Murmurs are common in newborn infants and are frequently innocent. A thorough search for other signs of cardiac disease should be made and an expert opinion arranged where appropriate. It is important to remember that the mention of a heart murmur can strike panic into even the calmest of parents and the situation needs to be handled with great tact. Rapid definitive diagnosis by echocardiography is the mainstay of successful management.

Respiratory

Congenital diaphragmatic hernia

Herniation of the abdominal contents into the hemithorax leads to severe respiratory difficulties with persistent pulmonary hypertension and maldevelopment of the pulmonary arteries of all sizes. Most cases are diagnosed antenatally but infants can present unexpectedly with respiratory distress and cyanosis at birth. Essential early management involves the passage of a large-bore nasogastric tube into the stomach to prevent gaseous distension, ventilation and rapid transfer to intensive care. All these infants require tertiary-level intensive care, with access to sophisticated mechanical ventilation and modern vasodilator therapy such as nitric oxide. Surgery is delayed until the infant's respiratory status has been stabilized. Survival depends on the degree of underlying pulmonary hypoplasia and the presence of associated congenital anomalies such as cardiac defects. Overall a survival figure of around 60% is often quoted when counselling parents. ECMO can be carried out on infants with a congenital diaphragmatic hernia where medical therapy has failed although it's use in this situation is controversial. Long-term complications include persistent gastro-oesophageal reflux and respiratory problems; neurodevelopmental problems can develop if neonatal hypoxia was severe and has been shown to be worse in those infants treated with ECMO.

Gastrointestinal and abdominal wall defects

Oesophageal atresia and tracheo-oesophageal fistula

These conditions should be suspected when there is polyhydramnios or excessive mucus from the mouth at birth. The baby may show rapid onset of respiratory distress and cyanosis particularly after the first feed. Radiography after a nasogastric tube has been inserted confirms the diagnosis, showing the nasogastric or orogastric tube curling up in the oesophageal pouch (if atresia is present). Associated congenital anomalies occur in 50% or more of infants. Survival is usually determined by the severity of associated congenital anomalies and not the defect itself.

Abdominal wall defects

Exomphalos, in which part or all of the intestine and abdominal organs are in a peritoneal sac outside the abdomen, should be differentiated from gastroschisis, where a congenital defect of the abdominal wall allows herniation of the abdominal contents without a peritoneal sac. The former is frequently associated with other congenital defects while the latter is not. Urgent surgery is required if the amniotic sac has broken and for gastroschisis; immediate management is to wrap the abdominal contents in a plastic wrapper, taking care not to twist the bowel and disrupt its vascular supply. This should help prevent hypovolaemia due to fluid loss from the exposed bowel. The long-term outcome for most with exomphalos is determined by the presence of associated congenital anomalies. In gastroschisis, 90% or more now survive. However, their postnatal course is often protracted and parenteral nutrition may be required for several weeks with its risks and complications. In addition, bowel atresia and necrotizing enterocolitis may develop.

Intestinal obstruction

High intestinal obstructions usually present with vomiting that may be bile stained, and this ominous sign demands urgent investigation. Plain radiography of the abdomen can confirm the presence of obstruction by showing a lack of air in the lower gut or a sign such as the 'double bubble' of duodenal atresia. An upper gastrointestinal contrast study is required in any infant who presents with bile-stained vomiting in order to exclude malrotation and/or volvulus. Both of these conditions are time critical and infants who have produced bile-stained vomit should arrive in a surgical centre for asessment within 4 hours of the onset of symptoms. Hypertrophic pyloric stenosis does not usually present until 2–6 weeks of age.

Lower intestinal obstruction usually presents as failure to pass meconium within 24 hours followed by abdominal distension with or without vomiting. Causes include Hirschsprung's disease, meconium ileus due to cystic fibrosis, low bowel atresia or hypoplasia, and imperforate anus. A meconium plug can sometimes mimic obstruction especially in preterm infants.

Breastfeeding

The importance of breast milk and nutrition cannot be over-emphasized. Human breast milk is the preferred source of nutrition for both term and preterm babies and is associated with a significant reduction in both morbidity and mortality. Every effort should be made to encourage a mother to breastfeed. Breastfeeding within 30 min of a normal birth and early breast massage and expression within 6 hours of a preterm delivery is essential to establish breastfeeding. All professionals who care for women and their babies need to offer support and expert council to promote successful breastfeeding in challenging conditions of stress and ill health.

There are few genuine contraindications to breastfeeding but include some rare inborn errors of metabolism in the baby such as galactosaemia. It is not the practice in the UK to encourage HIV-positive mothers to breastfeed, but this is not the case in developing countries. Breastfeeding is generally safe for the baby if the mother requires medication; rarely, breastfeeding is absolutely contraindicated. Examples of drugs which require caution are given in Table 32.2. When prescribing for a breastfeeding mother it is wise to check that the drug prescribed is safe. Information can be found in the *British*

Table 32.2 Drugs and breastfeeding.

Breastfeeding contraindicated
Cytotoxics, immunosuppressants, ergotamine, lithium, phenindione, chloramphenicol, tetracyclines
Example of drugs to be used with caution during breastfeeding
Antiarrhythmics: amiodarone
Antibiotics: metronidazole
Anticonvulsants: gabapentin, levetiracetam, oxcarbazepine, phenobarbital, phenytoin, pregabalin, primidone, topiramate, vigabatrin
Antidepressants: doxepin, selective serotonin reuptake inhibitors (SSRIs)
Antihypertensives: beta-blockers
Anxiolytics: benzodiazepines, buspirone
Radioisotopes

Table 32.3 Frequently asked questions.

Is milk from the newborn infant's breast normal? *Answer*: Normal in boys and girls
Is vaginal bleeding in girls normal? *Answer*: Normal
What causes persistent sticky eye after culture and treatment of infection? *Answer*: Blocked nasolacrimal duct. Will recannulate spontaneously. Does not need probing
How often should a baby feed 'on demand'? *Answer*: Usually about 2–4 hours, but every 6 hours is not uncommon in healthy infants
My baby is squinting. Is this normal? *Answer*: Yes, in the first week after birth
Is my breastfed baby getting enough milk? *Answer*: If the baby is gaining weight properly, yes

National Formulary; if a contraindication, caution or a potential problem is identified, the advice of the local paediatric pharmacist or local drug information centre should be sought. Often alternative drugs can be prescribed and breastfeeding continued. Information is also available via websites such as www.ukmi.nhs.uk.

Many minor alterations in physiology cause alarm to parents. Some common questions and responses to them are outlined in Table 32.3. In the absence of disease, reassurance is all that is required.

Perinatal Epidemiology and Statistics

Dharmintra Pasupathy

Department of Women and Children's School of Life Course Sciences, King's College London, London, UK

Background

John Last in the *Dictionary of Epidemiology* defines epidemiology as the 'The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems'. It does not represent a body of knowledge or a specific organ system such as cardiology or neurology but instead represents methodology focused on improved understanding of the determinants of illness and disease. Modern epidemiology remains a young discipline of science. Although many excellent studies were conducted before, it was in the twentieth century where highly informative epidemiological studies were performed that have significantly informed clinical practice and public health. This includes, amongst others, the Framingham Heart Study, an ambitious cohort study which commenced in 1948 with the primary objective of identifying common factors or characteristics that contribute to cardiovascular disease (CVD) by following its development over a long period of time in a large group of participants, who had not yet developed overt symptoms of CVD or suffered a heart attack or stroke. In the original cohort of 5209 men and women between the ages of 30 and 62 from the town of Framingham, Massachusetts, extensive physical examinations and lifestyle interviews were conducted that were used to study the common patterns related to CVD development. From 1948 onwards, the original participants returned at regular intervals for collection of detailed information on medical history, clinical examination and laboratory tests. Subsequent second-generation participants were also recruited and in 2002 the study entered a new phase, the enrolment of a third generation of participants, the grandchildren of the original cohort. In the UK there have also been large-scale cohort studies, including the MRC-funded Richard Doll study in the 1950s, in which a cohort of general practitioners were followed up to study the influence of smoking on health and disease [1]. This pioneering work has had a global impact and was key in understanding the harmful effects of smoking. The UK is also home to a number of large-scale cohort studies, including the longest running birth cohort in the world, the 1946 Birth Cohort, and the Southampton Women's Survey, which recruited women prior to conception. In the MRC Cohort Strategic Review in 2014 it was reported that approximately 3.5% of the UK population are cohort members [2].

Reproductive and perinatal epidemiology is a branch of epidemiology that focuses on diseases and disorders of reproduction and/or events in the perinatal period. Perinatal epidemiology includes the study of both maternal and neonatal events. The interrelated nature of human reproduction and development provides the opportunity to develop well-designed prospective cohort studies with collection of longitudinal data at key periods of development in pregnancy and following birth, to understand the impact of pregnancy and development on long-term maternal and offspring health. The Avon Longitudinal Study of Parents and Children (ALSPAC), also known as Children of the 90s, based at the University of Bristol is a world-leading birth cohort study in which, between April 1991 and December 1992, more than 14 000 pregnant women were recruited. These women and the children of ALSPAC have since been followed up over two decades with annual questionnaires for the mothers, fathers and the children from age 5. Over 1200 publications have been published from data collected in this cohort. Perinatal medicine has also been informed by randomized controlled trials including some large international multicentre studies. These have informed and improved our obstetric practice in many areas, including the management of severe pre-eclampsia (MAGPIE Trial 2002), fetal growth restriction (GRIT Trial 2003, TRUFFLE Trial 2015) and breech delivery (Term Breech Trial 2000).

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

This chapter provides an overview of the different study design and quantitative methodologies available to address many of the key research questions in the discipline. Finally, it also provides an overview of the commonly used definitions, statistical methodology and inferences.

Study design

The premise of any research question or hypothesis is based on the relationship between an exposure and outcome of interest. In epidemiology, *exposures* are potential causal characteristics. It can refer to treatment (pharmacological and non-pharmacological behavioural interventions), behaviour (e.g. smoking, drug use), genotype or trait (e.g sickle cell disease, *BRCA1* gene mutation) or environmental (e.g. dust, pollution). *Outcome* refers to either disease states (e.g stillbirth) or clinical phenotypes that have the potential to increase adverse outcomes (e.g small for gestational age).

Study design is defined as the process in which a researcher or research team translates the hypothesis of interest through a detailed project plan into an operational study. The types of research conducted are broadly divided into observational and interventional research (Fig. 33.1). An observational study is when research is focused on the collection of health and socio-demographic variables related to exposure and outcome. These variables can range from population-based data (e.g census data) to specifically designed health-related questionnaires, clinical examination and collection of biomarker samples. Specifically in observational studies the data available from the subjects in the study are not dependent on an intervention administered by the study investigators. Observational research can further be categorized as descriptive or analytical. Descriptive studies are cross-sectional studies that report the incidence or prevalence of health-related states at a specific time point. They do not attempt to provide an association between the exposure and outcome. Observational studies which are analytical in nature are focused on determining the relationship between exposure and outcome through different study designs. In contrast, interventional studies are studies in which the investigator specifically provides an intervention with the aim of exploring the effect of the intervention on health-related outcomes. The choice of study design adopted by researchers will depend on the type of exposure and outcome being studied. All types of observational and interventional studies are described in detail in the following sections.

Cross-sectional studies

Cross-sectional studies involve observation of a total population, or a random subset of it, at a defined time. They provide information on an entire population under study and can describe absolute risks and not just relative risks. They can also describe the prevalence of disease. National audits of maternal and perinatal deaths are variants of cross-sectional surveys [3].

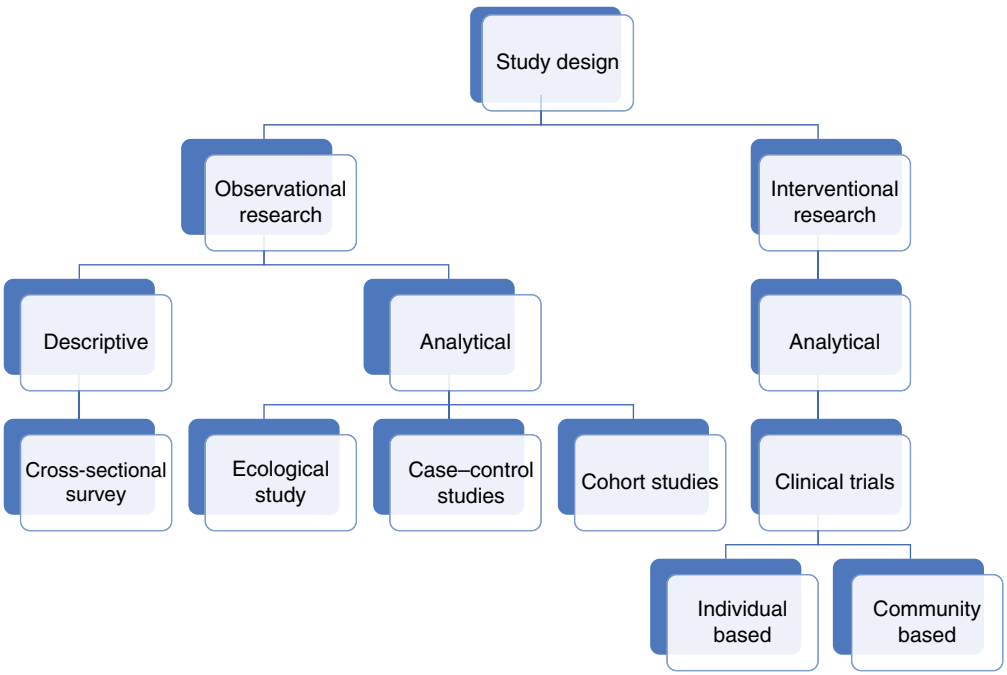

Fig. 33.1 Study design.

Summary box 33.1

Definitions used in maternal death audits

- *Maternal mortality ratio* (MMR): number of maternal deaths per 100 000 live births.
- *Maternal mortality rate*: number of maternal deaths per 100 000 maternities.
- *Total number of maternities*: the number of pregnancies that result in a live birth at any gestation or stillbirths occurring at or after 24 completed weeks of gestation and which are required to be notified by law. Multiple pregnancies are counted only once.
- *Direct maternal death*: the result of a complication of pregnancy, delivery or puerperium from interventions, omissions, incorrect treatment or from a chain of events resulting from any of the above.
- *Indirect maternal death*: a pregnancy-related death in a patient with a pre-existing or newly developed health problem that was not the result of direct obstetric causes but which was aggravated by the physiological effects of pregnancy.
- *Coincidental (fortuitous) maternal death*: other fatalities during, but unrelated to, pregnancy or the puerperium.
- *Late maternal death*: a death occurring after 42 days up to 1 year after abortion, miscarriage or delivery that is the result of direct or indirect maternal causes.

Summary box 33.2

Classification of perinatal deaths

- *Stillbirth*: a baby born without signs of life after 23^{+6} weeks of pregnancy. This can be further divided into:
  - Intrapartum stillbirth: a baby known to be alive at the beginning of labour but stillborn.
  - Neonatal death: death of a liveborn baby occurring before 28 completed days after birth. This can be further divided into (i) early (0–6 completed days) and (ii) late (7–27 completed days).
- *Perinatal death*: death of a fetus or a newborn in the perinatal period, which commences at 24 completed weeks' gestation and ends before seven completed days after birth (total of stillbirths and early neonatal death).

Cohort studies

Cohort studies are a form of longitudinal observational study used to analyse risk factors by studying groups of people who do not have the disease either retrospectively or prospectively (the preferred method). These are analytical observational studies in which the comparison of health outcomes between groups is defined by the exposure of interest. Participants in the cohort are defined by exposure and are followed up for a specific period. In pregnancy, examples of cohort studies in recent years include the SCOPE cohort (Screening for Pregnancy Endpoints), a multicentre international prospective cohort study of nulliparous women, and the POPS study (Pregnancy Outcome Predictive Study), also a prospective cohort of low-risk nulliparous women in Cambridge [4,5]. Both cohorts are focused on identifying predictors of preterm birth, pre-eclampsia and small-for-gestational-age (SGA) infants. SCOPE is primarily focused on early pregnancy factors associated with the outcomes of interest, whilst in the POPS study longitudinal clinical data, serum biomarker samples and ultrasound measurements were collected throughout pregnancy which may also provide mechanistic insight to development of disease. The cohort can also be selected by a specific event such as year of birth (a birth cohort). Examples include the 1946 Birth Cohort and the ALPSAC study previously described. The cohort design, which can be either retrospective or prospective, allows the study of multiple outcomes and exposures and specifically rare exposures (e.g. asbestos exposure). It is costly and not appropriate for rare diseases with a long latent period for the development of the outcome of interest.

Case–control studies

Case–control studies can be used for both retrospective and prospective studies. In a case–control study, participants are selected on the basis of the outcome of interest. People with the disease are cases and appropriate controls are selected without the outcome of interest to allow comparisons to be made between exposures of interest. Often controls are matched for characteristics within the group to reduce the bias in the comparison between the groups. For example, in the determinants of factors associated with endometrial cancer in postmenopausal women (cases), healthy controls are matched for age. Data are then collected in both groups and factor(s) that are different between the groups may demonstrate an association with the outcome of interest. Matching in case–control studies precludes the factor in which the groups are matched to be explored as a factor associated with the disease. In the example cited, the effect of age on endometrial cancer cannot be determined. In common with all observational studies, case–control studies do not prove causation but instead demonstrate association. The strength of association, coupled with biological plausibility, are some of the criteria used to suggest association as reported by the Bradford Hill Criteria (Table 33.1) [6].

Table 33.1 Bradford Hill Criteria.

1	Strength of effect size	A small association does not mean that there is not a causal effect, though the larger the association, the more likely that it is causal
2	Consistency	Consistent findings observed by different persons in different places with different samples strengthens the likelihood of an effect
3	Specificity	Causation is likely if there is a very specific population at a specific site and disease with no other likely explanation. The more specific an association between a factor and an effect, the bigger the probability of a causal relationship
4	Temporality	The effect has to occur after the cause (and if there is an expected delay between the cause and expected effect, then the effect must occur after that delay)
5	Biological gradient	Greater exposure should generally lead to greater incidence of the effect. However, in some cases, the mere presence of the factor can trigger the effect. In other cases, an inverse proportion is observed: greater exposure leads to lower incidence
6	Plausibility	A plausible mechanism between cause and effect is helpful
7	Coherence	Coherence between epidemiological and laboratory findings increases the likelihood of an effect
8	Experiment	Occasionally it is possible to appeal to experimental evidence
9	Analogy	The effect of similar factors may be considered

Inherent within the design of case–control studies, the selection of cases and controls by the investigator precludes any estimation of disease incidence. However, relative risk can be demonstrated between the groups. The control group is a sample of the total population and selected because they do not have the disease. To determine true population risk (incidence of the disease in a population) a larger cross-sectional study or cohort study is required. A variation of this method is the nested case–control study, where cases with a disease in a defined cohort (the nest) are identified and, for each, a specified number of matched controls are selected from the same cohort who have not yet developed the disease. The nested case–control design is easier and less expensive than a full cohort approach. Case–control studies are also particularly useful for rare diseases and diseases with long latency periods. If well designed, this approach will also allow examination of multiple exposures of interest. The temporal sequence of exposure and disease can sometimes be difficult to study in a case–control study and certainly the size of the study will need to be sufficiently large to study rare exposures, which often limits this design in some settings.

A retrospective study is one where the records are studied after all the events and outcomes have already occurred. The data are collected from a given population. Risk factors or disease outcomes are compared between subgroups that have different known outcomes. The study can be designed using a case–control or cohort model. This differs from a prospective study, which is conducted by starting with two groups that are selected by risk factor or randomized and subsequent future outcomes are noted. Retrospective studies have the following benefits: they are cheap, it is easier to collect large numbers and to select cohorts of disease and non-disease, and they are less time-consuming since the main effort required is the collection of data. However, they are limited by incomplete collection of data and recall bias. In contrast, prospective studies follow populations over time to study outcome. In population risk studies, a large number of negative controls will be collected depending on the disease incidence. Although the costs of these studies are significantly higher, they provide an opportunity to specifically tailor data collection.

Issues of confounding and bias limit all observational studies. A well-designed study does have the potential to limit these issues. *Confounding* is defined as the alternative explanation to the association found between exposure and outcomes. A confounder must be associated with both the exposure and the outcome and not be on the causal pathway between the exposure and the outcome. An example of a confounder in the association between coffee drinking and cancer is smoking. It is recognized that coffee drinkers are more likely to smoke and smoking is certainly associated with cancer. Identifying potential confounders allows investigators to design and collect data appropriately, which then has the potential to minimize confounding. At the design stage this includes restricting the study population, matching in case–control studies and randomization in interventional studies. At analysis stratification, standardization and statistical modelling (regression) are methods that can be utilized to minimize confounding. However, this is reliant on the data collected on potential confounders.

Bias is a systematic error that leads to a result which does not represent the truth (e.g. information bias, bias in data collection and reporting, selection of study

participants). Unfortunately, bias cannot be corrected through statistical analysis and can only be minimized by appropriate study design.

Randomized controlled trials

Randomized controlled trials (RCTs) are a type of interventional study design with superior methodology in medical statistical research because they reduce the potential for bias by random selection of participants to one intervention arm or to another intervention, non-intervention or placebo arm. The participants can be patients, health volunteers or communities (randomized cluster trials). This minimizes the possibility that confounding variables will differ between the two groups. However, not all studies are suitable for RCTs and the methodologies mentioned previously may be more suitable. In order to further reduce bias, the randomized trial may be designed as a double-blind RCT, where neither the clinician nor the participant knows which treatment arm the participant is in, or a single-blind RCT, where the clinician knows but the participant does not. In some circumstances an open label trial is carried out, where it is not possible to blind either the clinician or the patient but randomization is performed without bias at time of therapy.

Meta-analysis

Independent trials although well powered and designed at conception, occasionally do not demonstrate an effect of the intervention. Often trials are also repeated with conflicting results. Meta-analysis provides the opportunity to pool results from different studies if sufficiently similar (heterogeneity) with respect to trial population and outcomes of interest. This approach increases the power to detect smaller differences that were not identified in individual studies. It also increases the precision of the effect size observed. The weighted average of the combined effect size is estimated. This is related to the sample size of the individual studies and the effect size observed.

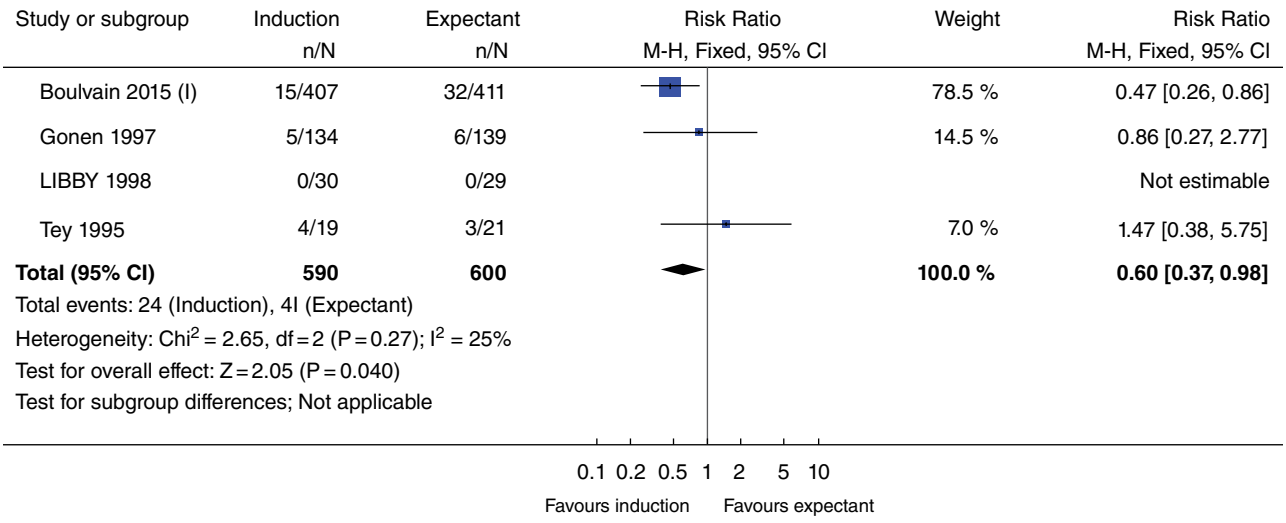
This process of meta-analysis can be part of a systematic review, for example Boulvain *et al.* [7] reported to the Cochrane Collaboration. Figure 33.2 demonstrates the results of a meta-analysis of the effect of induction of labour at 37–40 weeks for suspected fetal macrosomia on the risk of shoulder dystocia. This is a forest (Peto) plot, a graphical display of the relative strength of treatment effects in the different trials. Down the left-hand side are the trials included. The trial quoted above is the last of the four trials listed (first author Boulvain). On the right-hand side is a plot of the risk ratio for each of these studies incorporating confidence intervals represented

Analysis 1.3. Comparison I Induction versus expectant management, Outcome 3 Shoulder dystocia.

Review: Induction of labour at or near term for suspected fetal macrosomia

Comparison: I Induction versus expectant management

Outcome: 3 Shoulder dystocia



(I) Any shoulder dystocia

Fig. 33.2 Summary output from meta-analysis [7].

by horizontal lines. The graph is plotted on a logarithmic scale so that the confidence intervals are symmetrical about the means to prevent apparent exaggeration in ratios greater than 1 when compared with those less than 1. The area of each square is proportional to the study's weight. The overall meta-analysed measure of effect is represented as the diamond on the bottom and the lateral points indicate the confidence intervals. A vertical line is plotted at unity and if the confidence intervals for individual studies or the total effect overlap with this line, then the results are not significant. One study included in this meta-analysis did not study this outcome of interest (LIBBY 1998). Two studies did not reach significance (Gonen 1997, Tey 1995) but the most recent published in 2015 (Boulvain) provided an overall significant result. This is the largest of the four studies. The overall pooled results also suggest a reduction in the risk of shoulder dystocia associated with induction of labour at 37–40 weeks.

Statistics

The primary principle in statistics that is often not well described nor understood is that analysis performed on a study population represents only a sample of the population. Therefore any findings from a study group or comparison between study groups reflect the population from which the study participants are sampled. The robustness of the sampling process will influence the strength of statistical inference which can be applied from the findings in the study population to the underlying population. An example of this is reflected in the size of the study population. If the sample of study population is small compared with the underlying population or in relation to the frequency of outcome, then the uncertainty of the statistical findings will increase, reflected by wider confidence intervals.

Incidence and prevalence

Incidence is a measure of the risk of developing some new condition within a specified period of time. Although sometimes loosely expressed simply as the number of new cases during some time period, it is better expressed as a proportion or a rate within a specific denominator to allow meaningful comparison. Therefore, the incidence (rate) is usually given as the number of new cases per given population in a given time period. In the examples above in pregnancy, the population and time period is self-selecting: the population is pregnant women and the time period is pregnancy and the puerperium. In the non-pregnant population it is more difficult. The time period is usually fixed at a year but the population denominator is more of a problem. In gynaecology, depending on the disease being studied, the at-risk female population may be different. Endometriosis is typically, but not absolutely, seen during the reproductive years; it has been estimated that it affects approximately 10% of all women at some point, but this is lifetime risk not incidence, which is risk of new cases within a risk group over a fixed period of time. Nor is it prevalence.

Prevalence is a measure of the total number of cases of disease in a specific population at any one period of time, rather than the rate of occurrence of new cases. This indicates the burden of the disease on society and is dependent on both the number of new cases and the length of time the disease is present (prevalence = incidence × duration). This equation demonstrates the relationship between prevalence and incidence: when the incidence goes up, prevalence must also rise. Incidence is more useful in understanding disease aetiology as it reflects disease occurrence and also the response to interventions. In the classical example of the cases of puerperal fever described by Semmelweis [8], the higher incidence in one group suggested an aetiological factor related to that group alone and the fall in incidence that followed the hand-washing initiative demonstrated a successful intervention. Therefore, incidence will vary with changes in aetiological factors and prevention. Prevalence is dependent on the duration of disease and the availability of cure. The longer the duration of disease, the higher the prevalence. The prevalence is also dependent on the study population. Using endometriosis as an example, its overall prevalence varies, ranging from 5 to 10%. A study of asymptomatic women undergoing sterilization reported a figure of 6% but this rises to 21% in women with infertility and as high as 60% in those with pelvic pain [9]. Endometriosis is recognized to influence fertility and also cause pelvic pain. This would explain the higher prevalence observed in those subgroups.

The incidence over time can also be studied using Kaplan–Meier plots, which present incidence data as a plot of cumulative incidence over time, taking into account variations in rate of events. This method was used in our recent study exploring the effects of maternal placental syndrome (MPS) in pregnancy on long-term incidence of maternal cardiovascular event (CVE) in women with systemic lupus erythematosus (SLE) (Fig. 33.3) [10]. This plot demonstrates the disease-free incidence over time (probability of CVE-free survival). In all groups this decreases over time. However, in women with a history of MPS in pregnancy, the disease-free incidence decreases further, especially if MPS is

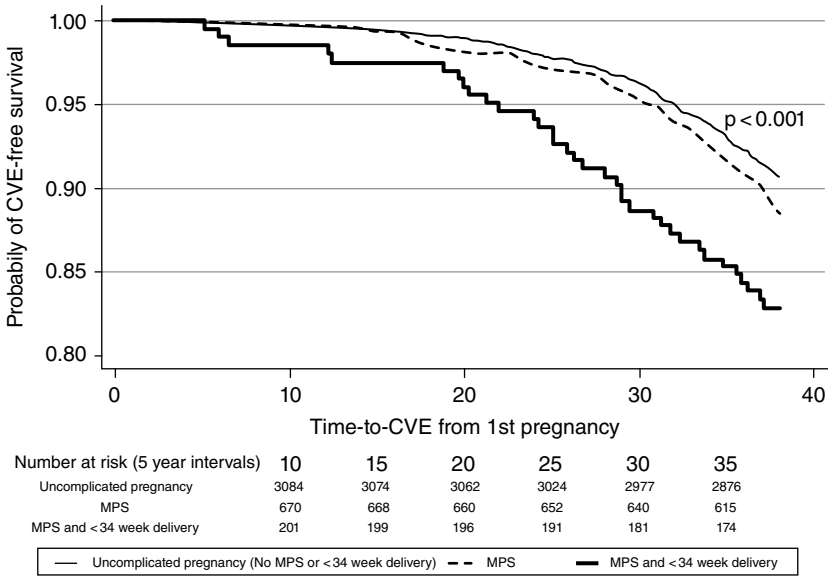


Fig. 33.3 Kaplan–Meier survival estimates for CVE in parous women with SLE [10].

also associated with preterm delivery less than 34 weeks. This may suggest shared etiological pathways leading to MPS in pregnancy and longer-term cardiovascular disease.

Pearl Index

The incidence of a disease or event is often quoted in rate per cent per year, for example the failure rate of contraceptives is quoted using the Pearl Index [11]. The following information is required to calculate the Pearl Index: the number of pregnancies and the total number of months or cycles of exposure of women. The index can then be calculated as follows:

- number of pregnancies in the study divided by the number of months of exposure and then multiplied by 1200;
- number of pregnancies in the study divided by the number of menstrual cycles experienced by the women and then multiplied by 1300; 1300 is used instead of 1200 because the average menstrual cycle is 28 days, giving 13 cycles per year.

These are normally calculated over a trial period of 1–2 years and claims to give the risk of pregnancy in 100 women over 1 year of use or 10 women over 10 years. This assumes that the pregnancy risk is static over the years of use and based on the rate in the first 1–2 years. Again, a Kaplan–Meier plot could be used to test for accumulative pregnancy rates over time when comparing different methods of contraception rather than the Pearl Index alone.

Statistical significance

In studies comparing outcomes between two or more groups, it is important to determine if any observed difference is simply due to chance or is truly different. A result is called statistically significant if it is unlikely to have occurred by chance alone. In the comparison between two groups, investigators are motivated to determine if there is any difference between groups. In the example on the effect of MPS and long-term CVE, are the differences observed between the groups merely due to chance or is there a true difference? It is important to remember that being statistically significant does not mean the result is important or clinically relevant. In large studies small differences can be found to be statistically significant but have little clinical or practical relevance. Tests of correlation may show significant correlations but have no or minor causative relation. Tests of significance should always be accompanied by assessments of relevance and effect-size statistics, which assess the size and thus the practical importance of the difference.

Tested often enough, in theory any result is possible but the likelihood that any given result would have occurred by chance is known as the significance level or *P*-value. In traditional statistical testing, the *P*-value is the probability of observing data similar to that observed by chance alone. If the obtained *P*-value is small, then it can be said that this is unlikely and the results are significantly different. To test whether the results are true or not, they are compared with those expected if the null hypothesis is true or there is no difference. So the basis of comparison of data is testing

whether the null hypothesis is true and the level of significance desired.

The null hypothesis and statistical tests

Statistical convention assumes that the experimental hypothesis (e.g. that one treatment is better than another) is wrong and assumes the *null hypothesis*, or no difference, as correct and that testing will assess whether this is wrong (i.e. that the treatment is better). When the null hypothesis is nullified (not supported within accepted confidence limits), the alternative hypothesis (that one treatment is better than the other) is accepted. Therefore, the null hypothesis is generally a statement that a particular treatment has no effect or benefit or that there is no difference between two particular measured variables in a study.

The result of the statistical test is given as a *P*-value. The size of the *P*-value relates to the likelihood of the result occurring by chance. The lower the *P*-value, the more likely the null hypothesis is nullified and the results are significantly different. A result of $P < 0.05$ means that the probability of this result being due to chance is less than 5% so the results are different to a 95% probability. The nearer to unity the *P*-value, the more likely that the null hypothesis is accepted and that there is no difference, but it should be remembered that 'the null hypothesis is never proved or established, but is possibly disproved'. In other words, if no significant difference is found, the test has not proven that there is no difference but has failed to show difference.

As stated previously, statistical findings are dependent on the population studied. The *P*-value of any test is dependent on the degree of difference in the test results and the number of people or values in the trial. If the trial is not of appropriate size, then two basic statistical errors can be made, type I and type II errors. Type I error, also known as the false positive, occurs when a statistical test falsely rejects a null hypothesis, for example where there is no difference between treatment arms in a trial as stated by the null hypothesis but the test rejects the hypothesis, falsely suggesting that there is benefit of treatment. The rate of type I error is denoted by the Greek letter alpha (α) and equals the significance level of the test, which by convention is usually taken as 0.05 or below. This means that any positive result is correct to a level of 95% probability.

Type II error, also known as the false negative, occurs when the test fails to reject a false null hypothesis, for example where there is a difference between treatment arms in a trial but the null hypothesis states that there is no difference and the test fails to reject the null hypothesis, falsely suggesting that there is no difference. The rate of type II error is denoted by the Greek letter beta (β) and is usually taken as 0.80, i.e. an 80% chance of rejecting a false null hypothesis.

Therefore when designing a trial, two considerations must be assessed:

- to reduce the chance of rejecting a true hypothesis to as low a value as possible;
- to devise the test so that it will reject the hypothesis tested when it is likely to be false.

The ability of a study to achieve this is assessed by the power. The power of a statistical test is calculated on the probability that the test will reject the null hypothesis when the null hypothesis is false and not produce a type II error or a false-negative result. As the power increases, the chance of a type II error occurring decreases as calculated by $\text{power} = 1 - \beta$. Statistical power may depend on a number of factors but, at a minimum, power nearly always depends on the following three factors:

- the statistical difference desired;
- the size of the effect of the treatment or difference between test groups;
- the sample size used to detect the effect.

The statistical difference desired is the chosen maximum *P*-value where the results are accepted as statistically significant, which is usually 0.05 but may be less than this if multiple testing is to be carried out. Once this *P*-value is agreed, power analysis can be used to calculate the minimum sample size required that is likely to detect a specified effect size (or difference). Similarly, the reverse is true and power analysis can be used to calculate the minimum effect size that is likely to be detected in a study using a given sample size. In general, a larger sample size will allow testing for a larger effect size and boost statistical power.

The specificity of the test is equal to $1 - \alpha$ ($1 - 0.05 = 0.95$). Increasing the specificity of the test lowers the probability of false-positive errors, but raises the probability of false-negative errors, which is a reflection on the sensitivity of the test. There are no formal standards for power but it is mostly calculated against the agreed *P*-value of 0.05 (95% specificity) and a 0.80 chance of avoiding a type II error (80% sensitivity). This convention implies a four-to-one trade-off between type II (β) risk and type I (α) risk and can be changed depending on whether a false-positive or false-negative rate is thought to be more important.

Summary box 33.3

Statistical terms

Specificity
Relates to the ability of the test to identify negative results:

True negatives / total condition negatives = $d / b + d$

where *d* is true negatives correctly identified and *b* is false positives. A high specificity implies a high probability that a positive result is positive and there is a low type I (α) error rate.

Sensitivity
Relates to the ability of the test to identify positive results:

True positives / total condition positives = $a / a + c$

where *a* is true positives correctly identified and *c* is false negatives. A high sensitivity implies a high probability that a negative result is negative and there is a low type II (β) error rate.

Power
Relates to the probability that the test will not produce a type II error:

$= 1 - \beta$

Positive predictive value (PPV)
The ratio of positives that are truly positive:

True positives/total test outcome positives = $a/a + c$

A high PPV gives an estimate of the chances that a positive result is truly positive.

Negative predictive value (NPV)
The ratio of negatives that is truly negative:

True negatives/total test outcome negatives = $d/b + d$

A high NPV gives an estimate of the chances that a negative result is truly negative.

Positive likelihood ratio
A measure of the change in the likelihood of a positive result from the prior test likelihood of positivity:

$= \text{Sensitivity} / (1 - \text{specificity}) = \left[a / (a + c)\right] / 1 - \left[d / (b + d)\right]$

It is commonly used in assessments of treatments or predictors of disease. The odds of positivity equals the pre-test odds multiplied by the positive likelihood ratio.

Negative likelihood ratio
A measure of the change in the likelihood of a negative result from the prior test likelihood of negativity:

$= (1 - \text{sensitivity}) / \text{specificity} = 1 - \left[a / (a + c)\right] / \left[d / (b + d)\right]$

It is commonly used in assessments of treatments or predictors of disease. The odds of negativity equals the pre-test odds multiplied by the negative likelihood ratio.

Odds ratio (OR)
A test of effect size as measured by the ratio of the positive odds in one arm against the positive odds in the other arm of the study:

$\text{OR} = (a/b) / (c/d) = ad/bc$

Relative risk (RR)
A test of the probability of an event occurring relative to the risk in the comparative group:

$\text{RR} = \left[a / (a + b)\right] / \left[c / (c + d)\right]$

Terms of significance

The OR is a test of effect size. It has been stated that 'statistics means that we never have to say we are certain'. Statistics is about probability not certainty. This is measured by confidence intervals. Confidence intervals are the range of probability (usually 95%) that if the test is repeated many times the result will always fall within that given range. To observe a true difference between two groups it is important that the confidence intervals do not cross 1 (or unity), meaning that in all cases the direction of difference is the same. The RR is simply the probability of an event occurring relative to the risk in the comparative group. This measure of effect size differs from the OR in that it compares probabilities instead of odds. For small probabilities, the RR and OR are similar.

Prediction testing

Another use for contingency tables is in studies evaluating potentially new tests that screen for disease. Each individual taking the test either does or does not develop the disease. The test can be assessed for its value in predicting the disease.

- True positive: correctly predicts those who will develop the disease.
- False positive: does predict disease but the patient does not get it.
- True negative: does not predict the disease and the patient does not get it.
- False negative: does not predict the disease and the patient does get it.

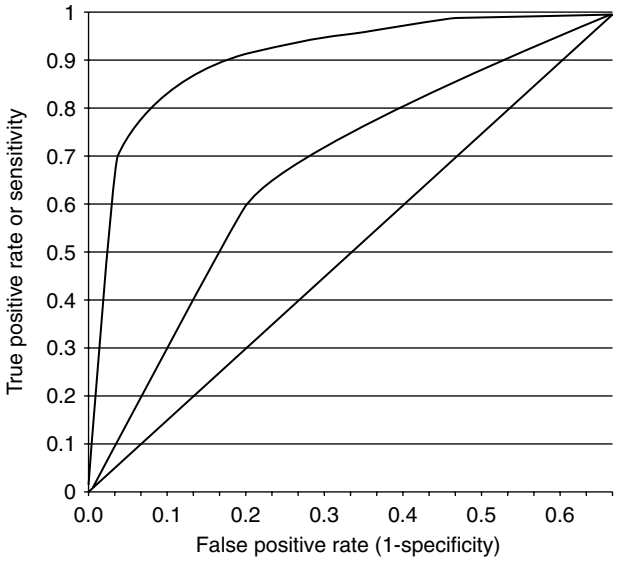

Fig. 33.4 Receiver operating characteristic (ROC) curve. *Source:* Edmonds DK. *Dewhurst's Textbook of Obstetrics and Gynaecology*, 8th edn. Oxford: Wiley-Blackwell, 2012. Reproduced with permission of John Wiley & Sons.

The balance between sensitivity and specificity can be assessed using the receiver operating characteristic (ROC) curve. The ROC curve is a graph of the sensitivity or true positive rate plotted against the false-positive rate (1 – specificity). It is called the ROC curve because it compares the two operating characteristics, the true positive rate and the true negative rate with changing cut-off levels. This allows the optimum cut-off level of a predictive or diagnostic test for any given disease to be determined by finding the optimum sensitivity and specificity for that test (Fig. 33.4).

In Fig. 33.4, the straight line running from zero to 1 is no better than chance alone. Any curve to the left of the line is better than chance. The more to the left, and the nearer the 'perfect' upper left-hand corner, the better the test. In this example the left-hand curve gives the best result for sensitivity 80–90% and specificity 80–90% (false-positive rate = 1 – sensitivity). What cut-off point is used depends to some extent on whether it is better to capture the maximum or miss the fewest in the disease being investigated. As the lines move further left, the more discriminating the test, with a higher sensitivity and low false-positive rate.

Descriptive statistics

Up to now we have discussed the assessment of rates and incidence of a given problem in a population but statistics are also used to describe a population and what values fall outwith the normal range that could be used for diagnostic purposes.

What is normal?

The term 'normal' is one of the most misunderstood terms in medical statistics and epidemiology. In its pure sense, it is the whole population, good and bad, and this should contribute to the normal range. However, in medical testing, normal is often taken as all individuals who are not abnormal, i.e. do not have the disease under study. This produces problems when comparisons are being made or predictors are being assessed, as 'not abnormal' is a post-test value. When using a predictor it is important to test it against the whole population including those who will develop the disease or other diseases as this is how it will function in the real world. Without doing this, the value of most predictive tests is overstated.

Normal distribution

The graph of most 'normal' populations is a bell-shaped curve demonstrating a Gaussian distribution with the mean in the middle and a mirror-image distribution on either side (Fig. 33.5). It is one of the statistical standards and implies that, in most populations, there is an even spread (symmetrical) around the mean or average. The mean is calculated by taking the sum of all the measurements and dividing it by the total number of measurements taken. It is the same as the average. If the dataset were based on a series of observations obtained from a

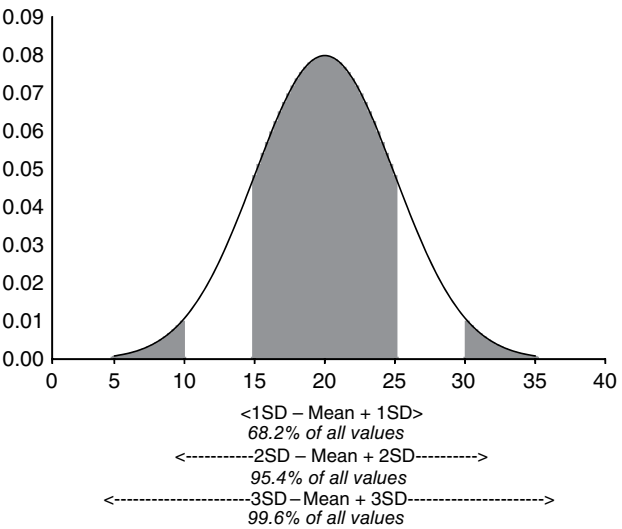

Fig. 33.5 Normal distribution and standard deviation. The mean is 20 and the SD 5. The bands correspond to 1, 2 and 3 SDs from the mean. Mean ±1SD takes in 68.2% of all values; mean ±2SD takes in 95.4% of all values and is equivalent to 95% CI; mean ±3SD takes in 99.6% of all values and is equivalent to the range. *Source:* Edmonds DK. *Dewhurst's Textbook of Obstetrics and Gynaecology*, 8th edn. Oxford: Wiley-Blackwell, 2012. Reproduced with permission of John Wiley & Sons.

sample of the population, it is known as the sample mean, which will relate to, but may not be exactly the same as, the true population mean. Knowing the mean of a population is only the start. Different populations will have different ranges of measurements, some with a far wider range of values making up the population.

The range is calculated by subtracting the smallest measurement (minimum) from the greatest (maximum) and provides an indication of sample spread. It is measured in the same units as the data. For example, if in a given dataset the mean body mass index (BMI) was 29.6, the lowest value 15.2 and the highest 47.3, the range would be 47.3 – 15.2 = 32.1. Because it is calculated from two measurements, the lowest and the highest, it is a weak statistical measure of distribution as it gives no indication of how the measurements are distributed throughout the range. Also, since it is often a measurement of a sample of a larger population, it does not necessarily give the full potential range of the population as a whole.

The measure of variation or spread around the mean can be assessed in many ways but the most common is the standard deviation. The mean and standard deviation describe a sample population and can be used to assess differences with other sample populations. The standard deviation (SD) is the assessment of variability of each individual measurement from the mean and is calculated by taking the average difference of each measurement from the calculated mean. A low SD indicates that the measurements tend to be very close to the mean as the variation is small and the distribution tight, producing a narrow peaked curve, whereas a high SD indicates that the data are spread out over a large range of values, giving a wider flatter curve.

Figure 33.5 shows the graph for a normal distribution and the SD. In a normal distribution, about 68% of the measurements will be within one standard deviation from the mean, while two standard deviations from the mean account for about 95% and three standard deviations for about 99.7%. Therefore, the range of the mean ±1SD will contain the majority of the measurements; the 95% confidence interval of the population will lie within the mean ±2SDs and the mean ±3SDs approximates to the range. This 68/95/99.7 rule holds for all normal distributions irrespective of the size of the range. Therefore, if a sample lies more than 2SDs from the mean of a sample set, it is statistically not part of the set to a level of 95% confidence. Similarly, if two populations are being compared and the means of the populations are further apart than the addition of each population's SD, then the probability is that they are statistically different although more formal testing should be done.

In scientific experimentation, the standard error of the mean (SEM) is sometimes used instead of the SD. The SEM is the SD of the estimated mean of the study sample compared with the true population mean. Therefore, whereas the SD demonstrates the spread or range of the individual sample measurements around the sample mean, the SEM gives the spread or range of the calculated sample mean. The mean ±2SEMs is the 95% confidence range of the sample mean. Therefore if another sample population was studied, the calculated mean will fall within that range 95% of the time. The SEM can be calculated by dividing the SD by the square root of the sample size. Therefore, it is dependent on both the sample range and the sample size.

Comparing sample groups

The most common method of testing two sample populations is Student's *t*-test. The test requires that the populations being compared are normally distributed. It can be used in one of two forms, the unpaired or the paired *t*-test.

The unpaired *t*-test is used when two separate unlinked normal populations are compared. For example, if you are studying two methods of induction of labour and you enrol 100 subjects into your study and randomize half into each treatment group, there are two independent samples to compare the outcomes, in this case the induction to delivery interval. The test used would be the unpaired form of the *t*-test. It does not need to be two randomized groups, just two groups that differ by a single parameter, for example primigravidae and multiparous women, where the same induction agent is used and the results of the primigravidae are compared with those of the multiparous women.

A paired *t*-test consists of matched pairs where a group of patients are tested twice, for example once before an intervention and repeated afterwards. An example would be to test for changes in the Bishop's score after application of vaginal prostaglandin. An unpaired *t*-test can be converted to a dependent *t*-test when the individuals in the two groups are assessed for similarities using measured variables that demonstrate similarities. This could be done in a cohort study looking at the effect of smoking on birthweight and matching each smoker with a matched control, matched for parity, BMI and gestation at delivery.

The *t*-test should be used when the population groups are assumed to be normal in distribution. Normality tests can assess any given dataset for the likelihood that it comes from a normal distribution, allowing the *t*-test to be used. If the data are not normally distributed or are skewed, a non-parametric test should be used. The most common simple tests are the Wilcoxon signed-rank test for paired samples and the Mann–Whitney *U* test for independent populations.

Skewness is a measure of the asymmetry of the population distribution around the mean due to a larger and longer tail on one side or the other. This can be positive or negative, indicating on which side of the mean the skewness lies. A negative skew indicates that the tail on the left side is longer than that on the right side and vice versa. The tail affects the mean, moving it towards the side of the tail and indicating that it is no longer representative of the sample as a whole and thus will overestimate or underestimate the 'average' of the population. The better measure of this is the median.

The median is the value separating the higher half of the population sampled from the lower half. It is calculated by ranging all the sample values from the lowest to the highest and finding the value in the middle. If there is an even number of values, then the median is defined to be the mean of the two middle values. In this case half the population have values less than the median and half have values greater than the median.

In a skewed population, the SD is not an accurate value of the distribution of the population around the median and in this case a better descriptor is the centile range. Just as the median is the value which describes the middle value within the range, the centile describes the percentage of the values contained within a given value range. In this case the median is the 50th centile as it describes the point where 50% of the population lie below and 50% above that value. Similarly, the 90th centile describes the value where 90% of the population are below and 10% above and the 10th centile the value where 10% are below and 90% are above.

It has to be remembered that the normal range statistically is the population range including all values, not a range of those who are designated 'normal' or disease-free. For example, if intrauterine growth restriction is classified as babies less than the 10th centile, then 10% of the normal baby population will fall into that category as well as those who may be truly growth restricted. Further evaluations are required to assess whether the baby is truly growth restricted or just a small normal baby. However, if the 5th centile is used, the baby lies outside the 95% confidence limit of what would be expected; similarly, the 3rd centile would make the baby even more likely to fall into the growth-restricted range as 97% of babies would be expected to be heavier. The 3rd centile is the equivalent of 2SDs from the population mean of a normal distribution. If two skewed or asymmetric populations are to be compared, then non-parametric tests are required.

Comparing asymmetric populations

The Mann–Whitney *U* test (also called Wilcoxon rank sum test) is a non-parametric test for assessing two independent populations. It is a variation of the original Wilcoxon test that is used to study populations of equal size. The Mann–Whitney *U* test is performed by putting all the values from each group into one ranked column from highest to lowest. The sum of the ranks for each group is compared and used to calculate the value *U*. If the samples are different, then one group will have a smaller value of *U*, implying a higher average ranking. This is then used to consult significance tables to assess whether the groups are statistically significant. Most statistical packages will do this automatically.

The Wilcoxon signed-rank test is a paired non-parametric test for assessing two populations which are related, for example a single population tested twice, once before and once after an intervention. It is used as an alternative to the paired Student's *t*-test where the population is not normally distributed. Since this is a paired test, the value from test 2 is subtracted from the value from test 1, giving a value *Z*. These values are ranked similarly to the Mann–Whitney *U* test, rank 1 being given to the smallest absolute value of *Z*. The ranks of the positive values for *Z* and the negative values of *Z* are summed. The smaller of the two rank sums is then used to compare against a table of critical values for a given sample size to assess whether there is a significant difference, with either an increase or decrease after the intervention. This test is powerful as it is less dependent on the size of individual pair changes and is a measure of a population shift, although the problem with this is that the changes could be very small but still statistically significant. As with all statistics, the results must be interpreted with clinical relevance.

Correlation and dependence

All the tests discussed have looked at ways of studying populations if they are different. Other tests look for the correlation between values within the population studied. These tests study the changes between two or more values to see if the changes in these values are linked, for example studies on the effect of maternal BMI on the incidence of caesarean section. In the National Sentinel Caesarean Section Audit, the higher the BMI, the higher the caesarean section rate in those women. Logic tells us that rising BMI affects caesarean section rate and not caesarean section rate affecting BMI. However, the statistics cannot make this assumption and this has to be interpreted by the investigator. Correlations can demonstrate a predictive relationship, for example a rise in BMI of x should be associated with a rise of y% in the caesarean section rate, and this can be used to predict how the BMI of women presenting in pregnancy would affect the caesarean section rate in an institution. Similarly, it may also suggest that a reduction in BMI might reduce the

risk of caesarean section in any given woman. However, just because the values are linked does not mean that they are causative; statistical dependence is not sufficient to demonstrate the presence of such a relationship. The two variables may both be influenced independently by a common third factor.

The result of a test for correlation is given as the correlation coefficient, usually denoted by r, which is a measure of the degree of correlation. The most common test is the Pearson correlation test, which tests for linear correlation. The nearer r is to 1 or −1, the closer the correlation, implying that for each unit rise in one variable there is an equal unit rise ($r = 1$) or fall ($r = -1$) in the other variable. A value P can be given, similar to other statistical tests, stating the confidence that the test is accurate (e.g. 95% confidence if $P < 0.05$), but does not assess how closely correlated the two variables are. The square of the r value gives an approximation of the percentage effect the change of one variable has on the other. Therefore, a test that gives a result of $r = 0.5$ and $P < 0.01$ indicates that there is a statistically valid correlation but only 25% (r^2) of any given change in variable 2 is associated with a change in variable 1. It is only when r is greater than 0.7 that the variable in 1 has over a 50% effect on the variable in 2.

What has been described in the preceding sections is standard statistics and what is seen as statistical significance. It has also been suggested that it is important to assess the results obtained from a clinical viewpoint to assess reality and how the results influence accepted pre-test thinking. This is part of the reasoning behind Bayesian inference.

Bayesian inference

Bayesian inference is the use of a priori belief or probability about a test result to determine the probability that a new test result is true. In other words, knowing what we know from experience or belief, can this new result be true? In day-to-day terms, this is the basis on how we change our beliefs and practices. If a study confirms our preconceived beliefs, we will accept it without question but if it disagrees, then we may struggle to accept it and only change our practice to a degree. However, as more evidence accumulates, the degree of confidence in a test result changes. With enough evidence, the degree of confidence should become either very high or very low. This means that results will naturally be biased due to pre-test prejudices but it allows the changing of that bias with more confirmatory evidence. This is really how we practise in the real world. Many observational studies suggested an increased risk of vaginal breech delivery but many practitioners did not accept these results due to their pre-existing prejudices. The Term Breech Trial, with its large randomized format, convinced those who already believed and some of those who were sceptical but others still found flaws in the study so they did not have to change their beliefs. In a statistical form, Bayesian inference estimates the degree of pre-test belief before any evidence is collected, and then re-estimates the degree of confidence after a set of evidence has been observed by combining the pre-test values with the test results. This process is then repeated whenever additional evidence is obtained, leading to a changing probability that the results are true or false.

Summary box 33.4

Descriptive statistics

- Mean: the sum of all the measurements divided by the total number of measurements taken.
- Range: calculated by subtracting the smallest measurement (minimum) from the greatest (maximum).
- Standard deviation (SD): the assessment of variability of each individual measurement from the mean, calculated by taking the average difference of each measurement from the calculated mean.
- Standard error of the mean (SEM): standard deviation of the estimated mean of the study sample compared with the true population mean.
- Student's *t*-test: used to compare normally distributed populations. The populations can be paired or unpaired.
- Skewness: a measure of the asymmetry of the population distribution around the mean.
- Median: the value separating the higher half of the population sampled from the lower half.
- Centiles: describe the percentage of values contained within a given value range.
- Mann–Whitney *U* test: a non-parametric test for assessing two independent populations.
- Wilcoxon signed-rank test: a paired non-parametric test for assessing two populations which are related.
- Correlation: studies the changes between two or more values within a population to see if the changes in these values are linked.
- Bayesian inference: a method that uses a priori belief or probability about a test result to determine the probability that a new test result is true.

How we use statistics

This chapter has considered examples of how we use statistics. Whatever the results, all are interpreted in the light of our own experience. If we have no preconceived

beliefs, we are open to the results of any trial. If we have a preconceived idea and the trial shows a null result, it confirms to us that what we do is correct, but that is also true of people with a preconceived idea opposite to our own. The Term PROM trial showed no difference between immediate induction of labour or delay in cases of pre-labour rupture of the membranes. This indicates that there is no evidence to support either action. This allowed people to continue to act as they previously did, believing themselves to be correct, but it should have told people that there is no correct answer and that women should be offered a choice of action.

Statistics is a powerful tool in medical research and epidemiology, but it is important to use it at the right time in the right way. If the wrong question is asked, the result is worthless irrespective of the outcome and statistical significance. It is important to think through the problem being addressed carefully and set the correct hypothesis and test it with a study of the appropriate power. Statistics will not cover up for a poorly designed trial with insufficient numbers testing the wrong hypothesis. It is also important to assess the results for clinical relevance and the consequences of changing actions potentially resulting in unforeseen consequences that were not tested for.

Clinical Anatomy of the Pelvis and Reproductive Tract

Alan Farthing

West London Gynaecological Cancer Centre, Queen Charlotte's Hospital, Imperial College Healthcare NHS Trust, London, UK

This chapter aims to summarize important aspects of the anatomy of the abdomen and the pelvis that should be known to the obstetric or gynaecological specialist. Many of the investigations and treatments we order on a daily basis require good anatomical knowledge in order to be properly understood.

Surface anatomy

The anterior abdominal wall can be divided into four quadrants by lines passing horizontally and vertically through the umbilicus (Fig. 34.1). In the upper abdomen is the epigastrium, which is the area just inferior to the xiphisternum, and in the lower abdomen lie the right and left iliac fossae and the hypogastrium.

The cutaneous nerve supply of the anterior abdominal wall arises from the anterior rami of the lower thoracic and lumbar vertebrae. The dermatomes of significant structures on the anterior abdominal wall are T7 (xiphisternum), T10 (umbilicus) and L1 (symphysis pubis).

The blood supply is via the superior epigastric (branch of the internal thoracic artery) and the inferior epigastric (branch of the external iliac artery) vessels. During laparoscopy, the inferior epigastric vessels can be seen between the peritoneum and rectus muscle on the anterior abdominal wall and commence their journey superiorly from approximately two-thirds of the way along the inguinal ligament closer to the symphysis pubis. Care needs to be taken to avoid them while using accessory trocars during laparoscopy and to ensure that they are identified when making a Maylard incision of the abdominal wall.

The anterior abdominal wall

Beneath the skin and the fat of the superficial anterior abdominal wall lies a sheath and combination of muscles including the rectus abdominis, external and internal oblique and tranversalis muscles (Fig. 34.2). Where these muscles coalesce in the midline, the linea alba is formed. Pyramidalis muscle is present in almost all women, originating on the anterior surface of the pubis and inserting into the linea alba. The exact configuration of the muscles encountered by the surgeon depends on exactly where any incision is made.

The umbilicus

The umbilicus is essentially a scar made from the remnants of the umbilical cord. It is situated in the linea alba and in a variable position depending on the obesity of the patient. However, the base of the umbilicus is always the thinnest part of the anterior abdominal wall and is the commonest site of insertion of the primary port in laparoscopy. The urachus is the remains of the allantois from the fetus and runs from the apex of the bladder to the umbilicus. Occasionally this can remain patent in newborns. In early embryological life, the vitelline duct also runs through the umbilicus from the developing midgut. Although the duct is severed long before delivery, a remnant of this structure is found in 2% of the population as a Meckel's diverticulum.

The aorta divides into the common iliac arteries approximately 1–2 cm below the umbilicus in most slim women (Fig. 34.3). The common iliac veins combine to form the inferior vena cava just below this and all these structures are a potential hazard for the laparoscopist inserting ports at the umbilicus.

Epithelium of the genital tract

The anterior abdominal wall including the vulva, vagina and perineal areas are lined with squamous epithelium. The epithelium lining the endocervix and uterine cavity

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

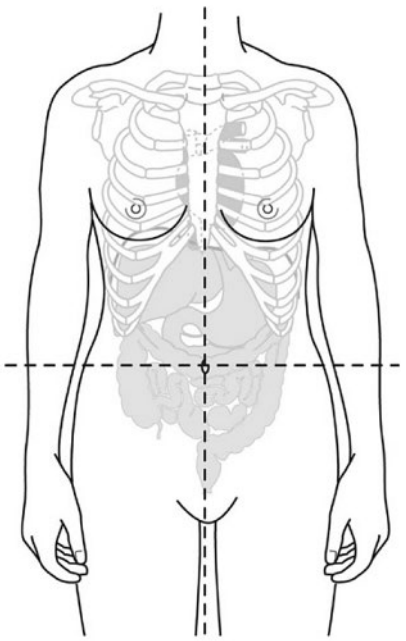

Fig. 34.1 The abdomen can be divided into quadrants.

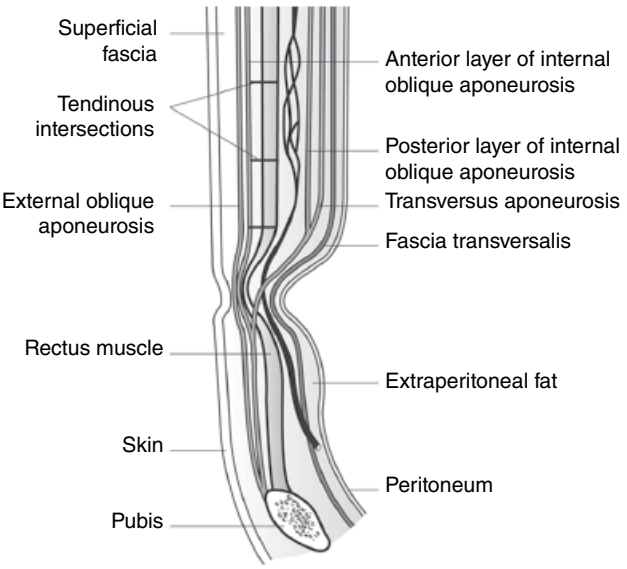

Fig. 34.2 The layers of the anterior abdominal wall in tranverse section.

is columnar and the squamocolumnar junction usually arises at the ectocervix in women of reproductive age. This is an important site as it is the area from which cervical intraepithelial neoplasia (CIN) and eventually cervical malignancy arises. The bladder is lined by transitional epithelium that becomes columnar as it lines the urethra. The anal margin is still squamous epithelium but this changes to columnar immediately inside the anus and into the rectum.

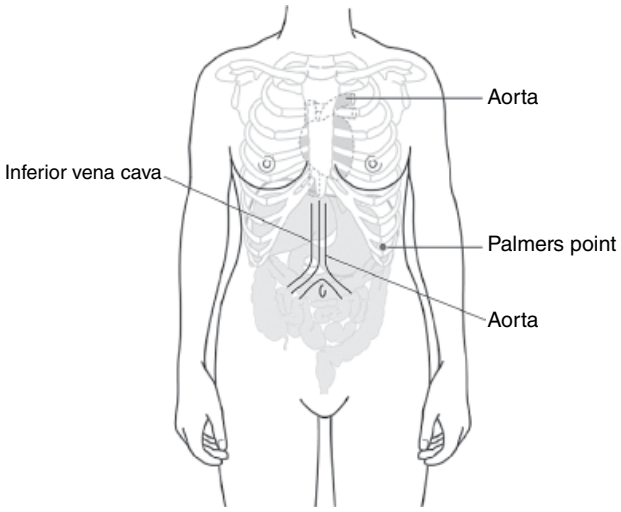

Fig. 34.3 The umbilicus in relation to the underlying vasculature in a thin patient.

The genital tract, from the vagina, through the uterus and out through the fallopian tubes into the peritoneal cavity, is an open passage. This is an essential route for sperm to traverse in the process of fertilization but unfortunately it also allows the transport of pathological organisms that may result in ascending infection.

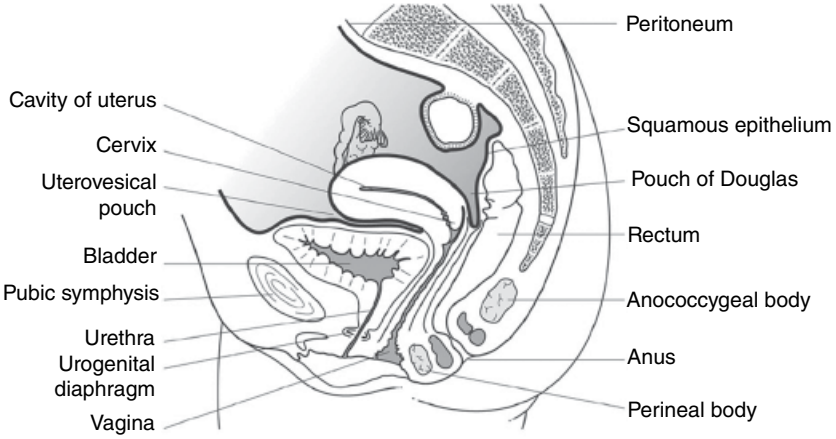
The peritoneum

The peritoneum is a thin serous membrane that lines the inside of the pelvic and abdominal cavities. In simplistic terms, it is probably best to imagine the pelvis containing the bladder, uterus and rectum (Fig. 34.4) and note that the peritoneum is a layer placed over these organs in a single sheet. This complete layer is then pierced by both the fallopian tubes and the ovaries on each side. Posteriorly the rectum also pierces the peritoneum where it connects to the sigmoid colon, and the area between the posterior surface of the uterus and its supporting ligaments and the rectum is called the pouch of Douglas. This particular area is important in gynaecology as the place where gravity-dependent fluid collects. As a result this is where blood is found in ectopic pregnancies, pus in infections and endometriosis caused by retrograde menstruation.

Vulva

The vulva is the area of the perineum comprising the mons pubis, labia majora and minora, and the opening into both the vagina and urethra (Fig. 34.5). The labia majora are areas of skin with underlying fat pads which bound the vagina. Medial to these are the labia minora, which consist of vascular tissue that engorges with blood during sexual

Fig. 34.4 Transverse view of the pelvic organs.



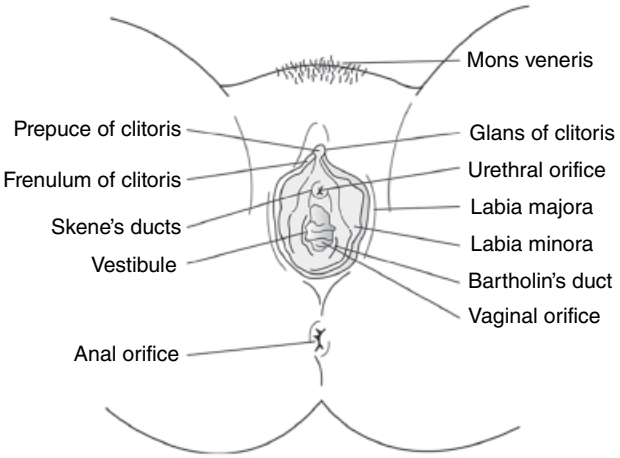


Fig. 34.5 Surface anatomy of the vulva.

arousal. Anteriorly they come together to form the prepuce of the clitoris and posteriorly they form the fourchette. The hymen is a fold of mucosa at the entrance to the vagina. It usually has a small opening in virgins and is only seen as an irregular remnant in sexually active women. To each side of the introitus are the ducts of the vestibular glands commonly known as Bartholin's glands, which produce much of the lubrication during sexual intercourse.

The vulval blood supply comes from the pudendal artery and lymphatic drainage is through the inguinal lymph nodes. The nerve supply comes mostly from the pudendal nerve and pelvic plexus, with branches of the perineal nerves and posterior cutaneous nerve of the thigh important in the posterior region.

The clitoris

The clitoris corresponds to the male penis and consists of the same three masses of erectile tissue (Fig. 34.6). The bulb of the vestibule is attached to the underlying urogenital diaphragm and splits into two because of the presence of the vagina. The right and left crura become the corpora cavernosa and are covered by the ischiocavernosus muscles.

Bony pelvis

The bony pelvis consists of two hip bones (comprising ilium and ischium) that are joined together by the sacrum posteriorly and the symphysis pubis anteriorly (Figs 34.7 and 34.8). In addition, the coccyx lies on the inferior aspect of the sacrum. A plane drawn between the sacral promontory and the superior aspect of the symphysis pubis marks the pelvic inlet and a similar plane drawn from the tip of S5 to the inferior aspect of the symphysis pubis marks the pelvic outlet.

Clinically the ischial spine is important as it can be felt vaginally and progress in labour can be measured using it as a landmark. Additionally, it is an insertion point of the sacrospinous ligament, which also attaches to the lower lateral part of the sacrum. Together with the sacrotuberous ligament and the bony pelvis, it forms the borders of the greater sciatic foramen (through which the sciatic nerve passes) and the lesser sciatic foramen (through which the pudenal nerve enters the pelvis).

The sacrum and ilium are joined by the very strong sacro-iliac joint. This is a synovial joint and is supported by the posterior and interosseous sacro-iliac ligaments. The symphysis pubis is a cartilaginous joint with a fibrocartilaginous disc separating the two bones, which are firmly bound together by the supporting ligaments. There should be virtually no movement of this joint.

Pelvic floor

The obturator internus muscle sits on the medial side of the ischial bone and, together with the body of the pubis, forms a wall that supports the origins of the pelvic floor.

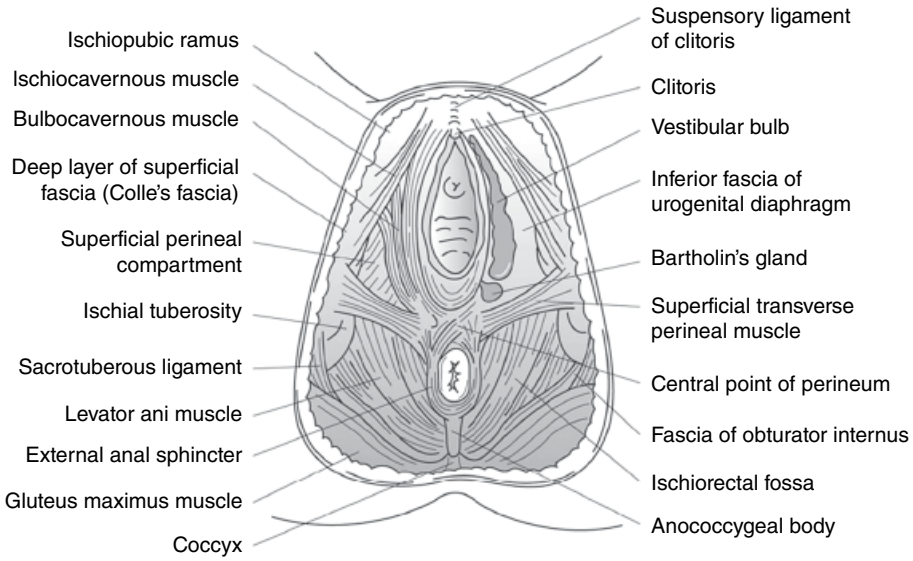

Fig. 34.6 The deeper vulval tissues.

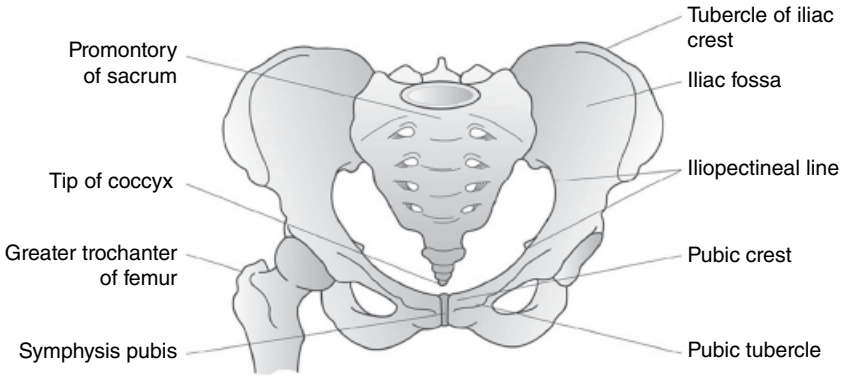

Fig. 34.7 Bony pelvis.

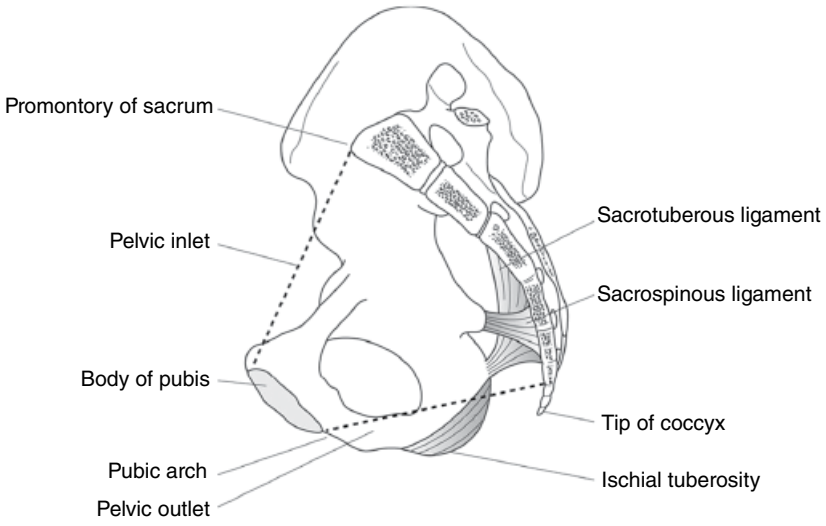

Fig. 34.8 Bony pelvis.

The pelvic floor itself is a sling of various muscles that are pierced by the urethra, the vagina and the anal canal. Posterior to the vagina these muscles form the perineal body. The puborectalis muscle forms a sling around the junction of the anus and rectum and posterior to the anus, and these fibres consist of the pubococcygeus that forms the anococcygeal body in the midline (Fig. 34.9). The collection of muscles is variously referred to as the

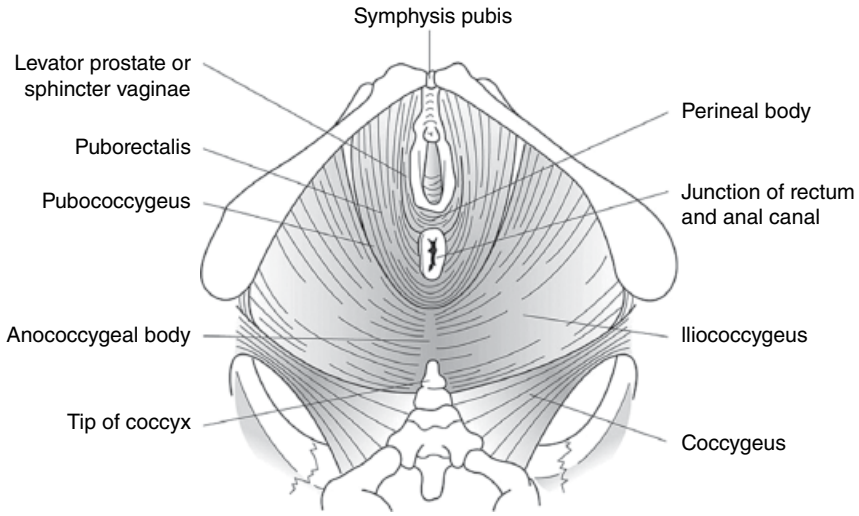

Fig. 34.9 Pelvic floor muscles.

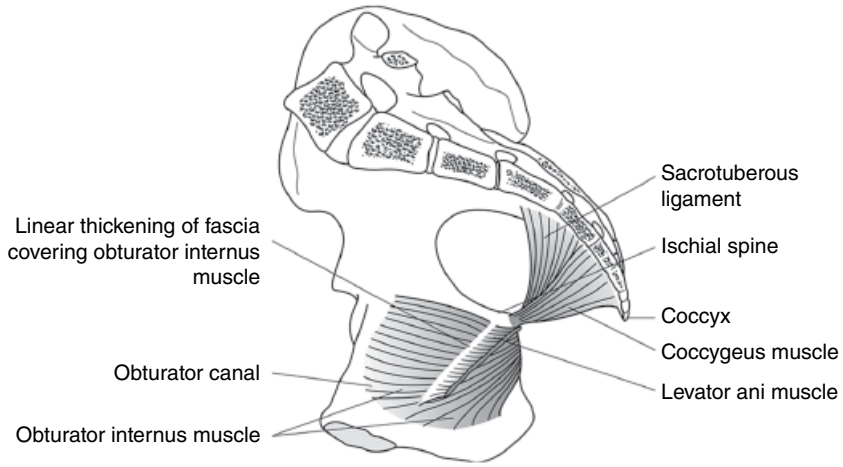

Fig. 34.10 Transverse view of the pelvic floor muscles.

pelvic diaphragm or levator ani muscles (Fig. 34.10). These muscles support the pelvic organs, holding them in position and resisting the forces created when the intraperitoneal pressure is raised as in coughing or straining. The nerve supply is from the fourth sacral nerve and pudendal nerve.

Pelvic organs (Fig. 34.11)

Vagina

The vagina is a distensible muscular tube that passes from the introitus to the cervix. It pierces the pelvic floor and then lies flat on its posterior surface using it as support. It is approximately 8 cm long and the anterior and posterior walls oppose each other. Anatomical textbooks can give a confusing impression when showing this structure as an open tube with a lumen. However, on imaging, the normal vagina should not be distended and does not contain air. Projecting into the top of the vagina is the uterine cervix. The areas of the vagina that border the cervix are referred to as the fornices and are labelled as anterior, posterior, right or left.

The vaginal wall consists of outer and inner circular layers of muscles that cannot be distinguished from each other. The epithelium contains no glands but is rich in glycogen in the premenopausal woman. The normal commensal, *Lactobacillus acidophilus*, breaks down this glycogen to create an acid environment.

Uterus

The uterus is approximately the size and shape of a pear with a central cavity and thick muscular walls (Fig. 34.12). The serosal surface is the closely applied peritoneum, beneath which is the myometrium. The myometrium is smooth muscle supported by connective tissue and comprises three layers of muscle: external, intermediate and internal layers. Clinically this is important as fibroids

leave the layers intact and removal through a superficial incision leaves the three layers intact. The three layers run in complementary directions, encouraging vascular occlusion during contraction, an important aspect of menstrual blood loss and postpartum haemostasis. The mucous membrane overlying the myometrium and which lines the cavity is the endometrium. Glands of the endometrium pierce the myometrium and a single layer of columnar epithelium on the surface changes cyclically in response to the menstrual cycle.

The uterus consists of a fundus superiorly, a body, an isthmus (internal os) and inferiorly the cervix (external os). The cervix is a cylindrical structure that is muscular in its upper portions but comprises fibrous connective tissue in its lower part where it connects with the vagina. The cervix is lined by columnar epithelium that secretes alkaline mucus that neutralizes the effects of vaginal acidity.

The cervix and uterus do not always lie in the same plane and when the uterine body rotates anteriorly it is referred to as 'anteflexed'; when rotated posteriorly, it is referred to as 'retroflexed'. The axis of the entire uterus can be anteverted or retroverted in relation to the axis of the vagina (Fig. 34.13).

The uterus is supported by the muscles of the pelvic floor together with three supporting condensations of connective tissue. The pubocervical ligaments run from the cervix anteriorly to the pubis, the cardinal ligaments

Fig. 34.11 Magnetic resonance image of the pelvis.

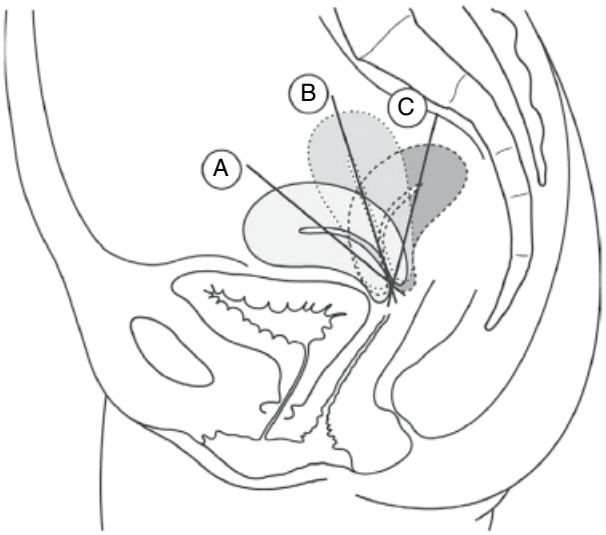

Fig. 34.13 The axis of the uterus in relation to the vagina.

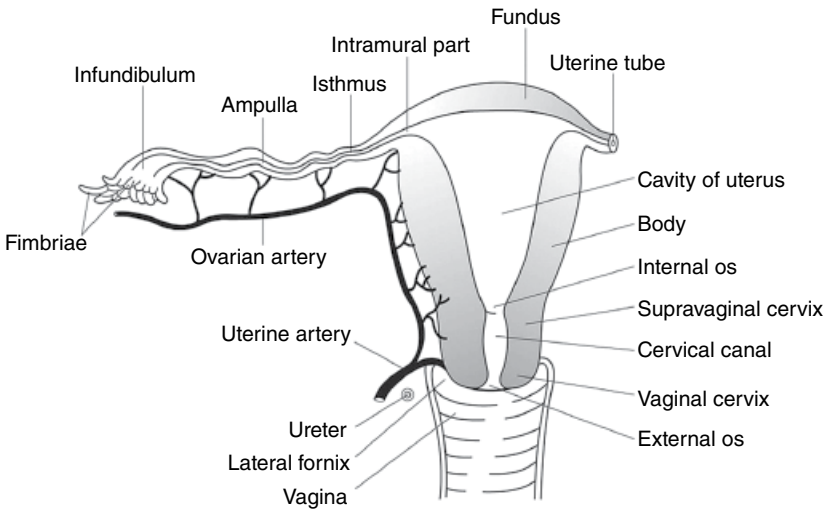

Fig. 34.12 Uterus and fallopian tubes.

pass laterally from the cervix and upper vagina to the lateral pelvic side walls, and the uterosacral ligaments run from the cervix and upper vagina to the sacrum. These uterosacral ligaments can be clearly seen posterior to the uterus in the pouch of Douglas and are a common site for superficial and deep infiltrating endometriosis.

The uterine blood supply is derived mainly from the uterine artery, a branch of the anterior division of the internal iliac artery. An anastomosis occurs with the blood supply delivered through the ovarian ligament and derived direct from the ovarian artery.

The round ligament is the remains of the gubernaculum and extends from the uterus laterally to the pelvic side wall and then into the inguinal canal before passing down into the labia majora. It holds the uterus in anteversion, although it is a highly elastic structure in pregnancy. It is usually the first structure divided at hysterectomy, allowing the surgeon to open the overlying folds of peritoneum known as the broad ligament.

Fallopian tubes

The fallopian tubes are delicate tubular structures that allow transport of the ovum or sperm between the ovary and uterine cavity. The tubes are divided into named regions, most medially the cornu and interstitial portion within the uterine wall, then the isthmus followed by the infundibulum, ampulla and finally fimbrial ends. They are lined by columnar epithelium and cilia which, together with the peristaltic action of the surrounding smooth muscle, propel the fertilized ovum towards the uterine cavity. The blood supply of the fallopian tubes arises from both the uterine and ovarian arteries through the mesosalpinx which is covered by peritoneum.

Ovaries

The ovaries vary in size depending on age and their function. They measure approximately 2×4 cm, with the long axis running vertically, and are attached to the posterior leaf of the broad ligament by the mesovarium. In addition, they are fixed in position by the ovarian ligament (to the uterus medially) and the infundibulopelvic ligament, which contains the ovarian blood supply direct from the aorta. Venous drainage is to the ovarian veins, which drain directly into the inferior vena cava on the right and into the renal vein on the left. The aortic nerve plexus also accompanies the ovary in its descent from around the level of the first lumbar vertebra.

The lateral pelvic side wall is covered by peritoneum that is folded to form the ovarian fossa. Pathological adhesions around the ovary will often cause it to become fixed into the ovarian fossa, causing cyclical pain or dyspareunia. The ovary is not covered by peritoneum but is surrounded by a thin membranous capsule, the tunica albuginea, which in turn is covered by the germinal epithelium.

Bladder

The urinary bladder is situated immediately behind the pubic bone and anterior to the uterine cervix and upper vagina. It has a strong muscular wall consisting of three layers of interlacing fibres, which together are known as the detrusor muscles (Fig. 34.14). The trigone is the only smooth part of the bladder as it is fixed to the underlying muscle. At the superior margins of the trigone lie the ureteric openings and at the inferior aspect the urethra. An inter-ureteric ridge can often be visualized horizontally between the ureters at cystoscopy and is useful for orientation. The rest of the bladder is highly distensible, ensuring that as it is expanded by urine, the pressure of its contents remains the same.

The bladder receives its blood supply from the superior and inferior vesical arteries, which originate from the internal iliac artery. The nerve supply is from the inferior hypogastric plexus. Sympathetic nerves arise in the first and second lumbar ganglia and the parasympathetic supply from the splanchnic nerves of the second, third and fourth sacral nerves.

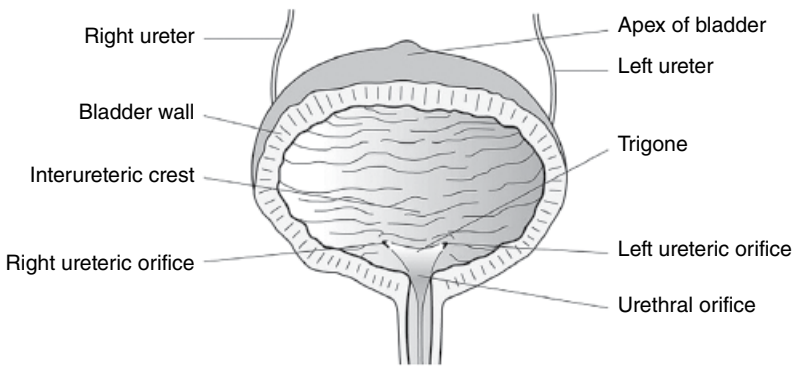

Fig. 34.14 The bladder.

Urethra

The urethra is approximately 4 cm long in the female adult, starting at the internal meatus of the bladder and passing through the pelvic floor to the vestibule. The epithelium is squamous near the external meatus but changes to transitional epithelium approximately 2.5 cm from the meatus. The deeper tissue is muscular and this maintains urethral tone. There are no anatomical sphincters but the muscle fibres of the bladder at the internal meatus act as an 'internal sphincter' and the pelvic floor as a voluntary external sphincter.

Ureters

The ureters run from the renal hilum to the trigone of the bladder and are approximately 30 cm in length. They enter the pelvis by passing over the common iliac bifurcation at the pelvic brim. They then pass along the lateral pelvic side wall before passing anteriorly and medially under the uterine artery as it originates from the internal iliac artery and into the base of the bladder. The ureter comes close to the ovarian artery and vein and can be adherent to these vessels or the overlying ovary in pathological cases. By passing close to the uterine artery it can be mistakenly clamped and divided as a rare complication of hysterectomy.

The ureters are muscular tubes lined by transitional epithelium. The blood supply varies during its course but small vessels along the surface of the ureter require careful preservation when dissecting it free from other structures.

Rectum

The rectum is approximately 12 cm in length and starts at S3 as a continuation of the sigmoid colon. The puborectalis part of the pelvic floor forms a sling around the lower end at the junction with the anal canal. The rectum is commonly depicted in anatomical drawings as being dilated, causing the other pelvic organs to be pushed forward. This is because the original drawings were taken from cadavers but in the live patient the rectum is often empty, allowing the other structures to lie supported on the pelvic floor. The mucosa of the rectum is columnar and this is surrounded by inner circular and outer longitudinal fibres of smooth muscle. The serosal surface is covered by peritoneum.

The blood supply is from the superior rectal artery from the inferior mesenteric artery, and the middle and inferior rectal arteries arise from the posterior division of the internal iliac artery. The nerve supply is from the inferior hypogastric plexus and ensures the rectum is sensitive to stretch only.

Conclusion

A clear knowledge of anatomy is required for many gynaecological diagnoses and certainly for surgery. Many clinicians do not gain a full understanding of pelvic anatomy until they start operating and then rarely refer back to anatomical textbooks. The advent of more sophisticated pelvic floor surgery and especially minimal access surgery has modified the skills required of a gynaecological surgeon, necessitating the need for greater practical anatomical knowledge.

Normal and Abnormal Development of the Genital Tract

D. Keith Edmonds[1,2]

[1] *Imperial College London, London, UK*
[2] *Queen Charlotte's and Chelsea Hospital, London, UK*

Sexual differentiation and its control are vital to the continuation of our species, and for every gynaecologist an understanding of the development of the genital tract is clearly important. Our knowledge of this process has greatly increased in recent years and with it an appreciation of normal and abnormal sexual development. Following fertilization the normal embryo contains 46 chromosomes, including 22 autosomes derived from each parent. The basis of mammalian development is that a 46XY embryo will develop as a male and a 46XX embryo as a female. However, it is the presence or absence of the Y chromosome which determines whether the undifferentiated gonad becomes a testis or an ovary.

