impairment of hearing and vision in very preterm babies is relatively low (hearing impairment not improved with aids <2%, blindness <3%). Less severe impairments are more common and include squints and refractive errors.

Academic attainment

Cognitive impairment appears to be the major determinant of school performance. At 8–9 years, approximately 20% of very low birthweight babies require special education and for those in regular schools, 25% repeat a year and 11–15% receive special help. At 11 years, the EPICure cohort showed significantly lower academic attainment compared with controls [13]. The proportions requiring special educational support was 62% of the extremely preterm group compared with 11% for the term controls (odds ratio, OR 13.1, 95% CI 7.4–23.3). Statements of Special Educational Needs were issued for 34% of the preterm cohort compared with 0.7% for controls (OR 76, 95% CI 10–552).

Behavioural/psychiatric sequelae

There is an excess of attention deficit hyperactivity disorder (ADHD) among preterm survivors. A meta-analysis of six follow-up studies revealed a relative risk of 2.64 (95% CI 1.85–3.78) among preterm babies. The EPICure study found ADHD in 11.5% of preterm babies and in 2.9% of term controls (OR 4.3, 95% CI 1.5–13) and autism spectrum in 8% compared with 0% in term controls [14].

Outcome in teenage and adult survivors

Various functional limitations occur in 86% of early teenage survivors with birthweight below 750 g. Growth disorders (49%), mental or emotional problems (58%), restrictions on physical activity (32%) and visual impairment (31%) are found and 75% use aids such as spectacles and medication. However, in a study of health-related quality of life in adolescent survivors with birthweight below 1000 g, the proportion that scored within the normal range was similar to normal-birthweight adolescents.

Although fewer adult very low birthweight survivors go on to higher education than their peers, they are less likely to engage in risk-taking behaviour and social integration is not impaired.

Health and social care and educational resource utilization

There is a significant increase in utilization of public health, social and educational services by extremely preterm survivors. During the 11th year of life, the EPICure study estimates of public sector costs were £4007 (SD £2537) for controls and £6484 (SD £2537) for the preterm cohort, a significant mean cost difference of £2477 (95% CI 1605–3360; P <0.001) [15].

Other morbidity

Many preterm survivors experience less severe problems such as clumsiness, visual impairment (e.g. squints, refractive errors), growth disorders and respiratory problems.

Respiratory

More than 50% of extremely low birthweight babies require hospital readmission during the first 12 months after discharge from the neonatal unit. These admissions are usually due to respiratory illness precipitated by lower respiratory infections. Chronic lung disease of prematurity or bronchopulmonary dysplasia (BPD) has been reported in up to 40% of very low birthweight survivors. The rate is higher as birthweight and gestation falls. Significant airflow limitation on lung function tests is found in adolescent survivors.

Growth

Growth failure is common during infancy and early childhood but adult stature within the normal range is achieved. Despite this catch-up, extremely low birthweight babies remain at a height disadvantage to normal birthweight controls. In the longer term, there are concerns that accelerated weight gain may lead to increased risk of hypertension and other cardiovascular diseases as well as type 2 diabetes.

Effect on family

The psychological distress that parents of high-risk preterm babies experience is greatest during the first month after birth and persists for the first 2 years. The greatest effect of stress is found in families of low income and lower parental education and with greater severity of functional disability in the child. By adolescence, despite the preceding years of emotional distress, families report positive interactions with friends and within the family, experience enhanced personal feelings of accomplishment and report both positive and negative effects on the marital relationship.

Summary box 32.2

Neonatal outcome in developed countries

- The majority of deaths before 1 year of age (infant mortality) follow preterm birth (66%).
- Advances in perinatal care have resulted in a significant increase in survival of preterm babies.
- Neurodevelopmental sequelae of prematurity present during the first 5 years after birth and include cerebral palsy, poor cognitive performance, attention deficit disorder and sensory impairments (visual and auditory deficits).

Important clinical conditions in neonatology

The most common reasons for babies to require neonatal management or admission are management of prematurity, respiratory distress and possible infection.