Although the sequence of genes required for differentiation of the gonads and development of the genital tract remains to be clearly defined, sex determination equates to gonadal development. This is then followed by a second process known as sex differentiation. Studies of the genetic control of gonadal development are based on animal data. The Y chromosome contains a region known as *SRY* (sex-determining region of the Y chromosome) and it has been shown that the testis-determining factor is on chromosome Yp11.31. In males this gene triggers testis formation from the undifferentiated gonad [1] but *SRY* is only one member of a family of genes that exist within the homeobox known as HMG. These genes, known as *SOX* genes, act in combination to differentiate the gonad to a testis. Mutations of *SRY* cause pure gonadal dysgenesis or hermaphroditism. Ovarian development is also dependent on genes on the short arm of the X chromosome, although the exact mechanism by which these genes invoke ovarian development remains to be defined.

Ovarian differentiation seems to be determined by the presence of two X chromosomes and the ovarian determinant is located on the short arm of the X chromosome; this was discovered by observing that the absence of the short arm results in ovarian agenesis [2]. At present, it is believed that *DAX1* is the gene which determines that the bipotential gonad will become an ovary. Other autosomal loci are certainly involved in ovarian development and development of the Wolffian and Müllerian structures is also under genetic control; this is thought to be a polygenic multifactorial inheritance, although autosomal recessive genes may also be involved [3]. The influence of the differentiated gonad on the development of other genital organs is thus fundamental and the presence of a testis will lead to male genital organ development and its absence means the individual will develop female genital organs whether ovaries are present or not.

Summary box 35.1

Mammalian development depends on the chromosome complement: a 46XY embryo develops as a male but the default state is female if the chromosome complement is anything other than male.

Development of the genital organs

Most embryological accounts agree on the principles of genital tract development, although some different views are held on the development of the vagina. The genital organs and those of the urinary tract arise in the intermediate mesoderm on either side of the root of the mesentery beneath the epithelium of the coelom. The pronephros, a few transient excretory tubules in the cervical region, appears first but quickly degenerates. The duct, which begins in association with the pronephros, persists and extends caudally to open at the cloaca, connecting as it does so with some of the tubules of the mesonephros shortly to appear. The duct is called the mesonephric (Wolffian) duct. The mesonephros itself, the second primitive kidney, develops as a swelling

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

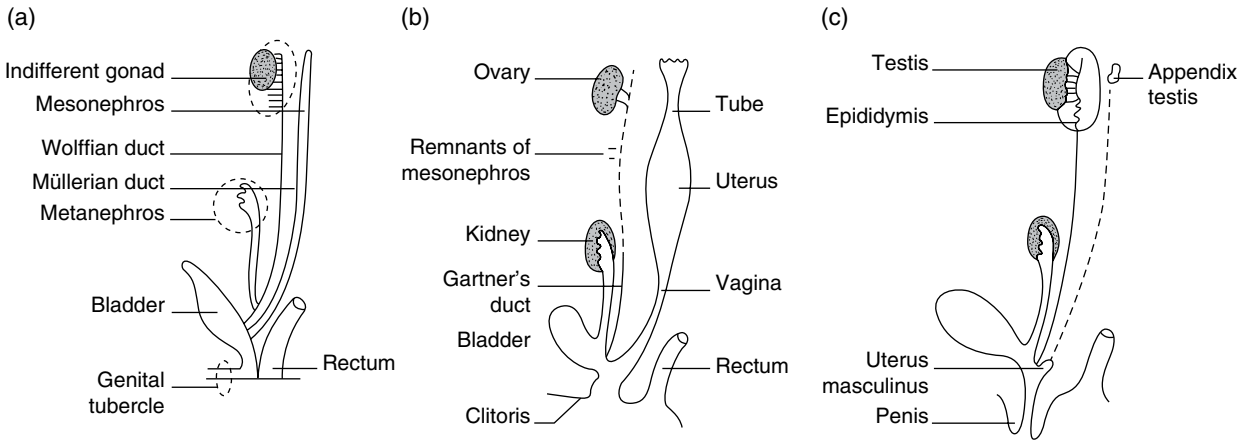

Fig. 35.1 Diagrammatic representation of genital tract development: (a) indifferent stage; (b) female development; (c) male development.

bulging into the dorsal wall of the coelom of the thoracic and upper lumbar regions. The mesonephros in the male persists in part as the excretory portion of the male genital system; in the female only a few vestiges survive (Fig. 35.1). The genital ridge in which the gonad of each sex is to develop is visible as a swelling on the medial aspect of the mesonephros; the paramesonephric (Müllerian) duct from which much of the female genital tract will develop forms as an ingrowth of the coelomic epithelium on its lateral aspect; the ingrowth forms a groove and then a tube and sinks below the surface.

Uterus and fallopian tubes

The two paramesonephric ducts extend caudally until they reach the urogenital sinus at about 9 weeks' gestation. It is important to remember that there is fusion between the caudal tip of the Müllerian and Wolffian ducts during this time The blind ends project into the posterior wall of the sinus to become the Müllerian tubercle (Fig. 35.2). At the beginning of the third month the Müllerian and Wolffian ducts and mesonephric tubules are all present and capable of development. From this point onwards in the female there is degeneration of the Wolffian system and marked growth of the Müllerian system. In the male the opposite occurs as a result of production of anti-Müllerian hormone by the fetal testis. The lower ends of the Müllerian ducts come together in the midline, fuse and develop into the uterus and the cervix. The cephalic ends of the duct remain separate to form the fallopian tubes. The thick muscular walls of the uterus and cervix develop from proliferation of mesenchyme around the fused portion of the ducts.

Vagina

At the point where the paramesonephric ducts protrude their solid tips into the dorsal wall of the urogenital sinus

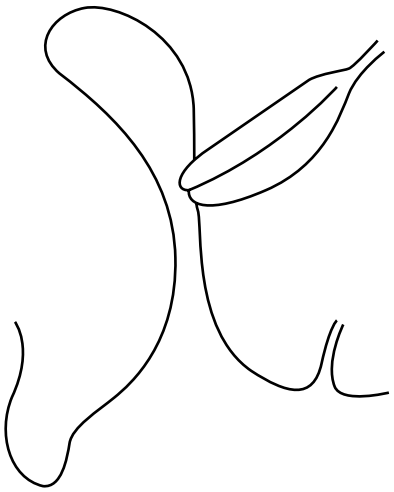

Fig. 35.2 Paired paramesonephric ducts protruding into the urogenital sinus as the Müllerian tubercle at 9 weeks of intrauterine life.

as the Müllerian tubercle, there is marked growth of tissue from which the vagina will form, known as the vaginal plate. This plate grows in all dimensions, greatly increasing the distance between the cervix and the urogenital sinus, and later the central cells of this plate break down to form the vaginal lumen. The complete canalization of the vagina does not usually occur until around weeks 20–24 of pregnancy and failure of complete canalization may lead to a variety of septa, which cause outflow tract obstruction in later years. The embryological development of the vagina has been the subject of debate for many years, but current molecular studies show that the whole vagina is derived from the paramesonephric duct.

External genitalia

The primitive cloaca becomes divided by a transverse septum into an anterior urogenital portion and a posterior

rectal portion. The urogenital portion of the cloacal membrane breaks down shortly after division is complete and this urogenital sinus develops into three portions (Fig. 35.3). There is an external expanded phallic part, a deeper narrow pelvic part between it and the region of the Müllerian tubercle, and a vesico-urethral part connected superiorly to the allantois. Externally in this region the genital tubercle forms a conical projection around the anterior part of the cloacal membrane. Two pairs of swellings, a medial part (genital folds) and a lateral pair (genital swellings), are then formed by proliferation of mesoderm around the end of the urogenital sinus. Development up to this time (10 weeks' gestation) is the same in the male and the female. Differentiation then occurs. The bladder and urethra form from the vesico-urethral portion of the urogenital sinus, and the vestibule from the pelvic and phallic portions. The genital tubercle enlarges only slightly and becomes the clitoris. The genital folds become the labia minora and the genital swellings enlarge to become the labia majora. In the male greater enlargement of the genital tubercle forms the penis and the genital folds fuse over a deep groove formed between them to become the penile part of the male urethra. The genital swellings enlarge, fuse and form the scrotum.

The final stage of development of the clitoris or penis and the formation of the anterior surface of the bladder and anterior abdominal wall up to the umbilicus is the result of the growth of mesoderm, extending ventrally around the body wall on each side to unite in the midline anteriorly.

Gonads

The primitive gonad appears in embryos at around 5 weeks' gestation. At this time coelomic epithelium develops on the medial aspect of the urogenital ridge and following proliferation leads to the establishment of the gonadal ridge. Epithelial cords then grow into the mesenchyme (primary sex cords) and the gonad now possesses an outer cortex and an inner medulla. In embryos with an XX complement, the cortex differentiates to become the ovary and the medulla regresses. The primordial germ cells develop by the fourth week in the endodermal cells of the yolk sac and during the fifth week they migrate along the dorsal mesentery of the hindgut to the gonadal ridges, eventually becoming incorporated into the mesenchyme and the primary sex cords by the end of the sixth gestational week.

The differentiation of the testis is evident at about 7 weeks by the disappearance of germ cells from the peripheral zone and gradual differentiation of remaining cells into fibroblasts, which form the tunica albuginea. The deeper parts of the sex cords give rise to the rete testis and the seminiferous and straight tubules. The first indication that the gonad will become an ovary is failure of these testicular changes to appear. The sex cords below the epithelium develop extensively with many primitive germ cells evident in this active cellular zone (Fig. 35.4). The epithelial cells in this layer are known as pre-granulosa cells. The active growth phase then follows, involving the pre-granulosa cells and germ cells, which are now very much reduced in size. This proliferation

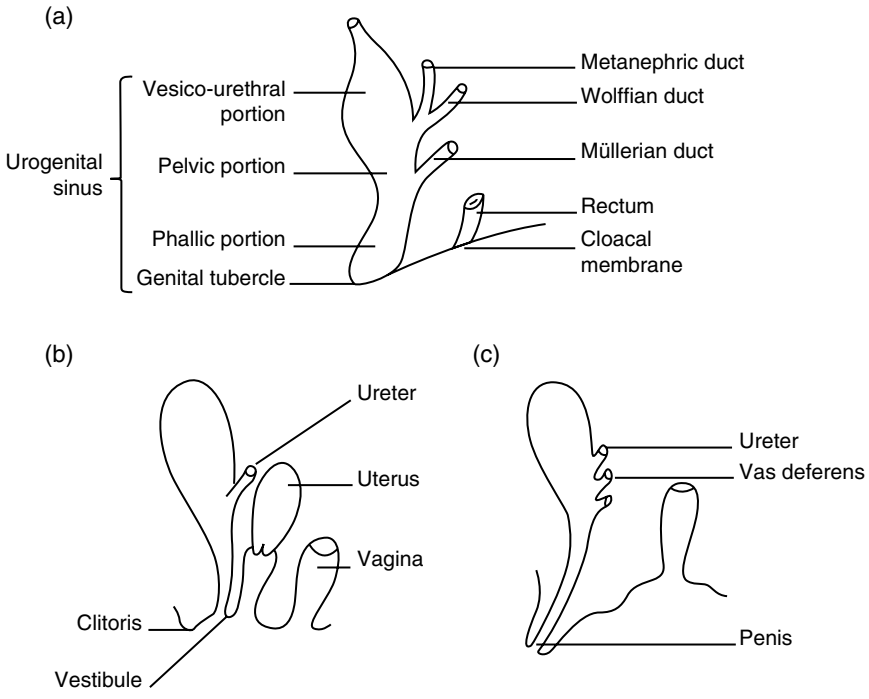

Fig. 35.3 Diagrammatic representation of lower genital tract development: (a) indifferent stage; (b) female development; (c) male development.

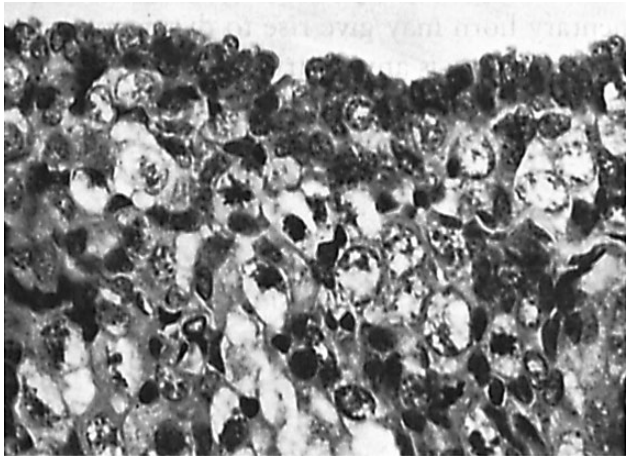

Fig. 35.4 Detail of immature ovary showing small epithelial cells (pre-granulosa cells) and larger germ cells.

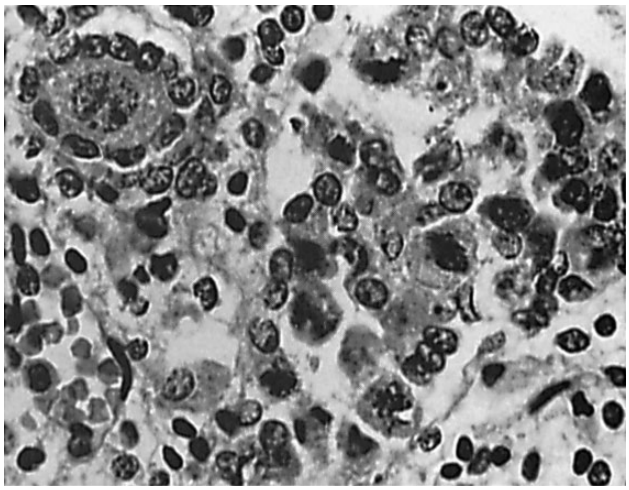

Fig. 35.5 A later ovary (31 weeks) showing a well-formed primary follicle (top left) and a germ cell (centre right) which is not yet completely surrounded by granulosa cells.

greatly enlarges the bulk of the gonad and the next stage (by 20 weeks onwards) shows the primitive germ cells, now known as oocytes, becoming surrounded by a ring of pre-granulosa cells; stromal cells develop from the ovarian mesenchyme later, surround the pre-granulosa cells and become known as granulosa cells and follicle formation is complete (Fig. 35.5). An interesting feature of the formation of follicles and the development of stroma is the disintegration of those oocytes which do not succeed in encircling themselves with a capsule of pre-granulosa cells.

The number of oocytes is greatest during intrauterine life and thereafter declines. Baker [4] found that the total population of germ cells rose from 600 000 at 2 months to a peak of 7 million at 5 months. At birth the number falls to 2 million, of which half are atretic. After 28 weeks

Fig. 35.6 Numerous primary follicles and one showing early development in the ovary of a child stillborn at 38 weeks.

or so of intrauterine life, follicular development can be seen at various stages and various sizes of follicles are also seen (Fig. 35.6).

Disorders of sexual development

Disorders of sexual development (DSD) have been reclassified by Hughes [5] and this has now been adopted as the best way of classifying these disorders (Table 35.1).

Sex chromosome disorders

This group of disorders includes Turner's syndrome (46XO), which is the most important in this group of disorders and the most common. Patients with Turner's syndrome have gonads that contain no oocytes and merely fibrous tissue and as a result of this they have no secondary sexual development (see Chapter 38).

46XY

This group of disorders is divided into three groups.

Disorders of gonadal (testicular) development

The gynaecologist may occasionally come across a case of ovotesticular DSD where both ovarian and testicular tissue exist within the same individual. These patients are rare in Europe and the USA but are notably more common in South Africa. They present with varying degrees of sexual ambiguity, with maleness predominating in some patients while female changes are more apparent in others. In the majority the uterus and vagina are present and the karyotype is usually normal female

Table 35.1 Classification of disorders of sexual development (DSD).

Sex chromosome DSD

A) 47XXY (Klinefelter's syndrome and variants)
B) 45X (Turner's syndrome and variants)
C) 45X/46XY (mixed gonadal dysgenesis)
D) 46XX/46XY (chimerism)

46XY DSD

A) *Disorders of gonadal (testicular) development*
   1) Complete or partial gonadal dysgenesis
   2) Ovotesticular DSD
   3) Testis regression

B) *Disorders of androgen synthesis or action*
   1) Disorders of androgen synthesis
      LH receptor mutations
      Smith–Lemli–Opitz syndrome
      Steroidogenic acute regulatory protein mutations
      Cholesterol side-chain cleavage
      3β-hydroxysteroid dehydrogenase
      17β-hydroxysteroid dehydrogenase
      5α-reductase
   2) Disorders of androgen action
      Androgen insensitivity syndrome
      Drugs and environmental modulators

C) *Other*

(46XX); in the largest series reported, Van Niekerk [6] found that 58% of cases had a normal karyotype, 13% had 46XX/XY, 11% had 46XY and 6% had 46XY/47XXY, with other mosaics accounting for 10%. Gonadal differentiation is interesting in that the commonest combination of ovotestis is for an ovotestis to be on one side and an ovary on the other, with a testis on one side and an ovary on the other being almost as frequent. Ovotestes can be bilateral or combined with a testis but this is much rarer. Diagnosis of true ovotesticular DSD can only be made after gonadal biopsy, and sex of rearing should be determined on the functional capability of the external genitalia after which inappropriate organs should be removed. In some cases it may be possible to identify the ovarian and testicular portions of an ovotestis for certain and to remove only that part that is unwanted. If this is not possible, both must be removed and then the patient needs to be brought up in the gender role for whichever is appropriate and hormone replacement therapy instituted at puberty.

Disorders of androgen synthesis

In group B1 (see Table 35.1), the most commonly seen, though rare, is 5α-reductase deficiency. These patients are genetic males who show ambiguous genitalia at birth and at puberty begin to virilize like normal males. This results in penile enlargement, increased facial hair and muscular hypertrophy but breast development does not occur. The phallus is rather small and a perineal urethral orifice is present. The disorder of androgen synthesis relates to deficiency of 5α-reductase, the enzyme responsible for the conversion of testosterone to dihydrotestosterone, which results in virilization of the external genitalia during embryogenesis. Testosterone is unable to induce virilization during fetal life but at puberty androgen receptors become sensitive to circulating levels of testosterone and therefore a degree of virilization can occur. Management of these patients after puberty can be difficult as they themselves may find sexual orientation difficult and may wish to change their gender role but they must be fully assessed before any permanent decisions are made.

Androgen insensitivity syndromes

In these conditions the individual has a chromosome complement of 46XY but an absence of functional androgen receptors. This is known as complete androgen insensitivity syndrome and during fetal life female external genitalia develop, but as the testis produces Müllerian inhibitor the internal structures of the Müllerian duct regress. However, the Wolffian duct cannot develop as it also lacks androgen receptors. These individuals usually present at puberty with failure of menstruation. They are shown to have bilateral testes and a blind-ending vagina

and they may well feminize at puberty as testicular production of oestrogen induces breast growth. Absence of the androgen receptor means that pubic hair and axillary hair growth is sparse and the diagnosis is often easy to make clinically. The testes are usually normal in size and located either in the abdomen or the inguinal canal and can present as inguinal hernias. These sometimes present in childhood when the diagnosis is made on surgical excision of the mass. Height is slightly increased compared with normal women. Testicular neoplasia is increased though very rare under the age of 30. It is therefore perfectly acceptable to leave the gonads *in situ* until pubertal development has been completed and then to remove them.

Partial androgen insensitivity occurs when the androgen receptor has a mutation and has partial function. At puberty therefore individuals feminize as do patients with complete androgen insensitivity but as they have some function in the androgen receptor, their external genitalia change, with phallic enlargement and partial labioscrotal fusion. Again, bilateral testes are present within the abdominal cavity or the inguinal canal and there are normal circulating levels of testosterone equivalent to a male. At birth phallic enlargement may already be present due to incomplete virilization and the intersex state at birth needs to be assessed and the sex of rearing determined.

Summary box 35.2

- Androgen insensitivity may be complete or partial depending on the defect in the androgen receptor.
- Phenotypic changes depend on the degree of function of the androgen receptor.

46XX

Patients with this group of disorders will most commonly present with congenital adrenal hyperplasia (CAH). Deficiency of 21-hydroxylase is the most common and this leads to elevated levels of androstenedione, 17-hydroxyprogesterone and testosterone. As this is a disorder which is present during fetal life, the elevated levels of androgen lead to virilization of the fetus and therefore clinically female fetuses show clitoral hypertrophy and labioscrotal fusion. The urethral orifice is displaced usually along the dorsal surface of the clitoris and the extent of virilization can vary considerably. Müllerian duct development is normal as are the ovaries. The most severe form at birth is a salt-losing syndrome that can be life-threatening and the administration of mineralocorticoids and sodium are usually needed to correct the hyperkalaemia. Cortisol administration remains necessary throughout life, although requirements may diminish with age.

These patients are diagnosed soon after birth by finding elevated levels of 17-hydroxyprogesterone. Little attention needs to be paid to the anatomy unless there is marked virilization, in which case discussion with the parents about surgical intervention should be considered. However, debate continues about whether or not surgical intervention should occur in infancy or at puberty when the individual can be involved in the decision-making process. Further discussion of this is outside the remit of this chapter.

46XX Müllerian agenesis

The most common of this group of disorders is Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome which is characterized by congenital absence of the uterus and vagina in individuals who are 46XX. These patients usually present with primary amenorrhoea at the age of 12–16 years with normal secondary sexual characteristics as the ovaries are normally developed and functional. The combination of normal secondary sexual characteristics and primary amenorrhoea suggests an anatomical cause. Inspection of the vulva will reveal that this is normal but there is a short vagina which is blind-ending (Fig. 35.7). The diagnosis of an absent vagina can generally be made without difficulty but subsequent ultrasound of the abdomen will define the absence of Müllerian structures. It must be remembered that a very short vagina may also occur in patients with androgen

Fig. 35.7 Vulval appearance in a case of absence of the vagina.

insensitivity but assessment of karyotype will differentiate these two groups of patients. In all patients found to have MRKH syndrome, the renal tract should be investigated using ultrasound as some 40% of patients will have renal anomalies, with 15% having an absent kidney. If further investigation is required, intravenous urography can be used to delineate any other renal anomalies [7]. It is extremely rare for laparoscopy to be required to determine the diagnosis but if undertaken must be used with great care as a pelvic kidney may be present. Once the diagnosis is certain, management can be divided into two phases. The first is devoted to the psychological counselling of patients and the second involves the correction of the vaginal anatomy. Some patients may present having already attempted intercourse and this may in fact be entirely satisfactory and therefore no attention needs to be paid to the anatomical side of their management. However, it is important that all patients with MRKH syndrome are assessed with great care so that appropriate therapy can be instigated at the correct time. A full psychological assessment must be carried out before any treatment is commenced or success will be extremely limited.

Psychological counselling of these patients is imperative as they may manifest problems that are devastating and profound. They have feelings of fear and confusion, particularly around their sexual orientation, and may express feelings of rejection and isolation. They have understandable concerns about the ability to embark on heterosexual relationships and of their feeling of inadequacy, as they are infertile. The help of a skilled psychologist in managing these patients and a multidisciplinary approach means that the outcome will be successful in a holistic way, not merely an anatomical success. Until patients are deemed psychologically capable of undergoing the rigours of treatment, all attempts to coerce the clinical team to begin treatment prior to this should be resisted [8,9].

Summary box 35.3

- MRKH syndrome is the second most common cause of primary amenorrhoea.
- Turner's syndrome is the most common.

Non-surgical management

The creation of a vagina should always be attempted by a non-surgical method as the treatment of first choice and only in the rare cases of failure should a surgical solution be considered. This technique was pioneered by Frank [10] and a recent review by Edmonds [7] suggests that success rates in excess of 95% can now be achieved. The principle of the method is that the vaginal dimple should be stretched into a potential space filled with comparatively loose connective tissue and this is capable of considerable indentation. The patient is instructed to use graduated glass dilators (Fig. 35.8) that are placed against the introitus and the blind vagina and gentle pressure is exerted in a posterior direction for approximately 10–20 min twice a day. Gradually the dilator distends the space and then increasing sizes of dilators are used until a neovagina is created. In general it takes between 8 and 10 weeks of repeated use to achieve a satisfactory result. The sexual satisfaction associated with this non-surgical technique far exceeds that of operative vaginoplasty.

Fig. 35.8 Graduated glass dilators.

Summary box 35.4

Vaginal dilator therapy is the therapy of choice for patients with MRKH syndrome.

Surgical techniques

In the few patients who fail a non-surgical technique, vaginoplasty will need to be considered. A large number of techniques have been devised to create a vagina surgically, the most widely used being that of McIndoe and Banister [11]. In this procedure a cavity is created between the bladder and the bowel at the site where the natural vagina would have been and the cavity is then lined by a split-thickness skin graft from the thigh and applied to the space on a plastic mould. The anatomical result can be very successful and remarkably good sexually. A review of 1311 reported cases gave a success rate of 92% [7].

However, there are a number of difficulties and disadvantages of this technique, not least the postoperative period which is painful and somewhat protracted. The graft does not always take well and granulation may form

over part of the cavity giving rise to discharge. Pressure necrosis between the mould and urethra, bladder or rectum may lead to fistula formation but the most important disadvantage is the tendency for the vagina to retract unless a dilator is worn or the vagina used for intercourse regularly. It is therefore best to perform this procedure when sexual intercourse is desired soon afterwards because failure of the patient to maintain the vagina means there will be surgical failure. A further disadvantage of this technique is the graft donor site, which remains visible as evidence of the vaginal problem and most women prefer not to have any external scarring. In order to avoid the use of skin grafts a number of other materials have been used including amnion, although this material is no longer desirable due to the risk of transmission of infection. Other reported techniques include the use of bowel [12] and skin flaps [13] and these have their own individual complications. A procedure known as Vecchietti's operation has been popular in Europe for many years and this involves the use of a small olive placed in the dimple of the absent vagina [14,15]. Laparoscopically, wires are then brought through from the dimple to the anterior abdominal wall and then pressure exerted on a spring device, thereby creating a neovagina in a way that mimics the non-surgical technique of Frank. However, it does not require the woman herself to use the dilators but after 7–9 days the olive is removed and the stretched vaginal skin needs to be further dilated with glass dilators. A recent review of this technique revealed success rates approximating to 90% [7].

Other anatomical anomalies

Fusion anomalies

Fusion anomalies of various kinds are not uncommon (Fig. 35.9) and may present clinically either in association with pregnancy or not. The lesser degrees of fusion defects are quite common, the cornual parts of the uterus remaining separate, giving the organ a heart-shaped appearance known as a bicornuate uterus. There is no evidence that such minor degrees of fusion defect give rise to clinical signs or symptoms. However, the presence of a septum extending down the uterine cavity is likely to give rise to clinical problems. Such a septate or subseptate uterus may be of normal external appearance or of

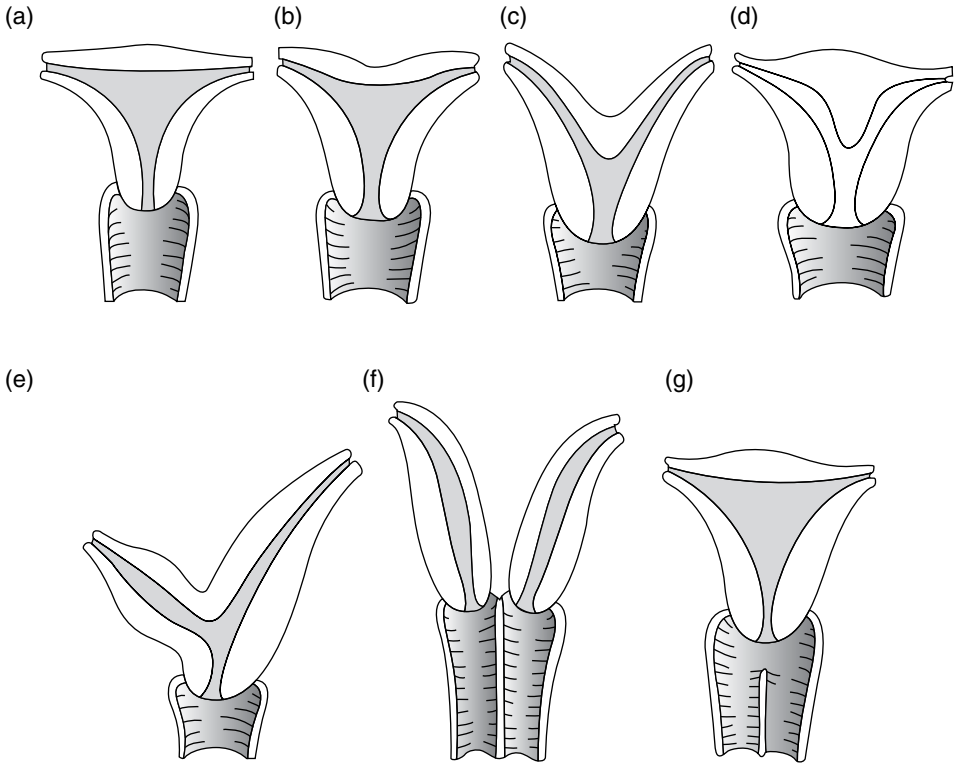

Fig. 35.9 Various fusion abnormalities of the uterus and vagina: (a) normal appearance; (b) arcuate fundus with little effect on the shape of the cavity; (c) bicornuate uterus; (d) subseptate uterus with normal outline; (e) rudimentary horn; (f) uterus didelphys; (g) normal uterus with partial vaginal septum.

bicornuate outline. Clinically, patients may present with recurrent spontaneous miscarriage or malpresentation of the fetus during pregnancy. A persistent transverse lie or breech presentation of the fetus in late pregnancy may suggest a uterine anomaly since the fetus tends to lie with its head in one cornu and the breech in the other.

In more extreme forms of failure of fusion the clinical features may be less, rather than more, marked. Two almost separate uterine cavities with one cervix are probably less likely to be associated with abnormalities than are the lesser degrees of fusion defect. Complete duplication of the uterus and cervix (uterus didelphys) is usually associated with a septate vagina. The septum should be removed before pregnancy.

Rudimentary development of one horn may give rise to a very serious situation if a pregnancy is implanted there. Rupture of the horn with profound bleeding may occur as the pregnancy increases in size. The clinical picture will resemble that of a ruptured ectopic pregnancy, with the difference that the amenorrhoea will probably be measured in months rather than weeks, and shock may be profound. A poorly developed or rudimentary horn may give rise to dysmenorrhoea and pelvic pain if there is any obstruction to communication between the horn and the main uterine cavity or the vagina. Surgical removal of this rudimentary horn is then indicated (see Fig. 35.9).

Transverse vaginal septum/imperforate hymen

An imperforate membrane may exist at the lower end of the vagina, which is loosely referred to as imperforate hymen, although the hymen can usually be distinguished separately (Fig. 35.10). These abnormalities of vertical fusion are seldom recognized clinically until puberty when retention of menstrual flow gives rise to the clinical features of haematocolpos, although rarely they may present in the newborn as hydrocolpos. The features of haematocolpos are predominantly abdominal pain, primary amenorrhoea and occasionally interference with micturition. The patient is usually 14–15 years old but may be older, and a clear history may be given of regular cyclical lower abdominal pain for several months previously. The patient may also present as an acute emergency if urinary obstruction develops. Examination reveals a lower abdominal swelling, and per rectum a large bulging mass in the vagina may be appreciated (Fig. 34.11). Vulval inspection may reveal the imperforate membrane, which may or may not be bluish in colour depending on its thickness. Diagnosis may be more difficult if the vagina is imperforate over some distance in its lower part or if there is obstruction in one-half of a septate vagina.

Fig. 35.10 An imperforate membrane occluding the vaginal introitus in a case of haematocolpos. Note the hymen clearly visible immediately distal to the membrane.

Treatment may be relatively simple or rather complex. If the membrane is thin, then simple excision of the membrane and release of the retained blood resolves the problem. Redundant portions of the membrane may be removed but nothing more should be done at this time. Fluid will then drain naturally over some days. Examination a few weeks later is desirable to ensure that no pelvic mass remains that might also suggest haematosalpinx. In fact, haematosalpinx is most uncommon except in cases of very long standing and is associated with retention of blood in the upper vagina. On these rare occasions when a haematosalpinx is discovered, laparoscopy is desirable, the distended tube being removed or preserved as seems best. Haematometra scarcely seems to be a realistic clinical entity, the thick uterine walls permitting comparatively little blood to collect therein. The subsequent menstrual history and fertility of patients who are successfully treated are probably not significantly different from those of unaffected women, although patients who develop endometriosis may have some fertility problems.

When the obstruction is more extensive than a thin membrane and a length of vagina is absent, diagnosis and management are less straightforward and the ultimate interference with fertility is greater. Resection of the absent segment and reconstruction of the vagina may be done by an end-to-end anastomosis of the vagina or by a partial vaginoplasty.

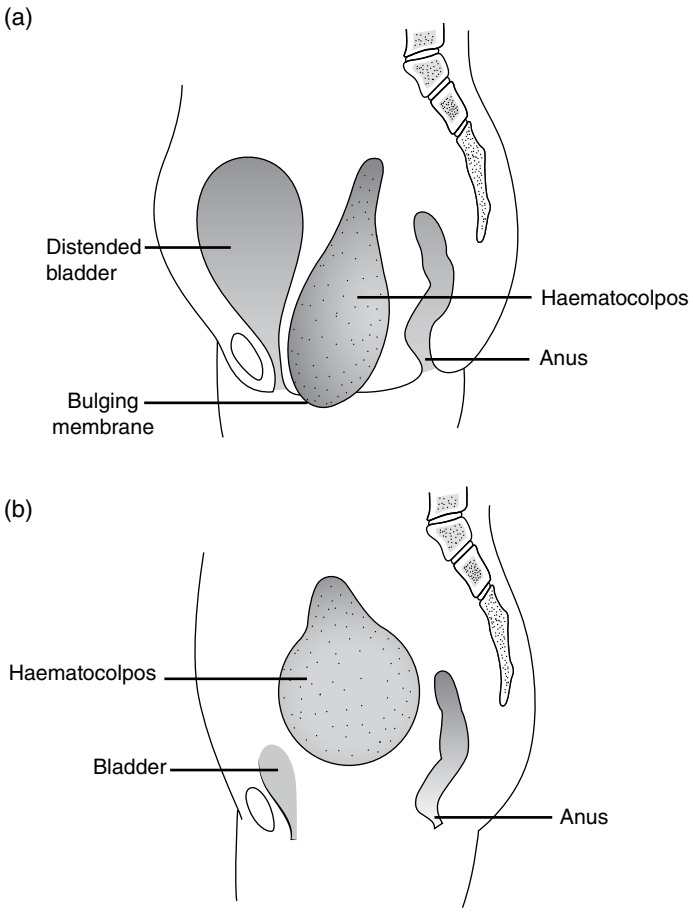

Fig. 35.11 (a) Haematocolpos: note how the blood collecting in the vagina presses against the urethra and bladder base, ultimately causing retention of urine. (b) Haematocolpos associated with absence of the lower portion of the vagina. Note that the retained blood is now above the bladder base and retention of urine is unlikely.

The combination of absence of most of the lower vagina together with a functioning uterus presents a difficult problem. The upper part of the vagina will collect menstrual blood and a clinical picture similar in many ways to haematocolpos will be seen. However, urinary obstruction is rare because the retained blood lies above the level of the bladder base (Fig. 35.11). Diagnosis is more difficult and it may not be at all certain how much of the vagina is absent or how extensive the surgery would need to be to release the retained fluid and recreate the normal anatomy. Imaging may be by ultrasound or MRI, and both these techniques may be successful in determining the exact anatomical relationships prior to surgery being performed. However, in the clinical situation the surgical approach is rarely entirely through the perineum and usually involves a laparotomy to establish finally how best the anatomy can be recreated.

Treatment is difficult and a dissection upwards is made as in the McIndoe–Read procedure. The blood is released, but its discharge for some time later may interfere with the application of a mould and skin graft. If possible, the upper and lower portions of the vagina should be brought together and stitched so that the new vagina with its own skin is created, obviating the risk of contraction. However, the upper fragment tends to retract upwards resulting in a narrow area of constriction some way up the vagina, and this results in subsequent dyspareunia.

Summary box 35.5

- Transverse vaginal septa cause primary amenorrhoea and cyclical abdominal pain.
- The most common septa are low and surgical treatment usually restores total reproductive function.
- High septa have a higher rate of fertility failure.

Longitudinal vaginal septum

A vaginal septum extending throughout all or part of a vagina is not uncommon; such a septum lies in the

sagittal plain in the midline, although if one side of the vagina has been used for coitus the septum may be displaced laterally to such an extent that it may not be obvious at the time of examination. The condition is found in association with a completely double uterus and cervix or with a single uterus and double cervix. In obstetrics this septum may have some importance if vaginal delivery is to be attempted. In these circumstances the narrow hemivagina may be inadequate to allow passage of the fetus and serious tears may occur if the septum is still intact at this time. It is therefore prudent to arrange to remove the vaginal septum as a formal surgical procedure whenever one is discovered, either before or during pregnancy. The septum may occasionally be associated with dyspareunia, when similar management is indicated.

Occasionally, a double vagina may exist in which one side is not patent, and a haematometra and haematocolpos may occur in a single side. Under these circumstances the vaginal septum must be removed to allow drainage of the obstructed genital tract and the results are generally excellent.

Vulval anomalies

Rarely, anomalies in the development of bowel or bladder may give rise to considerable abnormality in the appearance of the vulva. The anus may open immediately adjacent to the vulva or just within it. Bladder exstrophy will give rise to a bifid clitoris and anterior displacement of the vagina, in addition to bladder deformities themselves. Further discussion of these complex problems may be found in Edmonds [16].

Wolffian duct anomalies

Remnants of the lower part of the Wolffian duct may be evident as vaginal cysts, whereas remnants of the upper part are evident as thin-walled cysts lying within the layers of the broad ligament (paraovarian cysts). It is doubtful if a vaginal cyst per se calls for surgical removal, although removal is usually undertaken. The cysts may cause dyspareunia and this is the most likely reason for their discovery and surgical removal. Cysts situated at the upper end of the vagina may be found to burrow deeply into the region of the broad ligament and the base of the bladder and should be approached surgically with considerable caution. A painful and probably paraovarian cyst will require surgery and its precise nature may be unknown until the abdomen is explored laparoscopically. Such cysts are normally easily removed from the broad ligament.

Fig. 35.12 An intravenous pyelogram in a patient with absence of the vagina, showing a single kidney and a gross abnormality of the course of the ureter.

Renal tract abnormalities

The association between congenital malformations of the genital tract and those of the renal tract has already been mentioned. When a malformation of the genital organs of any significant degree presents, some investigation to confirm or exclude a renal tract anomaly would be wise. An ultrasound scan can be performed and will probably be sufficient in the first instance; however, if any doubt arises, an intravenous urogram may be performed. Lesions such as absence of a kidney, a double renal element on both or one side, a double ureter or a pelvic kidney (Fig. 35.12) may not call for immediate treatment but may do so later; moreover, it is as well to be aware of such abnormalities if the abdomen is to be explored or for treatment of the genital tract lesion itself.

Fig. 35.13 An intravenous pyelogram in a child with an imperforate vagina. Both ureters open ectopically into the posterior urethra.

Ectopic ureter

One abnormality which apparently presents with gynaecological symptoms is the ectopic ureter (Fig. 35.13). A ureter opening abnormally is usually an additional one, although sometimes a single one may be ectopic. The commonest site of the opening is the vestibule, followed closely by the urethra and then the vagina. Other sites are less common. The main symptom is uncontrollable wetness. However, the amount of moisture appearing at the vulva may be small and is sometimes mistaken for a vaginal discharge. This confusion, together with difficulties in confirming the diagnosis of an ectopic ureter, even when one is suspected, may lead to many patients being investigated for years before the condition is recognized. Diagnosis can sometimes be easy but is usually not so. The orifice at the vestibule may be clearly visible but more often careful search is necessary to locate it, if it can be seen at all. Cystoscopy and urethroscopy may be necessary to establish if normal ureteric openings exist in the bladder. Radiological study may be helpful by indicating a double element on one or both sides. Treatment will involve the help of a urological surgeon, and partial nephrectomy and ureterectomy or reimplantation of the ectopic ureter into the bladder may be undertaken.

XY females

Faults in androgen production

In this group of patients androgen production may fail from either anatomical or enzymatic testicular failure.

Anatomical testicular failure

Failure of normal testicular differentiation and development may be the result of a chromosome mosaicism affecting the sex chromosomes or possibly associated with an abnormal isochromosome [17], but usually the sex chromosomes appear normal and the condition is referred to as pure gonadal dysgenesis. Clinically, such cases show variable features depending on how much testicular differentiation is present. Since differentiation is often poor, most patients have mild masculinization or none at all, and the uterus, tubes and vagina are generally present. The presence of the uterus in this condition contrasts with the other forms of XY female described below.

Management of this group of patients is concerned with the reconstruction of the external genitalia in the manner described previously and removal of the streak or rudimentary gonads in view of their raised potential for cancer. The degree of masculinization of such patients is often minimal and if it is limited to a minor degree of clitoral enlargement with little or no fusion of the genital folds, surgery need not be undertaken. The risk of malignancy in the rudimentary testes is probably in the order of 30% and gonadal removal during childhood would be wise. Around the age of puberty replacement oestrogen–progestogen therapy must be started in order to initiate secondary sexual development and menstruation.

Enzymatic testicular failure

Several metabolic steps are necessary for the complete formation of testosterone from cholesterol (Fig. 35.14). A number of biosynthetic defects have been reported at each stage of the process. As a result, clinical features are somewhat varied but since such enzyme defects are generally incomplete there is external genital ambiguity of varying degrees, the uterus, tubes and upper vagina being absent since the production of Müllerian-inhibiting substance by the testes is normal.

The decision on the sex of rearing will depend on the degree of masculinization of the external genitalia but the female role is often the chosen one. Surgical management is as already described. The identification of the precise enzyme defect can be difficult, but may be approached through human chorionic gonadotrophin stimulation of the gonads and measurement of various androgens to determine where the enzyme block occurs.

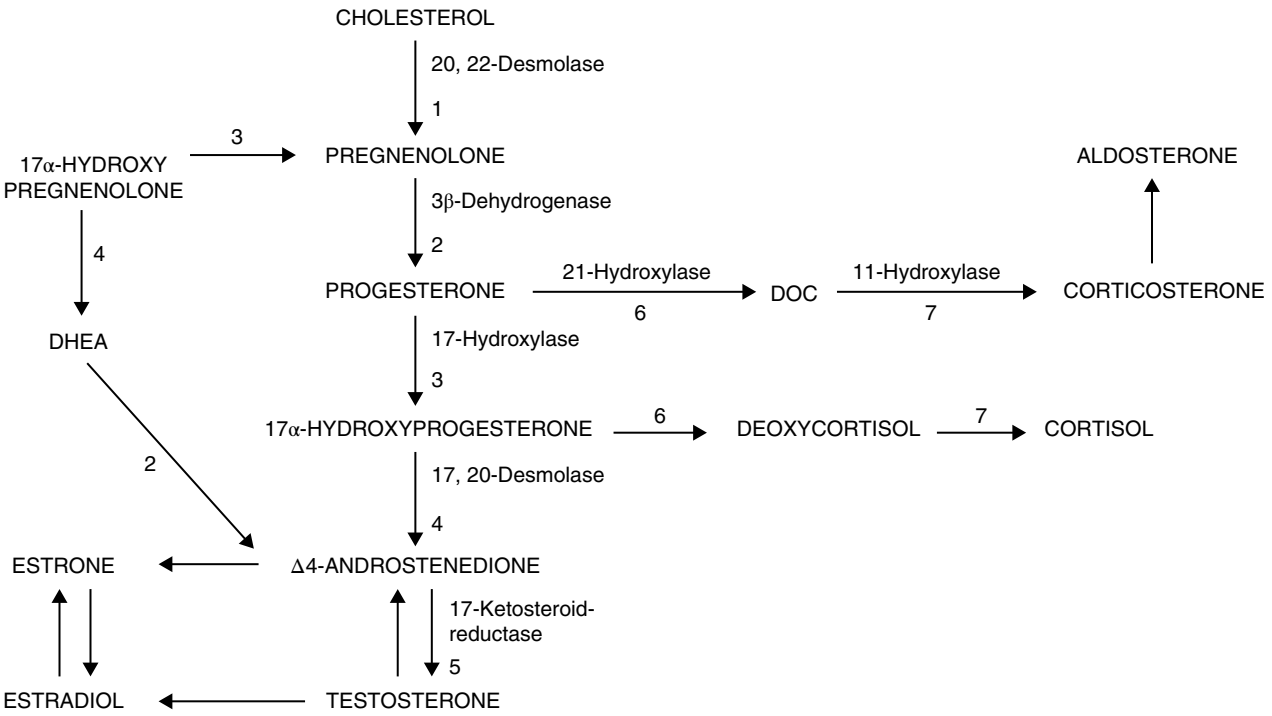

Fig. 35.14 The enzyme steps necessary to convert cholesterol through its various intermediate stages to aldosterone, cortisol and testosterone. Note that 3β-dehydrogenase (labelled 2) is active at two points, as are 17-hydroxylase (labelled 3), 17,20-desmolase (labelled 4), 21-hydroxylase (labelled 6) and 11-hydroxylase (labelled 7). DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone.

Role of Imaging in Gynaecology

Wouter Froyman and Dirk Timmerman

Department of Development and Regeneration, University Hospitals KU Leuven, Leuven, Belgium

A good medical history-taking and clinical examination are the first steps in the management of a patient presenting with gynaecological symptoms. However, to confirm or exclude a diagnosis suspected on the basis of these, imaging methods are often indicated.

The introduction of ultrasound has changed the approach to many disorders in gynaecology. It has redefined the diagnostic criteria and management of problems in early pregnancy, decreased the need for more invasive procedures in women with abnormal uterine bleeding or infertility, enabled the accurate characterization of pelvic masses and allowed significant advances in the management of patients with pelvic pain. However, as ultrasound assessment might not give a final answer in all cases, second-stage tests such as MRI may be required.

In this chapter, we focus on practical guidance in performing gynaecological ultrasound and discuss the role of different imaging modalities in common clinical conditions encountered in gynaecological practice.

Ultrasound techniques

An ultrasound examination of the pelvis is one of the most common procedures in gynaecology, with most women presenting to a gynaecology department undergoing a scan at some point in their management pathway. Ultrasound is in general readily available, safe, low in cost and less time-consuming compared to other maging modalities. Another important advantage is its possibility for dynamic evaluation, which helps in understanding the origin of lesions and in the detection of adhesions or site-specific tenderness [1]. A potential disadvantage is that the quality of ultrasound imaging, more than in other imaging techniques, not only relies on the equipment but also on its settings as well as on the experience of the ultrasound investigator. Therefore, it is very important to have a good basic knowledge of how the technical features of the machine can be adjusted.

Physical properties and settings

The term 'ultrasound' describes sound waves of such a high frequency that they cannot be heard by humans. The higher the probe frequency, the narrower the beam width. This results in improved resolution, but with the trade-off of poorer penetration. As a result such probes need to be used close to the area of interest. In gynaecology, transabdominal probes tend to range from 3 to 5 MHz and transvaginal probes from 5 to 8 MHz. However, improvements in probe design have led to them being significantly more adaptable than in the past [2]. Besides adjusting the frequency, it is also important to change the focus of the ultrasound beam to optimize the resolution of the image at the depth of interest. Altering the gain is indispensable to acquire proper illumination. Harmonic imaging can further improve image quality, especially in cystic lesions (e.g. ovarian masses). Once the area of interest has been located, the image can be magnified in order to obtain maximum detail.

The use of colour or power Doppler is useful for assessing both the amount of blood flow and the pattern of any blood vessels present. This is helpful in visualizing normal anatomy (e.g. finding the ovaries), defining the origin of structures and, if used in a standardized way, characterizing pathology [1,3–6]. The option of three-dimensional ultrasound is a further advance. This is helpful for the characterization of congenital uterine abnormalities and for the delineation of the endometrial–myometrial junction to assess acquired uterine pathology [7,8].

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Ultrasound approaches

Transvaginal ultrasonography is the method of choice, as it results in the best image quality, due to the proximity of the probe to the gynaecological organs. However, a transabdominal scan may be required to assess the uterus in the presence of large fibroids or to evaluate the adnexa when these are enlarged and extending beyond the level of the pelvis. When a transvaginal scan is considered inappropriate (e.g. virginity, vaginismus or vaginal stenosis due to atrophy, surgery or pelvic irradiation) and if the transabdominal approach is inconclusive, a transrectal ultrasound examination should be considered.

During transvaginal ultrasonography the hand not holding the probe can be used to press on the abdomen and help optimize the image or assess mobility or pain [1]. Although a full bladder can be useful for transabdominal scanning, in many cases it is not required. A good technique is to identify the femoral vessels and follow these upwards to the iliac vessels and finally to the bifurcation of the aorta. An ovarian mass and any lymphadenopathy present can be assessed in this way. A gynaecologist learning to scan should be aware that an examination of the abdomen does not stop in the pelvis and the examiner should be familiar with the normal appearances of the organs of the upper abdomen and the likely sites of metastatic disease in the event of gynaecological malignancy. These might include the peritoneum, lymph nodes around the large vessels, the spleen, liver or the omentum. Ascites may be present in the upper abdomen.

In the event of suspected intra-abdominal blood loss, the presence of fluid above the fundus of the uterus or in the utero-vesical pouch is significant. A further marker of serious intra-abdominal bleeding is the presence of fluid in Morrison's pouch between the liver and the kidney [9].

The uterus should be assessed in the sagittal plane, including detailed evaluation of the cervix, the body of the uterus, the fundus and the endometrial cavity. Views obtained in the transverse plane may help in defining the location of focal pathology. The detection of congenital uterine abnormalities is best achieved using three-dimensional ultrasound whereby the unique coronal view allows most anomalies to be characterized relatively easily [10].

The endometrial thickness, the maximal measurement across the lumen of the endometrial cavity in the sagittal plane including both endometrial layers (double endometrial thickness), is an important assessment. In premenopausal women, endometrial thickness generally varies from 4 to 8 mm in the follicular phase and from 7 to 14 mm in the secretory phase. A sonographic examination in this population should preferably be performed in the early proliferative phase (cycle day 4–6) [3]. Recent consensus documents have outlined proposed terminology to describe the endometrium and myometrium, with any pathology that may be present [3,6].

Difficulties in assessment due to variations in uterine position (particularly when axial) or uterine rotation (endometriosis or adhesions) can be overcome by pressing on the abdomen with the non-scanning hand, or by filling the bladder [3]. The ovaries can be visualized by tracking the vessels in the broad ligament in the transverse plane from the uterus and moving laterally to the pelvic wall nearby the external iliac vessels. It might be useful to apply abdominal pressure to displace superimposed intestines or to use a transabdominal approach if necessary [1].

Sonohysterography

Sonohysterography is the instillation of fluid through a catheter into the uterine cavity to act as a negative contrast agent to outline any focal intra-cavity pathology. Sterile saline or gel may be used [3]. In saline instillation, a neonatal suction catheter may be used, although backflow may necessitate the use of a more expensive balloon catheter to obtain a more stable filling of the uterine cavity. The higher viscosity of gel results in a smaller instillation volume, which makes the procedure better tolerated by patients compared with saline instillation [11]. Moreover, transtubal spillage is less likely to occur and this may be an additional argument for the use of gel instead of saline, as endometrial malignancy is never completely excluded with ultrasonography. A small neonatal suction catheter (2 mm) is sufficient, but it might be helpful to warm the gel to 37 °C to promote flow through the catheter.

It might be prudent in fertile women to advocate contraception during the cycle when the sonohysterography procedure is planned, and some examiners advise that prophylactic antibiotics should be administered prior to the procedure in all potentially fertile women to avoid pelvic inflammatory disease [11,12].

Possible indications for sonohysterography include a thickened or irregular endometrium, poor views of the endometrium (e.g. due to axial position of uterus) and further characterization of focal intra-cavity pathology such as polyps, submucous fibroids and adhesions (Fig. 36.1). There is a large amount of data to suggest that sonohysterography is comparable to hysteroscopy for the assessment of most focal endometrial pathology [13]. Ultrasound without saline instillation is significantly less accurate for this purpose [14]. In the event of uncertainty regarding the endometrial findings, sonohysterography is always a good option to consider. It is also important to

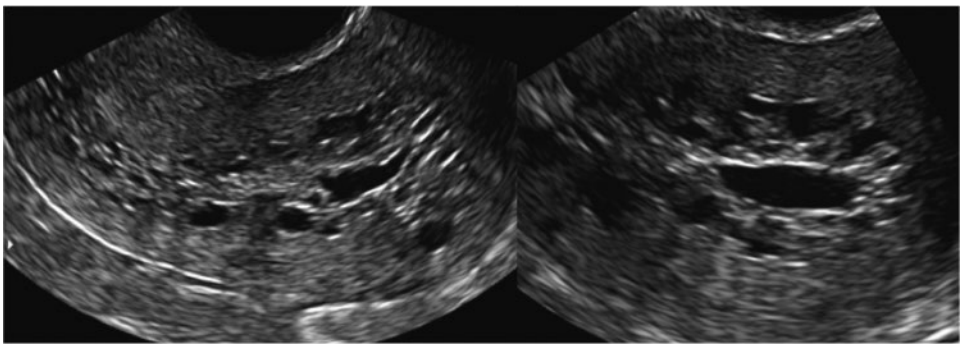

Fig. 36.1 Gel instillation sonohysterography. (*Left*) Unenhanced ultrasound image of the endometrium in a patient using tamoxifen. The endometrial lining is not well assessable. (*Right*) After gel instillation, the endometrium shows a regular lining, besides tamoxifen-induced changes. Focal pathology can be excluded.

remember that the endometrium in premenopausal women is a dynamic structure and so simply repeating a scan after menstruation will often clarify whether there is focal intrauterine pathology or not.

Hysterosalpingo-contrast sonography and hysterosalpingo-foam sonography

The gold standard test to assess tubal patency is laparoscopic chromoperturbation with methylene blue. However, this procedure is associated with the risks of laparoscopy under general anaesthesia. Therefore, as a less invasive radiography technique, X-ray hysterosalpingography has been applied for decades in the diagnostic work-up of the patient presenting with infertility [15]. At present, this exposure to radiation and risk of allergy to the contrast agent can be avoided by tracking the movement of a suspension of air bubbles through the fallopian tubes during hysterosalpingo-contrast sonography [16]. In general, a balloon catheter is used. The contrast media are commercially available, but a cheaper option is to use an alternating injection of water and air in the uterine cavity and to sonographically detect air bubbles around the ovary and free fluid in the pouch of Douglas [17]. More recently, hysterosalpingo-foam sonography was introduced, using 'gel foam', with advantageous physical properties compared with saline [18] (Fig. 36.2). Both hysterosalpingo-contrast sonography and hysterosalpingo-foam sonography are well tolerated by the patient, and show very good agreement in assessing tubal patency compared with laparoscopic chromoperturbation [18–20].

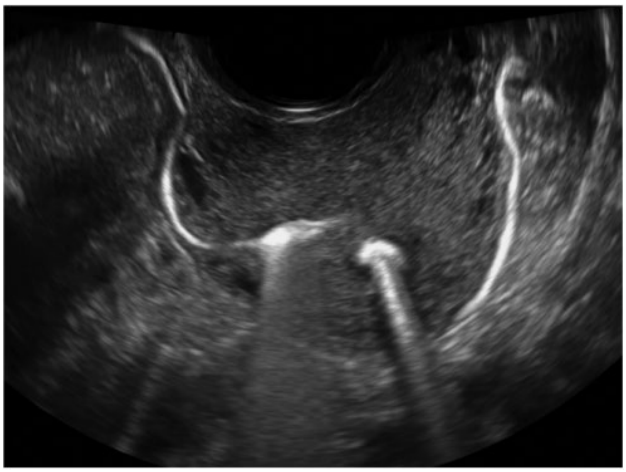

Fig. 36.2 Hysterosalpingo-foam sonography is a dynamic investigation that allows tracking of foam as a hyperechoic suspension through the fallopian tubes. On this image, there is visible bilateral patency through the isthmic and intramural portion of the tubes.

Ultrasound-guided procedures

Ultrasound can guide different invasive procedures in gynaecology. Besides the well-known application in reproductive medicine for oocyte retrieval, there is increasing interest in the field of gynaecological oncology. Ultrasound-guided Tru-cut biopsy has been shown to be an accurate and safe, minimally invasive technique to acquire tissue diagnosis in the management of advanced or recurrent gynaecological tumours or when pelvic metastatic disease from another primary origin is suspected [21,22].

In general, this procedure is performed with a core-cut biopsy needle inserted through a needle guide mounted on the transvaginal probe. Local anaesthesia is not required in a transvaginal approach. A similar approach with an aspiration needle connected to a syringe or vacuum container allows the drainage of symptomatic pelvic cysts, on condition that there is no suspicion of malignancy. Examples are large peritoneal pseudocysts, simple ovarian cysts or tubo-ovarian abscesses in pelvic inflammatory disease [23].

Summary box 36.1

- A good basic knowledge of the technical features of the ultrasound machine is important, as quality of ultrasound imaging relies on the settings of the device.
- Ultrasound assessment and reporting of gynaecological structures, with any pathology that may be present, should be based on international consensuses.
- Transvaginal ultrasound is the method of choice in the assessment of the female pelvis. In certain conditions, a transabdominal or transrectal approach can be considered.
- Pressing on the abdomen with the non-scanning hand can improve the visualization of structures or aid in the evaluation of adhesions or site-specific tenderness.
- Sonohysterography is indicated in the evaluation of a thickened or irregular endometrium, or for further characterization of focal intra-cavity pathology such as polyps, submucous fibroids and adhesions.
- Hysterosalpingo-contrast sonography and hysterosalpingo-foam sonography can replace more invasive and harmful techniques in the assessment of tubal patency.
- Ultrasound-guided biopsy is increasingly being used for diagnosis in the field of gynaecologic oncology.

Imaging in common gynaecological conditions

Abnormal uterine bleeding

Over recent years transvaginal ultrasonography has significantly improved our ability to accurately manage patients with abnormal uterine bleeding. Ultrasound findings are described according to international consensuses [3,6]. Other imaging modalities such as MRI are indicated as second-stage tests in certain circumstances.

Premenopausal bleeding

In 2011, the International Federation of Gynecology and Obstetrics (FIGO) published the PALM-COEIN system (polyp; adenomyosis; leiomyoma; malignancy and hyperplasia; coagulopathy; ovulatory dysfunction; endometrial; iatrogenic; not yet classified), which classifies the aetiology of abnormal uterine bleeding [24]. From these causes, imaging methods can only confirm or exclude anatomical abnormalities, i.e. the 'PALM group'. However, these might or might not be the cause of the bleeding problem, as they may also be found in asymptomatic women. In the large majority of premenopausal women, abnormal uterine bleeding is associated with benign lesions such as an endometrial polyp or an intra-cavitary fibroid, whereas endometrial cancer is an uncommon cause. In abnormal uterine bleeding, the usefulness of an ultrasound evaluation of the endometrial thickness to detect pathology is much less obvious in premenopausal women compared with postmenopausal women [25].

Endometrial polyps are a very common finding in women with abnormal uterine bleeding. On ultrasound, they are often hyperechoic and feature a 'bright edge' [3] (Fig. 36.3). In a large proportion of patients, the feeding blood vessels can be visualized on colour Doppler imaging, the so-called 'pedicle artery' sign, which is pathognomonic for focal endometrial pathology [26] (Fig. 36.4). Fluid instillation should be considered if the endometrium is not well visualized on unenhanced ultrasonography, or if within a thickened endometrium no pedicle artery is detectable on colour Doppler examination [27]. MRI is not considered useful in the assessment of endometrial polyps [28].

Fibroids are the most common uterine tumours. Their location is described according to the FIGO leiomyoma

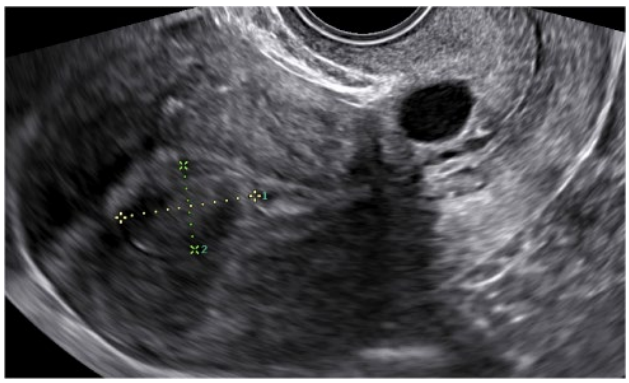

Fig. 36.3 Endometrial polyp with 'bright edge'.

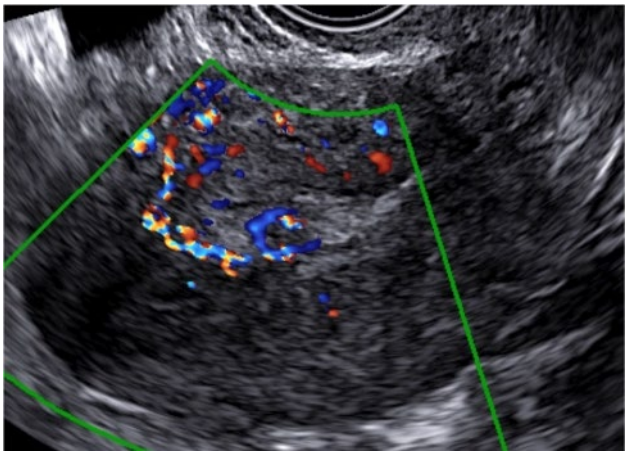

Fig. 36.4 Endometrial polyp with 'pedicle artery' sign on colour Doppler imaging. (*See also colour plate 36.4*)

classification, where the submucosal lesions (i.e. types 0–2) are the most likely to result in abnormal uterine bleeding [24]. Besides the number of fibroids and their size, the relationship to the endometrium is an important factor in choosing the proper surgical strategy should one be needed, and in particular for hysteroscopic or laparoscopic myomectomy. At ultrasonography, fibroids are generally well-circumscribed round lesions within the myometrium or attached to it, often showing shadows at the edge of the lesion and/or internal fan-shaped shadowing due to calcifications. On colour or power Doppler imaging, circumferential flow around the lesion is often visible (Fig. 36.5). However, some fibroids do not exhibit such typical features [6,29]. Three-dimensional ultrasound may help in localizing the fibroid with respect to the uterine cavity. MRI and ultrasound seem to have similar ability to diagnose uterine fibroids, but MRI is superior to ultrasound in determining the exact location of a fibroid, particularly in a large uterus with multiple fibroids [30].

It is often very challenging to discriminate between fibroids and malignant tumours of mesenchymal origin, the so-called leiomyosarcoma. Although several features at ultrasonography and MRI can raise suspicion of a uterine sarcoma, there are no pathognomonic features on any imaging technique [31]. On ultrasound, a sarcoma is generally solitary, large and oval-shaped with heterogeneous echogenicity. There might be irregular anechoic areas due to internal necrosis or haemorrhage. On colour Doppler imaging, a sarcoma is more often highly vascularized, with prominent irregular intralesional vascularity more often seen than in fibroids. The vessels are of unequal size and exhibit irregular branching. Because of their rapid growth, most sarcomas are large at diagnosis. Myometrial lesions with a large diameter (e.g. >8 cm) should be managed with circumspection [6,29] (Fig. 36.6).

Findings in uterine leiomyosarcomas on MRI vary and include a lobulated mass of high-signal intensity on T2-weighted images, a sharply marginated mass of low signal intensity that closely resembles a leiomyoma, or a mass with focally infiltrative margins. Detection of scattered foci of haemorrhage or necrosis can suggest the diagnosis of uterine leiomyosarcoma. A consistent finding in uterine leiomyosarcomas is the absence of calcifications [32]. Presence of these features at imaging should discourage the clinician to select the patient for minimally invasive surgery with tissue morcellation in order to avoid the fragmentation and intra-abdominal spread of malignant disease [29].

Note that computed tomography (CT) is unable to differentiate between different types of uterine pathology. In particular, it has been shown that CT is not able to differentiate between fibroids and sarcomas [31].

Another differential diagnostic difficulty with fibroids relates to their discrimination from adenomyosis. Adenomyosis may be present at one or more sites within the uterine wall or involve most of the myometrium, and may often be dispersed within the myometrium rather than forming a confined lesion, i.e. diffuse adenomyosis. On the other hand, it may be present in only one part of the myometrium, i.e. focal adenomyosis. In rare cases it may present as a large cyst (an adenomyotic cyst or cystic adenomyoma) [6].

The ultrasound features of adenomyosis are myometrial asymmetry, cystic areas within the myometrium, hyperechoic islands, fan-shaped shadowing, echogenic subendometrial lines and buds, and blood vessels passing

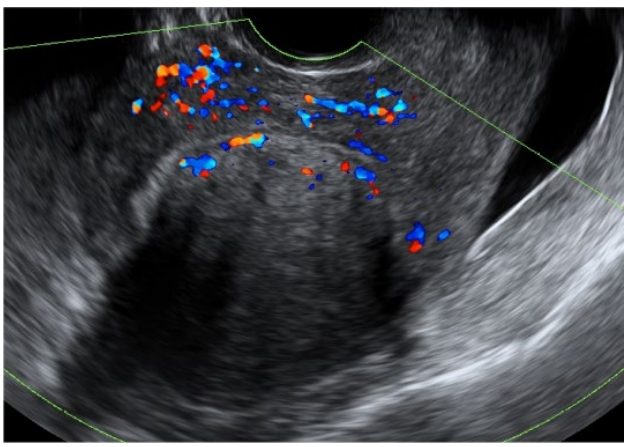

Fig. 36.5 Uterine fibroid with typical features: a well-circumscribed round lesion, presence of acoustic schadowing and limited circumferential vascularization on colour Doppler imaging. (*See also colour plate 36.5*)

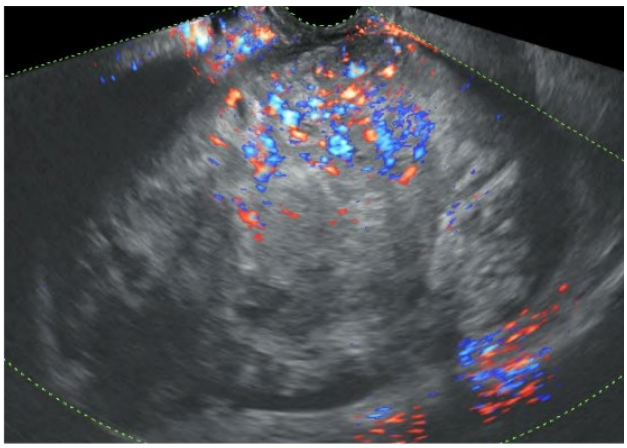

Fig. 36.6 Uterine sarcoma: large oval-shaped lesion with heterogeneous echogenicity and prominent intralesional vascularization on colour Doppler. (*See also colour plate 36.6*)

through the abnormal-looking area as opposed to around the lesion as is seen with fibroids. More recently, the presence of an irregular or interrupted endometrial–myometrial junctional zone imaged using three-dimensional ultrasound in the coronal plane has been reported to have a high diagnostic accuracy for adenomyosis [6,8]. Comparable with ultrasound, MRI can confidently diagnose adenomyosis, and can be used when transvaginal ultrasonography provides indefinite findings or when dealing with difficult cases with coexistence of other abnormalities (e.g. multiple fibroids) [33].

Pedunculated and broad ligament fibroids present their own problems. These principally relate to how confident the examiner is that he or she is not looking at a solid ovarian lesion. This is important given the higher likelihood of malignancy in solid masses thought to be ovarian fibromas [34]. The demonstration of two normal ovaries is the obvious solution to this problem. The use of Doppler to demonstrate that the blood supply originates from the uterus may identify the lesion as uterine in origin and acoustic shadowing is a reassuring sign.

Postmenopausal bleeding

The causes of abnormal premenopausal uterine bleeding, such as polyps and uterine sarcomas, can be found in postmenopausal women as well. However, it is most important that endometrial cancer should be excluded, as this disease will be detected in 10% of patients with postmenopausal bleeding [35]. A simple measurement of endometrial thickness on transvaginal ultrasound examination can reliably discriminate between women who are at low or high risk of endometrial cancer. An endometrial thickness of 4 mm or less decreases the likelihood of endometrial cancer by a factor of ten, regardless of the use of hormone replacement therapy [35]. If the endometrial thickness is 5 mm or more, an evaluation of endometrial morphology and vascularization using grey-scale and Doppler ultrasound imaging with or without fluid instillation can be used to assess for any pathology. If a focal lesion is detected, targeted hysteroscopic resection should be planned. If no focal lesion is visible, blind endometrial sampling is recommended, to exclude pathology and endometrial cancer in particular.

The role of ultrasound in discriminating between benign and malignant pathology in patients with postmenopausal bleeding and a thickened endometrium is the subject of current investigation. Heterogeneous echogenicity and an irregular surface of a focal lesion or of the endometrium in a fluid-filled uterine cavity seem to be useful criteria for predicting malignancy [36] but these and other features need to be confirmed in larger prospective trials [3]. About one in five cases of cancer in women with postmenopausal bleeding do not show a clearly visible endometrium on unenhanced transvaginal ultrasonography. Therefore, if the endometrium is not measurable or not completely visible, it should be considered abnormal until proven otherwise. Sonohysterography should be performed in these circumstances [37].

Other imaging modalities have no role in the primary investigation of women with postmenopausal bleeding, but are used for endometrial cancer staging. MRI using high spatial resolution T2-weighted and contrast-enhanced T1-weighted images provides tumour delineation for the assessment of myometrial invasion with high accuracy. The technique has developed rapidly, especially with the addition of new functional techniques over the past decade, such as diffusion-weighted imaging. Several studies have concluded that ultrasound and MRI can assess the probability of deep stromal invasion and the presence of cervical invasion with similar accuracy.

It has been shown that the grey-scale and vascular sonomorphological appearance of endometrial cancer is significantly associated with endometrial tumour stage, grade and size. High-risk endometrial cancer more often has a mixed or hypoechoic echogenicity, a higher colour score, and multiple vessels with multifocal origin, whereas less-advanced tumours are more often hyperechoic, have no or low colour score, and a single or multiple vessels with a focal origin. Subjective ultrasound assessment of myometrial and cervical invasion has been shown to work better than, or as well as, any objective measurement technique. The best objective measurement technique is tumour–uterine anteroposterior ratio; however, the clinical value and optimal cut-off needs to be established in larger studies. The role of CT and positron emission tomography (PET)-CT is primarily to detect lymph node metastasis and other metastasis [38].

Other possible causes of postmenopausal bleeding should be considered, such as cervical polyps, adnexal pathology and bladder pathology. An advantage of transvaginal ultrasound is that it enables the examiner to investigate the entire pelvis.

Summary box 36.2

- In postmenopausal bleeding, a simple measurement of endometrial thickness on transvaginal ultrasound examination can reliably discriminate between women who are at low or high risk of endometrial cancer.
- Endometrial polyps are a very common finding in women with abnormal uterine bleeding. On ultrasound, the 'pedicle artery' sign is pathognomonic for focal endometrial pathology.

- Fluid instillation should be considered if the endometrium is not well visualized on unenhanced ultrasonography.
- MRI and ultrasonography seem to have a similar ability to diagnose uterine fibroids, but MRI is superior to ultrasound for determining the exact location of a fibroid, particularly in a large uterus with multiple fibroids.
- Although several features at ultrasonography and MRI can raise suspicion of a uterine sarcoma, there are no pathognomonic features using any imaging technique.

Adnexal masses

When ultrasound evaluation of a pelvic mass has excluded non-adnexal pathology (e.g. pedunculated fibroids, see section on premenopausal bleeding), it is very important to discriminate between pathological and functional findings. Since fibroids are only found in premenopausal women, they can be expected to resolve spontaneously and rarely require surgical intervention.

Follicular cysts originate from anovulatory follicles. Usually they appear as unilocular and thin-walled lesions with anechoic contents. They rarely exceed 8–10 cm in diameter and typically resolve spontaneously within 6 weeks [39]. *Corpus luteum cysts* are formed following ovulation. They are thick-walled cysts that often show circumferential blood flow, described on ultrasound as the 'ring of fire'. The cyst content may have a 'spider-web' appearance or contain blood clots, resembling solid components (Fig. 36.7). In these cases, Doppler examination (a clot will have no blood flow) and 'pushing' the lesion with the probe (a clot will have typical jelly-like movement) can be used to help differentiate between clots and solid parts [1]. In most cases, haemorrhagic cysts resolve within 6–12 weeks without intervention [39]. If a lesion does not meet the clinical and ultrasound features of functional changes or persists during follow-up, further investigation is recommended.

Distinguishing between benign and malignant pathology is important both to lessen unnecessary anxiety and to select the optimal patient-tailored management. Depending on the clinical presentation of the patient, benign pathology may be best treated conservatively or in a general gynaecology unit using a minimally invasive approach. On the other hand, masses suspicious for malignancy should be referred to specialized units for appropriate staging and treatment, for example in the case of ovarian cancer where this is known to improve survival [40].

Certain types of ovarian tumours exhibit characteristic ultrasound features which make them very easy to recognize. *Mature teratomas* or *dermoid cysts* are the most frequently encountered non-functional ovarian masses in premenopausal women. Usually they appear as unilocular cysts with mixed echogenicity, due to the presence of different tissue components such as fat, bone, hair and fluid. Acoustic shadowing is typically present and often prevents the cyst being completely visualized ('tip of the iceberg' phenomenon). Different hyperechoic tissues often pack together into a Rokitansky nodule (Fig. 36.8) and the presence of hair is often seen as multiple stripy hyperechoic interfaces ('dermoid mesh'). In general, vascularity is minimal [39]. *Endometriomas* are typically unilocular tumours with echogenic content representing old blood ('ground glass' appearance) and limited vascularity (Fig. 36.9). However, atypical features may be present. Debris within the cyst may give the impression of solid components. It is important to consider the age of the patient when a lesion with the features of an

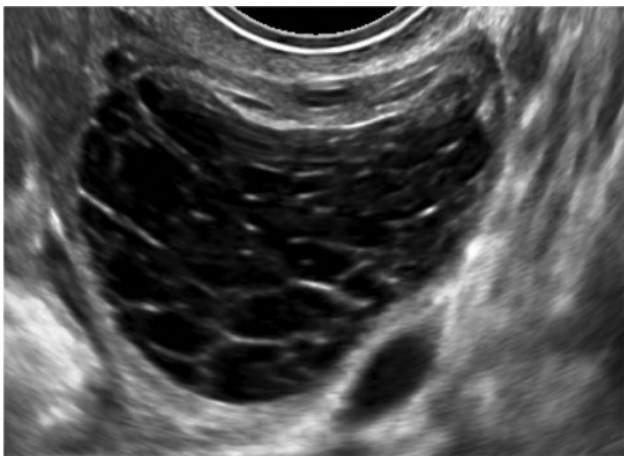

Fig. 36.7 Haemorrhagic corpus luteum cyst with 'spider-web' appearance.

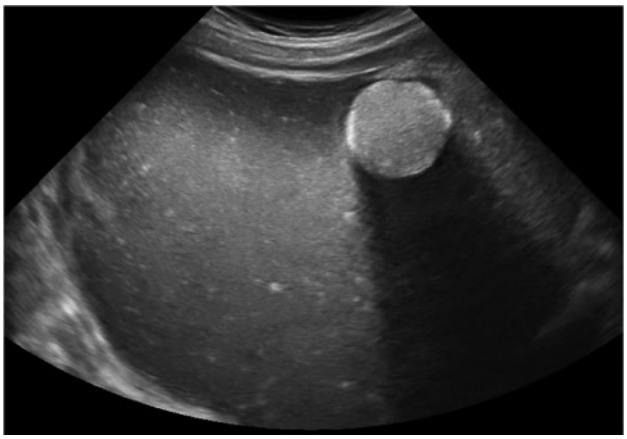

Fig. 36.8 Dermoid cyst with Rokitansky nodule and prominent acoustic shadowing.

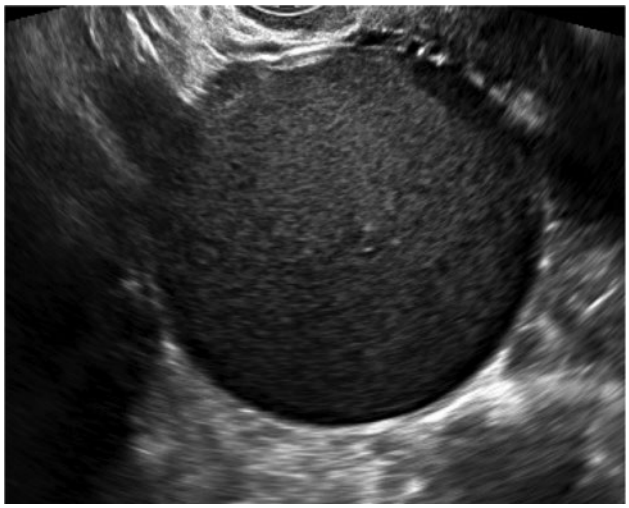

Fig. 36.9 Endometrioma: unilocular tumour with echogenic content representing old blood ('ground glass' appearance).

endometrioma is observed, as in postmenopausal women the risk of malignancy in such lesions is significant [41].

Subjective assessment of the morphology and vascularity, also called 'pattern recognition', by an experienced operator is known to be the best-performing strategy for characterizing adnexal masses. Besides predicting whether a mass is likely to be benign or malignant, in most cases a reasonably accurate evaluation of the likely histological outcome is also possible [42,43]. However, as pattern recognition is very user-dependent [44], more objective methods are needed to allow accurate ultrasound evaluation by less-experienced examiners. The risk of malignancy index (RMI) is one such method that has been in use since the 1990s. It combines ultrasound information with menopausal status and serum CA-125 to produce a numerical score, where a result of 200 or more is usually considered to indicate malignancy [45]. As the RMI score is largely influenced by the serum CA-125 level, it suffers from the inherent problems associated with that marker: a relatively low sensitivity for early-stage and borderline disease, especially in premenopausal women [46]. Despite accumulating evidence in favour of more recent ultrasound-based models, many national guidelines for the management of ovarian masses still advocate the use of RMI.

In 2000, the International Ovarian Tumour Analysis (IOTA) group published a consensus paper in order to standardize the terms, definitions and measurements used to characterize ovarian pathology [5]. With more than 20 000 patients included, this prospective multicentre project aims to develop diagnostic algorithms to classify adnexal masses. In 2008, the IOTA group published the Simple Rules, which are based on five ultrasound features suggestive of a benign lesion (B-features) and five features suggestive of a malignant lesion (M-features) [4]. The Simple Rules have been validated extensively; even in the hands of less-experienced examiners, they retain excellent performance in discriminating between benign and malignant pathology [47].

The IOTA Simple Rules have become very popular because they do not require access to a computer and are perceived to be easy to use. They are incorporated in the guidelines of the Royal College of Obstetricians and Gynaecologists (RCOG) on how to manage premenopausal women with adnexal masses [48]. A weakness of the IOTA Simple Rules is that they cannot classify all adnexal masses as benign or malignant. This means that in about 20% of cases another diagnostic method is needed to classify the 'inconclusive' masses. A reasonable alternative is to consider this group as malignant, as in 40% of these cases this will be proven by histopathology [49]. Table 36.1 shows the ultrasound features of the Simple Rules as a simple tick box system to usefully assess a mass.

In their meta-analysis in 2013, comprising 96 validation studies reporting on 19 different diagnostic ultrasound methods in 26 438 adnexal masses, Kaijser *et al.* [47] showed that IOTA strategies such as the Simple Rules had the best performance in differentiating between the benign and malignant nature of adnexal masses in a preoperative setting. The Simple Rules outperformed

Table 36.1 Simple Rules to identify a benign or malignant adnexal tumour.

Features for predicting a malignant tumour (M-features)	
M1	Irregular solid tumour
M2	Presence of ascites
M3	At least four papillary structures
M4	Irregular multilocular-solid tumour with largest diameter ≥100 mm
M5	Very strong blood flow (colour score 4)
Features for predicting a benign tumour (B-features)	
B1	Unilocular
B2	Presence of solid components where the largest solid component has a largest diameter <7 mm
B3	Presence of acoustic shadows
B4	Smooth multilocular tumour with largest diameter <100 mm
B5	No blood flow (colour score 1)
Simple rules	
If one or more M-features apply in the absence of a B-feature, the mass is classified as malignant	
If one or more B-features apply in the absence of an M-feature, the mass is classified as benign	
If both M-features and B-features apply, the mass cannot be classified	
If no feature applies, the mass cannot be classified	

the RMI, with a sensitivity and specificity of 93% and 81%, respectively, for Simple Rules versus 72% and 92%, respectively, for RMI. In 2016, Meys *et al.* [46] performed a meta-analysis assessing IOTA methods, RMI and subjective assessment by an expert investigator, investigating 47 articles that included 19 674 tumours. They concluded that a two-step approach with Simple Rules as a first step and subjective assessment for inconclusive tumours yielded the best results and matched the test performance of expert ultrasound examiners.

In general, individual features of ovarian masses have not proved useful as predictors of the likely histology. Accordingly, attention turned to mathematical models using multiple variables. The IOTA group has created different prediction models based on logistic regression analysis that give an individual risk of malignancy for the patient [50–52]. Unlike the Simple Rules, risk prediction models require the use of a computer, an application for smartphone or a calculator integrated in the ultrasound device to acquire the result. As a multiclass prediction model, the recent Assessment of Different NEoplasias in the adneXa (ADNEX) model incorporates clinical and ultrasound information not only to calculate the likelihood of malignancy in adnexal masses but also the likelihood that the mass is borderline malignant, stage I primary invasive ovarian cancer, stage II–IV primary invasive ovarian cancer or a metastasis to the ovary from another primary tumour [52]. This is highly relevant given the differences in the clinical management of women with these different tumours.

Adding information on serum CA-125 levels to ultrasound information does not seem to improve earlier mathematical models in discriminating between benign and malignant adnexal masses [53]. Neither does CA-125 in ADNEX, where it is an optional variable. However, in ADNEX the inclusion of CA-125 allows more accurate risk predictions for the different subgroups of malignancy [52]. A two-step approach could be adopted to make clinical use of the predicted risks from ADNEX. First, the risk calculation can be used to discriminate between benign and malignant masses based on the specific risk cut-off value used by individual centres to define malignancy, where the adopted cut-off may depend on local healthcare policy. Second, we can differentiate between the four subgroups of malignant tumours using the predicted risks for these subgroups. In this step, absolute predicted risks as well as the relative change of these risks versus the baseline risks provide clinically useful information to select an appropriate patient-specific management strategy. ADNEX has only recently been developed, but has shown excellent discriminative ability when prospectively validated on IOTA phase 3 data [52] as well as in the first external validation studies [54,55]. ADNEX is freely available online (http://www.iotagroup.org/adnexmodel/) or can be downloaded as an application for smartphone. Figure 36.10 shows the clinical and ultrasound features used in the ADNEX model with the risk calculations for a case example.

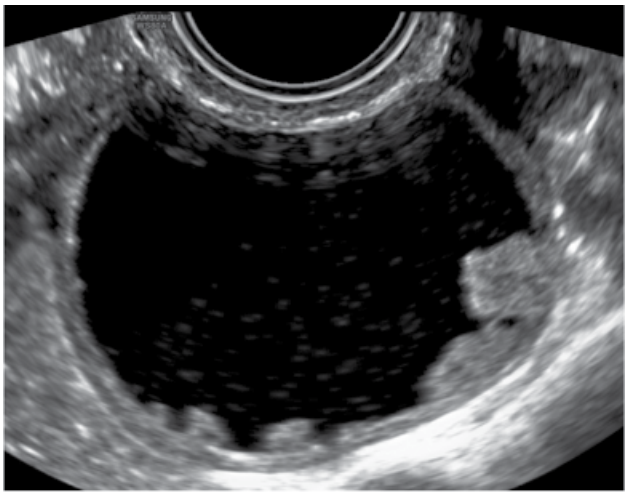
Research is ongoing on how to manage adnexal masses that are unclassifiable by ultrasound, whether using the Simple Rules or subjective assessment by an expert investigator, as evidence shows that 8% of tumours will still be indeterminate even with these methods. In a systematic review and meta-analysis, Anthoulakis *et al.* [56] concluded that pelvic MRI with intravenous contrast administration should be considered the most useful of all diagnostic approaches when investigating adnexal masses that remain unclassified after assessment by ultrasound. This strategy outperformed other imaging modalities including CT.

An extensive description of staging in malignant disease would be beyond the scope of this chapter. Although ultrasound has been shown to be accurate in the assessment of the abdominal spread of gynaecological malignancies in the hands of experienced examiners [57], most centres will use CT for preoperative staging and follow-up [58]. There is also increasing interest in whole-body diffusion-weighted MRI for this purpose, as this technique shows higher accuracy for the evaluation of peritoneal and distant disease compared with CT and PET-CT [59].

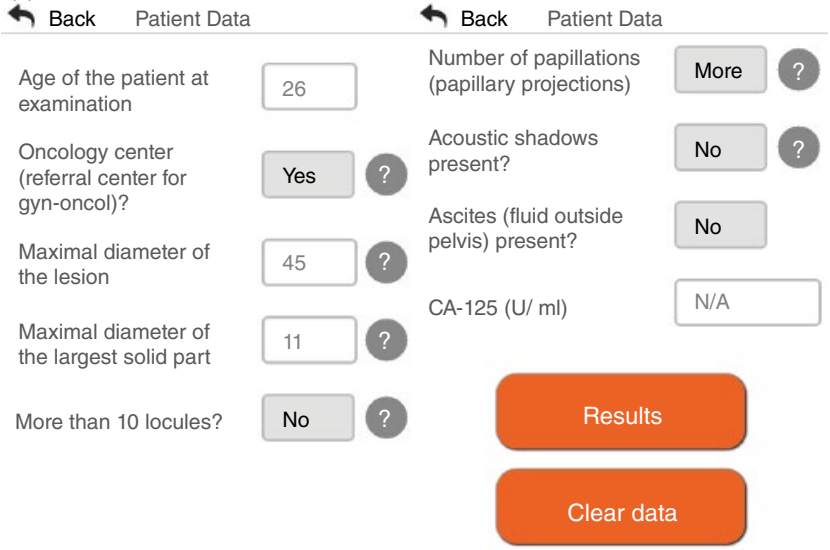
Summary box 36.3

- Subjective assessment by an experienced ultrasound operator is known to be best-performing strategy to characterize adnexal masses.
- Certain types of ovarian tumours, such as endometriomas or dermoid cysts, exhibit characteristic ultrasound features that make them easy to recognize.
- IOTA's Simple Rules have been extensively validated and show the best performance of currently available diagnostic tools for discriminating between benign and malignant adnexal pathology, irrespective of the user's level of experience.
- The recent IOTA ADNEX model includes clinical and ultrasound information not only to calculate the likelihood of malignancy in adnexal masses but also the likelihood of four subclasses of malignant tumours.
- Adding information on serum CA-125 levels to ultrasound information does not improve mathematical models for discriminating between benign and malignant adnexal masses.
- Pelvic MRI with intravenous contrast administration can be used as a second-stage test to evaluate adnexal masses that remain unclassified after assessment by ultrasonography.

(a)



(b)



(c)

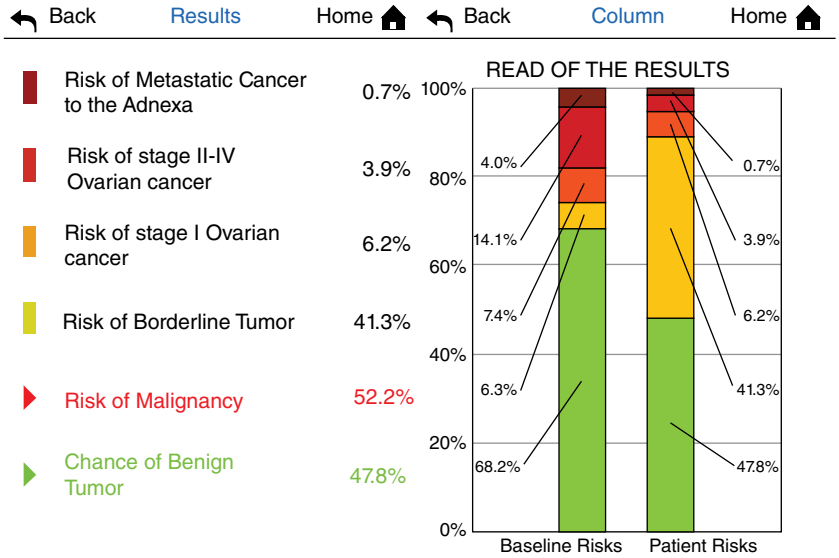


Fig. 36.10 (a) Unilocular-solid ovarian tumour with a maximum diameter of 45 mm detected in a 26-year-old patient. There were four papillary projections, the largest having a maximum diameter of 11 mm. Acoustic shadowing and ascites were absent. (b) Introduction of the clinical and ultrasound variables of this patient in an ADNEX application for smartphone. CA-125 was not available during scanning of the patient. (c) Results of the ADNEX calculation. On the left are the results for the risk of malignancy and the risks of four different subgroups of malignant tumours. On the right is the column chart showing patient risks compared with the baseline risks (general IOTA population). Besides having the highest absolute risk of 41.3%, borderline ovarian tumour has the highest relative risk (6.6). This patient underwent surgery and was shown to have a serous borderline ovarian tumour.

Investigation of pelvic pain in non-pregnant women

It is important to take a history of the nature and location of pelvic pain prior to performing imaging. There are many causes of pelvic pain, many of which may be non-gynaecological, and imaging findings taken in isolation may be misleading. For example, pelvic lesions such as simple ovarian cysts or hydrosalpinges may be an incidental finding, without them being the cause of the pain.

Ultrasound should be considered an extension of the bimanual clinical examination; indeed it is unlikely that a woman with a normal pelvic examination and a negative ultrasound scan has any significant gynaecological pathology. This is true in both the acute and chronic setting. In a study by Haider *et al.* [60] of women attending an acute gynaecology unit, a normal scan was found to be associated with resolution of symptoms in 94.5% of cases. Okaro *et al.* [61] found that for women with chronic pelvic pain and a normal scan, a subsequent laparoscopy was abnormal in only 20% of cases compared with the 58% of cases that would be expected. The commonest pathologies where ultrasound may be of use are cyst accidents, endometriosis and pelvic inflammatory disease. Adenomyosis may also be related to pelvic pain (discussed in the section on abnormal uterine bleeding).

Complications of adnexal masses

An adnexal cyst in isolation may not cause pain and there are few data to tell us what size of cyst is significant in this respect. However, cyst accidents such as haemorrhage, rupture or torsion may lead to varying degrees of acute pelvic pain.

Besides occurring in functional findings such as luteal cysts (see section Adnexal masses), haemorrhage can occur within any ovarian lesion. The enlarged ovary may have a variety of ultrasound features, as the appearance of blood is likely to change from anechoic in the acute stage, to blood clot, retraction and resolution [62]. A haemoperitoneum may be present. Pushing with the probe will provoke pain. Haemorrhage may also present with ground-glass appearance, which is more typical for old blood accumulating over time, as found in an endometrioma (see section Adnexal masses). Here, recent haemorrhage might be visible as a fluid level within the cyst.

Torsion of the adnexae may occur when there is a mass in the ovary, but also in polycystic ovaries after fertility treatment or even in normal ovaries. If an ovarian mass is present, then a mature cystic teratoma is the commonest aetiology. A torted ovary appears congested and oedematous; follicles may be seen at the periphery (Fig. 36.11). Doppler is often misleading as venous flow is lost first with torsion but arterial flow will still be seen [62]. In some cases, the vascular supply may be visualized as a coil (so-called 'whirlpool' sign). Free fluid will be present in about one-third of cases.

In the case of cyst rupture, the ovary may seem either normal or show collapsed cyst walls, in the presence of free fluid in the pouch of Douglas. Pushing with the probe may provoke site-specific tenderness [62]. Rupture of a dermoid cyst may lead to chemical peritonitis.

In most cases, ultrasound is sufficient for the diagnosis of ovarian cyst accidents. However, these patients often present at the emergency department where it is not unusual for them to undergo other imaging techniques as first-line investigations. These conditions may be associated with typical features on CT or MRI [63]. Second-stage imaging with these modalities might be useful in differential diagnostic problems, especially to exclude non-gynaecological pathology.

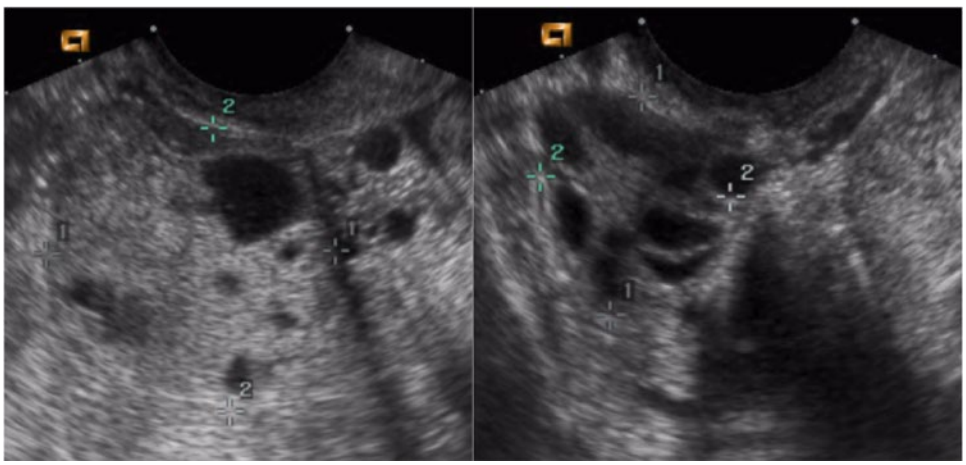

Fig. 36.11 Adnexal torsion. (*Left*) Torted left ovary with congested and oedematous appearance; follicles are seen at the periphery. (*Right*) Normal contralateral right ovary.

Endometriosis

Chronic pelvic pain may be caused by endometriosis. In 2006, Okaro *et al.* [61] introduced the concept that site-specific pelvic tenderness and reduced ovarian mobility (known as 'soft markers') are associated with the presence of endometriosis at laparoscopy. Increasingly, transvaginal ultrasonography is the first-line investigation in the work-up of women with potential underlying endometriosis. The ability of ultrasound to detect ovarian endometriosis and deep infiltrating endometriosis (bowel and non-bowel) is helpful in planning a multidisciplinary surgical approach [64]. Recently, a consensus document was published to ensure that the ultrasound assessment of endometriosis is performed in a standardized manner, with standardized descriptions and measurement techniques [65].

The characteristics of endometriomas within the ovary have been discussed in the section on adnexal masses. Transvaginal ultrasonography has fair performance with high specificity for detecting deep infiltrating endometriosis in the uterosacral ligaments, rectovaginal septum, vagina and bladder [66], whereas it has good performance for detecting deep endometriosis in the rectosigmoid [67]. In the event of negative findings in a patient with symptoms, it is recommended that MRI is used for mapping deep infiltrating endometriosis prior to surgery [68].

Pelvic inflammatory disease

Acute pelvic infection is a clinical diagnosis and should be considered in any sexually active woman with a history of pelvic pain, vaginal discharge or intermenstrual bleeding. In normal circumstances, the fallopian tube may be hard to visualize at ultrasound. In acute salpingitis, however, as the tube becomes inflamed and oedematous with accumulation of pus or exudate, it becomes more prominent. A pyosalpinx has a unilocular and sausage-shaped structure, thick walls, anechoic or low-level echogenic fluid content within the tube and presence of incomplete septa due to folding. In a transverse section it often shows the well-described 'cogwheel' sign, due to central sonolucent fluid surrounded by thickened endosalpingeal folds [69]. Colour or power Doppler examination generally shows significant vascularity. Presence of fluid in the pouch of Douglas is common [39]. The inflamed structures are generally tender on pushing with the ultrasound probe. Adhesions may be visible between different pelvic structures and also on transabdominal scanning in the upper abdomen surrounding the liver, as in Fitz-Hugh–Curtis syndrome due to *Chlamydia trachomatis*. The ovary may or may not be involved in the process. A tubo-ovarian complex represents the involvement of ovarian tissue in the inflammatory process. Normal ovarian parenchyma is visible, but cannot be separated from tubal structures when pushing with the probe. The term 'tubo-ovarian abscess' should be reserved for a later phase in this acute pelvic process, when ovarian tissue is no longer visible, caused by the total breakdown of the normal architecture resulting in loculations of pus and debris [69] (Fig. 36.12). In practice, the clinical features associated with an abscess make the diagnosis relatively straightforward.

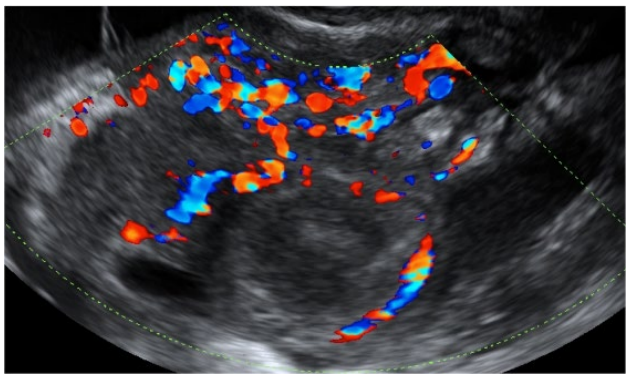

Fig. 36.12 Tubo-ovarian abscess: loculated process with oedematous walls and prominent vascularization on colour Doppler. Normal ovarian stroma is no longer visible. (*See also colour plate 36.12*)

When the acute inflammation stops spontaneously or because of medical treatment, chronic changes may persist. In a hydrosalpinx, the tube appears as an elongated fluid-filled structure, with incomplete septa, but the thickening of the wall is no longer visible. It is characterized by the typical sonographic 'beads on a string' sign, due to 2- to 3-mm-sized hyperechoic structures on the tubal wall, seen on transverse section [69]. Intra-abdominal adhesions may result in peritoneal pseudocysts.

Ultrasound-guided treatment is an important option for tubo-ovarian abscesses. In a study of 302 women, a total of 282 (93.4%) were successfully treated by transvaginal aspiration of purulent fluid, together with antibiotic therapy. In the other 20 women (6.6%), surgery was performed [23].

In circumstances of diagnostic difficulty at ultrasonography, CT or MRI may be considered as second-stage tests, the former often being the first-line examination in an emergency department. These techniques enable discrimination between pelvic inflammatory disease and gastrointestinal or urinary aetiology. It should be mentioned that the visualization of pelvic oedema caused by inflammatory disease of genital origin may be deceptive, since it can induce thickening of adjacent organ walls and suggest an incorrect diagnosis (appendicitis in particular) [70].

Summary box 36.4

- Certain pelvic lesions can be an incidental finding, without being the cause of the patient's symptoms.
- Haemorrhage can occur within any ovarian lesion, but is most common in functional findings such as luteal cysts. Ultrasound features differ depending on the time since the bleeding.
- Adnexal torsion mostly occurs when an adnexal mass is present (e.g. dermoid) but can also occur in normal ovaries. Presence of certain ultrasound features in a patient with pain should raise suspicion.
- The ability of ultrasound to detect ovarian endometriosis and deep infiltrating endometriosis is helpful in planning a multidisciplinary surgical approach.
- In case of negative findings on ultrasound in a patient with symptoms suggestive of the presence of endometriosis, it is recommended that MRI is used for mapping deep infiltrating endometriosis prior to surgery.
- Pelvic inflammatory disease may have different ultrasound characteristics, depending on the stage of the infection. When the acute inflammation stops spontaneously or because of medical treatment, chronic changes may persist (e.g. hydrosalpinx, adhesions).

Investigation of infertility

Transvaginal ultrasound can be used as a screening test for women presenting with subfertility. Strandell *et al.* [71] showed that a simplified ultrasound-based investigation protocol with hysterosalpingo-contrast sonography can replace more expensive and invasive algorithms including hysterosalpingography or laparoscopy. At present, hysterosalpingo-foam sonography is gaining ground in the field of tubal patency testing (see earlier section).

Unenhanced two-dimensional ultrasound is the first-line technique for excluding congenital uterine anomalies in asymptomatic women. The European Society of Human Reproduction and Embryology (ESHRE)/European Society for Gynaecological Endoscopy (ESGE) consensus recommends three-dimensional ultrasound in the evaluation of high-risk patients (with symptoms suggestive of the presence of genital anomaly or history of poor reproductive outcome). MRI and endoscopic evaluation are suitable for the subgroup of patients with suspected complex anomalies or in diagnostic dilemmas [7]. The same three-dimensional approach can be used to detect submucosal fibroids, as these are thought to be associated with reproductive dysfunction. More recently, attention has focused on the endometrial–myometrial junction (or junctional zone) and how this may relate to implantation and early pregnancy [8].

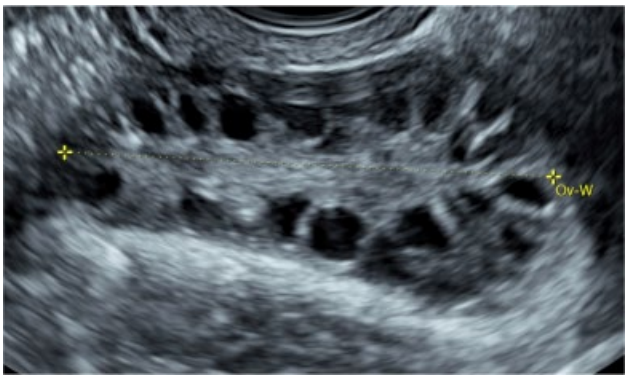

Fig. 36.13 Polycystic ovarian morphology: presence of 12 or more follicles measuring 2–9 mm in at least one ovary and an ovarian volume greater than 10 mL (Rotterdam criteria).

Ultrasound assessment of the ovaries has long been a significant part of the assessment of women with irregular or absent periods. The principal aim is to identify polycystic ovaries (PCO). This morphological finding is defined according to the Rotterdam criteria as the presence of 12 or more follicles measuring 2–9 mm in one or both ovaries and an ovarian volume greater than 10 mL [72] (Fig. 36.13). There is some debate over the clinical relevance of this ultrasound-based definition of PCO, as research has shown that ovaries with this appearance are a common finding in the normal population, especially when assessed with modern ultrasound equipment. Therefore, it has been suggested that the threshold for the number of follicles per ovary used to define PCO be increased to 25 or more [73]. Ultrasound has also become important for the assessment of ovarian reserve, as this is reflected in the number of small (2–6 mm) antral follicles within the ovary [74]. The software that now exists to automatically count follicles has further stimulated interest in this area and seems likely to give us more information about the number and distribution of follicles in various clinical situations [73,75].

Finally, in patients presenting with infertility, ultrasound has an important role in the assessment for the presence of pelvic endometriosis (see section Investigation of pelvic pain in non-pregnant women).

Summary box 36.5

- Ultrasound is the first-line technique in the detection of congenital uterine anomalies. MRI and endoscopic evaluation can be used as second-stage tests.
- Ultrasound features of PCO are defined according to the Rotterdam criteria.

Role of ultrasound in early pregnancy

When a woman presents with symptoms of pain or bleeding in early pregnancy, the main diagnostic options are a currently viable intrauterine pregnancy, a failed (or failing) intrauterine pregnancy and an ectopic pregnancy. The condition where the urinary or serum pregnancy test is positive but neither an intrauterine pregnancy nor ectopic pregnancy can (yet) be visualized on transvaginal ultrasound is described as pregnancy of unknown location (PUL). CT is contraindicated in early pregnancy. MRI can be used but does not play an important role in the management of women with bleeding and pain in early pregnancy because most diagnostic problems can be solved using ultrasound [76].

Normal pregnancy

Transvaginal ultrasonography is the principal diagnostic tool for assessing women in early pregnancy. The sequence of events in early pregnancy follows a nearly fixed pattern. At approximately 5 weeks of gestational age, the gestational sac appears as a small fluid collection with rounded edges and no visible contents, located between the thickened and hyperechoic endometrial layers, the decidua. The yolk sac, a circular structure about 3–5 mm in diameter, makes its appearance at about 5.5 weeks of gestation. Adjacent to the yolk sac, the embryo appears at about 6 weeks, with the heartbeat visible [77].

An early pregnancy can be dated by comparing the crown–rump length of the embryo with established reference curves derived from large numbers of apparently normal pregnancies [78]. It has commonly been thought that the size of an embryo in the first trimester can be translated into a gestational age value with impunity, but the size and growth of the first-trimester embryo are affected by maternal age, ethnicity, chromosomal abnormalities in the embryo and imminent miscarriage [79,80]. Finding a smaller than expected embryo is not necessarily a reflection of inaccurate dating and it is often wise to schedule a follow-up scan in these circumstances in view of the risk of miscarriage.

Sensitive home pregnancy tests inform women they are pregnant before their missed period. The potential impact of this was illustrated by Bottomley *et al.* [81], who showed that the likelihood of a scan showing an intrauterine pregnancy of uncertain viability was 60% at 35–41 days' gestation and 29% at 42–48 days. It is likely that if women attend for an ultrasound scan soon after a positive pregnancy test result, a viable pregnancy will not be confirmed, leaving potential for errors about possible miscarriage [81].

Miscarriage

In diagnosing non-viability of an early pregnancy, a false-positive diagnosis carries much worse consequences than a false-negative diagnosis, as a false-positive diagnosis may lead to a medical or surgical intervention that eliminates or severely damages a viable pregnancy, while a false-negative diagnosis causes a short delay in intervention for a failed pregnancy. Thus, the criteria for diagnosing non-viability in early pregnancy should virtually eliminate false-positive results [77]. When in 2011 several papers showed that previously accepted criteria for ruling out a viable pregnancy were not safe, the Royal College of Obstetricians and Gynaecologists (RCOG), the UK National Institute for Health and Care Excellence (NICE) and the American College of Radiology changed their guidelines for defining miscarriage [82–84]. There is agreement regarding the initial scan criteria, based on measurement of crown–rump length and mean gestational sac diameter. These cut-offs are associated with 100% specificity and narrow confidence intervals [85]:

- empty gestational sac of mean diameter ≥25 mm;
- embryo with a crown–rump length ≥7 mm and no heartbeat.

On the other hand, guidance on repeat scan criteria is not unanimous. Based on expert opinion rather than evidence, Doubilet *et al.* [77] stated that the absence of an embryo with a heartbeat 14 days or more after a scan showing an empty gestational sac or the absence of an embryo heartbeat 11 days or more after a scan showing a gestational sac and yolk sac were both categorically a miscarriage. No current guidelines take into account the influence of gestational age.

It is important for anyone carrying out a scan in early pregnancy to always remember that doctors should do no harm, and so repeating an ultrasound scan after an interval is mandatory if there is any doubt about the outcome.

Ectopic pregnancy

The clinical features of ectopic pregnancy are covered in detail elsewhere in this book, but it is important to emphasize the long-held maxim that every fertile woman has a potential ectopic pregnancy until proved otherwise. At one time the assessment of women with possible ectopic pregnancy was built on the principle of failing to identify an intrauterine pregnancy, in other words a diagnosis of exclusion. In most cases the diagnosis is now based on the positive visualization of the ectopic pregnancy [2].

Transvaginal ultrasonography is the primary diagnostic tool for clinically stable women with a suspected ectopic pregnancy [86]; of these patients, 73.9% are diagnosed on an initial assessment [87] and 94% are diagnosed prior to surgical intervention [88]. This difference is explained by the fact that in a number of cases an early pregnancy is categorized as PUL, before the ectopic pregnancy mass is subsequently seen using ultrasonography. This appears to

be simply a reflection of the gestational age of the pregnancy; at early gestations the ectopic mass may simply be too small to visualize with ultrasound [89]. The most common finding in tubal ectopic pregnancy, seen in around 60% of cases, is an inhomogeneous or a non-cystic adnexal mass sometimes referred to as the 'blob' sign. The mass is generally spherical, but a more tubular appearance may be seen if bleeding creates a haematosalpinx. It may also be possible to visualize an empty extrauterine gestational sac or 'bagel' sign, which may contain a yolk sac and/or an embryonic pole that may or may not have cardiac activity (Fig. 36.14). The term 'viable ectopic' is applied when embryonic cardiac activity is visualized [88,89]. Doppler is not considered to significantly contribute to the diagnosis of ectopic pregnancy.

The morphology of an ectopic pregnancy when imaged with ultrasound is important. The majority are inhomogeneous masses. However, visualizing a yolk sac or fetal embryonic heartbeat has management implications as these cases tend to do badly when treated medically with methotrexate [90]. There is no specific endometrial appearance or thickness that reliably supports a diagnosis of ectopic pregnancy. A collection of fluid may be seen within the endometrial cavity, classically referred to as a 'pseudosac' [9]. The amount of echogenic fluid visualized in the pelvis correlates closely with findings at surgery. As a rule of thumb, if fluid reaches the fundus of the uterus or is present in the utero-vesical pouch, the haemoperitoneum is considered to be significant [2].

About 7% of ectopic pregnancies are located outside the fallopian tube. Diagnostic criteria for these conditions exist but data on their diagnostic performance are scarce, and care must be taken to avoid misdiagnosis. Examples are confusion between a normal intrauterine pregnancy implanted laterally in an arcuate uterus and an interstitial pregnancy, or a gestational sac implanting over a caesarean scar, without extending into it, and a caesarean scar pregnancy. Because correct assessment in these cases is pivotal in selecting the proper management, referral to specialized ultrasound centres is a sensible strategy [9].

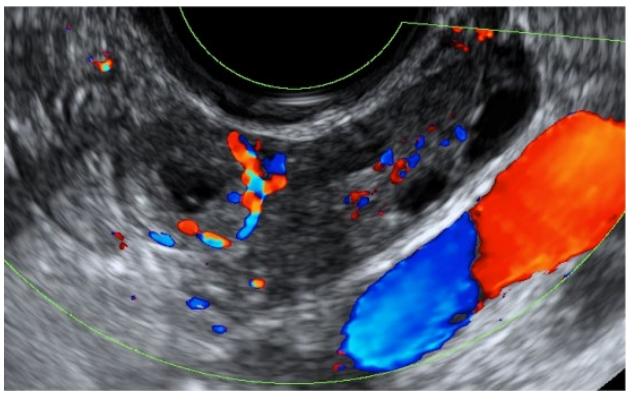

Fig. 36.14 Tubal ectopic pregnancy with 'bagel' sign. Extrauterine gestational sac is visible in a transverse section through the fallopian tube, which could be mobilized from the normal ovary on pushing with the probe. (*See also colour plate 36.14*)

Pregnancy of unknown location

PUL is a common management problem in early pregnancy [81]. It is a clinical scenario defined as a positive urinary or serum pregnancy test but neither an intrauterine pregnancy nor ectopic pregnancy can be visualized on a transvaginal ultrasound scan. Pregnancies classified as PUL include a very early intrauterine pregnancy, an ectopic gestation or a failing pregnancy, whether intrauterine or extrauterine [91]. The incidence of PUL in any given unit is multifactorial and reflects the patient population attending a unit, the ultrasound equipment used and the experience of those carrying out the scans. PUL rates have been reported to be between 8 and 31% [92]. In many cases the inability to locate a pregnancy is simply a reflection of gestational age, and it has been shown in asymptomatic women that restricting scans until 49 days' gestation would optimally reduce the PUL rate without missing ectopic pregnancies [81]. Because of a lack of standardized protocols, the management of PUL varies and may be stressful for women, who are often subjected to repeated blood tests and scans before the final outcome of the pregnancy is known. To some extent the emphasis for the management of PUL has shifted from detection of ectopic pregnancies in the population to selection of pregnancies that are highly likely not to be an ectopic pregnancy in order to reduce follow-up [93].

Clinically, the most commonly used method to predict PUL outcome is the human chorionic gonadotrophin (hCG) ratio (serum hCG at 48 hours/hCG at 0 hours). An hCG ratio of less than 0.87 is associated with a failing PUL and a ratio over 1.66 with a likely viable intrauterine pregnancy. A suboptimal rise between 0.87 and 1.66 indicates an increased risk of ectopic pregnancy [94]. In order to standardize and rationalize PUL management, a number of mathematical models have been developed that have high predictive value for ectopic pregnancy. The most widely evaluated prediction model developed is M4 [95,96], which is based on the initial serum hCG and the hCG ratio. A PUL is classified as 'high risk' (probable ectopic pregnancy) if the predicted risk of ectopic pregnancy is 5% or more. Use of this model has the potential to reduce follow-up in 70% of cases of PUL with a negative predictive value of 97% for the presence of ectopic pregnancy. A recent study investigating the safety of clinical triage with the model showed no serious adverse effects associated with correct use of M4 in over 1000 PULs [92]. If the M4 model depicts a risk of ectopic pregnancy of 5% or more (or if the hCG ratio exceeds 0.87) and the patient is asymptomatic, it is recommended

to repeat serum hCG and ultrasound after 48 hours, as an ectopic pregnancy might become visible at this time. In the case of pain or abnormal bleeding, prompt assessment is required. The M4 model is freely available online (http://www.earlypregnancycare.com/m4triage/index.html).

Summary box 36.6

- The sequence of events in early pregnancy follows a nearly fixed pattern.
- In diagnosing non-viability of an early pregnancy, a false-positive diagnosis carries much worse consequences than a false-negative diagnosis. Therefore, repeating an ultrasound scan after an interval is mandatory if there is any doubt about the outcome.
- Transvaginal ultrasonography is the primary diagnostic tool for clinically stable women with a suspected ectopic pregnancy.
- Ectopic pregnancies located outside the fallopian tube can cause diagnostic difficulties. In these cases, referral to specialized ultrasound centres can be recommended.
- The most commonly used method to predict PUL outcome is the hCG ratio. In order to standardize and rationalize PUL management, a number of mathematical models have been developed that have a high predictive value for ectopic pregnancy.

Conclusion

Ultrasound is now at the centre of many decisions in modern gynaecology. We have seen that in the management of abnormal uterine bleeding, adnexal masses, infertility, pelvic pain, early pregnancy and many other conditions, ultrasound is the first-choice diagnostic tool. In some conditions and in diagnostic dilemmas, other imaging methods such as MRI have proven their value for second-step evaluation. It is important not to be misled by ultrasound findings in isolation, as many lesions may be an incidental finding without being the real cause of the clinical problem. Therefore, attention to clinical history-taking and physical examination is mandatory. If these do not match with ultrasound findings, further investigation is recommended to exclude other (possibly non-gynaecological) pathology.

As ultrasonography is a user-dependent technique, it is important to perform this investigation according to an international consensus, with the use of agreed definitions and measurement techniques. Like all practical skills, becoming proficient at ultrasonography takes time and requires the operator to build up experience based on repetition, feedback and reinforcement for improvement to take place. This requires that clinicians carrying out ultrasound scans know the final outcomes of their patients. The best way to learn to scan is to make the diagnosis and then reinforce the findings by being present at any surgery that then occurs [2].

Ambulatory Gynaecology, Hysteroscopy and Laparoscopy

T. Justin Clark[1,2] and Lynne L.L. Robinson[1]

[1] *Birmingham Women's and Children's Hospital, Birmingham, UK*
[2] *University of Birmingham, Birmingham, UK*

Endoscopic surgery is now the default surgical method for most gynaecological procedures, impacting on every area of modern gynaecology from diagnosis to therapy, from reproductive medicine to urogynaecology and oncology. These minimally invasive approaches enhance recovery from the insult of surgery by avoiding large surgical incisions, allowing more rapid discharge from hospital and a quicker return to normal functioning. In previous editions of this textbook, hysteroscopy and laparoscopy were often considered novel interventions, restricted to diagnosis for most practitioners and with therapeutic interventions essentially the preserve of those with a particular interest in minimal access surgery. The complexities of some advanced endoscopic surgical procedures, such as radical cancer surgery, endometriosis excision or resection of large submucous fibroids, are for the 'super-specialized'. However, most day-to-day gynaecological procedures, such as removal of uterine polyps, ectopic pregnancies, ovarian cysts and uteri, can be performed endoscopically and the techniques are within the capabilities of many 'generalists'.

This paradigm shift has arisen primarily as a result of the enthusiasm of surgeons, the expectations of patients and advances in technology. The latter factor is of key importance as visualization, surgical instrumentation and energy modalities have hugely improved the safety and feasibility of endoscopic surgery. Operative hysteroscopy has benefited from the development of new technologies such as bipolar electrosurgery to resect uterine pathologies and tissue removal systems to simultaneously cut and aspirate tissue (overcoming issues over compromised visualization from collected debris and its removal). Advances in instrumentation have not only impacted on the feasibility, safety and effectiveness of existing hysteroscopic procedures, they have also allowed new procedures to be introduced such as hysteroscopic sterilization and global semi-automated endometrial destruction for the treatment of heavy menstrual bleeding. Moreover, the miniaturization and portability of equipment now facilitate ambulatory or outpatient/office-based intervention in traditional hospital or contemporary community-based settings. Ambulatory gynaecology avoids the costs and morbidity of hospital admission, providing safe, acceptable and convenient treatment to women.

In operative laparoscopy, advanced bipolar and ultrasonic instruments have facilitated haemostasis and tissue dissection. Laparoscopic instruments are now smaller and have greater degrees of articulation that facilitate single-port laparoscopy and natural orifice transluminal endoscopic surgery. The enhanced visualization, instrumentation and ergonomics associated with robotic surgery are manifest in many centres but at present the costs are prohibitive for more generalized adoption in the absence of data supporting enhanced effectiveness.

The scientific evidence supporting the adoption of minimal access surgery is expanding, with the publication of diagnostic studies examining the accuracy of endoscopic tests, observational series/registries scrutinizing complications of endoscopic interventions and randomized controlled trials evaluating effectiveness of interventions. The young gynaecologist embarking on training in endoscopy will now find a plethora of evidence produced by organizations such as the Cochrane Collaboration and national evidence-based guidance such as that produced by the National Institute of Health and Care Excellence (NICE) in the UK.

Endoscopic surgery is not confined to the practice of gynaecology. However, as pointed out by a previous author of this chapter, it is worth reminding readers, and especially the new cadre of gynaecologists in training, that laparoscopic surgery was first developed by gynaecologists not general surgeons. Indeed, it was Semm, a gynaecologist, who carried out the first laparoscopic appendicectomy in 1983 [1].

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Equipment common to hysteroscopy and laparoscopy

Light source and light lead

One of the great advantages of endoscopic over open surgery is the visualization of the anatomy and so adequate illumination is vital. Light sources have evolved from the initial platinum wire loop to fibreoptics and the rod-lens system. Illumination is now usually achieved using an incandescent bulb and heat generated is in the form of infrared light. A condensing lens concentrates light from the bulb into a narrow beam at the cable input and the light is then transmitted to the laparoscope via a gel or fibre cable. High-definition cameras require a higher performance light source because they have reduced sensitivity given the smaller pixel size.

Camera and monitor system

The camera system consists of three key components: the camera head, the camera control unit and the monitor to visualize the image. The image is captured as a digital signal from a distal mounted lens and transmitted through a rod-lens system to an ocular mounted lens which magnifies it and the image is visualized on a monitor.

Current three-chip cameras consist of a goal lens, a prism assembly and three sensors for acquiring the primary colours, providing more natural colour reproduction than earlier technologies. Video laparoscopes are now also available where the chips are built into the end of the optic, capturing the image at the tip of the laparoscope and improving image quality and accuracy. Three-dimensional imaging provides greater depth perception [2], although the technology has yet to achieve widespread popularity. A video cable transmits the digital image data between the camera head, camera control unit, and monitor. Flat screens in high definition have superseded earlier monitors and provide a much superior image. Narrow-band imaging is a recent innovation, which uses a specific narrow wavelength to change the normal colour contrasts of the laparoscopic image.

Energy modalities

Electrosurgery, often referred to as diathermy, has been used in surgery for over 100 years and has become an integral component of both hysteroscopic and laparoscopic surgery. Laparoscopic energy modalities are essential for dissection, ligation and haemostasis [3]. Monopolar, bipolar, ultrasonic and advanced bipolar energy sources are currently used. Electrosurgical cutting

Fig. 37.1 Advanced bipolar (LigaSure™). *Source:* Medtronic, USA. Reproduced with permission of Medtronic, USA.

depends on electrical arcing between the electrode and tissue resulting in vaporization and cell explosion, whereas coagulation is achieved with the electrode in contact with tissue causing heating and coagulation.

Monopolar electrosurgery delivers an electrical current via one active electrode that disperses through the patient to an attached passive return electrode. The advantages of monopolar diathermy include the ability to chose pure or mix/blend currents so that cutting and dissection can be achieved while providing haemostasis and coagulation. Disadvantages include (i) unintentional thermal injury due to thermal spread and unintentional visceral contact with active or heated electrodes, (ii) direct or capacitive coupling and (iii) improper placement of the return electrode or contact with volatile substances such as cleaning fluids.

Bipolar electrosurgery differs from monopolar in that the current travels only between the two active prongs of the electrodes. Therefore, the energy travels only through the target tissue and not through the patient. Both electrodes are of equal size, producing similar temperature changes at both ends, allowing for targeted desiccation at lower temperatures. This translates to a lower risk of collateral damage. The advantages of bipolar electrosurgery include a virtually eliminated chance of alternate site burns or direct and capacitative coupling. As no return electrode is required, the risk of a dispersive electrode burn is eradicated. The disadvantage of bipolar electrosurgery is its inability to cut tissue.

Advanced bipolar electrosurgery refers to devices that have been developed to more precisely manage delivery of bipolar electrical energy, providing consistent and rapid tissue and blood vessel sealing. They also incorporate a mechanical cutting blade at the electrode site. This blade is deployed to provide bloodless cutting after very effective desiccation of the tissue (Fig. 37.1).

Ultrasonic energy can also be used to dissect, cut and coagulate tissue, avoiding the potential dangers associated with electrical currents (Fig. 37.2). Mechanical energy is generated from rapid vibrations of a blade or shears at the tip of the instrument, causing water to evaporate from the tissues at a low temperature. This desiccates the tissues and allows precise cutting and dissection. The other mechanism it uses is stretching of the tissue by the blade edge, causing friction and generating heat, cutting the tissue. The advantage of the ultrasonic scalpels compared with electrosurgery is the reduction in tissue charring, desiccation and spread of thermal energy, lowering the risk of inadvertent injury to other structures. Devices are now also available that combine both advanced bipolar electrosurgery with ultrasonic energy.

Advanced bipolar devices and ultrasonic energy appear to provide more rapid and bloodless operating compared with conventional electrosurgery. To date, studies have not demonstrated a significant difference in complication rate between devices but this may be due to a relatively low complication rate in gynaecological procedures [4,5]. However, there is a need for properly designed and powered comparative studies to guide surgeons regarding the most effective and safe modes of energy to use for specific operations.

Fig. 37.2 Harmonic Ace® + 7 curved shears (Ethicon, Somerville, NJ, USA) and generator. Ultrasonic energy is used to dissect and desiccate tissue

Laser energy in minimal access gynaecological surgery has diminished with the advent of the newer, easier to use and cheaper energy modalities described here.

Photo and video documentation

The universal use of video cameras at endoscopic surgery lends itself to recording still images, short excerpts of procedures or even whole procedures. Photographs are clinical records that can be discussed with the patient as well as colleagues if a second opinion is sought. Video recordings are excellent for teaching, and can also be

used for research, to measure performance and to assess new instruments and techniques. Review of recordings can also help with the understanding of operative complications and are increasingly useful with regard to complaints and negligence claims.

Equipment for hysteroscopy

Direct imaging within the uterine cavity utilizing hysteroscopy requires an endoscope, outer sheath(s) for passage of distension media, a light lead and camera relaying to a monitor.

Hysteroscopes

Hysteroscopes can be rigid or flexible. The majority of gynaecologists use rigid hysteroscopes because the image tends to be superior, the equipment is more robust and it can be sterilized. Moreover, operative procedures can be undertaken using rigid hysteroscopes whereas flexible hysteroscopes are restricted to diagnosis. Rigid hysteroscopes generally have a Hopkins rod-lens optical system whereas flexible and very narrow rigid hysteroscopes contain optical fibres.

Rigid hysteroscopes come in different sizes in terms of their outer diameter, 2.7, 2.9 and 4 mm being popular sizes. The distal lens can be straight or oblique, the most frequently used being 0° and 30° angles of view. Oblique lenses have the advantage of a wider field of view, enabling diagnosis and facilitating operative procedures as instrumentation can be visualized under higher magnification. Diagnostic procedures can be performed using a single outer sheath fitted around the optic to allow irrigation of fluid or gas distension media thereby achieving uterine distension. Continuous flow permits simultaneous irrigation/suction and tends to be used for surgery where removal of blood and tissue debris is necessary to maintain visualization within the uterine cavity. To achieve continuous flow, operative hysteroscopes have both inflow and outflow channels (inner sheath for inflow, outer sheath for outflow) in addition to a working channel which can accommodate miniature ancillary instruments. Most diagnostic and operative hysteroscopic set-ups are less than 5.5 mm in outer diameter. Resectoscopes and tissue removal systems can be up to 9 mm in outer diameter.

Uterine distension

The uterine cavity is a potential space and has to be distended at relatively high pressure to afford a panoramic view. To achieve this, gas (CO_2), low-viscosity fluids (e.g. normal saline, 5% dextrose, 1.5% glycine, 3% sorbitol, 5% mannitol) or high-viscosity fluid (e.g. Hyskon, which is 32% dextran 70 in dextrose) can be used. Normal saline is most frequently used for diagnostic hysteroscopy, replacing the use of gaseous CO_2 media. The choice of fluid distension media for operative hysteroscopy depends on the type of instrumentation; physiological media, namely normal saline, should be preferred when using mechanical instruments. Resectoscopic electrosurgery traditionally required the use of electrolyte-free solutions such as glycine, sorbitol or mannitol because they employed monopolar electrical circuits. Bipolar electrosurgery using miniature electrodes or conventionally sized resectoscopes are now widely available and these necessitate the use of electrolyte-containing fluid distension media, i.e. normal saline which is safer as it minimizes the sequelae of inadvertent fluid overload and induced hypo-osmolar hyponatraemia.

The pressure required to provide an adequate view of the uterine cavity depends on a number of factors, but tends to be around 100 mmHg (13.3 kPa). An enlarged non-compliant uterus, leakage of distension medium through the cervix or excessive suction when using a continuous flow system will mean that a higher inflow pressure is required. The desired distension is achieved by using gravity, pressure bags or special hysteroscopic pumps, which can also more accurately monitor fluid balance, thereby reducing the risk of fluid overload.

Mechanical instruments

Miniature flexible or semi-rigid mechanical instruments such as scissors, grasping and biopsy forceps can be used with operating sheaths for minor procedures such as target biopsy or polypectomy. These instruments tend to be fragile because of their size, typically 7 or 5 French gauge (3 Fr = 1 mm), so replacements should be available should they break. On the plus side, they are very unlikely to injure the patient.

Bipolar electrodes

The first miniature bipolar electrodes were introduced in the late 1990s; the Versapoint™ Bipolar Electrosurgery System (Ethicon, Somerville, NJ, USA) allows electrosurgical resection of structural anomalies such that they can be used for polypectomy, removal of small intra-cavity fibroids and metroplasty. The 5 Fr Versapoint electrodes include the spring, twizzle and ball design (Fig. 37.3). Other bipolar electrodes are now available. As these electrodes are bipolar, physiological solutions such as normal saline and Hartmann's solution can be used for uterine distension, but a dedicated electrosurgical

Fig. 37.3 Versapoint Bipolar Electrosurgery System™ (Ethicon, USA). Spring-tip electrode suitable for removing polyps, and grade 0 fibroids) is shown with the electrosurgical generator. A needle-like twizzle-tip electrode is also available (not shown) for removing polyps, septa, and adhesions. *Source:* photos by T. Justin Clark.

generator is required. The flow of electricity is limited to the distal tip of the electrode with current circulating between the distal active and slightly more proximal passive return surfaces. The electrodes are versatile because they can be passed down the 5 Fr working channel of any standard operative hysteroscope.

Resectoscopes

Hysteroscopic resectoscopes are used to resect or ablate the endometrium and excise focal lesions such as polyps and fibroids, remove septa and lyse adhesions. Originally the resectoscopes used a monopolar electrode but advances in technology have led to the development of equally effective bipolar resectoscopes that have the safety advantage of using isotonic distension media with reduced risks of serious complications arising from fluid overload and induced hypervolaemic hyponatraemia.

The modern resectoscope consists of five components: the optic, handle mechanism, inflow and outflow sheaths and an electrode (Fig. 37.4). The handle mechanism can be active or passive in design; for hysteroscopy, a passive handle is preferable as it maintains the electrode inside the sheathing system out of view and out of harms way. A typical resectoscope has an outer diameter of 26 or 27 Fr (8.7–9 mm) and uses a 4-mm oblique view optic. Narrower 'mini' resectoscopes are now also available although they are not established in routine practice [6]. The electrodes themselves come in different designs, but

Fig. 37.4 Bipolar Resectoscope™ (Olympus, Hamburg; Storz, Tuttlingen, Germany). Key components include the optic, handle mechanism, inflow and outflow sheaths, and loop electrode. *Sources:* Storz, Germany and Olympus, USA. Reproduced with permission of Storz, Germany and Olympus, USA.

the cutting loop (for polypectomy, myomectomy and endometrial resection), rollerball or rollerbar (for endometrial ablation or tissue vaporization) and the knife electrode (for metroplasty) are the most popular.

Tissue removal systems

Tissue removal systems are the most recent technological advance in hysteroscopic surgery. They were developed to provide simultaneous mechanical cutting and tissue retrieval thereby maintaining better views during surgical procedures within the uterine cavity and avoiding the use of more hazardous thermal energy. A tissue removal system consists of a bespoke operating 0° hysteroscope with an operating channel that allows the insertion of a disposable cutting handpiece comprising two rotating hollow metal tubes which rotate and shave away the pathology being approximated. Each tube incorporates a small aperture or 'window' distally through which removed tissue is extracted by the application of external suction tubing; the removed tissue is then trapped in a tissue collector. A generator provides the electrical energy to rotate the mechanical tissue removal system. The first of these systems was the TruClear™ (Medtronic, Minneapolis, MN, USA) (Fig. 37.5), which has been followed by similar products from Hologic (Bedford, MA, USA) called Myosure™ and Karl Storz (Tuttlingen, Germany) called Intrauterine BIGATTI Shaver (IBS®). More recently, the Symphion™ (Boston Scientific, Natick, MA, USA) has been produced which combines a tissue removal system with bipolar radiofrequency energy.

Equipment for laparoscopy

Laparoscopes

Laparoscopes are built around a rod-lens system that transmits images to the camera. Fibreoptic microlaparoscopes are also available but are more fragile and provide an inferior image. Laparoscopes come in a range of diameters (3–12 mm) and various angles of view (0–30°). The 10-mm 0° laparoscope is most widely used in gynaecological surgery. The vast majority of gynaecologists prefer a multi-puncture approach with instruments inserted through ancillary ports usually sited to facilitate triangulation and manoeuvrability. Ancillary port sites are usually 5–15 mm depending on the diameter of the instruments to be accommodated. More recently, miniature surgical instruments, typically with diameters of 3 mm or less, can be utilized with less scarring [7].

Veress needle

The Veress needle [8] is a spring-loaded needle used to create a pneumoperitoneum at laparoscopy, most commonly inserted at the umbilicus. The Veress needle is usually inserted transabdominally, but in obese patients can be introduced through the uterine fundus or vagina [9]. It is available in reusable and disposable forms. For patients with suspected periumbilical adhesions or a previous umbilical hernia repair, Palmer's point (left subcostal) entry should be performed. An alternative is open entry (Hassan's technique) where the layers of the anterior abdominal wall are dissected through a small linear incision. This may reduce the incidence of major vessel injury though not bowel injury [10]. Optical entry techniques are also favoured by some surgeons and can be used before or after insufflation. They generally consist of a hollow transparent trocar in which is loaded a 0° laparoscope [11].

Trocars and cannulae

Trocars and cannulae act as conduits for the laparoscope and other instruments. They come in a variety of sizes depending on the diameter of the instrumentation to be accommodated, with 5 mm and 10–12 mm ports being the most commonly used. The older types of trocar are made of steel, are reusable and are sharp-tipped. Now

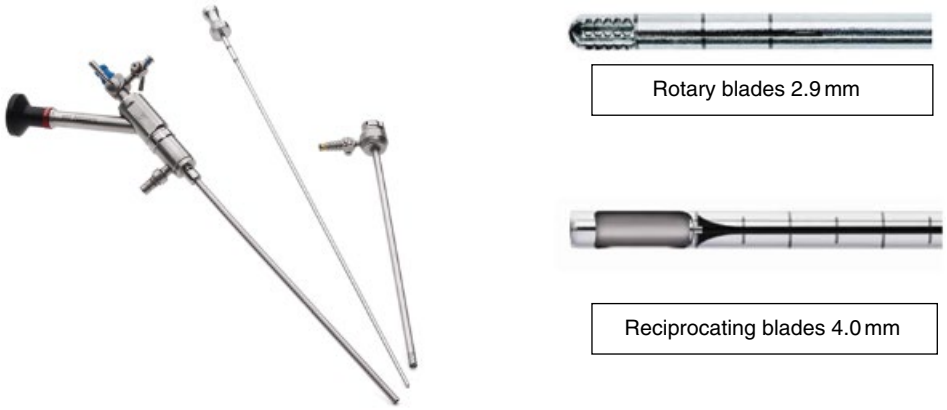

Fig. 37.5 TruClear™ tissue removal system (Medtronic, Dublin, Ireland): operating hysteroscope, outflow sheath, obturator and rotary (polyps) and reciprocating (fibroids) cutting blades. *Source:* Medtronic, USA. Reproduced with permission of Medtronic, USA.

there are a host of disposable trocars and cannulae with modifications to optimize performance. A recent Cochrane review comparing visceral and vascular complications did not show any difference in incidence between trocar types [8]. Mini-laparoscopy is performed through 3.5–5 mm ports and although visualization is not yet comparable to that of standard laparoscopy, it is satisfactory and this approach has the advantage of better cosmetic results and a lower incidence of postoperative pain or incisional hernias.

Laparo-endoscopic single-site surgery

Laparo-endoscopic single-site surgery (LESS) is the term coined for single incision laparoscopic surgery. This technique uses a single umbilical port that is adapted such that not only a laparoscope but additional operating instruments can be passed. Bespoke multi-access ports are available with expandable retractors and even home-made designs with a surgical glove attached to the port and instruments passed through small incisions in the 'fingers', which have been inflated by the CO_2 used to create the pneumoperitoneum. The potential advantages of LESS include a better cosmetic result due to a single scar, decreased risk of wound infection and a reduced risk of herniation. However, a meta-analysis comparing LESS with multi-port laparoscopy has not demonstrated any significant difference in operative outcomes, postoperative recovery, postoperative morbidity and patient satisfaction, operating time or cosmetic results [9].

Robotic laparoscopic surgery

Robotic-assisted laparoscopic surgery has been utilized in gynaecology as an alternative to standard 'straight stick' laparoscopy. The da Vinci® surgical system (Intuitive Surgical Inc., Sunnyvale, CA, USA) consists of three components: the console, which allows the surgeon to control the robot remotely; the inSite® vision system, which provides a three-dimensional image of the operative field via a 12-mm laparoscope; and the patient side-cart fitted with three to four robotic arms to control Endowrist® instruments. Robotic surgery may offer several advantages in gynaecology, including magnified three-dimensional vision, wristed instruments that aid dexterity and precision, and less fatigue and reduced back and shoulder injuries for surgeons because they can operate sitting down at a console [12]. There remains a lack of robust randomized controlled trial data on robotic surgery compared with standard multi-port laparoscopy and at present, in the absence of compelling evidence of improved effectiveness, the costs associated with robotic surgery for the most part remain prohibitive [13,14].

Laparoscopic insufflator

One of the great advantages of laparoscopy over open surgery is superior visualization of the anatomy. This is achieved by creating a CO_2 pneumoperitoneum. CO_2 is used because it is odourless, non-combustible, cheap, colourless and rapidly eliminated from the systemic circulation. Insufflators control intra-abdominal pressure rather than flow, and this should be set at 12–15 mmHg (1.6–2.0 kPa) during surgery; a higher pressure of up to 25 mmHg (3.3 kPa) is recommended during trocar entry as this has the effect of increasing the distance between any trocar being inserted and bowel or large blood vessels thereby, in theory at least, reducing the risk of injury [15].

Suction/irrigation pump

The provision of suction (negative pressure aspiration) and irrigation (instillation of fluid under pressure) helps maintain visualization within the operative field. A 5- or 10-mm suction/irrigation cannula can be used to aspirate blood and clean the pelvis (and more accurately estimate blood loss during surgery), deflate ovarian cysts and aspirate blood during pelvic procedures such as ruptured ectopic pregnancies.

Ancillary instruments

Mechanical instruments

Typically, 5-mm grasping forceps are used to grip tissue. They can be atraumatic, suitable for holding delicate structures such as fallopian tubes, bladder and bowel, or traumatic to ensure a firm grip of more robust tissue, such as when performing ovarian cystectomies (Fig. 37.6). Sharp curved laparoscopic scissors are the other essential ancillary instrument used to dissect tissues.

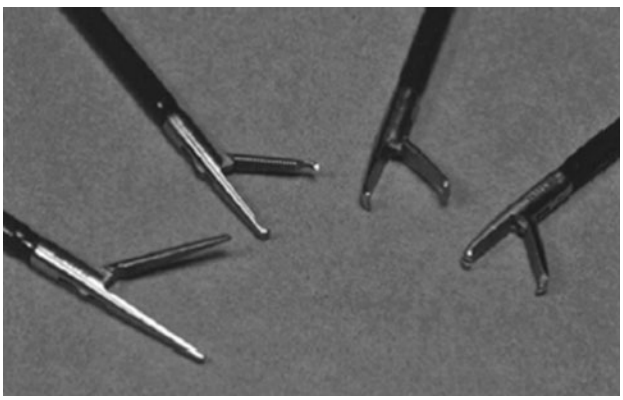

Fig. 37.6 5-mm laparoscopic grasping forceps.

Electrosurgical instruments

Electrosurgical energy encompasses monopolar and bipolar diathermy, as discussed earlier. The basic instruments available consist of scissors or hooks which use monopolar energy to divide or cut tissue. Bipolar forceps can be used to coagulate tissue with less thermal spread than monopolar energy. The tissue can then be divided using passive mechanical or monopolar instruments. Vessel-sealing technologies utilize bipolar energy and optimal mechanical pressure to fuse vessel walls and create a seal. Vessels up to 7 mm in diameter and large tissue bundles can be ligated using these instruments. The LigaSure™ (Medtronic, Fridley, MN, USA) (see Fig. 37.1), Olympus PK™ (Olympus, Southborough, MD, USA) and Enseal™ (Ethicon, Somerville, NJ, USA) systems are examples of these technologies and can reduce operating time and blood loss by securing pedicles more rapidly and effectively than standard bipolar energy combined with suturing. However, they are more costly than standard bipolar diathermy forceps. Ultrasonic scalpels can also be used to dissect, cut and coagulate tissue using energy created through mechanical vibration, avoiding the need for electrical current (see Fig. 37.2).

Sutures

There are many different absorbable and non-absorbable sutures and knot types in laparoscopic surgery. Knots can be tied extracorporeally and intracorporeally and barbed sutures can also be used that retain tension and do not require knot tying, reducing operating times. The types of sutures chosen depend on the type of surgery performed.

Specimen retrieval

Power morcellation

Removal of solid tissue such as ovarian masses, fibroids and the uterus through 'keyhole' port sites can be problematic during laparoscopic surgery. At total hysterectomy, the vagina is opened and the uterus can be removed this way unless it is exceptionally large, in which case mechanical or power morcellation may be required. Power morcellators are inserted through ancillary port sites and consist of a fixed outer tube encapsulating an inner tube with a cutting device. A large grasper is passed through the lumen of the device and tissue drawn up and morcellated within it. They are available in various dimensions and can be reusable or disposable. There has been a recent move towards 'in-bag' morcellation when removing fibroids (leiomyomas) during laparoscopic myomectomy and hysterectomy. This development is in response to the US Food and Administration (FDA) warning regarding the potential risk of tumour spread in cases of undiagnosed leiomyosarcoma during power morcellation (https://www.fda.gov/downloads/MedicalDevices/ ProductsandMedicalProcedures/SurgeryandLifeSupport/UCM584539.pdf).

Culdotomy

Culdotomy (i.e. incision within the posterior fornix of the vagina) can be performed to retrieve specimens, and prior to the advent of retrieval bags was the principal method of specimen removal. However, when the pouch of Douglas is obliterated, such as in the presence of deep infiltrating endometriosis, this is not a safe option.

Retrieval bags

Retrieval bags are now used routinely to remove specimens such as adnexal masses from the pelvis through one of the ancillary abdominal ports. Most specimen bags are 10 or 15 cm in size, the former fitting through a 10-mm port and the latter requiring a 12-mm port. Larger-diameter bags can be passed via a culdotomy. Smaller bags can be used through the umbilical port, avoiding the need for fascial closure; if a larger bag is used, then fascial closure of an ancillary port is required to prevent herniation.

Experimental minimally invasive laparoscopy

*Percutaneous surgical system*s consist of a less than 3-mm laparoscopic shaft percutaneously inserted using a Veress-like needle tip and then an interchangeable 5-mm tool (e.g. scissors, graspers, irrigation systems) is inserted in place of the needle tip [16]. Tools such as monopolar scissors, graspers, hook and irrigation systems can be utilized [17]. *Natural orifice transluminal endoscopic surgery* (NOTES) describes a technique utilizing a natural body orifice for entry into the peritoneal cavity rather than percutaneously. The most common site of entry is the stomach but for gynaecologists the site of entry is the vaginal vault. Laparoscopic surgery can then be performed through this using flexible instruments and the vault can be sutured closed from the vaginal approach [18,19].

Operating theatre organization

Hysteroscopy

While diagnostic hysteroscopy has become an outpatient procedure in most cases, with even minor operative procedures being done under local anaesthesia, more major surgery (e.g. hysteroscopic myomectomy for a sizeable submucous fibroid) usually requires general anaesthesia. It is best to have all the necessary equipment together on a surgical cart, with the monitor at a

comfortable height and position for the operator (and patient if she is awake) (Fig. 37.7).

Laparoscopy

The set-up for laparoscopy is more varied than for hysteroscopy partly because there tends to be more equipment and partly because laparoscopy is not 'solo' surgery but, as is the case with laparotomy, requires the help of assistants. Most gynaecologists prefer to use 0° optics and it is common for one of the assistants to stand on the contralateral side of the patient and control the laparoscope, leaving the lead surgeon free to operate with two hands (Fig. 37.8). However, ergonomically this set-up is not ideal and so where the operating assistant is suitably experienced, the operator or assistant (whether standing adjacent or opposite the operator) can control the laparoscope and ancillary ports to cut, ligate, hold and retract tissue as well as irrigate, suck, suture and retrieve specimens.

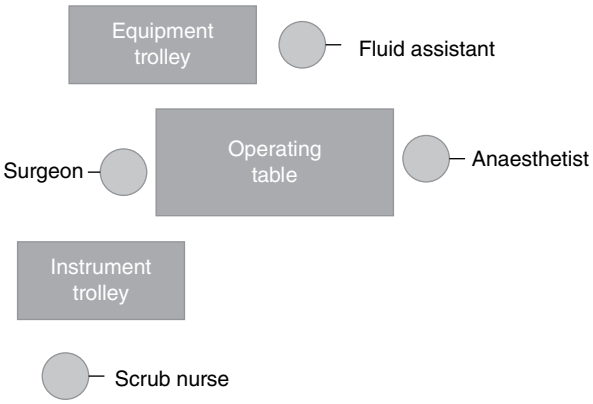

Fig. 37.7 Theatre set-up for hysteroscopic surgery.

Diagnostic hysteroscopy

Diagnostic hysteroscopy is one of the commonest procedures in gynaecology. Technological advances have led to the miniaturization of hysteroscopes and ancillary equipment such that the majority of procedures are feasible in an outpatient setting in conscious women without anaesthesia [20]. Hysteroscopy is highly accurate for the diagnosis of serious endometrial disease [21] and structural uterine anomalies including polyps, fibroids and uterine septa [22]. The indications and contraindications are summarized in Table 37.1.

Transvaginal ultrasound and endometrial biopsy are also useful outpatient tests for evaluating the uterine cavity and can be used as an alternative to, or in conjunction with, hysteroscopy for the diagnostic work-up of women with abnormal uterine bleeding [23] and reproductive problems.

Technique

The patient should positioned in lithotomy with the hips well flexed and the buttocks slightly over the edge of the table to allow unimpeded access irrespective of uterine position (Fig. 37.9). A 'no touch' vaginoscopic approach (Box 37.1) should be adopted as this is associated with reduced pain with no evidence of reduced feasibility or morbidity.

The hysteroscope should be guided into the uterine cavity under direct vision. Routine blind dilatation of the cervix should be avoided to minimize the risk of uterine trauma. When traversing the endocervical canal it is important to have the hysteroscope aligned in the correct relative axis. Light is absorbed along the endocervical canal such that it appears as a dark

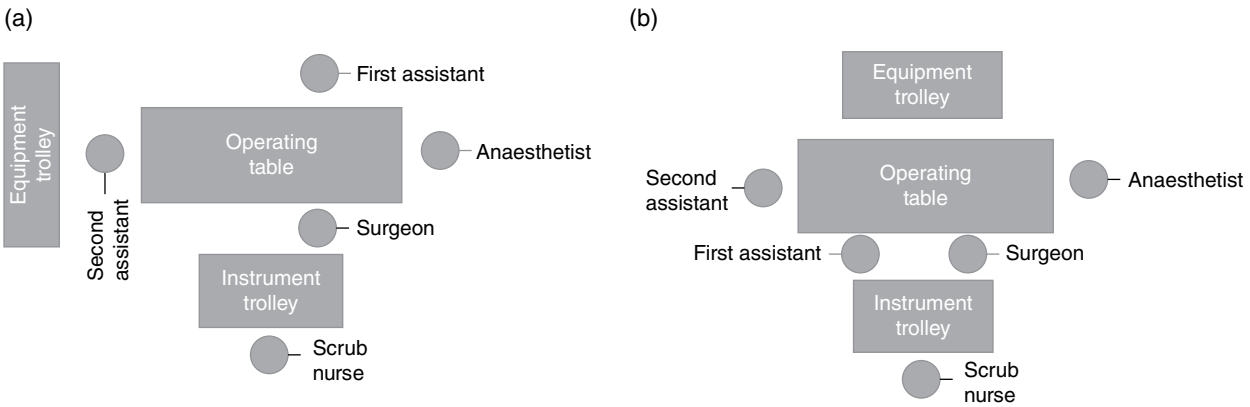

Fig. 37.8 Two schemes for theatre set-up for laparoscopic surgery: (a) first assistant holds camera (better with 0° optic); (b) operating surgeon or assistant holds camera.

Table 37.1 Indications and contraindications for diagnostic hysteroscopy.

Indications
Abnormal uterine bleeding
Heavy menstrual bleeding
Irregular menstrual bleeding
Intermenstrual bleeding (≥3 months)
Postmenopausal bleeding (recurrent or endometrial thickness ≥4 mm/focal anomaly seen on TVS/non-diagnostic EB)
Reproductive failure
Subfertility
Recurrent miscarriage/preterm delivery
Contraindications
Pelvic infection
Pregnancy

EB, endometrial biopsy; TVS, transvaginal ultrasound.

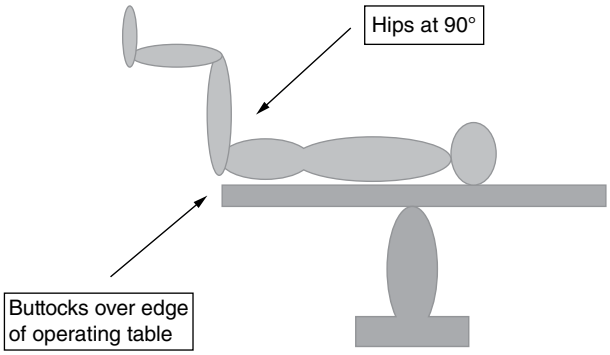

Fig. 37.9 Patient position for hysteroscopy.

ellipse on the monitor; the position of this ellipse can be central or at the 3, 6, 9 or 12 o'clock positions. When using a 0° hysteroscope the cervical canal should appear centrally whereas it should be eccentrically placed when using an oblique-view optic, the exact position depending on the orientation of the hysteroscope (Fig. 37.10).

Once in the uterine cavity, it is simply a matter of systematically inspecting the fundus, cornua and tubal ostia and the four walls of the uterus by a combination of rotating (if using an oblique-view hysteroscope) and moving the hysteroscope up and down and left to right. Panoramic views allow a global appreciation of the cavity shape and size and the presence of structural abnormalities. Magnified views, by approximating the hysteroscope close to the uterine walls, allow a more detailed inspection of the endometrium and surface of focal lesions. Once the uterine cavity has been inspected, the hysteroscope is withdrawn and this is the best time to inspect the endocervical canal. A global biopsy can then be taken, if indicated, using a small curette or a miniature suction biopsy device usually based on the Pipelle™ prototype, H-pipelle, or a change made to an operative sheath for a targeted biopsy.

A Royal College of Obstetricians and Gynaecologists (RCOG) Green-top Guideline has detailed best practice in outpatient diagnostic hysteroscopy aimed at minimizing pain and complications and optimizing patient experience [24]. A summary of the recommendations based on published evidence and expert opinion is provided in Summary box 37.1.

Box 37.1 'No touch' (vaginoscopic) hysteroscopy

This technique is ideally suited to the outpatient clinic as it minimizes patient discomfort by the simple fact that the vagina does not need to be distended by insertion of antiseptic swabs or vaginal specula and tenaculums do not need to be applied to the ectocervix. The approach is also quicker and not associated with loss of feasibility or increased morbidity. The tip of the hysteroscope is introduced into the vaginal introitus, the low-viscosity distension medium is turned on, and as the vagina distends the hysteroscope is guided along the vaginal axis until the external cervical os is identified. As most uteri are anteverted, in practice the external cervical os will be identified in the posterior aspect of the vagina (hands holding the proximal hysteroscope/camera head externally move upwards) and, once approximated, the hysteroscope is angulated anteriorly (hands holding the proximal hysteroscope/camera head externally move downwards) to traverse the cervical canal and thence the uterine cavity. If the cervix is not easily identified, then the hysteroscope should be passed to the posterior vaginal vault and thence withdrawn slowly until the external cervical os comes into view within the distended vagina. The external cervical os can be more difficult to see with small nulliparous external os, long intravaginal cervices or where there is uterine prolapse. This method works in the majority of cases unless there is cervical stenosis, where cervical dilatation after application of local cervical anaesthesia will be required. A large randomized controlled trial is underway evaluating conventional approaches using a vaginal speculum with or without cervical tenaculum/dilatation versus vaginoscopy (https://clinicaltrials.gov/ct2/show/NCT01972945)

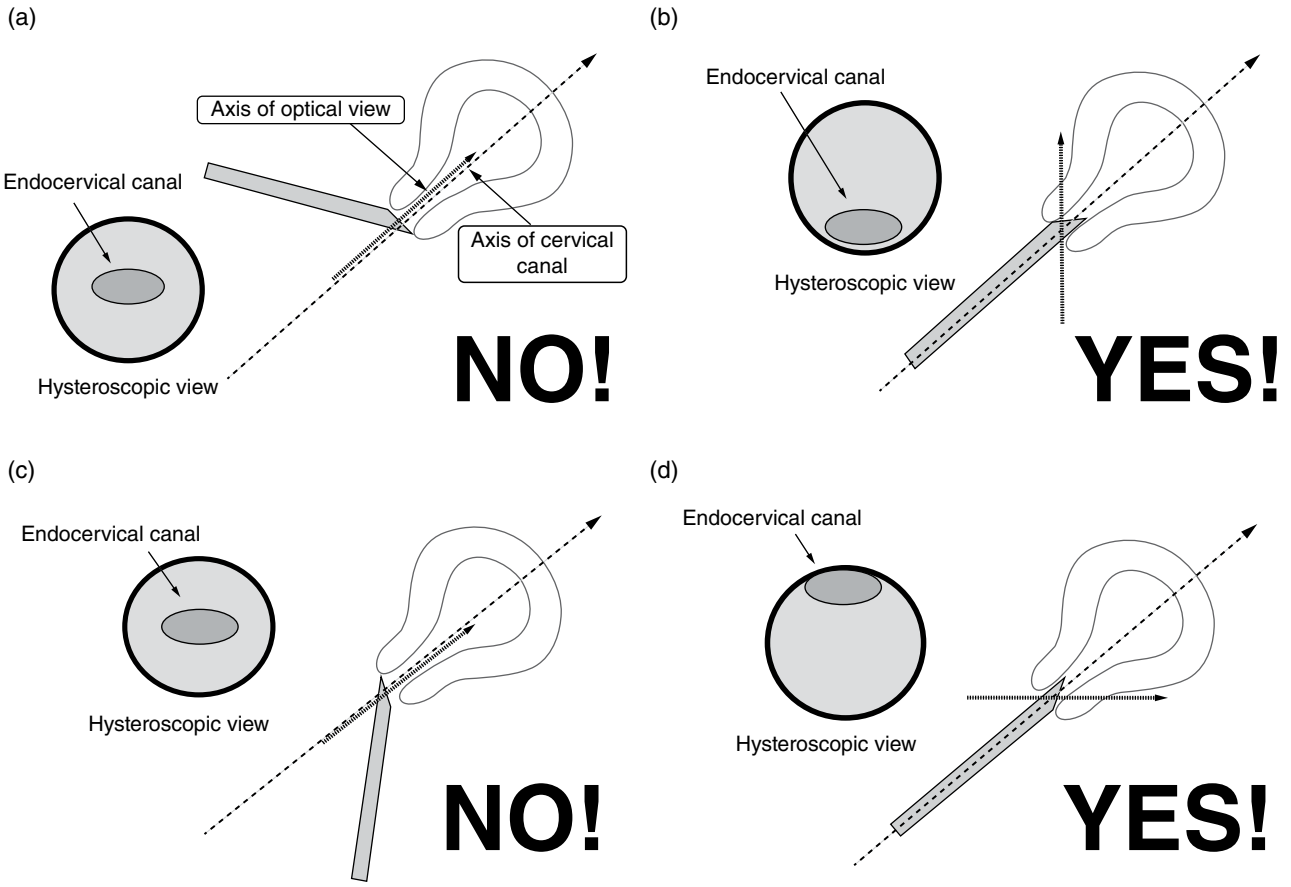

Fig. 37.10 How to insert an oblique-view hysteroscope into the uterus: (a) incorrect insertion with hysteroscope looking upwards; (b) correct insertion with hysteroscope looking upwards; (c) incorrect insertion with hysteroscope looking downwards; (d) correct insertion with hysteroscope looking downwards.

Complications

Diagnostic hysteroscopy is a safe procedure, and complications are uncommon [21]. In a prospective multicentre study of 13 600 women looking at complications of hysteroscopy, diagnostic procedures had significantly fewer complications (0.13%) than operative procedures (0.28%) [25]. The most frequently seen problem with outpatient hysteroscopy is pain when negotiating the cervix or distending the uterine cavity, and vasovagal reactions in response to cervical stimulation. Uterine perforation should not happen if the hysteroscope is introduced under direct vision unless there is extreme cervical stenosis.

Summary box 37.1

Best practice in ambulatory hysteroscopy [24]

- All gynaecology units should provide a dedicated outpatient hysteroscopy service that is appropriately sized, equipped and staffed and located outside the formal operating theatre setting. The healthcare professional(s) should have the necessary skills and expertise to carry out diagnostic and/or therapeutic outpatient hysteroscopy.
- Written patient information should be provided before the appointment and consent for the procedure should be taken.
- Women without contraindications should be advised to consider taking standard doses of non-steroidal anti-inflammatory drugs (NSAIDs) 1 hour before their appointment, but routine use of opiate analgesia should be avoided.
- Routine cervical preparation before outpatient hysteroscopy should not be used unless dilatation beyond Hegar 6 is anticipated.
- Miniature hysteroscopic systems (≤4 mm outer diameter) should be used for diagnostic outpatient hysteroscopy.

Choice of hysteroscope (e.g. flexible or rigid; 0° or fore-oblique distal lenses) should be left to the discretion of the operator.
- Carbon dioxide or normal saline can be used as distension media for diagnostic outpatient hysteroscopy, but normal saline should be used for operative procedures.
- Routine, blind cervical dilatation should be avoided.
- Topical application of local anaesthetic to the ectocervix should be considered where a cervical tenaculum is necessary. Routine administration of intracervical or paracervical local anaesthetic should be used where larger-diameter hysteroscopes are being employed (outer diameter >5 mm) and where the need for cervical dilatation is anticipated (e.g. cervical stenosis). Standard protocols regarding the type, maximum dosage and route of administration of anaesthesia should be implemented.
- Conscious sedation should not be routinely used in outpatient hysteroscopic procedures.
- Vaginoscopy (avoiding the use of a vaginal speculum or cervical instrumentation) should be the standard technique for outpatient hysteroscopy.

Operative hysteroscopy

Hysteroscopic surgery has a number of well-defined indications and these are itemized in Table 37.2.

Polypectomy

The removal of uterine polyps appears to confer benefit in terms of resolving symptoms and obtaining tissue for histological examination [26,27]. Traditional blind removal of polyps (e.g. dilatation and curettage, blind avulsion) risked incomplete removal and uterine perforation. Improvements in hysteroscope design and ancillary instrumentation, coupled with enhanced visualization due to improvements in fibreoptics and digital imaging, has allowed polyps to be removed under direct hysteroscopic vision predominantly in an outpatient setting consigning blind methods to the history books.

Mechanical instruments such as scissors and grasping forceps designed to pass down 5 and 7 Fr operating channels have been used successfully, but their utility is affected by their diminutive size and fragility. The introduction of bipolar intrauterine electrosurgical systems (e.g. Versapoint Bipolar Electrosurgical System) has facilitated rapid resection of focal uterine lesions, all but replacing mechanical approaches. Large observational and randomized trials have demonstrated the feasibility, acceptability and effectiveness of hysteroscopic polypectomy using such approaches [28,29]. However, these studies showed that nearly one in five attempts to remove polyps (detach and retrieve in entirety) failed primarily because of inadequate visualization, patient intolerance or difficulties in retrieval from the uterine cavity down the relatively narrow endocervical canal.

The introduction of tissue removal systems (formerly referred to as hysteroscopic morcellators) with their inherent ability to simultaneously cut and aspirate polyp tissue has overcome these obstacles. A recent randomized controlled trial comparing the TruClear system with the Versapoint Bipolar Electrosurgical System in an outpatient setting demonstrated lower failure rates (<2% vs. 17%) and pain scores along with increased speed of procedure and patient acceptability [30].

Myomectomy

Submucous fibroid(s) that are entirely within the cavity are classified as type 0. If a portion of the fibroid is intramural, then they are classified as type 1 if less than 50% is intramural and type 2 if more than 50% is intramural [31]. Types 0 and 1 are suitable for hysteroscopic resection and clinical outcomes in terms of perioperative complications, need for further surgery, alleviation of bleeding symptoms [32–34] and optimization of natural and assisted fertility [35] are good. In contrast, removal of type 2 fibroids is more challenging because risks of perioperative bleeding, incomplete removal and uterine trauma are significantly greater. Furthermore, the requirements for repeated hysteroscopic or other surgical interventions are greater to treat ongoing abnormal bleeding symptoms compared with type 0 and 1 fibroids [34].

Whilst most operative hysteroscopic procedures described in this chapter are feasible in an outpatient setting, removal of submucous fibroids generally requires general/regional anaesthesia. The Versapoint electrode can rapidly excise non-fundal grade 0 fibroids although retrieval down the narrow cervical canal, even under general anaesthesia, can be difficult. Moreover, grade 1 and 2 fibroids cannot be resected by point electrodes and for this reason hysteroscopic removal is mostly done with resectoscopes utilizing cutting loop electrodes. Advanced hysteroscopic skills are required and an appropriate caseload to maintain surgical proficiency.

Tissue removal systems are gaining popularity as they are simple to use, avoid the production of 'tissue chips', do not use potentially hazardous thermal energy, are quicker and associated with a reduced learning curve [36]. They are suited to grade 0 and 1 fibroids.

Endometrial ablation/resection

Hysteroscopic endometrial resection and ablation have been subjected to numerous randomized controlled trials and cost–benefit analyses showing that they are effective and useful alternatives to hysterectomy but are no more effective than the newer second-generation techniques [37]. These hysteroscopic first-generation techniques of endometrial destruction have been superseded to some extent by the newer second-generation ablative techniques which are technically easier to perform and associated with comparable clinical outcomes and fewer complications [37].

The development of miniature second-generation, semi-automated ablative technologies has allowed the concept of outpatient local anaesthetic endometrial ablation to progress. The majority of women undergoing the procedure in the outpatient setting find it acceptable [38].

Metroplasty

The most common congenital uterine anomaly amenable to hysteroscopic treatment is the partial or complete uterine septum (septoplasty). The fibroelastic tissue comprising a uterine septum can be divided mechanically using scissors, with electrosurgery (Versapoint electrode or resectoscopic division using a Collins knife electrode) or a combination of mechanical and electrosurgical techniques. Other uteroplastic procedures have been reported including restoration of the shape of a hypoplastic or T-shaped uterus by scoring the myometrium with activated miniature bipolar electrodes in an attempt to increase the uterine capacity [39]. Bipolar electrodes can also be used to create outflow channels in non-communicating rudimentary uterine horns.

Adhesiolysis

Intrauterine adhesions (Asherman's syndrome) occur where there is scar tissue between the uterine walls as a response to infection (endometritis) or trauma from intrauterine surgery, typically vigorous curettage of the endometrium in a recently pregnant or pregnant uterus. Hysteroscopy is the gold standard for accurate diagnosis and assessment of intrauterine adhesions. Hysteroscopic techniques include blunt or sharp adhesiolysis, using mechanical or electrosurgical instruments. In some patients, landmarks remain obscure and entry into the uterus may not be possible by hysteroscopy alone. In these patients it is necessary to perform simultaneous laparoscopy, fluoroscopy or ultrasound to reduce the risk of perforation. Increased uterine cavity size can be achieved by myometrial scoring with scissors or a Collins knife electrode [39].

Proximal fallopian tube cannulation

Tubal catheterization is a technique used to treat a proximal fallopian tube blockage diagnosed following a hysterosalpinogram. Hysteroscopic tubal catheterization is reported to be successful in approximately 50% of patients and 20–40% of these women have been reported to become pregnant either spontaneously or after ovulation induction or intrauterine insemination [40].

Tubal sterilization

The Essure® (Conceptus Inc., Mountain View, CA, USA) permanent birth control system involves placing a micro-insert, consisting of a stainless steel inner coil with polyester fibres and a super-elastic nitinol outer anchoring coil, into the intra-myometrial portion of each fallopian tube. This is done via a fine delivery catheter which is passed down the 5 Fr operating channel of a 30° 5–5.5 mm continuous-flow rigid hysteroscope (Fig. 37.11). The majority of procedures are performed in conscious women in the outpatient setting and most women are discharged home within 30 min following completion of the procedure [41,42]. Occlusion of the narrow tubal lumen occurs over the following 3 months as the polyester fibres cause inflammation and subsequent tissue ingrowth into the micro-insert. Radiology is scheduled at 3 months to confirm the adequacy of sterilization, usually by two-dimensional transvaginal ultrasound to verify satisfactory positioning of devices or hysterosalpingogram to identify tubal occlusion.

Hysteroscopic occlusion of hydrosalpinges

The same Essure technique can be used in women who require tubal occlusion prior to *in vitro* fertilization as treatment for hydrosalpinges. Successful pregnancy

Fig. 37.11 Essure™ permanent birth control system (Bayer, Germany). The expanded micro-insert which is used to occlude the myometrial component of the fallopian tube is shown along with the hand-held operating system. An operating hysteroscope with a 5 Fr working channel is needed [5-mm Storz Bettocchi® hysteroscope (Storz, Tuttlingen, Germany) shown]. *Source:* Storz, Germany. Reproduced with permission of Storz, Germany.

outcomes have been reported and no adverse effects on the fetus or pregnancy are apparent [43].

Treatment of placental remnants

Chronically retained products of conception (RPOC) or 'placental remnants' (i.e. RPOC that have been retained beyond 6 weeks) can be associated with infection, abdominal pain and uterine bleeding and, in the longer term, the formation of intrauterine adhesions affecting subsequent fertility. Chronic RPOC can be mechanically removed using a 'cold' (inactivated) resection loop by entrapment of tissue between the loop and the hysteroscope. More recently, the use of tissue removal systems has been reported and seems well suited to this task as electrosurgical energy is not needed and tissue can be simultaneously cut away and extracted [44].

Ambulatory hysteroscopy

Outpatient hysteroscopy, ambulatory hysteroscopy and office hysteroscopy all describe procedures that are done without general anesthesia and avoid admission to hospital. Advances in equipment, in particular the reduction in size of optics (operative hysteroscopes ≤5.5 mm outer diameter) and the introduction of miniature 5–7 Fr ancillary operative instruments (mechanical tools, electrosurgical snares/electrodes and bespoke tissue removal systems) has allowed first diagnostic and now a range of minor operative procedures to be performed in an outpatient setting [20,45]. These technological advances have initiated the age of efficient, safe and convenient 'see and treat' gynaecology in an ambulatory setting: the patient 'ambulates in' and 'ambulates out'. Women value the convenience of an immediate diagnosis and treatment in what is known as a 'one-stop' service. Not only is outpatient treatment well accepted and convenient, but it has also been shown to be more cost-effective [46,47]. Most uterine operations can be conducted in an outpatient setting in conscious women with or without local anaesthesia (Table 37.3). The exceptions include the majority of fibroid resections, metroplasty procedures and fibrous adhesiolysis, as cutting into the underlying myometrium is necessary and this induces pain.

Recent multicentre randomized controlled trials have demonstrated the safety, feasibility, effectiveness and cost-effectiveness of outpatient hysteroscopic polypectomy [28–30] and endometrial ablation [38]. In addition to the utility of hysteroscopy in facilitating operative procedures, outpatient hysteroscopy is also increasingly fundamental in the management of menstrual disorders – not just making diagnoses but also aiding safe intrauterine instrumentation, for example endometrial biopsy and insertion of levonorgestrel intrauterine system

Table 37.3 Operative hysteroscopic procedures feasible in an ambulatory setting.

(LNG-IUS), and planning treatment, for example estimating the likely response of symptoms to minimally invasive treatments with LNG-IUS and endometrial ablation, optimizing management of submucous fibroids and determining the most appropriate treatment setting for interventions.

Complications

Although complications are uncommon with operative hysteroscopy [49], anyone carrying out hysteroscopic surgery should be aware of the risks and their prevention and management (Table 37.4). The most serious complications associated with operative procedures relate to uterine trauma and fluid overload.

Uterine perforation is estimated to occur in less than 1% of procedures [25]. Infection and excessive bleeding are rarely seen. The operative procedures associated with most complications are adhesiolysis and resection of type 2 submucous fibroids [25]. If uterine perforation occurs while the cutting or electrical equipment are active, then there is the potential for major intra-abdominal trauma resulting in haemorrhage and viscus injury. A laparoscopy and arguably a laparotomy is mandatory to check the abdominal contents; if there is no injury, hysteroscopic surgery can continue once the perforation has been sutured.

All fluid distension media can cause complications from intravascular absorption of large volumes of fluid into the circulatory system. However, excessive absorption of hypotonic solutions used with monopolar electrosurgery will lead to electrolyte disturbance, lowering serum osmolality and inducing hyponatraemia. Excessive fluid absorption is most likely with prolonged hysteroscopic procedures using larger-diameter endoscopes with continuous irrigation of fluid or where blood vessels within the myometrium are opened. Thus, particular care is required with transcervical resection of the endometrium and hysteroscopic myomectomy (transcervical resection of fibroids, TCRF). Rapid expansion of the extracellular fluid volume ('fluid overload') can lead to acute pulmonary oedema, cerebral oedema and cardiac failure [50]. Therefore, it is important to accurately measure the input and output of fluid during operative hysteroscopy so that significant fluid deficits can be recognized and managed promptly [51,52].

Table 37.4 Complications of operative hysteroscopy.

Early
Uterine perforation
Fluid overload
Haemorrhage
Gas embolism
Infection
Cervical trauma
Electrosurgical burn
Late
Intrauterine adhesions
Uterine rupture in pregnancy (after metroplasty or myomectomy)
Haematometra (after endometrial ablation)
Post-ablation sterilization syndrome (after endometrial ablation)

Intraoperative haemorrhage can accompany uterine perforation but is more often a sign of surgery deep in the myometrium. Air embolism is a rare but devastating complication [53]. It usually happens if air is allowed to enter the distension tubing, typically when bags of irrigant are being changed. Infection is rare after hysteroscopic surgery. There is no evidence for routine use of antibiotics [54], although some surgeons prefer to administer them. The late adverse consequences of endometrial ablation are all relatively rare [55].

Summary box 37.2

Operative hysteroscopy

- Bipolar resectoscopes should be used in preference to monopolar instruments because a more physiological, electrolyte-containing fluid can be used for uterine distension and irrigation. Fluid overload can still occur, but the associated electrolyte disturbances will be less serious.
- TCRF of grade 1/2 fibroids and major uterine adhesiolysis are technically the most challenging operative hysteroscopic procedures. Surgeons undertaking such procedures should have a sufficient caseload to maintain their skills.

- Most operative procedures, with the exception of most fibroid excisions, metroplasty and adhesiolysis, can be undertaken as effectively in the outpatient setting. Women should be offered the choice of treatment setting.
- Proficiency should be attained through structured training programmes including the use of simulation.

Diagnostic laparoscopy

Diagnostic laparoscopy is a basic minimally invasive surgical procedure that is used to diagnose a variety of gynaecological problems but is most commonly used for pelvic pain and subfertility (Table 37.5).

Technique

The vast majority of laparoscopies are performed under general anaesthesia. As with hysteroscopy, it is important to position the patient correctly on the operating table. The buttocks are placed at the edge of the table to allow full uterine anteversion. The legs are placed in leg supports with the thighs at about 45° to the horizontal while ensuring that the hips can be extended sufficiently to bring the thighs in line with the trunk should the need arise for any abdominal surgery.

After washing and draping the bladder is emptied with a catheter. Bimanual examination should be performed to assess the size and mobility of the uterus and to help identify any adnexal masses. The cervix is identified and grasped using a vulsellum forceps and the uterus then sounded and instrumented using a Spackman forceps. This allows uterine manipulation and the option of hydrotubation if tubal patency testing is required.

Table 37.5 Indications and contraindications for diagnostic laparoscopy.

Indications
Acute or chronic pelvic pain
Ectopic pregnancy
Pelvic inflammatory disease (including TB)
Endometriosis
Adnexal torsion
Subfertility
Congenital pelvic abnormality
Abnormal pelvic scan
Unexplained pelvic mass
Staging for ovarian malignancy
Absolute and relative contraindications
Mechanical or paralytic bowel obstruction
Generalized peritonitis
Diaphragmatic hernia
Major intraperitoneal haemorrhage (e.g. shock)
Severe cardiorespiratory disease
Massive obesity
Inflammatory bowel disease
Large abdominal mass
Advanced pregnancy
Multiple abdominal incisions
Irreducible external hernia

Laparoscopic entry

In the UK over 250 000 laparoscopic procedures are performed annually. The overall risk of a major complication is approximately 1 in 1000 [56]. The time of highest risk for injury is during entry to the peritoneal cavity, prior to its visualization. There are various entry techniques, the closed approach being most favoured by gynaecologists. The Royal College of Surgeons favours the open technique. However, there is no evidence to recommend one particular approach over another. A meta-analysis of over 350 000 closed laparoscopic procedures reported a risk of bowel damage of 0.4 per 1000 and of major vessel injury of 0.2 per 1000 [56]. A comparative review of open and closed techniques found a higher risk of bowel injury with the open technique and the risk of vessel injury was so low that no difference was observed [49].

Closed

The closed technique uses the Veress needle for insufflation of CO_2 to distend the abdomen so that the trocar can be inserted safely. A small incision is made vertically from the base of the umbilicus for insertion of the Veress needle. It should be sharp at the tip and the spring-loaded action and patency of the needle tested prior to insertion. A disposable needle is preferable. The operating table should be horizontal for the laparoscopic entry and the Veress needle should be inserted at 90° to the abdominal wall (Fig. 37.12). It should be pushed through the fascia and peritoneum so that two audible clicks are heard. The needle should not be moved laterally during or after insertion. Various tests have been employed to ensure correct placement of the needle but the most reliable one is to check that the initial insufflation pressure is low (e.g. <8 mmHg). Insufflation should be continued until the pressure reaches 20–25 mmHg and then the Veress needle is removed and trocar inserted through the same incision. This again is performed at 90° to the abdominal wall and a two-handed approach with steady pressure should be used. Once the peritoneal cavity is visualized, a 360° inspection of the peritoneal cavity performed and ancillary ports placed, the pressure is reduced to 12–15 mmHg.

Open

The open technique avoids the use of blind needle entry and allows the insertion of a blunt-tipped trocar under direct vision. Once the skin incision is made, the sheath is then opened under vision and a suture placed either side of the incision. These are then pulled into the suture holders on the cannula. On opening the peritoneum, the

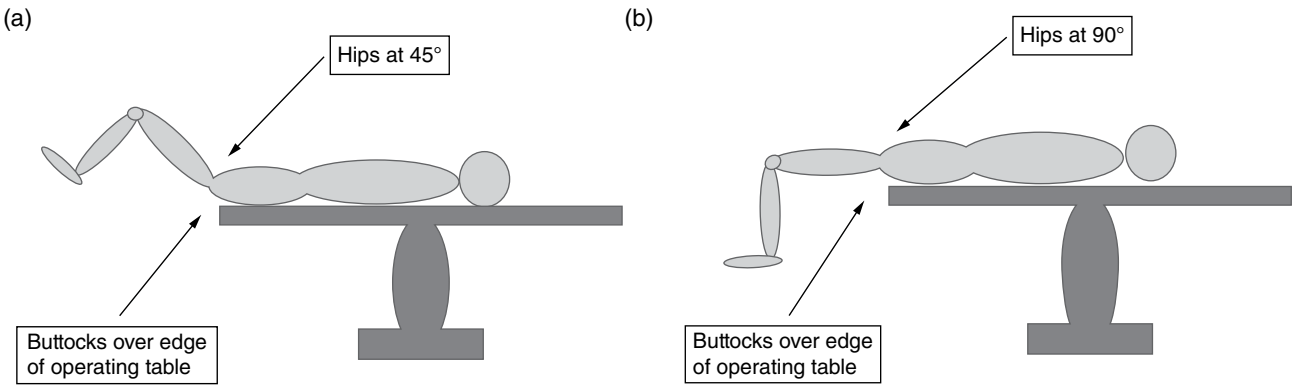

Fig. 37.12 Patient positioning during laparoscopy: (a) position during setting up and diagnostic laparoscopy; (b) position during operative laparoscopy which allows pelvic and abdominal surgery.

cannula is inserted under vision and the sutures then pulled tight to avoid gas leakage. The peritoneal cavity is insufflated and the blunt trocar removed and laparoscope inserted after achieving some abdominal distension. At the end of the procedure after removal of the cannula the sutures are tied together to close the sheath.

Direct entry and optical entry devices

Some practitioners advocate direct entry to the peritoneal cavity using a sharp-tipped trocar without the use of a Veress needle for prior insufflation. While it is not common practice in the UK, meta-analysis comparing it with the closed technique does not demonstrate any significant difference in major complications [57]. Some alternative devices have been developed to improve safety and ease of laparoscopic entry. These include the use of optical trocars, radially expanding trocars and, more recently, optical Veress needles [57–61].

Palmer's entry

Alternative entry sites may be required in patients with a history of previous surgery or a very low body mass index (BMI). Patients with a previous midline laparotomy have a risk of umbilical adhesions of 50% and those with a previous transverse lower abdominal incision have a risk of 23% [62]. Women with a very low BMI have a higher risk of vascular injury as the aorta may be as close as 2.5 cm below the skin surface. Palmer's point provides a safe entry point and is found three fingerbreadths below the left costal margin in the midline. This can be used for all patients except those with a history of surgery in the left upper quadrant or splenomegaly.

Culdoscopy and alternative entry sites

Palmer's point is the safest alternative site of laparoscopic entry for gynaecologists but other sites are often used. Suprapubic insertion can carry the risk of bladder injury and has a higher risk of failed entry [63]. Some gynaecologists use insufflation through the fundus of the uterus but this does increase the risk of ascending pelvic infection. Lastly, culdoscopy can be used but is not advised if there is a history of endometriosis, previous surgery or bowel pathology as the pouch of Douglas may be obliterated and rectal perforation is possible.

Inspecting the pelvis and abdomen

Once the peritoneal cavity is visualized a 360° inspection should be performed before placing the patient in a head-down tilt to displace bowel, allowing better access to the pelvis. Ancillary ports can then be placed under direct vision before lowering the pressure to 12–15 mmHg. For lateral port placement the inferior epigastric arteries should be identified and the ports placed away from these. These can be visualized just lateral to the lateral umbilical ligaments (obliterated hypogastric arteries).

Ending the procedure

Removal of the ports at the end of the procedure should also be done under vision and the sheath closed for any lateral ports over 7 mm or midline ports over 10 mm to avoid an incisional hernia. Gas is released and the peritoneal cavity completely deflated. By keeping the laparoscope inside the cannula as it is being withdrawn, it is possible to check that this port site is not bleeding and has not caught a loop of bowel or omentum. The skin is usually closed with absorbable sutures or glue.

Outcomes and complications

The benefits of laparoscopic surgery over laparotomic surgery include enhanced recovery (i.e. minimizing postoperative pain), quicker mobilization, reduced hospital stay and earlier return to work or normal functioning [64]. Diagnostic laparoscopy is a safe procedure with published complication rates of 2 per 1000 [65]. Most

injuries occur during the laparoscopic entry process (e.g. injury to the inferior epigastric vessels or major retroperitoneal vessels, bowel injury). Therefore care must be taken in planning the most appropriate type and site of entry. Injury to retroperitoneal vessels usually requires immediate laparotomy, whereas it is possible to manage bladder or bowel injury laparoscopically provided the perforation is small.