Common problems in neonatal care

Prematurity

Temperature control

Preterm infants are particularly susceptible to hypothermia due to their reduced body fat and energy stores. For this reason, the temperature of the delivery room should be maintained around 25 °C. Also, delivering very preterm infants into a plastic bag significantly increases their temperature on admission to the neonatal unit and improves early survival [16].

Respiratory distress syndrome (surfactant deficiency)

The respiratory distress syndrome caused by inadequate surfactant production is mainly a disease of the preterm infant. However, it can occur in term infants, particularly those of diabetic mothers or after caesarean section without labour. Affected infants may require mechanical ventilation and intensive care. The classical clinical presentation is an infant with tachypnoea, subcostal and intercostal recession and nasal flaring that becomes progressively worse over the first 60 hours after birth, and chest radiography shows a ground-glass appearance with air bronchograms. It can be associated with pneumothorax and intraventricular haemorrhage, although in more mature infants it normally resolves without sequelae. The combined use of antenatal corticosteroids and surfactant modify the illness, improving survival and reducing the rates of complications but have little effect on reducing the incidence of BPD or chronic lung disease, which occurs mainly in preterm babies.

Bronchopulmonary dysplasia or chronic lung disease of prematurity

This is a chronic condition affecting up to 50% of infants born at 26 weeks or less. For infants born at 32 weeks' gestation or less, it is defined as either an oxygen requirement at 36 weeks postmenstural age or at discharge, depending on which comes first [17]. Premature delivery, prenatal and postnatal inflammation and infection, ventilation, oxygen and poor nutrition are among the many factors contributing to the development and persistence of BPD. The underlying problem is an arrest in alveolar and peripheral vascular development. The severity is variable, ranging from the need for supplemental oxygen for several weeks to prolonged respiratory support with a ventilator or continuous positive airways pressure and even death. A small proportion of babies are discharged home on supplemental oxygen; most outgrow the need by 12 months of age. All babies born prematurely have an increased risk of respiratory illness within the first few years of life. This is increased in the group with BPD and respiratory problems may persist into adult life.

Retinopathy of prematurity

Infants who are born prematurely or have intrauterine growth restriction (IUGR) are at risk of developing abnormal retinal blood vessels which can lead to blindness. For this reason, retinal screening must take place in all infants born at less than 32 weeks' gestation and those who have a birthweight of less than 1501 g. Retinopathy of prematurity is associated with high levels of oxygen, although the BOOST II trial demonstrated that targeting lower levels of oxygen saturation was associated with an increase in mortality [18]. Laser therapy with ablation of the abnormal vessels results in improved outcome. Intravitreal injections of anti-VEGF (vascular endothelial growth factor) monoclonal antibodies are also being investigated as an alternative to laser therapy.

Brain injury in preterm babies

Preterm infants are at high risk of cerebral injury and consequent neurodevelopmental impairment. The proportion of preterm babies that have injury and impairment is inversely related to gestational age. There are two major patterns of brain injury.

1) Intraventricular haemorrhage may affect only the germinal layers or ventricles, in which case the prognosis is good. However, haemorrhage into the brain parenchyma is caused by haemorrhagic infarction and is associated with neurodevelopmental impairment.
2) Periventricular leucomalacia reflects loss of white matter, sometimes with cavitation. Whereas haemorrhagic parenchymal infarctions can usually be seen by cerebral ultrasonography, periventricular leucomalacia is difficult to see and is probably under-diagnosed.

Both these conditions seem to be becoming less common than a more subtle loss of cerebral matter. The usefulness of cerebral ultrasonography alone to predict neurological prognosis in extremely preterm infants is therefore limited. The more mature preterm infants with normal ultrasound scans at discharge from intensive care have a very low risk of neurodevelopmental impairment, whereas those with definable loss of brain tissue from whatever cause have a greater than 50% chance of long-term impairment. Early MRI scanning of the preterm brain is increasingly being used to delineate neuronal damage and predict long-term neurological outcomes [19].

Necrotizing enterocolitis

This poorly understood inflammatory disease is primarily a condition of preterm infants and those with congenital heart disease. It presents as an acute abdomen in the days or weeks after birth and varies in severity from mild to fatal. Diagnosis is clinical, aided by characteristic radiographic changes such as air in the bowel wall or biliary tree. Treatment can be conservative, with antibiotics and cessation of enteral feeding, but if there is a perforation of the bowel or medical treatment fails, surgery has to take place. Recent trials have suggested that probiotics might reduce the incidence of necrotizing enterocolitis [20] but this has not been supported by the PiPS trial, which could not demonstrate this finding using *Bifidobacterium breve* [21].