Operative laparoscopy

Laparoscopy is becoming the preferred route of surgery for an increasing number of conditions traditionally carried out by laparotomy (Table 37.6). This does not mean that laparoscopy is the best option or should be done in all these cases, and there is much debate about the more complex procedures in particular. In fact, only a few procedures have been subjected to prospective randomized comparisons (e.g. ectopic pregnancy, colposuspension, endometriosis, hysterectomy), so in many cases the decision about the route of surgery depends more on the particular skills of the gynaecologist, the presence of contraindications, and the relative risks of complications.

Table 37.6 Classification of laparoscopic procedures.

Basic
Diagnostic laparoscopy
Sterilization
Aspiration of ovarian cyst
Ovarian biopsy
Intermediate
Division of filmy adhesions
Linear salpingotomy or salpingectomy for ectopic pregnancy
Salpingostomy for infertility
Ovarian cystectomy
Excision of endometriomas
Salpingo-oophorectomy
Ovarian drilling with laser or diathermy for polycystic ovaries
Treatment of AFS stage I and II endometriosis
Myomectomy for pedunculated subserous fibroid
Laparoscopic-assisted vaginal hysterectomy without significant associated pathology
Advanced
Division of thick adhesions
Laparoscopic-assisted vaginal hysterectomy with significant associated pathology
Laparoscopic subtotal hysterectomy
Total laparoscopic hysterectomy
Myomectomy for intramural fibroids
Treatment of AFS stage III and IV endometriosis
Pelvic and aortic lymphadenectomy
Pelvic side wall and ureteric dissection
Presacral neurectomy
Incontinence procedures
Prolapse procedures

AFS, American Fertility Society.

Complications

Laparoscopic surgery appears to be inherently safer than conventional surgery [66]. However, although the overall complication rate is generally less, this is not inevitable [67] (Table 37.7). What is definitely true is that (i) major complications such as viscus injury and bleeding from retroperitoneal vessels are more common and (ii) many of the injuries are unfortunately not recognized during the procedure.

The reported rate of complications from major national surveys give an overall figure of 7–12.6 per 1000 procedures, with the more complex procedures having a greater risk of injury [68,69]. Comparing laparoscopic hysterectomy to other methods, there appears to be no significant difference in injury rates except for urinary tract injuries, which are higher [70]. About one-third to half of complications occur during the set-up phase, and one-quarter are not recognized during the surgery, including more than half of bowel and ureteric injuries [71]. The mortality after gynaecological laparoscopy is 4.4 per 100 000, which compares with a mortality of 150 per 100 000 for hysterectomy for benign indications [72].

Summary box 37.3

Laparoscopy

- Palmer's point is the safest entry point if there is concern about adhesions from previous surgery.
- Any instrument which produces heat (e.g. electrosurgery, laser, harmonic scalpel) should be used extremely carefully, if at all, close to vital structures such as bowel and ureter.
- The course of the ureter must be identified when performing any surgery on the pelvic side wall to avoid accidental injury.
- Most ureteric and bowel injuries are not recognized at the time of primary surgery. Excessive postoperative pain should be deemed as secondary to bowel injury unless proven otherwise.

Training in endoscopic surgery

Recognition of the importance of hysteroscopic and laparoscopic surgery to modern gynaecological care, coupled with a wish to improve and structure training in this area, has led surgical colleges such as the RCOG along with specialist societies such as the British Society

Table 37.7 Complications of laparoscopic surgery.

Intraoperative

for Gynaecological Endoscopy and the American Association of Gynecologic Laparoscopists to provide structured training and accreditation packages for minimal access surgery. Alternatives to training on 'real' patients have been sought through simulation with the aim of enhancing the surgical proficiency of trainees, enabling them to ascend the 'learning curve', ideally prior to them being instructed and supervised on real patients. Basic simulation involves the use of plastic models or box trainers where fundamental surgical skills including dexterity, spatial awareness, hand–eye coordination and familiarity with instrumentation can be gained. Animal tissue or objects such as vegetables can be used to mimic procedures, for example pig bladders are good 'wet' models for hysteroscopic endometrial ablation or potatoes for fibroid resection [73]. Models and computerized simulators are now available to improve performance and virtual reality simulators provide a standardized environment allowing objective assessment of the performance of a trainee.

Part 8

Childhood and Adolescence

38

Puberty and Its Disorders

D. Keith Edmonds[1,2]

[1] *Imperial College London, London, UK*
[2] *Queen Charlotte's and Chelsea Hospital, London, UK*

The transition from childhood to adolescence and adulthood is one of the most dynamic changes that occur during the life of a woman. The changes are not only physical, but emotional, psychological, behavioural and sexual, and all these changes encompass the maturation of the female to become reproductively capable. There is enormous variation between individuals in the processes involved in puberty but the five major physical changes are growth, breast development, pubic hair development, axillary hair development and, ultimately, menstruation. Whilst these changes occur temporally at different rates, there may be changes that occur prematurely or in a delayed fashion which alter this process. Finally, some girls may undergo pubertal change without menstruation and others may fail to enter puberty entirely.

Control of the onset of puberty

The age of onset of puberty in girls ranges from 8 to 13 years and the appearance of secondary sexual characteristics before this age is known as precocious puberty; failure of appearance of any secondary sexual characteristics after 13 years in girls is considered delayed puberty. A number of factors are known to play a role in the timing of puberty. Genetics has a clear and dominant role and there is a clear correlation between age at puberty of a woman and that of her daughter. However, there are racial differences, with black females showing an earlier age of pubertal onset compared with white [1]. Furthermore, nutritional status in all ethnic groups seriously influences the age of onset of puberty. Children living in areas of malnutrition have significantly delayed onset of puberty and transfer of these girls to a socioeconomically superior environment reduces the age of onset of puberty significantly [2]. At the other extreme, evidence now exists to suggest that a high body mass index (BMI) is linked to earlier age of maturation, and the relationship between body fat and the onset of puberty is linked to the release of leptin from adipose sites [3]. Leptin and kisspeptin would seem to act as a primary signal to the hypothalamus to allow puberty to commence [4].

The hypothalamus–pituitary–gonadal axis is active during fetal life and quiescent during childhood. It is the reactivation of this axis that leads to sexual maturation, although the mechanism by which this occurs remains unclear. The arcuate nucleus in the basal hypothalamus is responsible for secretion of gonadotrophin-releasing hormone (GnRH) into the hypothalamus–pituitary portal circulation. As puberty commences, the arcuate nucleus begins to secrete GnRH in a pulsatile manner, initially solely at night; however, as time progresses GnRH release adopts a low-frequency low-amplitude pulsatile pattern that starts to induce release of luteinizing hormone (LH) from the pituitary. The low-amplitude pulsatile pattern gradually extends to include daytime secretion and gonadotrophin levels themselves start to increase, reflecting higher pulse amplitude and increasing frequency of GnRH production. As the pattern of follicle-stimulating hormone (FSH) and LH release becomes established, so ovarian activity commences and initially this is disordered as it is uncoordinated. This means that there is follicular growth without coordinated ovulation and although estradiol levels start to rise, there is no evidence of ovulation. The ovary may have appearances that are multicystic due to this chaotic gonadotrophin stimulation and, over time (about 5–10 years), coordinated pulsatile release of GnRH leads to adult frequency of FSH release (approximately every 90 min). At this stage the ovulatory cycle is established.

From age 7, most girls will begin activation of adrenal androgen production, a phenomenon known as adrenarche. As with ovarian estradiol production, androgen production is initially at extremely low levels and increases over time.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Physical changes of puberty

Growth

An increase in vertical growth is the initial physical sign of the onset of puberty. Growth during infancy is relatively rapid until age 3–4 and then it rapidly decelerates when the childhood phase begins. Growth velocity during infancy is approximately 15 cm/year but in middle childhood, until the onset of puberty, slows to 5–6 cm/year. Interestingly, childhood growth rates are usually at their slowest in the 12–18 months immediately preceding puberty and thus if puberty is delayed this effect is exaggerated. At puberty, girls may reach a peak growth velocity of 10 cm/year and will gain approximately 25 cm of growth during puberty. Males in contrast have their growth spurt approximately 2 years later than females but eventually gain approximately 28 cm of added height. Once the final stage of growth velocity decreases, epiphyseal fusion occurs which prevents further growth. During the adolescent growth phase, bone density increases rapidly. Control of the growth spurt is primarily through growth hormone and its major secondary messenger insulin-like growth factor (IGF)-1. Estradiol plays an important role in the increased secretion of growth hormone during puberty, particularly in the early stages. As bone growth and height are maximally achieved, estradiol initiates epiphyseal fusion as it reaches its maximum towards the end of puberty. Thyroid hormone also plays a key role in growth and development as illustrated in severe childhood hypothyroidism, which results in a dramatic decrease in the velocity of growth.

Breast development

Although the growth spurt is usually the first sign of the onset of puberty, in females it is breast change that is usually used as an indicator of development. The initiation of breast development is known as thelarche and Tanner has classified this into five stages [5]. Breast growth is often unequal between the two breasts and Tanner stage 5 represents the mature end stage of breast development. This takes approximately 5 years.

Pubic and axillary hair growth

The adolescent development of female pubic hair occurs in conjunction with androgen release and it is the presence of androgen that determines both pubic and axillary hair growth. In approximately 20% of females, pubic hair growth may precede breast development.

Age of onset of puberty and subsequent health

Early age of menarche is associated with increased risk of breast cancer, cardiovascular disease, depression, behavioural disorders, diabetes and increased early mortality [6].

Summary box 38.1

Development of secondary sexual characteristics is characterized by:

- growth;
- breast development;
- pubic and axillary hair development;
- menstruation.

Precocious puberty

This phenomenon has received increased attention over the last few years with the belief that the age of onset of puberty has been falling. However, in accepting some guidance over age, the appearance of secondary sexual characteristics prior to 8 years should be considered precocious and prompt the clinician to carry out investigations.

Differential diagnosis of early onset of puberty

Premature adrenarche

This is due to the precocious increase in adrenal androgen secretion and is the most common cause of referral for precocious puberty. There seems to be an association between premature adrenarche and increased BMI [7], and in the overweight child referred with precocious puberty it is important not to assume that breast tissue is truly breast development and not adipose tissue. Signs of virilization such as clitoral enlargement, severe acne or increased muscle mass would lead to concerns of a virilizing ovarian or adrenal tumour or late-onset congenital adrenal hyperplasia (CAH). Late-onset CAH can present with pubic hair growth from the age of 1 and should be appropriately investigated.

Premature thelarche

Here, breast growth tends to appear earlier than age 8 and progresses very slowly and usually occurs in isolation of the growth spurt or any other secondary sexual characteristic. The cause of this condition remains unknown and although it is appropriate to exclude an ovarian cyst, these are rarely found.

Central precocious puberty

This refers to progressive breast development prematurely due to early activation of the hypothalamic–pituitary–ovarian axis and is accompanied by the growth spurt; pubic hair is frequently but not always found. This therefore mimics normal onset of puberty but at a very early age. A positive family history of early onset of puberty may be discovered where an *MKRN-3* gene

mutation can be found [6], but in the majority of cases the aetiology is idiopathic. Brain imaging is important, especially in girls with an onset of puberty before the age of 6, where 20% will be found to have a central nervous system (CNS) tumour.

Peripheral precocious puberty

This is far less common than central precocious puberty and is usually induced by excess production of sex steroids. Causes include the following.

- Androgen secretion from a virilizing adrenal tumour.
- Late-onset CAH.
- Oestrogen-secreting tumour causing rapid breast development. If a large ovarian cyst is present, this may be part of McCune–Albright syndrome, with associated classical features of irregular café-au-lait spots and cystic bone lesions called polyostotic fibroid dysplasia.
- Exposure to exogenous hormones, e.g. inadvertent ingestion of birth control pills by children causing excess levels of oestrogens; topical androgen exposure.

Investigations

A number of hormonal studies may be carried out in children with precocious puberty. However, they are of limited value and should be focused on specific clinical entities. LH may be used to distinguish between premature thelarche and central precocious puberty. FSH is of limited value. Estradiol is usually elevated in girls with precocious puberty and very high levels may suggest a tumour. Dehydroepiandrosterone is always elevated in children with premature adrenarche; testosterone when markedly elevated would suggest an androgen-secreting tumour; and in those children who are considered to have late-onset CAH, the diagnosis can be confirmed by measuring 17-hydroxyprogesterone. Radiological studies have somewhat limited value, although pelvic ultrasound may be used if an abdominal tumour is suspected and brain MRI may be used in those children with extreme precocious puberty, where the chances of a positive finding are around 20% and *MKRN-3* gene mutation should be screened for.

Treatment

The majority of girls with central precocious puberty do not require hormonal treatment, because most development is extremely slow and will result in maturity at an age which would be expected even though onset has been early. It is therefore prudent to review children with precocious development of secondary sexual characteristics 6 months later to see whether there has been rapid development of secondary sexual characteristics or not. In these cases, there is a high chance that sexual maturity will be reached by age 9 and therefore suppression of the progress of puberty would be sensible. While it is possible to suppress the pituitary, growth hormone cannot be suppressed and therefore treatment will result in adult height that is significantly greater than would be expected than if the child were left untreated. Children with extremely early puberty are often tall at the time of diagnosis and they tend to finish their growth early but achieve normal adult height. It is appropriate in these young children to suppress the development of secondary sexual characteristics. The standard treatment for central precocious puberty is GnRH analogues, which may be given nasally or by intramuscular injection. Three-monthly preparations are available and therefore four injections a year is all that is required to suppress puberty. GnRH analogues can then be administered until such time as the child reaches approximately age 11, when withdrawal will result in the normal resumption of pubertal changes. Peripheral precocious puberty, when due to an ovarian or adrenal tumour, requires surgical intervention; however, for girls with androgen excess due to CAH, suppression of the adrenal with hydrocortisone will reverse the changes.

Delayed puberty

Delayed puberty is usually considered when girls have no secondary sexual characteristics by age 13.5 years. Delay in puberty occurs in only 2.5% of the population but the identification of those children who do have a significant aetiology for this may be extremely important. It is mandatory to take a detailed history as the presence of chronic medical conditions or excessive athletic participation may be an explanation for delay in the onset of puberty. In females, approximately 50% will have constitutional delay with no explanation and the vast majority will commence the onset of puberty by age 18. A further 40% have been found to have a genetic defect [6]. In the presence of secondary sexual characteristics, menstruation ought to occur within 2 years of the establishment of Tanner stage 2 breast change. However, any child presenting at any stage because of concern over failure to establish either secondary sexual characteristics or menstruation should be investigated at that time. There are often extremely good reasons why a mother will bring her daughter for investigation and this often relates to the fact that a sibling completed her pubertal development at an earlier age or she herself went through puberty at an earlier age. While investigations may not lead to a diagnosis of abnormality, proof of normality is extremely important.

Summary box 38.2

Precocious puberty is usually idiopathic and requires treatment only if changes are accelerated such that completion of puberty will occur prematurely.

Aetiology of primary amenorrhoea

From a clinical point of view it is probably best to classify the aetiologies of primary amenorrhoea based on the presence or absence of secondary sexual characteristics. This is the basis of the classification system shown in Table 38.1. Finally, there is the group of patients in whom there is heterosexual development.

Normal secondary sexual characteristics

Imperforate hymen

The imperforate hymen may present at two stages of development. It may present in early childhood when the infant presents with a bulging hymen behind which is a mucocele, the vagina expanded by vaginal secretions of mucus. This is easily released and does not subsequently cause any problems following hymenectomy. It may also present in later life when a pubertal girl complains of intermittent abdominal pain, which is usually cyclical. The pain is due to dysmenorrhoea associated with the accumulation of menstrual blood within the vagina. The vagina is a very distensible organ and can allow quite large quantities of blood to collect in some cases. This condition is known as haematocolpos. It is very unusual for blood to accumulate within the uterus as the uterus is a muscular organ that is difficult to distend. When some blood does accumulate within the cavity it is known as haematometra. As the vaginal mass enlarges there may be associated difficulty with micturition and defecation. Examination will occasionally reveal an abdominal swelling and observation of the introitus will display a tense bulging bluish membrane, which is the hymen (see Chapter 35).

Transverse vaginal septum

In circumstances where the vagina fails to cannulate, the upper and lower parts of the vagina are separate. These girls present with cyclical abdominal pain due to the development of haematocolpos, but the thickness of the transverse vaginal septum means that the clinical appearance is very different from that of an imperforate hymen. Again, an abdominal mass may be palpable but inspection of the vagina shows that it is blind-ending and although it may be bulging, it is pink not blue. The hymenal remnants are often seen separately. Transverse vaginal septum may occur at three levels, known as a lower, middle or upper third septum. If the space between the upper and lower vagina is considerable, no introital swelling may be visible and rectal examination may disclose a mass. The management is very different from imperforate hymen and very careful assessment must be made before embarking on any management strategy (see Chapter 35).

Table 38.1 Classification of primary amenorrhoea.

Secondary sexual characteristics normal
Imperforate hymen
Transverse vaginal septum
Absent vagina and functioning uterus
Absent vagina and non-functioning uterus
XY DSD: androgen insensitivity
Resistant ovary syndrome
Constitutional delay
Secondary sexual characteristics absent
Normal stature
Hypogonadotrophic hypogonadism
Congenital
Isolated GnRH deficiency
Olfacto-genital syndrome
Acquired
Weight loss/anorexia
Excessive exercise
Hyperprolactinaemia
Hypergonadotrophic hypogonadism
46XX or 46XY DSD
Gonadal agenesis
XX agenesis
XY agenesis
Gonadal dysgenesis
Turner mosaic
Other X deletions or mosaics
XY enzymatic failure
Ovarian failure
Galactosaemia
Short stature
Hypogonadotrophic hypogonadism
Congenital: hydrocephalus
Acquired
Trauma
Empty sella syndrome
Tumours
Hypergonadotrophic hypogonadism
Sex chromosome DSD
Turner's syndrome
Other X deletions or mosaics
Heterosexual development
46 XX DSD
Congenital adrenal hyperplasia
Androgen-secreting tumour
Absent Müllerian inhibitor
46 XY DSD
5α-Reductase deficiency
Partial androgen receptor deficiency
Sex chromosome DSD
True hermaphrodite

DSD, disorders of sexual development.

Absent vagina and a functioning uterus

This is a rare phenomenon when embryologically the uterine body has developed normally but there is failure of development of the cervix. This leads to failure of the development of the upper vagina. The presenting

symptom is again cyclical abdominal pain, but there is no pelvic mass to be found because there is no vagina to be distended. Although a small haematometra may be present, retrograde menstruation occurs leading to the development of endometriosis and in some patients pelvic adhesions. Reconstructive surgery is possible.

Absent vagina and a non-functioning uterus

This is the second most common cause of primary amenorrhoea, second only to Turner's syndrome. Secondary sexual characteristics are normal as would be expected, as ovarian function is unaffected. Examination of the genital area discloses normal female external genitalia but a blind-ending vaginal dimple which is usually not more than 1.5 cm in depth. This is known as Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome and uterine development is usually absent. Often small uterine remnants (anlage) are found on the lateral pelvic side walls. It is important to remember that 40% of these patients have renal anomalies, 15% of which are major, for example an absent kidney, and there are also recognizable skeletal abnormalities associated with this syndrome [8] (see Chapter 35).

46 XY

There are a number of ways in which an individual may have an XY karyotype and a female phenotype, and these include failure of testicular development, enzymatic failure of the testis to produce androgen (particularly testosterone), and androgenic receptor absence or failure of function. In androgen insensitivity there is a structural abnormality of the androgen receptor, due to defects in the androgen receptor gene, which results in a non-functional receptor. This means that the masculinizing effect of testosterone during normal development is prevented and patients are therefore phenotypically female with normal breast development. This occurs because of peripheral conversion of androgen to oestrogen and subsequent stimulation of breast growth. Pubic hair is very scanty in these patients as there is no androgen response in target tissues. The vulva is normal and the vagina is usually short. (see Chapter 35).

Resistant ovary syndrome

This is an extremely rare cause of primary amenorrhoea, but it has been described. There are elevated levels of gonadotrophin in the presence of apparently normal ovarian tissue; patients do have some development of secondary sexual characteristics, but never produce adequate amounts of oestrogen to result in menstruation. It is believed that these women have an absence or malfunction of FSH receptors in the ovarian follicles, and are unable to respond properly to FSH.

Constitutional delay

A number of girls have constitutional delay and normal secondary sexual characteristics, but there is no anatomical anomaly and endocrine investigations are all normal. If serial sampling is carried out over a 24-hour period, these young women are found to have immature pulsatile release of GnRH. This is the sole reason for their constitutional delay. These young women will eventually menstruate spontaneously as the maturation process proceeds.

Summary box 38.3

The management of primary amenorrhoea should be based on the presence or absence of secondary sexual characteristics and treatment appropriately instituted.

Absent secondary sexual characteristics (normal height)

Isolated GnRH deficiency (olfacto-genital syndrome, Kallman's syndrome)

In this condition the hypothalamus lacks the ability to produce GnRH and there is therefore a hypogonadotrophic state. The pituitary gland is normal and stimulation with exogenous GnRH leads to normal release of gonadotrophins. This condition arises due to maldevelopment of neurones in the arcuate nucleus of the hypothalamus. These neurones are derived embryologically from the olfactory bulb and therefore some patients may also have failure of development of the ability to smell (anosmia). When this occurs it is known as Kallman's syndrome. The genetic basis of these two syndromes remains to be clarified. Currently, 24 gene mutations have been described but these only explain 60% of cases [9].

Weight loss/anorexia

Weight loss is more commonly associated with secondary amenorrhoea than primary amenorrhoea, but unfortunately it is increasingly apparent that younger girls may suffer from anorexia nervosa in the prepubertal state. This leads to failure of initiation of puberty and therefore a persistent hypogonadotrophic state exists. The growth spurt is not usually influenced by this, but secondary sexual characteristics are absent.

Excessive exercise

Over recent years it has become increasingly recognized that excessive exercise in pubertal children leads to decreased body fat content, without necessarily affecting body mass. Development of muscle contributes to overall weight, and therefore weight alone cannot be used to

decide whether this is an aetiology for their amenorrhoea via this mechanism. It is essential to obtain an assessment of body fat, which is much more discriminatory. Examples include ballet dancers, athletes and gymnasts and some of these girls may actually develop associated anorexia nervosa.

Hyperprolactinaemia

This is an unusual cause of primary amenorrhoea and is much more commonly seen as a cause of secondary amenorrhoea. There may be a recognizable prolactinoma in the pituitary, but often no apparent reason is seen. A CT scan may reveal evidence of a tumour.

Gonadal agenesis

In this condition there is complete failure of development of the gonad. These girls may be either 46XX or 46XY. The 46XX pure gonadal agenesis is an autosomal recessive disorder and genes other than those located on the X chromosome may be involved. The location of these genes remains unclear and in all these patients their genotype does not affect their phenotype, all of them being female. In 46XY or 45X/46XY, when the absence of testicular determining factor or its receptor is postulated as the cause of the failure of differentiation of the gonad, there is absence of testicular development. These individuals therefore fail to produce any androgen or Müllerian inhibitor. Therefore Wolffian structures regress and Müllerian structures persist and menstruation will occur when oestrogen is administered. The external genitalia reflect the normal female phenotype. Height is normal as the growth spurt occurs at the normal time. However, in those girls who are 46XY, the failure of production of androgen or oestrogen means that their long bones do not undergo epiphyseal closure at the normal time and therefore final height may be above normal.

Ovarian failure

These unfortunate girls have ovarian failure as a result of either chemotherapy or radiotherapy for childhood malignancy.

Galactosaemia

This inborn error of galactose metabolism is due to deficiency of galactose 1-phosphate uridyltransferase. The aetiology of the association between this enzyme and hypogonadotrophic hypogonadism is still to be clarified but patients with galactose 1-phosphate uridyltransferase deficiency have an acute toxic syndrome that causes ovarian cellular destruction thought to be due to the accumulation of galactose metabolites, which may induce programmed cell death (apoptosis).

Gonadal dysgenesis

The gonad is described as dysgenetic if it is abnormal in its formation. This encompasses a spectrum of conditions that vary with the degree of differentiation. The commonest is Turner's syndrome, where there is a single X chromosome giving a 45X karyotype. The missing chromosome may be either X or Y. There are other circumstances in which the gonadal dysgenesis may be associated with mosaicism and here two cell lines exist within one individual, the most common being 45X/46XX. Other structural chromosomal anomalies associated with gonadal dysgenesis involve deletions. If the deletion involves part of the long or short arm of the X chromosome, then loss of this genetic material may affect gonadal development. In Turner's syndrome ovarian development is normal until 20 weeks' gestation and at this stage oocytes are found in the ovaries. However, further maturation is impaired and massive atresia occurs during the latter part of pregnancy. The ovaries in most individuals consist solely of stroma and as there are no oocytes remaining, they are unable to produce oestrogen. There is a normal female phenotype and internal genital development is also normal. The loss of an X chromosome results in short stature as the genes for height are on the short arm of the X chromosome. In mosaicism the proportion of each cell line determines the manifestation of the condition. The higher the percentage of 45X cells, the more likely the features of Turner's syndrome.

In XY individuals, there may be a dysgenetic gonad associated with enzymatic failure and there is failure of testosterone production. This is usually associated with normal production of Müllerian inhibitor and therefore internal development leads to Müllerian atrophy, but the external genitalia fail to masculinize due to the lack of testosterone. Wolffian structures also fail to develop. The external phenotype is therefore female with a short vagina.

Absent secondary sexual characteristics (short stature)

Congenital infection

The most common aetiology in this group is hydrocephalus, as a result of childhood or neonatal infection. It is believed that this damages the hypothalamus and renders the GnRH-secreting neurones functionless, thereby creating a hypogonadotrophic hypogonadic state.

Trauma

Trauma to the skull base may also damage the hypothalamus and prevent GnRH secretion.

Empty sella syndrome

In this unusual condition, the sella turcica is found to be empty and there is congenital absence of the pituitary

gland or at least part of it, leading to failure to produce gonadotrophins. Thus secondary sexual characteristics do not develop.

Tumours

A number of tumours have been described in the pituitary which may lead to destruction of the gland. The most common of these is craniopharyngioma. This is a tumour which usually arises in childhood and results in destruction of the pituitary gland. These children present already on maintenance therapy for other hormonal deficiencies and are hypogonadotrophic.

Turner's syndrome

In pure Turner's syndrome the chromosome complement is 45X and here a syndrome of short stature and ovarian failure leads to the typical features, including growth failure, ovarian failure and cardiovascular abnormalities. These children usually present in infancy or early childhood, but rarely present in the teenage years because of failure of development of secondary sexual characteristics. More commonly, they may be referred from paediatric endocrinology clinics for induction of secondary sexual characteristics. Attempts to improve height have proved difficult to achieve.

Heterosexual development

Congenital adrenal hyperplasia

This occurs as a result of an enzyme deficiency in the steroid pathway of the adrenal gland (see Chapter 35) and children with this condition require steroid replacement [10]. It is imperative that there is good control of CAH at puberty if the children are to develop secondary sexual characteristics at the appropriate time. However, many of these girls fail to comply with their steroid therapy and are therefore uncontrolled. As a result of this, they fail to establish the normal process of puberty. It is therefore quite common to find that puberty is delayed and steroid control needs to be addressed.

Androgen-secreting tumour

This is extremely rare and arises when the ovary contains an arrhenoblastoma. Here excessive production of androgen results in virilization and removal of the tumour resolves the problem.

5α-Reductase deficiency

This form of XY female results from an enzyme deficiency that prevents the conversion of testosterone to 5-hydroxytestosterone, which is a necessary biochemical step in the development of the external genitalia in the male. The cloaca can only respond to this testosterone derivative and not to testosterone itself. The external genitalia are therefore female, but the internal genitalia are normal male as secretion of Müllerian inhibitor leads to Müllerian agenesis. These patients are therefore amenorrhoeic.

True hermaphrodite

In this condition the child has both testicular and ovarian tissue. This may occur either in isolation, such that there is an ovary and a testis in the same individual, or the gonad may contain both ovarian and testicular tissue. This leads to intersex problems at birth (see Chapter 35) and subsequently, if not resolved at birth, amenorrhoea due to androgen production at puberty, thereby preventing the development of the normal menstrual cycle.

Absent Müllerian inhibitor

There is a rare condition in which an XY individual may not produce Müllerian inhibitory substance, which means that the internal genitalia are female with persistence of the Müllerian structures; in addition, because testosterone is produced, the Wolffian structures also persist. In this extremely rare syndrome, there are male and female internal organs.

Evaluation and management

Having understood the classification of these syndromes, it becomes apparent that most of the conditions are rare and constitutional delay is undoubtedly the most common diagnosis. However, as the rest of the diagnoses have serious implications, the diagnosis of constitutional delay should only be made when all other syndromes have been excluded. It is vital to record a full history and examination, including most importantly the development of secondary sexual characteristics and height. Secondary sexual characteristics should be classified according to the staging system of Tanner. Individuals can then be classified according to their secondary sexual characteristics.

Normal secondary sexual characteristics

The presence of normal secondary sexual characteristics should alert the clinician to the presence of outflow tract obstruction. This is the most common cause of primary amenorrhoea in the presence of normal secondary sexual characteristics. It is thus appropriate to carry out investigations to make this diagnosis. It is inappropriate to perform any physical pelvic examination on these young adolescents and imaging techniques should be used. It is simple to arrange a pelvic ultrasound scan to assess the pelvic anatomy, and only in rare circumstances where this cannot be delineated by ultrasound should it be necessary to use MRI. If the uterus is absent, the karyotype should be performed; if this is 46XX, then MRKH

syndrome is the most likely diagnosis. If the chromosome complement is 46XY, the patient is, by definition, an XY female. If the uterus is present on ultrasound, then there may be an associated haematocolpos and haematometra and appropriate reconstructive surgery should be carried out. If the pelvic anatomy is normal, then it is essential to assess gonadotrophin and prolactin levels as this would tend to indicate a hypothalamic cause for the amenorrhoea, so-called constitutional delay. In some conditions the LH to FSH ratio may be elevated (see Table 38.1), and if resistant ovary syndrome is the diagnosis these gonadotrophin levels will be very elevated. Elevation of prolactin levels suggests a prolactinoma.

Management

Patients with an absent uterus require special psychological counselling and their care should be managed in a centre able to offer the complete range of psychological, psychosexual and gynaecological expertise. These young girls will have major problems with future sexual activity and their infertility and require very careful counselling. At the appropriate time a vagina may be created either non-surgically or surgically. In 95% of cases the use of vaginal dilators is successful (see Chapter 35).

In girls found to have an XY karyotype, again careful counselling is necessary about the malignant potential of their gonads, this being reported in around 30%. It is therefore necessary for them to have their gonads removed and this should be performed at a time when counselling is complete. Sharing the information of the karyotype with the patient should be entertained at the time when the relationship between the clinician and the patient warrants it. All patients should be informed of their karyotype when appropriate.

In outflow tract obstruction, surgical management depends on the level of obstruction. The simplest form is an imperforate hymen and in this condition a cruciate incision in the hymen allows drainage of the retained menstrual blood. Transverse vaginal septa are much more difficult to deal with and require specialist reconstruction to create a vagina which is subsequently functional (see Chapter 35) [8].

If investigations suggest that constitutional delay and development of secondary sexual characteristics is complete, there is no need to suggest any treatment other than annual review. These young women very much appreciate the opportunity to return for monitoring until such time as their menstruation commences. In some circumstances it may be useful to promote menstruation using the oral contraceptive pill for one cycle to prove that menstruation can occur and this can be extremely reassuring. If the diagnosis of resistant ovary syndrome is suspected, then diagnosis can really only be made by ovarian biopsy and subsequent histology confirming or illustrating the absence of oocytes. Finally, elevated prolactin levels should provoke the clinician to perform imaging of the pituitary fossa, probably best done by CT, to determine the presence or absence of a microadenoma and management subsequently with bromocriptine.

Absence of secondary sexual characteristics

In this situation, it is extremely important to make an assessment of the patient's height. If the patient is of normal height for age, measurement of gonadotrophin will reveal levels that are either low or high. Low levels of gonadotrophins confirm the diagnosis of hypogonadotrophic hypogonadism, while elevated levels should provoke the clinician to perform a karyotype. The 46XX patient will have premature ovarian failure, resistant ovary syndrome or gonadal agenesis, whereas the XY female will have 46XY gonadal agenesis or testicular enzymatic failure. If stature is short, gonadotrophin levels will either be low (associated with an intracranial lesion) or high (which, following a karyotype, almost certainly indicates Turner's syndrome or a Turner mosaic).

Management

In patients with hypogonadotrophic hypogonadism, treatment should be to manage any acquired problem. Weight-related amenorrhoea may require the input of specialist psychiatrists and psychologists. In isolated GnRH deficiency, seconadary sexual characteristics will need to be induced using hormone replacement therapy. These patients can be informed that they are fertile and that ovulation induction in the future can be performed. Hormone replacement therapy is essential and regimens exist for the induction of secondary sexual characteristics over 3–5 years. Oestrogen should be used alone for about 2 years, and then 2–3 years of gradual introduction of progestogens, thereby establishing normal breast growth over a time frame that is equivalent to normal. Any attempt to accelerate breast growth by using higher doses of oestrogen will result in abnormal breast growth and this should be avoided at all costs. Controversy currently exists over the choice of oestrogen, and the mode of administration. Increasing evidence would suggest that transdermal estradiol is the preferred medication, but compliance in teenagers is an issue. It is likely that both oral and transdermal regimens will continue for some time.

Patients with Turner's syndrome are a special group. Turner's syndrome occurs in 1 in 2500 female births and is the commonest cause of primary amenorrhoea. After the diagnosis is made, paediatric endocrinologists will use growth hormone as early as possible to improve final adult height attainment, and recent studies suggest this can be very successful [11]. Previous recommendations

to delay the induction of puberty until age 15 to maximize height attainment would seem unjustified. Induction of puberty should begin at age 12 and is associated with improved cognitive function. Recent studies have shown that patient's with Turner's syndrome have increased risk of thrombosis, and transdermal estradiol has been shown to be safer and to improve overall body composition [10]. Patients with an XY dysgenesis or enzymatic failure should have gonadectomies performed to avoid malignancy.

It must always be remembered that any chronic medical illness which prevents normal growth will result in delayed onset of puberty and these causes must be considered in any patient presenting in this way.

Gynaecological Disorders of Childhood and Adolescence

D. Keith Edmonds[1,2]

[1] *Imperial College London, London, UK*
[2] *Queen Charlotte's and Chelsea Hospital, London, UK*

Gynaecological problems in the child and at adolescence can create anxiety in parents particularly, but fortunately very few of these disorders could be considered common or serious. However, when they do present, it is important that the clinician has an appropriate understanding of the various conditions so that the correct advice may be given to the patient. Management is frequently through simple means, with education and a sympathetic approach being essential. The disorders fall into two groups: those related to pre-puberty and those of adolescence.

Summary box 39.1

- Vulvovaginitis is usually due to non-specific bacterial contamination.
- Child sexual abuse should always be borne in mind.
- Treatment is usually through hygiene techniques.

Prepubertal child

Examination of the prepubertal child requires cooperation from both the patient and the mother and requires extreme sensitivity if a successful examination is to be carried out. Positioning the child for examination may require considerable time in order to gain the confidence of the child to allow examination. External examination should be performed with minimal handling of the vulva and, in order to expose the vaginal orifice, gentle traction on the buttocks to expose the vaginal opening can be performed. This can often be more effectively achieved by the mother rather than the physician. Specimens can be obtained using syringes with flexible catheters or occasionally a swab may be inserted if the hymenal orifice allows. In adolescents, vaginal examination should be avoided unless there is good evidence that it is absolutely necessary in order to make a diagnosis. Imaging is the preferred investigation if further information is required.

Vulvovaginitis

This is the only gynaecological disorder of childhood which can be thought of as common. Its aetiology is based on opportunistic bacteria colonizing the lower vagina and inducing an inflammatory response. At birth the vulva and vagina are well oestrogenized due to the intrauterine exposure of the fetus to placental oestrogen. This oestrogenization causes thickening of the vaginal epithelium, which is entirely protective against any bacterial invasion. However, within 2–3 weeks of delivery the resultant hypo-oestrogenic state leads to changes in the vulval skin, which becomes thinner, and the vaginal epithelium also becomes much thinner. The vulval fat pad disappears and the vaginal entrance becomes unprotected. The vulval skin is thin, sensitive and easily traumatized by injury, irritation, infection or any allergic reaction that may ensue. The lack of labial protection and the close apposition of the anus mean that the vulva and lower vagina are constantly exposed to faecal bacterial contamination. The hypo-oestrogenic state in the vagina means that there are no lactobacilli and therefore the vagina has a resulting pH of 7, making it an ideal culture medium for low-virulence organisms.

The complaint is usually of discharge which may be offensive, yellow or green in colour and parents often bring stained underwear as evidence of the condition. It occurs most commonly between the ages of 2 and 7 years. Examination of the vulva reveals inflammation and occasionally excoriation. Children also have the habit of exploring their genitalia and in some cases masturbating. This chronic habit may lead to vulvovaginitis, which can prove extremely difficult to treat. Vulvovaginitis may also occur in childhood in those who have an impaired

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Foreign body

local host defence deficiency due to the lack of an innate local protective response from neutrophils.

The causes of vulvovaginitis in children are shown in Table 39.1. The vast majority of cases are due to non-specific bacterial contamination, which in the majority of cases is due to poor hygiene. If a specific pathogen is isolated, for example *Streptococcus pneumoniae*, *Staphylococcus aureus* or *Haemophilus influenzae*, antibiotics can be considered. *Escherichia coli* is a contaminant from poor hygiene.

Candidal infection in children is extremely rare, although as a common cause of vulvovaginitis in the adult, it is a common misdiagnosis in children. *Candida* in children is usually associated with diabetes mellitus or immunodeficiency and almost entirely related to these two medical disorders. The presence of viral infections, for example herpes simplex or condylomata acuminata, should alert the clinician to the possibility of sexual abuse.

Vulval skin disease is not uncommon in children, particularly atopic dermatitis in those children who also have eczema. Referral to a dermatologist is appropriate in these circumstances. Lichen sclerosus is also seen in children and may cause persistent vulval itching. The skin undergoes atrophy and fissuring and is very susceptible to secondary infection.

Sexual abuse in children may present with vaginal discharge. Any child who has recurrent attacks of vaginal discharge should alert the clinician to this possibility. However, as non-specific bacterial infection is a common problem in children, the clinician must proceed with considerable caution in raising the possibility of sexual abuse. Only those bacterial infections related to venereal disease, for example gonorrhoea, may be cited as diagnostic of sexual abuse.

It is important that the clinician remembers that many girls suffer from urinary incontinence, particularly at night, and this creates a moist vulva allowing secondary infection by bacteria leading to vulvovaginitis.

Diagnostic procedures

There are two aspects of the diagnosis in this condition in children. The first is inspection of the vulva and vagina. It is imperative that the clinician has good illumination, particularly if there is a history of a vaginal foreign body. It is usually possible to examine the vagina through the hymen using an otoscope. This may well allow the diagnosis of a foreign body to be made.

The second aspect of diagnosis involves the taking of bacteriological specimens. This can be extremely difficult in a small child, as it is unlikely that the child will be cooperative. Any object which touches the vulva causes distress. The best way to take a bacteriological specimen is to use a pipette, which is much less irritating than a cottonwool swab. The pipette allows 1–2 mL of normal saline to be expelled into the lower part of the vagina, the tip of the pipette having been passed through the hymenal orifice. The fluid is then aspirated and sent for bacteriology. If a diagnosis of pinworms is to be excluded, then a piece of sticky tape over the anus early in the morning before the child gets out of bed will reveal the presence of eggs on microscopy.

Treatment

The vast majority of children do not have a pathological organism. The primary treatment in this group is advice about perineal hygiene. All parents of children with chronic vaginal disease are extremely worried that this may cause long-term detrimental effects to their daughters, particularly the fear of sexual dysfunction or subsequent infertility. There is no evidence that this is the case and therefore parents should be reassured that this is a local problem only. Management of these children is directed towards diligent hygiene of the perineum. The child must be taught to clean her vulva, particularly after defecation, from front to back, as this avoids the transfer of enterobacteria to the vulval area. After micturition the mother and child should be instructed to clean the vulva completely and not to leave the vulval skin wet, as this damp warm environment is an ideal culture surface for bacteria that cause vulvovaginitis. The mother must also be informed that vulval hygiene through daily washing should be performed, but that the soap should be gentle and not scented. Excessive washing of the vulva must be avoided as this leads to recurrent exfoliation and vulval dermatitis. During acute attacks of non-specific recurrent vulvovaginitis, children often complain of burning during micturition due to the passage of urine across the inflamed vulva. The use of barrier creams in these circumstances may be very useful. There is no evidence that topical oestrogen and antibiotic creams are of any benefit and should not be prescribed.

Foreign body

Foreign bodies are occasionally found in the vagina and may lead to vaginal discharge. In patients who have persistent vaginal discharge despite treatment, an ultrasound scan may detect a foreign body or, if a history of a foreign body is forthcoming, it is probably best to carry out an examination under anaesthetic and remove any foreign body at that time.

Vaginal bleeding

Vaginal bleeding in childhood is extremely rare and should always be treated with suspicion. The causes of genital bleeding in childhood include a vaginal foreign body, trauma, a neoplasm, premature menarche or urethral prolapse and the diagnosis can almost always be made on clinical inspection. Treatment should be appropriate but if trauma is suspected, sexual abuse must always be considered with referral to the appropriate team.

Labial adhesions

Labial adhesions are usually an innocent finding and a trivial problem, but its importance is that it is frequently misdiagnosed as congenital absence of the vagina. They occur most frequently in children aged between 3 months and 3 years, with a prevalence of about 3%. The physical signs of labial adhesions are easily recognized. It is believed that labial adhesions result from vulvar inflammation in a hypo-oestrogenic environment. The labia minora stick together in the midline, usually from posterior to anterior until only a small opening is left through which urine is passed. Similar adhesions sometimes bind down the clitoris. It may be difficult to distinguish the opening at all. The vulva has the appearance of being flat, and there are no normal tissues beyond the clitoris evident. However, a translucent, dark, vertical line in the midline where the adhesions are thinnest can usually be seen, and these appearances are quite different from congenital absence of the vagina. There are usually no symptoms associated with this condition, although older children may complain that there is some spraying when they pass urine. As late childhood ensues and ovarian activity begins, there is spontaneous resolution of the problem in 80% of children. In the majority of cases no treatment is required and the parents should be reassured that their daughters are entirely normal. In those children in whom there are some clinical problems, local oestrogen cream can be applied for about 2 weeks. There is complete resolution of the labial adhesions in 90% of cases. In the case of failure of oestrogen treatment, topical betamethasone 0.05% may be used and success in this group is about 70%. In the small minority of unresolved cases, surgical separation may be needed but this is extremely rare and should be avoided if possible as recurrence rates are high. Application of a bland barrier cream at this stage may help to prevent further adhesion formation. Finally, in taking a history it is important to establish that there has not been any trauma to the vulva, as very rarely labial adhesions may be the result of sexual abuse.

Summary box 39.2

- Labial adhesions are frequently misdiagnosed as congenital abnormalities.
- Treatment is advice about vulval hygiene.
- Topical oestrogen may be required.

Adolescence

The adolescent gynaecological patient usually presents with one of three disorders: (i) problems associated with the menstrual cycle and menstrual dysfunction, (ii) primary amenorrhoea (see Chapter 38); and (iii) teenage hirsutism.

Menstrual problems

As can be seen in the description of puberty (Chapter 38), menstrual cycles are rarely established as normal ovulatory cycles from the beginning of puberty. It is usual for cycles to be irregular and bleeding sometimes prolonged initially, and it can take some girls several years to achieve a regular menstrual cycle. It is extremely important that the gynaecologist understands this phenomenon, as the management of these cases is usually not active treatment but support and explanation to the mother and daughter.

Heavy menstruation

Trying to establish a history of heavy menstrual bleeding can be challenging in this age group. The patients have little experience and may well not understand normality. Expectation from maternal influence is also a contributory factor and so efforts should be made to interview the daughter alone if possible. Normal menstrual loss should not exceed 80 mL during a period, although in 5% of individuals it is heavier than this and causes no trouble. Getting some idea from frequency of pad change or bleeding in excess of 7 days is helpful. If a history of prolonged bleeding during surgical or dental procedures is obtained, screening for a coagulopathy is appropriate. Some reports suggest that 2–33% of these patients will have an underlying bleeding disorder [1].

The clinician is faced with attempting to assess whether the child truly has menstrual loss that is medically serious or menstrual loss that is irritating and distressing without being medically harmful. The best way to establish which of these is the case is by measuring the haemoglobin. If the haemoglobin level is normal (i.e. >120 g/L), then an explanation should be given to the mother and child of the normal physiology of menstrual establishment, that the manifestation of the menstrual loss is normal and that it may take some time for the cycle to be established. This condition requires no active treatment. However, it is imperative that the child is followed up at 6-monthly intervals until the pattern of menstruation is established, as reassurance is the most important part of the management process of these girls.

In those girls with haemoglobin levels between 100 and 120 g/L, menstrual loss is significantly more than normal. Again, an explanation is required so that the mother and daughter understand the cause of the problem and the child should be administered iron therapy to correct what will be mild iron deficiency anaemia. In terms of management, menstrual loss needs to be reduced and this may be achieved by using either progestogens cyclically for 21 days in every 28-day cycle or the combined oral contraceptive pill. It would be unusual for either of these therapies to be unsuccessful in controlling the menstrual loss. If these therapies are used, they should be stopped on an annual basis so that assessment may be made about whether or not the normal pattern of menstruation has been established by maturation of the hypothalamic–pituitary–ovarian axis. Thereafter, the child requires no further medication. Again, follow-up is essential if reassurance is to be given appropriately.

Finally, in the child with a haemoglobin of less than 100 g/L, it is obvious that serious anaemia has resulted from menstrual loss. This again requires an explanation but more urgent attention from a medical point of view. Blood transfusion should be given if clinically indicated. Progestogens are very much less likely to be effective in this group and the oral contraceptive pill is by far the treatment of choice. It may be given continuously for a short period of time so that the anaemia can be corrected using oral iron and then the pill may be used in the normal way so that menstrual loss occurs monthly, if desired.

Any girl who continues to have menstrual loss which is reported to be uncontrolled by these management strategies should have an ultrasound scan performed to exclude uterine pathology.

Menstrual suppression

Some girls will require menstrual suppression as a means of controlling their blood loss whilst hypothalamic maturity is attained. The most widely used is depot medroxyprogesterone acetate administered every 12 weeks. Amenorrhoea rates of 60% at 1 year and 70% at 2 years can be achieved. The newer alternative is the levonorgestrel intrauterine system which has similar rates of amenorrhoea. It requires a skilled physician to fit and in some cases this may require sedation. The newer, smaller device is not recommended, as amenorrhoea rates at 1 year are at best 12%. Oral progestogens are seldom used for long-term use and have significantly higher side-effect rates. Progesterone-only pills and etonorgestrel implants are not used, as menstrual suppression is not reliably achieved. The combined oral contraceptive pill is also used and the 30-μg pills are best. Continuous use can achieve amenorrhoea rates of 30–50%, although breakthrough bleeding is a common problem.

Summary box 39.3

- Menstrual disorders in adolescents are usually a reflection of normal physiology.
- Treatment should only be instigated if the adolescent is found to be anaemic.
- Treatments should be as simple as possible.

Primary dysmenorrhoea

Primary dysmenorrhoea is defined as pain which begins in association with menstrual bleeding. The management of dysmenorrhoea in the teenager is no different from that in the adult (see Chapter 34). The use of both non-steroidal anti-inflammatory drugs and the oral contraceptive pill is pertinent in teenagers, but again failure of these medications to control dysmenorrhoea should alert the clinician to the possibility of uterine anomaly and ultrasound imaging of the uterus should be performed to establish whether an anomaly exists.

Premenstrual syndrome

This is a difficult problem in adolescence as the psychological changes that are occurring during this time in a woman's life are often complex and stressful. It has been established that premenstrual syndrome is a stress-related disorder. Therefore in teenage girls undergoing puberty the stresses and emotional turbulence associated with this may, not surprisingly, lead to premenstrual problems. These are very difficult to manage and are usually not medically treated but addressed through the help of psychologists, if reassurance from the gynaecologist and an understanding of the process to the mother is not successful.

Hirsutism

Hair follicles cover the entire body and different types of hair are found in different sites. Androgens affect some

areas of the human body and increase hair growth rate and also the thickness of terminal hairs. Androgens are also involved in sebum production and may cause this to be excessive. In some women excessive hair growth may occur on the arms, legs, abdomen, breasts and back such that it constitutes the problem of hirsutism. This may also be associated with acne, which may occur not only on the face but also on the chest and back.

Differential diagnosis

Four major groups of disorders may cause hirsutism in adolescence (Table 39.2). Androgenic causes include congenital adrenal hyperplasia and its late-onset variant and also androgen-secreting tumours. The commonest group constitutes women with polycystic ovarian syndrome and while this is sometimes a difficult diagnosis to make in adolescents, it constitutes by far the greatest problem group. The diagnosis of XY gonadal dysgenesis is something that should be borne in mind when considering a child with hirsutism but a large percentage of patients have idiopathic hirsutism. It is important to remember that some girls will have a constitutional basis for their hirsutism and familial body hair patterns should be borne in mind when considering whether a young patient does in fact have hirsutism. Treatment for hirsutism is the same as in the adult and is covered in Chapter 47. In adolescence the mainstay in the treatment of androgen excess has been the oral contraceptive pill and without doubt this remains the main form of therapy. As the majority of these girls have some ovarian dysfunction, be that polycystic ovarian syndrome or an undefined problem, suppression of ovarian activity is very effective at lowering circulating androgens. If this is insufficient to gain control of hair growth, then the use of cyproterone acetate or spironolactone may be considered.

Table 39.2 Causes of hirsutism in adolescents.

Androgenic causes
Congenital adrenal hyperplasia
Classic
Late onset
Androgen-secreting tumours
Polycystic ovarian syndrome
Idiopathic
XY gonadal dysgenesis

In those patients who are not considered to have hirsutism due to a medical disorder, drug therapies may be ineffective and supportive measures may be necessary for cosmetic benefit. These include hair removal by shaving, waxing or electrolysis of those areas which are particularly cosmetically sensitive and also the use of bleaches to change hair colour, thereby gaining cosmetic benefit.

Summary box 39.4

- Hirsutism in adolescents is often idiopathic or cultural.
- Treatment, as in the adult, is by cosmetic means or endocrine manipulation.

Early Pregnancy Problems

40

Spontaneous Miscarriage

Christine I. Ekechi and Catriona M. Stalder

Queen Charlotte's and Chelsea Hospital, Imperial College Healthcare NHS Trust, London, UK

Spontaneous miscarriage is responsible for considerable emotional and psychological trauma for patients. Recognizing and addressing this issue allows doctors to improve patient care. In the UK this has led to the development of early pregnancy units providing dedicated care for these women. These units also improve clinical care from a diagnostic and management standpoint.

In the UK, early pregnancy complications rarely result in maternal death. The triennial report (2005–2007) reported one maternal death from spontaneous miscarriage, although there were 18 direct deaths from maternal sepsis including deaths in early pregnancy [1].

With the advent of commercially available, sensitive and affordable pregnancy tests, women present at increasingly earlier points in pregnancy looking for reassurance and confirmation of viability. It is important that while their anxiety is recognized, we proceed along safe and accepted diagnostic pathways to avoid misdiagnosis. It is also important to recognize that pregnancy is a dynamic process and that a diagnosis of viability early on in the first trimester does not necessarily signify that the pregnancy will continue, although if a fetal heart pulsation is detected at 6 weeks, there is a 90% chance that the pregnancy will continue beyond the first trimester [2].

The rate of miscarriage varies depending on the gestation of pregnancy and maternal age (Fig. 40.1). Up to 50% of early pregnancies will fail within 4 weeks from the last menstrual period (LMP), so-called biochemical pregnancies. By 6 weeks' gestation, the rate is one in five pregnancies and by the second trimester that has fallen to 1 in 40 [3]. Simple scoring systems and models exist that can help advise women on the likely viability of their pregnancy using both clinical and ultrasound information [4].

Definition

Spontaneous miscarriage is defined as the spontaneous loss of a pregnancy prior to viability, taken legally in the UK as 23 weeks and 6 days of gestation. Beyond this gestation, fetal demise is classified as a stillbirth. The majority of first-trimester miscarriages occur below 12 weeks' gestation with an overall rate of around 20%. Second-trimester miscarriages are less common, accounting for 1–4% of all miscarriages [5]. While some second-trimester miscarriages can be explained as first-trimester losses where the diagnosis is only made in the second trimester, it seems likely that the causes are different.

Terminology has moved away from the word 'abortion', which is firmly associated with therapeutic abortion among the general public. The importance of accurately defining the different types of miscarriage is that it provides the bedrock upon which comparative research can be built, to better understand the relative benefits and outcomes of treatment options (Table 40.1).

The definitions can be seen to be a mixture of clinical and ultrasound-based diagnoses and are often suggested prospectively and confirmed retrospectively. Care must be taken when relying solely on a clinical diagnosis because this is often refuted by ultrasound. For example, in cases where the clinical picture suggests complete miscarriage, there will be ultrasound evidence of retained products in 45% of patients [6].

Aetiology

Although the causes of miscarriage in the first and second trimester appear different, there is inevitably some overlap, in addition to the occasional situation where

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

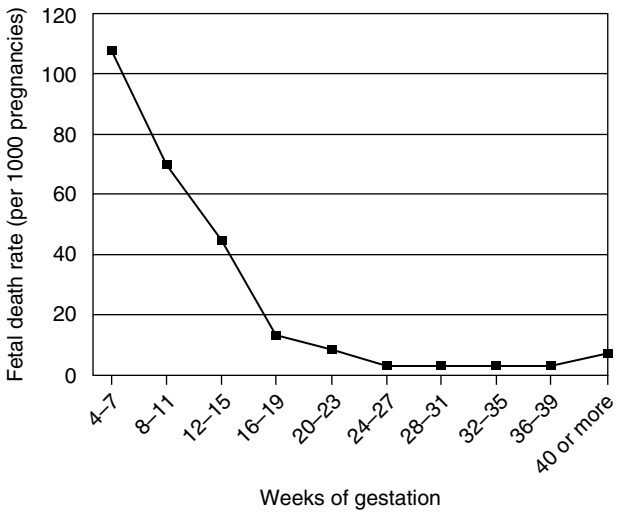

Fig. 40.1 Estimated rates of fetal mortality by weeks of gestation [1].

diagnosis of a first-trimester miscarriage is delayed until the second trimester.

First-trimester miscarriage

Evidence suggests that a significant proportion of miscarriages result from chromosomal and genetic abnormalities. It is likely that abnormal implantation has a role to play in some cases and this is an area of current research. It is thought that up to 95% of chromosomally abnormal embryos result in miscarriage [7]. The following chromosomal abnormalities are associated with miscarriage.

- Trisomies: 68%, mainly trisomy 16, 21 and 22.
- Triploidy: 17.1%.
- Monosomy: 9.8% (XO Turner's syndrome).

Other causes implicated in first-trimester miscarriage include the following.

- Maternal disease: antiphospholipid syndrome, diabetes, thyroid disease.
- Drugs: methotrexate, some antiepileptic drugs.

Table 40.1 Definitions of terms in common usage.

Term	Definition
Threatened miscarriage	Vaginal bleeding in the presence of a viable pregnancy
Inevitable miscarriage	Vaginal bleeding in the presence of an open cervical os and pregnancy-associated tissue still present*
Incomplete miscarriage	Vaginal bleeding that is ongoing where pregnancy tissue has already been passed but ultrasound suggests the presence of further tissue within the uterine cavity
Complete miscarriage	Clinical definition: cessation of bleeding and a closed cervix following miscarriage Ultrasound definition: an empty uterus with a falling hCG where an intrauterine pregnancy was previously confirmed
Missed miscarriage/early fetal demise	Miscarriage occurring in the absence of symptoms or minimal symptoms, where the empty gestation sac or non-viable embryo is still visible within the uterus
Recurrent miscarriage	Three or more consecutive early pregnancy losses
Biochemical pregnancy loss	Pregnancy not located on scan where there is/has been a positive pregnancy test which subsequently becomes negative
Empty sac	A gestation sac with absent or minimal structures
Pregnancy of unknown location (PUL)	Positive pregnancy test where the location of the pregnancy is not currently identifiable using transvaginal ultrasonography†
Pregnancy of unknown viability (PUV)	The presence of intrauterine structures confirming the location of the pregnancy, but where no embryo heartbeat has been seen to confirm its viability. By definition the measurements of the embryo or gestation sac do not meet the criteria for the diagnosis of a missed miscarriage. In this circumstance a repeat scan at an interval is required to confirm viability (see section on ultrasound diagnosis)

*Extreme caution needs to be taken before making this diagnosis as it can be easy to mistake a parous os (external os open as a result of previous vaginal delivery) and the open cervix of inevitable miscarriage. It is a term probably best avoided.
†This is an ultrasound-based classification and not a diagnosis in itself. Further investigations may reveal an intrauterine pregnancy, an ectopic pregnancy or a miscarriage.

- Uterine abnormalities: the role of fibroids is uncertain but they may be implicated [5].
- Infection: varicella, rubella and other viral illnesses.

Second-trimester miscarriage

- Cervix: cervical injury from surgery, cone biopsy and large loop excision of the transformation zone [8].
- Infection: may occur with or without ruptured membranes. May be local to the genital tract or systemic.
- Thrombophilias.
- Uterine abnormalities: submucous fibroids and congenital distortion of the cavity (uterine septa) may be implicated.
- Chromosomal abnormalities: these too may not become apparent until the second trimester.

Summary box 40.1

It is important to recognize that pregnancy is a dynamic process and although at any point viability of a pregnancy can be confirmed, it does not necessarily imply that the pregnancy will continue.

Diagnosis

Diagnosis is based on appropriate history-taking, examination and suitably directed diagnostic tests.History-taking

- LMP: remember to confirm length of cycle, regularity, use of contraception around time of conception, any of which can alter the presumed timing of ovulation (assumed as 15 days after LMP for the purpose of calculating gestation) and hence result in overestimation or underestimation of gestational age.
- Symptoms: pain and/or bleeding. It used to be taught that the presentation of one before the other helped differentiate between ectopic and intrauterine pregnancy but it is clear that this is not the case. The location and nature of the pain is also a poor prognostic indicator. Urinary frequency or diarrhoea can be subtle signs of peritoneal irritation due to intraperitoneal bleeding, associated with ectopic pregnancy.
- Past obstetric and gynaecological history may provide evidence for risk factors for other non-pregnancy related causes of bleeding or indicate risk factors for ectopic pregnancy such as sexually transmitted infection or pelvic inflammatory disease. It is important to ascertain the last smear date and any history of cervical abnormality/colposcopic treatment.
- Past medical history: poorly controlled diabetes mellitus is known to be associated with miscarriage and other chronic illnesses may also be implicated, although these tend to be associated with reduced fertility (capacity to conceive) rather than fecundity (capacity to maintain a pregnancy).
- Medication: prescribed, non-prescribed and recreational.

Examination

General examination to assess the immediate well-being of the patient is mandatory. Young women can mask blood loss and significant decompensation is a late sign and therefore attention should be given to more than just blood pressure, for example tachycardia and/or a raised respiratory rate. Pallor, a reduced conscious level or reduced capillary return are all important. It is useful to note that peritoneal distension may also result in bradycardia.

Abdominal palpation

- Determine the fundal height: the uterus generally becomes palpable above the pelvic brim at 12 weeks' gestation, though this will be affected by multiple pregnancy and the presence of uterine fibroids.
- Evidence of other pelvic masses which may explain the presence of pain, for example ovarian torsion, degenerating fibroids.
- Evidence of intra-abdominal bleeding: generalized tender distension of the abdomen.
- Confirm location of pain.

Vaginal examination

Vaginal examination will reveal whether the cervix is open or if products of conception are identifiable at the cervical os. If so, the relevant tissue should be removed and sent for histopathological diagnosis, as on rare occasions a decidual cast (in the presence of an ectopic pregnancy) can mimic products of conception. Products of conception cannot be confirmed on macroscopic inspection unless fetal parts are seen. Where there is a history of complete miscarriage, 45% of patients will show ultrasound evidence of retained products and up to 6% will have an ectopic pregnancy [9].

Speculum examination of the vagina is also a good opportunity to inspect the cervix and vagina to exclude local causes of blood loss in addition to the quantity of loss at presentation, as patient description can be misleading.

Differential diagnosis (Table 40.2)

Hydatidiform mole is a relatively rare but important complication of pregnancy which should be considered

Table 40.2 Differential diagnosis.

	Uterine size*	Cervix	Blood loss	Pain
Threatened miscarriage	Equivalent to dates	Closed	Any	Variable
Incomplete miscarriage	Smaller than dates	Open	Usually heavy	Present
Complete miscarriage	Smaller than dates	Closed	Previously heavy, now settling	Previously present, now absent
Missed miscarriage	Variable	Closed	Variable	Variable

*Remember that the presence of fibroids may give a distorted assessment of uterine size or large body habitus may make this difficult to accurately assess.

in all cases of miscarriage and, where possible, tissue sent for histological confirmation of products of conception and appropriate follow-up arranged. It is clear, however, that in the presence of spontaneous miscarriage at home that this is not possible. It is likely that in these cases, where there is clinically significant molar change, women will present with ongoing bleeding and the diagnosis considered at this stage. There is no evidence that delay in the diagnosis of molar pregnancy increases the likelihood of molar invasion.

Diagnostic tools

Ultrasound

Ultrasound has progressed enormously since its first use in pregnancy in 1967. It has a pivotal role in the diagnosis of miscarriage. Transvaginal ultrasound has helped identify the early ultrasonographic features seen in a normal early intrauterine pregnancy (Fig. 40.2). The ultrasound landmarks visible on transvaginal scan are as follows.

- Week 5: visible gestation sac.
- Week 6: visible yolk sac.
- Week 6: visible embryo.
- Week 7: visible amnion.

Fig. 40.2 A viable fetus of 7 weeks' gestation with amniotic sac clearly visible.

Failure to identify these landmarks at the presumed gestational age may not necessarily indicate a miscarriage. Dating in early pregnancy is taken from the first day of the LMP and conception presumed to have taken place on day 15. Clearly this leaves a large window for inaccuracy due to varying cycle lengths, delayed ovulation, variability in the ovulation–implantation window and inaccurate recall of menstrual dates.

In the current climate of sensitive urinary pregnancy tests where women are presenting at increasingly earlier gestations with the expectation of reassurance of a viable intrauterine pregnancy, it is imperative that care is given to obtain the correct diagnosis. In these scenarios it may be a number of weeks before a viable pregnancy can be visualized due to natural variation in the appearance of structures and the inevitable uncertainty that surrounds dating.

In 2011, new research demonstrated that previously used criteria for the ultrasound diagnosis of missed miscarriage were unsafe, resulting in an unacceptably high false-positive rate. This implied that a number of pregnancies were being incorrectly diagnosed as missed miscarriages with the potential for the termination of wanted intrauterine pregnancies [10]. Following this, a conference of the Society of Radiologists in Ultrasound in the USA resulted in a consensus paper in the *New England Journal of Medicine* [11] that proposed sensible guidelines for the diagnosis of pregnancy failure based on the 2011 paper by Abdallah *et al.* [10].

Subsequently, the UK National Institute for Health and Care Excellence (NICE) [12], the Royal College of Obstetricians and Gynaecologists (RCOG) [13] and the American College of Radiology [14] have all changed their ultrasound criteria for the diagnosis of miscarriage, which are now based on:

- an empty gestational sac of mean sac diameter (MSD) ≥25 mm; *or*
- an embryo with a crown–rump length (CRL) ≥7 mm and no heartbeat (Fig. 40.3).

Where neither of these criteria has been satisfied on the initial ultrasound scan, the pregnancy should be

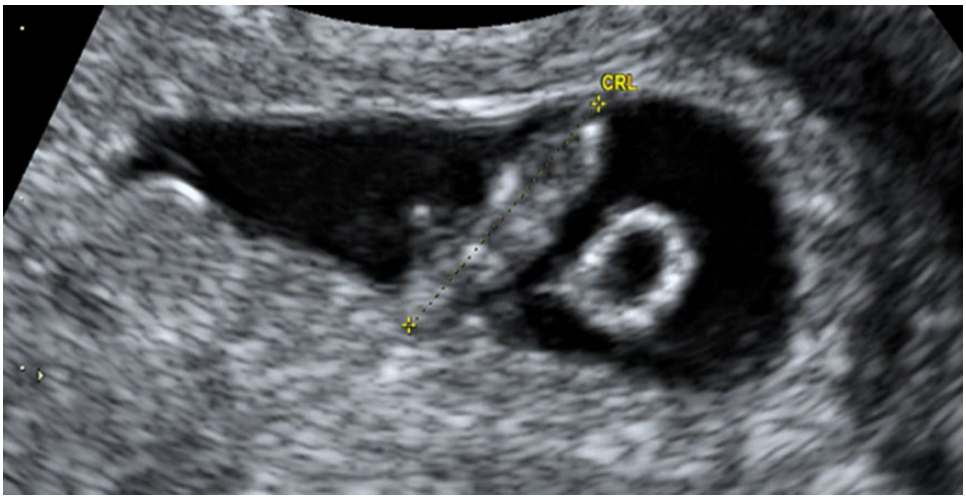

Fig. 40.3 Ultrasound diagnosis of miscarriage must be based on either a mean sac diameter of ≥ 25mm or an embryo with crown-rump length (CRL) of ≥ 7mm.

classified as a pregnancy of unknown viability (PUV) and an ultrasound scan then performed at an interval in order to definitively comment on viability. When considering the optimal interval between ultrasound scans for the diagnosis of miscarriage to be made with certainty, in the study by Preisler *et al.* [15] a minimal time interval of 7 days was 100% specific for miscarriage where the initial scan identified a pregnancy with an embryo of less than 7 mm with no heart activity or a pregnancy with no embryo and an empty gestational sac with an MSD of 12 mm or more.

Where the initial scan identified an empty gestational sac with an MSD of less than 12 mm, a minimal time interval of 14 days was 100% specific for miscarriage if sac size had not doubled. Although the data for these criteria were scanty, this paper also showed that initial scans demonstrating an embryo with a CRL of 3 mm or more with no heartbeat or an MSD of 18 mm or more at 70 days (10 weeks) or older of gestational age was very highly predictive of a missed miscarriage. This has been suggested as a possible new additional criterion to the guidelines for the definitive diagnosis of missed miscarriage [15].

Summary box 40.2

New ultrasound criteria for the diagnosis of miscarriage on initial scan

- An empty gestational sac of MSD ≥25 mm, *or*
- An embryo with a CRL ≥7 mm and no heartbeat.

These findings should be confirmed with a second opinion or repeat scan performed 7 days after the initial scan.

Where scan measurements lie close to the cut-off points, it is prudent to err on the side of caution as there is evidence of significant intra- and inter-observer error even in the case of experienced sonographers [16].

Serum β-human chorionic gonadotrophin

There is little evidence to support the role of β-human chorionic gonadotrophin (β-hCG) in determining viability after the visualization of an intrauterine gestation sac and yolk sac, as considerable variation exists in the normal increase in β-hCG and occasionally falls are identified in the presence of subsequently viable pregnancy. Furthermore, the effect of twin pregnancy on the rise in β-hCG is uncertain. However, serum measurements of β-hCG do have a role in managing pregnancy of unknown location (PUL): a rise of 66% over 48 hours is associated with a viable intrauterine pregnancy; levels between a 65% increase and a 13% decrease are associated with a possible ectopic pregnancy; and a decrease of more than 13% is associated with a failing pregnancy [17]. Furthermore, it is important to recognize that tests are rarely exactly 48 hours apart due to timing of presentation and this will determine interpretation as well. Mathematical prediction models have also been developed that assign PUL as either a high or low risk of complications [18].

Progesterone

The main role of progesterone lies in the assistance it provides in determining the likely outcome of PUL rather than in diagnosing miscarriage. A meta-analysis of cohort studies into the accuracy of single progesterone measurement to predict early pregnancy outcome in symptomatic women revealed that a progesterone level

equal to or below 10 ng/mL predicted a non-viable pregnancy in 96.8% of cases [19].

Management

Management options fall into three groups, medical, surgical or expectant. Factors to be taken into account when discussing these options with patients include the following.

- Type of miscarriage.
- Gestation at which miscarriage is diagnosed: care needs to be taken where miscarriage is diagnosed at later gestations. At 11 weeks and above where there is a missed miscarriage and an embryo measuring significantly less than expected, these patients are at risk of heavier bleeding compared with earlier gestations and should be warned of such. Surgical evacuation may be preferable as the first line of treatment. If the preference is for medical evacuation, then this may be more appropriately carried out in an inpatient setting.
- Facilities available at individual units: out-of-hours access to emergency care and advice in case of heavy bleeding with medical or expectant management; capacity of units to offer inpatient medical management.
- Medical history, for example cardiac disease and sickle cell anaemia. The risks are increased in the presence of haemorrhage and so generally among these patients, surgical evacuation, being associated with less blood loss, is the most appropriate choice. The same applies if there is evidence of infection.
- Patient choice.
- Cost.
- NICE guidance [20].

Expectant management

Historically, women have been offered surgical management as the mainstay of miscarriage treatment. However, the recognition of potentially serious risks associated with curettage has resulted in a move away from intervention and a wider choice of options being offered to women. Up to 85% of miscarriages will resolve spontaneously within 3 weeks of the diagnosis. The rate of success in part depends on the length of delay in intervention. There is also debate as to how to confirm the diagnosis of complete miscarriage, whether by ultrasound or symptoms. It seems likely that the best course to take involves both rather than relying solely on a defined thickness of endometrium. Furthermore, the regularity and vascularity of the contents of the endometrial cavity are probably more important than the thickness alone. Again, the lack of agreement in defining completeness of a miscarriage hampers efforts to assess effectiveness of treatment options.

Patient satisfaction with expectant management depends on appropriate patient selection (earlier gestation/singleton pregnancy/social circumstances) and counselling. Patients should be made aware of what to anticipate (pain and bleeding) and given advice regarding analgesia and what to do with the tissue passed. The advice should be backed up with written information and contact details in case of concern or complications. The recent NICE guidance advocates that all women should be offered expectant management as first line unless there are extenuating circumstances. However, this has been criticized as reducing patient choice [21] and most clinicians would take the view that when the clinical circumstances permit, the management will largely be a matter of patient preference.

Surgical management

Surgical management involves evacuation of the uterus by dilation and suction curettage. 'Surgical management of miscarriage' or SMM is the term in general usage in the UK, having replaced 'evacuation of retained products of conception'. The procedure can be performed under general or local anaesthesia depending on local experience. Cervical dilation can be assisted by cervical priming with prostaglandin or misoprostol a minimum of 1 hour prior to the procedure and is strongly recommended where the woman has not had a previous vaginal delivery [1]. This is believed to reduce the pressure required to dilate the cervix and hence risk of failure of the procedure, retained products and uterine perforation. Curettage is usually safe but it is important to counsel women about the associated risks. These include the risk of general anaesthesia (if relevant), the risk of infection or retained products (3–5%) and the potential bleeding in association with this, and the 0.5% risk of uterine perforation which could lead to other organ damage and the need to progress to laparoscopy or laparotomy in those circumstances. Patients should be reassured that in the presence of a uterine perforation and the absence of additional complications, the implications for future fertility are negligible. Asherman's syndrome, where intrauterine synechiae develop and interfere with conception, used to be said to arise from over-vigorous curettage. However, there is little supporting evidence for this. Manual vacuum aspiration is an alternative option for surgical management of miscarriage. The procedure uses a vacuum aspirator to gently empty the contents of the uterus, using local anaesthesia. Used frequently in developing settings, it has started to gain favour universally for the management of retained products, where patients wish to avoid

the risks associated with medical management and a general anaesthetic.

Medical management

Medical management of miscarriage involves using uterotonic therapy alone or in conjunction with anti-hormone therapy to achieve evacuation of the uterine cavity.

Available uterotonic agents include gemeprost and misoprostol, which are both prostaglandin (PG)E_1 analogues. Gemeprost is licensed for use in the management of uterine evacuation. It requires refrigeration and is more expensive than misoprostol. Misoprostol is not licensed for use, can be stored at room temperature and costs significantly less. It can also be given orally as well as per vagina or rectum. Side effects include nausea, vomiting and diarrhoea, which can be problematic. PGE_1 analogues can be used in conjunction with anti-hormone therapy. Mifepristone, an anti-progesterone, was previously used to sensitize the uterus to the effects of uterotonics and improve complete evacuation rates, but recent NICE guidance does not support its use [20]. There is no evidence to support the use of other uterotonics such as ergometrine, oxytocin or other prostaglandins in this situation.

Overall, the success rate of medical management (72–93%) is similar to that of expectant management (75–85%) [22] but medical management has the advantage that patients can control the course of events by timing medication to allow miscarriage to take place. However, these success rates are dependent on how much time has elapsed following treatment: the longer the wait, the higher the success rate.

When compared with surgical management, there is significantly more associated blood loss but no increased requirement for blood transfusion [23,24]. Reassuringly, differing rates of infection between the three options are not statistically significant.

Summary box 40.3

- Expectant, medical and surgical management of miscarriage are all viable options for the management of first-trimester miscarriage and choice should be based on patient wishes as well as the clinical situation.
- The incidence of infection is not significantly higher in any management group.
- Blood loss is heaviest in medical and expectant management compared with surgical, though with no increased risk of blood transfusion, and this should be taken into account when counselling certain groups, for example patients with sickle cell anaemia, in whom blood loss should be kept to a minimum.

Rhesus status

Despite the absence of antigens on the surface of embryonic red blood cells until 12 weeks' gestation, there is concern regarding the possibility of sensitization of rhesus-negative women from early pregnancy events. Current guidelines from the British Blood Transfusion Society and the RCOG are quoted here.

Spontaneous miscarriage

Anti-D immunoglobulin should be given to all non-sensitized RhD-negative women who have a spontaneous miscarriage after 12 weeks of pregnancy. Published data on which to base recommendations in earlier miscarriages are scant. There is evidence that significant fetomaternal haemorrhage only occurs after curettage to remove products of conception but does not occur after complete spontaneous miscarriage [25,26]. Anti-D immunoglobulin should therefore be given when there has been an intervention to evacuate the uterus. On the other hand, the risk of immunization by spontaneous miscarriage before 12 weeks' gestation is negligible when there has been no instrumentation to evacuate the products of conception and anti-D immunoglobulin is not required in these circumstances. Anti-D immunoglobulin is also recommended in cases of ectopic or molar pregnancies and in cases of uterine bleeding where this is repeated, heavy or associated with abdominal pain.

NICE guidance recommends anti-D prophylaxis of 250 IU for women with early pregnancy loss undergoing surgical procedures. It recommends that women should not be offered prophylaxis for:

- medical management for ectopic pregnancy or miscarriage;
- threatened miscarriage;
- complete miscarriage;
- PUL.

There is no need to perform a Kleihauer test to assess the volume of fetomaternal haemorrhage prior to prophylaxis.

Threatened miscarriage

Anti-D immunoglobulin should be given to all non-sensitized RhD-negative women with a threatened miscarriage after 12 weeks of pregnancy. Where bleeding continues intermittently after 12 weeks' gestation, anti-D immunoglobulin should be given at 6-weekly intervals. Evidence that women are sensitized after uterine bleeding in the first 12 weeks of pregnancy where the fetus is viable and the pregnancy continues is scant [27], although there are very rare examples. Against this background,

routine administration of anti-D immunoglobulin cannot be recommended. However, it may be prudent to administer anti-D immunoglobulin where bleeding is heavy or repeated or where there is associated abdominal pain, particularly if these events occur as gestation approaches 12 weeks.

It is recommended that a Kleihauer test be performed to assess the quantity of fetomaternal haemorrhage after 20 weeks.

Summary box 40.4

Anti-D immunoglobulin is required in the following circumstances for non-sensitized RhD-negative women.

- Spontaneous miscarriage at 12 weeks' gestation and beyond.
- Miscarriage at any gestation where there has been surgical intervention or, if spontaneous, where the bleeding has been heavy or repeated.
- Threatened miscarriage at 12 weeks and beyond. If repeat episodes, repeat anti-D at 6-week intervals.

Psychology and counselling

Pregnancy loss at any gestation is an emotional time for women and it is important that counselling reflects that. Recent data have confirmed high levels of depression and anxiety in women following a miscarriage or ectopic pregnancy. It has also shown that a significant proportion (28%) of women 3 months after such an event screened positive for post-traumatic stress disorder [28]. The language used should be sensitive, avoiding terms such as pregnancy failure or abortion, which in layman's terms implies therapeutic abortion and has no place in the terminology relating to miscarriage. Where possible, all information given should be supported by written material as, again, it is recognized that while as doctors we believe our counselling to have been comprehensive, in reality a distressed patient may absorb very little. It is quite possible that any information given will need to be repeated before it is fully understood. Early pregnancy services should allow for the provision of counselling and psychological treatment when required.

Conclusion

Miscarriage is unfortunately a frequent outcome of pregnancy. Guidelines have been refined to ensure that the use of ultrasound to make a diagnosis of miscarriage based on measurements of the gestation sac or embryo are safe. Patient management should be focused on making the experience as bearable as possible by taking time to explain and discuss options, thus allowing patients to feel supported and in control. Within the framework described, patients should be allowed to make choices best suited to them. Information should be reinforced with a written explanation for patients to read, using a format that is easy to understand. Psychological sequelae to miscarriage are not uncommon and clinicians should be alert to the fact that depression, anxiety and post-traumatic stress disorder may occur in these women.

Recurrent Miscarriage

D. Keith Edmonds[1,2]

[1] *Imperial College London, London, UK*
[2] *Queen Charlotte's and Chelsea Hospital, London, UK*

Definition

Recurrent miscarriage has several definitions. The Royal College of Obstetricians and Gynaecologists (RCOG) defines recurrent miscarriage as the loss of three or more consecutive pregnancies before viability [1]. The term therefore includes all pregnancy losses from the time of conception until 24 weeks of gestation. However, advances in neonatal care have resulted in a small number of babies surviving birth before 24 weeks of gestation. Hence some late second-trimester miscarriages can also be considered as extreme preterm labour. At the other end of the spectrum is the issue of biochemical pregnancy losses. The European Society of Human Reproduction and Embryology defines biochemical losses as a transient positive pregnancy test without ultrasonic visualization of the pregnancy [2]. Miscarriage can be further classified, on ultrasound findings, into loss of an empty gestation sac (loss of pregnancy before 10 weeks' gestation) or loss of fetus (loss of a pregnancy after visualization of fetal heart activity) [2] (Table 41.1).

Despite attempts at standardization of definitions, some investigators consider two consecutive losses as a recurrent miscarriage, as two losses have been found to increase the chance of a subsequent pregnancy ending in miscarriage [3].

Epidemiology

Approximately 15% of all pregnancies that can be visualized on ultrasound end in pregnancy loss [4]. Three or more losses affect 1–2% of women of reproductive age and two or more losses affect around 5% [4]. Despite extensive investigation of women with three or more miscarriages, the cause of recurrent pregnancy loss remains unknown in the majority of cases [5].

Advancing maternal age is associated with miscarriage. Age-related miscarriage rates are as follows: 12–19 years, 13%; 20–24 years, 11%; 25–29 years, 12%; 30–34 years, 15%; 35–39 years, 25%; 40–44 years, 51%; and 45 or more years, 93% [6]. This is because with increasing maternal age there is a decline in both the number and quality of the remaining oocytes. Paternal age over 40 also increases the risk.

An increasing number of previous miscarriages also adversely affects the risk of future miscarriage [5]. A history of a live birth followed by consecutive miscarriages does not reduce the risk of further miscarriage substantially [5]. Being both underweight and obese has been associated with recurrent miscarriage [7]. A body mass index (BMI) over 30 kg/m^2 is an independent variable with significant increase in miscarriage risk (odds ratio of 1.7–3.5).

Summary box 41.1

- Recurrent miscarriage is defined as three consecutive pregnancy losses.
- Miscarriages should be further classified on the basis of ultrasound findings into biochemical, empty gestation sac, fetal or second trimester.
- In women with recurrent miscarriage, poor prognostic factors for further miscarriage include number of previous losses, maternal age and obesity.

Other associated factors and their management

Factors that have been associated with early recurrent miscarriage include parental and fetal chromosomal abnormalities [8,9], structural uterine abnormalities [10],

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 41.1 Classification of miscarriage.

Type of miscarriage	Gestation range (weeks)	Fetal heart activity	Ultrasound findings
First trimester			
Biochemical	0–6	Never	Not visualized
Empty gestation sac	4–10	Never	Empty gestation sac or large sac with minimal structures without fetal heart activity
Fetal	6–12	Lost	Crown–rump length and fetal heart activity previously identified
Second trimester	12–24	Lost	Fetus identified of size equivalent to 12–24 weeks' gestation

antiphospholipid syndrome [11], some thrombophilias [12], autoimmune disease, and endocrinological disorders such as polycystic ovarian syndrome and untreated diabetes [13]. It is important to realize that many of these associations are weak and there are only a very few published observational studies that give prognostic implications for positive tests for conditions associated with recurrent miscarriage. Hence the evidence that many of the associated factors are causative is poor. There are even fewer high-quality, large-scale, randomized controlled trials showing that a treatment for women with recurrent miscarriage is effective at preventing a subsequent miscarriage. Ideally, evaluation of a couple with recurrent miscarriage would achieve the aim of guiding management options by finding contributory factors to the pregnancy losses, providing prognostic value in the subsequent pregnancy and directing treatment of proven benefit to improve live birth rates. This ideal has not been achieved by current research.

Structural genetic factors

Fetal chromosomal abnormality

Chromosomal abnormality in the miscarried pregnancy is the most common cause of early pregnancy loss, especially in older women. This accounts for up to 70% of early pregnancy losses, falling to only 20% when the pregnancy loss is between 13 and 20 weeks' gestation [8]. Defects are commonly trisomy, polyploidy or monosomy. Ideally, products of conception should be sent for karyotyping, as an abnormal fetal karyotype is diagnostic for the cause of miscarriage and is an important prognostic factor, suggesting a successful outcome of more than 75% in the next pregnancy [8]. However, this investigation is not perceived to be cost-effective.

Parental chromosomal abnormalities

Parental chromosomal abnormalities are found in about 2% of women with recurrent pregnancy loss, with the most common being a balanced reciprocal translocation [14]. Couples with balanced translocations are at risk of conceiving future children with unbalanced translocations. However, a large case series of couples with recurrent miscarriage and balanced translocation have found the risk of unbalanced translocation in offspring to be less than 1% [15]. This 1% miscarriage rate is close to the miscarriage rate of normal pregnancies after invasive prenatal diagnosis. Observational studies of couples with recurrent miscarriage and balanced translocations have found live birth rates of over 70% in the subsequent pregnancy [15]. This 70% live birth rate is similar to that in couples with recurrent miscarriage without chromosomal abnormalities [4]. Thus, the cost-effectiveness of investigating parental karyotype has been questioned [14]. If balanced translocation is detected, supportive care with the option of invasive prenatal diagnosis is appropriate [1]. A significant number of candidate genes have been studied to try to demonstrate a genetic basis for recurrent miscarriage but no conclusive results have emerged [16].

There was hope that pre-implantation genetic diagnosis (PGD) and assisted reproductive techniques (ART) would improve the live birth rate for women with recurrent miscarriage and balanced translocations. However, in practice PGD-ART has a series of disadvantages. Not all the cells in a four- or eight-cell embryo are genetically identical, so PGD is not a reliable measure of the pregnancy karyotype. The pregnancy rate and live birth rate from PGD-ART is lower than from natural conception [17]. Furthermore, natural conception involves the selection of normal oocytes, then the selection of normal pregnancy, allowing genetically abnormal pregnancies to miscarry. These natural selection steps are circumvented in PGD-ART, creating large numbers of abnormal embryos. Consideration can be

given to PGD where women have subfertility and recurrent miscarriage and a balanced translocation, as observational studies show that PGD-ART has better pregnancy outcomes, despite lower rates of embryo transfer and shorter time to a successful pregnancy [17]. However, a recent study comparing natural conception and PGD-ART in patients with a balanced translocation failed to demonstrate improved live birth rates [18].

Summary box 41.2

- Recurrent miscarriage is associated with parental balanced translocations.
- In the presence of a balanced translocation, couples still have a 70% live birth rate in a subsequent pregnancy.
- Only 1% of offspring from couples with balanced translocations have unbalanced translocations.
- Parental karyotyping is no longer thought to be cost-effective.

Anatomical factors

Congenital uterine anomaly

The prevalence of congenital uterine anomaly, such as septated, bicornuate or arcuate uterus, in the general population is about 6.7% but approximately 16.7% in women with recurrent miscarriage [10], though a direct causative link is uncertain due to the vast difference in criteria and techniques for diagnosing abnormal uterine morphology. Advances in hysteroscopic surgery mean that these malformations can be corrected using a resectoscope. Observational studies suggest that surgery (hysteroscopic metroplasty) may improve pregnancy outcome [19,20] and a recent prospective case-controlled study demonstrated improved live birth outcome in resected septated uteri but not bicornuate uteri [21]. However, there have been no randomized controlled trials of this treatment so efficacy of intrauterine surgery has yet to be demonstrated [19].

Cervical weakness

Cervical weakness is a recognized contributing factor to second-trimester loss. There is no satisfactory objective test of cervical weakness as the diagnosis is a clinical one. Treatment with cervical cerclage is associated with potential hazards related to the surgery and the risk of stimulating uterine contractions and hence should only be considered in women who are likely to benefit [1]. Cervical cerclage is discussed in more detail in Chapter 28.

Acquired uterine anomaly

Acquired uterine abnormalities such as fibroids or intrauterine adhesions (Asherman's syndrome) have also been associated with recurrent miscarriage (Fig. 41.1). In a study by Saravelos *et al.* [22], the incidence of fibroids in recurrent miscarriage was 8.2% and women with intra-cavitary distortion, whose fibroids were resected, significantly reduced their mid-trimester miscarriage rate (21% to 0%). However, women with fibroids not distorting the cavity behaved similarly to women with unexplained recurrent miscarriage, with 70% birth rates in both groups. There are very few studies of any beneficial intervention for Asherman's syndrome [23].

Summary box 41.3

- Recurrent miscarriage is associated with uterine structural abnormalities.
- Observational studies suggest that hysteroscopic surgery is effective for septate uteri.
- Hysteroscopic surgery is effective in reducing mid-trimester loss if fibroids are distorting the uterine cavity.

Fig. 41.1 Submucous fibroid projecting significantly into the endometrial cavity.

Prothrombotic factors

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) has a prevalence of 15% in women with first-trimester recurrent miscarriage and this, as well as a single second-trimester miscarriage, is one of the clinical components for diagnosis of the syndrome [24]. Treatment options including low-dose aspirin (LDA), heparin, prednisolone and intravenous immunoglobulin (IVIG) have been investigated. A systematic review showed that prednisolone and IVIG do not improve pregnancy outcomes and are associated with increased risk of diabetes and premature birth [25]. Current RCOG guidance [1] suggests that patients with APS should be treated with LDA and low-molecular-weight heparin but there is a lack of evidence to support this. A Cochrane systematic review in 2014 concluded that there was no evidence of a beneficial effect [26] and a similar conclusion was reached in a Bayesian network meta-analysis [27]. Currently, a randomized controlled trial (ALIFE2) is ongoing in an attempt to finally clarify this issue.

Thrombophilia

Some thrombophilias, such as factor V Leiden mutation, activated protein C resistance, prothrombin gene G20210A mutation and protein S deficiency, have been significantly associated with recurrent miscarriage [12]. However, there is still controversy about the prognostic implications of positive tests. A full thrombophilia screen can produce abnormal results in 20% of women with uncomplicated obstetric histories. Thus it is uncertain if all women with early recurrent miscarriage should be screened for thrombophilia [28]. Treatment with LDA with or without low-molecular-weight heparin has been proposed as thromboprophylaxis to prevent putative placental infarcts or vascular thrombosis. Small initial studies suggest there may be beneficial effects with thromboprophylaxis in terms of improved live birth rates [29,30]. However, more recently, high-quality large randomized controlled trials have failed to substantiate an improvement in live birth rate in women with either idiopathic or thrombophilia-associated recurrent miscarriage [31–34]. Thus, there is no evidence to support the use of LDA and heparin in the treatment of these women with recurrent miscarriage.However, thromboprophylaxis to prevent maternal thrombosis does need to be considered in women with multiple risk factors for this.

Summary box 41.4

- Recurrent miscarriage is associated with thrombophilia.
- In the presence of APS, aspirin and heparin are not thought to be effective treatments.
- In the absence of APS, neither aspirin and heparin nor aspirin alone have been found to prevent miscarriage.