Small for gestational age associated with IUGR

In utero chronic hypoxia can affect many of the organs of the newborn infant with IUGR. In particular, fetal distribution reduces blood flow to the bowel, which can lead to necrotizing enterocolitis. The infants have poor thermoregulation and can become hypothermic or hyperthermic. Hypoglycaemia or hyperglycaemia can also be problematic. Polycythaemia can result in a hypercoagulable state leading to renal vein thrombosis and also jaundice due to the increase in erythrocyte numbers. A fetus with IUGR is more likely to develop birth asphyxia and also respiratory distress syndrome.

Hypoglycaemia

Conditions commonly associated with transient low blood glucose are hypothermia, infection, prematurity, IUGR and maternal diabetes. Some infants develop transient hyperinsulinaemia, particularly infants of diabetic mothers with poor antenatal control or those with severe rhesus disease. Rare causes include

Beckwith–Wiedemann syndrome and metabolic defects such as cortisol deficiency, galactosaemia and other enzyme defects of glycogenolysis, gluconeogenesis or fatty acid oxidation. Preterm infants are much less able to mount a ketotic response and hypoglycaemia should be treated promptly. Treatment is initially to give calories in the form of milk or as intravenous glucose infusion. If hypoglycaemia persists, investigations including insulin and counter-regulatory hormone measurements are required.

Jaundice

Jaundice is the most common clinical condition needing medical attention in newborn babies. It occurs in 60% of term and 80% of preterm babies during the first week. Jaundice beginning in the first 24 hours after birth is always pathological. It is usually unconjugated and the commonest causes are haemolytic anaemia or infection. Jaundice beginning on days 2–5 is commonly physiological, but unconjugated hyperbilirubinaemia may have many causes, including haemolytic disease, ABO incompatibility and glucose 6-phosphate dehydrogenase deficiency.

Phototherapy is the mainstay of treatment where treatment is indicated. Failure to control bilirubin levels with phototherapy may necessitate an exchange blood transfusion to avoid neurotoxicity such as kernicterus and hearing impairment. In the UK, the National Institute for Health and Care Excellence (NICE) guidelines for the screening and management of neonatal jaundice were published in 2010 [22]. Conjugated hyperbilirubinaemia signifies liver disease and requires urgent specialist investigation. These infants may be at risk of complications such as significant bleeding and neurological damage.

Respiratory conditions

Respiratory distress

Respiratory distress is one of the commonest problems encountered in the neonatal period. It is manifest by the clinical signs of tachypnoea (persistently over 60 breaths/min), intercostal recession, grunting, nasal flaring and tachycardia. If the baby becomes hypoxic, then cyanosis, apnoea and bradycardia may result. The presence of any signs of respiratory distress needs further evaluation and investigation. Tachypnoea with recession and nasal flaring is frequently the presentation of respiratory or cardiac disorders, while apnoea may be the presentation of a great many systemic disorders such as septicaemia, meningitis, gastrointestinal obstruction or heart disease.

Congenital pneumonia

Congenital pneumonia is a relatively common problem associated with a variety of microorganisms. The infant presents with respiratory distress and chest radiography shows patchy inconsistent shadowing. Treatment is with antibiotics and intensive care as required.

Meconium aspiration

Inhalation of meconium before or during delivery can be an extremely severe problem if pulmonary hypertension with reduced lung perfusion and severe hypoxaemia develop. Meconium may block large or small airways or both and lead to a ventilatory deficit. Although meconium aspiration may be apparent at birth, severe disease may present an hour or more later and it is important that babies suspected of having aspirated are carefully observed.

Treatment of meconium aspiration and associated pulmonary hypertension requires expert intensive care. Early surfactant administration may be beneficial, while high-frequency oscillatory ventilation and the administration of nitric oxide reduce mortality. When other measures fail, extracorporeal membrane oxygenation (ECMO) should be considered.

Transient tachypnoea of the newborn

Transient tachypnoea of the newborn is due to delayed reabsorption of lung liquid and leads to a moderate degree of intercostal recession and tachypnoea. In the preterm infant this can lead to marked respiratory distress, but in a term baby needing high inspired oxygen concentrations, other causes of respiratory distress should be excluded.

Infections

Newborn infants are particularly prone to perinatal infection. Risk factors include low birthweight, prolonged ruptured of membranes, maternal fever or chorioamnionitis. Indwelling cannulae, central venous lines and invasive mechanical ventilation increase the risk of nosocomial infection in those who require neonatal intensive care. Organisms responsible for later neonatal infection frequently come from the skin or gut. Breastfeeding helps promote normal gut flora and reduces the risk of acquired neonatal infections. Adherence to good hand-washing practices by all staff, parents and visitors can significantly reduce the risk of acquired infection.

Septicaemia

The signs of systemic sepsis are non-specific. Infants may present with apnoea, bradycardia or cyanotic episodes and poor feeding is a common association. They may be lethargic and hypotonic and are hyperthermic or hypothermic. Sepsis frequently presents as a metabolic acidosis or shock and occasionally causes petechial skin rash or severe jaundice.

Organisms that commonly cause infection in the newborn period include group B *Streptococcus* (GBS) and

Gram-negative organisms such as *Escherichia coli* or *Klebsiella*. The prolonged use, or multiple changes, of antibiotics in the antenatal period may increase the risk of infection with resistant organisms. Rapid treatment with antibiotics, immediate resuscitation and, frequently, mechanical ventilation is required. Investigations include chest radiography, blood cultures, urine culture, and examination and culture of the placenta. A lumbar puncture is performed once the baby is stable and will tolerate the procedure. The mortality of infants who develop septicaemia in the neonatal period is high, with a significant number of survivors developing subsequent impairment.

Group B *Streptococcus* infection

Mortality due to maternal colonization by GBS is reduced by antibiotic therapy to the mother during labour and early treatment of infants with evidence of infection. About 2% of infants of colonized mothers develop infections, and 70% of these manifest risk factors at birth such as preterm labour, prolonged rupture of membranes or meconium-stained liquor. Urgent antibiotic therapy is indicated for these infants. Well infants shown by surface cultures to be colonized do not require treatment. Recurrent GBS infection can occur, but more commonly GBS infection occurs later in infancy when meningitis is the presenting problem.

Meningitis

Signs of meningitis in newborn infants are non-specific. Meningitis usually presents as septicaemia and can be complicated by cerebral oedema, cerebral infarction, brain abscess or deafness. Common causal organisms are GBS and *E. coli*. *Listeria monocytogenes* is a rare cause of perinatal infection in the UK.

Eye infection

The majority of sticky eyes are not infected but are due to a blocked nasolacrimal duct. In the absence of conjunctival redness or swelling, investigation for infection and treatment with topical antibiotics is not required. Simple measures such as cleaning with boiled water and lacrimal duct massage suffice, with symptoms usually resolving in 3–6 months. Neonatal conjunctivitis can be caused by organisms such as *Staphylococcus aureus*, *Chlamydia trachomatis*, *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Neisseria gonorrhoeae*. Gonococcal ophthalmia usually presents within 24 hours of delivery with profuse purulent conjunctival discharge, and immediate diagnosis and treatment (systemic and topical) is required to prevent damage to the cornea.

Chlamydial ophthalmia, which is now among the commonest causes of neonatal conjunctivitis, presents between 5 and 12 days postnatal age; some babies infected as neonates will develop chlamydial pneumonia later in infancy. Corneal scarring is rare. Two weeks of systemic and topical treatment is required. The identification of either *N. gonorrhoeae* or *Chlamydia* in the baby requires referral of mother and her sexual partner for investigation and treatment.

Skin infection

Simple hygienic methods such as bathing and handwashing can prevent many skin infections. The infant's skin is vulnerable to infection by staphylococci, which usually leads to small pustules or lesions but which can also cause scalded skin syndrome with severe exfoliation. Staphylococcal infections should therefore be treated with antibiotics after appropriate cultures have been taken. Streptococci can also cause skin infection and both may cause systemic illness.