Endocrinological factors

Polycystic ovarian syndrome

There is an association between polycystic ovarian syndrome and recurrent miscarriage. The possible mechanisms for this are hyperandrogenism and insulin resistance [35]. However, the variation in criteria for diagnosing polycystic ovarian syndrome makes it difficult to assess the importance and the prognostic value of detecting it. Nevertheless, a simple, safe and cheap way to reduce pregnancy loss in obese women with polycystic ovarian syndrome is weight loss [36]. Small studies suggest there may be a role for metformin in reducing miscarriage rates, especially in the presence of an abnormal glucose tolerance test, and metformin is now regarded as having low risks in pregnancy [35,37]. There are no randomized controlled trials to support this approach however. A randomized controlled trial in infertile women indicated that clomifene is superior to metformin in achieving live births but made no difference to the rates of miscarriage [38].

Abnormalities of glucose metabolism and thyroid disorders

It is known that well-controlled thyroid disorders and diabetes are not risk factors for recurrent miscarriage. Thus national guidelines do not recommend routine screening in the absence of symptoms [1,28].

Immunological factors

Immunological mechanisms are thought to play a part in the success of pregnancy where the maternal immune system interacts with the allogeneically dissimilar embryo.

Antithyroid antibodies

The presence of antithyroid antibodies has been associated with a higher pregnancy loss rate, the underlying mechanisms of which are either autoimmune or mild

thyroid insufficiency [13,39]. A small study suggested that women with recurrent miscarriage and antithyroid antibodies but normal thyroid function tests may benefit from levothyroxine treatment [40] but further large-scale trials are needed to substantiate this finding.

Natural killer cells

Another immunological factor of interest involves the natural killer (NK) cells that can be found in the peripheral blood or endometrium. Both peripheral and uterine NK cells have been associated with recurrent miscarriage [41,42]. However, there is still considerable controversy regarding the exact role and function of NK cells in recurrent miscarriage and the prognostic value of increased numbers or function of these cells is uncertain [43]. A systematic review of 20 trials of various immunotherapies, such as paternal cell immunization, third-party-donor-cell immunization, trophoblast membrane infusion and intravenous immune globulin, showed no significant beneficial effect over placebo in improving live birth rates [44,45].

Endometrial factors

It is long been suggested that defective implantation my contribute to recurrent early pregnancy loss. However, evidence for this has been lacking until recently. There is now evolving evidence that endometrial stem cells are depleted in cases of recurrent miscarriage, predisposing to pregnancy failure [46,47]. Early work on the role of chronic endometritis and recurrent miscarriage has suggested improved live birth rates in treated cases [48]. Further larger studies are needed to verify these findings.

Idiopathic recurrent miscarriage

Tender loving care

Women with recurrent miscarriage are anxious and appreciate reassurance when they fall pregnant again. Three-quarters of these women with idiopathic recurrent miscarriage will achieve a live birth in the subsequent pregnancy, with tender loving care involving regular reassurance scans and psychological support in a dedicated early pregnancy assessment unit [5,49].

Aspirin

Empirical use of aspirin is common. However, a recent systematic review showed no evidence of an improvement in live birth rates in women with recurrent miscarriage [50] and in a randomized controlled trial there was a trend towards aspirin increasing the chance of miscarriage [32].

Progesterone

Progesterone is needed for successful early pregnancy and thus a lack of progesterone could be surmised to lead to pregnancy loss. A recent randomized, double-blind, placebo-controlled trial (PROMISE) has established that there is no evidence that first-trimester progesterone therapy improves outcomes for women with unexplained recurrent miscarriage [51].

Human chorionic gonadotrophin

Suggestions that the use of human chorionic gonadotrophin in the first trimester might help salvage failing pregnancies by stimulating progesterone production by the corpus luteum would seem to be unlikely based on the PROMISE trial outcome and a recent meta-analysis confirmed the lack of evidence [52].

Conclusions

The management of recurrent miscarriage is challenging because of lack of evidence-based effective treatments. Couples with recurrent miscarriage can be offered investigations but the majority will be negative. Supportive care has been shown to be beneficial. Empirical treatment in women with idiopathic recurrent miscarriage should be avoided and entry into high-quality and methodologically sound trials should be considered whenever possible in order to improve the evidence base for this distressing condition.

Gestational Trophoblast Neoplasia

Michael J. Seckl

Department of Surgery and Cancer, Charing Cross Hospital, Campus of Imperial College London, London, UK

Gestational trophoblast neoplasms (GTNs) arise from the cells of conception and form a range of related conditions, from the generally benign partial hydatidiform mole through to the aggressive malignancies of choriocarcinoma and rare placental site trophoblast tumour (PSTT) and epithelioid trophoblastic tumour (ETT) [1]. The combination of this unique biology, relative rarity and effective therapies makes GTNs an extremely interesting and important area of gynaecological and oncological care.

Despite the rarity of these illnesses, patients with molar pregnancies requiring additional treatment after evacuation can expect successful treatment outcomes, with overall cure rates for GTNs approaching 100% [2]. For patients with choriocarcinoma and PSTT/ETT, using the treatments that have been established for over 25 years, the majority of patients can also be treated with a high expectation of cure with minimal long-term toxicity [3,4].

Despite this major progress, developments in management of trophoblast disease are still required to help further reduce toxicity, eliminate remaining deaths and refine diagnostic tools. For over 40 years the UK has had centralized registration of all cases, and human chorionic gonadotrophin (hCG) hormone monitoring, pathology review and management has been essential in achieving the best outcomes for patients. This chapter is based on the experience from the UK's and the world's largest trophoblast tumour centre at Charing Cross Hospital in London.

Classification, demographics and risk factors

The World Health Organization classification of GTNs divides trophoblast tumours into premalignant partial and complete hydatidiform moles and the malignant diagnoses of invasive mole, choriocarcinoma and PSTT/ETT. More recently, we have recognized a new potential premalignant member of the gestational trophoblastic disease (GTD) spectrum known as atypical placental site nodules [5].

The reported incidence of molar pregnancies in Europe and North America is on the order of 0.2–1.5 per 1000 live births [1] and a recent study from the UK has indicated an overall incidence of one molar pregnancy per 591 viable conceptions for the period 2000–2009 [6]. Overall, partial molar pregnancies are slightly more common than complete moles, with an approximate ratio of 60 : 40 in the UK series. Similar data have been reported from other European countries where whole-population analyses are possible [7]. Whilst there are some modest variations in the incidence of molar pregnancies based on race and geography, there are two clearly documented risk factors for an increased risk of molar pregnancy: the extremes of maternal age and a previous molar pregnancy [8,9].

The relative risk for molar pregnancies is highest at the extremes of the reproductive age group. The results from the recent England and Wales analysis, summarized in Table 42.1, indicate that there is a modest increased risk for younger teenagers, a relatively level risk for women aged 16–45 and then increasing risks after the age of 45 and particularly for those over the age of 50. Of interest, the risk of partial molar pregnancy remains relatively unchanged across the age group, with most of the change in overall risk due to an increased incidence of complete molar pregnancies. In the 18–40 age group, complete moles make up about 40% of all molar pregnancies, but in the 45+ age group they account for over 90% of cases [6,8]. Interestingly, most of the risk for a second molar pregnancy resides in complete rather than partial moles and the risk of three consecutive molar pregnancies is almost exclusively for

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 42.1 Risk of molar pregnancy compared with the number of viable conceptions at varying maternal ages in England and Wales.

Age	Per cent partial moles of viable conceptions	Per cent complete moles of viable conceptions	Overall risk of molar pregnancy
13	0.08	0.32	1 in 250
14	0.07	0.20	1 in 370
15	0.04	0.21	1 in 400
20	0.05	0.06	1 in 909
25	0.09	0.06	1 in 666
30	0.11	0.05	1 in 625
35	0.11	0.05	1 in 625
40	0.18	0.09	1 in 370
45	0.29	0.75	1 in 96
50+	0.59	16.2	1 in 6

complete moles [9]. The latter should raise the possibility of a rare genetic variant known as familial recurrent hydatidiform mole (FRHM) syndrome (discussed in a subsequent section).

Premalignant pathology and presentation

Partial mole

The genetic origins of complete and partial molar pregnancies are demonstrated in Fig. 42.1. Partial moles are triploid with 69 chromosomes comprising two sets of paternal and one set of maternal chromosomes. Macroscopically and on ultrasound scanning during the first trimester, partial mole will often resemble normal products of conception. The embryo can appear viable on an early ultrasound scan but becomes non-viable by week 10–12. The histology of partial mole shows less swelling of the chorionic villi than in a complete mole and there may be only focal changes. As a result the diagnosis of partial mole can often be missed after a miscarriage or evacuation, unless the products are sent for expert pathological review.

The clinical presentation of partial mole is most frequently via a failed pregnancy rather than irregular bleeding or by detection on routine ultrasound. The obstetric management is by suction evacuation and histological review; all patients with partial mole should be followed up by registration and serial hCG measurement.

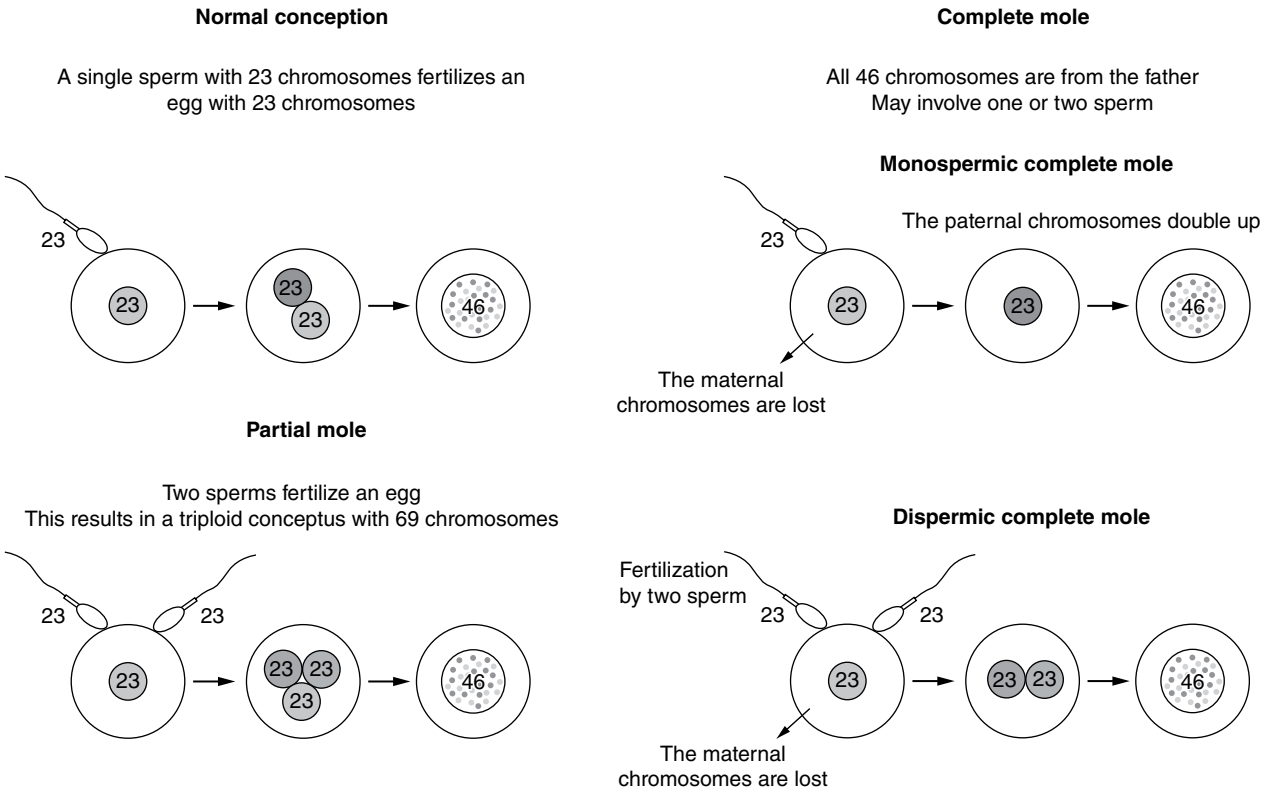

Fig. 42.1 Genetic origin and structure of a normal conception, partial mole and complete molar pregnancy.

Fortunately, partial mole rarely transforms into malignant disease, and there is an overall risk of 0.5–1% of patients requiring chemotherapy after a partial mole [10].

Complete mole

In complete moles the genetic material is totally male in origin (Fig. 42.1), resulting from the fertilization of an 'empty' anucleate oocyte lacking maternal DNA. The chromosome complement is most commonly 46XX, which results from one X chromosome-carrying sperm that duplicates its DNA, or less frequently 46XY or 46XX from the presence of two separate sperm [1].

The clinical diagnosis of complete mole most often occurs as a result of first-trimester bleeding or an abnormal ultrasound. There is no fetal material and the histology shows the characteristic oedematous villous stroma. The textbook 'bunch of grapes' appearance is only seen in the second trimester and as most cases are diagnosed earlier, this is now rarely observed in UK practice. The typical macroscopic appearances of a complete mole are shown in Fig. 42.2. Obstetric management is by suction evacuation followed by registration and serial hCG measurement. Complete molar pregnancies have an appreciable risk of proceeding to invasive disease, with approximately 15% of patients with complete mole requiring chemotherapy.

Familial recurrent hydatidiform mole syndrome

Occasionally we see patients who have repetitive complete molar pregnancies and who have failed to conceive a normal baby. Patients who have had three consecutive complete moles should be genetically tested to determine whether they have FRHM syndrome where the DNA is biparental in origin rather than androgenetic [11]. Thus far, mutations in two genes have been associated with this autosomal recessive condition, *NLRP7* [12] and *KHD3CL* [13], that account for about 75% and 5–10% of cases respectively, so additional gene(s) remain to be discovered [14]. Affected women have rarely been reported to achieve a normal pregnancy, with most just suffering repeated complete moles or pregnancy losses where no pathology is available. Unfortunately, the risk of subsequent malignancy requiring chemotherapy is the same for these patients as for those with androgenetic complete moles. Therefore recommending repeated rounds of attempted natural conception does not seem appropriate. As these genes are normally expressed in both the egg and the genital tract/uterus, the question then arises as to whether the recurrent moles are due to a defective egg or a problem with uterine implantation. To help resolve this, one affected patient agreed to try egg donation from an unaffected relative and this resulted in a normal pregnancy [15]; since then, several other women with FRHM have similarly had normal babies.

Fig. 42.2 Macroscopic appearance of a complete molar pregnancy from early in the second trimester.

Twin pregnancies

The risk of having a twin pregnancy comprising a complete mole and healthy co-twin is estimated to be 1–5 per 100 000 [16,17]. These pregnancies cause considerable anxiety for both the patient and managing clinicians as there is a perception that they are likely to be associated with an increased risk of serious and potentially life-threatening complications for the mother, including haemorrhage, uterine perforation, pre-eclampsia, toxaemia and malignant change in the mole requiring chemotherapy. In addition, it was thought that the possibility of carrying the healthy co-twin to viability or term was remote. These concerns were underpinned by several small case series based on local hospital reports [17] and so suffered from case ascertainment bias. We examined this issue in a UK population-based series of 77 women that was the largest of its kind and which was not subject to case ascertainment bias. To our surprise, we discovered that the risk of malignancy was not increased by allowing such pregnancies to continue, a fact that we subsequently substantiated in singleton molar pregnancies evacuated in the second and third rather than first trimester [18]. Moreover, nearly 40% of them resulted in a healthy take-home baby with most of the rest undergoing spontaneous loss from presumed continued molar growth. Importantly, there was only a small increased risk in pre-eclampsia that could be safely managed and no cases of uterine perforation or maternal death [17].

Since then a further 90 patients have been offered the choice of early termination versus continuing their pregnancies. This has confirmed our earlier findings, with no maternal losses and no increased risk of malignancy by allowing the pregnancy to continue. Moreover, the healthy take-home baby rate has risen to just under 60% (unpublished observations). The mode of delivery has been a mixture of normal vaginal and caesarean section depending on local assessment of what was considered the safest option. Therefore, after appropriate counselling, it seems reasonable to allow women to continue such pregnancies but under close monitoring to ensure that potential complications are detected early and dealt with promptly.

Atypical placental site nodules

Following a normal pregnancy, placental remnants in the uterine wall usually spontaneously regress and disappear. Occasionally, they may persist and form placental site nodules. These may present with irregular bleeding that often results in dilation and curettage. The subsequent pathology reveals the placental site nodule material. This has always been regarded as a benign condition. However, recent data suggest that some placental site nodules may have atypical histopathological features and, if so, can in 10–15% of cases be associated with or subsequently develop into either a PSTT or ETT [5]. Consequently, patients found to have placental site nodules where there may be atypical features are now having their pathology reviewed centrally in the UK. If atypical placental site nodule is confirmed, then these patients are registered and seen centrally for monitoring. If the nodule is thought to be typical, then at present local MRI pelvis imaging is suggested and if this is normal no further monitoring is currently undertaken. However, as we learn more it is likely that the advice will change.

Registration and surveillance

Overall, 90% of patients with molar pregnancies will not need any additional treatment following their evacuation. In these patients the residual trophoblast tissue cells fail to proliferate and as the cells stop growing, hCG levels return to normal. At present there is no effective prognostic method that allows accurate distinction between the patients who will develop malignant disease after evacuation and the majority who will not [19]. As a result all patients with molar pregnancy should be registered for an hCG follow-up system. The use of this approach allows the early identification of patients whose disease is continuing to proliferate, while also allowing careful observation of patients with more slowly falling hCG levels, so minimizing unnecessary chemotherapy.

Table 42.2 The indications used at Charing Cross Hospital for initiating chemotherapy treatment in patients with gestational trophoblast tumours.

Rising hCG in two or plateaued in three consecutive serum samples
Raised hCG level 6 months after evacuation (even if falling)
Histological evidence of choriocarcinoma
Metastases to the brain, liver, gastrointestinal tract, spleen, kidneys or other solid organs
hCG >20 000 IU/L more than 4 weeks after evacuation
Heavy vaginal bleeding or gastrointestinal/intraperitoneal bleeding
Lung or vaginal metastases >2 cm

hCG, human chorionic gonadotrophin.

Patients taking part in an hCG surveillance programme usually have the need for additional treatment determined by the pattern of their hCG results. Thus, an hCG level that has plateaued or is rising following evacuation of a molar pregnancy is the commonest indication of malignant change requiring chemotherapy. Table 42.2 shows the Charing Cross Hospital recommended indications for treatment. The first four of these are also used by the International Federation of Gynecology and Obstetrics (FIGO) [2]. However, based on our recent work, the second indication has been dropped because nearly all women with a falling but elevated hCG 6 months after evacuation will normalize hCG levels spontaneously without chemotherapy [20]. The last three indications are UK-specific reasons for commencing treatment. Typically, about 1–2% of patients start therapy because of excessive bleeding requiring transfusion even if hCG is falling because the treatment helps to settle the bleeding. An hCG concentration above 20 000 IU/L 4 weeks after uterine evacuation is associated with a high risk of developing malignant change that requires chemotherapy and with a small risk of uterine perforation and accounts for probably another 1–2% of patients who require chemotherapy in the UK. The presence of more than 2 cm lung and/or vaginal metastases as a sole indication for treatment has not been seen for over 25 years, likely because of improved early diagnosis within the first trimester and better surveillance. Those patients recovering from molar pregnancy enrolled in the surveillance service and who go on to require treatment have a cure rate approaching 100% [21], and over 95% will initially fall into the low-risk treatment group.

Malignant pathology and presentation

Invasive mole (chorioadenoma destruens)

Invasive mole nearly always arises from a complete mole and is characterized by invasion of malignant cells into the

myometrium, which can lead to perforation of the uterus. Microscopically, invasive mole has a similar histological appearance to complete mole but is characterized by the ability to invade into the myometrium and local structures if untreated. Fortunately, the incidence of invasive mole in the UK has fallen substantially with the introduction of routine ultrasonography, the early evacuation of complete moles and effective hCG surveillance, and is now rare.

Choriocarcinoma

Choriocarcinoma is histologically and clinically overtly malignant and presents the most frequent emergency medical problems in the management of trophoblast disease. The diagnosis often follows a complete mole, when the patients are usually in a surveillance programme, but can also arise after any other type of pregnancy including a partial mole, a non-molar abortion, miscarriage, ectopic or term pregnancy. The clinical presentation of choriocarcinoma can be due to local disease in the uterus leading to bleeding in two-thirds of cases, or from distant metastases that can cause a wide variety of symptoms, with the lungs, central nervous system (CNS) and liver the most frequent sites of distant disease. About one-third of patients will have no obvious residual abnormality within the uterus [1].

The cases of choriocarcinoma presenting with symptoms from distant metastases can be diagnostically challenging [22]. However, the combination of the gynaecological history and elevated serum hCG usually makes the diagnosis clear and so avoids biopsy, which can be hazardous due to the risk of severe haemorrhage, as demonstrated following a liver biopsy (Fig. 42.3). On the occasions when choriocarcinoma pathology is available, the characteristic findings show the structure of the villous trophoblast but sheets of syncytiotrophoblast or cytotrophoblast cells, haemorrhage, necrosis and intravascular growth are common [1]. The genetic profile of choriocarcinoma can reflect its origin from a complete or partial mole [10] or a normal diploid conception combined with a range of gross abnormalities without any specific characteristic patterns [23]. Some cases will prove to be non-gestational choriocarcinomas that pathologically are identical to gestational choriocarcinomas but are in fact germ cell or epthelial tumours that have trophoblastic differentiation and genetically originate from the patient. These tumours may initially respond well to combination agent chemotherapy used to treat gestational trophoblastic tumours but then revert to their true phenotype, and if epithelial in origin do badly [3].

Fig 42.3 CT scan of the abdomen in a patient with choriocarcinoma demonstrating multiple liver metastases and a large subcapsular haematoma secondary to a core biopsy.

Placental site trophoblast tumour and epithelioid trophoblastic tumour

PSTT was originally described in 1976 [6] and is the rarest form of GTD, accounting for 0.2% of all registered cases of GTD in the UK [4]. ETT is an even rarer variant first described in 1998 [24] and although it is thought to behave in a similar fashion to PSTT, in reality we are still learning about the similarities and differences of these two entities [2]. PSTT/ETT most commonly follows a normal pregnancy but can also occur after a non-molar abortion or a molar pregnancy.

In contrast to the more common types of trophoblast disease, which characteristically present fairly soon after the index pregnancy, in PSTT the average interval between the prior pregnancy and presentation is 3.4 years. The most frequent presentations are amenorrhoea or abnormal bleeding. In nearly all cases the serum hCG level is elevated, but is characteristically lower for the volume of disease than in the other GTNs. The tumour can arise after any type of pregnancy including complete and partial moles [25] and is believed to be derived from the non-villous trophoblast. The pathology is characterized by intermediate trophoblastic cells with vacuolated cytoplasm, the expression of placental alkaline phosphatase and hCG, and the absence of cytotrophoblast and villi. ETT develops from the chorionic-type intermediate trophoblast present in other parts of the placenta such as the chorionic plate and fetal membranes. Pathologically, ETT is distinguished from PSTT by its smaller cells, its smaller, more monomorphic cells and by its nested, nodular, well-circumscribed growth pattern unlike the sheet-like infiltrative pattern seen with PSTT [26]. In addition, clinically, ETT tends to secrete even less hCG than PSTT. The clinical presentation of PSTT/ETT can range from slow-growing disease limited to the uterus to metastatic disease, with lung and liver the most common sites of distant spread [7]. Spread to lymphatics is a bit more

common in PSTT/ETT compared with choriocarcinoma where it is exceptionally rare [4].

Role of hCG in trophoblast disease diagnosis and management

Produced predominantly by syncytiotrophoblast cells, hCG is a glycosylated heterodimer protein consisting of α and β units held together by non-covalent bonds. In malignant disease a number of hCG variants can occur, including hyperglycosylated hCG, nicked hCG, hCG missing the β subunit C-terminal peptide and the free β subunit [1]. With the potential exception of a few atypical cases of PSTT/ETT, hCG is constitutively expressed by all forms of premalignant and malignant GTD.

The measurement of hCG allows estimation of tumour bulk, forms an important part of the assessment of the patient's disease risk and provides a simple method to follow the response to treatment. The hCG level can be measured by a variety of immunoassays but at present there is no internationally standardized assay and the various commercially available kits used in different hospitals can vary in their ability to detect different forms of partially degraded hCG molecules and so can give divergent results and occasional false negatives [27]. It is also important to be aware that patients with exceptionally high hCG levels may produce a false-negative result through the high-dose 'hook' effect. Moreover, any assay might produce a false-positive hCG value. Consequently, if the clinical situation does not correspond with an elevated hCG value, then another hCG assay should be employed and/or the hCG should be checked in the urine. This is because heterophilic antibodies, which are the commonest cause of false-positive hCG values by occasionally allowing two independent assays to report positively, are too large (unlike hCG) to pass into the urine [1]. In the UK we are very fortunate to have an hCG assay that detects all forms of hCG produced in cancer and because of the way it is configured is highly unlikely to suffer false-positive results.

In the absence of tumour hCG production, the serum half-life of hCG is 24–36 hours; however, for patients receiving chemotherapy, total hCG levels characteristically show slower rates of fall as the tumour cells continue to produce some hCG as their number decreases with treatment.

Prognostic factors and treatment groups

Data from the early days of successful chemotherapy treatment for trophoblast disease show clearly that there is a relationship between the level of elevation of hCG at presentation, the presence of distant metastases and the reducing chances of cure with single-agent chemotherapy. This relationship and the impact on treatment choice and cure rate were first codified by the Bagshawe scoring system published in 1976 [28]. Subsequently, there have been a number of revisions and parallel systems introduced that are broadly similar to this original. Table 42.3 shows the revised 2000 FIGO prognostic score. From assessment of these parameters, an estimate of the risk category can be obtained and patients offered initial treatment either with single-agent chemotherapy if their score is 6 or less or multiagent combination chemotherapy for scores of 7 and over [29].

Low-risk disease management

In the UK, over 90% women with molar pregnancies who require additional treatment following their initial evacuation fall into the low-risk treatment category as defined by the FIGO prognostic scoring system. The role of

Table 42.3 International Federation of Gynecology and Obstetrics (FIGO) prognostic scoring system employed for assessing the intensity of the initial chemotherapy treatment.

Scores*	0	1	2	4
Age (years)	<40	≥40	–	–
Antecedent pregnancy	Mole	Abortion	Term	–
Months from index pregnancy	<4	4–6	7–13	≥13

Largest tumour size	<3 cm	3–5 cm	≥5 cm	–
Site of metastases	Lung	Spleen, kidney	Gastrointestinal	Brain, liver
Number of metastases	–	1–4	5–8	>8
Previous chemotherapy	–	–	Single agent	Two or more drugs

* Scoring is done using data obtained within 24 hours prior to starting chemotherapy.

repeated uterine evacuation in the management of these patients has been a subject of uncertainty until recently. A number of studies looking at the impact of repeated evacuation in women with rising or static hCG levels following their first evacuation have suggested that a repeated procedure is rarely curative [30,31]. Based on these data, the current recommendation is that a repeated evacuation should only be considered if the hCG level is under 5000 IU/L and tissue is seen in the uterine cavity on ultrasound.

For patients meeting the FIGO standard for low-risk treatment, the most widely used protocol is methotrexate given intramuscularly with oral folinic acid rescue following the schedule shown in Table 42.4. The first course of treatment should be administered in hospital with the subsequent courses administered at home. This is because they have a higher risk of bleeding as therapy starts, particularly if the tumour shrinks rapidly with the initial chemotherapy. Bleeding usually responds well to strict bed rest and less than 1% of low-risk patients require emergency interventions such as embolization, vaginal packing or hysterectomy.

Table 42.4 The low-risk methotrexate and folinic acid chemotherapy treatment schedule.

Day 1	Methotrexate 50 mg i.m. at noon
Day 2	Folinic acid 15 mg p.o. at 6 p.m.
Day 3	Methotrexate 50 mg i.m. at noon
Day 4	Folinic acid 15 mg p.o. at 6 p.m.
Day 5	Methotrexate 50 mg i.m. at noon
Day 6	Folinic acid 15 mg p.o. at 6 p.m.
Day 7	Methotrexate 50 mg i.m. at noon
Day 8	Folinic acid 15 mg p.o. at 6 p.m.

The low-risk chemotherapy treatment is usually well tolerated without much major toxicity. Methotrexate does not cause alopecia or significant nausea and myelosuppression is extremely rare. Of the side effects that do occur, the most frequent problems, occurring in about 2–3% of cases, are mucositis, a gritty feeling in the eyes and, more rarely, pleuritic chest or abdominal pains from serositis. Mild elevation of liver function tests can occur but rarely prevents ongoing therapy. For low-risk patients with lung metastases visible on their chest radiographs, the policy at Charing Cross Hospital is to perform MRI of the head and if normal to add CNS prophylaxis with intrathecal methotrexate administration to minimize the risk of development of CNS disease. A maximum of three doses of intrathecal methotrexate is given unless the cerebrospinal fluid to serum hCG ratio exceeds 1 : 60 [1].

Treatment is continued until normalization of the serum hCG level (0–4 IU/L) and then a further three cycles (6 weeks) to ensure eradication of any residual disease that is below the level of serological detection. In the Netherlands, the policy had been to only give two cycles of consolidation therapy after normalization of the hCG and their relapse rate was double that of the UK so the Dutch have recently modified their policy to emulate the UK [32]. A typical example of the treatment graph for a patient successfully completing methotrexate chemotherapy is shown in Fig. 42.4.

An overview of the data for the 1990s indicates that 67% of patients in the low-risk group will only require treatment with the methotrexate protocol to successfully complete

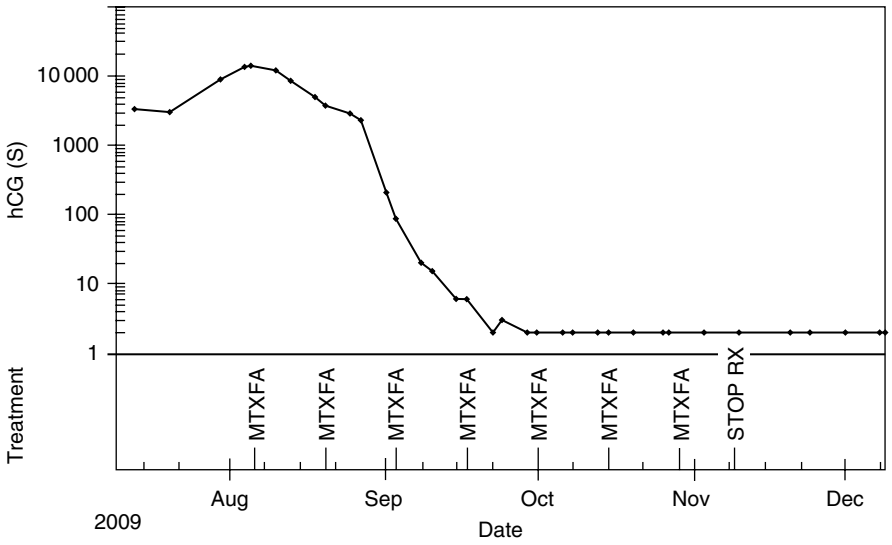

Fig. 42.4 Treatment and human chorionic gonadotrophin (hCG) graph of a low-risk patient with a gestational trophoblast tumour, successfully treated with methotrexate (MTX) and folinic acid (FA) chemotherapy.

their therapy. Patients who have an inadequate response to methotrexate therapy, as shown by an hCG plateau or rise, have their treatment changed to second-line therapy. This comprises single-agent actinomycin D (1.25 mg/m^2 i.v. repeated every 2 weeks) which, like methotrexate, is relatively less toxic than the alternative etoposide, methotrexate, actinomycin D, cyclophosphamide and vincristine (EMA/CO) combination chemotherapy (Table 42.5). To minimize the number of patients proceeding to EMA/CO we have increased the hCG cut-off at the point of methotrexate resistance from 100 to 300 IU/L, and since this resulted in equally good results [21,33] we are now testing an hCG cut-off of 1000 IU/L.This means that only patients with an hCG above 1000 IU/L at the point of methotrexate resistance proceed to EMA/CO whilst the rest receive a trial of single-agent actinomycin D.

An individual example of the pattern of hCG levels during the course of management is shown in Fig. 42.5.

Table 42.5 EMA/CO chemotherapy.

Week 1	
Day 1	Actinomycin D 0.5 mg i.v. Etoposide 100 mg/m^2 i.v. Methotrexate 300 mg/m^2 i.v.
Day 2	Actinomycin D 0.5 mg i.v. Etoposide 100 mg/m^2 i.v. Folinic acid 15 mg p.o. 12-hourly × 4 doses Starting 24 hours after commencing methotrexate
Week 2	
Day 8	Vincristine 1.4 mg/m^2 (maximum 2 mg) Cyclophosphamide 600 mg/m^2

This demonstrates the rise in hCG that led to the introduction of methotrexate chemotherapy; following this, the hCG initially falls but after two cycles appears to plateau. The introduction of second-line treatment with EMA/CO chemotherapy leads to a rapid fall in hCG to normal and the completion of chemotherapy after 6 weeks of further treatment. Overall the survival in this group is currently running at 100% and the sequential introduction of additional chemotherapy as necessary minimizes the potential long-term carcinogenic risks of excess treatment.

High-risk disease management

Historical data from treatment prior to the introduction of multiagent chemotherapy demonstrated that less than one-third of high-risk patients would be cured with single-agent therapy [34]. The introduction of combination chemotherapy treatments in the 1970s transformed this situation, and modern data indicate a cure rate for high-risk patients of 85–94% using EMA/CO chemotherapy [3,35–37]. This combination delivers a dose-intense treatment with the five chemotherapy agents, delivered in two groups 1 week apart as shown in Table 42.5. Delivering therapy on a weekly as opposed to 3–4 weekly basis appears to be the most effective approach to this rapidly proliferating malignancy. EMA-CO is myelosuppressive and most patients require granulocyte colony-stimulating factor support each week to maintain treatment intensity and to minimize the risk of neutropenic sepsis. Nausea and vomiting are now rarely a problem with modern antiemetics that include the 5HT$_3$

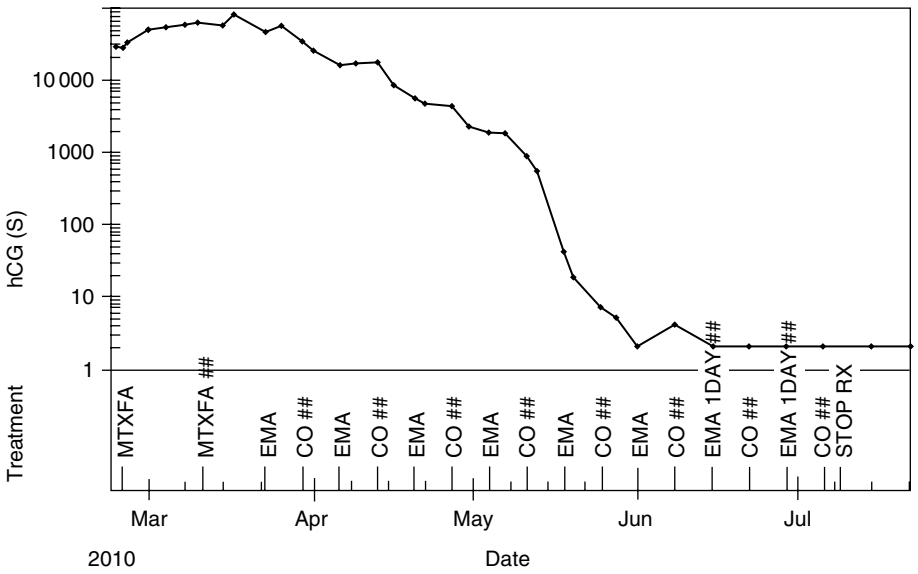

Fig. 42.5 Treatment and human chorionic gonadotrophin (hCG) graph of a low-risk patient with a gestational trophoblast tumour, initially treated with methotrexate (MTX) and folinic acid (FA) chemotherapy, changing to EMA-CO treatment in response to an hCG plateau.

receptor antagonists such as ondansetron combined with domperidone. The addition of dexamethesone is rarely required and we prefer to avoid this given the rare but unpleasant problem of avascular necrosis of the femoral and humeral heads requiring joint replacements in young patients. Increasing lethargy with progressive cycles of EMA/CO is common and some patients develop peripheral neuropathy that can be aided by stopping the vincristine. Overall, the regimen is well tolerated compared with many other multiagent therapies and serious or life-threatening toxicity is very rare.

As in the low-risk situation, treatment is continued for 6 weeks after the normalization of hCG. Moreover, the second day of the EMA comprising etoposide and actinomycin D can be dropped once the hCG is normal. An example of a high-risk patient treated in this case with the high-risk chemotherapy regimen is shown in Fig. 42.6, which demonstrates the resolution of extensive lung metastases and normalization of hCG levels in response to treatment.

Ultra-high-risk disease

Ultra-high-risk disease is a new term to try to define those high-risk patients at greatest risk of death. Analysis of the causes of death in patients with high-risk disease revealed that this occurred either early or late. The early deaths took place within 4 weeks of admission due to organ failure associated with one or more of the following: fatal haemorrhage, metabolic upset from tumour lysis and very adavanced disease. The late deaths were from multiresistant disease. In addition, some deaths were due to cancers that were in fact non-gestational epithelial malignancies histopathologically mimicking gestational choriocarcinomas. Factors associated with early or late deaths included a FIGO score above 12,

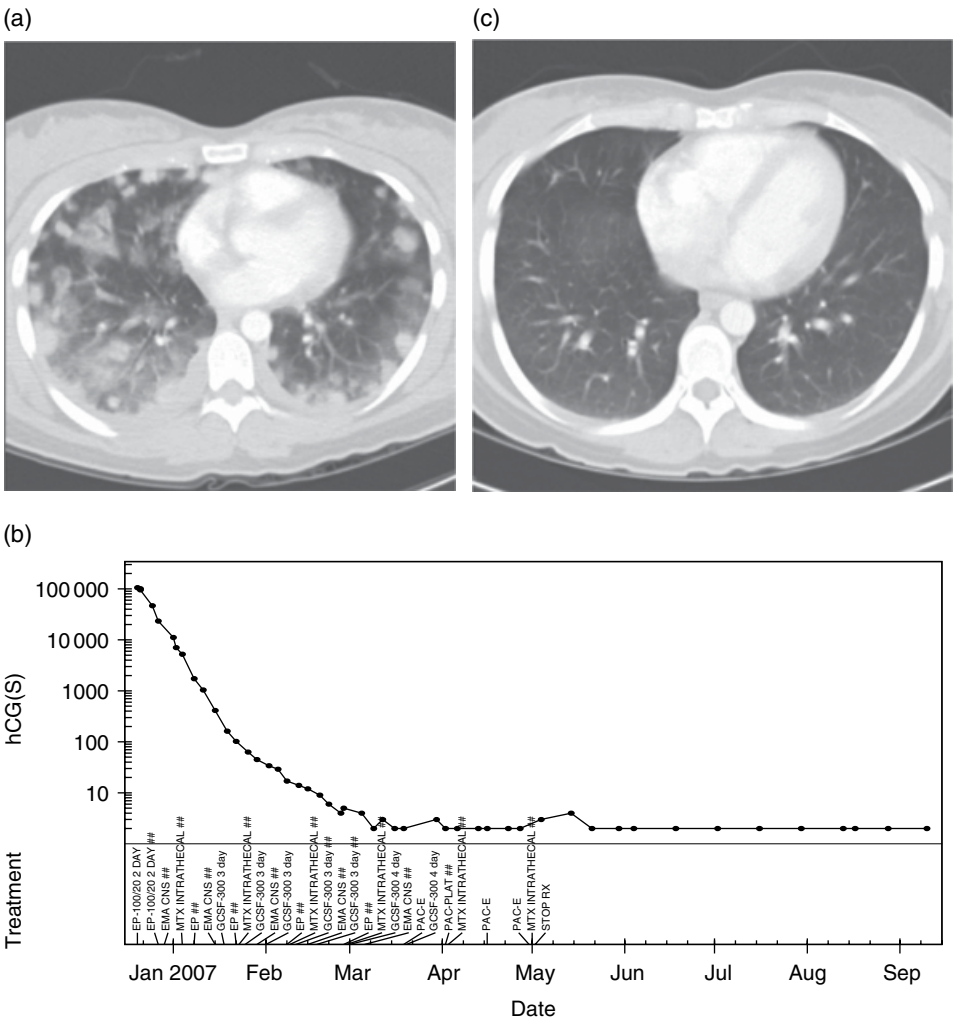

Fig. 42.6 Pre-treatment chest CT scan (a), treatment graph (b) and post-treatment CT scan (c) in a 29-year-old woman presenting with respiratory failure secondary to choriocarcinoma 2 months after the birth of a healthy child.

very advanced lung disease, liver with or without brain metastases, and an interval from the last-known and presumed causative pregnancy greater than 2.8 years [3]. To reduce early deaths, we developed a gentle induction chemotherapy comprising low-dose etoposide 100 mg/m^2 and cisplatin 20 mg/m^2 (EP) given intravenously on days 1 and 2 and repeated weekly for up to 3 weeks until the patient is well enough to tolerate standard-dose therapy. This has almost completely eliminated early deaths from patients with advanced GTN [3]. Those patients with liver metastases or liver and brain metastases have a particularly poor long-term survival and so they should be considered for more prolonged platinum-containing therapy. In the UK these patients now all receive etoposide and cisplatin alternating with 1 day of EMA [38]. Moreover, for patients with brain metastases, the methotrexate dose is increased to 1 g/m^2 in the EMA and intrathecal methotrexate is given with the EP to ensure adequate CNS penetration. We also extend the duration of consolidation therapy in ultra-high-risk patients to 8 weeks. Further details of how to manage such complex patients is beyond the scope of this chapter but can be found elsewhere [38–40].

Salvage of EMA/CO failures

Of the high-risk patients treated with EMA/CO, approximately 18–20% develop resistance to this combination and require a change to second-line drug treatment. In this situation, the EP/EMA [41] or TE/TP [42] regimens may be used, which incorporate cisplatin and additional etoposide into the combination along with paclitaxel in the TE/TP regimen. These treatments, combined with surgery, both appear to salvage about 80% of patients failing EMA/CO. Since TE/TP seems much better tolerated and is given every 2 weeks rather than the weekly EP/EMA, TE/TP is now frequently the preferred option for EMA/CO failures [2].

Patients relapsing after EP/EMA and/or TE/TP can still be salvaged by surgery and/or further chemotherapy. Several other agents have activity in these tumours including gemcitabine, pemetrexed and capecitabine either alone or in combinations with other drugs. In addition, high-dose chemotherapy with peripheral stem cell support may help to salvage some patients [2]. Recent work presented at international meetings has suggested that some antibodies that target surface molecules on either the trophoblastic tumour cells or surrounding immune cells may also salvage some patients who have failed all other therapies. Consequently, there is considerable optimism that the remaining 5% of deaths from highrisk disease will be eliminated in the near future.

Management of PSTT/ETT

PSTT/ETT, unlike choriocarcinoma, tend to be much more slow-growing, remain confined to the uterus for longer, have a greater liklihood of lymphatic spread, produce less hCG, and tend to be less chemosensitive. However, like choriocarcinoma, they can metastasize widely.

The FIGO scoring system is not an effective way to determine management. Instead analysis of the UK experience has shown that the key independent prognostic factor is the interval from the last-known or causative pregnancy. Patients presenting beyond 4 years do exceptionally badly whereas those presenting within 4 years have a 98% long-term survival regardless of stage [4]. A more recent and as yet unpublished update suggests that stage is also an independent prognostic factor. Therapy is therefore stage and interval adapted. For patients with stage I disease within 4 years of the causative pregnancy, a simple hysterectomy with lymph node sampling and sparing of the ovaries but without adjuvant chemotherapy is all that is needed. However, those with stage I diease presenting more than 4 years from the causative pregnancy should be considered for adjuvant chemotherapy with or without high-dose chemotherapy given the comparative reduced sensitivity to standard-dose chemotherapy. Women who present with metastatic disease within 4 years are currently treated with EP/EMA chemotherapy until their hCG level is normal for 8 weeks and then offered surgery to remove all residual disease sites. If there is still active disease then high-dose therapy is considered. The latter is now included for all metastatic patients presenting beyond 4 years, along with other novel therapies. Some young patients presenting with PSTT/ETT within 4 years of the presumed causative pregnncy are understandably keen to preserve their fertility and wish to avoid hysterectomy. Several experimental approaches are being examined including focal resection of uterine disease using a modified Strassman procedure, followed by either nothing or adjuvant chemotherapy. Alternatively, neoadjuvant chemotherapy has been tried followed by observation or focal resection if a residual uterine lesion is seen. The problem with these approaches resides in persisting diffuse microscopic disease causing subsequent relapse with the potential to place patients in a poor prognostic group [43]. These approaches therefore remain experimental.

To gain more insight into PSTT/ETT the International Society for the Study of Trophoblastic Diseases has established a database for these cases which is run by Sheffield and Charing Cross in the UK (http://stdc.group.shef.ac.uk/psttuhr/index.html).

Risk of relapse and late treatment complications

For the majority of patients with trophoblast disease who achieve a serological remission the outlook is very bright in terms of the very low risks of relapse, the high possibility of further successful pregnancies and only modest long-term health risks from the chemotherapy exposure. Once the hCG level has fallen to normal, the risk of relapse is less than 4% for patients starting in the low-risk category and 8% for patients in the high-risk EMA/CO category [44]. Generally, recurrences occur within the first 12 months after treatment.

Subsequent fertility

Importantly, fertility is not clearly affected by single-agent therapy with methotrexate and apart from hastening the menapause by 3 years [45], EMA/CO appears to also have no impact on the chances of a successful pregnancy, which for both methotrexate alone or EMA/CO is 83% [46]. Despite this good news, some patients attending for fertility testing have been very worried by reports of low to undetectable anti-Müllerian hormone levels. Fortunately, all these women were menstruating normally, subsequently conceived and have had babies [47].

Further pregnancy should be deferred for 12 months after treatment to avoid any teratogenic effects on developing oocytes and to minimize possible confusion from the rising hCG levels between a new pregnancy and disease relapse. Despite this advice 500 of our treated patients have conceived in the first year of follow-up. Interestingly, the risk of relapse appeared to be lower, there were no abnormal babies and only the expected rate of miscarriages/pregnancy losses and second molar pregnancies. Only one patient suffered severe difficulty with lung metastases but fortunately both the patient and her baby were saved [48,49]. Therefore, for women who are worried about their declining fertility, it seems reasonable to let them make their own informed choice about earlier attempts to conceive.

Many patients after experiencing one molar pregnancy, and particularly those who require chemotherapy, are anxious about the problem occurring again in any subsequent pregnancy. While the data suggest that the risk of a further molar pregnancy is about 10-fold higher than in the normal population, this only equates to an approximate 1 in 100 risk [8,9]. This risk appears to be independent of chemotherapy exposure, being similar for those patients who required chemotherapy and those where the molar pregnancy was cured by evacuation alone.

Long-term toxicities

Although our prior analysis with 15 000 patient-years of follow-up suggested a slightly increased risk of second cancers in patients treated with combination chemotherapies [50], more recent data with over 30 000 patient-years of follow-up has revealed a different story [51]. These data show that EMA/CO if kept under 6 months in total duration carries no overall increased risk of triggering a second cancer in later life [51]. This is very important information to share with our patients. Of course, those that rarely need high-dose chemotherapy may not be in the same position and it is also true that high-dose chemotherapy will almost certainly destroy fertility. Fortunately, though, very few of our patients end up needing this.

Personal and psychological issues

Despite the high cure rate and relatively low long-term toxicity from chemotherapy treatment, it is unsurprising that the diagnosis of a gestational tumour and particularly treatment with chemotherapy can result in a number of psychological sequelae.

The main areas that can lead to stress in the short term include the loss of the pregnancy, the impact of the 'cancer' diagnosis, the treatment process and the delay of future pregnancy. During chemotherapy treatment issues regarding potential side effects, emotional problems and fertility concerns are frequent and patients will benefit from the support of an experienced counsellor. A number of studies have shown that these concerns can remain for many years, with feelings regarding the wish for more children, a lack of control of fertility and an ongoing mourning for the lost pregnancy still frequently reported 5–10 years after successful treatment [52,53]. A number of surveys have demonstrated the wish of many patients to have more support throughout their diagnosis and treatment through counselling and other forms of support. With the rarity of the diagnosis, providing expert counselling close to home is likely to be challenging, but support in the form of the patients internet forum

(https://mymolarpregnancy.com/) has proved extremely useful to many patients in the UK and elsewhere.

Summary

Over 90% of molar pregnancies will be cured with the first evacuation, the cases that require chemotherapy are generally cured with very low toxicity treatment, and the overall cure rate is approximately 100%. Patients presenting with high-risk disease can now expect to be cured in nearly 95% of cases and the development of new therapies provides promise that the remaining 5% of deaths will be eliminated in the not too distant future. PSTT/ETT, the rarest forms of GTN when presenting with advanced disease or beyond 4 years from the presumed causative pregnancy, still cause significant problems and major advances are required to improve cure rates.

In the UK there is a well-established centralized surveillance and treatment service that links all the obstetric and gynaecology teams with an effective registration, follow-up and expert treatment service. There is 24-hour emergency advice and treatment available in both major centres and they are always willing to give advice on any UK and overseas patient. The establishment of similar centralized care elsewhere in the world is to be encouraged to help improve outcomes for women with GTD globally.

Summary box 42.1

- Molar pregnancies occur at an approximate rate of 1 per 500 viable conceptions for women in the UK. The risk of a molar pregnancy increases with maternal age: for women aged 45, the risk is 1 in 96; for women aged 50 and over, the risk is 1 in 6.
- The risk of requiring chemotherapy treatment after the evacuation is approximately 15% for complete molar pregnancies and 1% for partial moles. Modern treatment produces cure rates of nearly 100% using primarily low-toxicity methotrexate chemotherapy.
- Choriocarcinoma is a rare diagnosis, with an incidence of 1 per 50 000–100 000 conceptions. The majority of cases occur after a normal pregnancy but the diagnosis can occur after a molar pregnancy or any other type of pregnancy including miscarriage. The presenting symptoms and findings in choriocarcinoma can be varied and it is recommended that every woman presenting with previously undiagnosed cancer should have a formal laboratory hCG check.
- The UK has a national service for the registration, surveillance and specialist treatment of gestational tumours. All patients with proven or suspected molar pregnancies should be registered and expert advice for emergency cases is available 24 hours a day.

Ectopic Pregnancy

George Condous

Sydney Medical School Nepean, University of Sydney, Nepean Hospital, Penrith, Sydney, Australia

The rate of ectopic pregnancy (EP) is 11 per 1000 pregnancies, with a maternal mortality of 0.2 per 1000 estimated EPs [1]. About two-thirds of these deaths are associated with substandard care [2]. In recent decades, there have been significant advances in the diagnosis and management of EP [3]. We have seen EP presentation change from being a life-threatening event requiring emergency surgery to a more benign early pregnancy complication in haemodynamically stable women. Consequently, women with an EP potentially present at earlier gestations, allowing for more conservative management strategies to be considered [3]. Contributing factors to this change are an increased awareness of risk factors for EP, introduction of high-resolution transvaginal ultrasound probes, availability of accurate and rapid serum human chorionic gonadotrophin (hCG) assays and the roll-out of early pregnancy assessment units [3]. Importantly, EP is still the most common cause of pregnancy-related deaths and morbidity worldwide, accounting for 54% of first-trimester maternal deaths in the UK, and 3–4% of all mortalities related to pregnancy [1,2]. This is despite the fact that the mortality from EP has significantly dropped over the last few decades [4,5].

In the emergency department setting, some 6–16% of all women who present with vaginal bleeding and/or lower abdominal pain in the first trimester will have an underlying EP [6]. Because of the often non-specific presentation of women with an underlying EP and the absence of a single diagnostic test, early diagnosis can be challenging in both the emergency department and general practice settings. In the most recent Confidential Enquiry into Maternal Deaths in the UK 2006–2008, gastrointestinal symptoms, particularly diarrhoea, and dizziness in early pregnancy were highlighted as important symptoms of EP. According to the authors, these clinical features need to be emphasized to all clinical staff in the primary care setting [2]. Although transvaginal ultrasound scan (TVS) and the rapid availability of quantitative hCG levels have significantly improved the early diagnosis and optimal management of EP [7–9], one cannot replace clinical acumen and a high index of suspicion for this condition at first presentation remains the key to early diagnosis, achieving the best outcome and avoiding maternal morbidity and mortality [10]. A detailed history, including assessment of possible risk factors for EP, as well as a focused physical examination and a quick office urinary pregnancy test can guide the clinician towards early diagnosis of EP.

Risk factors

Importantly, only about 50% of women diagnosed with an EP have identifiable risk factors. Recognition of these risk factors can assist the clinician not only in the early diagnosis of EP, but also in reducing the risk of massive intra-abdominal haemorrhage and its morbidity and mortality [11]. The incidence of EP increases among women who have a history of EP [12–14]. A woman who has had two prior EPs has a 10-fold increased risk of future EP. This increased risk could be attributable to underlying tubal dysfunction or secondary to the treatment of EP: after surgical or non-surgical management the EP recurrence rate is 8–15% and after conservative management 15% [13,14]. The risk of EP also increases in women who have a history of any type of pelvic surgery. For example, previous appendectomy has a twofold increased risk of EP [15,16]. Among the group of women in whom tubal sterilization has failed, pregnancy can result in an EP rate as high as 33% [13].

The incidence of EP increased by more than twofold during the period 1970–1985, from 7 to 16 per 1000, and then declined by 30% during the years 1985–1997. This was explained by the increase and decline of pelvic

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

inflammatory disease (PID) within those periods [17]. It has also been shown that having multiple sexual partners is a strong risk factor for EP, with an odds ratio of 2.1 [18,19]. There is an association between previous exposure to *Chlamydia trachomatis* and subsequent EP. In a recent study, previous exposure to *Chlamydia trachomatis*, as indicated by serum antibodies, doubled the risk of EP and was highest among women 35 years or older [20,21]. Overall, a history of genital infections including sexually transmitted infection, PID and/or any tubal pathology or surgery is a significant risk factor for tubal EP.

Smoking is a major risk factor for EP [22]. The risk of EP increases by threefold to fourfold in women who smoke more than one packet of cigarettes per day. The level of risk has been related to the number of cigarettes smoked per day. After stratification by the amount of daily smoking during the peri-conception period, the odds ratio rises from 1.6 for women who have smoked one to five cigarettes, to 1.7 for women who have smoked six to ten cigarettes, to 2.3 for women who have smoked 11–20 cigarettes, and to 3.5 for women who have smoked more than 20 cigarettes per day [23].

Historically, EP rates following assisted reproductive technologies are known to have increased over time. The rate of EP is 2–3% higher in women undergoing *in vitro* fertilization (IVF) compared with natural conception [24]. In addition, treatment with gonadotrophin and other drugs such as clomifene in IVF pregnancy increases the incidence of EP [23]. The rate of heterotopic pregnancy in the assisted reproductive population could be up to 1 in 100 to 1 in 45 [25,26]. More recently, however, a population-based retrospective analysis was carried out on all pregnancies following assisted reproductive cycles carried out in the UK between 2000 and 2012, in the anonymized database of the Human Fertilisation and Embryology Authority ($N = 161\,967$ treatment cycles). The authors concluded that EP rates in the UK following IVF/intracytoplasmic sperm injection have progressively decreased, and this appeared to be associated with a reduction in the incidence of tubal factor infertility and the increased use of both a lower number of embryos transferred and extended embryo culture [27].

Intrauterine contraceptive devices containing copper and the Mirena® intrauterine system (IUS) decrease the risk of an EP, but if pregnancy does occur with the device *in situ*, the risk of EP is higher [28–30]. Of the 0.5 per 100 Mirena IUS users who become pregnant in 5 years (cumulatively), half are EPs. Women aged 35–44 years have a three times higher risk of EP compared with younger women [31–33]. Diethylstilbestrol exposure *in utero* increases the relative risk of EP by 3.84 [34].

Summary box 43.1

- Ectopic pregnancy is still the principal cause of maternal death in the first trimester.
- Risk factors include:
  - previous ectopic pregnancy;
  - previous pelvic surgery (tubal ligation, appendicectomy);
  - history of PID, *Chlamydia*;
  - smoking cigarettes;
  - use of assisted reproductive technologies;
  - increasing maternal age;
  - diethylstilbestrol exposure *in utero*.

Types of ectopic pregnancy

Current evidence supports the hypothesis that tubal EP is caused by a combination of retention of the trophoblast/embryo within the fallopian tube due to impaired tubal transport of the embryo and alterations in the tubal environment allowing early implantation to occur [35]. Over 95% of EPs are tubal in origin, with 80% located in the ampullary portion of the fallopian tube [35]. Therefore approximately 5% of cases represent non-tubal EPs.

Non-tubal EPs can be located in the cervix, ovary, interstitial portion of the fallopian tube (i.e. that part of the fallopian tube which traverses the myometrium of a normally shaped uterus), caesarean scar or abdomen [7,8]. Note that cornual pregnancies are extremely rare (1 in 100 000 to 1 in 140 000 pregnancies) [36] and these occur in the non-communicating horn of a unicornuate uterus [37]. The term 'interstitial pregnancy' should not be used interchangeably with 'cornual pregnancy' [38]. Caesarean scar pregnancies occur when there is implantation into a lower anterior uterine segment at the level of a previous caesarean scar [39]. This incidence is quoted to be between 1 in 1800 and 1 in 2226 of all pregnancies, with a rate of 0.15% in women with a previous caesarean scar and a rate of 6.1% of all EPs in women who have had at least one caesarean delivery [40–42].

Summary box 43.2

- Types of ectopic pregnancy:
  - tubal (95%) vs. non-tubal (5%).
- Types of non-tubal ectopic pregnancy:
  - interstitial;
  - cervical;
  - ovarian;
  - caesarean scar;
  - cornual;
  - abdominal.
- The term 'interstitial pregnancy' should not be used interchangeably with 'cornual pregnancy'.

Diagnosis

TVS is the single best diagnostic modality for evaluating women with suspected EP [43–45]. This is the case for both tubal and non-tubal EPs. The presence of abdominal pain and/or vaginal bleeding in a premenopausal woman who is sexually active should prompt urinary pregnancy testing and in the event that this is positive should result in an assessment of the pelvis by an experienced operator using TVS. In a meta-analysis of the use of emergency-physician ultrasonography in the evaluation of patients at risk of EP, bedside ultrasonography provides excellent sensitivity and negative predictive value as a diagnostic test for EP [46]. Visualization of an intrauterine pregnancy by an emergency physician is generally sufficient to rule out EP [46].

In experienced hands, when there are no signs of intrauterine or extrauterine pregnancy on TVS, women should be classified as pregnancy of unknown location (PUL) [1,9,47,48]. Importantly, PUL is a descriptive term and should not be used interchangeably with EP [49,50]. The final outcome for a PUL includes a failed PUL, intrauterine pregnancy, EP or persistent PUL (PPUL), with EP and PPUL considered to be high-risk PUL [45,51]. An EP seen at the first ultrasound scan appears to be more symptomatic and larger in diameter and volume compared with an EP which starts as a PUL [52].

Tubal ectopic pregnancy

In experienced hands, over 70% of EPs are seen on ultrasound on the first scan [52,53] and well over 90% before surgery [54]. The diagnosis of a tubal EP by ultrasonography is based on one of the following grey-scale morphological appearances [54]:

1) an inhomogeneous mass or 'blob' sign adjacent to the ovary and moving separately to this (Fig. 43.1); *or*
2) a mass with a hyperechoic ring around the gestational sac or 'bagel' sign; *or*

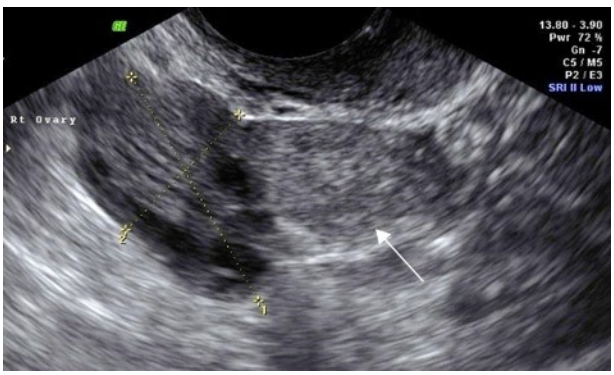

Fig. 43.1 An inhomogeneous mass or 'blob' (arrow) seen on transvaginal ultrasound.

3) a gestational sac with an embryonic pole with cardiac activity, i.e. a viable extrauterine pregnancy; *or*
4) a gestational sac with an embryonic pole without cardiac activity, i.e. a non-viable extrauterine pregnancy.

These various morphological ultrasound forms of tubal EP are reported with the following frequencies: 'blob' sign, 57.9%; 'bagel' sign, 20.4%; or gestational sac with a measurable embryonic pole, with or without positive cardiac beat, 13.2% [54,55]. In a recent meta-analysis assessing the accuracy of first-trimester ultrasound in diagnosis of tubal EP, TVS was more useful for confirming a tubal pregnancy rather than excluding one [56].

Non-tubal ectopic pregnancy

The differences between interstitial, angular and cornual pregnancies on two-dimensional sonography are subtle. Three-dimensional sonography has the advantage of providing coronal views of the uterus that cannot be obtained with conventional two-dimensional sonography, resulting in distinctive differences that assist in differentiating between interstitial, angular and cornual pregnancies [57].

Interstitial pregnancy

The following historical diagnostic criteria have been proposed based on two-dimensional sonography [58]:

1) an empty uterine cavity;
2) a chorionic sac separate and at least 1 cm from the lateral edge of the uterine cavity; and
3) myometrial thinning (a thin, <5 mm, myometrial layer surrounding the gestational sac).

However, these two-dimensional sonographic criteria only detect 40% of interstitial pregnancies. Ackerman *et al.* [59] added the term 'interstitial line', an echogenic line that runs from the endometrial cavity to the cornual region, abutting the interstitial mass or gestational sac. This criterion in particular provides a better sensitivity (80%) and specificity (98%) compared with the previously described eccentric gestational sac location (sensitivity 40%, specificity 88%) [60] and myometrial thinning (sensitivity 40%, specificity 93%) [58].

Although there are limited data on the use of three-dimensional sonography for the diagnosis of interstitial pregnancy, this modality could well be the likely successor to two-dimensional evaluation of potential interstitial pregnancies [57] (Fig. 43.2).

Cornual pregnancy

Mavrelos *et al.* [37] proposed the following ultrasound diagnostic criteria for a cornual pregnancy:

1) there is a single interstitial portion of the fallopian tube in the main uterine cavity;

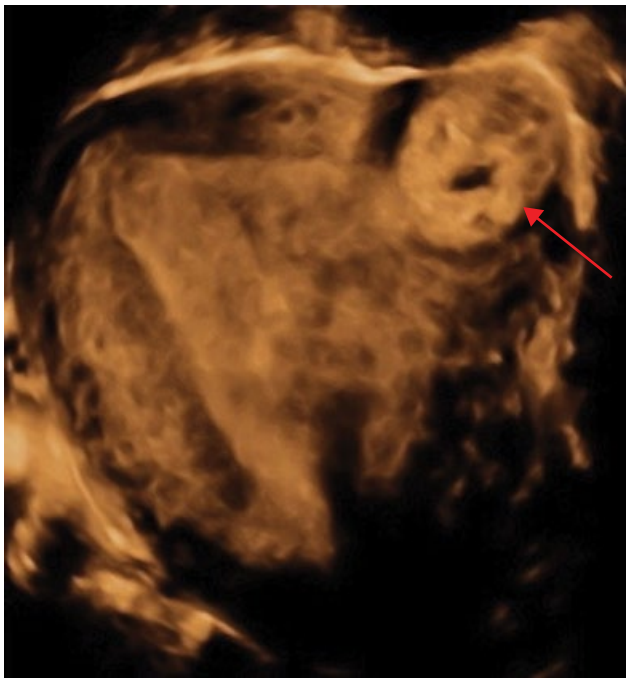

Fig. 43.2 Coronal view of the uterus showing an interstitial ectopic pregnancy (arrow). (*See also colour plate 43.2*)

2) a gestational sac, mobile and separate from the uterus, is surrounded by the myometrium; and
3) a vascular pedicle joins the gestational sac to the unicornuate uterus.

Caesarean scar pregnancy

The following ultrasound criteria have been proposed for the diagnosis of caesarean scar pregnancy [61]:

1) empty uterine cavity and empty cervical canal;
2) presence of the gestation sac with or without a fetal pole with or without fetal cardiac activity (depending on gestational age) located anteriorly at the level of presumed site of the previous scar in the lower uterine segment;
3) Doppler examination showing evidence of functional trophoblastic/placental circulation; and
4) negative 'sliding' sign.

Godin *et al.* [62] further described an empty cervical canal and absence of healthy myometrium between bladder and gestational sac.

Summary box 43.3

- In experienced hands, when there are no signs of intrauterine or extrauterine pregnancy on TVS, women should be classified as PUL.
- PUL is a descriptive term and should not be used interchangeably with EP.
- TVS in experienced hands is the diagnostic tool of choice for the diagnosis of ectopic pregnancy.
- 70% of tubal ectopic pregnancies are seen on ultrasound on the first scan and well over 90% before surgery.
- The various morphological features seen on ultrasound that indicate tubal ectopic pregnancy include:
  - 'blob' sign;
  - 'bagel' sign;
  - a gestational sac with a measurable embryonic pole, with or without positive cardiac beat.

Management

Clinical stability is the most important factor when determining whether the subsequent management of EP is surgical or not [63]. This is relevant to both tubal and non-tubal EPs (management of non-tubal EP is not discussed in this chapter). Ultrasound findings including the morphological appearance of the EP (i.e. the presence of an embryonic pole with or without cardiac activity) and the presence or absence of haemoperitoneum are also important considerations. TVS findings that include the presence of an embryonic pole with cardiac activity and the presence of haemoperitoneum are accepted indicators for surgical intervention [62,63]. The principle of preserving fertility also needs to be taken into account in the decision-making process before management is implemented.

Tubal ectopic pregnancy

Treatment options for tubal EP include surgery (e.g. salpingectomy or salpingotomy, performed laparoscopically or by open surgery), medical treatment using a variety of drugs that can be administered systemically and/or locally by various routes, and expectant management [64].

Conservative management (expectant and medical management)

Expectant management of tubal EP eliminates the need for medical or surgical treatment in more than one-third of women diagnosed with tubal EP, with minimum risk of adverse outcome [65]. Women with a conclusive ultrasound diagnosis of tubal EP who are clinically stable with no or minimal abdominal pain, no evidence of significant haemoperitoneum on ultrasound (Fig. 43.3), EP mass measuring less than 30 mm in mean diameter with no evidence of embryonic cardiac activity on ultrasound scan and serum hCG levels below 1500 IU/L can be selected for expectant management [65]. Importantly, all women selected for expectant management must be followed up until serum hCG levels are less than 5 IU/L.

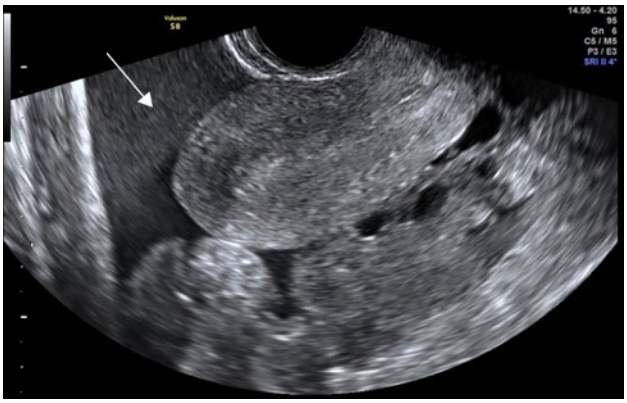

Fig. 43.3 Significant haemoperitoneum on transvaginal ultrasound: note the presence of 'ground glass' fluid (arrow) above the fundus of the uterus.

In another study, also including women with a conclusive ultrasound diagnosis of tubal EP, the most important variable for predicting the likelihood of successful non-surgical management was the pretreatment hCG ratio (defined as hCG 48 hours/hCG 0 hour) [66]. The pretreatment hCG ratio was related to the failure of both expectant (area under curve 0.86) and medical (area under curve 0.79) management.

In a recent randomized controlled trial, women with EP or PUL with low or plateauing hCG levels were assigned to systemic single-dose methotrexate (MTX) treatment or expectant management [67]. There was no difference in primary treatment success rate of single-dose MTX versus expectant management. After expectant management, 60% of women had an uneventful clinical course with steadily declining serum hCG levels without any intervention, indicating that MTX, a potentially harmful drug, can be withheld in these women. One criticism of this study is that women with a PUL were included in the randomization, some of which represented failing PUL, thus potentially overinflating the success in the MTX arm. Another criticism of this study is the inclusion of PUL, which means that these results cannot necessarily be extrapolated to other populations that classify an EP on the basis of conclusive ultrasound evidence.

If MTX is to be given to women with a tubal EP, single-dose MTX (50 mg/m^2) can be administered intramuscularly in selected cases with conclusive ultrasound evidence of an EP. Women need to be clinically stable and have TVS evidence showing an EP mass measuring less than 35 mm in diameter and absence of embryonic cardiac activity and haemoperitoneum [68]. If the serum hCG level falls more than 15% between days 4 and 7, then this is a good prognostic indicator for MTX response. If the serum hCG level falls by less than 15% between days 4 and 7, then a second dose of MTX can be given [68]. Importantly, all women selected for expectant management must be followed up until serum hCG levels are below 5 IU/L. If a woman does not respond to two doses of MTX, it is worthwhile considering other underlying pathologies such as gestational trophoblastic disease [69].

Surgical management

In the event that a woman with a tubal EP has haemodynamic instability and/or the presence of an EP mass containing an embryonic pole with cardiac activity on TVS and/or the presence of significant haemoperitoneum on TVS, then surgery is the appropriate course of action [64] (Fig. 43.4). Compared with laparotomy, the laparoscopic approach is less costly and associated with less blood loss and analgesic requirements and shorter hospital stay [64]. Single-dose MTX is less effective than laparoscopic salpingotomy [64]. Multiple-dose MTX is comparable to laparoscopic salpingotomy but the former has higher costs due to subsequent interventions. Only EPs with low initial hCG levels have cost savings when comparing MTX with laparoscopic salpingotomy [64].

In modern practice, tubal EPs can be surgically treated by laparoscopic salpingectomy, in which the affected fallopian tube is removed, or salpingotomy, in which the tube is preserved. Despite potentially increased risks of persistent trophoblast and repeat EP, salpingotomy is often preferred over salpingectomy because the preservation of both tubes is assumed to offer favourable fertility prospects, although little evidence exists to support this assumption. In the recent ESEP study, 446 women were randomly assigned to either laparoscopic salpingotomy or salpingectomy [70]. The cumulative ongoing pregnancy rate was 60.7% after salpingotomy and 56.2% after salpingectomy. Persistent trophoblast occurred more frequently in the salpingotomy group than in the salpingectomy group [14 (7%) vs. 1 (<1%)]. Repeat EP

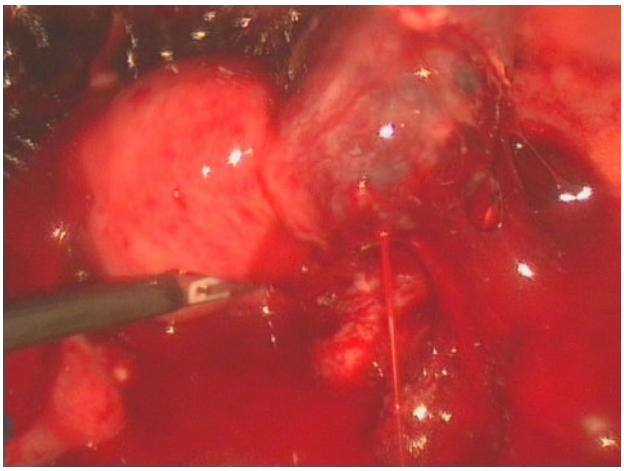

Fig. 43.4 A ruptured ectopic pregnancy at the time of laparoscopic intervention.

Summary box 43.4

- Various management strategies for tubal EP include:
  - expectant;
  - medical;
  - surgical.
- Expectant management is an option if the following are present:
  - there is conclusive ultrasound diagnosis of tubal EP;
  - clinical stability;
  - no or minimal abdominal pain;
  - no evidence of significant haemoperitoneum on ultrasound scan;
  - EP mass measuring < 30 mm in mean diameter with no evidence of embryonic cardiac activity on ultrasound scan;
  - quantitative serum hCG levels <1500 IU/L.

occurred in 18 women (8%) in the salpingotomy group and in 12 (5%) women in the salpingectomy group. The authors concluded that in women with a tubal EP and a healthy contralateral tube, salpingotomy did not significantly improve fertility prospects compared with salpingectomy.

Conclusion

Access to expertise and equipment for high-quality TVS means the majority of women with EP in developed countries can be diagnosed rapidly and accurately. The ultrasound diagnosis of EP not only enables clinicians to set out a clear management plan but also contributes to the improvement in maternal morbidity and mortality outcomes.

Induced Abortion

Patricia A. Lohr

British Pregnancy Advisory Service, Stratford-Upon-Avon, UK

Induced abortion is an essential component of comprehensive reproductive healthcare. An estimated 56 million abortions are undertaken worldwide [1] and, in Britain, one in three women will terminate a pregnancy [2]. Over the last decade, the number of abortions undertaken yearly in the UK has remained fairly constant at about 200 000 [3,4]. Over 90% of abortions occur at under 13 weeks' gestation.

Women from all racial/ethnic, religious and socioeconomic backgrounds have abortions. Some demographic characteristics are more strongly associated with the decision to terminate a pregnancy than others. Age is one of the strongest factors, likely reflecting a readiness for parenthood. For example, conception rates in teenagers have declined steeply in Britain but in those under 16 years of age, 63% end in abortion [5]. In contrast, women aged 30–34 have seen continuous increases in conception rates since 1990, yet only 13% of these pregnancies are aborted. The majority of women resident in England and Wales who have abortions are single and white, although those who identify as Asian, Black or Black British are overrepresented relative to the proportion of these ethnicities in the general population. Over 50% of women who have an abortion have already had a child. Scottish statistics demonstrate a clear relationship between greater economic deprivation and a higher rate of abortion.

Just over one-third of women having an abortion in Britain will have had more than one abortion. This percentage has been rising since 2005, possibly due to greater accessibility of abortion services and acceptability of abortion as a means of fertility regulation. Older age and parity are associated with having more than one abortion as well as identifying as Black, leaving school at an earlier age, living in rented accommodation, reporting an earlier age at first sexual experience, being less likely to have used a reliable method of contraception at sexual debut, and reporting a greater number of sexual partners [2]. Intimate partner violence is also associated with having one or more abortions [6].

Although some planned pregnancies end in abortion, most women who have abortions did not intend to become pregnant. In the third National Survey of Sexual Attitudes and Lifestyles, 57% of unplanned pregnancies ended in abortion compared with 33% categorized as ambivalent and 10% as planned [7]. Unplanned pregnancy results from failures of contraception in some cases, but many occur because no contraception was used or because the method was used inconsistently or incorrectly [8]. Pregnancy intention is, however, only a first level signifier of the decision to terminate a pregnancy. Underneath is a complex set of reasons including educational aspiration, financial resources, health concerns or relationship difficulties.

Induced abortion using modern methods is very safe. When performed by trained clinicians with the appropriate resources, the chance of a woman dying from an induced abortion is considerably lower than chance of dying from childbirth. However, where abortion is provided by unskilled practitioners in unhygienic environments, it results in significant morbidity and mortality. Worldwide, an estimated 6.9 million women are treated for complications of unsafe abortion each year and up to 40 000 die [9].

This chapter focuses on elective induced abortion up to 24 weeks gestation; termination of pregnancy for fetal or maternal indications is not considered in detail. At these gestations abortion may be performed surgically or with medications. The choice of method is determined by multiple factors, including a woman's preferences, medical eligibility and service availability.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

The law and abortion

The legal criteria surrounding abortion are country-specific. In the UK, the 1861 Offences Against the Person Act (OAPA) made having or providing an abortion a crime carrying a potential life sentence. The 1967 Abortion Act, which does not extend to Northern Ireland, did not replace the OAPA or decriminalize abortion. Rather, it defined the circumstances in which an abortion could be performed without the risk of prosecution. These include having two registered medical practitioners agree that a woman meets one of five grounds (Table 44.1). This is indicated by signing a certificate (HSA1 form), which must be retained with the woman's clinical notes for a period of at least 3 years. In cases where an abortion is necessary as an emergency to save a woman's life or prevent grave permanent injury, only one doctor need authorize the abortion using an HSA2 form. A notification form (HSA4) must be signed by the doctor taking responsibility for the abortion and forwarded to the Chief Medical Officer of the relevant country. In the case of surgical abortion, the HSA4 form is signed by the doctor who carried out the uterine evacuation. For medical abortion, the doctor who prescribes the medications signs the form, although nurses or midwives commonly administer the drugs. The location where abortion may be performed is also defined in the Act and is limited to NHS hospitals or premises approved by the Secretary of State for Health.

Most abortions in Britain are undertaken under grounds C or D, which state that the pregnancy has not exceeded its 24th week and where continuance of the pregnancy would involve greater risks of injury to the physical or mental health of the woman or her existing children than if the pregnancy were terminated. In determining whether these grounds are met, account may be taken of the pregnant woman's actual or reasonably foreseeable environment. This 'health exception' has been very broadly interpreted by doctors in Britain, tending toward the World Health Organization definition, which states that health is not just the absence of disease but the presence of well-being.

Table 44.1 Statutory grounds for legal abortion in the UK.

A	The continuance of the pregnancy would involve risk to the life of the pregnant woman greater than if the pregnancy were terminated
B	The termination is necessary to prevent grave permanent injury to the physical or mental health of the pregnant woman
C	The pregnancy has not exceeded its 24th week and the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of the pregnant woman
D	The pregnancy has not exceeded its 24th week and the continuance of the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of any existing child(ren) of the family of the pregnant woman
E	There is a substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be seriously handicapped

Since the Abortion Act does not extend to Northern Ireland, abortion there remains highly restricted. Guidance for professionals on the termination of pregnancy in Northern Ireland was published in 2016 [10], reiterating that it is only lawful to perform an abortion in order to preserve the life of the woman or if there is a risk of 'real and serious adverse effect on her mental or physical health, which is either longer term or permanent'. The guidance is explicit in that it is not possible to create a reference list of potential circumstances in which a lawful termination could be carried out but that it is for a doctor to assess, on a case-by-case basis. This guidance appears to have had little effect on improving access to abortion in Northern Ireland. Almost all women needing abortion care travel to Britain or Europe and there is evidence that many obtain medications online to induce their own abortions outside the legal framework [11].

There is a conscientious objection clause within the Abortion Act that permits refusal to undertake abortions. This right is confined to participating in treatment and is excepted when an abortion is necessary to save the woman's life or prevent grave permanent injury to her physical or mental health. The limitation of the right to direct abortion care was reaffirmed by the UK Supreme Court in December 2014. Two midwives claimed that their right was breached when asked to answer telephone calls to book women for abortions and to delegate to or supervise staff providing abortion care. The Supreme Court considered the definition of the word 'participate' in the Act and concluded it to be 'taking part in a hands-on capacity: actually performing the tasks involved in the course of treatment'. Guidance from the General Medical Council also makes clear that while an individual doctor's personal beliefs should be respected, they must not interfere with access to information about and services for treatments to which they object [12]. A doctor with a conscientious objection to abortion is obliged to make sure a woman has enough information to arrange to see another doctor without an objection or, if it is not practical for a woman to arrange to see another doctor herself, provide or facilitate a prompt referral.

An assessment of an individual's capacity to give valid consent is essential before any medical procedure, including abortion. Separate legislation exists in England and Wales, and Scotland regarding medical

decision-making in the absence of capacity (Mental Capacity Act 2005 and Adults with Incapacity (Scotland) Act 2000). The management of women requesting abortion who may lack capacity is discussed in detail in guidance from the Royal College of Obstetricians and Gynaecologists (RCOG) [13]. Particular note is made of the decision-making capacity of girls less than 16 years of age. The Abortion Act does not stipulate that a woman must be of a certain age to request abortion or require parental consent or notification. Legal precedent in England and Wales, as determined in the House of Lords ruling in the Gillick case, and legislation in Scotland (Age of Legal Capacity (Scotland) Act 1991) are similarly constructed in that following demonstration of comprehension of treatment and its consequences, individuals less than 16 years of age are able to consent for medical care. The Fraser criteria, which guides doctors asked to provide contraception to girls who refuse to involve their parents, is applicable to abortion care. The RCOG recommends that practitioners encourage a young woman to involve her parent(s) or another adult but state that this should generally not override the views of the young person.

Summary box 44.1

- Safe abortion is an essential component of comprehensive reproductive healthcare.
- One in three women will have had an abortion, meaning that all healthcare practitioners will encounter a woman who has had or needs an abortion.
- Healthcare providers must be able to manage requests for induced abortion according to principles of good medical practice and within the law.

Assessment for abortion

The assessment of a woman requesting induced abortion is focused on confirming that she is sure of her decision and providing sensitive decision-making support if needed, determining gestational age, identifying any contraindications that will restrict a choice of abortion method or anaesthesia, and determining whether treatment needs to be performed in a hospital setting or with cross-specialty liaison. There is strong evidence supporting a lower risk of complications for abortions undertaken at earlier gestations. Services therefore need to be organized to minimize delay. The assessment also provides an opportunity to discuss and plan for initiation of a contraceptive method, should a woman choose to use one after the abortion, and to screen for genital tract infections that increase the risk of infective complications.

Most women requesting abortion will have decided to have a termination of pregnancy before coming to a healthcare provider for assistance [14]. Compulsory counselling is not recommended as it delays treatment unnecessarily and may be viewed as intrusive by a woman who is certain of her decision. A non-judgemental interaction with a provider, an explanation of treatment options and risks, and prompt referral for treatment summarizes the expectations of most women once the decision to have an abortion has been made. For the small proportion of women for whom the decision is not straightforward, healthcare providers can assist with non-directive decision-making support or arrange for counselling. Either option may be assisted by the use of a tool, such as that created by the Family Planning Association (www.fpa.org.uk), which provides information about abortion, adoption and parenting and a list of considerations when deciding between them. Practitioners and women can be reassured that whether an unintended pregnancy is continued or terminated, the mental health outcomes will be the same [15]. The development of psychological problems after an abortion or a birth is most reliably predicted by a history of mental health problems. Referral pathways to therapeutic counselling should be in place for those situations regardless of the outcome of the pregnancy.

The clinical history should include relevant medical conditions, obstetric and gynaecologic history including prior ectopic pregnancy and sexually transmitted infections, allergies, medications, and recreational drug or alcohol use or abuse. It is important to explore any history of pain or bleeding in the current pregnancy as this may affect the decision to utilize ultrasound for gestational age determination and pregnancy location. There should be routine enquiry about intimate partner violence with appropriate support and information provided.

Most abortions can be safely carried out in day-case units or freestanding clinics. Indications for treatment in hospital include conditions that necessitate prolonged or intensive monitoring, such as severe cardiopulmonary disease, and those which place the woman at high risk of haemorrhage such as placenta praevia in women with prior caesarean deliveries, or coagulopathy. Some conditions, such as obesity or uterine anomalies including large fibroids, can make surgical abortion more challenging so prior knowledge of them is useful for procedure planning.

Establishing gestational age is important because it is the primary determinant of the way in which a medical or surgical abortion will be performed. Limits on gestational age are also integral to most abortion laws, including in Britain. The duration of the pregnancy is often determined by abdominal or vaginal ultrasound, as relevant to the anticipated gestation, where it is readily available. However, this should not be a barrier to service delivery as there is no evidence

that the routine use of ultrasound for this purpose improves either the safety or effectiveness of abortion procedures [16]. Last menstrual period (LMP) and a bimanual pelvic examination are sufficient in most cases with selective use of ultrasound where there is a discrepancy between LMP and uterine size or a concern for an ectopic pregnancy. Ultrasound is also often used to determine placental location in the second trimester in women with prior caesarean deliveries. It is important that a scan is undertaken in a sensitive setting and manner with a chaperone if the woman wishes to have one present. She should be advised that it is not necessary for her to watch the ultrasound examination in progress but she may be allowed to do so if this is her preference. It is useful to ask whether or not she wishes to be informed of any findings, such as multiple gestations.

Physical examination can be tailored to the anticipated treatment and the woman's medical history. Observations and height and weight (to determine body mass index) are routine, with cardiac, pulmonary, abdominal, pelvic or other examinations undertaken as needed. Blood testing is typically limited to determination of rhesus (D) antigen status. The risk of iso-immunization in the early first trimester appears negligible [17], but most services offer anti-D immunoglobulin to rhesus-negative women regardless of gestational age. Testing for haemoglobin is performed when there is a concern for anaemia and, often, if significant blood loss is anticipated, although data to support this practice are limited [18].

Ovulation can resume within 2 weeks of an abortion and many women will resume sexual activity during this time. Therefore, a woman who wishes to use a contraceptive method should initiate it as soon as possible after the procedure. This is facilitated by discussing contraception during the abortion assessment and providing a method at the time of treatment. Initiation of any hormonal method including the contraceptive implant, or insertion of intrauterine contraception (IUC) can occur immediately following completion of an uncomplicated surgical abortion at any gestation [19]. The risk of IUC expulsion may be increased slightly with immediate insertion after second-trimester surgical abortion but is far lower than the risk of not returning at all for insertion at a separate visit. Similarly, women may start any hormonal contraceptive method at the time of a medical abortion. IUC may be inserted once the gestational sac is confirmed as expelled, which is typically by ultrasound 1–2 weeks after taking the medications. Depending on the type used, a cervical cap or diaphragm will require refitting after second-trimester abortion. Condoms (male and female) can be used at any time after abortion and women may be offered emergency contraception (levonorgestrel or ulipristal acetate) to have in advance of need.

Screening for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* is helpful because they increase the risk of post-abortion upper genital tract infection and its long-term sequelae of tubal factor infertility and ectopic pregnancy. The role of bacterial vaginosis (BV) in post-abortion infection is less clear and screening would be atypical. Rates of post-abortion upper genital tract infection vary widely but when objective criteria are used it is diagnosed in less than 1% of cases, regardless of abortion method and gestation.

Prophylactic antibiotics before first-trimester surgical abortion reduces the risk of infection by 41% (95% CI 25–54%) [20]. Evidence is limited in the context of second-trimester surgical abortion but it is reasonable to expect a similar impact on the reduction of infection. Universal prophylaxis before surgical abortion is standard but the evidence is poor for an optimal regimen. Recommendations vary from a single dose or short (3-day) course of doxycycline to presumptive treatment of *Chlamydia* and BV. The benefit of antibiotic prophylaxis with medical abortion is less clear. There have been no randomized controlled trials of antibiotic prophylaxis with medical abortion. Very rare deaths have been reported due primarily to *Clostridium* species. One before-and-after study of 227 823 women in the USA showed a 93% reduction in serious infection when two simultaneous changes were made: implementation of a routine 7-day course of doxycycline and a switch from the vaginal to buccal route of misoprostol [21]. As with surgical abortion, the RCOG recommends presumptive treatment of *Chlamydia* and BV at the time of medical abortion, but gives it a 'C' rating due to the limitations of existing studies.

Opportunistic screening for sexually transmitted infections (STIs), including HIV, also allows for active follow-up and partner notification and treatment. Screening for infections such as syphilis, hepatitis B and hepatitis C may occur on a selective basis, influenced by sexual health risk assessment and population disease prevalence. Cervical screening is not essential to abortion care but is an opportunity to check that screening is up to date and, where it is not, offering a cervical smear. For all tests it is important to ensure that the result can be communicated to the woman and appropriate action taken on any abnormal result.

Summary box 44.2

- Non-judgemental decision-making support and prompt referral for treatment characterizes the needs of most women requesting induced abortion.
- The medical assessment for abortion should be focused on establishing gestational age, eligibility for a choice of treatment options and location of care, and the need for anti-D prophylaxis.
- Discussing contraception and undertaking screening for STIs also form part of pre-abortion care.

Choice of method

Choice is an integral part of abortion care. Provision of information, along with decision-making support if needed, are essential to helping a woman select an abortion method that is right for her and which will optimize her abortion experience. In both the first and second trimesters, presuming no contraindications, abortion may be performed surgically or by the administration of abortifacient medications (Fig. 44.1). Both methods can be used in the case of multiple gestations. Some women prefer surgical abortion because it is predictable and quick, can be performed with a general or local anaesthetic or sedation, and has a low risk of complications. Others prefer medical abortion because it does not involve surgical instrumentation or anaesthesia and is perceived as more natural, like a miscarriage. In addition, medical abortion at a gestation of 70 days or less may be managed safely and effectively by the woman in the privacy of her own home which is preferred by many to care in a clinical setting.

Trials comparing medical and surgical abortion have been challenging to undertake because many women have an a priori preference for a method and refuse randomization. In the few studies available, some of which have included preference arms, acceptability with medical abortion has been found to be lower than with surgical abortion mainly due to greater pain and prolonged or heavier bleeding with medical abortion [22–25]. However, acceptability and satisfaction with either method is greatest when women are able to receive the type of abortion they want. Services with appropriately trained providers should therefore make both methods available at all gestational ages for which abortion is offered. If a service can only offer one method, referral pathways into other providers should be in place.

Information provided to a woman during the decision-making process should include which abortion methods and pain management options are available to her; what will be done before, during and after the procedure including any tests or examinations; what she is likely to experience (e.g. pain and bleeding, side effects, complications); where the procedure will occur; and how long the process is likely to take, including the need for any follow-up. Women undergoing medical abortion in the second trimester should be advised of the variable duration of the induction and possible need for overnight stay. Surgical abortion in the second trimester may require cervical preparation up to 24 hours before the evacuation so women need to be prepared for a procedure over 2 days although admission is not required.

Other aspects of care which may be important to address are whether her partner or another support person may be present during treatment and whether she may see the fetus or need to dispose of the products of conception after the abortion herself (i.e. with medical abortion at home). The World Health Organization's Clinical Practice Handbook for Safe Abortion (www.who.int/reproductivehealth/publications/en/) includes charts comparing the characteristics of various methods.

Summary box 44.3

- Choice between medical and surgical abortion methods is important and a primary determinant of satisfaction with care.
- Services should aim to provide both methods within the gestational age limit at which abortion is offered.
- Most abortions, regardless of method and gestational age, can be safely conducted in non-hospital settings as day-case procedures.

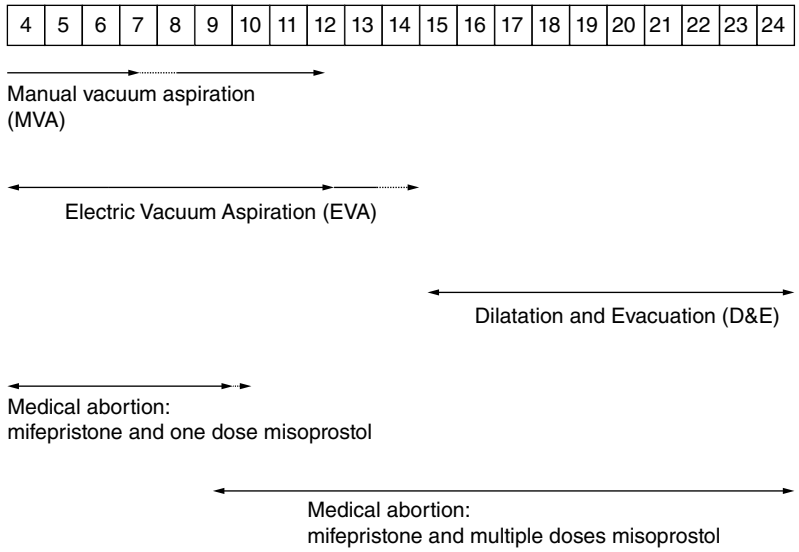

Fig. 44.1 Methods of abortion by gestational age in weeks.

Surgical abortion

Surgical abortion in the first trimester

Vacuum aspiration is the recommended method of surgical abortion in the first trimester. Compared with dilation and sharp curettage (D&C), vacuum aspiration is faster and associated with less pain and blood loss. Vacuum aspiration is also advantageous in that it can be performed in an office setting with local anaesthesia or conscious sedation whereas D&C requires treatment in theatre with general anaesthesia.

Vacuum aspiration may be performed with an electric suction machine or a manual vacuum aspirator which employs one or two valves and a locking plunger in a 60-mL hand-held syringe (Fig. 44.2). Safety, effectiveness and acceptability of electric and manual aspiration are equivalent [26]. Rigid or flexible plastic cannulae are used, the diameter chosen typically being the same in millimetres as the weeks of gestation. It is not uncommon, however, for manual vacuum aspiration to be performed with sequential use of 4-, 5- and 6-mm cannulae, avoiding the need to mechanically expand the cervical os with rigid tapered metal or plastic dilators. The single valve manual vacuum aspirator can accommodate cannulae up to 6 mm in diameter and the double value with cannulae up to 12 mm in diameter. With larger-bore tubing and cannulae available up to 16 mm, electric vacuum aspiration can be used into the second trimester although forceps are often needed to remove larger fetal parts, such as the calvarium or spine [27].

Historically, vacuum aspiration has been avoided under 7 weeks' gestation based on a cohort study that found a higher rate of missed abortion at gestations below 7 weeks' compared with 7–12 weeks' gestation [28]. However, with the increased sensitivity of urine pregnancy tests, many women now present at very early gestations, shortly after a first period has been missed. For these women, it is not acceptable to defer the abortion and their preference might not be for medical abortion; indeed there could be contraindications to medical abortion. Protocols which incorporate routine inspection of the uterine aspirate for the gestational sac, ultrasound and serial serum beta-human chorionic gonadotrophin (β-hCG) levels if ectopic pregnancy or missed abortion is suspected allow for very early surgical abortion to be provided safely with a failure rate ranging from 0.13 to 2.3% [29,30].

Fig. 44.2 Single- and double-valve manual vacuum aspirators. *Source:* Womancare Global. Reproduced with permission of Womancare Global.

Cervical priming agents are often used before vacuum aspiration to reduce or eliminate the need for mechanical dilatation. Options include medications, such as the progesterone antagonist mifepristone and the prostaglandin analogue misoprostol, and osmotic dilators which swell after insertion. Priming agents soften the cervix and open the os, leading to a slightly faster aspiration [31]. One trial demonstrated a decreased need for uterine re-evacuation for incomplete abortion among women who received misoprostol for cervical preparation as compared to a placebo (0.78% vs. 2.26%) [32]. Only osmotic dilators have been shown to reduce the risk of cervical laceration and uterine perforation; studies of pharmacological agents have not been sufficiently powered to determine whether they too lead to a reduction in these rare but serious complications.

Misoprostol is the most commonly used agent for cervical preparation before first-trimester surgical abortion. A dose of 400 μg is effective when administered per vagina 3 hours before the evacuation or sublingually 1 or 2 hours before surgery [33]. Side effects include nausea, vomiting, diarrhoea, chills, cramping and bleeding. Gemeprost is licensed in the UK for cervical priming but is no longer considered a first-line preparatory agent because it requires refrigeration, is expensive and may only be given per vagina. Mifepristone is better tolerated and achieves greater baseline cervical dilation than misoprostol, but requires administration at least 24 hours preoperatively and is significantly more expensive.

Given the side-effect profile of misoprostol and limited evidence of risk reduction, many providers base its use on risk factors for cervical or uterine injury. Common indications are age 17 years or less, prior cervical surgery, and gestational age over 12 weeks.

Pain management options for vacuum aspiration include local cervical anaesthesia with oral analgesia, conscious sedation, and general anaesthesia. Intravenous propofol and fentanyl without intubation characterizes general anaesthesia for abortion care. While there remains a lack of consensus on the ideal cervical anaesthetic, a randomized trial demonstrated improved pain

control with a regimen of 20 mL 1% buffered lidocaine and four deep (3 cm) paracervical injections compared with placebo [34]. Non-steroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen are the mainstay of oral analgesia in abortion care.

Advantages of local anaesthesia include faster recovery, a greater sense of control for the woman, and a reduction in procedural risks such as haemorrhage and cervical laceration [35]. However, local anaesthesia does not eliminate discomfort and some women may find being awake unacceptable. For women who want greater pain and anxiety management than local anaesthesia provides but do not want to be asleep, low-dose intravenous fentanyl and midazolam can be provided to achieve a state of conscious sedation. Women's preference, risk factors for anaesthetic complications, setting and resources should be considered when choosing a method of pain control during surgical abortion.

Performing vacuum aspiration

Vacuum aspiration is a straightforward procedure but careful practice is important so that pregnancies are evacuated completely and safely. Asepsis cannot be maintained during an abortion because contamination of gloved hands occurs once the woman is touched. Operators should employ a no-touch technique, in which the parts of the instruments that enter the uterus (e.g. cannula or dilators tips) are not handled. Careful and gentle instrumentation avoids injury to the cervix or uterus and good communication is needed between the operator, the woman and other members of the surgical team. Precise techniques vary among providers and with anaesthetic regimens. This section describes electric vacuum aspiration with local anaesthesia.

Once pre-procedure checks have been completed, the woman is assisted into the lithotomy position on a gynaecologic couch. After confirming the position, size and shape of the uterus by bimanual examination, a bivalve speculum is placed in the vagina. The cervix and vagina are cleansed with an antiseptic solution such as chlorhexidine. Local anaesthetic is administered by first injecting 1–2 mL 1% buffered lidocaine at the 12 o'clock position on the cervical face. A vulsellum or tenaculum is applied and, with gentle outward traction, an additional 18 mL of buffered lidocaine is injected in equal aliquots paracervically at the 2, 4, 8 and 10 o'clock positions. Cervical dilation to the diameter of the suction cannula is performed with tapered metal or plastic dilators (e.g. Pratts or Hawkin Amblers). The suction cannula is inserted into the mid to upper fundus, taking care not to touch the fundus which causes pain. When the operator is sure of correct placement, suction is engaged until negative pressure of 60 mmHg is reached. During the aspiration, which takes between 3 and 5 min, the cannula is gently rotated and/or moved back and forth, withdrawing only as far as the internal os until the flow of tissue and fluid has ceased and a gritty sensation is felt as the cannula moves against the wall of the contracted empty uterus. At this stage, the woman may feel a strong cramp. Calm and comforting conversation to distract the woman and explaining the meaning of unpleasant sensations will help her tolerate the procedure. Sharp curettage should be avoided. The vulsellum or tenaculum is removed and the cervix inspected for bleeding. Because of low rates of haemorrhage, oxytocics are not routinely administered. The operator should ascertain that the gestational sac and any fetal parts, consistent with the gestational age, have been removed. Continuous ultrasound guidance is increasingly used but is not required if the aspirate will be inspected. Once the operator is certain of completion, the woman should be reassured. Any concomitant procedures (e.g. insertion of IUC) can be performed before the woman is escorted into the recovery area.

Surgical abortion in the second trimester

Electric vacuum aspiration can be performed up to 16 weeks' gestation but the most frequently used method of surgical abortion in the second trimester is dilatation and evacuation (D&E). Characterized by advanced cervical preparation and removal of the fetus and placenta with specialized forceps, D&E is associated with a low risk of complications and is highly acceptable to women. When second-trimester surgical abortion was compared in a randomized trial with medical abortion, significantly fewer women found the surgical option worse than expected (0% vs. 53%, $P = 0.001$), and more would opt for a surgical procedure again if needed (100% vs. 53%, $P \leq 0.001$) [32]. A variant of D&E, intact dilatation and extraction (D&X), is performed after very wide (median 5 cm) cervical dilation is achieved using osmotic dilators over two or more days. This is followed by an assisted partial breech delivery, decompression of the calvarium, and delivery of the fetus otherwise intact. Hysterotomy and hysterectomy are outdated methods and only used when a transcervical approach is not possible. Obstruction by a large, distorting cervical or uterine tumour is an example of when these methods might be employed.

Adequate cervical preparation is essential for safe D&E provision. The amount of cervical expansion needed is related to gestational age, provider skill and the instruments being used. As a general rule, dilation should be sufficient to insert and open the extraction forceps and remove the fetal parts without resistance. Until about 16–17 weeks of gestation, sponge or McClintock forceps may be used so 1–1.5 cm dilation will suffice. After this point, longer forceps with wider

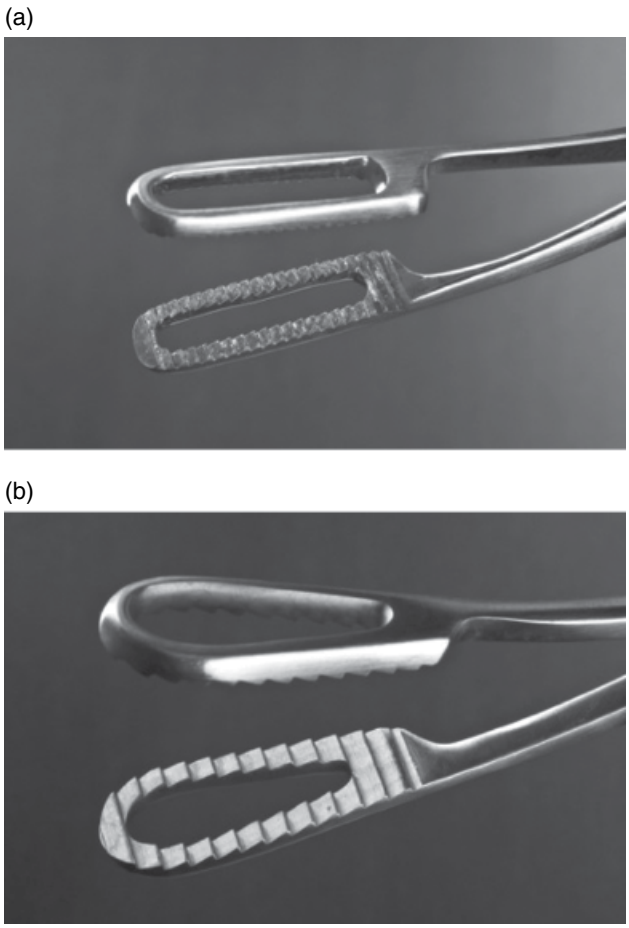

Fig. 44.3 (a) Sopher forceps; (b) Bierer forceps. *Source:* Ipas. Reproduced with permission of Ipas.

serrated jaws are used, requiring 1.5–3 cm or more dilation. Sopher and Bierer forceps, the jaws of which range from 12 to 19 mm in diameter, are typical (Fig. 44.3). Misoprostol or mifepristone can be used for cervical priming before D&E but additional mechanical dilatation is often required. Osmotic dilators provide superior cervical dilation throughout the second trimester [36] and are used by most providers from approximately 18 weeks' gestation. There are two types: laminaria made of compressed seaweed and Dilapan-S made of polyacrylate-based hydrogel. After insertion into the cervical canal, these devices swell over several hours causing expansion of the os. They also induce the release of natural prostaglandins leading to cervical softening. A preference for Dilapan or laminaria is provider-dependent and although more laminaria are required to achieve the same amount of dilation as Dilapan, a comparative trial found no differences in procedure time, blood loss or need for additional dilatation between devices [37].

Feticide is used before D&E by some abortion providers in the belief that the softening of fetal tissue after demise facilitates an easier, faster and safer evacuation. It is also used in response to patient preference or to avoid the risk of transient signs of life should extramural delivery occur. The most frequently used methods are intra-amniotic or intra-fetal injection of digoxin, and fetal intra-cardiac potassium chloride injection. Research is limited, but the few existing comparative studies suggest that feticide before D&E does not confer a clinical benefit and may increase risks. The only randomized controlled trial available found that intra-amniotic digoxin administered 24 hours before D&E did not reduce the duration of the procedure, blood loss or subjective difficulty of the procedure compared with placebo [38]. In addition, a before and after study found low but increased risks of extramural delivery and infection with the digoxin compared to non-use [39]. Cohort studies of fetal intracardiac potassium chloride injection before D&E differ as to whether it decreases operative times but found increased risks of cervical laceration and uterine atony compared with non-use or D&E in the setting of spontaneous demise [40,41].

D&E can be performed with local anaesthesia, conscious sedation or general anaesthesia. General anaesthesia or sedation predominates from about 18 weeks' gestation. In a study of over 11 000 second-trimester surgical abortions with intravenous anaesthesia without intubation, there were no cases of pulmonary aspiration supporting the safety of this technique beyond the first trimester [42].

Performing dilatation and evacuation

As with any surgical procedure, D&E requires competency-based training and ongoing operative experience. Skills are usually acquired in a graduated fashion, with competence demonstrated at earlier gestational ages before advancing to later ones. As with vacuum aspiration, techniques vary. The following describes the typical steps of a D&E with general anaesthesia.

Following pre-procedure checks, anaesthesia is induced and the woman is placed into the lithotomy position. A bivalve or Sims speculum is inserted and any osmotic dilators *in situ* are removed and counted. The cervix and vagina are cleansed. A vulsellum or tenaculum is placed and, applying gentle traction, additional mechanical dilatation is undertaken if required. The amniotic fluid is drained passively or actively with vacuum aspiration. This reduces the risk of amniotic fluid embolism and facilitates extraction from the lower uterine segment, which lessens the risk of perforation. Continuous ultrasound is recommended to guide instrumentation. Maintaining steady traction on the cervix, the forceps are inserted with the tips facing upward. Once the internal os is traversed, and remaining in the lower uterus, the jaws of the forceps are opened widely to grasp the presenting fetal part and then withdrawn while gently rotating. Multiple passes are used although the number can be

limited by achieving ample cervical dilation. Fetal parts and the placenta should be noted as they are removed and inspected afterward for completeness. A final vacuum aspiration is performed to remove any remaining blood or tissue. The amount of bleeding is assessed and the instruments are removed. A bimanual examination can ensure the uterine tone is firm and, if needed, uterotonics administered before the woman is moved into the recovery area.

Complications with surgical abortion

Among 170 000 first-trimester vacuum aspirations in low-risk women, minor complications occurred in 8.5 per 1000 cases and complications requiring hospitalization in 0.7 per 1000 cases [43]. D&E has a similar low rate of complications, although the risk of a major complication increases with gestational age. A history of two or more caesarean deliveries is the strongest predictor of a major complication with D&E (OR 7.4, 95% CI 3.4–15.8) [44].

Uterine perforation during vacuum aspiration ranges from 0.1 to 4 per 1000 procedures. With D&E, perforation occurs in 2–3 per 1000 procedures. A perforation with a small-diameter dilator or cannula in a haemodynamically stable woman may be managed conservatively with careful observation. Larger injuries, including those associated with D&E, or where there is active bleeding or haemodynamic instability, require laparoscopy or laparotomy. Cervical tears occur in 0.1–10 per 1000 procedures. External tears that are bleeding or larger than 1 cm will typically require repair with absorbable sutures. Larger or full-thickness tears at the level of the internal os will usually require operative intervention or embolization. Serious haemorrhage requiring hospitalization or transfusion occurs in fewer than 1 in 1000 cases. Significant bleeding is most commonly due to uterine atony, but may also be caused by trauma, retained tissue or coagulopathy. Retained tissue requiring re-aspiration occurs in up to 2 in 100 cases after first-trimester surgical abortion and up to 3 in 100 following second-trimester surgical abortion. Continuing pregnancy occurs in fewer than 1 in 1000 procedures performed at 12 weeks' gestation or less but is higher with uterine anomalies, multiparity, very early gestational age, and when performed by a less experienced surgeon.

Women and clinicians may be concerned that the amount of artificial dilation needed to perform D&E will affect the integrity of the internal cervical os, resulting in an increased risk of cervical incompetence, miscarriage and preterm birth. Neither retrospective case series nor a case–control study have found an association between D&E preceded by cervical preparation with overnight osmotic dilators and future pregnancy complications [45–47].

Summary box 44.4

- Vacuum aspiration is the preferred method for first-trimester surgical abortion and D&E in the second trimester.
- Surgical abortion may be offered in the earliest weeks of pregnancy following a protocol that includes inspection of the aspirate for the gestational sac and serum β-hCG determination if a missed abortion or ectopic pregnancy is suspected.
- Women should be reassured that the risk of major and minor complications with surgical abortion at all gestations is low.

Medical abortion

Medical abortion up to 9–10 weeks' gestation

The development of simple, highly effective regimens for abortion using mifepristone has transformed abortion care in the UK. Introduced in 1991, it is now the case that 50% of abortions in England and Wales and 81% in Scotland are conducted medically. Along with better funding of and access to abortion services in Britain, widespread availability of medical abortion in the earliest weeks of pregnancy has likely contributed to the growing proportion of abortions performed at less than 10 weeks' gestation. Early medical abortion refers to the use of abortifacient medications up to 63 days' gestation, although some regimens are effective beyond 63 days.

Mifepristone causes cervical softening, decidual necrosis and increased myometrial sensitivity to prostaglandins. Initially studied for use alone in very early pregnancy, it was found to be effective in only 60–80% of cases. However, when administered 24–48 hours before a prostaglandin analogue, efficacy increased to nearly 100%. Multiple randomized trials have since demonstrated that the combination of mifepristone and misoprostol is the most effective, well-tolerated and cost-effective regimen for early medical abortion [15]. Complete abortion without surgical intervention is achieved in upwards of 95% in most studies, with an ongoing pregnancy rate of 1% or less [48]. Misoprostol can be used alone but is less effective.

Contraindications to mifepristone/misoprostol are few but include chronic adrenal failure, inherited porphyria, coagulopathy, hypersensitivity to the medicines, and known or suspected ectopic pregnancy. Mifepristone is an anti-glucocorticoid, and thus caution is also advised for women using long-term corticosteroids or with conditions that may require steroid treatment in case of exacerbation such as severe, poorly controlled asthma. Caution is advised with hepatic or renal failure or malnutrition. If a woman has an intrauterine contraceptive in

place, it will need to be removed before initiating treatment. Most protocols also exclude women with haemoglobin levels less than 90–100 g/L as blood transfusion rates, although very low, are higher with medical than surgical procedures.

The recommended regimen at a gestation of 63 days or less consists of 200 mg oral mifepristone followed 24–48 hours later by 800 μg misoprostol which may be given by the vaginal, sublingual or buccal route. For many years, 600 mg mifepristone was recommended but the lower dose is as effective [49]. Mifepristone and 400 μg oral misoprostol may be used at 49 days or less of gestation, but has an unacceptably high failure rate after this gestation, even if the dose of misoprostol is doubled.

Several studies have explored whether the interval between mifepristone and misoprostol can be reduced below 24 hours or extended beyond 48 hours. A meta-analysis of randomized trials found no difference in overall efficacy with intervals of 0–72 hours, but there was a trend toward lower success with less than 8 hours between medications [50].

The extension of an early medical abortion regimen to 70 days' gestation has been the subject of recent research. A review of published studies using 200 mg oral mifepristone and a range of misoprostol doses and routes showed no statistically significant difference in overall success at 57–63 days' gestation and at 64–70 days' gestation (93.9% vs. 92.3%, $P = 0.08$) [51]. The ongoing pregnancy rate was 3.1% at 64–70 days (95% CI 2.9–4.5) but most women reported satisfaction with treatment.

Most early medical abortions are undertaken outside of a medical facility. In many countries, women are given tablets of misoprostol to take home and use within a specified interval, followed by abortion at home. A large body of evidence demonstrates that this is safe, effective and acceptable to women [52]. Recent research also shows that use of mifepristone at home is safe and preferred by many women. The Secretary of State for Health has the power to allocate 'home' as a class of place for the purposes of early medical abortion in Britain. This has recently occurred in Scotland and is planned for Wales, but it remains the case that women in England may not use medications for abortion outside of a clinical setting. Where home use is not allowed, women must attend for both mifepristone and misoprostol administrations. They need not be admitted after either and the vast majority go home after misoprostol to pass the pregnancy at home.

Symptoms after mifepristone are minimal but some women will bleed in the interval before misoprostol is administered and a small number will miscarry. Misoprostol induces bleeding and uterine cramping within 2 hours of use. Most women will pass the pregnancy within 4 hours and almost all by 24 hours. Oral analgesia with NSAIDs or mild opioids is commonly needed. Paracetamol is less effective than ibuprofen for pain reduction [53]. Other side effects caused by misoprostol include nausea and vomiting, diarrhoea, and transient fever and chills. Vaginal administration is associated with the fewest gastrointestinal side effects and sublingual with the most frequent reports of fever and chills. Information must be provided about expected signs and symptoms as well as the signs of possible complications and whom to contact should they occur. These include vaginal bleeding that soaks more than two sanitary pads for two consecutive hours, a persistent temperature greater than 38 °C, severe abdominal pain unrelieved by analgesics, nausea, vomiting or diarrhoea that continues more than 24 hours after misoprostol administration, and the persistence of pregnancy symptoms 1–2 weeks after medication administration. Women aborting at home should be told what if anything they may see (i.e. gestational sac, clots, fetus) and advised on appropriate disposal of fetal remains [54].

Medical abortion after 9–10 weeks' gestation

Medical abortion may be used throughout the late first and second trimester. Failure rates and bleeding complications are higher with medical than surgical abortion at these gestations; however, if clinicians are not trained to provide D&E, medical abortion is an effective alternative. Mifepristone and misoprostol regimens are the most efficacious with the shortest induction-to-abortion interval (the time between the administration of misoprostol and the passage of the fetus). The median induction-to-abortion interval with a combined regimen is 6–8 hours in most studies. Misoprostol may also be used alone but the median interval is increased significantly to 12–16 hours.

The regimen for which there is the most evidence employs a 200-mg oral dose of mifepristone followed 24–48 hours later by admission to a clinical facility and administration of an initial 800-μg dose of vaginal misoprostol. Every 3 hours, a further 400 μg of misoprostol is administered vaginally, sublingually or orally until expulsion occurs. Routine instrumental removal of the placenta after fetal expulsion is not necessary; misoprostol may be continued.

In a consecutive series of 1076 women at 64–91 days' gestation treated with this regimen, the overall complete abortion rate was 96% and the median induction-to-abortion interval was 4.8 hours (range 0–74.9 hours) [55]. The rate of surgical evacuation increased linearly with gestational age: 2.7% at 64–70 days, 3.3% at 71–77 days, 5.1% at 78–84 days, and 8.0% at 85–91 days ($P = 0.02$). The same group published the outcomes of 1002 cases at 13–21 weeks' gestation and reported that 97% aborted within five doses of misoprostol and the median induction-to-abortion interval was 6.25 hours (range 0–67.5 hours) [56]. The interval between mifepristone and the initiation of misoprostol can be reduced to 12 or 24 hours, which increases the induction-to-abortion interval by 1–2 hours [57].

The severity of pain with medical abortion increases with gestational age and several oral and parenteral NSAIDs and opioids should be made available. Diclofenac given with the first dose of misoprostol between 13 and 22 weeks of gestation does not interfere with the action of the misoprostol and reduces the need for opioid injections [58].

Complications with medical abortion

Serious adverse events with early medical abortion are rare. Among 233 805 early medical abortions provided within a large network of abortion clinics in the USA, the rate of clinically significant adverse events (e.g. hospital admission, blood transfusion, treatment with intravenous antibiotics, death) was 1.6 per 1000 cases. Two significant adverse outcomes were also reported in this study, undiagnosed ectopic pregnancy and ongoing pregnancy, with rates of 7 in 10 000 and 5 in 1000 cases, respectively. Overall, 3–5 per 1000 early medical abortions will require surgical intervention, typically due to persistent bleeding, continuing pregnancy or retained non-viable pregnancy or tissue.

In the late first and second trimester, complications with medical abortion are comparatively higher than with surgical abortion, mainly due to retained placental tissue and associated heavy bleeding. Transfusion is required in 5–7 per 1000 second-trimester medical abortions and surgical intervention in up to 8 per 100 procedures. Cervical and uterine injury is largely obviated by avoiding instrumentation with medical abortion. However, uterine rupture can occur with second-trimester medical abortion and is associated with a prior history of caesarean delivery. A systematic review estimated the risk of uterine rupture in women with prior caesarean delivery to be less than 3 in 1000, and 4 in 10 000 without a history of caesarean delivery [59].

Mifepristone is not feticidal and transient signs of life can present medicolegal and emotional challenges for women and healthcare providers offering medical abortion in the peri-viable period. The RCOG recommends feticide from 22 weeks' gestation to avoid signs of life at delivery [15].

Summary box 44.5

- Mifepristone and misoprostol is the most effective regimen for first- and second-trimester medical abortion and has the shortest induction-to-abortion interval.
- Early medical abortion with mifepristone and misoprostol may be safely undertaken in a non-clinical environment; after 9-10 weeks' gestation, admission to a clinical facility is typically required.
- Complications are mainly due to retained tissue and bleeding and may require surgical managment.

Aftercare

When a surgical or medical abortion is uncomplicated and the success of the procedure is immediately verified, routine follow-up is not necessary. Providing a 24-hour aftercare telephone line is common and ready access to follow-up visits should be available if needed. A woman should be advised to be in contact if she experiences signs of ongoing pregnancy or for other medical reasons such as prolonged heavy bleeding, fever, and persistent or severe pain.

Protocols for early medical abortion undertaken outside of a clinical setting often require the woman to return 7–14 days after treatment to confirm that she is no longer pregnant. Where ultrasound is used, measurement of endometrial thickness as an indicator of incomplete abortion is not recommended as it is an unreliable predictor of the need for surgical evacuation and can lead to unnecessary interventions.

The use of a low- or high-sensitivity urine pregnancy test 2–4 weeks after early medical abortion often alongside a symptom checklist is also accurate at identifying failed procedures and is preferred by women. Protocols may include a telephone assessment of symptoms with a provider or self-assessment. Urine pregnancy tests are affordable, readily available and user-friendly but caution should be used when interpreting a positive result. Even though β-hCG levels drop precipitously after an abortion, highly sensitive tests (25 mIU/mL) are still inconclusive or falsely positive 66% of the time at 2 weeks [60] and 20% of the time at 4 weeks after abortion [61]. In these cases, an ultrasound can be performed to determine whether the pregnancy is continuing. Self-assessment with a semi-quantitative urine pregnancy test that measures urine β-hCG levels of 25, 100, 500, 2000 and 10 000 mIU/mL has been studied with promising results [62]. In a prospective open label trial, the test was performed before and 1 week after medication administration and pregnancy was considered ongoing if the follow-up reading was the same or higher than the baseline results. Sensitivity and specificity were calculated at 100% and 97%, respectively, and 91% of participants found the test to be 'very easy' or 'easy' to use.

Summary box 44.6

- Routine follow-up after surgical abortion or where a medical abortion has been verified as complete is not required.
- All women should be able to access a follow-up visit if they want one.
- Follow-up after early medical abortion conducted outside of a medical facility can be safely and effectively managed without an in-clinic visit by employing a high- or low-sensitivity pregnancy test and checklist of symptoms.

Conclusions

Abortion is an integral part of women's healthcare. Healthcare practitioners should be familiar with the standards of care relevant to this common procedure. Counselling before treatment should be supportive, non-directive and focused on the patient's needs. Surgical and medical abortion methods are both safe and effective throughout the first and second trimesters of pregnancy. A choice should be available to women. For those women wishing to use it, contraception can be easily integrated into abortion care.

Acute Pelvic Infection

Jonathan D.C. Ross

University Hospital Birmingham NHS Foundation Trust, Birmingham, UK

Summary box 45.1

Overview of pelvic infection

- Pelvic inflammatory disease is a common and often asymptomatic problem in young women.
- Confirmation with a microbiological diagnosis is often not possible.
- Antibiotics are very effective in controlling symptoms when present.
- Surgical intervention is seldom required.
- A single episode of pelvic inflammatory disease treated early with appropriate antibiotics is associated with well-preserved fertility.

Pelvic infection is common and usually results from sexually transmitted pathogens ascending from the lower to upper genital tract. Infection can also occur following pelvic surgery, in the puerperium and after instrumenting the uterus.

Epidemiology and risk factors

How common is pelvic inflammatory disease?

Pelvic inflammatory disease (PID) is a major cause of morbidity in young women, although its incidence in primary and secondary care has been falling for several years. About 2% of young women in the UK give a history of PID when asked, and about 1 in 50 consultations made by young women with general practitioners relate to PID [1].

Who gets pelvic inflammatory disease?

The risk factors for PID strongly reflect those of any sexually transmitted infection (STI) – young age, multiple sexual partners, lack of condom use, lower socioeconomic status and Black Caribbean/Black African ethnicity. What is less certain is why some women with lower genital tract infection go on to develop upper genital tract disease. What factors encourage infection to spread from the vagina or cervix to the endometrium and fallopian tubes?

Cervical mucus provides an important barrier to ascending infection. Young women with anovulatory cycles have thinner cervical mucus and this, combined with higher rates of cervical ectopy and riskier sexual behaviour, may account for their high rates of PID. The ability of the immune response to control and contain infection will also determine the risk of upper genital tract involvement. Part of that immune response is genetically determined and an increased risk of PID is observed in women of human leucocyte antigen (HLA) subtype A31, while women with HLA-DQA 0501 and HLA-DQB 0402 have lower rates of infertility following a diagnosis of PID. Polymorphisms in TLR4 and CCR5 antigen receptors, and variable expression of interleukin (IL)-10, may also have a role. It is possible that certain strains of bacteria are more likely to cause PID than others, but the evidence for this is limited (e.g. serogroup A *Neisseria gonorrhoeae,* serovar F *Chlamydia trachomatis*).

Differences in behaviour have been linked to the risk of PID. A clear association can be seen between vaginal douching and PID but more recent longitudinal studies suggest that douching does not cause PID; rather, it would appear that the vaginal discharge and menstrual

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

irregularities associated with PID may themselves lead to more douching [2]. Women who smoke are at higher risk of PID but it is unclear whether this is a marker for high-risk sexual behaviour or a direct effect of smoking itself on immune surveillance.

Many women with PID also have bacterial vaginosis with overgrowth of the normal commensal bacteria in the vagina and loss of vaginal lactobacilli. These same vaginal commensal bacteria are often isolated from the upper genital tract, raising the possibility that bacterial vaginosis may lead to PID. Longitudinal studies do not support a direct causal association, although women who contract gonorrhoea or chlamydia are at higher risk of PID if they also have pre-existing bacterial vaginosis, suggesting some synergy between the different infections [3].

The cost of treating pelvic inflammatory disease

The psychological and fiscal costs of PID are substantial. The uncertainty of the diagnosis and difficulty in predicting the subsequent risk of infertility, chronic pelvic pain or ectopic pregnancy add to the anxiety, and are in addition to the feelings of blame, guilt and isolation that the diagnosis of an STI may instil. Most of the monetary costs of PID arise from surgical interventions to diagnose and treat the consequences of tubal damage, and have been estimated at between £200 and £2000 per case [4]. These costs will rise substantially with improved availability of infertility treatments in the future.

Microbiology

Pelvic inflammatory disease is a polymicrobial infection. *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most frequently recognized pathogens but a wide variety of other bacteria and viruses can also be isolated from the fallopian tubes of women with PID (Table 45.1).

Table 45.1 Organisms associated with pelvic inflammatory disease.

Aerobic/facultative anaerobic
Neisseria gonorrhoeae
Chlamydia trachomatis
Ureaplasma urealyticum
Mycoplasma genitalium
Gardnerella vaginalis
Streptococcus pyogenes
Coagulase-negative staphylococci
Escherichia coli
Haemophilus influenzae
Mycoplasma hominis
Streptococcus pneumoniae
Mycobacterium tuberculosis
Anaerobic
Bacteroides sp.
Peptostreptococcus sp.
Clostridium bifermentans
Fusobacterium sp.
Viruses
Herpes simplex virus
Echovirus
Coxsackievirus
Respiratory syncytial virus

Bacteria

Neisseria gonorrhoeae

Neisseria gonorrhoeae is a Gram-negative diplococcus, so that when a sample of cervical discharge is spread and fixed on a slide the bacteria can be seen on microscopy as pairs of red kidney-shaped organisms, mostly sitting within polymorphs. Gonorrhoea causes about 2–3% of PID in the UK (see Table 45.5 and Further reading for data sources).

Neisseria gonorrhoeae initially infects the cervix but ascends to the upper genital tract in 5–10% of untreated cases. Around half of women with gonorrhoea are asymptomatic, but when symptoms are present the vaginal discharge tends to be thick and purulent. Although detecting gonorrhoea from the cervix supports a diagnosis of PID, its absence in the lower genital tract cannot exclude infection in the fallopian tubes or ovaries.

Chlamydia trachomatis

Chlamydia trachomatis is an unusual bacterium as it requires a host cell to grow (obligate intracellular organism), behaving in some ways more like a virus. The availability of sensitive nucleic acid amplification tests (NAATs) allows the use of vulvo-vaginal swabs for testing (which the patient can take herself after appropriate instruction). Urine has a lower detection rate but can be used if it is the only sample available. Light microscopy is not useful since *C. trachomatis* is too small to be seen.

Chlamydia, like gonorrhoea, initially infects the cervix and sometimes also the urethra. It is the commonest identified cause of PID in the UK, accounting for 30% of cases, and causes a more chronic low-grade infection than gonorrhoea. Over two-thirds of women with chlamydial infection are asymptomatic.

Mycoplasma genitalium

The evidence for a role of *Mycoplasma genitalium* in the pathogenesis of PID is substantial [5]. It has been isolated

from the cervix, endometrium and, in a small number of cases, fallopian tubes of women with PID. Tubal factor infertility is strongly associated with past infection with *M. genitalium*, and inoculation of the lower genital tract with mycoplasma causes PID in female monkeys [6]. Testing for *M. genitalium* has recently become available as a commercially available test.

Anaerobes

Anaerobic bacteria are of particular importance in women with severe PID, and can often be isolated from tubo-ovarian abscesses. Their role in mild to moderate PID is less clear. *Bacteroides fragilis*, *Peptostreptococcus* and *Peptococcus* can all be isolated from the genital tract of women with PID and the production of mucinases and sialidases by anaerobic bacteria may break down cervical mucus, thus facilitating the passage of other bacteria into the upper genital tract.

Actinomyces

Actinomyces israeli is occasionally detected in women with an intrauterine contraceptive device (IUCD) *in situ*. If there are no symptoms of vaginal discharge, intermenstrual bleeding or pelvic pain, then the woman should be advised that neither treatment nor removal of the IUCD is required, but she should be reviewed in 6 months or earlier if symptoms develop. If symptoms are present, then at least 2 weeks' therapy with a penicillin, tetracycline or macrolide antibiotic is indicated and the IUCD should be removed.

Mycobacterium tuberculosis

Tuberculous PID is largely limited to patients from developing countries. Pelvic infection usually occurs secondary to haematogenous spread from an extragenital source, but occasionally *Mycobacterium tuberculosis* can be transmitted sexually [7]. Usually it is not possible to detect the organism in the lower genital tract and samples should be obtained by uterine curettage or from the fallopian tubes at laparoscopy to be sent for culture or nucleic acid testing. Standard quadruple antituberculous therapy with isoniazid, rifampicin, ethambutol and pyrazinamide is effective but surgical intervention may be required for extensive disease.

Viruses

A number of viruses have been isolated from the upper genital tract in women with PID (Table 45.1) but their role in pathogenesis is unclear.

Clinical presentation

Clinical features

The clinical diagnosis of PID is based on the presence of lower abdominal pain, usually bilateral, combined with either adnexal tenderness or cervical excitation on vaginal examination (Fig. 45.1). A comprehensive medical history and examination including an accurate menstrual and sexual history may help to reach a diagnosis. A pelvic examination is essential and a speculum examination is useful for identifying lower genital tract inflammation and excluding foreign bodies in the vagina such as retained tampons. The poor specificity and associated low positive predictive value of this approach (65–90%) is justified because a delay in antibiotic therapy of even a few days may increase the risk of impaired fertility [8]. The risks of giving antibiotics to a woman who turns out not to have PID are low, although important differential diagnoses first need to be excluded.

Other clinical features can support a diagnosis of PID but are not essential before starting empirical therapy:

- intermenstrual or post-coital bleeding, resulting from endometritis and cervicitis;
- deep dyspareunia;
- abnormal vaginal discharge, indicating lower genital tract infection;
- fever is non-specific and usually only present in moderate to severe PID;
- nausea/vomiting may occur in severe PID but is more commonly associated with appendicitis.

PID caused by gonorrhoea presents more acutely and is more severe compared with chlamydial PID [9]. It is

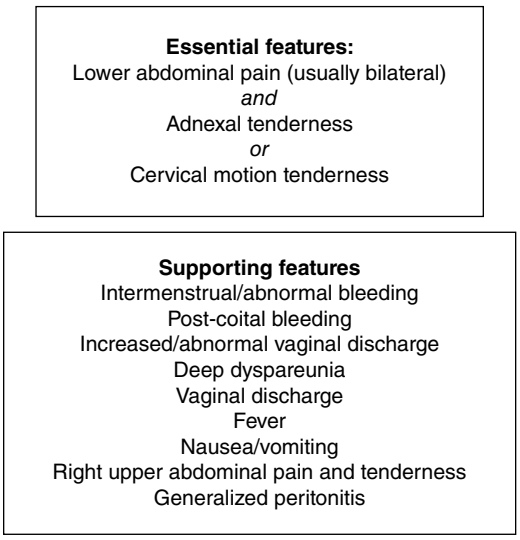

Fig. 45.1 Diagnosing pelvic infection.

worth remembering that for every woman presenting with clinical features of PID there are two others who are asymptomatic.

Fitz-Hugh–Curtis syndrome

Inflammation and infection of the liver capsule (perihepatitis) affects 10–20% of women with gonococcal or chlamydial PID and occasionally dominates the clinical presentation. Patients complain of right upper abdominal pain and have tenderness at the liver edge, occasionally accompanied by a hepatic friction rub.

Differential diagnosis

The main differential diagnoses are given in Table 45.2. The features that classically lead towards a diagnosis of PID are the typical 'G string' distribution of the pain and bilateral tenderness on pelvic examination. In bowel-related disorders the pain tends to be higher in the abdomen and more central or to the left. Other conditions tend to give unilateral pain, at least at their onset. The main diagnoses to exclude are ectopic pregnancy and causes of an acute abdomen, which may require surgical intervention, such as appendicitis and ovarian 'accident' (e.g. torsion or persistent bleeding from a ruptured cyst). If the diagnosis is not clear, then empirical treatment with antibiotics should be commenced, but the patient kept under close observation to ensure that an alternative diagnosis has not been missed.

Table 45.2 Differential diagnosis of pelvic inflammatory disease.

Differential diagnosis	Significant features
Ectopic pregnancy	Menstrual history, initially unilateral pain
Ovarian cyst rupture/torsion	Initially unilateral pain, often mid-cycle
Appendicitis	Gastrointestinal symptoms, right-sided pain
Irritable bowel syndrome	Central or left-sided pain, no cervical excitation, bowel symptoms
Inflammatory bowel disease, e.g. Crohn's disease, ulcerative colitis, diverticular disease	Colicky central or left-sided abdominal pain, bowel symptoms
Urinary tract infection	Urinary frequency with or without loin pain
Bowel torsion	Central abdominal pain
Psychosomatic pain	Usually inconsistent symptoms

Investigation

Summary box 45.2

Before diagnosing pelvic inflammatory disease:

- perform a pregnancy test to help exclude ectopic pregnancy;
- screen for STIs.

Rather like signs and symptoms, the investigations available to diagnose acute PID lack accuracy. Blood tests such as a white cell count, erythrocyte sedimentation rate and C-reactive protein are all relatively non-specific. They may be elevated in PID but in mild cases can be normal. In particular, a leucocytosis is often not seen in non-pyogenic infections.

A urinary pregnancy test is mandatory to exclude an ectopic pregnancy. Ideally this should be performed before commencing empirical antibiotic treatment.

Microbiological tests

All women presenting with possible PID should be offered an NAAT to check for the presence of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* on a vulvo-vaginal swab (Fig. 45.2). The alternative enzyme-linked immunosorbent assays lack sensitivity. NAATs for *N. gonorrhoeae* have greater sensitivity than culture but confirmation of a positive NAAT (using a second NAAT which has a different primer target) is required because of the risk of false-positive results. Testing for *Mycoplasma genitalium* is advisable and should be performed when available since it may alter the choice of therapy.

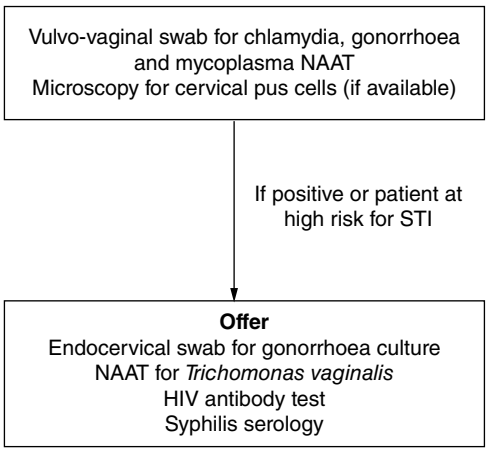

Fig. 45.2 Microbiological investigation of women with pelvic infection.

The detection of gonorrhoea, chlamydia or mycoplasma in the lower genital tract greatly increases the likelihood of PID as the cause of lower abdominal pain, but many women with PID also have a negative infection screen from the lower genital tract.

A lack of polymorphs on a Gram-stained smear of cervical discharge makes PID unlikely but their presence is non-specific, i.e. the absence of polymorphs has good negative predictive value but their presence has poor positive predictive value for PID [10].

Screening for other STIs should be offered to women who test positive for gonorrhoea or chlamydia, and to those who are at higher risk of infection (e.g. two or more partners within the past year, lack of condom use or previous history of an STI). An appropriate screen would include:

- NAAT for *Trichomonas vaginalis* from a vulvo-vaginal sample;
- endocervical swab for *N. gonorrhoeae* culture, which should be placed in transport medium (either Stuart or Amies) and arrive at the laboratory preferably within 6 hours but certainly within 24 hours, otherwise viability is rapidly lost;
- HIV antibody test; and
- syphilis serology.

If laparoscopy or laparotomy is performed, then specimens from the fallopian tube should also be sent requesting bacterial culture, including gonorrhoea. *Chlamydia* NAATs are not licensed for use for fallopian tube samples and therefore require cautious interpretation.

Radiology investigations

Transvaginal ultrasound of the pelvis may be useful where there is diagnostic difficulty. However, there are no features that are pathognomonic of acute PID. Free fluid in the pouch of Douglas is a common normal finding and is therefore not helpful. The value of ultrasonography generally lies in helping to exclude other pathology such as ectopic pregnancy, ovarian cysts or appendicitis, although it can also identify dilated fallopian tubes or a tubal abscess [11]. However, this investigation may not be readily available in an emergency setting.

MRI can assist in making the diagnosis where there is difficulty, but it is also not widely available and has not entered routine management. CT scanning in acute PID may show obscuring of the pelvic fascial planes, thickening of the uterosacral ligaments and accumulation of fluid in the tubes and endometrial canal. In the upper abdomen it can provide evidence of perihepatitis. Enhancement of the hepatic and splenic capsules on abdominal CT scan has been suggested as characteristic of Fitz-Hugh–Curtis syndrome but it is of little value as a routine investigation.

Surgical investigation

For many years the definitive diagnostic procedure for PID was considered to be laparoscopy and it probably remains more sensitive than any other investigation currently available. In many cases there will be clear evidence of dilated hyperaemic tubes with an inflammatory fibrinous exudate covering the tubes and the fundus of the uterus. In mild cases, however, intraluminal inflammation of the tubes may be missed and significant inter- and intra-observer variation in interpreting the appearance of salpingitis at laparoscopy has been reported [12]. It does enable swabs to be taken from the fimbrial ends of the tubes, which may be more accurate than endocervical swabs, but the principal benefit of laparoscopy is to exclude other diagnoses. As an invasive procedure it should be reserved for those cases where there is an element of doubt as to the diagnosis of acute PID or in cases where the patient fails to respond to antibiotics within 48–72 hours.

There is no evidence to support the routine use of hysteroscopy or endometrial biopsy in the diagnosis of acute PID. More invasive endoscopic techniques, such as fallaposcopy, may be potentially dangerous and have no place in management.

Histology and pathology

The spread of infection from the cervix to the endometrium leads to an acute, predominantly polymorph-mediated endometritis [13]. Transcervical suction biopsy of the endometrium allows assessment of the endometrial inflammation, which correlates well with salpingitis. Unfortunately, the usefulness of this approach to diagnose PID is limited by the risk of introducing infection during the procedure, the time delay in fixing and staining the sample, and the uncertain significance of isolated endometritis.

The inflammatory response seen in the fallopian tubes depends on the underlying pathogen. Gonorrhoea infects the non-ciliated epithelial cells but production of tumour necrosis factor and gamma interferon soon lead to collateral damage to the surrounding tissue and invasion of the submucosa. The tissue damage associated with *Chlamydia* is mediated primarily by the immune response to the infection that occurs as a result of a delayed-type hypersensitivity reaction to a chlamydial heat shock protein. This is characterized by a low-grade lymphocytic response compared with the acute neutrophil response of gonococcal salpingitis.

Recurrent infection with *Chlamydia* causes further immune stimulation, possibly mediated by a cross-reaction between chlamydial and human heat shock protein 60 [14]. This exaggerated immune response following

re-exposure to *Chlamydia* may explain the exponential increase in the risk of tubal damage that occurs with repeated infection.

Severe inflammation is associated with tubal occlusion and the production of a tubo-ovarian abscess or hydrosalpinx. Healing following acute inflammation may produce chronic fibrosis with associated damage to the ciliated epithelium, tubal blockage and/or pelvic adhesions. Histologically, this chronic damage produces lymphoid follicles and a mononuclear cell infiltrate.

Treatment

Summary box 45.3

Treating pelvic infection

- Start appropriate antibiotics promptly after making a clinical diagnosis.
- Arrange for the patient's partner to be screened for STI and receive empirical antibiotics.
- Ensure that the patient and her partner(s) are treated concurrently.
- Provide information about future use of condoms.
- Discuss the implications of a diagnosis of PID on future fertility.

Patients who are systemically unwell should be advised to rest and should be prescribed adequate analgesia. Regular review to assess progress is required. If no improvement is observed after 3 days of antibiotic therapy, then alternative diagnoses should be considered. Most patients can be managed as outpatients, but those with severe symptoms, such as an acute abdomen, will require inpatient care. If the diagnosis is in doubt or if intravenous antibiotics are considered to be necessary, the patient should be admitted to hospital.

Antimicrobials

Broad-spectrum antibiotic cover to include gonorrhoea, chlamydia and anaerobes is required. The optimal choice of antibiotics may be affected by knowledge of local bacterial resistance patterns, severity of disease, cost and patient convenience. Parenteral therapy should be continued until 24 hours after clinical improvement and then switched to oral. Randomized controlled trial evidence is available to support the use of the antibiotic regimens listed in Table 45.3 for outpatients and in Table 45.4 for inpatients. Women with *M. genitalium*-associated PID should be treated with moxifloxacin.

Table 45.3 Outpatient antibiotic regimens.

Regimen 1*	Ofloxacin 400 mg b.d. *plus* metronidazole 400 mg b.d.
Regimen 2*	Moxifloxacin 400 mg once daily
Regimen 3*	Ceftriaxone 500 mg i.m. immediately *plus* doxycycline 100 mg b.d. *plus* metronidazole 400 mg b.d.

*To complete 14 days of therapy.
b.d., twice daily.

Table 45.4 Inpatient antibiotic regimens.

Regimen 1	Ceftriaxone 2 g i.v. daily *plus* i.v. or oral doxycycline 100 mg b.d. *followed by** oral doxycycline 100 mg b.d. *plus* metronidazole 400 mg b.d.
Regimen 2	Clindamycin 900 mg i.v. t.i.d. *plus* i.v. gentamicin 2 mg/kg loading dose followed by 1.5 mg/kg t.i.d. (a single daily dose may also be used) *followed by** oral doxycycline 100 mg b.d. *plus* metronidazole 400 mg b.d.
Regimen 3	Ofloxacin 400 mg i.v. b.d. *plus* metronidazole 500 mg i.v. t.i.d. *followed by** oral ofloxacin 400 mg b.d. *plus* oral metronidazole 400 mg b.d.

*Parenteral therapy should be continued until 24 hours after clinical improvement. Oral therapy to continue to complete 14 days of antibiotics in total.
b.d., twice daily; t.i.d., three times daily.

Quinolone resistance in gonorrhoea is common in many areas of the world and is rising in the UK. Ofloxacin or moxifloxacin should therefore be avoided if there is clinical suspicion of gonococcal PID as a result of, for example, clinically severe disease, a history of a partner with gonorrhoea, or sexual contact abroad. Oral metronidazole can be discontinued in those with mild to moderate PID if the patient is unable to tolerate it.

A 'test of cure' to ensure resolution of the infection is required for women infected with *N. gonorrhoeae* (2 weeks after treatment) or *M. genitalium* (4 weeks after treatment).

Management of partners

PID is usually secondary to a sexually acquired infection, so unless the male partner(s) are identified and either screened for infection or treated empirically, the woman with PID is at high risk of recurrence. Current male partners should be offered screening for gonorrhoea and chlamydia (and *M. genitalium* if his partner was found to be infected), and attempts made

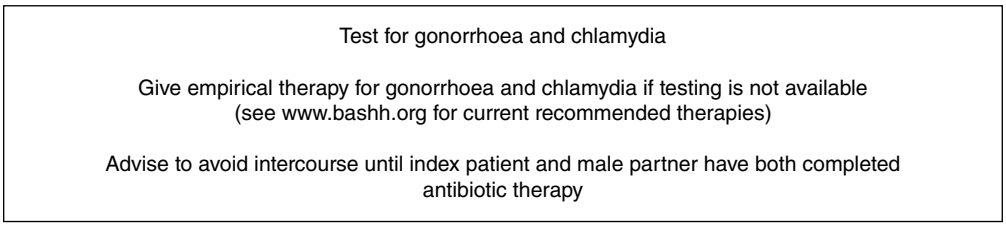

Fig. 45.3 Management of the male partners of women with pelvic infection.

to contact other partners within the past 6 months, although the exact time period will be influenced by the sexual history. If screening for sexually acquired infections is not possible, then antibiotic therapy effective against gonorrhoea and chlamydia should be given empirically to the male partner(s) (see British Association for Sexual Health and HIV guidelines for up-to-date treatment recommendations at www.bashh.org) (Fig. 45.3).

The patient and her partner(s) should be advised to avoid intercourse until both have either completed the treatment course or tested negative for STIs.

Summary box 45.4

Clinical review after PID

- Review response to treatment.
- Ensure that the full course of antibiotics has been taken.
- Check whether the patient's partner(s) has been seen and treated.
- Reinforce advice regarding future condom use.

Surgical intervention

Surgical intervention is rarely required as a treatment for acute PID. Most patients present at an early enough stage of the disease for antibiotic treatment to be fully effective. However, there may be an indication for laparoscopy or laparotomy to drain a pelvic abscess if this is diagnosed on ultrasonography and does not appear to be resolving with conservative antibiotic treatment.

On the rare occasion when pelvic actinomyces is suspected, surgery should be avoided. The history is likely to be more chronic than in acute PID and there is usually clear clinical evidence of a pelvic mass which does not appear to be an abscess on ultrasound scanning. There is also usually a history of recent use of an IUCD. If surgery is performed, then there is a significant risk of bowel damage.

Prognosis

The evidence quantifying the frequency of sequelae of PID is complicated by the variable definitions and diagnostic criteria used to identify the index episode of infection.

Chronic pelvic pain

It is generally accepted that episodes of acute PID can lead to symptoms of chronic pelvic pain. However, the cause of the chronic pelvic pain remains controversial. It may be that damaged tubes act as a nidus for recurrent infections or it may be due to adhesions tethering or encapsulating the pelvic organs. It is even possible that the pain is due to altered behaviour of pelvic nerves damaged by infection. There is also limited evidence as to the incidence of chronic pelvic pain resulting from single or multiple episodes of acute PID. It can be as high as 33% after recurrent episodes [15] and can have a significant effect on a patient's future quality of life [16]. The precautionary use of condoms after an episode of pelvic infection has been found to reduce the risk of chronic pelvic pain developing.

Subfertility and ectopic pregnancy

There is clear, population-based, epidemiological evidence of the relationship between a finding of *Chlamydia trachomatis*-specific IgG antibodies and subsequent tubal subfertility [17]. Some cohort studies have shown a rate of subsequent involuntary infertility of up to 40% after a single episode of PID [18]. There is a relationship between the risk of subfertility and the severity of infection, with a relative risk of 5.6 for severe infection compared with mild infection [19]. More recent prospective studies (in clinically mild/moderate disease) have suggested that infertility rates are not significantly increased following a single episode of PID treated appropriately [15]. There is also clear epidemiological evidence of a relationship between the risk of ectopic pregnancy and a previous episode of PID. In laparoscopically proven cases of PID, the risk of an ectopic in the subsequent index pregnancy

is six times greater than in controls [19]. However, the absolute risk of ectopic pregnancy remains low at 0.5–1%, at least in women with mild to moderate disease [15].

Special circumstances

Pregnancy

PID associated with an intrauterine pregnancy is extremely rare except in cases of septic miscarriage. Cervicitis is more common and associated with increased fetal and maternal morbidity. Treatment regimens will depend on the organisms isolated while avoiding those antibiotics that are contraindicated in pregnancy (e.g. tetracycline). Erythromycin and amoxicillin are not known to be harmful in pregnancy. In cases of septic abortion the organisms are more likely to be pyogenic than sexually transmitted. The use of broad-spectrum antibiotics, such as a third-generation cephalosporin together with azithromycin and metronidazole, would comprise a suitable regimen.

Mild endometritis following surgical termination of pregnancy is relatively common (approximately 1–2%) and needs to be treated aggressively to ensure future fertility. If pretreatment screening for STI has been employed, it is very unusual to find a positive result on repeat swabs. However, it is prudent to treat with a broad spectrum of antibiotics effective against both *Chlamydia* and anaerobes (e.g. ofloxacin plus metronidazole, or moxifloxacin).

Post pelvic surgery

Pelvic surgery such as hysterectomy is invariably associated with a significant risk of postoperative infection because it is virtually impossible to render the vagina totally aseptic. Prophylactic antibiotics are usually used during surgery, but postoperative pelvic infections, usually secondary to haematoma formation, are not uncommon. Most infections are caused by anaerobes and should be treated with a regimen that includes metronidazole or co-amoxiclav.

Pelvic infection and intrauterine contraceptive devices

An IUCD only increases the risk of developing PID in the first few weeks after insertion and, except for subacute infections with *Actinomyces*, there appears to be no evidence of increased risk with the continuing use of an IUCD. Routine screening for chlamydia, gonorrhoea and bacterial vaginosis before insertion is likely to reduce the risk of PID in those women requiring an IUCD. The use of progesterone IUCDs has been associated with very low rates of PID.

The randomized controlled trial evidence for whether an IUCD should be left *in situ* or removed in women presenting with PID is limited [20,21]. Removal of the IUCD should be considered and may be associated with better short-term clinical outcomes [20], but the decision to remove the device needs to be balanced against the risk of pregnancy in those who have had otherwise unprotected intercourse in the preceding 7 days. Hormonal emergency contraception may be appropriate for some women in this situation.

Human immunodeficiency virus

Women with HIV may have a more severe clinical presentation of PID, particularly in late-stage HIV disease associated with severe immunosuppression. No alteration in therapy is required, although caution is needed to check for any interactions between the PID treatment and antiretroviral medication.

Prevention

Chlamydia screening programme

Chlamydia is the commonest identified pathogen causing PID in the UK. Initial infection with *Chlamydia* is usually asymptomatic but, if identified, can be treated simply and cheaply with antibiotics such as doxycycline or azithromycin, thus preventing the development of PID. Screening young women for chlamydia to prevent PID is feasible [22–24], and a national screening programme operates in the UK targeting women under the age of 25 (further information is available at www.chlamydiascreening.nhs.uk).

Instrumentation of the uterus

There is a significant risk of introducing infection into the upper genital tract when instrumenting the uterus, particularly in women at high risk of a subclinical cervical *Chlamydia* infection. The most common indications for instrumenting the uterus are therapeutic surgical termination of pregnancy, insertion of an IUCD and investigations for subfertility. It is appropriate to test for chlamydia and gonorrhoea prior to instrumentation of the cervix for women at risk of STIs (e.g. partner known to have an infection, past history of STI, age <25, new partner within previous 3 months, two or more partners in past year). In cases where prior screening is not possible (e.g. insertion of an IUCD for emergency contraception), testing should

be combined with empirical treatment, such as doxycycline 100mg twice daily for 1 week.

Particular vigilance is needed in patients who are on immunosuppressant treatment (e.g. renal transplant patients) and in those who are immunocompromised because of chemotherapy or HIV.

Contraception

Consistent use of barrier methods has been shown to reduce the risk of recurrent episodes of pelvic infection and also the chronic sequelae of pelvic infection by between 30 and 60%.

All forms of hormonal contraception (e.g. combined oral contraceptive pill, progesterone-only pill, progesterone injections and implants, and Mirena® intrauterine system) have been shown to reduce the incidence of symptomatic PID compared with either the use of a standard IUCD or unprotected intercourse. This is presumed to be due to the protective effect of the progestogens, which decrease the permeability of the cervical mucus to both sperm and pathogens.

Contraception may also have an effect through endometrial suppression or a direct steroid-induced effect on the inflammatory response in the tubes. However, the beneficial effect of the oral contraceptive pill may be limited to PID which is symptomatic and caused by *C. trachomatis* [25] and it has been suggested that hormonal contraception may simply be masking infection rather than preventing it [25]. A study that appeared to suggest that injectable progesterone contraception increased the risk of PID was methodologically flawed and hence may not be valid [26]. The true relationship between hormonal contraception and PID therefore still needs to be elucidated.

Part 10

Menstruation

46

The Menstrual Cycle

William L. Ledger

School of Women's and Children's Health, University of New South Wales Medicine, New South Wales, Australia

The human female is monotocous. Multiple pregnancy is a rare event in our species and frequently leads to complications that, in the days before modern medicine, would have led to maternal or fetal demise. Hence we have evolved a complex and highly regulated sequence of events that exists to ensure that only one oocyte is ovulated in any one cycle. Regular monthly menstruation is an obvious marker that the various levels of interaction between hypothalamus, pituitary, ovary and uterus are functional. Interruption of this axis at any point leads to disordered menses. Gynaecologists will frequently have to investigate and treat such disorders and a clear understanding of the regulation of the normal cycle is therefore necessary in order to guide rational management when things go wrong.

The normal menstrual cycle is mostly a reflection of ovarian events. The selection and growth of the dominant follicle leads to increasing concentrations of oestrogens in the blood, stimulating endometrial growth in synchrony with the development of a competent oocyte. Later, following the luteinizing hormone (LH) surge, ovarian oestrogens and progesterone from the corpus luteum induce endometrial secretory changes, and the decline in luteal steroid production in the absence of pregnancy leads to the onset of menstruation. Hence a description of clinical relevance of the menstrual cycle should focus on ovarian physiology, while not overlooking events in the hypothalamus and pituitary and at the level of the uterus.

The menstrual cycle is regulated at both endocrine and paracrine levels. Endocrinologically, there are classical feedback loops that modulate release of gonadotrophin hormones from the pituitary, with the ovarian steroids as the afferent arm. More recent studies have begun to elaborate a complex series of paracrine processes that operate within the tissues of the ovary and uterus to impose local regulation.

Step one: ensuring mono-ovulation

Folliculogenesis and the 'follicular phase'

At birth, the human ovaries contain approximately 1 million primordial follicles, arrested at prophase of the first meiotic division. This number already reflects considerable attrition from the maximum size of about 7 million in the follicle 'pool' at 5 months of fetal life [1]. Further depletion of the follicle pool will continue throughout reproductive life, with regular escape of follicles from the primordial 'resting phase' by re-entry into meiosis. The process of 'escape' from the resting state is not dependent on extra-ovarian influences: follicle depletion occurs before and after menarche, during use of the oral contraceptive pill and during pregnancy, and whether or not regular menstruation occurs. The majority of follicles will never develop beyond the pre-antral stage, travelling instead towards atresia. Of the original pool of 7 million primordial follicles, only about 400 will ever acquire gonadotrophin receptors and the possibility of ovulation [2]. This dramatic attrition defines the female arm of natural selection, mirrored by the huge wastage of spermatogenesis in the male, in which millions of sperm are produced each day during fertile life, with only a tiny proportion ever fertilizing an oocyte.

The early stages of follicle development in the human are independent of gonadotrophins. Studies using transgenic animal species have begun to elucidate the contribution of locally acting intra-ovarian paracrine regulators of primordial follicle development, including bone morphogenetic proteins (BMPs), growth differentiation factor (GDF)-9, anti-Müllerian hormone (AMH) and the Bax family of regulators of apoptosis (Table 46.1).

Such studies are of more than theoretical interest: understanding the mechanisms regulating rate of entry into the pool of growing follicles should help to explain

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 46.1 Specific gene knockouts and their effects on ovarian function in the mouse.

Transgenic/mutant mouse	Ovarian phenotype
C-Kit deficiency, Kit ligand deficiency	Loss of germ cells (migration/proliferation failure)
WT1 knockout	Failure of gonadal development
BMP15/GDF9 knockout	Folliculogenesis arrest (primary stage)
IGF1 knockout	Folliculogenesis arrest (before antral follicle stage)
Kisspeptin/*GPPSU* knockout	Folliculogenesis alternation of LU stage
Oestrogen receptor gene knockout	Failure to ovulate
WNT4 knockout	Reduced germ cell number, masculinization

such common clinical problems as 'idiopathic' premature ovarian failure and early onset of menopause, as well as suggesting means of prolonging the reproductive lifespan. For example, some patients with premature ovarian failure have been found to carry mutations in the *BMP15* gene that lead to defective secretion of bioactive BMP15 dimer. BMPs are involved in the earlier stages of egress of follicles from the primordial pool, and such mutations may provide a diagnosis in cases of previously unexplained premature ovarian failure.

Once a developing follicle reaches the pre-antral stage of development (Fig. 46.1), further progression to the antral and preovulatory stages appears to be absolutely dependent on the presence of gonadotrophins. The temporary elevation in circulating concentration of follicle-stimulating hormone (FSH) seen in the early follicular phase of the ovarian cycle allows a limited number of pre-antral follicles to reach this stage of maturity, creating a cohort of practically synchronously developing follicles. However, only one 'lead' follicle will acquire significant aromatase enzyme activity within its granulosa cells, leading to increased synthesis and secretion of estradiol from androgenic precursors. The 'two-cell, two gonadotrophin' hypothesis specifies the need for both LH, to stimulate production of precursor androgens, particularly androstenedione, by the theca cell layer, and FSH, to drive aromatization to estradiol within the adjacent granulosa cell layer [3]. FSH, LH and human chorionic gonadotrophin (hCG) are structurally similar, sharing an identical α-subunit. Their specificity lies in structural differences in the β-subunit (Fig. 46.2). Hence assays for these molecules use antibodies directed against β-subunit epitopes.

The necessity for both LH and FSH at this stage of the cycle is demonstrated when exogenous gonadotrophin replacement is given to patients with Kallmann's syndrome. These patients are unable to secrete gonadotrophins into the circulation, but have normal ovarian physiology. The results of a study of such a patient are shown in Fig. 46.3. The patient had Kallmann's syndrome with anosmia, primary amenorrhoea and hypogonadotrophic hypogonadism. Ovulation induction was undertaken using two different preparations of gonadotrophin. Treatment with both FSH and LH in the form of human menopausal gonadotrophins (hMG) induces both normal follicle growth, monitored by transvaginal ultrasound (bottom panel), and estradiol secretion (top left panel), leading to high luteal phase progesterone concentrations after an artificial LH surge with hCG injection. This indicates that successful ovulation and luteinization occurred. In contrast, treatment with FSH in the absence of LH, using a recombinant FSH preparation, led to identical follicle development on ultrasound but little elevation in circulating estradiol concentration in the phase of follicular growth and no increase in progesterone after hCG injection. The genetic basis of hypogonadotrophic hypogonadism has recently been partially explained. Study of a patient with Kallman's syndrome and a deletion on the X chromosome led to the identification of the *KAL1* gene as a cause of X-linked Kallman's syndrome. More than 10 other gene defects have been identified in cases of hypogonadotrophic hypogonadism.

The pituitary secretes the gonadotrophins LH and FSH in response to pulses of gonadotrophin-releasing hormone (GnRH) from the hypothalamus, which travel to the anterior pituitary via the hypothalamo-hypophyseal portal tract. LH secretion appears to be closely regulated by GnRH pulsatility, while secretion of FSH is coregulated by hypothalamic GnRH and other factors which act directly on the pituitary, possibly including the inhibins and activins. In the normal follicular phase, GnRH pulse frequency is approximately once per 90 min. GnRH pulses are less frequent in the luteal phase, occurring approximately once in 4 hours. Disorders that slow GnRH pulsatility, such as anorexia nervosa, result in failure of secretion of pituitary gonadotrophins and a state of hypogonadotrophic hypogonadism, with undetectable serum LH and FSH and amenorrhoea.

The peptide kisspeptin acts as a potent stimulant to GnRH secretion in the human and mutations in the

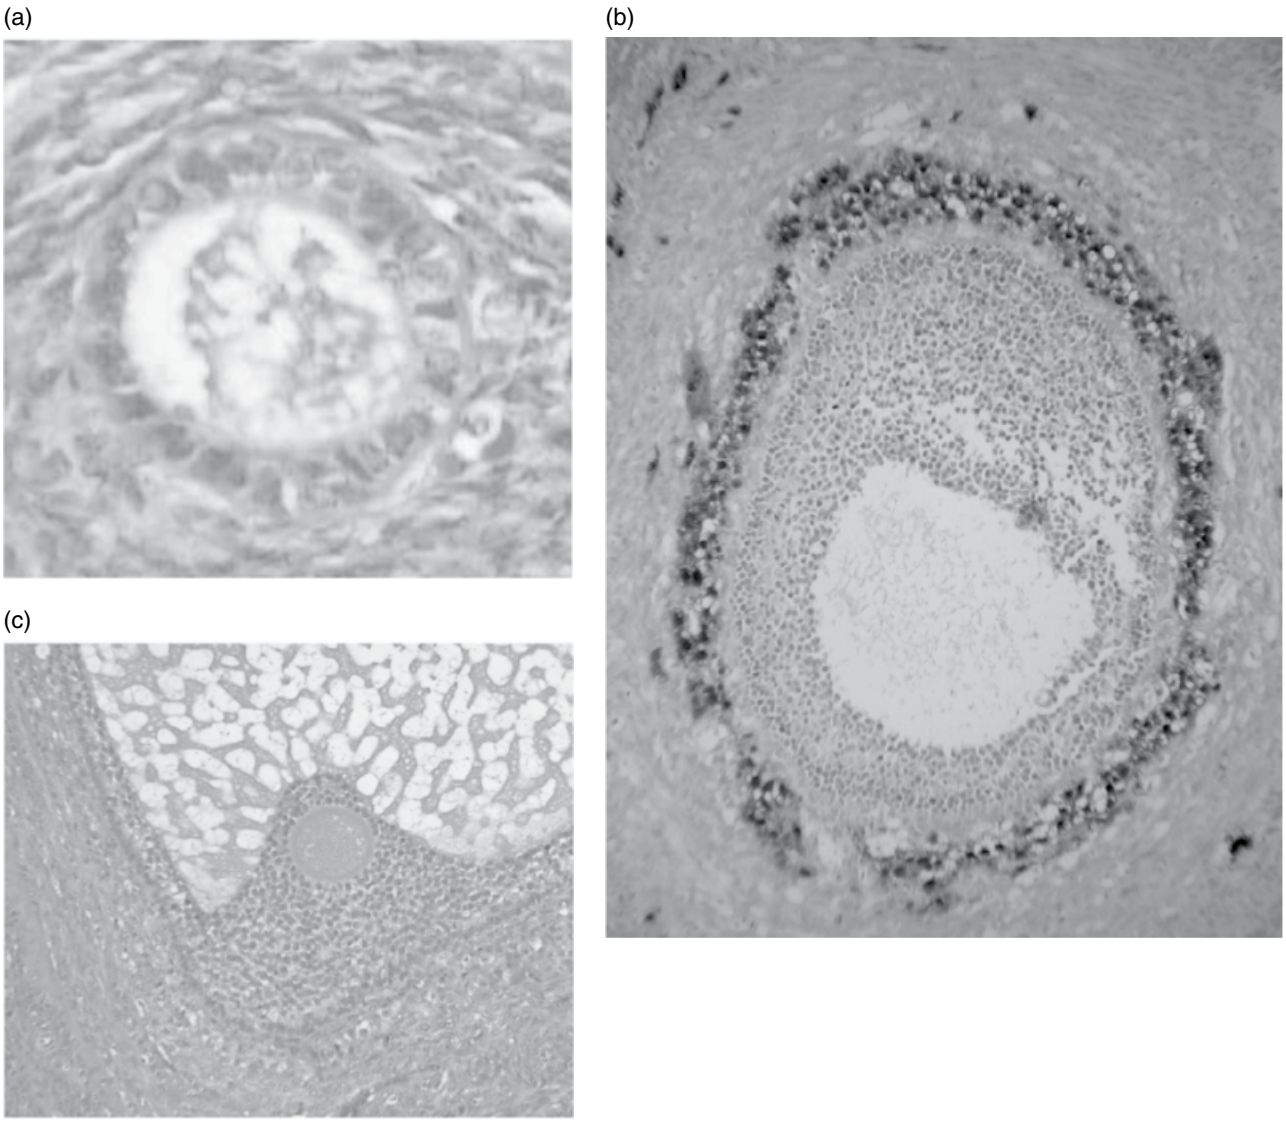

Fig. 46.1 The development of a follicle, from (a) primordial, (b) small antral and (c) preovulatory stages. (a) The primordial follicle is surrounded by a single layer of undifferentiated epithelial cells, and is insensitive to gonadotrophins. (b) The early antral follicle has well-differentiated theca (immunostained brown) and granulosa cell layers surrounding the developing antral cavity with the oocyte. (c) The preovulatory follicle with the oocyte surrounded by the cumulus oophorus with well-differentiated granulosa and theca cell layers.

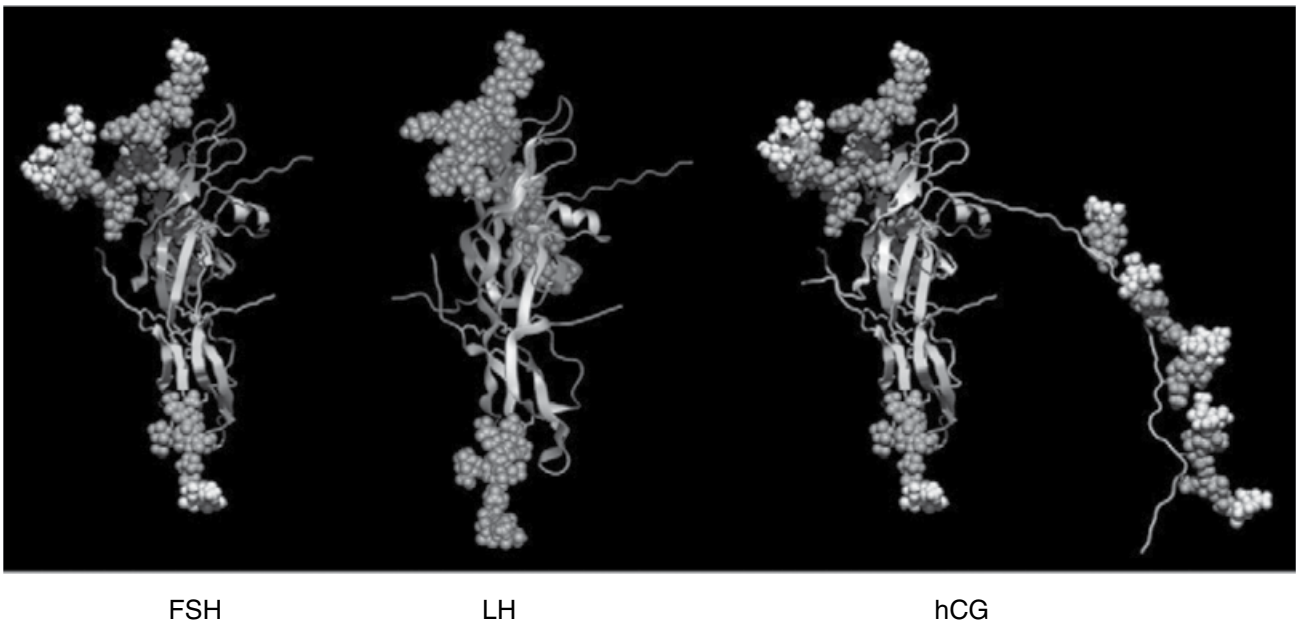

Fig. 46.2 Molecular structure of FSH, LH and hCG.

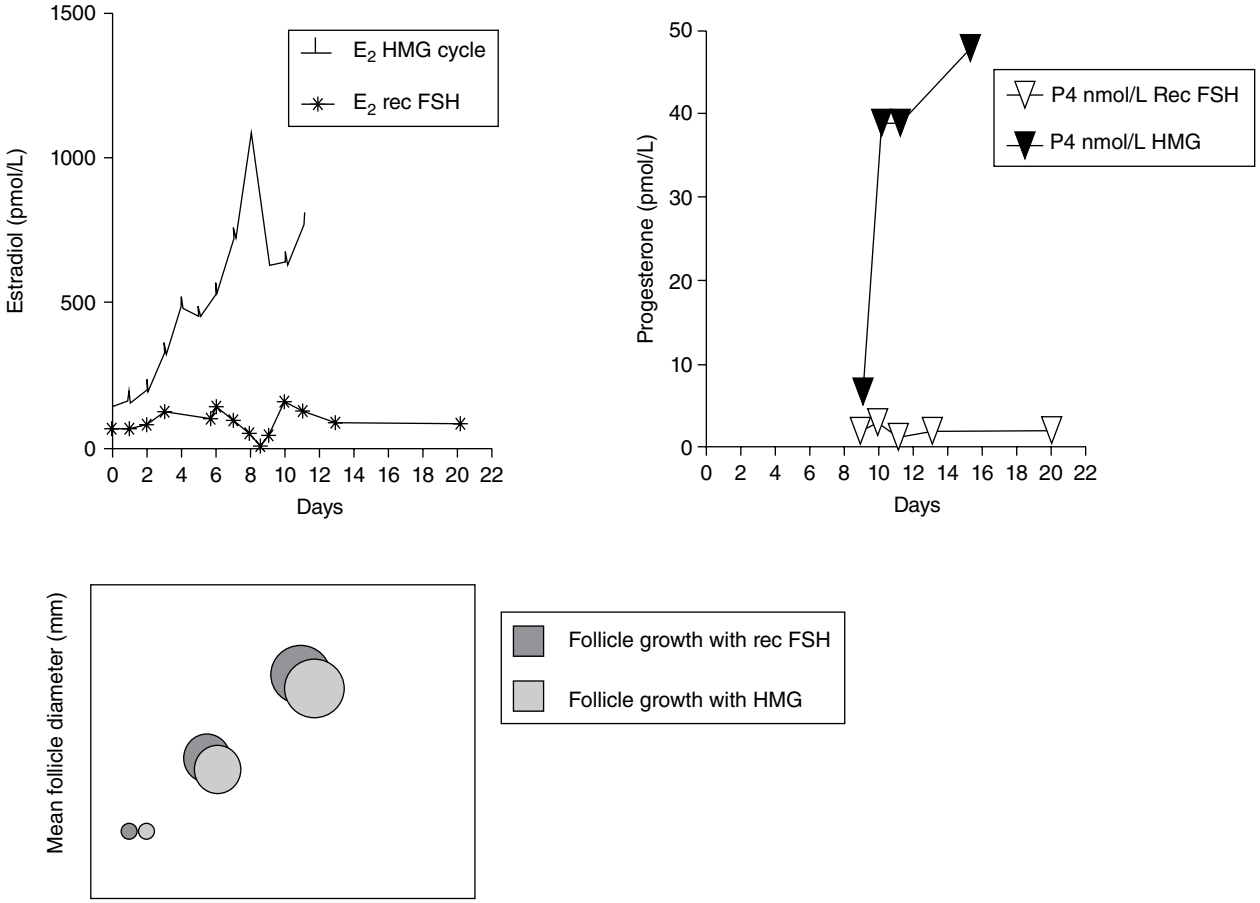

Fig. 46.3 Effects of FSH alone, and FSH and LH in combination on follicle development in a hypogonadotrophic patient with Kallmann's syndrome.

KISS1 gene leading to loss of kisspeptin signalling have been identified as rare causes of hypogonadotrophic hypogonadism [4]. Central kisspeptin release is also modulated by stress and nutritional status, providing a possible mechanism for 'hypothalamic' amenorrhoea in anorexia and in situations of excessive emotional stress. These changes may occur in response to alterations in leptin secretion from adipocytes, leading to kisspeptin-mediated alterations in pulsatile GnRH secretion. Recently, peripheral administration of synthetic kisspeptin has been shown to be effective in inducing ovulation in hypothalamic amenorrhoea and other therapeutic roles in treatment of infertility are being explored. A second neuropeptide, neurokinin B, is also expressed on GnRH neurones and stimulates GnRH secretion and both kisspeptin and neurokinin B expression are down-regulated by oestrogen. Hence it appears likely that kisspeptin and neurokinin B may participate in the relay of feedback from oestrogens, acting at the level of the hypothalamus, to GnRH production, regulating follicle growth and the onset of the LH surge (Fig. 46.4).

Once the concentration of serum estradiol begins to rise in the mid-follicular phase, there is rapid suppression of pituitary FSH production by negative feedback (Fig. 46.5). Recent studies have suggested that suppression of pituitary FSH secretion in the follicular phase might be co-mediated by rising serum concentrations of inhibin B, a glycoprotein secreted by the granulosa cells of the developing dominant follicle. It is perhaps not surprising that a dual mechanism to control follicular-phase FSH secretion has evolved, since mono-ovulation is so essential to healthy reproduction in humans. The resulting decrease in the circulating concentration of FSH withdraws gonadotrophin 'drive' from the remainder of the growing cohort of follicles. The result is progression to atresia for all but the dominant follicle, leading to mono-ovulation [5].

The mechanism by which this selection of a single dominant follicle occurs has been described by the 'threshold' concept, in which the rising concentration of FSH exceeds the threshold and thereby opens a 'window' that allows one follicle to continue growth and

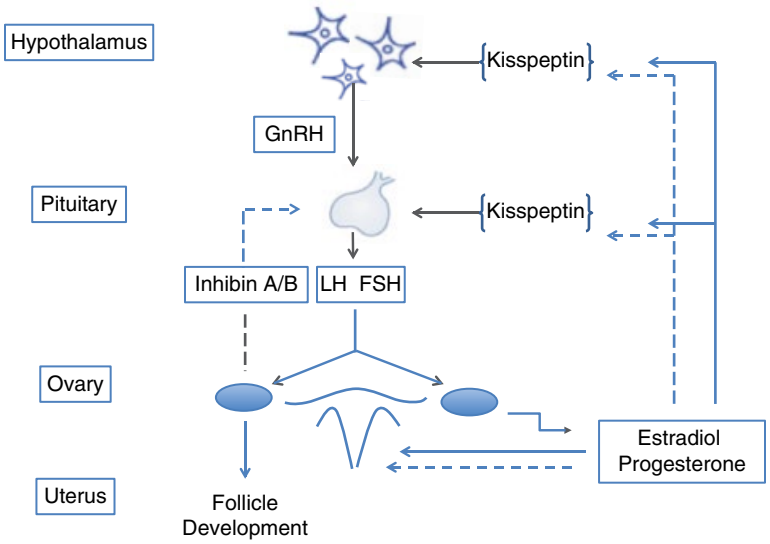

Fig. 46.4 Hypothalamic–pituitary–gonadal axis. *Source:* Dr May Wong. Reproduced with permission of Dr May Wong.

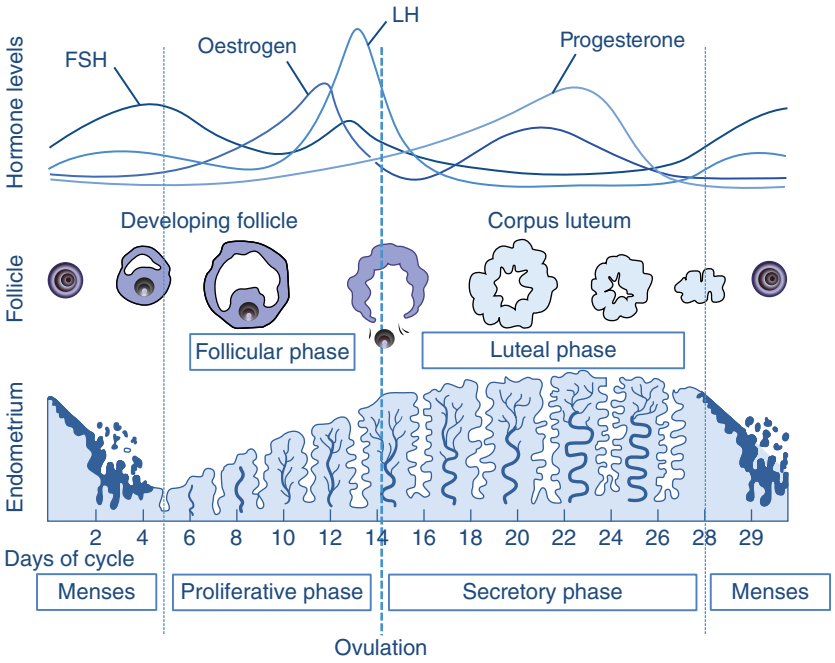

Fig. 46.5 Synchronization of the menstrual and ovarian cycles. *Source:* Dr May Wong. Reproduced with permission of Dr May Wong.

development. Suppression of FSH concentration then closes the window, preventing growth of multiple mature follicles (Fig. 46.6).

The threshold concept is useful in understanding the pitfalls of superovulation, in which daily injections of high doses of FSH are given as part of *in vitro* fertilization (IVF). The aim is to produce a cohort of eight or more mature follicles suitable for ultrasound-guided oocyte retrieval. However, if the follicle pool is small (e.g. if the patient is nearing menopause), then the yield of mature follicles will be disappointing, while if the follicle pool is large (e.g. if the patient has polycystic ovary syndrome), then there is a danger of over-response with ovarian hyperstimulation syndrome. The recent introduction of rapid and reliable automated assays for AMH has allowed measurement of this dimeric glycoprotein before starting exogenous gonadotrophin superovulation. Serum AMH is high in patients with polycystic ovary syndrome who are in danger of over-response and hyperstimulation, and low in patients who are closer to menopause with low ovarian reserve. Hence those women with high AMH are given low doses of gonadotrophins, with careful monitoring, whilst those with low AMH can safely be given higher doses in an attempt to improve oocyte yield.

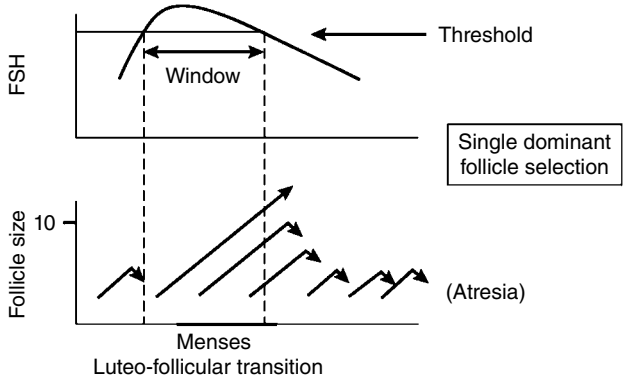

Fig. 46.6 The 'threshold concept' illustrating dependence of advanced follicle growth and maturation on a rise in circulating FSH concentration above an arbitrary threshold, with subsequent suppression of FSH preventing multiple follicle development. *Source:* Macklon NS, Fauser BC. Follicle-stimulating hormone and advanced follicle development in the human. *Arch Med Res* 2001;32:595–600. Reproduced with permission of Elsevier.

Physiologically, AMH is secreted by small antral follicles and is not seen in large preovulatory follicles. Hence measurement gives a direct assessment of the number of small antral follicles in the developing pool, which in turn depends on the size of the primordial follicle pool remaining in the ovaries. Measurement of AMH can therefore provide an estimate of the size of the remaining pool of follicles in the ovaries. Recent studies have suggested that this can provide a reasonably accurate assessment of a woman's time to menopause, with clear clinical implications for management of infertility. The serum concentration of AMH varies little across the menstrual cycle and is not significantly affected by use of combined oral contraceptives, facilitating easy measurement in clinical practice.

Step two: ensuring maintenance of very early pregnancy

The LH surge and ovulation

Final maturation of the oocyte only occurs after initiation of the LH surge. This ensures that the oocyte is mature and ready for fertilization only after release from the follicle into the ampulla of the fallopian tube, where fertilization may occur. The LH surge represents a coordinated discharge of LH from the gonadotroph cells of the anterior pituitary. This occurs in response to the rapid rise in estradiol during the latter days of the follicular phase of the ovarian cycle. Pulses of GnRH from the hypothalamus increase in both magnitude and frequency, triggering the LH surge with a rapid outpouring of LH and, to a lesser extent, FSH from the anterior pituitary (see Fig. 46.5).

The LH surge is also preceded by a rise in serum concentration of progesterone. The contribution of this rise to the periovulatory phase of the cycle is unclear, but prevention of the preovulatory rise in serum progesterone concentration using progesterone receptor antagonists such as mifepristone prevents efficient ovulation. Compounds with effects similar to mifepristone are being tested as possible contraceptive agents, possibly acting by inhibiting both ovulation and implantation.

The LH surge initiates final maturation of the oocyte with completion of meiosis and extrusion of the first polar body, which contains one of the two haploid sets of chromosomes, from the oocyte. The LH surge also induces an inflammatory-type reaction at the apex of the follicle adjacent to the outer surface of the ovarian cortex. A process of new blood vessel formation, with associated release of prostaglandins and cytokines, leads to rupture of the follicle wall and ovulation about 38 hours after the initiation of the LH surge. A chemotactic effect of ovarian cytokines draws the fimbria of the fallopian tube to within close proximity of the rupturing follicle. A thin mucus strand seems to join the mouth of the fallopian tube to the ovular follicle, forming a bridge for transit of the oocyte into the tube.