Infection of the umbilical cord is commonly limited to periumbilical redness with a small amount of discharge. The presence of oedema indicating cellulitis can occasionally lead to complications such as spreading cellulitis of the abdominal wall, fasciitis and septicaemia and requires treatment with systemic antibiotics.

Candidiasis usually presents after the first week with napkin dermatitis with or without oral thrush. Topical and oral treatment is required to prevent the candidiasis returning as the gut is colonized with *Candida*. Maternal nipple candidial infection can occur in breastfeeding mothers.

Tuberculosis

Tuberculosis is a re-emergent disease and many hospitals now offer bacille Calmette–Guérin (BCG) immunization to newborn infants. Infants born to mothers infected with active tuberculosis should be vaccinated with isoniazid-resistant BCG vaccine and kept with the mother while both receive treatment with appropriate drugs. Breastfeeding should be encouraged.

Tetanus

Neonatal tetanus due to infection of the umbilical stump by *Clostridium tetani* is the result of poor hygiene and is a distressing and severe condition with extremely high mortality. Opisthotonus and muscle spasms of the jaw and limbs are presenting features and can appear very rapidly after birth. Prevention centres on maternal vaccination during pregnancy and education to improve hygiene and change of local cultural practices.

Neurological conditions

Neonatal encephalopathy

Neonatal encephalopathy can be caused by hypoxic ischaemia due to birth asphyxia but also by other conditions including metabolic disorders and infections. These conditions should be excluded before a confident diagnosis of hypoxic–ischaemic encephalopathy (HIE) due to birth asphyxia can be accepted.

Hypoxia–ischaemia followed by resuscitation may lead to apparent recovery followed by inexorable deterioration beginning 6–8 hours later and ending in severe cerebral injury. Consequently, it is frequently difficult to determine the prognosis soon after birth on clinical grounds alone. However, if asphyxia is severe or happened some time before delivery, the infant will not develop spontaneous breathing; therefore, if despite advanced life support there is no sign of spontaneous breathing 20 min after birth, the outcome is extremely poor.

HIE is graded clinically and a frequently used grading system was described by Sarnat and Sarnat [23]. Infants with grade 1 encephalopathy have a very good prognosis whereas infants with grade 3 almost all die or are severely impaired. About half the infants with grade 2 have severe neurodevelopmental impairment. Unfortunately, a large number of infants at risk fall into grade 2, limiting the utility of the system.

Moderate hypothermia for perinatal HIE

In therapeutic hypothermia, the infant is cooled to between 33 and 35 °C in order to prevent neuronal loss following an asphyxial injury. Hypothermia can be induced by selectively cooling either the head using a cap or the whole body using a cooling mattress. The publication of studies using therapeutic hypothermia for 72 hours for HIE confirmed a significant reduction in death and disability. The Treatment of Perinatal Asphyxial Encephalopathy (TOBY) study showed that the treated group had a significantly increased survival without neurological abnormality at 18 months (relative risk, RR 1.57, 95% CI 1.16–2.12; $P = 0.003$) [24]. The risk of cerebral palsy in survivors was reduced (RR 0.67, 95% CI 0.47–0.96; $P = 0.03$) and there were significant improvements in both the Mental Development Index (MDI) and the Psychomotor Development Index (PDI) of the Bailey Scales of Infant Development 11 and also in the Gross Motor Function Classification System. A meta-analysis of three trials (767 patients) confirmed the significant reduction in death and severe disability at 18 months (risk ratio 0.81, 95% CI 0.71–0.93; $P = 0.002$), with a number needed to treat of 9 (95% CI 5–17) [25]. At 6 years of age, more children in the hypothermia group survived without neurological abnormalities (45%) compared with the control group (28%) (RR 1.6, CI 1.15–2.22) [26].

Therapeutic hypothermia is now accepted by most neonatologists in the UK as the standard of care for perinatal HIE. Research is progressing to find additional interventions to augment the benefit of hypothermia. It is important that eligible babies (36 weeks or more) are considered soon after birth for treatment as cooling should be commenced before 6 hours of age. The British Association of Perinatal Medicine has recently published recommendations for the use of therapeutic hypothermia in the UK [27].