The 'empty' follicle rapidly fills with blood and the theca and granulosa cell layers of the follicle wall luteinize, with formation of the corpus luteum (see Fig. 46.6). A rapid synthesis of progesterone, along with estradiol, follows. Concentrations of progesterone in serum rise rapidly to above 25 nmol/L, one of the highest concentrations seen for any hormone in the circulation. These concentrations rise still further if pregnancy follows.

Endometrial development during the menstrual cycle and early pregnancy

The follicular phase of the ovarian cycle is characterized by the appearance in the circulation of increasing amounts of estradiol. Estradiol acts on the basalis layer of endometrium, which persists from cycle to cycle in contrast to the monthly shedding of the more superficial layers of endometrium. The follicular phase of the ovarian cycle therefore equates to the proliferative phase of the endometrial cycle as proliferative endometrium develops in synchrony with the growth and maturation of the oocyte and its follicle. An organized endometrial architecture appears, with glandular and stromal compartments. The LH surge is followed by luteinization of the ruptured follicle and formation of the corpus luteum,

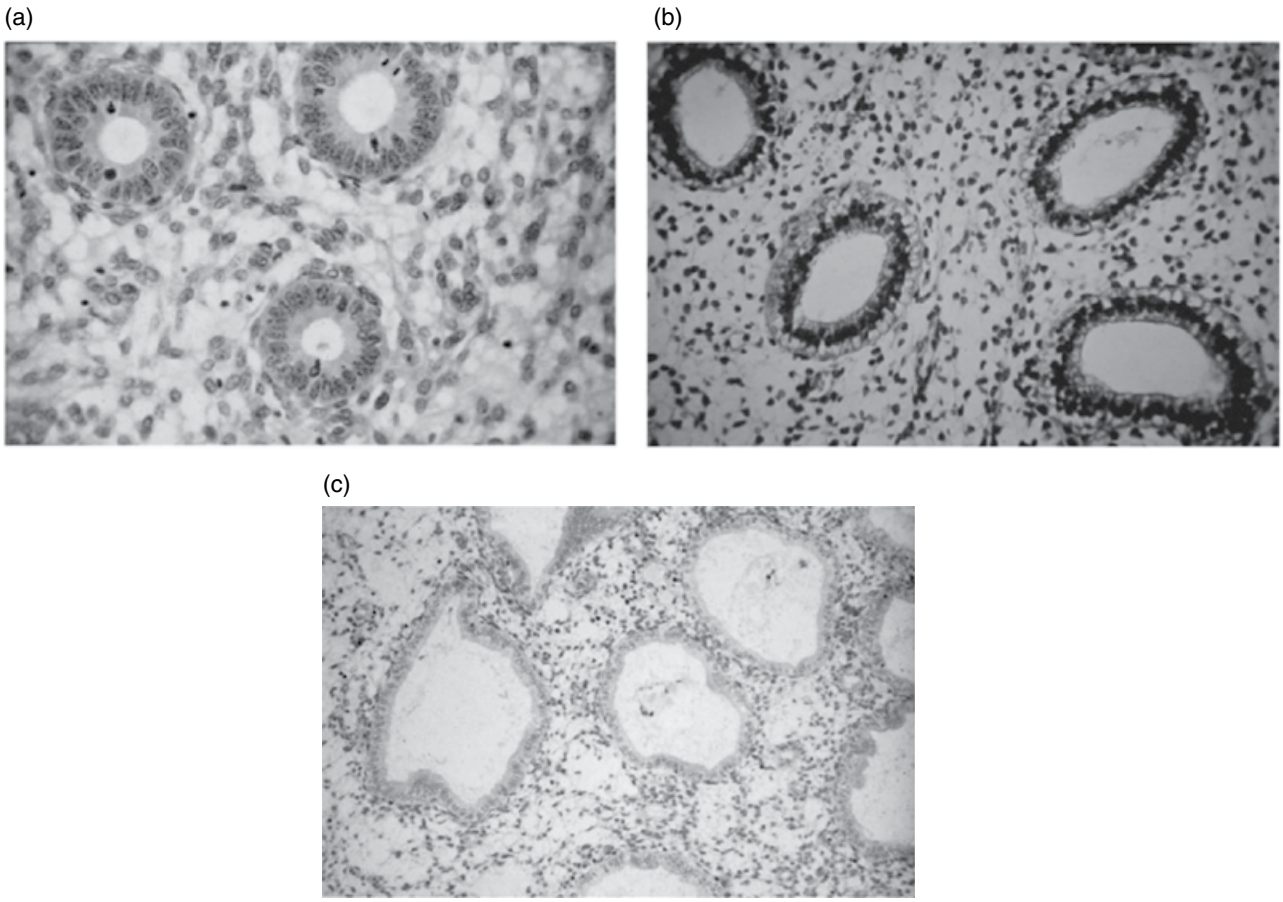

Fig. 46.7 The histological appearances of the endometrial cycle showing the menstrual, proliferative and secretory phases.

with secretion of large amounts of progesterone. This in turn stimulates the onset of secretion from the endometrial glands, initiating the secretory phase of the endometrial cycle in concert with the luteal phase of the ovarian cycle (Fig. 46.7).

A key element in growth of healthy endometrium is formation of new blood vessels (endometrial angiogenesis), which seems to occur by elongation and expansion from pre-existing small vessels in the basalis. Endometrial angiogenesis can be divided into three stages: first, during menstruation, to re-form the vascular bed; second, during the proliferative phase, to develop endometrial vascular supply; and, finally, with spiral arteriole growth and coiling during the secretory phase, with the aim of providing an adequately vascularized site for implantation [6]. Therefore, in contrast to most vascular beds, which keep a persistent structure throughout life, the endometrial vascular network grows and regresses during each menstrual cycle. Numerous angiogenic and angiostatic factors have been identified in the human endometrium. Most of these studies have focused on vascular endothelial growth factor (VEGF) and interleukins, which may be directly responsive to changing concentrations of ovarian steroids.

The development of a healthy secretory endometrium is essential for implantation and successful development of pregnancy. In the human, the oocyte is fertilized in the ampullary portion of the fallopian tube and then travels to enter the uterus on day 3, at the morula stage of development. The blastocyst, with distinct trophectoderm and inner cell mass, forms on day 4. The blastocyst sheds the zona pellucida and then adheres to the endometrial epithelium, beginning the process of implantation. Implantation is the first step in the interaction between the cells of the blastocyst and endometrium, i.e. between the mother and the fetus. Hence this interaction is critical to successful pregnancy, and a number of endometrial proteins have been identified as potential regulators of blastocyst development and implantation. These include endometrial integrins, glycosylated cell adhesion molecule (GlyCAM)-1 and osteopontin [7].

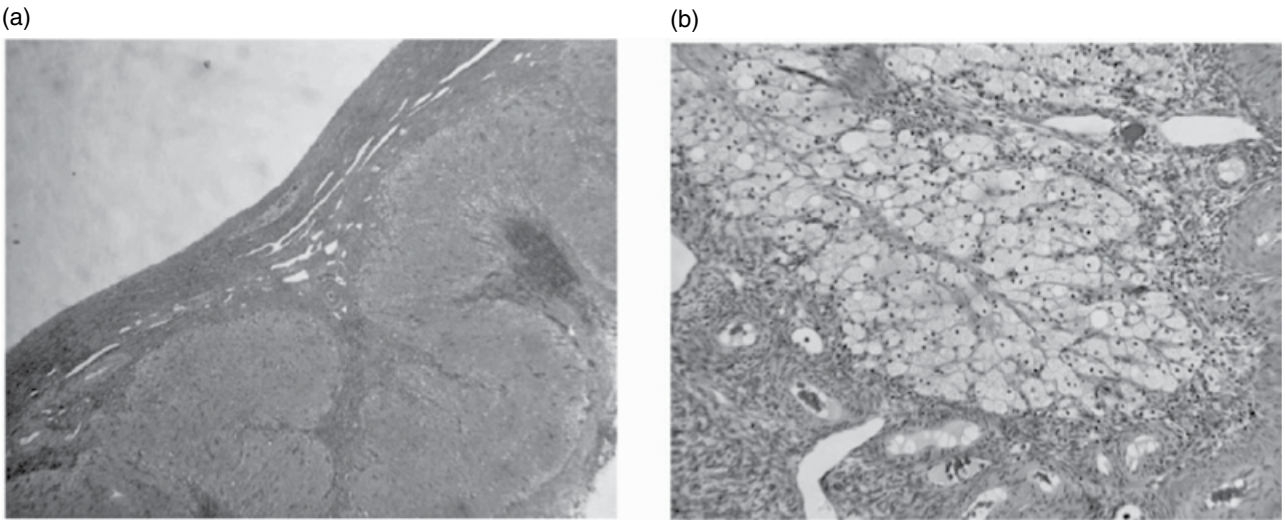

Fig. 46.8 The histological appearances of the corpus luteum, showing (a) an active corpus luteum and (b) regression of the corpus luteum with histiocyte infiltration.

Continuous exposure of the endometrium to progesterone in early pregnancy downregulates progesterone receptors in the epithelia, a process associated with loss of the cell-surface mucin MUC1 and induction of secreted adhesion proteins.

High circulating concentrations of progesterone are essential for the continuation of pregnancy. hCG secretion by the trophoblast of the developing pregnancy 'rescues' the corpus luteum, providing an LH-like stimulus to maintain luteal progesterone secretion. Interruption of luteal progesterone synthesis and secretion, for example using the progesterone receptor antagonist mifepristone, is used in clinical practice to induce termination of early pregnancy. In contrast, luteal-phase support in the form of hCG injection or injected or vaginal progestogens is used to maintain IVF pregnancies, since normal luteinization is interrupted by the GnRH agonist drugs used to prevent premature LH surges and unwanted ovulation.

Menstruation

Menstruation refers to the shedding of the superficial layers of the endometrium with subsequent repair in preparation for regrowth from the basalis layer. Menstruation is initiated by the fall in circulating progesterone that follows luteal regression, i.e. failure of 'rescue' of the corpus luteum by an implanted early pregnancy (Fig 46.8). During luteolysis, progesterone secretion falls despite maintained serum concentrations of LH, since the corpus luteum becomes less sensitive to gonadotrophic support and becomes increasingly unable to maintain production of progesterone. In contrast, in a conception cycle, the increasing block to progesterone synthesis is overcome by the rapidly increasing concentrations of hCG which act on the corpus luteum through its LH receptors.

In the immediate premenstrual phase, progesterone withdrawal initiates a complex series of intrauterine signals, including expression of chemotactic factors that draw leucocytes into the uterus and expression of matrix metalloproteinase enzymes, prostaglandins and other compounds that act on the uterine vessels and smooth muscle. The 'invasion' of leucocytes and subsequent expression of inflammatory mediators has led to menstruation being likened to an inflammatory event [8,9]. Prostaglandins of the E and F series are present in high concentrations in the endometrium, and their synthesis is regulated by the ovarian steroids. Increased production of $PGF_2\alpha$ produces the myometrial contractions and vasoconstriction seen at menstruation, while E series prostaglandins increase pain and oedema, and are vasodilatory. PGE_2 also appears to induce synthesis of the cytokine interleukin (IL)-8, another key inflammatory and chemotactic mediator [10]. Pronounced vasoconstriction in turn leads to localized tissue hypoxia, further reinforcing release of inflammatory mediators. The end result of this cascade of events is constriction of the spiral arterioles with contraction of the uterine muscle, leading to expulsion of the shed tissue (Fig. 46.9).

These studies have clear relevance to clinical management of menorrhagia and other menstrual disorders. Inhibitors of prostaglandin synthesis are widely

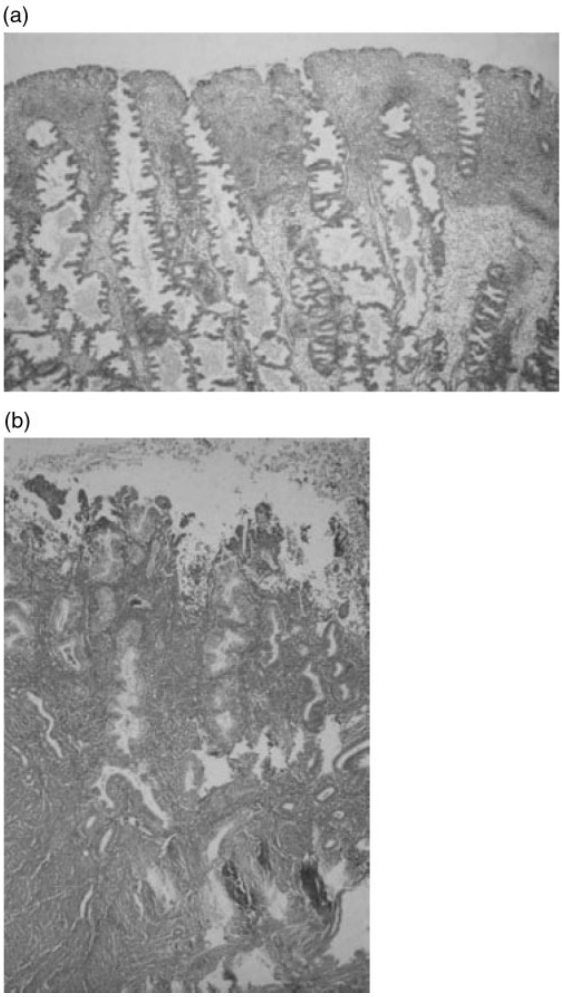

Fig. 46.9 Histological appearance of (a) late secretory and (b) menstrual endometrium. *Source:* Professor M. Wells, University of Sheffield. Reproduced with permission of Professor M. Wells.

used in these conditions, with good scientific basis. However, prostaglandin synthesis is also an important component of ovulation, and the use of powerful inhibitors of prostaglandin synthesis, such as non-steroidal anti-inflammatory agents, can lead to anovular cycles and involuntary infertility.

Conclusion

Although complex, the endocrine and paracrine events that regulate the normal ovarian and uterine cycles are well understood. This chapter illustrates several examples by which understanding of the basic physiology of the cycle has led to scientifically based therapeutics. Further exploration of these regulatory mechanisms will produce new approaches to diagnosis and treatment for gynaecologists and their patients.

Summary box 46.1

- The physiological events of the menstrual cycle represent the outcome of a complex system of inter-regulation by endocrine and paracrine factors.
- Understanding of the physiology of the ovarian and menstrual cycle is critical before attempting to understand the various pathological states associated with anovulation and premature menopause.
- New research into the genetic basis of regulation of re-entry of primordial follicles into the growing pool will provide new insights into the determination of ovarian reserve and timed menopause.

Polycystic Ovary Syndrome and Secondary Amenorrhoea

Adam Balen

Leeds Centre for Reproductive Medicine, Seacroft Hospital, Leeds, UK

Defining polycystic ovary syndrome and secondary amenorrhoea

The current understanding of polycystic ovary syndrome (PCOS) is that it is a condition that presents with ovarian dysfunction and endocrine problems and is also associated with hyperinsulinaemia and metabolic disease. PCOS is a heterogeneous condition which is defined by the presence of two of the following three criteria: (i) oligo-ovulation and/or anovulation, (ii) hyperandrogenism (clinical and/or biochemical), or (iii) polycystic ovaries as seen by ultrasound scan, with the exclusion of other causes of androgen excess and menstrual cycle irregularity or amenorrhoea. PCOS therefore encompasses symptoms of menstrual cycle disturbance and as such is the commonest cause of secondary amenorrhoea and also of anovulatory infertility. The second part of the chapter discusses the pathophysiology and management of other causes of secondary amenorrhoea.

Amenorrhoea is the absence of menstruation, which may be temporary or permanent. Amenorrhoea may occur as a normal physiological condition, such as before puberty and during pregnancy, lactation or the menopause, or as a feature of a systemic or gynaecological disorder. Primary amenorrhoea may be a result of congenital abnormalities in the development of the ovaries, genital tract or external genitalia, or a perturbation of the normal endocrinological events of puberty. Most of the causes of secondary amenorrhoea can also cause primary amenorrhoea.

Examination and investigation of patients with polycystic ovary syndrome and secondary amenorrhoea

A thorough history and a careful examination should always be carried out before investigations are instigated, looking particularly at stature and body form, signs of endocrine disease, secondary sexual development and the external genitalia. A history of secondary amenorrhoea may be misleading, as the 'periods' may have been the result of exogenous hormone administration in a patient who was being treated with hormone replacement therapy (HRT) for primary amenorrhoea. In most cases, however, a history of secondary amenorrhoea excludes congenital abnormalities. A family history of fertility problems, autoimmune disorders or premature menopause may also give clues as to the aetiology.

Exclude pregnancy

It is always important to exclude pregnancy in women of any age, and whereas some may think this statement superfluous, it is not infrequent for women to present with amenorrhoea who are pregnant despite denying the possibility.

Examination

Measurement of height and weight should be performed in order to calculate the patient's body mass index (BMI).

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

The normal range is 20–25 kg/m^2, and a value above or below this may suggest a diagnosis of weight-related amenorrhoea (which is a term usually applied to underweight women).

Signs of hyperandrogenism – acne, hirsutism, balding (alopecia) – are suggestive of PCOS, although biochemical screening helps to differentiate other causes of androgen excess. It is important to distinguish between hyperandrogenism and virilization, which also occurs with high circulating androgen levels and causes deepening of the voice, breast atrophy, increase in muscle bulk and cliteromegaly (see Summary box 47.1). A rapid onset of hirsutism suggests the possibility of an androgen-secreting tumour of the ovary or adrenal gland. Hirsutism can be graded and given a Ferriman–Gallwey score by assessing the amount of hair in different parts of the body (e.g. upper lip, chin, breasts, abdomen, arms, legs). It is useful for monitoring the progress of hirsutism, or its response to treatment, by making serial records, either by using a chart or by taking photographs of affected areas of the body. It should be remembered, however, that not all hair on the body is necessarily responsive to hormone changes (e.g. the upper thighs). There may also be big ethnic variations in the expression of hirsutism, with women from South Asia and Mediterranean countries often having more pronounced problems, whereas those from the Far East may not have much in the way of bodily hair. Furthermore, the degree of hirsutism does not correlate that well with the actual levels of circulating androgens.

A measurement of total testosterone is considered adequate for general screening (Table 47.1). It is unnecessary to measure other androgens unless total testosterone is above 5 nmol/L (this will depend on the normal range of your local assay). Insulin may be elevated in overweight women and suppresses the production of sex hormone-binding globulin (SHBG) by the liver, resulting in a high free androgen index in the presence of a normal total testosterone. The measurement of SHBG is not required in routine practice but is a useful surrogate marker for insulin resistance.

One should be aware of the possibility of Cushing's syndrome in women with stigmata of PCOS and obesity as it is a disease of insidious onset and dire consequences; additional clues are the presence of central obesity, moon face, plethoric complexion, buffalo hump, proximal myopathy, thin skin, bruising and abdominal striae (which alone are a common finding in obese individuals). Acanthosis nigricans is a sign of profound insulin resistance and is usually visible as hyperpigmented thickening of the skin folds of the axilla and neck; acanthosis nigricans is associated with PCOS and obesity (Fig. 47.1).

Summary box 47.1

- A testosterone concentration above 5 nmol/L should be investigated to exclude androgen-secreting tumours of the ovary or adrenal gland, Cushing's syndrome and late-onset congenital adrenal hyperplasia (CAH). Whereas CAH often presents at birth with ambiguous genitalia (see Chapter 35), partial 21-hydroxylase deficiency may present in later life, usually in the teenage years, with signs and symptoms similar to PCOS. In such cases, testosterone may be elevated and the diagnosis confirmed by an elevated serum concentration of 17-hydroxyprogesterone (17-OHP); an abnormal ACTH stimulation test may also be helpful (250 µg ACTH will cause an elevation of 17-OHP, usually between 65 and 470 nmol/L).
- In cases of Cushing's syndrome, a 24-hour urinary-free cortisol will be elevated (>700 nmol per 24 hours). The normal serum concentration of cortisol is 140–700 nmol/L at 8 a.m. and less than 140 nmol/L at midnight. A low-dose dexamethasone suppression test (0.5 mg 6-hourly for 48 hours) will cause a suppression of serum cortisol by 48 hours. A simpler screening test is an overnight suppression test, using a single midnight dose of dexamethasone 1 mg (2 mg if obese) and measuring the serum cortisol concentration at 8 a.m. when it should be less than 140 nmol/L. If Cushing's syndrome is confirmed, a high-dose dexamethasone suppression test (2 mg 6-hourly for 48 hours) should suppress serum cortisol by 48 hours if there is a pituitary ACTH-secreting adenoma (Cushing's disease); failure of suppression suggests an adrenal tumour or ectopic secretion of ACTH. Further tests and detailed imaging will then be required.
- The measurement of other serum androgen levels can be helpful. Dehydroepiandrosterone sulfate (DHEAS) is primarily a product of the adrenal androgen pathway (normal range <10 µmol/L). If the serum androgen concentrations are elevated, the possibility of an ovarian or adrenal tumour should be excluded by ultrasound or CT scan. The measurement of androstenedione can also be useful in some situations.

Amenorrhoeic women might have hyperprolactinaemia and galactorrhoea. It is important, however, not to examine the breasts before taking blood as the serum prolactin concentration may be falsely elevated as a result of physical examination. Stress may also cause minor elevation of prolactin. If there is suspicion of a pituitary tumour, the patient's visual fields should be checked, as bitemporal hemianopia secondary to pressure on the optic chiasm requires urgent attention.

Table 47.1 Endocrine normal ranges.

FSH*	1–10 IU/L (early follicular)
LH*	1–10 IU/L (early follicular)
Prolactin*	<400 mIU/L
TSH*	0.5–4.0 IU/L
Thyroxine (T_4)	50–150 nmol/L
Free T_4	9–22 pmol/L
Triiodothyronine (T_3)	1.5–3.5 nmol/L
Free T_3	4.3–8.6 pmol/L
TBG	7–17 mg/L
Testosterone (T)*	0.5–3.5 nmol/L (ranges depend on the assay being used)
SHBG	16–120 nmol/L
Free androgen index [(T × 100) ÷ SHBG]	<5
Dihydrotestosterone	0.3–1 nmol/L
Androstenedione	2–10 nmol/L
Dehydroepiandrosterone sulfate	3–10 µmol/L
Cortisol	140–700 nmol/L
8 a.m.	0–140 nmol/L
Midnight	<400 nmol/24 hours
24-hour urinary	
Estradiol	250–500 pmol/L
Estrone	400–600 pmol/L
Progesterone (mid-luteal)	>25 nmol/L to indicate ovulation
17-hydroxyprogesterone	1–20 nmol/L
Inhibin B	5–200 pg/mL
AMH	Values should be assessed with respect to age-related nomograms. Low levels indicate poor ovarian reserve, normal levels suggest normal fertility and high values are often seen in women with polycystic ovaries

* Denotes those tests performed in routine screening of women with amenorrhoea.
AMH, anti-Müllerian hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; SHBG, sex hormone-binding globulin; TBG, thyroid-binding globulin; TSH, thyroid-stimulating hormone.

Thyroid disease is common and the thyroid gland should be palpated and signs of hypothyroidism (dry thin hair, proximal myopathy, myotonia, slow-relaxing reflexes, mental slowness, bradycardia) or hyperthyroidism (goitre with bruit, tremor, weight loss, tachycardia, hyperreflexia, exophthalmos, conjunctival oedema, ophthalmoplegia) elicited.

A bimanual examination is inappropriate in a young woman who has never been sexually active, and examination of the external genitalia of an adolescent should be undertaken in the presence of the patient's mother. Furthermore, it may be more appropriate to defer this from the first consultation in order to assure the patient's confidence in future management. A transabdominal ultrasound examination of the pelvis is an excellent non-invasive method for obtaining valuable information in these patients. Although an examination under anaesthetic is sometimes indicated for cases of disorders of sexual development with primary amenorrhoea, it is rarely required in cases of secondary amenorrhoea (Table 47.2).

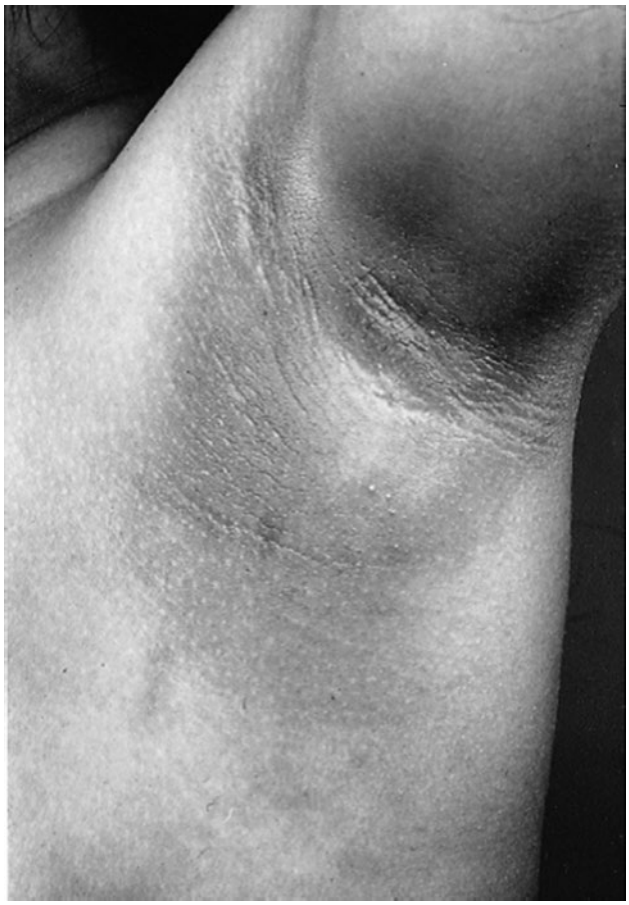

Fig. 47.1 Acanthosis nigricans, as seen typically in the skin folds (axilla, neck, elbow, vulva). *Source:* Balen AH. *Infertility in Practice*, 4th edn. London: Informa Healthcare, 2014. Reproduced with permission of CRC Press.

A baseline assessment of the endocrine status should include the measurement of serum prolactin and gonadotrophin concentrations and an assessment of thyroid function. Prolactin levels may be elevated in response to a number of conditions, including stress, a recent breast examination or even having a blood test; however, the elevation is moderate and transient. A more permanent, but still moderate, elevation (>700 mIU/L) is associated with hypothyroidism and is also a common finding in women with PCOS, where prolactin levels up to 2500

Table 47.2 Classification of secondary amenorrhoea.

Uterine causes	Asherman's syndrome
	Cervical stenosis
Ovarian causes	Polycystic ovary syndrome
	Premature ovarian insufficiency, formerly known as premature ovarian failure (genetic, autoimmune, infective, radiotherapy/chemotherapy)
Hypothalamic causes (hypogonadotrophic hypogonadism)	Weight loss
	Exercise
	Chronic illness
	Psychological distress
	Idiopathic
Pituitary causes	Hyperprolactinaemia
	Hypopituitarism
	Sheehan's syndrome
Causes of hypothalamic/ pituitary damage (hypogonadism)	Tumours (craniopharyngiomas, gliomas, germinomas, dermoid cysts)
	Cranial irradiation
	Head injuries
	Sarcoidosis
	Tuberculosis
	Chronic debilitating illness
Systemic causes	Weight loss
	Endocrine disorders (thyroid disease, Cushing's syndrome, etc.)

mIU/L have been reported [1]. PCOS may also result in amenorrhoea, which can therefore create diagnostic difficulties, and hence appropriate management, for those women with hyperprolactinaemia and polycystic ovaries. Amenorrhoea in women with PCOS is secondary to acyclical ovarian activity yet oestrogen production by the ovaries continues and so the endometrial thickness will be greater than 6 mm. A positive response to a progestogen challenge test, such as medroxyprogesterone acetate 10–20 mg (depending on body weight) daily for 7 days which induces a withdrawal bleed, will distinguish patients with PCOS-related hyperprolactinaemia from those with polycystic ovaries and unrelated hyperprolactinaemia, because the latter causes oestrogen deficiency and therefore failure to respond to the progestogen challenge because the endometrium is thin.

A serum prolactin concentration of greater than 1000 mIU/L warrants a repeat and then further investigation if still elevated. CT or MRI of the pituitary fossa may be used to exclude a hypothalamic tumour, a non-functioning pituitary tumour compressing the hypothalamus or a prolactinoma. Serum prolactin concentrations greater than 5000 mIU/L are usually associated with a macroprolactinoma, which by definition is greater than 1 cm in diameter.

Serum measurements of estradiol are of limited value as they vary considerably, even in a patient with amenorrhoea. If the patient is well oestrogenized, the endometrium will be clearly seen on an ultrasound scan and should be shed on progestogen withdrawal.

Serum gonadotrophin measurements help to distinguish between cases of hypothalamic or pituitary failure and gonadal failure. Elevated gonadotrophin concentrations indicate a failure of negative feedback as a result of primary or premature ovarian insufficiency (POI, formerly known as premature ovarian failure). A serum follicle-stimulating hormone (FSH) concentration of greater than 15 IU/L that is not associated with a preovulatory luteinizing hormone (LH) surge suggests impending ovarian failure. FSH levels of greater than 40 IU/L are suggestive of irreversible ovarian failure. The exact values vary according to individual assays, and so local reference levels should be checked. It is also important to assess serum gonadotrophin levels at baseline (during the first 3 days of a menstrual period). In patients with oligomenorrhoea/amenorrhoea, it may be necessary to perform two or more random measurements, although combining an endocrine assessment with an ultrasound scan on the same day aids the diagnosis.

An elevated LH concentration, when associated with a raised FSH concentration, is indicative of ovarian failure. However, if LH is elevated alone (and is not attributable to the preovulatory LH surge), this suggests PCOS. This may be confirmed by a pelvic ultrasound scan. Rarely, an elevated LH in a phenotypic female may be due to androgen insensitivity syndrome, although this condition presents with primary amenorrhoea.

Inhibin B is thought to be the ovarian hormone with the greatest influence on pituitary secretion of FSH. Previously, it was thought that serum concentrations of inhibin B might provide better quantification of ovarian reserve than serum FSH concentrations; however, the assay is no longer being used.

Anti-Müllerian hormone (AMH) is best known as a product of the testes during fetal development that suppresses the development of Müllerian structures. AMH is also produced by the pre-antral and antral follicles and appears to be a more stable predictor of the ovarian follicle pool as it does not fluctuate through the menstrual cycle. Indeed, it has been reported that higher AMH concentrations are associated with increased numbers of mature oocytes, embryos and clinical pregnancies during *in vitro* fertilization (IVF) treatment. Assays for AMH are now available for routine use and it is this hormone that currently offers the greatest promise for future assessment of ovarian reserve and function. The number

of antral follicles in the ovary, as assessed by pelvic ultrasound, also correlates well with ovarian reserve and serum AMH levels. Indeed, it is the number of small antral follicles, 2–6 mm in diameter, that declines significantly with age while there is little change in the larger follicles of 7–10 mm, which is still below the size at which growing follicles have been recruited.

Failure at the level of the hypothalamus or pituitary is reflected by abnormally low levels of serum gonadotrophin concentrations, and gives rise to hypogonadotrophic hypogonadism. Kallmann's syndrome is the clinical finding of anosmia and/or colour blindness associated with hypogonadotrophic hypogonadism, usually a cause of primary amenorrhoea. CT or MRI should be performed if indicated.

Karyotype and other tests

Women with POI (under the age of 40 years) may have a chromosomal abnormality, for example Turner's syndrome (45X or 46XX/45X mosaic) or other sex chromosome mosaicisms. A number of genes have also been associated with familial POI, but have not been assessed in routine clinical practice. An autoantibody screen should also be undertaken in women with POI, although it can be difficult to detect anti-ovarian antibodies and many will have evidence of other autoantibodies (e.g. thyroid), which then indicates the need for further surveillance.

A history of a recent endometrial curettage or endometritis in a patient with normal genitalia and normal endocrinology, but with absent or only a small withdrawal bleed following a progestogen challenge, is suggestive of Asherman's syndrome. An ultrasound scan and/or a hysterosalpingogram (HSG) may be helpful and hysteroscopy will confirm the diagnosis (Fig. 47.2).

Measurement of bone mineral density (BMD) is indicated in amenorrhoeic women who are oestrogen deficient. Measurements of density are made in the lumbar spine and femoral neck. The vertebral bone is more sensitive to oestrogen deficiency and vertebral fractures tend to occur in a younger age group (50–60 years) than fractures at the femoral neck (70+ years). However, it should be noted that crush fractures can spuriously increase the measured BMD. An X-ray of the dorsolumbar spine is therefore often complementary, particularly in patients who have lost height.

Amenorrhoea may also have long-term metabolic and physical consequences. In women with PCOS and prolonged amenorrhoea, there is a risk of endometrial hyperplasia and adenocarcinoma. If on resumption of menstruation there is a history of persistent intermenstrual bleeding, or on ultrasound there is a postmenstrual endometrial thickness of greater than 10 mm, an endometrial biopsy is indicated.

Fig. 47.2 Conventional X-ray hysterosalpingogram demonstrating Asherman's syndrome, with intrauterine synechiae. There is no flow of contrast through the right tube, although thickening of the cornual end of the tube suggests the possibility of tubal spasm. There is flow to the end of the left fallopian tube, although no free spill into the peritoneal cavity. This raises the possibility of sacculated adhesions around the fimbrial end of the tube. *Source:* Balen AH. *Infertility in Practice*, 4th edn. London: Informa Healthcare, 2014. Reproduced with permission of CRC Press.

Serum cholesterol measurements are important because of the association of an increased risk of heart disease in women with POI. Women with PCOS, although not oestrogen deficient, may have a subnormal ratio of high-density lipoprotein (HDL) to total cholesterol. This is as a consequence of the hypersecretion of insulin that occurs in many women with PCOS.

Glucose tolerance

Women who are obese, and also many slim women with PCOS, may have insulin resistance and elevated serum concentrations of insulin (usually <30 mIU/L fasting, although not measured in clinical practice). A 75-g oral glucose tolerance test should be performed in women with PCOS and a BMI above 30 kg/m^2, with an assessment of the fasting and 2-hour glucose concentration (Table 47.3). It has been suggested that South Asian women should have an assessment of glucose tolerance if their BMI is greater than 25 kg/m^2 because of the greater risk of insulin resistance at a lower BMI than seen in the white population.

Polycystic ovary syndrome

PCOS is a heterogeneous collection of signs and symptoms that form a spectrum of disorders, with mild presentation in some but severe disturbance of repro-

Table 47.3 Definitions of glucose tolerance after a 75-g glucose tolerance test.

	Diabetes mellitus	Impaired glucose tolerance	Impaired fasting glycaemia
Fasting glucose (mmol/L)	≥7.0	<7.0	≥6.1 and <7.0
2-hour glucose (mmol/L)	≥11.1	≥7.8 and ≤11.1	<7.8

ductive, endocrine and metabolic function in others. The pathophysiology of PCOS appears to be multifactorial and polygenic. The definition of the syndrome has been much debated. Key features include menstrual cycle disturbance, hyperandrogenism and obesity. There are many extra-ovarian aspects to the pathophysiology of PCOS, yet ovarian dysfunction is central. The joint ESHRE/ASRM (European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine) consensus defined PCOS as requiring the presence of two of the following three criteria:

1) oligo-ovulation and/or anovulation (i.e. oligomenorrhoea or amenorrhoea);
2) hyperandrogenism (clinical features and/or biochemical elevation of testosterone); and/or
3) polycystic ovaries assessed by ultrasound [2].

The consensus meeting that provided this definition was held in Rotterdam and so the ESHRE/ASRM criteria are often known as the Rotterdam criteria [2].

Other aetiologies of hyperandrogenism and menstrual cycle disturbance should be excluded by appropriate investigations, as described in this chapter. The morphology of the polycystic ovary has been redefined as an ovary with 12 or more follicles measuring 2–9 mm in diameter and/or increased ovarian volume (>10 cm^3) [3]. The use of higher resolution ultrasound than was available at the time of the Rotterdam meeting has led some to suggest that more follicles (19 or even 25) should define the polycystic ovary, but no consensus has been reached [4].

There is considerable heterogeneity of symptoms and signs among women with PCOS and for an individual these may change over time [1,2] (Table 47.4). PCOS may be familial, and various aspects of the syndrome may be differentially inherited. Polycystic ovaries can exist without clinical signs of the syndrome, which may then become expressed in certain circumstances. There are a number of factors that affect expression of PCOS, for example a gain in weight is associated with a worsening of symptoms while weight loss may ameliorate the endocrine and metabolic profile and symptomatology.

Genetic studies have identified a link between PCOS and disordered insulin metabolism, and indicate that the syndrome may be the presentation of a complex genetic trait disorder. The features of obesity, hyperinsulinaemia and hyperandrogenaemia, which are commonly seen in PCOS, are also known to be factors that confer an increased risk of cardiovascular disease and non-insulin-dependent diabetes mellitus (NIDDM) [5]. There are studies indicating that women with PCOS have an increased risk for these diseases, which pose long-term risks for health, and this evidence has prompted debate as to the need for screening women for PCOS [5] (Fig. 47.3).

Polycystic ovaries are commonly detected by ultrasound or other forms of pelvic imaging, with estimates of the prevalence in the general population being in the order of 20–33% [6]. Although the ultrasound criteria for the diagnosis of polycystic ovaries have not, until now, been universally agreed, the characteristic features are accepted as being an increase in the number of follicles and the amount of stroma compared with normal ovaries, resulting in an increase in ovarian volume. The 'cysts' are not cysts in the sense that they do contain oocytes and indeed are follicles whose development has been arrested. The actual number of cysts may be of less

Table 47.4 Signs and symptoms of polycystic ovary syndrome.

Symptoms
Hyperandrogenism (acne, hirsutism, alopecia – not virilization)
Menstrual disturbance
Infertility
Obesity
Sometimes: asymptomatic, with polycystic ovaries on ultrasound scan

Serum endocrinology
↑ Fasting insulin (not routinely measured; insulin resistance or impaired glucose tolerance assessed by GTT)
↑ Androgens (testosterone and androstenedione)
↑ or normal LH, normal FSH
↓ SHBG, results in elevated free androgen index
↑ Estradiol, estrone (neither measured routinely as very wide range of values)
↑ Prolactin

Possible late sequelae
Diabetes mellitus
Dyslipidaemia
Hypertension, cardiovascular disease
Endometrial carcinoma

FSH, follicle-stimulating hormone; GTT, glucose tolerance test; LH, luteinizing hormone; SHBG, sex hormone-binding globulin.

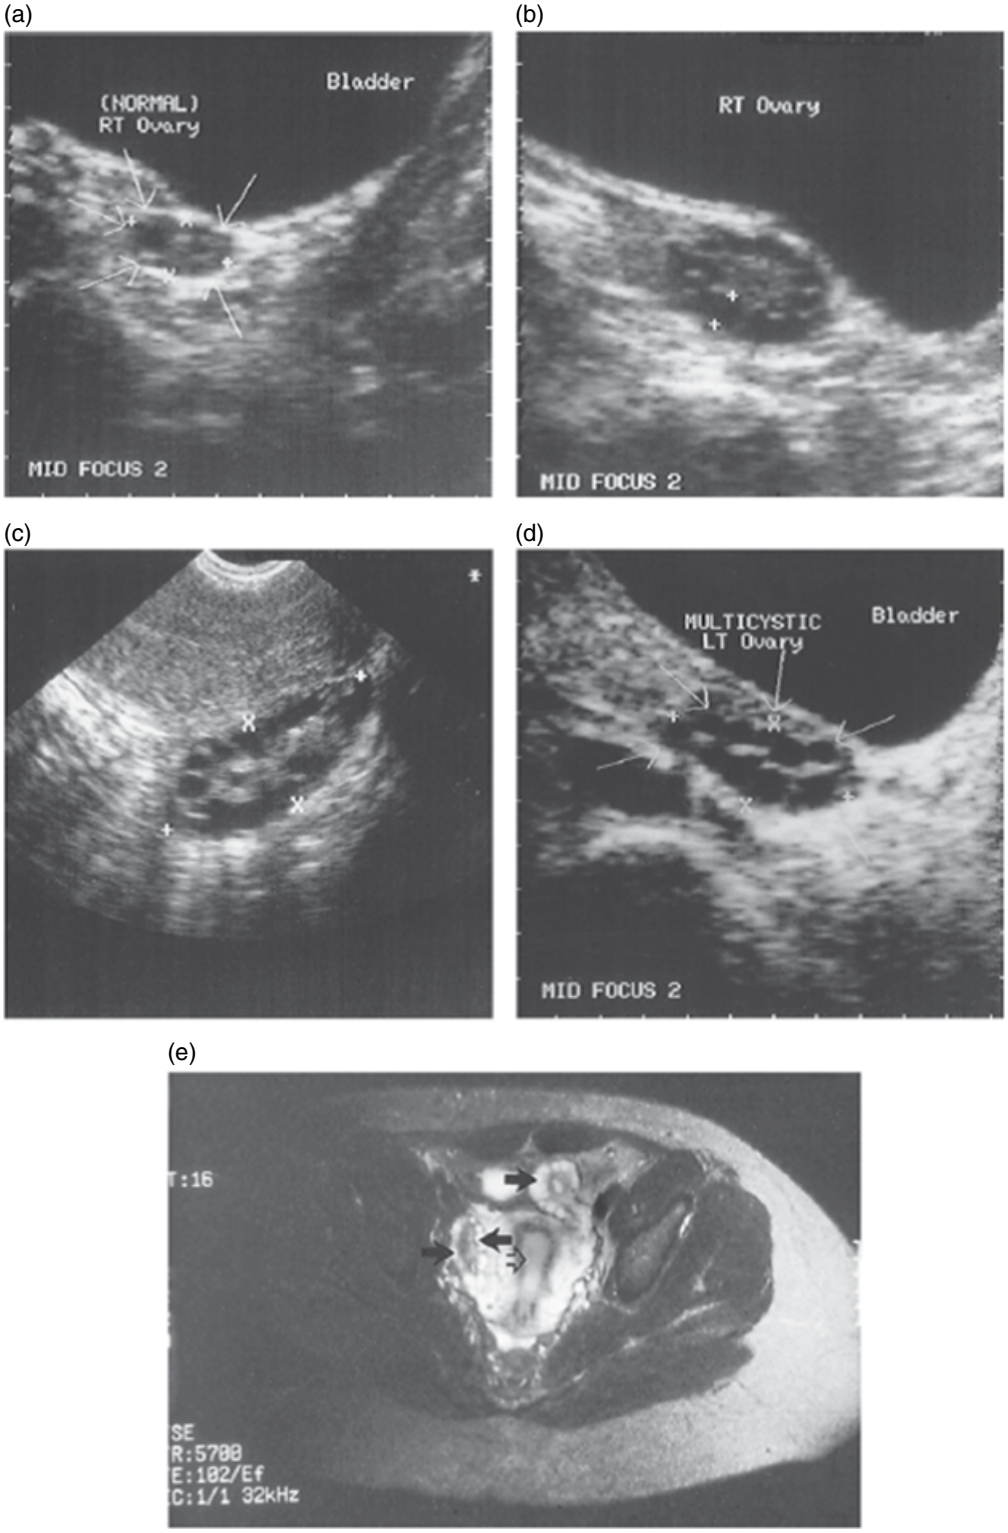

Fig. 47.3 (a) Transabdominal ultrasound scan of a normal ovary. (b) Transabdominal ultrasound scan of a polycystic ovary. (c) Transvaginal ultrasound scan of a polycystic ovary. (d) Transabdominal ultrasound scan of a multicystic ovary. (e) MRI of a pelvis, demonstrating two polycystic ovaries (closed arrows) and a hyperplastic endometrium (open arrow). *Source:* Balen AH. *Infertility in Practice*, 4th edn. London: Informa Healthcare, 2014. Reproduced with permission of CRC Press.

relevance than the volume of ovarian stroma or of the ovary itself, which has been shown to closely correlate with serum testosterone concentrations.

Genetics of polycystic ovary syndrome

Polycystic ovary syndrome has long been noted to have a familial component. Genetic analysis has been hampered by the lack of a universal definition for PCOS. Most of the criteria used for diagnosing PCOS are continuous traits, such as degree of hirsutism, level of circulating androgens, extent of menstrual irregularity, and ovarian volume and morphology. To perform genetic analyses, these continuous variables have to be transformed into nominal variables. Family studies have revealed that about 50% of first-degree relatives have PCOS, suggesting a dominant mode of inheritance [2,5]. Commonly, first-degree male relatives appear more likely to have the metabolic syndrome [7]. Further discussion of this complex area is beyond the scope of this chapter and much research is being performed to provide a more detailed account of the various genetic abnormalities that may be involved in the pathogenesis of PCOS.

Pathophysiology of polycystic ovary syndrome

Hypersecretion of androgens by the stromal theca cells of the polycystic ovary leads to the cardinal clinical manifestation of the syndrome, hyperandrogenism, and is also one of the mechanisms whereby follicular growth is inhibited with the resultant excess of immature follicles. Hypersecretion of LH by the pituitary – a result of both disordered ovarian–pituitary feedback and exaggerated pulses of gonadotrophin-releasing hormone (GnRH) from the hypothalamus – stimulates testosterone secretion by the ovary. Furthermore, insulin is a potent stimulus for androgen secretion by the ovary, which, by way of a different receptor for insulin, does not exhibit insulin resistance. Insulin therefore amplifies the effect of LH, and additionally magnifies the degree of hyperandrogenism by suppressing liver production of the main carrier protein, SHBG, thus elevating the free androgen index. It is a combination of genetic abnormalities combined with environmental factors, such as nutrition and body weight, which then affect expression of the syndrome.

Racial differences in expression of polycystic ovary syndrome

The highest reported prevalence of PCOS has been 52% among South Asian immigrants in Britain, of whom 49.1% had menstrual irregularity [8]. Rodin *et al.* [8] demonstrated that South Asian women with PCOS had a comparable degree of insulin resistance to controls with established type 2 diabetes mellitus. Insulin resistance and hyperinsulinaemia are common antecedents of type 2 diabetes, with a high prevalence in South Asian people. Type 2 diabetes also has a familial basis, inherited as a complex genetic trait that interacts with environmental factors, chiefly nutrition, commencing during fetal life. We have found that South Asian people with anovulatory PCOS have greater insulin resistance and more severe symptoms of the syndrome than anovulatory white people with PCOS [9]. Furthermore, we have found that women from South Asia living in the UK appear to express symptoms at an earlier age than their white British counterparts [10].

Health consequences of polycystic ovary syndrome

Obesity and metabolic abnormalities are recognized risk factors for the development of ischaemic heart disease in the general population, and these are also recognized features of PCOS. The question is whether women with PCOS are at an increased risk of ischaemic heart disease, and whether this will occur at an earlier age than women with normal ovaries. The basis for the idea that women with PCOS are at a greater risk for cardiovascular disease is that these women are more insulin resistant than weight-matched controls and that the metabolic disturbances associated with insulin resistance are known to increase cardiovascular risk in other populations. Insulin resistance is defined as a diminution in the biological responses to a given level of insulin. In the presence of an adequate pancreatic reserve, normal circulating glucose levels are maintained at higher serum insulin concentrations. In the general population, cardiovascular risk factors include insulin resistance, obesity, glucose intolerance, hypertension and dyslipidaemia.

There have been a large number of studies demonstrating the presence of insulin resistance and corresponding hyperinsulinaemia in both obese and non-obese women with PCOS [5]. Obese women with PCOS have consistently been shown to be more insulin resistant than weight-matched controls. It appears that obesity and PCOS have an additive effect on the degree and severity of the insulin resistance and subsequent hyperinsulinaemia in this group of women. The insulin resistance causes compensatory hypersecretion of insulin, particularly in response to glucose, so euglycaemia is usually maintained at the expense of hyperinsulinaemia. Insulin resistance is restricted to the extrasplanchnic actions of insulin on glucose dispersal. The liver is not affected (hence the fall in SHBG and HDL), neither is the ovary (hence the menstrual problems and hypersecretion of androgens) nor the skin, hence the development

of acanthosis nigricans. Women with PCOS who are oligomenorrhoeic are more likely to be insulin resistant than those with regular cycles, irrespective of their BMI, with the intermenstrual interval correlating with the degree of insulin resistance [5].

Women with PCOS have a greater truncal abdominal fat distribution as demonstrated by a higher waist to hip ratio. The central distribution of fat is independent of BMI and associated with higher plasma insulin and triglyceride concentrations and reduced HDL cholesterol concentrations. From a practical point of view, if the measurement of waist circumference is greater than 80 cm, there will be excess visceral fat and an increased risk of metabolic problems.

Thus, there is evidence that insulin resistance, central obesity and hyperandrogenaemia have an adverse effect on lipid metabolism, yet these are surrogate risk factors for cardiovascular disease. Significantly, Pierpoint *et al.* [11] reported the mortality rate in 1028 women diagnosed as having PCOS between 1930 and 1979. All the women were older than 45 years and 770 women had been treated by wedge resection of the ovaries. A total of 786 women were traced; the mean age at diagnosis was 26.4 years and the average duration of follow-up was 30 years. There were 59 deaths, of which 15 were from circulatory disease. Of these 15 deaths, 13 were from ischaemic heart disease. There were six deaths from diabetes as an underlying or contributory cause compared with the expected 1.7 deaths. The standard mortality rate both overall and for cardiovascular disease was not higher in the women with PCOS than the national mortality rates in women, although the observed proportion of women with diabetes as a contributory or underlying factor leading to death was significantly higher than expected (odds ratio 3.6, 95% CI 1.5–8.4). Thus, despite surrogate markers for cardiovascular disease, no increased rate of death from cardiovascular disease could be demonstrated in this study [5,11].

Polycystic ovary syndrome in younger women

The majority of studies that have identified the risk factors of obesity and insulin resistance in women with PCOS have investigated adult populations, commonly including women who have presented to specialist endocrine or reproductive clinics. However, PCOS has been identified in much younger populations [6], in which women with increasing symptoms of PCOS were found to be more insulin resistant. These data emphasize the need for long-term prospective studies of young women with PCOS in order to clarify the natural history and to determine which women will be at risk of diabetes and cardiovascular disease later in life. A study of women with PCOS and a mean age of 39 years followed over a period of 6 years found that 9% of those with normal glucose tolerance developed impaired glucose tolerance (IGT) and 8% developed NIDDM [12], while 54% of women with IGT at the start of the study had NIDDM at follow-up. The risks of disease progression, not surprisingly, were greatest in those who were overweight.

Whilst PCOS may evolve during adolescence, many of the symptoms (e.g. menstrual irregularity and acne) occur commonly in normal adolescent girls and so it is generally considered unwise to make the diagnosis until more than 2 years after menarche [5].

Endometrial cancer

Endometrial adenocarcinoma is the second most common female genital malignancy, but only 4% of cases occur in women aged under 40 years. The risk of developing endometrial cancer has been shown to be adversely influenced by a number of factors, including obesity, long-term use of unopposed oestrogens, nulliparity and infertility. Women with endometrial carcinoma have had fewer births than controls, and it has also been demonstrated that infertility per se increases the risk [5]. Hypertension and type 2 diabetes mellitus have long been linked to endometrial cancer – conditions that are now known also to be associated with PCOS. However, the true risk of endometrial carcinoma in women with clearly defined PCOS is difficult to ascertain [5].

Endometrial hyperplasia may be a precursor to adenocarcinoma, although the rate of progression is difficult to predict. Although the degree of risk has not been clearly defined, it is generally accepted that for women with PCOS who experience amenorrhoea or oligomenorrhoea, the induction of artificial withdrawal bleeds to prevent endometrial hyperplasia is prudent management [5]. Indeed, we consider it important that women with PCOS shed their endometrium at least every 3 months. For those with oligomenorrhoea/amenorrhoea who do not wish to use cyclical hormone therapy, we recommend an ultrasound scan to measure endometrial thickness and morphology every 6–12 months (depending on menstrual history). An endometrial thickness greater than 10 mm in an amenorrhoeic woman warrants an artificially induced bleed, which should be followed by a repeat ultrasound scan and endometrial biopsy if the endometrium has not been shed. Another option is to consider a progestogen-secreting intrauterine system such as Mirena® (Bayer Pharma, Newbury, UK).

Breast cancer

Obesity, hyperandrogenism and infertility occur frequently in PCOS and are features known to be associated

with the development of breast cancer. However, studies examining the relationship between PCOS and breast carcinoma have not always identified a significantly increased risk [5]. Pierpoint *et al.* [11] assessed mortality from the national registry of deaths and standardized mortality rate (SMR) calculated for patients with PCOS compared with the normal population. The average follow-up period was 30 years. The SMR for all neoplasms was 0.91 (95% CI 0.60–1.32) and for breast cancer was 1.48 (95% CI 0.79–2.54). In fact, breast cancer was the leading cause of death in this cohort.

Ovarian cancer

In recent years there has been much debate about the risk of ovarian cancer in women with infertility, particularly in relation to the use of drugs to induce superovulation for assisted conception procedures. Inherently the risk of ovarian cancer appears to be increased in women who have multiple ovulations – that is those who are nulliparous (possibly because of infertility) with an early menarche and late menopause. Thus, it may be that inducing multiple ovulations in women with infertility will increase their risk, a notion that is by no means proven. Women with PCOS who are oligo-ovulatory/anovulatory might therefore be expected to be at low risk of developing ovarian cancer if it is lifetime number of ovulations rather than pregnancies that is critical. Ovulation induction to correct anovulatory infertility aims to induce unifollicular ovulation, and so in theory should raise the risk of a woman with PCOS to that of a woman with normal ovulation. However, the polycystic ovary is notoriously sensitive to stimulation and it is only in recent years with the development of high-resolution transvaginal ultrasonography that the rate of unifollicular ovulation has attained acceptable levels. There are a few studies which have addressed the possibility of an association between polycystic ovaries and ovarian cancer. The results are conflicting and the ability to generalize is limited owing to problems with the study designs [5]. In the large UK study by Pierpoint *et al.* [11], the SMR for ovarian cancer was 0.39 (95% CI 0.01–2.17).

Management of polycystic ovary syndrome

Obesity

The clinical management of a women with PCOS should be focused on her individual problems. Obesity worsens both symptomatology and the endocrine profile and obese women (BMI >30 kg/m^2) should therefore be encouraged to lose weight. Weight loss improves the endocrine profile, the likelihood of ovulation and a healthy pregnancy. Much has been written about diet and PCOS. The right diet for an individual is one that is practical, sustainable and compatible with her lifestyle. It is sensible to keep carbohydrate content down and to avoid fatty foods. It is often helpful to refer to a dietitian. Bariatric surgery (either gastric banding or gastric bypass procedures) are also very effective for women with a BMI over 35 kg/m^2, although it is inadvisable to conceive immediately after surgery until metabolism has stabilized after the initial rapid loss of weight [13].

Menstrual irregularity

Amenorrhoeic women with PCOS are not oestrogen deficient and are not at risk of osteoporosis. Indeed, they are oestrogen replete and at risk of endometrial hyperplasia (see section on endometrial cancer). The easiest way to control the menstrual cycle is the use of a low-dose combined oral contraceptive preparation. This will result in an artificial cycle and regular shedding of the endometrium. An alternative is a progestogen such as medroxyprogesterone acetate (Provera) for 12 days every 1–3 months to induce a withdrawal bleed, or the continuous provision of progesterone into the uterine cavity by Mirena. It is important once again to encourage weight loss.

Hyperandrogenism and hirsutism

The bioavailability of testosterone is affected by the serum concentration of SHBG. High levels of insulin lower the production of SHBG and so increase the free fraction of androgen. Elevated serum androgen concentrations stimulate peripheral androgen receptors, resulting in an increase in 5α-reductase activity, directly increasing the conversion of testosterone to the more potent metabolite dihydrotestosterone. Women with PCOS do not become virilized (i.e. they do not develop deepening of the voice, increased muscle mass, breast atrophy or clitoromegaly). A total testosterone level greater than 5 nmol/L or rapid onset of signs of hyperandrogenism requires further investigation. Late-onset CAH is not common in the UK but is more prevalent in certain ethnic groups (e.g. Mediterranean, South American and some Jewish populations).

Hirsutism is characterized by terminal hair growth in a male pattern of distribution, including the chin, upper lip, chest, upper and lower back, upper and lower abdomen, upper arm, thigh and buttocks. A standardized scoring system, such as the modified Ferriman–Gallwey score, may be used to evaluate the degree of hirsutism before and during treatments (Fig. 47.4). Many women attend having already tried cosmetic techniques and so it may be difficult to obtain a baseline assessment.

Drug therapies may take 6–9 months or longer before any improvement in hirsutism is perceived. Physical treatments including electrolysis, waxing and bleaching

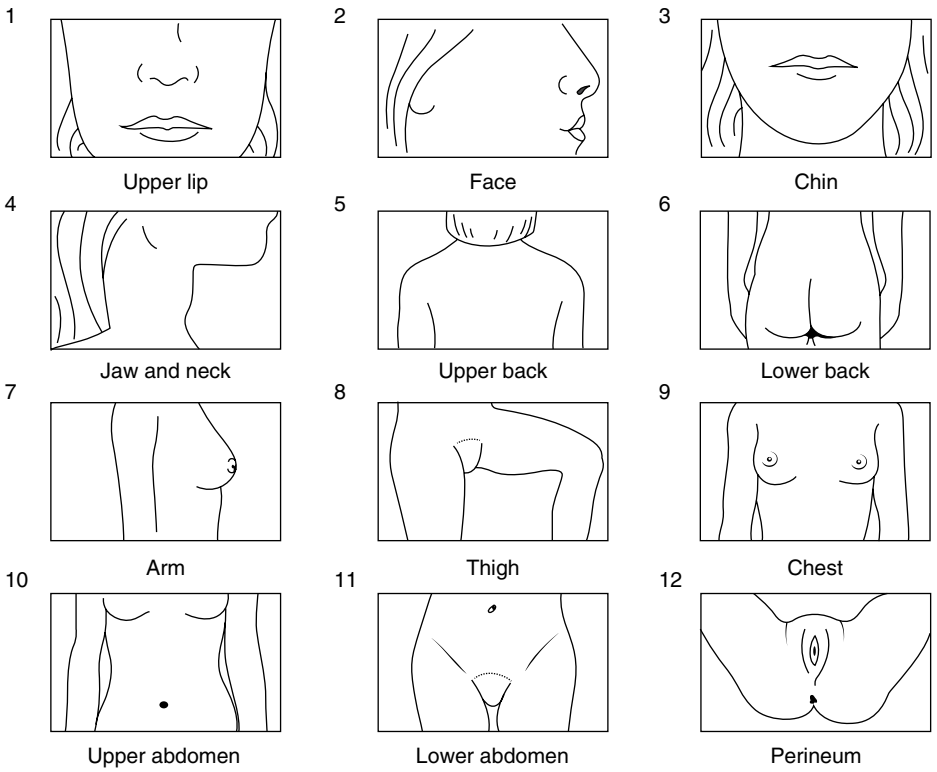

Fig. 47.4 The Ferriman–Gallwey Hirsutism Scoring System. The chart is used both to provide an initial score, with a scale of 0–3 at each of 12 points, depending on severity, and for the monitoring of progress with therapy. *Source:* Balen AH. *Infertility in Practice*, 4th edn. London: Informa Healthcare, 2014. Reproduced with permission of CRC Press.

may be helpful while waiting for medical treatments to work. Electrolysis is time-consuming, painful and expensive, and should be performed by an expert practitioner. Regrowth is not uncommon and there is no really permanent cosmetic treatment. Laser and photothermolysis techniques are more expensive but may have a longer duration of effect. Comparative studies, however, have not been performed. Repeated treatments are required for a near-permanent effect because only hair follicles in the growing phase are obliterated at each treatment. Hair growth occurs in three cycles, so 6–9 months of regular treatments are typical. The topical use of eflornithine may be effective. It works by inhibiting the enzyme ornithine decarboxylase in hair follicles and may be a useful therapy for those who wish to avoid hormonal treatments, but may also be used in conjunction with hormonal therapy. Eflornithine may cause some thinning of the skin and so high-factor sun block is recommended when exposed to the sun.

Medical regimens should stop further progression of hirsutism and decrease the rate of hair growth. Adequate contraception is important in women of reproductive age as transplacental passage of anti-androgens may disturb the genital development of a male fetus. First-line therapy has traditionally been the preparation Dianette, which contains ethinylestradiol (30 μg) in combination with cyproterone acetate (2 mg). The addition of higher doses of the synthetic progestogen cyproterone acetate (50–100 mg) do not appear to confer additional benefit. The effect on acne and seborrhoea is usually evident within a couple of months. Cyproterone acetate can rarely be associated with liver damage, and liver function should be checked after 6 months and then annually. Once symptom control has been obtained, it is advisable to switch to a combined oral contraceptive pill containing a lower dose of ethinylestradiol because of concerns about the increased risk of thromboembolism with Dianette [5].

In women in whom the combined oral contraceptive pill is contraindicated, spironolactone, a weak diuretic with anti-androgenic properties, may be used at a daily dose of 25–100 mg. Drospirenone is a derivative of spironolactone and is contained in the combined oral contraceptive pill Yasmin, which may also be beneficial for women with PCOS.

Other anti-androgens such as ketoconazole, finasteride and flutamide have been tried, but are not widely

used in the UK for the treatment of hirsutism in women owing to their adverse side effects. Furthermore, they are no more effective than cyproterone acetate [5].

Infertility

Various factors influence ovarian function, and fertility is adversely affected by an individual being overweight or having elevated serum concentrations of LH. Strategies to induce ovulation include weight loss, oral antioestrogens (principally clomifene citrate or tamoxifen), parenteral gonadotrophin therapy and laparoscopic ovarian surgery. Clomifene is the traditional first-line therapy and can be continued for 6–12 cycles of treatment if the patient is ovulating with normal endocrinology. Aromatase inhibitors, such as letrozole, may also stimulate ovulation and appear to be associated with a lower risk of multiple pregnancy; however, they are not currently licensed for the treatment of infertility. For those who do not ovulate, the options include daily injections of either recombinant FSH, human menopausal gonadotrophins (hMGs, which contain both FSH and LH activity) or laparoscopic ovarian diathermy [14]. Women with PCOS are at risk of ovarian hyperstimulation syndrome (OHSS) and multiple pregnancy, and so ovulation induction has to be carefully monitored with serial ultrasound scans.

Improvements in lifestyle, with a combination of exercise and diet to achieve weight reduction, are important for improving the prospects of both spontaneous and drug-induced ovulation. In addition, overweight women with PCOS are at increased risk of obstetric complications, gestational diabetes mellitus and pre-eclampsia, and their fetuses are at increased risk of congenital malformations and miscarriage [15].

Ovulation can be induced with the antioestrogen clomifene citrate (50–100 mg) taken from days 2–6 of a natural or artificially induced bleed. While clomifene is successful in inducing ovulation in over 80% of women, pregnancy only occurs in about 40%. Clomifene citrate should only be prescribed in a setting where ultrasound monitoring is available (and performed) in order to minimize the 10% risk of multiple pregnancy and to ensure that ovulation is taking place [14]. A daily dose of more than 100 mg rarely confers any benefit and can cause thickening of the cervical mucus, which can impede passage of sperm through the cervix. Once an ovulatory dose has been reached, the cumulative conception rate continues to increase for up to 10–12 cycles [14].

The therapeutic options for patients with anovulatory infertility who are resistant to antioestrogens are either parenteral gonadotrophin therapy or laparoscopic ovarian diathermy. Because the polycystic ovary is very sensitive to stimulation by exogenous hormones, it is extremely important to start with very low doses of gonadotrophins and follicular development must be carefully monitored by ultrasound scans. The advent of transvaginal ultrasonography has enabled the multiple pregnancy rate to be reduced to less than 5% because of its higher resolution and clearer view of the developing follicles. Cumulative conception and live-birth rates after 6 months may be 62% and 54%, respectively, and after 12 months 73% and 62%, respectively [16] (Fig. 47.5). Close monitoring should enable treatment to be suspended if more than two mature follicles develop, as the risk of multiple pregnancy increases (Fig. 47.6).

Women with PCOS are also at increased risk of developing OHSS. This occurs if too many follicles (>10 mm) are stimulated and results in abdominal distension, discomfort, nausea, vomiting and sometimes difficulty in breathing. The mechanism for OHSS is thought to be secondary to activation of the ovarian renin–angiotensin pathway and excessive secretion of

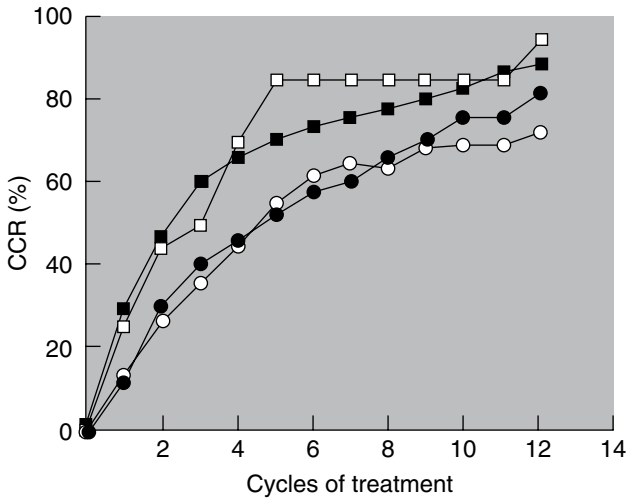

Fig. 47.5 Cumulative conception rates (CCR) over successive cycles in normal women (closed square) and after ovulation induction in 103 women with anovulatory PCOS (open circle), 77 women with hypogonadotrophic hypogonadism (closed circle) and 20 patients with weight-related amenorrhoea (open square). While patients with weight-related amenorrhoea conceive readily after ovulation induction, we now believe that their management should be weight gain before conception (see text). *Source:* Balen AH, Braat DDM, West C, Patel A, Jacobs HS. Cumulative conception and live birth rates after the treatment of anovulatory infertility. *Hum Reprod* 1994;9:1563–1570. Reproduced with permission of Oxford University Press.

vascular epidermal growth factor (VEGF). The ascites and pleural and pericardial effusions exacerbate this serious condition and the resultant haemoconcentration can lead to thromboembolism. The situation worsens if a pregnancy has resulted from the treatment as human chorionic gonadotrophin from the placenta further stimulates the ovaries. Hospitalization is sometimes necessary in order for intravenous fluids and heparin to be given to prevent dehydration and thromboembolism. Although OHSS is rare, it is potentially fatal and should be avoidable with appropriate monitoring of gonadotrophin therapy.

Ovarian diathermy is free of the risks of multiple pregnancy and OHSS and does not require intensive ultrasound monitoring. Laparoscopic ovarian diathermy has taken the place of wedge resection of the ovaries (which resulted in extensive periovarian and tubal adhesions) and carries a reduced risk of multiple pregnancy compared with gonadotrophin therapy in the treatment of clomifene-insensitive PCOS. Pregnancy rates are higher with 6 months of gonadotrophin therapy compared with 6 months after laparoscopic ovarian diathermy [17].

Insulin-sensitizing agents and metformin

A number of pharmacological agents have been used to amplify the physiological effect of weight loss, notably metformin. This biguanide inhibits the production of hepatic glucose and enhances the sensitivity of peripheral tissue to insulin, thereby decreasing insulin secretion. It has been shown that metformin may ameliorate hyperandrogenism and abnormalities of gonadotrophin secretion in some women with PCOS, and therefore it was suggested that it might restore menstrual cyclicity and fertility. The insulin-sensitizing agent troglitazone also appeared to significantly improve the metabolic and reproductive abnormalities in PCOS, although it was withdrawn because of reports of deaths from hepatotoxicity, and other thiazolidinediones such as rosiglitazone and pyoglitazone are not advocated for women trying to conceive.

Most of the initial studies of metformin in the management of PCOS were observational. Metformin appears to be less effective in those who are significantly obese (BMI >35 kg/m^2). The largest appropriately powered, prospective, randomized, double-blind, placebo-controlled study set out to evaluate the combined effects of lifestyle modification and metformin in 143 obese anovulatory women with a mean BMI of 38 kg/m^2 [18]. All subjects had an individualized assessment by a dietitian in order to set a realistic goal that could be sustained with an average reduction of energy intake of 500 kcal/day. As a result, both the metformin-treated and placebo groups managed to lose weight, but the amount of weight reduction did not differ between the two groups. An increase in menstrual cyclicity was observed in those who lost weight but again did not differ between the two arms of the study, reinforcing the key role of weight reduction.

Summary box 47.2

- PCOS is the commonest endocrine disorder in women (prevalence 15–20%).
- PCOS runs in families and affects approximately 50% of first-degree relatives.
- PCOS is a heterogeneous condition. Diagnosis is made by the presence of two of the following three criteria: (i) oligo-ovulation and/or anovulation, (ii) hyperandrogenism (clinical and/or biochemical) or (iii) polycystic ovaries, with the exclusion of other aetiologies of menstrual irregularity and androgen excess.
- Management is symptom-orientated.
- If obese, weight loss improves symptoms and endocrinology and should be encouraged. A glucose tolerance test should be performed if BMI is above 30 kg/m^2 (>25 kg/m^2 if Asian). Dietary advice and exercise are essential components of a weight-reduction programme. Anti-obesity surgery may be indicated.
- Menstrual cycle control may be achieved by using cyclical oral contraceptives or progestogens.
- Ovulation induction may be difficult and require progression through various treatments, which should be monitored carefully to prevent multiple pregnancy.
- Hyperandrogenism is usually managed with Dianette, which contains ethinylestradiol in combination with cyproterone acetate, or Yasmin, which contains drospirenone. Alternatives include spironolactone, and reliable contraception is required.
- There is no place for insulin-sensitizing agents (e.g. metformin) in the absence of impaired glucose tolerance or type 2 diabetes.

Two large randomized controlled trials also concluded that as first-line therapy for the treatment of anovulatory infertile women with PCOS, metformin alone was significantly less effective than clomifene citrate alone, and that the addition of metformin to clomifene citrate produced no significant benefit [19,20]. The recent Cochrane review has also concluded that there is no benefit of metformin in achieving an increased rate of live birth either alone or in combination, and so the use of metformin is only recommended when there is impaired glucose tolerance or type 2 diabetes [21].

Secondary amenorrhoea

Cessation of menstruation for six consecutive months in a woman who has previously had regular periods is the usual criterion for investigation. However, some authorities consider 3 or 4 months of amenorrhoea to be pathological, but this is a debate between the definition of amenorrhoea and oligomenorrhoea. Women with secondary amenorrhoea must have a patent lower genital tract, an endometrium that is responsive to ovarian hormone stimulation and ovaries that have responded to pituitary gonadotrophins.

Secondary amenorrhoea is best classified according to its aetiological site of origin and can be subdivided into disorders of the hypothalamic–pituitary–ovarian–uterine axis and generalized systemic disease. The principal causes of secondary amenorrhoea are outlined in Table 47.2. The frequency with which these conditions present, on the other hand, can be seen in Table 47.5.

Table 47.5 The aetiology of secondary amenorrhoea in 570 patients attending an endocrine clinic [31].

Polycystic ovary syndrome	37%
Premature ovarian insufficiency	24%
Hyperprolactinaemia	17%
Weight-related amenorrhoea	10%
Hypogonadotrophic hypogonadism	6%
Hypopituitarism	4%
Exercise-related amenorrhoea	3%

Management of secondary amenorrhoea

Genital tract abnormalities

Asherman's syndrome

Asherman's syndrome is a condition in which intrauterine adhesions prevent normal growth of the endometrium [22]. This may be the result of an over-vigorous endometrial curettage affecting the basalis layer of the endometrium or adhesions that may follow an episode of endometritis. It is thought that oestrogen deficiency increases the risk of adhesion formation in breast-feeding women who require a puerperal curettage for retained placental tissue. Typically, amenorrhoea is not absolute, and it may be possible to induce a withdrawal bleed using a combined oestrogen/progestogen preparation. Intrauterine adhesions may be seen on an HSG (see Fig. 47.2). Alternatively, hysteroscopic inspection of the uterine cavity will confirm the diagnosis and enable treatment by adhesiolysis. The adhesions bridge the anterior and posterior walls of the uterine cavity

and are usually avascular, although may contain vessels, muscle and even endometrium. Following surgery, high-dose oral oestrogens are initially prescribed followed by a 3-month course of cyclical progesterone/oestrogens. Some clinicians insert a Foley catheter into the uterine cavity for 7–10 days postoperatively or an intrauterine contraceptive device for 2–3 months in order to prevent recurrence of adhesions. A 'second-look' hysteroscopy or HSG may be required.

Cervical stenosis

Cervical stenosis is an occasional cause of secondary amenorrhoea. It was relatively common following a traditional cone biopsy for the treatment of cervical intraepithelial neoplasia. However, modern procedures, such as laser or loop diathermy, have less postoperative cervical complications. It still occasionally occurs following curettage of the uterus which inadvertently damages the endocervix. Treatment for cervical stenosis consists of careful cervical dilatation, usually under ultrasound guidance.

Ovarian causes of secondary amenorrhoea

Polycystic ovary syndrome

See above.

Premature ovarian insufficiency

Ovarian failure by definition is the cessation of periods accompanied by a raised gonadotrophin level prior to the age of 40 years [23]. It may occur at any age. The exact incidence of this condition is unknown as many cases go unrecognized, but estimates vary between 1 and 5% of the female population. Studies of amenorrhoeic women report the incidence of POI (formerly known as premature ovarian failure) to be between 10 and 36%.

Chromosomal abnormalities have been found in up to 70% of patients with primary amenorrhoea and in 2–5% of women with secondary amenorrhoea due to POI. Ovarian failure occurring before puberty is usually due to a chromosomal abnormality or a childhood malignancy that required chemotherapy or radiotherapy. Adolescents who lose ovarian function soon after menarche are often found to have a Turner mosaic (46XX/45X) or an X-chromosome trisomy (47XXX). There are some genetic anomalies that run in families with POI, although these are not assessed in routine clinical practice.

Ovarian autoantibodies can be measured and have been found in up to 70% of women with POI. However, the assay is expensive and not readily available in most units. It is therefore important to consider other autoimmune disorders and screen for autoantibodies to the thyroid gland, gastric mucosa parietal cells and adrenal gland if there is any clinical indication.

Before the absolute cessation of periods of true POI, some women experience an intermittent return to menses, interspersed between variable periods of amenorrhoea. Gonadotrophin levels usually remain moderately elevated during these spontaneous cycles, with plasma FSH levels of 15–20 IU/L. This occult ovarian failure, or resistant ovary syndrome, is associated with the presence of primordial follicles on ovarian biopsy (which incidentally is not a procedure that should be performed to make the diagnosis). Pregnancies are sometimes achieved, although the ovaries are usually resistant to exogenous gonadotrophins as they are to endogenous hormones. It is probable that reports of pregnancy in women with POI represent cases of fluctuating ovarian function rather than successes of treatment [23].

However, it is possible to achieve pregnancy by oocyte donation as part of IVF treatment. For women who are predicted to develop ovarian failure as a result of sterilizing chemotherapy for malignancy, it is now possible to cryopreserve oocytes collected during an IVF-stimulation protocol, which are frozen either as oocytes or as fertilized oocytes (embryos) if the patient has a partner. An alternative approach is the surgical removal of a whole ovary and transplantation of cryopreserved ovarian tissue once the cancer treatment is completed. Live births have been achieved by all these methods, although the technology for oocyte cryopreservation is less efficient than for embryo cryopreservation and ovarian tissue freezing is still in its infancy [23].

The diagnosis and consequences of POI require careful counselling of the patient. It may be particularly difficult for a young woman to accept the need to take oestrogen preparations that are clearly labelled as being intended for older postmenopausal women while at the same time having to come to terms with the inability to conceive naturally. The short- and long-term consequences of ovarian failure and oestrogen deficiency are similar to those occurring in the fifth and sixth decade. However, the duration of the problem is much longer and therefore HRT is advisable in order to reduce the consequences of oestrogen deficiency in the long term [23].

Younger women with premature loss of ovarian function have an increased risk of osteoporosis. A series of 200 amenorrhoeic women between the ages of 16 and 40 years demonstrated a mean reduction in BMD of 15% compared with a control group and after correction for body weight, smoking and exercise [24]. The degree of bone loss was correlated with the duration of the amenorrhoea and the severity of the oestrogen deficiency rather than the underlying diagnosis, and was worse in patients with primary amenorrhoea than in those with secondary amenorrhoea. A return to normal oestrogen status may improve bone mass density, but BMD is unlikely to improve by more than 5–10% and it probably

does not return to its normal value. However, it is not certain if the radiological improvement seen will actually reduce the risk of fracture, as remineralization is not equivalent to the restrengthening of bone. Early diagnosis and early correction of oestrogen status is therefore important.

Women with POI may have an increased risk of cardiovascular disease. Oestrogens have been shown to have beneficial effects on cardiovascular status in women. They increase the levels of cardioprotective HDL but also total triglyceride levels, while decreasing total cholesterol and low-density lipoprotein levels. The overall effect is of cardiovascular protection.

The HRT preparations prescribed for menopausal women are also preferred for young women. The reason for this is that even modern low-dose combined oral contraceptive preparations contain at least twice the amount of oestrogen that is recommended for HRT in order to achieve a contraceptive suppressive effect on the hypothalamic–pituitary axis. HRT also contains 'natural' oestrogens (estradiol) rather than the synthetic ethinylestradiol found in most combined oral contraceptive preparations.

Pituitary causes of secondary amenorrhoea

Hyperprolactinaemia is the commonest pituitary cause of amenorrhoea. There are many causes of a mildly elevated serum prolactin concentration, including stress, and a recent physical or breast examination. If the prolactin concentration is greater than 1000 mIU/L then the test should be repeated, and if still elevated it is necessary to image the pituitary fossa (with CT or MRI). Hyperprolactinaemia may result from a prolactin-secreting pituitary adenoma or from a non-functioning 'disconnection' tumour in the region of the hypothalamus or pituitary, which disrupts the inhibitory influence of dopamine on prolactin secretion. Large non-functioning tumours are usually associated with serum prolactin concentrations of less than 3000 mIU/L, while prolactin-secreting macroadenomas usually result in concentrations of 8000 mIU/L or more. Other causes include hypothyroidism, PCOS (up to 2500 mIU/L) and several drugs (e.g. the dopaminergic antagonists phenothiazines, domperidone and metoclopramide).

In women with amenorrhoea associated with hyperprolactinaemia, the main symptoms are usually those of oestrogen deficiency. In contrast, when hyperprolactinaemia is associated with PCOS, the syndrome is characterized by adequate oestrogenization, polycystic ovaries on ultrasound scan and a withdrawal bleed in response to a progestogen challenge test. Galactorrhoea may be found in up to one-third of patients with hyperprolactinaemia, although its appearance is correlated neither with prolactin levels nor with the presence of a tumour. Approximately 5% of patients present with visual field defects.

A prolactin-secreting pituitary microadenoma is usually associated with a moderately elevated prolactin (1500–4000 mIU/L) and is unlikely to result in abnormalities on a lateral skull X-ray. On the other hand, a macroadenoma, associated with a prolactin greater than 5000–8000 mIU/L and by definition greater than 1 cm diameter may cause typical radiological changes: an asymmetrically enlarged pituitary fossa with a double contour to its floor and erosion of the clinoid processes. Skull X-rays are rarely performed these days as CT and MRI scans now allow detailed examination of the extent of the tumour and, in particular, identification of suprasellar extension and compression of the optic chiasma or invasion of the cavernous sinuses. Prolactin is an excellent tumour marker, and so the higher the serum concentration, the larger the size of the tumour expected on the MRI scan. In contrast, a large tumour on the scan with only a moderately elevated serum prolactin concentration (2000–3000 mIU/L) suggests a non-functioning tumour with 'disconnection' from the hypothalamus (Fig. 47.7).

The management of hyperprolactinaemia centres around the use of a dopamine agonist, of which bromocriptine and cabergoline are the most widely used. Of course, if the hyperprolactinaemia is drug induced, stopping the relevant preparation should be commended. However, this may not be appropriate if the cause is a psychotropic medication, for example a phenothiazine being used to treat schizophrenia. In these cases it is reasonable to continue the drug and prescribe a low-dose combined oral contraceptive preparation in order to counteract the symptoms of oestrogen deficiency. Serum prolactin concentrations must then be carefully monitored to ensure that they do not rise further. Most patients show a fall in prolactin levels within a few days of commencing bromocriptine therapy and a reduction in tumour volume within 6 weeks. Side effects can be troublesome (nausea, vomiting, headache, postural hypotension) and are minimized by commencing the therapy at night for the first 3 days of treatment and taking the tablets in the middle of a mouthful of food. The longer-acting preparation cabergoline appears to have fewer side effects and is more commonly used these days. Longer-term side effects include Raynaud's phenomenon, constipation and psychiatric changes, especially aggression, which can occur at the start of treatment. Bromocriptine and cabergoline have been associated with pulmonary, retroperitoneal and pericardial fibrotic reactions and so echocardiography is recommended before starting treatment in order to exclude valvulopathy and this should be repeated after 3–6 months and then annually, although young patients are less at risk than older patients who may be prescribed

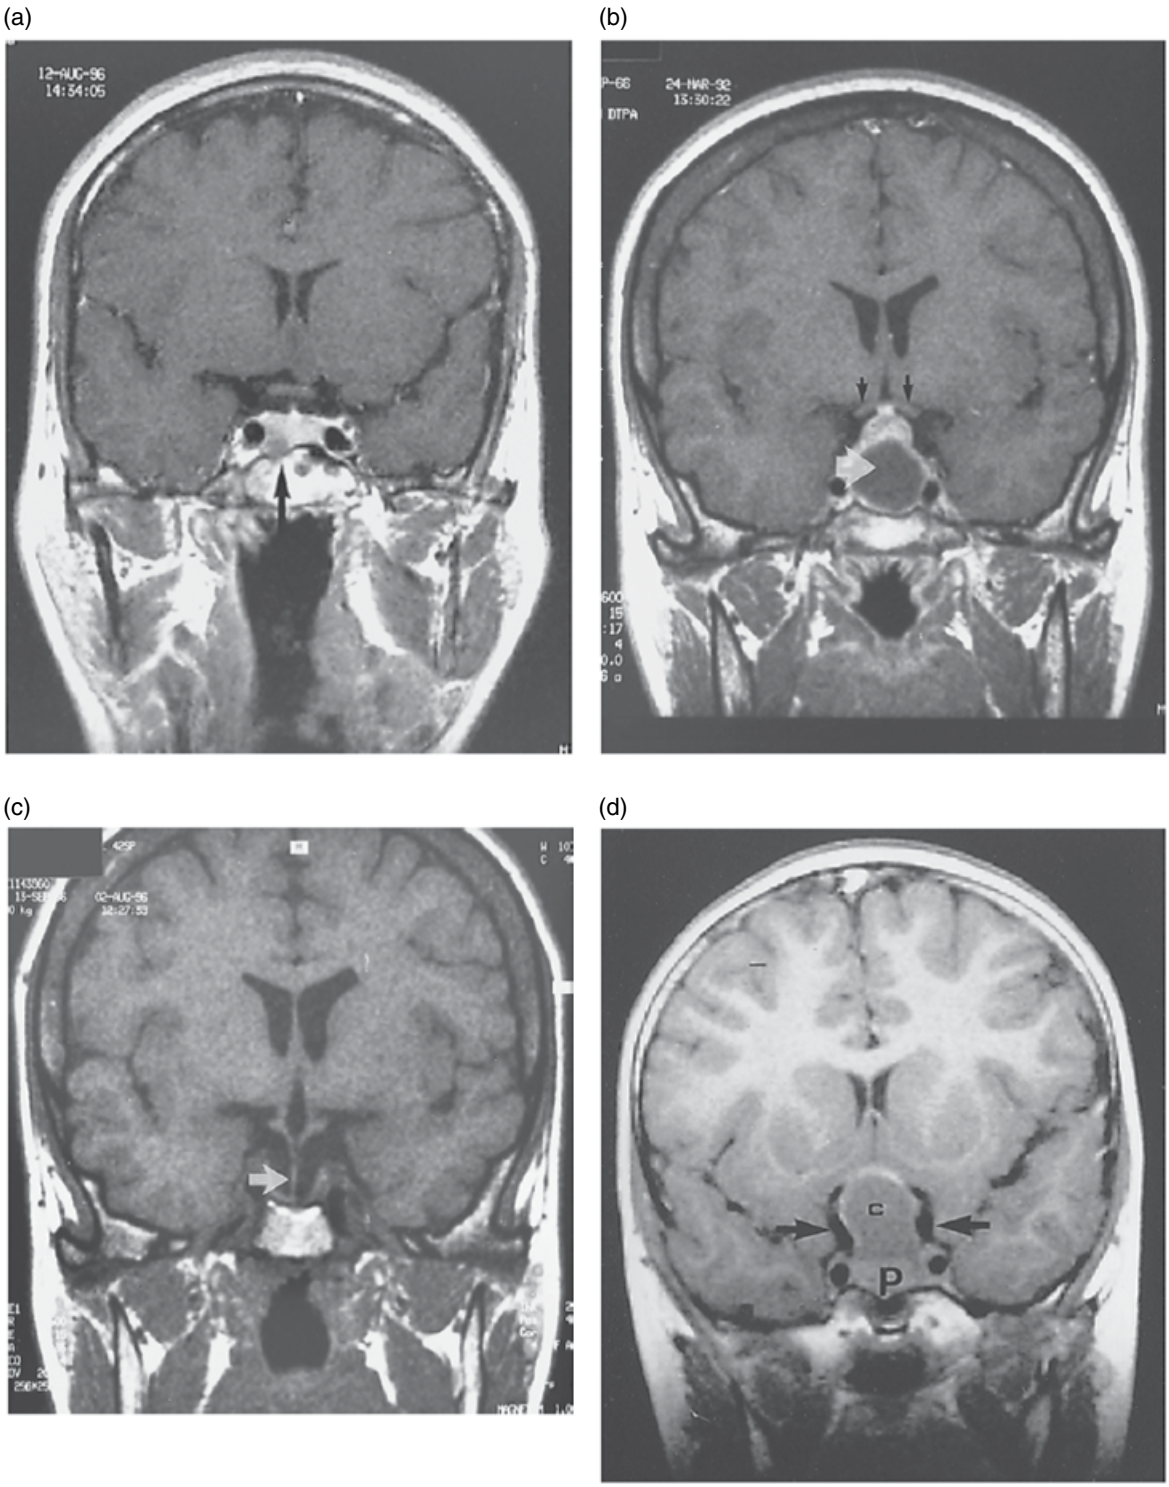

Fig. 47.7 (a) Pituitary microadenoma. Cranial MRI: coronal section T1-weighted spin echo sequence after intravenous gadolinium. The normal pituitary gland is hyperintense (bright) while the tumour is seen as a 4-mm area of non-enhancement (grey) in the right lobe of the pituitary, encroaching up to the right cavernous sinus. It is eroding the right side of the sella floor (arrow). (b, c) Pituitary macroadenoma. MRI scans of a pituitary macroadenoma before and after bromocriptine therapy: (b) T1-weighted image post-gadolinium enhancement demonstrating a macroadenoma with a large central cystic component (large arrow). There is suprasellar extension with compression of the optic chiasm (small arrows). (c) After therapy the tumour has almost completely resolved and there is tethering of the optic chiasm (arrow) to the floor of the sella. (d) Craniopharyngioma. Cranial MRI: coronal T1-weighted section after gadolinium enhancement. The tumour signal intensity on the T1 image and only part of the periphery of the tumour enhances. The carotid arteries have a low signal intensity (black arrows) due to the rapid flow within them and are deviated laterally and superiorly by the mass (C), which arises out of the pituitary fossa (P). *Source:* Balen AH. *Infertility in Practice*, 4th edn. Table 47.6 Drug therapy for hyperprolactinaemia.

Bromocriptine	2.5–20 mg daily, divided doses	Maintenance usually 5–7.5 mg/day
Cabergoline	0.25–1 mg twice weekly	Maintenance usually 1 mg/week
Quinagolide	75–150 μg daily, at night	

higher doses for the management of Parkinson's disease. The maintenance dose should be the lowest that reduces prolactin to normal levels and is often lower than that needed to initiate a response (Table 47.6).

Surgery, in the form of trans-sphenoidal adenectomy, is reserved for cases of drug resistance and failure to shrink a macroadenoma or if there are intolerable side effects of the drugs (the most common indication). Non-functioning tumours should be removed surgically and are usually detected by a combination of imaging and a serum prolactin concentration below 3000 mIU/L. When the prolactin level is between 3000 and 8000 mIU/L, a trial of bromocriptine is warranted, and if the prolactin level falls it can be assumed that the tumour is a prolactin-secreting macroadenoma. Operative treatment is also required if there is suprasellar extension of the tumour that has not regressed during treatment with bromocriptine and a pregnancy is desired. With the modern skills of neurosurgeons in trans-sphenoidal surgery, it is seldom necessary to resort to pituitary irradiation, which offers no advantages, and long-term surveillance is required to detect consequent hypopituitarism (which is immediately apparent if it occurs after surgery).