Summary box 32.3

Hypoxic–ischaemic encephalopathy

- Neonatal encephalopathy can be caused by hypoxia–ischaemia due to birth asphyxia but other causes have to be excluded.
- The severity of HIE is graded clinically.
- Therapeutic hypothermia is effective in significantly reducing death and disability following perinatal HIE and is now a standard of care.

Cerebral palsy

Cerebral palsy is an umbrella term that describes the consequences of a non-progressive injury to the developing brain. The clinical manifestations include motor, sensory and cognitive deficits that may not be apparent until after 1 year of age and cannot be confidently diagnosed at birth. Although there is an association between neonatal encephalopathy and cerebral palsy, population-based studies have shown that only about 10% of all cases of moderate to severe neonatal encephalopathy in term babies are associated with intrapartum risk factors. Other risk factors for cerebral palsy are preterm birth or very low birthweight, perinatal infection, congenital malformations or multiple pregnancies [28–30].

Convulsions

Convulsions occurring just after delivery in term infants may be due to HIE, metabolic disorders, infections, hypoglycaemia, hypocalcaemia, and hypomagnesaemia or pyridoxine deficiency. Many otherwise idiopathic fits are caused by focal cerebral infarction, which have a much better prognosis than generalized hypoxic–ischaemic injury but are difficult to diagnose without MRI.

Brachial plexus injury

Brachial plexus injury occurs in 0.4–2.5 per 1000 live births. The commonest type, Erb's palsy, involves C5 and C6 nerve roots. The incidence has not declined over the past few decades but the prognosis for recovery has improved, with full recovery expected in the majority of babies with Erb's palsy. A fracture to the clavicle may also be present. Careful neurological examination is needed to determine the level of the lesion as this affects the prognosis for recovery of function. Associated Horner's syndrome is a bad prognostic sign.

Effects of maternal drug use

Infants of mothers who take drugs such as opiates, cocaine, amphetamines, barbiturates, benzodiazepines

and some other medical drugs may develop a withdrawal syndrome, with irritability, poor feeding, apnoea and fits. The babies of mothers who have high alcohol or nicotine intake may also exhibit withdrawal. Wherever possible the mother and baby should be kept together; in many cases breastfeeding is not contraindicated. If a history of maternal drug abuse was known antenatally, a plan of management can be agreed before birth and referral to the social work team may be appropriate. Management of a baby at risk of drug withdrawal involves careful observation and skilled nursing. If withdrawal is severe, treatment with opiates may be required. Naloxone should never be given to infants at risk of opiate withdrawal as it can provoke convulsions. Many labour wards no longer stock naloxone for fear it will be given inadvertently to an infant of a substance-abusing mother.

Congenital abnormalities

Cardiac

Some form of congenital heart disease affects between 7 and 9 per 1000 live births, of whom approximately one-quarter will present in the newborn period. Fetal anomaly ultrasound can detect many lesions but some are more difficult to diagnose. Neonatal presentation is normally due to cyanosis, heart failure and respiratory distress, and shock. Some conditions present with asymptomatic findings on neonatal examination such as a murmur, absent femoral pulses or tachyarrhythmia.

Cyanosis

Causes of cyanotic heart disease include transposition of the great arteries and conditions that reduce pulmonary blood flow such as tetralogy of Fallot and pulmonary or tricuspid atresia. Pulmonary blood flow in these conditions depends on arterial ductal patency and the degree of blood mixture between heart chambers. For those presenting in the neonatal period, immediate treatment is required to prevent the arterial duct (ductus arterious) from closing (by infusion of prostaglandin E_1) and transfer to a specialist paediatric cardiac centre.

Cardiorespiratory distress and heart failure

Causes of cardiorespiratory distress due to increased pulmonary blood flow or heart failure include left-to-right shunting though septal defects. The commonest causes are large ventricular septal defect and persistent patent ductus arteriosus.

Shock

Neonatal shock is usually due to major sepsis, significant hypovolaemia or blood loss or congenital heart disease. Congenital heart diseases causing shock include major interruption to the systemic circulation such as hypoplastic left heart syndrome, critical aortic stenosis and severe coarctation of the aorta or complex cardiac defects.

The asymptomatic murmur