Women with a microprolactinoma who wish to conceive can be reassured that they may stop bromocriptine when pregnancy is diagnosed and require no further monitoring, as the likelihood of significant tumour expansion is very small (<2%). On the other hand, if a patient with a macroprolactinoma is not treated with bromocriptine, the tumour has a 25% risk of expanding during pregnancy. This risk is probably also present if the tumour has been treated but has not shrunk, as assessed by CT or MRI scan. The first-line approach to treatment of macroprolactinomas is therefore with bromocriptine combined with barrier methods of contraception. In cases with suprasellar expansion, a follow-up CT (or MRI) scan should be performed after 3 months of treatment to ensure tumour regression before it is safe to embark upon pregnancy. Bromocriptine can be discontinued during pregnancy, although an MRI scan should be performed if symptoms suggestive of tumour re-expansion occur, and it is necessary to recommence bromocriptine therapy if there is continuing suprasellar expansion. These patients also require expert assessment of their visual fields during pregnancy.

If the serum prolactin is found to be elevated and the patient has a regular menstrual cycle, no treatment is necessary unless the cycle is anovulatory and fertility is desired. Amenorrhoea is the 'bioassay' of prolactin excess and should be corrected for its sequelae, rather than for the serum level of prolactin.

Hypothalamic causes of secondary amenorrhoea

Hypothalamic causes of amenorrhoea may be either primary or secondary. Primary hypothalamic lesions include craniopharyngiomas, germinomas, gliomas and dermoid cysts. These hypothalamic lesions either disrupt the normal pathway of prolactin inhibitory factor (dopamine), thus causing hyperprolactinaemia, or compress and/or destroy hypothalamic and pituitary tissue. Treatment is usually surgical, with additional radiotherapy if required. HRT is required to mimic ovarian function, and if the pituitary gland is damaged either by the lesion or by the treatment, replacement thyroid and adrenal hormones are required.

Secondary hypogonadotrophic hypogonadism (HH) may result from systemic conditions including sarcoidosis and tuberculosis as well as following head injury or cranial irradiation. Sheehan's syndrome, the result of profound and prolonged hypotension on the sensitive pituitary gland enlarged by pregnancy, may also be a cause of HH in someone with a history of major obstetric haemorrhage [25]. It is essential to assess the pituitary function fully in all these patients and then instigate the appropriate replacement therapy. Ovulation may be induced with pulsatile subcutaneous GnRH or hMGs. The administration of pulsatile GnRH provides the most 'physiological' correction of infertility caused by HH and will result in unifollicular ovulation, while hMG therapy requires close monitoring to prevent multiple pregnancy (unfortunately the GnRH preparations are no longer manufactured for this use). Purified or recombinant FSH preparations are not suitable for women with HH (or pituitary hypogonadism) as these patients have absent endogenous production of LH, and so while follicular growth may occur, oestrogen biosynthesis is impaired [26]. Thus, hMG, which contains FSH and LH activity, is necessary for these patients.

Systemic disorders causing secondary amenorrhoea

Chronic disease may result in menstrual disorders as a consequence of the general disease state, weight loss or the effect of the disease process on the hypothalamic–pituitary axis. Furthermore, a chronic disease that leads to immobility, such as chronic obstructive airways disease, may increase the risk of amenorrhoea-associated osteoporosis.

Some diseases affect gonadal function directly. Women with chronic renal failure have a discordantly elevated LH, possibly as a consequence of impaired clearance. Prolactin is also elevated in these women owing to failure of the normal inhibition by dopamine. Liver disease affects the level of circulating SHBG and thus hormone levels, thereby disrupting the normal feedback mechanisms. Metabolism of various hormones including testosterone are also liver-dependent; both menstruation and fertility return after liver transplantation.

Endocrine disorders such as thyrotoxicosis and Cushing's syndrome are commonly associated with gonadal dysfunction. Autoimmune endocrinopathies may be associated with POI because of ovarian antibodies. Diabetes mellitus may result in functional hypothalamic–pituitary amenorrhoea.

Management of these patients should concentrate on the underlying systemic problem and on preventing complications of oestrogen deficiency. If fertility is required, it is desirable to achieve maximal health and where possible to discontinue teratogenic drugs.

Weight-related amenorrhoea

Weight can have profound effects on gonadotrophin regulation and release. Weight and eating disorders are also common in women. A regular menstrual cycle will not occur if the BMI is below 19 kg/m^2. Fat appears to be critical to a normally functioning hypothalamic–pituitary–gonadal axis. It is estimated that at least 22% of body weight should be fat in order to maintain ovulatory cycles [27]. This level enables the extra-ovarian aromatization of androgens to oestrogens and maintains appropriate feedback control of the hypothalamic–pituitary–ovarian axis. Therefore, girls who are significantly underweight prior to puberty may have primary amenorrhoea, while those who are significantly underweight after puberty will have secondary amenorrhoea. The clinical presentation depends on the severity of the nutritional insult and its age of onset. To cause amenorrhoea, the loss must be 10–15% of the woman's normal weight for height. Weight loss may be due to a number of causes including self-induced abstinence, starvation, illness and exercise.

Whatever the precipitating cause, the net result is impairment of gonadotrophin secretion. In severe weight loss, oestrogen may be catabolized to the antioestrogen 2-hydroxyestrone rather than to the usual estradiol, which may further suppress gonadotrophin secretion. This pathway is enhanced by cigarette smoking. Weight-related gonadotrophin deficiency is more pronounced with LH than FSH. This, and the reduction in pulsatility of gonadotrophin secretion, may result in a 'multicystic' pattern in the ovary. This appearance is typical of normal puberty and is seen when there are several cysts (about 5–10 mm in diameter) together with a stroma of normal density.

Anorexia nervosa is at the extreme end of a spectrum of eating disorders and is invariably accompanied by menstrual disturbance, and indeed may account for 15–35% of patients with amenorrhoea. Women with anorexia nervosa should be managed in collaboration with a psychiatrist, and it is essential to encourage weight gain as the main therapy. An artificial cycle may be induced with the combined oral contraceptive pill, although this may validate the woman's denial of weight loss as the underlying problem.

Similarly, while it is possible to induce ovulation with exogenous gonadotrophins, treatment of infertility in the significantly underweight patient is associated with a notable increase in intrauterine growth retardation and neonatal problems. Furthermore, since three-quarters of the cell divisions that occur during pregnancy do so during the first trimester, it is essential that nutritional status is optimized before conception. Low birthweight is also now being related to an increased risk of cardiovascular disease, obstructive lung disease and schizophrenia in adult life [28].

Weight-related amenorrhoea may also have profound long-term effects on BMD. The age of onset of anorexia nervosa is also important, as prolonged amenorrhoea before the normal age at which peak bone mass is obtained (approximately 25 years) increases the likelihood of severe osteoporosis.

Worldwide, involuntary starvation is the commonest cause of reduced reproductive ability, resulting in delayed pubertal growth and menarche in adolescents and infertility in adults. Acute malnutrition, as seen in famine conditions, has profound effects on fertility and fecundity. Ovulatory function usually returns quickly on restoration of adequate nutrition. The chronic malnutrition common in developing countries has fewer profound effects on fertility but is associated with small and premature babies.

Psychological stress

Studies have failed to demonstrate a link between stressful life events and amenorrhoea of greater than 2 months. However, stress may lead to physical debility such as weight loss, which may then cause menstrual disturbance.

Exercise-related amenorrhoea

Menstrual disturbance is common in athletes undergoing intensive training, with 10–20% experiencing oligomenorrhoea or amenorrhoea compared with 5% in the general population [29]. Amenorrhoea is more common in athletes under the age of 30 years and is particularly common in women involved in the endurance events

(such as long-distance running). Up to 50% of competitive runners training 80 miles per week may be amenorrhoeic [30].

The main aetiological factors are weight and percentage body fat content, but other factors have also been postulated. Physiological changes are consistent with those associated with starvation and chronic illness.

Ballet dancers provide an interesting subgroup of sportswomen, because their training begins at an early age. They have been found to have a significant delay in menarche (starting at the age of 15.4 years compared with 12.5 years in non-ballet dancers) and a retardation in pubertal development which parallels the intensity of their training. Menstrual irregularities are common, and up to 44% have secondary amenorrhoea. In a survey of 75 dancers, 61% were found to have stress fractures and 24% had scoliosis; the risk of these pathological features was increased if menarche was delayed or if there were prolonged periods of amenorrhoea. These findings may be explained by delayed pubertal maturation resulting in attainment of a greater than expected height and a predisposition to scoliosis, as oestrogen is required for epiphyseal closure.

Exercise-induced amenorrhoea has the potential to cause severe long-term morbidity, particularly with regard to osteoporosis. Studies on young ballet dancers have shown that the amount of exercise undertaken by these dancers does not compensate for these osteoporotic changes. Oestrogen is also important in the formation of collagen, and soft-tissue injuries are also common in dancers. Whereas moderate exercise has been found to reduce the incidence of postmenopausal osteoporosis, young athletes may be placing themselves at risk at an age when the attainment of peak bone mass is important for long-term skeletal strength. Appropriate advice should be given, particularly regarding diet, and the use of a cyclical oestrogen–progestogen preparation should be considered.

Iatrogenic causes of amenorrhoea

There are many iatrogenic causes of amenorrhoea, which may be either temporary or permanent. These include malignant conditions that require either radiation to the abdomen/pelvis or chemotherapy. Both of these treatments may result in permanent gonadal damage, the amount of damage being directly related to the age of the patient, the cumulative dose and the patient's previous menstrual status.

Gynaecological procedures such as oophorectomy, hysterectomy and endometrial resection inevitably result in amenorrhoea. Hormone replacement should be prescribed for these patients where appropriate. Hormone therapy itself can be used to deliberately disrupt the menstrual cycle. However, iatrogenic causes of ovarian quiescence have the same consequences of oestrogen deficiency due to any other aetiology. Thus, the use of GnRH analogues in the treatment of oestrogen-dependent conditions (e.g. precocious puberty, endometriosis, uterine fibroids) results in a significant decrease in BMD in as little as 6 months. However, the demineralization is reversible with the cessation of therapy, especially for the treatment of benign conditions in young women who are in the process of achieving their peak bone mass. The concurrent use of an androgenic progestogen or oestrogen 'add-back' therapy may protect against bone loss.

Heavy Menstrual Bleeding

Andrew W. Horne and Hilary O.D. Critchley

MRC Centre for Reproductive Health, University of Edinburgh, The Queen's Medical Research Institute, Edinburgh, UK

Definition

There has been confusion over the various terminologies used for abnormalities of menstrual blood loss. Heavy menstrual bleeding (HMB) is now the preferred symptom description as it is simple and easily translatable into other languages. Use of the word 'menorrhagia' is discouraged [1]. The word itself, meaning to 'burst forth each month', was first used in English medical texts by William Cullen, a professor at the University of Edinburgh in the late 1700s. The term is confusing, being used as a symptom, sign and diagnosis. Similarly, the term 'dysfunctional uterine bleeding' (DUB) should also no longer be used [1]. DUB was traditionally used to describe excessive bleeding (heavy, frequent or prolonged) of uterine origin which was not due to pelvic pathology or systemic disease. Descriptions of menstrual bleeding were standardized in 2009 by the Menstrual Disorders Group (FMDG) of the Fédération International de Gynécologie et d'Obstétrique (FIGO). Definitions of normality were described, nomenclature standardized, and underlying aetiologies classified in a structured manner. HMB is defined as excessive menstrual blood loss (over several consecutive cycles) that has a major effect on a woman's quality of life [2]. The objective definition of HMB (defined as blood loss of greater than 80 mL per menstruation) is no longer used except for research purposes [2]. It is also important in clinical practice to distinguish between regular and abnormal bleeding, such as intermenstrual and post-coital bleeding.

Summary box 48.1

- 'Heavy menstrual bleeding' replaces 'menorrhagia'.
- 'Bleeding of endometrial origin' replaces 'dysfunctional uterine bleeding'.
- Distinguish between 'regular' and 'abnormal' bleeding.

Prevalence and impact

HMB affects one in three women of reproductive age [2]. The complaint of HMB results in significant morbidity and impact on quality of life. In addition to the direct effect on the woman and her family, there are significant socioeconomic costs. Menstrual bleeding complaints are the fourth most common reason for referral to UK gynaecological services [3]. The recent national audit in England and Wales [3] reported that at 1-year post referral, only one-third of women (including those managed with surgery) were 'satisfied' (or better) with the current treatment of their menstrual symptoms [3]. Unfortunately, current medical therapy may be associated with undesirable side effects. As many as one in five women discontinue use of progestin therapies (systemic and locally delivered) for HMB on account of unscheduled bleeding [4]. Despite continually emerging new medical therapies, surgery is still favoured by many women with severe symptoms and HMB remains a leading indication for hysterectomy. In the UK, regional differences in surgical rates for HMB have persisted despite changes in practice and improved evidence, suggesting there is still scope for improving the management of HMB within health services. There remains a pressing need for continuing development of effective and acceptable medical treatment options for women with HMB.

Aetiology

Correct management is facilitated by careful classification of HMB with the now widely used FIGO PALM-COEIN system [1] (Fig. 48.1). The 'PALM' (Polyp, Adenomyosis, Leiomyoma [fibroids], Malignancy) are assessed visually (imaging and histopathology) and the 'COEIN' (Coagulopathy, Ovulatory and Endometrial dysfunction, Iatrogenic and Not otherwise classified) are

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

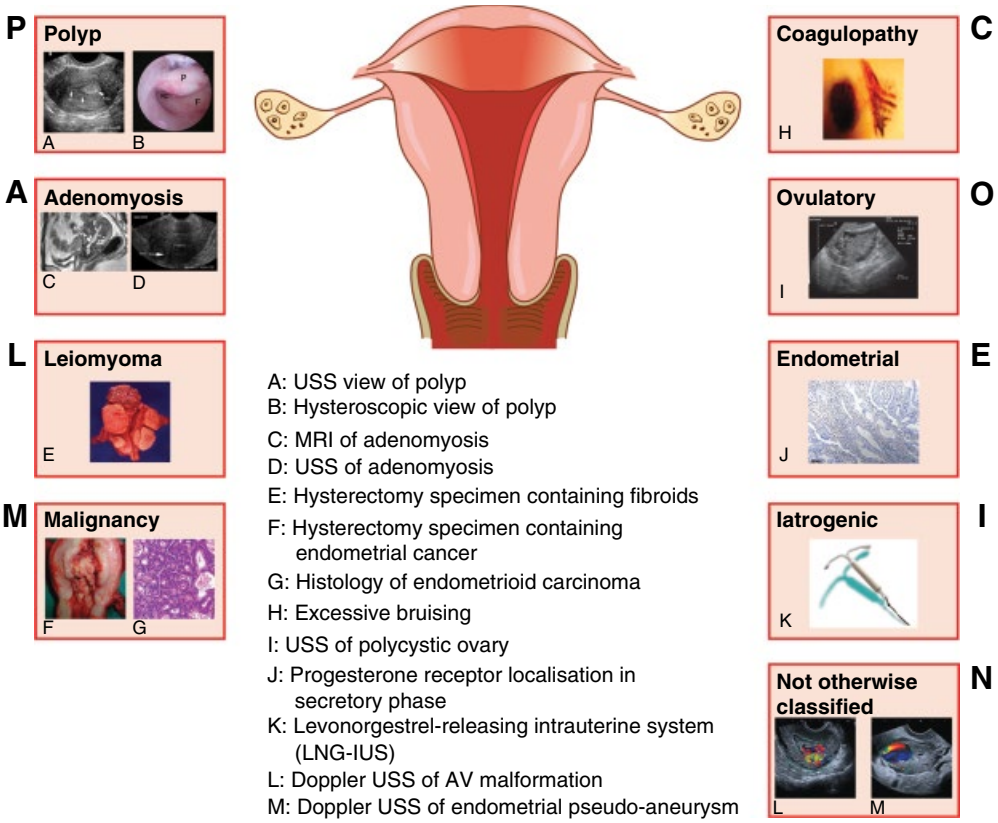

Fig. 48.1 FIGO PALM-COEIN classification of causes of HMB. Reproduced from Whitaker L, Critchley HOD. Abnormal uterine bleeding. *Best Pract Res Clin Obstet Gynaecol* 2016;34:54–65. Creative Commons Attribution License (CC BY 4.0) (https://creativecommons.org/licenses/by/4.0/).

non-structural and are identified through meticulous history-taking and appropriate investigations. The classification system accepts that women may have more than one underlying cause and also that where structural abnormalities are present, many women may in fact be symptom-free.

Polyps

Polyps are common (incidence increasing with age), frequently asymptomatic and their exact cause remains unknown. It is important to be aware that both polyps and fibroids may frequently coexist, and that polyps may be mistaken for submucous fibroids on ultrasound. Polyps may cause unpredictable intermenstrual bleeding as well as being associated with an increased volume of bleeding [5].

Adenomyosis

Any relationship between adenomyosis and HMB is still unclear. Adenomyosis is associated with increasing age and often coexists with endometriosis and fibroids. Adenomyosis is increasingly being diagnosed on MRI and ultrasonography but it is harder to establish the diagnosis of adenomyosis if fibroids are also present.

Leiomyoma (fibroids)

Submucosal and intramural fibroids are the subtype most commonly associated with HMB but the exact number of cases of HMB resulting from fibroids is not known. About 50% of fibroids cause no symptoms. Furthermore, the mechanisms involved in fibroid-associated HMB are yet to be determined. Theories include an increased endometrial surface area and the presence of fragile and dilated vasculature around the fibroid [6]. Knowledge regarding the complex cellular and molecular changes found in association with fibroids is increasing. Data are emerging on the impact of uterine fibroid presence on angiogenesis, on alteration in the production of vasoactive substances and growth factors, as well as modulation of coagulation.

Malignancy (and hyperplasia)

Both endometrial and cervical carcinoma are potential causes of intermenstrual and post-coital bleeding, and rarely HMB. The most relevant premalignant condition that may cause abnormal bleeding is endometrial hyperplasia. Sarcomas of myometrial origin, such as leiomyosarcoma, are rare but not infrequently present with abnormal bleeding in perimenopausal and

postmenopausal women. A recent meta-analysis reported that leiomyosarcoma was diagnosed unexpectedly following surgery for anticipated 'benign' myomas (fibroids) in 2.94 per 1000 women (1 in 340 women) [7]. Age is a risk factor for the development of leiomyosarcoma, with less than one case per 500 among women under 30 years and up to 1 in 98 among women in the age range 75–79 years.

Coagulopathy

As many as 10–20% of women with HMB will have a systemic disorder of haemostasis [6]. These disorders may be inherited or acquired and severity of disorder varies (but the majority are mild to moderate). The overall clinical impact is unknown. The most common inherited disorder is von Willebrand disease, found in 13% of women with HMB. This aetiology should be considered in women who fail to respond to medical management and women who present at a young age. Acquired conditions include severe thrombocytopenia, thrombocytopathies such as Glanzmann's disease, and other rare bleeding/factor deficiencies. Currently, the use of anticoagulants in women with thromboembolic disease also falls within this category.

Ovulatory dysfunction

Anovulatory menstrual cycles may contribute to HMB by the effects of unopposed oestrogen on the endometrium causing marked proliferation. This most commonly occurs at the extremes of reproductive age (adolescence and perimenopause). Anovulatory menstrual cycles are associated with polycystic ovarian syndrome (PCOS), hyperprolactinaemia, hypothyroidism and other factors such as obesity. Women in this group often report menstrual cycles that extend beyond 38 days or vary by more than 21 days. Pharmacological drugs known to impact ovulation by prolactin-related disruption of the hypothalamic–pituitary–ovarian axis (e.g. tricyclic antidepressants and phenothiazines) currently fall within this category.

Endometrial dysfunction

In the majority of cases of HMB, it is likely that the precise cause of heavy bleeding lies at the level of the endometrium itself. This is a diagnosis of exclusion. Hypoxia, inflammation, haemostasis and angiogenesis all play crucial roles in the shedding and subsequent scar-less repair of the functional upper layer of the endometrium. Perturbation of local glucocorticoid metabolism, aberrant prostaglandin synthesis and excessive plasminogen (resulting in premature clot lysis) have all been implicated in HMB. However, the exact endometrial mechanisms leading to HMB remain undefined and an area of active research enquiry [8,9].

Iatrogenic

Iatrogenic causes of HMB include exogenous therapies than may result in unscheduled bleeding. This is typically associated with continuous oestrogen or progestin therapies (intrauterine, systemic or oral delivery). The use of an intrauterine device may cause a low-grade endometritis which may also contribute to HMB.

Not otherwise classified

Inevitably, there are pathologies that do not easily fit within the categories described. Examples include infection and arteriovenous malformations. Data exist to support an association between chronic endometrial infection and abnormal uterine bleeding, both intermenstrual and heavy bleeding [5]. *Chlamydia trachomatis* has been proposed as a cause of HMB, and the prevalence of *C. trachomatis* in women with abnormal uterine bleeding may be underestimated. This is confounded by the fact that 85% of cases of chlamydial infection are asymptomatic. Further research is required to determine whether all women with HMB should be screened for *C. trachomatis*. An arteriovenous malformation (AVM) is a congenital, or acquired, localized collection of abnormally connected arteries and veins. When they occur in the uterus they have been associated with episodes of acute excessive bleeding. Congenital AVMs are rare, as are acquired AVMs, which may occur following uterine curettage after pregnancy. These vascular lesions of the uterus pose difficult management decisions and may present with heavy uterine bleeding following early pregnancy loss. Colour Doppler ultrasound imaging is a useful diagnostic modality if an AVM is suspected. In cases associated with an early pregnancy loss (likely due to sub-involution of the placental bed), the uterine lesion resolves once the human chorionic gonadotrophin (hCG) level has returned to normal. Acute heavy bleeding from an AVM require management with therapeutic uterine artery embolization or intrauterine balloon tamponade.

Summary box 48.2

- In most women no cause for HMB is found.
- Coagulopathies account for 10–20% of cases of HMB.
- Malignancy should always be excluded.
- Remember iatrogenic causes.

Clinical evaluation

History

The primary aim of the history is to determine the full impact that the bleeding is having on the woman's

quality of life and a menstrual diary is often helpful to determine the degree and timing of the bleeding [10], and flooding and clots generally indicate significant loss. An accurate history may also indicate the cause of the bleeding. Intermenstrual bleeding and post-coital bleeding are suggestive of an anatomical cause whereas associated pressure symptoms, including bowel and urinary symptoms, may indicate the presence of a large fibroid(s). A coagulation disorder may be implicated in the complaint of HMB and a structured history to elicit such is valuable and an onward referral for formal haematological assessment may be indicated [5]. A coagulation disorder is likely if there is:

1) a history of excessive bleeding since menarche, postpartum haemorrhage, surgery-related bleeding, or bleeding associated with dental work; or
2) a history of two or more of (i) bruising greater than 5 cm, (ii) epistaxis once a month, (iii) frequent bleeding or (iv) a family history of bleeding symptoms.

A sexual, smear and contraceptive history are essential and should include questioning about the woman's desire for future pregnancy as this will affect therapeutic options for future symptom management.

Table 48.1 Investigations of patients complaining of heavy menstrual bleeding (HMB).

Investigation	Indication
Full blood count	All women with HMB
Coagulation screen	If a structured history is suggestive of a coagulation disorder
Thyroid function tests	Only from women with other symptoms of thyroid disease
Endocervical/high vaginal swabs	If history suggestive of risk of infection
Colposcopic examination	Suspicion of cervical pathology
Histological assessment of the endometrium	Symptomatic women ≥45 years old, younger women when medical treatment has failed, younger women with risk factors (e.g. PCOS, obesity) and all women prior to surgical intervention
Evaluation of the uterine cavity (pelvic ultrasound, MRI, and outpatient hysteroscopy)	Intermenstrual or post-coital bleeding, irregular HMB, suspected structural pathology, or when medical management has failed

Examination

A general evaluation of the patient should be performed to exclude signs of anaemia, evidence of systemic coagulopathy (e.g. bruising, petechiae) and thyroid disease (e.g. goitre). An abdominal examination should be performed to reveal a pelvic mass (eg, fibroid); a speculum examination should be performed to assess the vulva, vagina and cervix (this may reveal sources of bleeding, such as a tumour, or a discharge suggesting infection); and a bimanual examination should be performed to elicit uterine enlargement.

Investigations

A full blood count is indicated in all women with HMB. If the history and examination strongly suggests cyclical HMB without the presence of pathology in a woman under 45 years old, it is appropriate to implement first-line medical treatment without further investigation, so long as no risk factor, such as raised body mass index (BMI), are identified [2]. In older women, and in younger women in whom medical treatment has failed, further investigation is warranted (Table 48.1).

Histological assessment of the endometrium

In the UK, current National Institute for Health and Care Excellence (NICE) guidelines advise endometrial sampling and histological assessment of HMB in women aged 45 years and above who have persistent intermenstrual bleeding or treatment failure. With the increase in rates of endometrial cancer, all gynaecologists should use their clinical judgement for those women aged under 45 years with HMB who have risk factors for premalignant change, in particular PCOS and obesity.

Evaluation of the uterus and uterine cavity

Blind sampling methodologies (outpatient endometrial biopsy) are reasonable screening techniques but they are ineffective at diagnosing focal lesions. Published research has provided the clinician with high-quality data regarding the accuracy of pelvic ultrasound and outpatient hysteroscopy in the diagnosis of structural lesions. In the UK, NICE suggests that pelvic ultrasound should be considered the primary investigation of suspected structural lesions, backed up by hysteroscopy for suspected polyps or submucous fibroids (Fig. 48.1). MRI is also now being used in specific clinical scenarios in the evaluation of HMB. This imaging modality will assist in further identification and localization of fibroids and also features of adenomyosis if present. Pelvic MRI is of value in determining the role of embolization as a treatment option. However, future research needs to be directed towards providing effectiveness and cost-effectiveness data (MRI is expensive) in order to determine the role for this mode of imaging in guiding best clinical practice.

Summary box 48.3

- Objective definition of HMB is no longer used in clinical practice.
- Determine impact of HMB on quality of life.
- Perform structured history to determine coagulation disorder.
- Full blood count should be performed in all patients.
- Controversy remains over clinical utility of imaging modalities.
- Endometrial histology is warranted in women aged over 45 years, in younger women in whom medical treatment has failed and in all women prior to surgical intervention, and should be considered in women with a raised BMI/risk factors for premalignant change in the endometrium.

Management

Management options should be patient-centred and embrace the contraceptive and fertility needs of each woman. For some women the demonstration that their blood loss is in fact 'normal' may be sufficient to reassure them and make further treatment unnecessary. When treatment is advised by the healthcare professional, women with HMB should be given detailed and up-to-date information (ideally supplemented by written or web-based material) about treatment options [2] and given adequate time and support in the decision-making process. These options include non-hormonal, hormonal and surgical approaches [11]. A care pathway for HMB is shown in Fig. 48.2 [2].

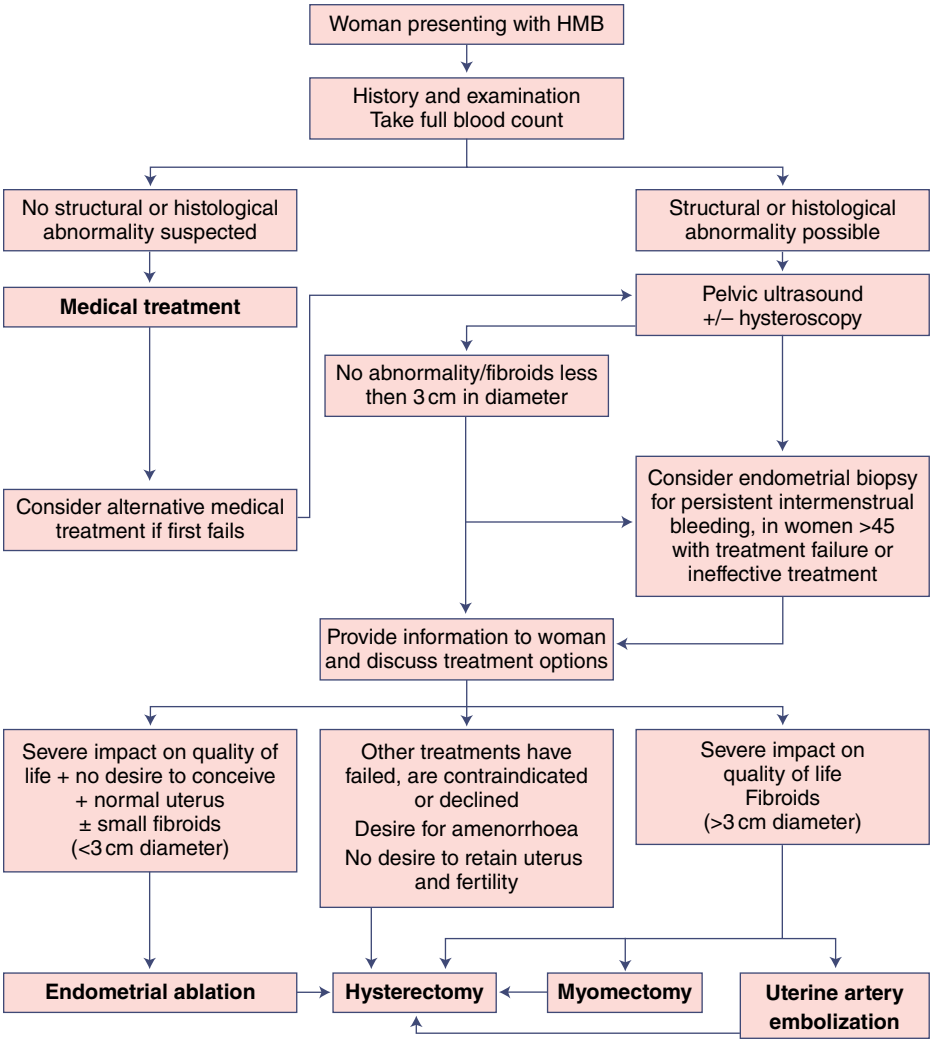

Fig. 48.2 Suggested care pathway for heavy menstrual bleeding (HMB). Adapted from National Institute for Health and Care Excellence [2].

Non-hormonal treatments

If a woman is wishing to conceive, hormonal treatments and most surgical interventions are unacceptable.

Antifibrinolytics

Antifibrinolytics, such as tranexamic acid, reduce blood loss by up to 50% by inhibiting endometrial fibrinolysis [12]. Side effects are rare but include gastrointestinal symptoms. Antifibrinolytics are not prescribed for women with a history of thromboembolism.

Prostaglandin synthetase inhibitors

Prostaglandin synthetase inhibitors, such as non-steroidal anti-inflammatory drugs (NSAIDs), inhibit endometrial prostaglandin production, leading to a reduction in menstrual blood loss. Mefenamic acid is the most frequently used agent and reduces blood loss by approximately 25% [13]. The drug is taken during menstruation and has the advantage of additional analgesic properties. However, NSAIDs are associated with gastrointestinal side effects.

Hormonal treatments

Combined oral contraceptive pill

From clinical experience, the combined oral contraceptive pill (COCP) is generally considered to be effective in the management of HMB. It reduces bleeding by around 50% and has the additional benefit of reducing dysmenorrhea. Furthermore, as amenorrhoea has become more acceptable (and indeed for some women even desirable), many women use the COCP continuously for periods of 3–6 months to avoid menstruation altogether. Risks of COCP treatment include breast cancer, thromboembolic and cardiovascular disease and migraine (increased in the older woman, particularly if she is a smoker [14]). A raised BMI imposes further risk.

Levonorgestrel-releasing intrauterine system

The levonorgestrel-releasing intrauterine system (LNG-IUS) is an excellent alternative to surgery for women with HMB who also seek reliable long-acting reversible contraception [2]. Most women use the LNG-IUS for contraception but the added health benefits of reduced menstrual bleeding and less anaemia makes this, together with the low cost, an attractive option for many women with HMB worldwide. The LNG-IUS may be inserted in the outpatient setting and requires changing every 3–5 years depending on the licence of the preparation inserted. The uptake of LNG-IUS has undoubtedly been further increased because the low dose of LNG released into the uterine cavity leads to endometrial atrophy, so for many women its use is associated with little or no vaginal bleeding. Although the not uncommon side effect of unscheduled bleeding is a problem (one in five users), leading to unacceptability of the method for a minority of women, randomized controlled trials show that the LNG-IUS will reduce menstrual loss by up to 96% after 1 year but that the full benefit may not be seen for 6 months [15]. As its action is local, progestogen-related side effects are much less than with oral agents. However, women should be fully counselled that they are likely to experience unscheduled spotting/bleeding during the initial months of use. At present, effective interventions to prophylactically ameliorate unscheduled bleeding in women using the LNG-IUS still remain elusive.

Oral progestogens

Oral progestogens are helpful in the management of women with irregular (anovulatory) HMB, particularly common at the extremes of reproductive life. Cyclical administration of progestogens for less than 21 days each cycle in ovulatory women is of no benefit. Only norethisterone acetate (5 mg three times daily), if prescribed cyclically for 21 days, is effective treatment for ovulatory HMB. Shorter courses of oral progestogens (14 days) are appropriate for women with definite anovulatory cycles (e.g. PCOS) and at risk of endometrial hyperplasia.

Injected/depot progestogens

It is well recognized that amenorrhoea occurs in many women when injected progestogens are used for contraception and they are commonly used for treatment of HMB. However, like all progestogen-based therapies, a proportion of women will experience unscheduled bleeding.

Gonadotrophin-releasing hormone analogues

Limited use of gonadotrophin-releasing hormone (GnRH) analogues may be considered when all other management options have been explored. GnRH analogues act by downregulating the hypothalamic–pituitary–ovarian axis and induce ovarian suppression, leading to amenorrhoea. Unfortunately, their beneficial effect does not continue after stopping treatment and their adverse effect on bone density limits their use beyond 6 months. If consideration is given to use beyond 6 months, the addition of 'add-back' hormone replacement therapy is recommended.

Selective progesterone receptor modulators

Selective progesterone receptor modulators (SPRMs) are a class of synthetic steroids that can exert agonist, antagonist or mixed effects on progesterone receptor binding in various progesterone target tissues *in vivo* [16]. SPRMs have been reported to reduce menstrual bleeding. The PEARL studies provide clinical evidence for the use of the SPRM ulipristal acetate (UPA) in

women with HMB and fibroids. The PEARL I study was a double-blind randomized controlled trial comparing 5 or 10 mg UPA with placebo for 12 weeks in women with symptomatic fibroids with HMB [17]. Over 91% of those on UPA achieved control of menstrual bleeding within 13 weeks and significant rates of amenorrhoea were reported (73%, 82% and 6% with 5 mg, 10 mg and placebo, respectively). A clinically and statistically significant reduction in fibroid volume was also described. The PEARL II study compared UPA with the GnRH analogue leuprolide acetate and similar rates of menstrual bleeding control and amenorrhoea were reported. There was a more rapid achievement of amenorrhoea in the UPA users. Subsequently, repeat 12-week courses of daily oral UPA have been shown to effectively control menstrual bleeding and to reduce fibroid volume. The potential utility of UPA for management of HMB in women without fibroids is currently being explored (UCON trial Eudra CT 2014-003408-65). Unfortunately, UPA is not suitable for women trying to conceive.

The administration of SPRMs is accompanied by a reversible morphological change in the endometrium, defined by histopathological criteria as progesterone receptor modulator-associated endometrial changes (PAEC) [18]. The implications of PAEC on bleeding pattern are not yet known. Further research is needed into the mechanisms of action of SPRMs [16], which appear to have great potential as a longer-term management option for reducing menstrual blood loss.

Danazol, etamsylate and gestrinone are no longer recommended for routine use in the treatment of HMB in part due to their unacceptable side effects.

Summary box 48.4

- Antifibrinolytics and prostaglandin synthetase inhibitors are appropriate first-line treatments.
- The combined oral contraceptive pill is considered effective.
- The levonorgestrel-releasing intrauterine system is an excellent long-term alternative to surgery.

Surgical treatments

It is unclear whether surgical interventions should be used as the initial treatment for HMB or whether medical intervention should always be tried first. Typically, surgical management is only considered in women who have completed their family, with the exception of polypectomy and myomectomy where fertility may be retained. Dilatation and curettage should not be used as a therapeutic treatment in any clinical situation.

Polypectomy

Endocervical polyps can be avulsed in the outpatient setting. Endometrial polyps can be removed blindly under general anaesthetic, or by hysteroscopic resection either under general anaesthetic or in the outpatient setting.

Endometrial ablation

Endometrial ablation is the targeted destruction of the endometrium and some of the underlying myometrium. The technique is suitable for women who have completed their family and in whom all organic and structural causes of HMB have been excluded (fibroids <4 cm are an exception). First-generation techniques include hysteroscopic transcervical resection of the endometrium using an electrical diathermy loop and roller-ball ablation. These techniques offer treatment for uterine cavities with submucous fibroids. Simpler, quicker second-generation alternatives have subsequently been developed for smoother smaller uterine cavities. These include fluid-filled thermal balloon endometrial ablation and impedance-controlled endometrial ablation. Overall, the existing evidence suggests that success rates and complication profiles of the newer techniques of ablation compare favourably with first-generation hysteroscopic techniques [19]. All can be performed as day-case procedures, either under general anaesthetic (with analgesia) or under local anaesthetic in the outpatient setting. Women who undergo this procedure should be advised that it is essential to use long-term effective contraception. It is also recommended that pre-ablation endometrial histology is obtained and that a hysteroscopy is performed before (following cervical dilatation) and after each treatment to exclude uterine perforation. Postoperatively, patients may complain of transient crampy abdominal pain and a watery brown discharge for 3–4 weeks. Prophylactic antibiotic therapy is often used to reduce the risk of endometritis. Patients must be counselled before the procedure about complications, which may include device failures at the time of the procedure, endometritis, haematometra, fluid overload due to absorption of distension medium (resection only), perforation and intra-abdominal injury (including visceral burns). Endometrial thinning agents (e.g. GnRH analogues) are not usually indicated for the newer ablative techniques but can be employed at the operator's preference for endometrial and fibroid resection. As a general rule, of all women undergoing endometrial ablation with a second-generation technique, 40–50% will become amenorrhoeic, 40–60% will have markedly reduced menstrual loss and 20% will have no difference in their bleeding. Nonetheless, it is clear from longer-term trials that while most women are initially satisfied, many subsequently choose or require repeat endometrial ablation (technique dependent) or hysterectomy.

Myomectomy

Myomectomy (abdominal, laparoscopic or hysteroscopic) is the surgical removal of fibroids from the uterine wall with conservation of the uterus. Advances in surgical instruments and techniques are expanding the role of laparoscopic myomectomy in well-selected individuals. If the fibroid protrudes into the uterine cavity, it may be removed hysteroscopically. GnRH analogues, and more recently SPRMs, are often used for up to 3 months prior to surgical intervention in an attempt to reduce the size and vascularity of the fibroids. Immediate complications of myomectomy usually relate to excessive blood loss and a blood transfusion may be required intraoperatively or postoperatively. Patients should therefore be carefully counselled preoperatively about this risk, including hysterectomy. Intermediate postoperative risks include infection and further bleeding. Pregnancy following myomectomy appears to be safe, with a very low risk of uterine rupture with a vaginal delivery. Indeed there are no reliable data available on the impact of 'full-thickness' myomectomy on the risk of uterine rupture.

As to whether further fibroid growth may occur, then this again is an area where there is a dearth of literature. It has been reported that a small proportion of women who undergo myomectomy may require subsequent intervention for management of their fibroids.

Uterine artery embolization

Uterine artery embolization (UAE) is a well-established technique for treatment of fibroids [20]. The procedure is usually carried out by an interventional radiologist, usually under local anaesthetic with or without sedation. The femoral artery is canalized on one or both sides and fed into the iliac and then uterine artery. Angiography is carried out to confirm the correct position before introduction of the embolic agent. Blockage of both uterine arteries results in fibroids becoming avascular and shrinking. Because the normal myometrium subsequently derives its blood supply from the vaginal and ovarian vasculature, UAE is thought to have no permanent effect on the remainder of the uterus. The procedure requires only a short hospital stay and may be carried out as a day case in selected women. After UAE, a mean reduction in fibroid volume of 30–46% has been reported and symptomatic improvement has been reported in up to 85% of women. However, there is no evidence of benefit of UAE compared with surgery (hysterectomy/myomectomy) for satisfaction [20]. In the immediate postoperative period, patients may experience ischaemic pain (usually responsive to simple analgesics) and infection is not uncommon. Occasionally, following UAE the rapid change in uterine size can result in passage of the fibroid vaginally. Rarely, subserosal fibroids can be adherent to the bowel and UAE can lead to bowel necrosis and peritonitis. Although there is a theoretical risk of premature ovarian failure after UAE, a recent study has shown that there is no evidence of deterioration in ovarian function after 1 year. A small risk of sepsis post procedure is acknowledged, even several months later.

Hysterectomy

A total hysterectomy is the only guaranteed 'no bleed' option for HMB. However, hysterectomy should only be considered in the treatment of HMB when a woman has completed her family and when medical and less invasive surgical options have been offered, failed or are inappropriate. Hysterectomy is an established and effective treatment for HMB that induces amenorrhoea, but this must be balanced against the potential morbidity associated with the procedure and the very low risk of mortality. In young patients with HMB, the ovaries are usually conserved but a bilateral salpingectomy should be carried out simultaneously due to recent evidence suggesting that ovarian cancer may have its origins within the fallopian tube. Those younger women who wish to have their ovaries removed, either by choice or due to family history of ovarian or breast cancer, must be appropriately assessed and counselled about the need for hormone replacement until the age of normal menopause. The routes for hysterectomy include laparoscopic, abdominal and vaginal. Individual patient characteristics and surgical expertise are important determinants of the chosen approach.

Laparoscopic hysterectomy

The proportion of hysterectomies performed laparoscopically continues to increase. Advantages include the opportunity to diagnose and treat other pelvic diseases (such as endometriosis), to carry out adnexal surgery, the ability to secure thorough intraperitoneal haemostasis at the end of the procedure, and a more rapid recovery time. Laparoscopic hysterectomy should be used as a general term, whereas operative laparoscopy before hysterectomy, laparoscopically assisted vaginal hysterectomy (with or without laparoscopic uterine vessel ligation), and laparoscopic total and subtotal hysterectomy should be used to describe the types of laparoscopic hysterectomy. In laparoscopically assisted vaginal hysterectomy, the procedure is performed partly laparoscopically and partly vaginally, but the laparoscopic component does not involve uterine vessel ligation. In uterine vessel ligation laparoscopic hysterectomy, although the uterine vessels are ligated laparoscopically, part of the

operation is carried out vaginally. In total laparoscopic hysterectomy, the entire operation, including suturing of the vaginal vault, is performed laparoscopically. A full description of each of these techniques is outwith the scope of this chapter.

Abdominal hysterectomy

An abdominal approach is indicated in women with an enlarged uterus (e.g. due to very large fibroids) or a long vagina and/or narrow pubic arch that makes the laparoscopic (or vaginal) approach technically difficult. An abdominal hysterectomy involves removal of the uterus and/or cervix (subtotal and total, respectively) through an abdominal incision under general anaesthetic. A subtotal abdominal hysterectomy may be performed due to patient preference or if the surgery is technically difficult due to adhesions or endometriosis. Although a subtotal hysterectomy is associated with decreased morbidity, patients must be warned of a 15% incidence of residual bleeding from the endocervix.

Vaginal hysterectomy

Vaginal hysterectomy is appropriate for women with HMB with a small uterus. Advantages of the vaginal route include the obvious absence of any abdominal wounds and minimal disturbance of the intestines.

Complications of hysterectomy

Mortality is a recognized complication of hysterectomy. The risk of death for the abdominal approach is estimated as 1 in 4000 procedures. Serious risks include damage to the bladder and/or ureters (7 per 1000), damage to the bowel (0.4 per 1000), major haemorrhage (15 per 1000), infection/pelvic abscess (2 per 1000), and thromboembolism (4 per 1000), and long-term increased risk of prolapse and urinary incontinence. Notwithstanding these complications, patient satisfaction following hysterectomy for HMB is as high as 95%.

Summary box 48.5

- Endometrial ablation is safe and effective but may not have longer-term benefits.
- Uterine artery embolization also has a significant re-intervention rate.
- Hysterectomy should only be considered when a woman has completed her family and when medical and less invasive surgical options have been considered.

Severe acute heavy menstrual bleeding

Severe acute HMB may occur due to a coagulopathy (most commonly von Willebrand disease), prolapsed fibroids, AVMs (see earlier section) or the use of anticoagulants. Initial management is based on haemodynamic stability. Prolapsed fibroids would then be managed surgically and AVMs generally by embolization. One reported regimen is ethinylestradiol 30 μg/norgestrel 0.3 mg four times daily for 4 days, followed by three times daily for 3 days, followed by two times daily for 2 days, followed by once daily for 3 weeks. Two further regimens that have been reported to be effective and reasonably well tolerated (randomized controlled trial, albeit limited by sample size) are (i) multidose oral contraceptive pill comprising norethindrone 1 mg/ethinylestradiol 35 μg three times daily for 1 week, then daily for 3 weeks and (ii) multidose medroxyprogesterone acetate 20 mg orally three times daily for 1 week and then daily for 3 weeks. Cessation of bleeding was achieved by 10–14 days in 88% and 76% of patients, respectively, with median time to cessation of bleeding being 3 days. Once the patient is clinically stable, an investigation into the cause of bleeding should be performed.

Premenstrual Syndrome

Zeiad A. El-Gizawy[1] and P.M. Shaughn O'Brien[1,2]

[1] *Royal Stoke University Hospital, University Hospitals of North Midlands NHS Trust, Stoke on Trent, UK*
[2] *Keele University School of Medicine, Royal Stoke University Hospital, Stoke on Trent, UK*

Premenstrual symptoms occur in most women and there may have been evolutionary benefit to this. Social behaviour resulting in intercourse would have occurred more frequently at the time of ovulation and less frequently once ovulation had passed. As the female becomes less receptive and possibly aggressive to males during the non-fertile premenstrual phase, the males would seek more receptive ovulating females leading to an increase in the population. This is pure conjecture of course – but that is the nature of evolutionary theory. As with all biological parameters there are extremes so that some women have minimal or no symptoms (5–9%) while a similar number have such severe symptoms that there is major impairment of their lives, that of their families, their interpersonal relationships and normal day-to-day functioning. This extreme is premenstrual syndrome (PMS).

Definitions

The terminology used for premenstrual disorders is complex. Premenstrual tension (PMT) was the term originally used, but it has now become the usual lay term; PMS is the medical term most often used in the UK. Premenstrual dysphoric disorder (PMDD) is the extreme, predominantly psychological end of the PMS spectrum, estimated to occur in 3–8% of women [1]. It is the term used increasingly by psychiatrists in the USA but, strictly speaking, originally only for research purposes. It should be noted that much recent research into aetiology and treatment has been undertaken on women who fulfil the criteria for PMDD, particularly for clinical trials on selective serotonin reuptake inhibitors (SSRIs). Women designated as having PMDD will also fulfil criteria for PMS but not necessarily vice versa.

PMS is defined in the Tenth Revision of the International Classification of Disease (ICD-10): a woman is considered to have PMS if she complains of recurrent psychological or somatic symptoms (or both) occurring specifically during the luteal phase of the menstrual cycle and which resolve in the follicular phase at least by the end of menstruation [2]. PMDD is more specific with regard to psychological symptoms and (reflecting the introduction of the term by psychiatrists) pays little attention to physical symptoms.

Because the ICD-10 definition makes no reference to impairment, it is probably too liberal to be of practical use clinically or for research purposes. The classification in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) is too restrictive for clinical use and may have the detrimental effect of under-recognizing patients who are severely debilitated.

Symptoms and classification of PMS

The International Society for Premenstrual Disorders (ISPMD) has published four consensus statements since the previous edition of this textbook. The first, widely cited, is on classification and diagnosis [3]. Core premenstrual disorders (PMDs) are the most common type of PMS. Because most normal women have some degree of symptomatology in the days leading up to menstruation, it is considered that it is the impact of symptoms, namely that they significantly disrupt normal functioning, that distinguishes those women with PMS from those with no more than normal physiological symptoms. The symptoms of core PMDs are non-specific and recur in ovulatory cycles. They must occur during the luteal phase and resolve as menstruation begins. There is no limit on the type or number of symptoms; however, some

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

women will have predominantly psychological symptoms, some will have predominantly physical symptoms and some will have a mixture of both.

There are also PMDs that are not typical core PMDs. These are called 'variant' PMDs and there are four categories.

1) *Premenstrual exacerbation of an underlying disorder*, such as diabetes, depression, epilepsy, asthma and migraine. These patients will experience symptoms characteristic of their medical condition throughout the menstrual cycle but they significantly worsen premenstrually.
2) *Non-ovulatory PMDs* occur in anovulatory ovarian activity. There is inadequate evidence to fully understand this, but follicular activity is believed to trigger the symptoms.
3) *Progestogen-induced PMDs* are caused by exogenous progestogens present in hormone replacement therapy (HRT) and the combined oral contraceptive pill. This can lead to the recurrence of PMD symptoms in women with extreme sensitivity to progestogens. Even though the same symptoms might occur with progestogen-only preparations, these will not be classified as PMDs due to the non-cyclicity of the symptoms and are thus considered to be adverse effects of the progestogen preparation.
4) *PMDs with absent menstruation* are symptoms experienced by women who have normal ovarian cycles but do not menstruate due to hysterectomy, endometrial ablation or the presence of a levonorgestrel intrauterine system (LNG-IUS).

Psychological symptoms of PMS vary greatly, from depression, anxiety, irritability, loss of confidence and mood swings up to suicidal ideation (and, in extreme cases, suicide) [4]. Physical symptoms are typically in the form of mastalgia and bloatedness.

Summary box 49.1

PMS is a condition that affects an enormous number of women to a significant degree; for a small number it can be devastating for the patient herself and for those family and colleagues around her.

Diagnosis

There are no objective tests (physical, blood, biochemical, endocrine or imaging) to assist the diagnosis of PMS and so the use of prospectively completed symptom charts is essential (Fig. 49.1). Retrospective reporting of symptoms is inaccurate, but significant numbers of women who present to a PMS clinic have separate underlying problems such as perimenopause, thyroid disorder, migraine, chronic fatigue syndrome, irritable bowel syndrome, seizures, anaemia, endometriosis, drug or alcohol abuse and menstrual disorders as well as psychiatric disorders such as depression, bipolar illness, panic disorder, personality disorder and anxiety disorder.

The confirmation of luteal-phase timing with the relief of symptoms by the end of menstruation is diagnostic, providing the symptoms are of such severity to impact on the patient's normal functioning. It is also important to identify patients who have a premenstrual exacerbation of their underlying psychological, physical or medical disorder. For example, there are many documented cases of premenstrual suicide, asthma and epilepsy.

Many validated assessment instruments are available, but they are all paper-based self-assessment scales and are not objective. Most researchers and clinicians opt for the Daily Record of Severity of Problems (DRSP) (Fig. 49.1), which is recommended in the 2016 (downloadable) Green-top Guideline No. 48 from the Royal College of Obstetricians and Gynaecologists (RCOG) [5]. Such charts are invaluable. They enable the clinician to characterize instantly the pattern of premenstrual symptoms, their absence during the follicular phase and the degree of impairment caused. Despite the earlier (2007) guideline's recommendation that the DRSP charts be administered for 2 months prospectively in order to establish the diagnosis before initiating treatment, less than 10% of clinical directors report that this strategy had been adopted in their gynaecology/PMS clinics (O'Brien and Samad, unpublished national survey data) (Fig. 49.2). More recently developed smartphone apps such as Prementrics (for smartphones) may be valuable.

Gonadotrophin-releasing hormone agonists in diagnosis

The use of the so-called gonadotrophin-releasing hormone (GnRH) analogue test may be of benefit in clarifying the diagnosis where there is a mixed or uncertain picture. Although there are several studies to demonstrate that this group of drugs successfully eradicates symptoms in well-defined patients, it has never been proven scientifically as a clinical test nor indeed even assessed as such. It is used extensively by gynaecologists (off-licence and with due discussion with the patient) for the purposes of removing the ovarian cycle to determine which of an individual patient's symptoms are clearly related to the menstrual cycle and which (i.e. those that persist despite suppression of the cycle) are not. It is also a valuable way of demonstrating whether symptoms or medical problems such as premenstrual migraine, asthma and epilepsy are truly related to the cycle or are independent. This can be illustrated by the following

DAILY RECORD OF SEVERITY OF PROBLEMS

Please print and use as many sheets as you need for at least two FULL months of ratings

Fig. 49.1 Daily Record of Severity of Problems (DRSP) chart prospectively completed by a patient suffering from moderately severe premenstrual syndrome (PMS) demonstrating (a) the cyclicity of symptoms, (b) occurrence premenstrually, (c) absence of symptoms in the follicular phase and (d) impairment.

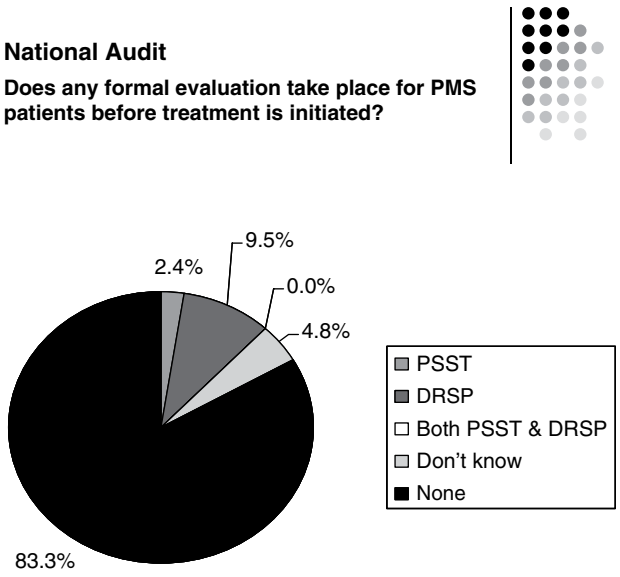

Fig. 49.2 National Survey of Clinical Directors. Implementation of RCOG Guidance on Diagnosis. DRSP, Daily Record of Severity of Problems; PSST, Premenstrual Symptom Screening Tool.

commonly encountered clinical problem. If a woman is to be considered for hysterectomy for a gynaecological indication such as heavy menstrual bleeding due to fibroids, symptom information gathered during GnRH therapy may help the patient make the decision about whether to conserve or remove her ovaries. If her PMS (or other significant premenstrual symptom) is severe and is eradicated by GnRH, it is likely (though not guaranteed) that she would also benefit from removal of ovaries when the hysterectomy is being undertaken. This information would be invaluable in the final preoperative counselling.

Aetiology

PMS is not due to a single factor but its basis is multifactorial, with genetic, environmental and underlying psychological influences being important. This is of course true for all mood disorders but in PMS the ovarian cycle comes into play, with ovulation being almost certainly the key factor.

Ovulation and progesterone

The principal cause of PMS is uncertain. There is evidence to suggest that the cyclical endogenous progesterone produced in the luteal phase of the cycle after ovulation is the key provoking factor. Women with PMS appear to be unusually 'sensitive' to normal levels of progesterone [6]; differences in progesterone levels have not been demonstrated between women with and without PMS [7]. It has been hypothesized that the mechanism of this increased sensitivity is related to a neurochemical factor, and most evidence points to a dysregulation of serotonin metabolism [6].

Throughout reproductive life, progesterone production seems to be linked to women's psychological health. Progesterone and metabolites, such as allopregnanolone, are produced by the ovary and the adrenals, and also *de novo* in the brain. These hormones are effectively neurosteroids that readily cross the blood–brain barrier. Progesterone has known mood-altering and sedative effects when administered. It is well known that women have no PMS symptoms before puberty, during pregnancy or after the menopause; these are times where ovarian hormone cycling has not begun or ceases temporarily or permanently. Not surprisingly, if the assumptions made above are true, PMS-like symptoms can also be reintroduced by the administration of oestrogen/progestogen hormone replacement therapy (HRT) and this is frequently seen in clinical practice.

Suppression of the ovarian endocrine cycle with danazol, by administration of analogues of GnRH or following bilateral oophorectomy results in the elimination of PMS symptoms. Therefore, the hypothesis that ovarian steroids, particularly ovulatory progesterones, have a role in the pathophysiology of the syndrome is intuitively obvious.

Research, none of which is recent, into PMS has generated data which could support theories of progesterone deficiency, oestrogen/progesterone imbalance or progesterone excess. However, the consensus is that ovarian steroid concentrations in blood do not differ in these women. Interactions of fluctuating levels of ovarian steroids or their metabolites with neurotransmitter systems or receptor imbalances in the brain are directly relevant to the pathogenesis of PMS [8]. This is believed to render women more sensitive to physiological levels of progesterone.

Summary box 49.2

Aetiology of PMS is uncertain, although ovulation is almost certainly the trigger in women who are sensitive to endogenous progesterone following ovulation and exogenous progestogen used therapeutically. It is likely that this sensitivity is related to an abnormality of neurotransmitter function. This has yet to be determined, but research evidence points to the serotonergic system.

Neurotransmitters

Oestrogen has clear effects on several neurotransmitters, including serotonin, acetylcholine, noradrenaline, γ-aminobutyric acid (GABA) and dopamine. It cumulatively acts as an agonist on serotonergic function by increasing the number of serotonin receptors, serotonin postsynaptic responsiveness and neurotransmitter transport and uptake. It also increases serotonin synthesis and boosts the levels of the metabolite 5-hydroxyindoleacetic acid (5-HIAA). It is well known that the serotonergic system plays a substantial role in regulating mood, sleep, sexual activity, appetite and cognitive ability. Serotonin dysregulation is a major component in the development of depression. Our knowledge of the role of serotonin in depression has been extended into PMS research [6] and several studies have demonstrated altered serotonin metabolism in these patients. Blood levels and platelet uptake of serotonin have been found to be low in patients with PMDD and acute depletion of tryptophan (the precursor of serotonin) aggravates symptoms of PMS and PMDD. This hypothesis is supported indirectly by the observation that serotonin-receptor concentrations vary with changes in the oestrogen and progesterone level and because the well-known SSRIs fluoxetine, paroxetine, citalopram and sertraline have been shown to be extremely efficacious in treating severe PMS and PMDD [8]. This gives additional, albeit indirect, support to the theory of involvement of serotonin in the aetiology of PMS.

Low activity of GABA has been reported in patients with depression, PMDD and PMS. Oestrogen increases binding of GABA agonists and the upregulation of GABA receptors. In addition to the effect of SSRIs on the serotonergic system, they have been shown to enhance GABA function, hence improving depressive symptoms. The GABA receptor is one of the principal receptors involved in the mechanism of action of alcohol and diazepam. Investigations of the metabolites of progesterone have shown that women with PMS have lower levels of allopregnanolone in the luteal phase [9]. This provides another plausible theory, as allopregnanolone has GABAergic activities and its deficiency can induce symptoms similar to those experienced in PMS (Fig. 49.2).

Vitamin B_6 (pyridoxine) is a cofactor in the final step in the synthesis of serotonin and dopamine from dietary tryptophan. However, no data have yet demonstrated consistent abnormalities of either brain amine synthesis or deficiency of cofactors such as vitamin B_6; supplementation studies have shown that it is possibly effective as a method of treatment but large randomized studies would be required to produce a conclusive answer.

Treatment

Summary box 49.3

Treatment can be achieved effectively either by suppressing or removing ovulation or by modulating central nervous function with psychological interventions or psychotropic drugs. SSRIs are particularly useful.

Non-medical therapies

Claims, mainly unsubstantiated, have been made for the supplementation of calcium, vitamin E, magnesium, dietary change, vitamin B_6, evening primrose oil, exercise, yoga, acupuncture, psychotherapy and many more. There is very little evidence that any of these treatments for PMS are effective, with the exception of exercise, and very limited evidence for the effects of calcium and magnesium. There is, however, strong evidence to support the use of cognitive behavioural therapy (CBT) for treating PMS and RCOG guidance recommends its use as routine early management [5]. It is important to realize that any treatment method may be associated with a very high placebo response, so many therapies appear on the face of it to be effective. Conversely, because of this placebo effect, therapeutic research requires the recruitment of such large numbers of patients to reach the power to demonstrate statistical superiority that many studies are almost impossible to undertake where the additional therapeutic effect over and above that of the placebo is only marginal.

Medical therapies

The management of PMS has, over the past few years, become increasingly easy to undertake, if somewhat more invasive. First, it should be stated that there is overwhelming evidence that progesterone pessaries and oral progestogens are ineffective [10]. Ironically, these are the only drugs in the UK that have a pharmaceutical licence for the management of PMS. All known effective therapies are unlicensed in the UK whilst most SSRIs and an oral contraceptive pill are licensed in the USA.

Our proposed aetiology of PMS suggests that normal postovulatory progesterone gives rise to symptoms in women who have increased sensitivity to endogenous progesterone and this sensitivity is considered to be due to a neurotransmitter dysregulation such as serotonin 'deficiency'. If this is so, then, broadly speaking, treatment should be achievable either by suppressing ovulation or by enhancing serotonin levels in the central nervous system to 'reduce the sensitivity to progesterone'.

The first of these is achieved pharmacologically or by surgical intervention, the former by elevating serotonin levels using drugs such as the SSRIs. Although theoretical, treatment based on this notion is very useful practically.

Psychotropics: selective serotonin reuptake inhibitors

Elevating serotonin levels can readily be achieved by the use of SSRIs [8]. Such treatment is clearly beneficial, although none of these drugs has a pharmaceutical licence for the management of either PMS or PMDD in the UK. Fluoxetine 20 mg daily is usually sufficient to improve symptoms in most women. Side effects such as loss of libido may be partially avoided by administering the drug during the luteal phase only, the effect of the SSRIs being more instantaneous for PMS symptoms than it is for the treatment of symptoms of depression. While SSRIs are not licensed in the UK or Europe for PMS, in the USA fluoxetine and indeed most other SSRIs are licensed for PMDD.

Ovarian cycle suppression

Suppression of the ovarian cycle can be achieved with oestrogen [11], danazol [12], GnRH agonist analogues [13] or bilateral oophorectomy [14].

Summary box 49.4

The few drugs that are licensed to manage PMS are ineffective; those that are effective must be used off-licence and patients should be made aware of this.

Surgery: bilateral oophorectomy

Bilateral oophorectomy with hysterectomy is almost always too invasive for the majority of patients with PMS and, even though it is the only certain cure [14], its use is rarely justifiable other than as a last-resort measure for the most severely affected women: those who have failed to respond to other measures. When removal of the ovaries and uterus is considered appropriate, oestrogen replacement can follow without the need to consider endometrial protection using progestogen, which inevitably would restimulate the PMS symptoms. We should note here that those studies that appear to have described (retrospectively) increased morbidity and mortality in later life if ovaries are removed are methodologically flawed. Women whose ovaries were conserved were compared with those having hysterectomy and bilateral oophorectomy but without any subsequent oestrogen replacement. No gynaecologist would withhold oestrogen replacement in such women and while such studies are not yet available, it would be anticipated that outcomes following bilateral oophorectomy plus oestrogen therapy would actually be far more favourable. It should be added that the studies described surgery for patients with other general gynaecological conditions and not for those undergoing surgery for PMS.

Any treatment technique where the uterus is retained and oestrogen replacement is given will require the administration of progestogen in order to protect the patient from the risk of endometrial cancer in the retained endometrium. Systemic progestogen will then almost certainly cause the reappearance of PMS symptoms in most women. Hence, if the ovaries are to be removed for PMS, then in most cases subsequent management is made simpler and more effective by removing the uterus at the same time. Laparoscopic bilateral oophorectomy has its attractions as it is less invasive, but the subsequent management difficulties posed by the presence of the endometrium are not inconsiderable. Whether it is preferable to use a Mirena® intrauterine system (see section Oestrogen) or to remove the uterus is probably more dependent on patient choice as there is no evidence to influence the decision either way. However, with advances in laparoscopic and robotic surgery, the uterus can also be removed through a minimally invasive route and clear RCOG guidance tends to favour removal of both uterus and ovaries in nearly all cases.

There is no logic in recommending endometrial ablation for PMS because cyclical ovarian function will continue along with the resulting PMS symptoms. Where claims were made for the beneficial effects of ablation, these were based on studies designed to evaluate the treatment of heavy periods and they are not valid for interpretation in terms of PMS treatment.

Danazol

When danazol is given orally, even at doses of 200 mg, it is particularly effective for most symptoms of PMS. Its use has been very much limited by anxieties related to the risk of masculinization. Attempts to reduce side effects by prescribing it for use in the luteal phase only (presumably through its direct effect on target tissue rather than ovulation suppression) have shown it be ineffective for nearly all symptoms of PMS with the exception of cyclical mastalgia [12].

GnRH agonist analogues (and add-back therapy)

GnRH agonist analogues are extremely effective [12]. These are best administered as injected depot preparations (goserelin or leuprorelin) as, unlike nasal preparations, compliance is virtually guaranteed. These drugs are agonist analogues and so omission of nasal doses (or indeed late administration of depot preparations) can result in incomplete suppression and restimulation of cycles.

Treatment without add-back therapy will almost always be successful for PMS, but confusion can arise owing to the development of new symptoms usually associated with the menopause. With continuous add-back therapy (particularly tibolone), the analogues remain equally effective for PMS while eliminating menopause symptoms [13], though not in all patients, hence the resort to surgery in some. It is difficult to know whether long-term use of this combination is justified either medically or economically. It is probably reasonable to use it in those women approaching the menopause and medium term in younger women. In those who do receive longer-term therapy, it is considered advisable to monitor bone density at yearly intervals as is recommended for patients being treated for endometriosis with long-term GnRH analogues and add-back. It is probably also appropriate to advise calcium, vitamin D and regular exercise for bone preservation.

Oestrogen

Suppression of ovulation using oestrogen has significant advantages over oophorectomy and GnRH analogues in that these latter approaches still require the addition of oestrogen to prevent the hypo-oestrogenic effects resulting from the primary treatment approach. Its disadvantage is that in those women who retain their uterus and endometrium, it is necessary to protect from endometrial cancer using potentially 'PMS-inducing' progestogens.

Oestrogen can be given in several ways, including the combined oral contraceptive pill, conventional cyclical or continuous HRT, and estradiol patches or implants. Standard preparations of HRT, be they cyclical, continuous combined or tibolone, are of insufficient dose to suppress ovulation and they would inevitably fail to improve symptoms and increase the incidence of abnormal uterine bleeding. They are only useful as add-back during GnRH therapy.

While the use of conventional combined oral contraception certainly suppresses ovulation, the progestogen component introduces a new progestogen cycle. This may be the reason why oral contraceptive therapy has in the main proven to be ineffective in several well-conducted trials. Progestogen-only pills will most often give rise to PMS-like side effects in these patients. Oral contraceptives containing a relatively newer progestogen, drospirenone, have been introduced. Drospirenone is derived from spironolactone and thus has anti-androgenic and anti-aldosterone properties which may antagonize or at least avoid restimulation of the PMS-like symptoms. Such preparations are licensed for PMDD in women requiring contraception in the USA and some European countries but not the UK. The use of this oral contraceptive therapy continuously would appear to be a logical approach.

Transdermal estradiol (as patches or implants) suppresses the ovarian cycle effectively without inducing the negative consequences of surgically induced premature menopause or 'medical oophorectomy' [10]. Consequently, they reliably treat PMS symptoms and this is demonstrated in a recent Cochrane review [11]. In the presence of an intact uterus, it remains necessary to prevent endometrial hyperplasia and cancer;- this, as has already been discussed, reintroduces 'PMS' [15].

While the possibility of giving oestrogen alone and regularly checking the endometrium with scans or endometrial sampling is feasible, the risk will remain and additionally the likelihood that patients will have troublesome bleeding is very considerable.

Other unresearched and potential alternatives to avoid restimulation of PMS symptoms exist, including:

- administering cyclical progestogen combined with simultaneous SSRI;
- the use of micronized progesterone preparations;
- the use of less androgenic progestogens;
- administration of the progestogen at less frequent intervals.

Probably the most realistic and effective method to achieve endometrial protection without reintroducing PMS would be to administer the progestogen into the uterine cavity using the Mirena LNG-IUS where it will act directly on the endometrium. With this approach, oestrogen suppresses ovulation and avoids menopausal symptoms. The intrauterine progestogen provides endometrial protection without achieving systemic levels (not in all patients) that would act on the central nervous system to reintroduce PMS symptoms. This combination could have the added benefit of improving any menstrual problem and would provide effective contraception. There is only limited evidence to support the use of this combination. There is, however, good evidence to demonstrate that oestrogen in sufficient doses achieves ovarian suppression and elimination of PMS symptoms – there is good evidence that the LNG-IUS can prevent and even reverse established endometrial hyperplasia. There is an enormous amount of clinical anecdotal experience to suggest that the combination is effective. Large-scale studies are required to demonstrate this efficacy as it has the ability to achieve all that hysterectomy and bilateral oophorectomy plus oestrogen achieves but without major surgery.

If general practitioners or gynaecologists should use this approach, it is important that they and their patients are aware that, as well as LNG-IUS-induced bleeding in the months following its insertion, there can be initial absorption of the LNG into the circulation, and thus return of PMS symptoms in the early months. Both are transient in most patients. Finally, O'Brien (unpublished

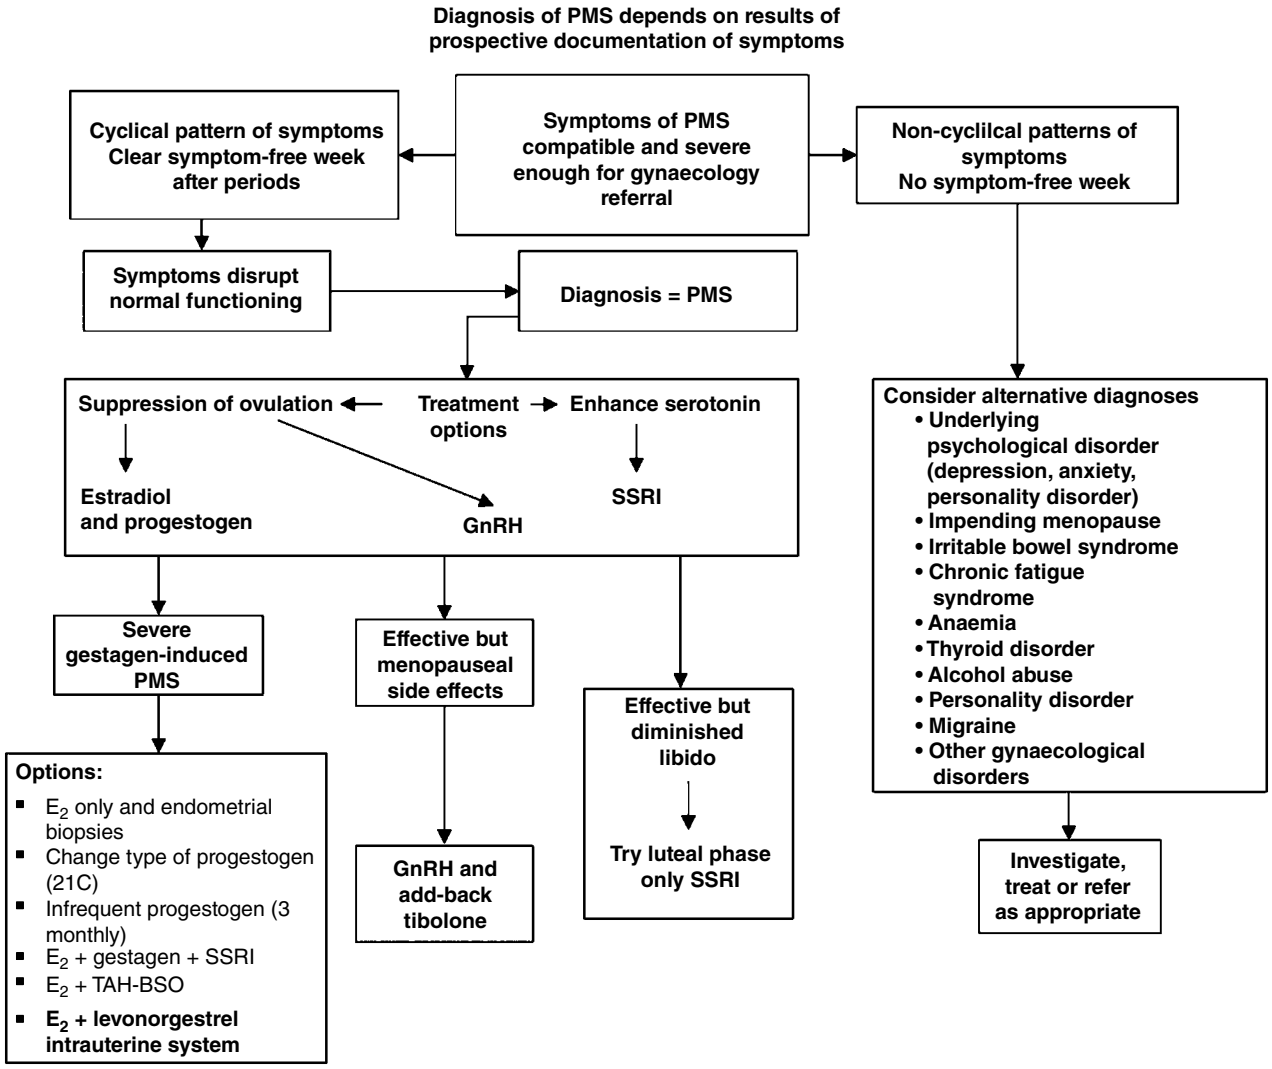

Fig. 49.3 Algorithm for the diagnosis and management of premenstrual syndrome (PMS). TAH-BSO = total abdominal hysterectomy and bilateral salpingo-oophrectomy.

data) has shown in a significant number of women who received pretreatment with GnRH suppression before insertion of LNG-IUS during the third month (when presumably the endometrium is thinned and avascular) that both bleeding and PMS are minimized. As yet, this requires formal evaluation in research studies (Fig. 49.3).

Summary box 49.5

In general, the more effective a treatment method is, the more invasive it is. Paradoxically, then, the worse the symptoms are, the easier it is to treat them as the more invasive treatment methods can be justified, assuming of course that the diagnosis is sound.

Conclusion

Suppression of the ovarian cycle eliminates PMS effectively. This can most precisely be achieved by GnRH analogues with add-back tibolone. The scope for long-term therapy using this approach is limited, and if it is required (rarely) it is prudent to monitor bone mineral density. Bilateral oophorectomy with hysterectomy is a last resort for all but a few well-selected women. Transdermal oestrogen suppresses ovulation reliably and eliminates PMS without generating menopausal side effects. Intrauterine progestogen (LNG-IUS) can be used to protect the endometrium and avoid restimulation of premenstrual symptoms; it also reduces periods and provides contraception. There can be initial bleeding and

restimulation of symptoms in the first months. The oral contraceptive pill appears to have extremely limited efficacy using conventional pills. Drospirenone-containing oral contraceptives have the potential to suppress ovulation without reintroducing PMS and should probably be used continuously. SSRIs are the simplest and most effective non-hormonal approach to treatment. Some consider that they should be used as first-line medical therapy, although many patients consider this form of therapy to be stigmatizing.

St John's Wort and agnus castus have been shown to be effective when used for depression. They could be tried as a self-help measure in PMS as there is limited evidence for their efficacy; there are known interactions if taken at the same time as SSRIs. There is evidence to demonstrate that exercise and particularly CBT are effective, but access to clinical psychology services and lifestyle intervention programmes within the National Health Service are extremely limited in the UK.

Other non-medical treatments are of doubtful efficacy but are usually harmless. They can be tried before resorting to medical therapy when there are no risks other than the inevitable delay in initiating a known effective therapy. The majority of patients can be treated simply in community-based practices by general practitioners or by self-help. Patient groups such as the National Association for PMS (NAPS) are very useful for this approach http://www.pms.org.uk.

Making a correct diagnosis is all important, and those patients without a symptom-free week probably have a continuous underlying psychological disorder. They should be referred back to the general practitioner or, in severe cases, referred on to a psychiatrist. Suicidal ideation and suicide attempts call for urgent referral to doctors with the specific skills to manage these problems.

Only the most severely affected patients with clear-cut PMS requiring medical or surgical intervention should be referred for secondary gynaecological management. Gynaecologists, preferably those with an interest, understanding and expertise in the area, should be asked to manage PMS patients only when symptoms are severe enough to justify such endocrine or surgical intervention.

Menopause and Postmenopausal Health

Nick Panay[1,2]

[1] *Queen Charlotte's & Chelsea and Westminster Hospitals, West London Menopause and PMS Centre, London, UK*
[2] *Imperial College London, London, UK*

Menopause, from the Greek *menos* (month) and *pausis* (cessation), is defined as the last menstrual period after a minimum of one year's amenorrhoea. The average age of the female menopause (51 years) has remained unchanged since ancient Greek and Roman times even though the average lifespan has increased. Thus, an increasing number of women are now spending almost half their lifespan in a hypo-oestrogenic state. The physiological changes which result in the final menstrual period start many years before the cessation of periods during the perimenopause. This episode of dynamic neuroendocrine change occurs due to a progressive reduction in ovarian reserve and is commonly associated with distressing physical and psychological symptoms in the last decade of a woman's reproductive lifespan. These endocrine, biomarker and menstrual changes have recently been studied and documented by the Stages of Reproductive Aging Workshop + 10 (STRAW + 10) [1] (Fig. 50.1).

Recent publication of the UK National Institute for Health and Care Excellence (NICE) menopause guidelines [2] has provided a much-needed rigorous analysis of the data on the diagnosis and management of the menopause. It is now vitally important that this information is efficiently disseminated to healthcare professionals, especially in primary care and gynaecology. This chapter uses the analyses of the NICE guidelines and the recently published guidelines from the various menopause societies as core information, which will be conveyed to the reader in a practical manner with signposts to key sources of information.

Consequences of the menopause

Aetiology of hot flushes and sweats

It is generally accepted that oestrogen plays an integral role in the genesis of vasomotor symptoms but the precise aetiology remains unknown. The hypothesis proposed by Robert Freeman still seems the most plausible [3,4]. In the asymptomatic woman there is a thermoneutral zone (about 0.4 °C) within which fluctuations of core body temperature do not trigger compensatory autonomic mechanisms such as flushing or sweating. In the symptomatic woman the thermoneutral zone is considerably reduced, so that even minor fluctuations in core body temperature reach the limits of the zone and initiate a thermoregulatory response. The narrowing of the zone may be due to elevated central noradrenergic activation and probably precipitated by changes in oestrogen. Recent data suggest that vasomotor symptoms such as flushes and sweats may be associated with an increased risk of cardiovascular disease [5,6].

Other early symptoms

Other typical immediate menopausal symptoms include insomnia, anxiety, irritability, memory loss, tiredness, poor concentration and musculoskeletal aches and pains. Falling oestrogen levels are thought to lead to similar falls in neurotransmitter levels, such as serotonin, which trigger mood symptoms. Women who have suffered from postnatal depression and premenstrual syndrome appear to be particularly predisposed to depression in the perimenopause [7]. The menopause transition is often associated with a significant reduction in sexuality and libido that is multifactorial but at least partly related to falling androgen levels [8].

Intermediate symptoms

Oestrogen deficiency leads to the rapid loss of collagen, which contributes to the generalized atrophy that occurs after the menopause. In the genital tract this is manifested by dyspareunia and vaginal bleeding due to

vulvovaginal atrophy (VVA). In the lower urinary tract, atrophy of the urethral epithelium occurs with decreased sensitivity of urethral smooth muscle and decreased amount of periurethral collagen. All this results in dysuria, urgency and frequency, commonly termed the urethral syndrome. The position statement from the International Menopause Society emphasizes the importance of enquiring about urogenital symptoms, the history of which might not be readily volunteered by the menopausal patient [9]. Recent studies have shown that the incidence of VVA is higher than originally thought due to under-reporting and that these symptoms often have a devastating effect on relationships [10]. A new classification system which encompasses VVA and urinary tract problems has recently been proposed in North America called the genitourinary syndrome of menopause (GSM) and could be adopted universally in due course [11].

Long term

Osteoporosis and sarcopenia

Osteoporosis is a systemic skeletal disorder of the bone matrix resulting in a reduction of bone strength, to the extent that there is a significantly increased risk of fracture when a woman suffers a fall from her own body height. Bone strength is determined by bone density and microarchitectural integrity. Osteoporosis is predominantly a disease of women, who achieve a lower peak bone mass than men and are then subjected to an accelerated loss of bone density following the menopause due to loss of oestrogen. Women lose 50% of their skeleton by the age of 70 years, but men only lose 25% by the age of 90 years. The loss of height occurs not only due to vertebral fractures but also loss of the intervertebral disc space as a result of deterioration and loss of collagen [12]. Osteoporosis-related fractures cause considerable morbidity in the

elderly, requiring prolonged hospital care and difficulties in remobilization. There is increasing awareness that avoiding sarcopenia (muscle loss and weakness) through regular exercise will maintain strength and posture and reduce the risk of injuries including osteoporosis-related fractures. Hormone therapy may help muscle as well as bone strength but this requires confirmation [13].

Cardiovascular

Cardiovascular disease is the principal cause of morbidity and mortality in women. Women are protected against cardiovascular disease before the menopause, after which the incidence rapidly increases, reaching a similar frequency to men by the age of 70 years. The protective effect of oestrogen in premenopausal women is also thought to be mediated by a favourable effect on the ratio of high-density lipoprotein (HDL) to low-density lipoprotein (LDL), by nitric oxide-mediated vasodilatation leading to increased myocardial blood flow, by an antioxidant effect on endothelial cells and by a direct effect on the aorta decreasing atheroma. Cross-sectional and prospective observational studies have shown that women going through the menopause transition have elevation of cholesterol, triglyceride and LDL levels, a reduction in HDL2 levels and a rise in insulin resistance. As oestrogen levels begin to fall, the somatotrophic axis becomes less active leading to insulin resistance and a rise in central adiposity. This in turn leads to the change in body shape from the female gynaecoid shape to the male android shape, itself an independent risk factor for coronary heart disease (CHD) [14]. A number of factors are involved in perimenopausal weight gain including genetic predisposition, socioeconomic influences, reduction in caloric need and expenditure, reduced lean body mass and a reduction in resting basal metabolic rate. Major primary prevention measures include smoking cessation, weight loss, blood pressure reduction, regular aerobic exercise and diabetes and lipid control.

Central nervous system

During the menopause transition, poor concentration and other cognitive problems are common [15]. Although these symptoms do not usually persist long term, the incidence of Alzheimer's dementia is significantly higher in women compared with men. Studies have demonstrated that oestrogen may improve cerebral perfusion and cognition in women below 60 years. Oestrogen appears to have a direct effect on the vasculature of the central nervous system and promotes neuronal growth and neurotransmission. In the long term, exogenous oestrogen may prevent diseases with a vascular aetiology such as vascular dementia and Alzheimer's, but long-term randomized data are required to confirm this. The failure of oestrogen to show benefit for dementia in women commencing treatment above 60 years, and possibly an increased risk in some studies, may reflect the predominance of the prothrombotic effect of oestrogen in women of this age group.

Advances in prediction of menopause

The prediction of menopause has progressed significantly over the last 5 years. These are not tests that are widely performed but can be useful where premature ovarian insufficiency (POI) is suspected or where there is a family history of POI. Follicle stimulating hormone (FSH) levels can be misleading even when the test is timed to the early follicular phase of the cycle and levels often vary from cycle to cycle depending on ovarian activity. The most accurate predictors of ovarian reserve currently available appear to be measurement of anti-Müllerian hormone (AMH) production by the primordial and pre-antral follicles and estimation of antral follicle count by ultrasonographic estimation. AMH is independent of the day of cycle and its predictive value of ovarian reserve is claimed to last for up to 2 years from when the sample is taken. A systematic review [16] was recently carried out to appraise data on prediction of age at natural menopause (ANM) based on AMH, antral follicle count and mother's ANM to evaluate clinical usefulness and to identify directions for further research. It found that AMH was currently the most promising marker for prediction of ANM. However, prediction models do not predict the extremes of menopause age very well and have wide prediction intervals. Markers need improvement before they can be used for individual prediction of menopause in the clinical setting.

Summary box 50.1

Routine FSH testing is not required in women aged 45 years or over with classic menopause symptoms such as hot flushes and sweats.

Patient assessment and ongoing monitoring

Initial diagnosis

The diagnosis of natural menopause can usually be made from the characteristic history of the vasomotor symptoms of hot flushes and night sweats and/or amenorrhoea.

Measurement of the concentrations of plasma hormones such as estradiol, FSH and luteinizing hormone (LH) in women over the age of 45 years with classical symptoms is not indicated as it is unlikely to change clinical management [2]. However, in the young woman aged below 45 years (and certainly under 40 years) or after hysterectomy with ovarian conservation, where the diagnosis is more difficult and the metabolic implications may be more serious, measurement of FSH levels may be helpful, in which case repeated concentrations of 40 IU/L or above may be regarded as being in the menopause range. Women diagnosed with spontaneous POI should, in addition to hormonal investigations, also have an autoantibody screen (thyroid and adrenal) and should be offered karyotype and fragile X genetic analysis, particularly if they are below 30 years of age. Online programs such as Manage my Menopause can be helpful for both the woman and the healthcare professional in individualizing overall care and specific management [17].

Monitoring

The NICE menopause guidelines recommend that women should be followed up within 3 months of initiation of treatment and annually thereafter. An oestrogen level is only helpful if there has been inadequate response to treatment due to low levels or if side effects suggest that the dose of estradiol is too high. Annual screening should include assessment of body mass index (BMI), blood pressure and a review of medication. A white paper written by cardiologists and menopause experts has highlighted the important role that gynaecologists can play in cardiovascular screening [18]. Fasting lipid profile and estimation of insulin resistance are recommended in women with risk factors (e.g. increased waist circumference or personal/family history of diabetes/cardiovascular disease).

Although advice should be given to women about being aware of changes in their breasts and perineum, routine breast palpation and pelvic examination is unnecessary; these need only be performed if clinically indicated. Mammography should be performed as part of the national screening programme every 3 years unless more frequent examinations are clinically indicated. However, if a woman chooses to use hormone replacement therapy (HRT) beyond the current age of breast screening cessation (70 years), mammographic screening should also continue. In women over 45 years of age it is best to arrange screening before starting oestrogen therapy to identify patients with subclinical disease. Ultrasound examination of the pelvis and/or endometrial biopsy are not a necessary prerequisite to treatment with HRT unless there is undiagnosed bleeding.

The gold standard measurement of the risk of osteoporosis is still dual-energy X-ray absorptiometry (DEXA) measurement of the lumbar spine and hip; some units are now using CT to perform this assessment. Markers of bone formation and breakdown can be useful in that changes occur more rapidly than with bone density, but their use is largely confined to research. The Royal College of Physicians advises that DEXA scans are performed no more frequently than every 2 years because changes in bone mineral density are so small that they often do not exceed the margin of error of the equipment and assessor. The World Health Organization (WHO) has advised that the decision to treat osteoporosis is made by taking into account bone mineral density, age and BMI. The formula for calculating the probability of fracture (FRAX) is available online [19].

Premature ovarian insufficiency

Premature ovarian insufficiency remains poorly understood and under-researched. It describes a syndrome consisting of early cessation of periods, sex steroid deficiency, and elevated levels of the pituitary hormones FSH and LH in women below the age of 40 years. POI can be primary (spontaneous POI) or secondary (induced by radiation, chemotherapy or surgery). Controversy persists over nomenclature, with terms such as 'premature menopause', 'premature ovarian failure/dysfunction' and 'primary ovarian insufficiency' still in use. POI has been estimated to affect about 1% of women younger than 40 years, 0.1% of those under 30 and 0.01% of those under 20. However, as cure rates for cancers in childhood and young women continue to improve it is likely that the incidence of prematurely menopausal women will rise. Data from Imperial College London suggest that the incidence of POI may be significantly higher than originally estimated. Islam and Cartwright [20] studied 4968 participants from a 1958 birth cohort. They found that 370 (7.4%) had either spontaneous or medically induced POI. Smoking and low socioeconomic status were predictive of POI, and poor quality of life (as determined by the SF36 Quality of Life Questionnaire) was twice as common in POI. The incidence of POI also varies according to the population studied. It appears to be significantly higher, greater than 20%, in some Asian populations (personal communications with Indian Menopause Society and Chinese Gynaecological Endocrinology Society).

In the past, the focus of medical care has been on improvement of survival rates. Very little attention has been given to the maintenance of quality of life in the short term and to the avoidance of the long-term sequelae of POI. One of the main reasons for this has been the

bias of economic expenditure and medical endeavour to the prolongation of life (e.g. cancer treatments) rather than towards optimizing quality of life in cancer survivors. Should this trend continue we are in danger of creating a population of young women who have been given back the gift of life but left without the zest to live it to its full potential.

Causes of spontaneous POI include idiopathic (no known cause), genetic, autoimmune and infective. The typical presentation of spontaneous POI is erratic or complete cessation of periods in a woman younger than 40 years, which may or may not necessarily be accompanied by symptoms. These symptoms may not be typical vasomotor in nature and include mood disturbances, loss of energy and generalized aches and pains. Our data indicate that the next most disturbing aspect of POI after the loss of fertility is the adverse impact on sexual responsiveness and other psychological problems [21]. Thus women with POI require integrated care to address physical, psychosocial and reproductive health as well as preventative strategies to maintain long-term health. Until recently, there has been an absence of specific evidence-based guidelines for diagnosis and management of POI, but this has recently been addressed by the European Society for Human Reproduction and Embryology (ESHRE) [22].

POI is a difficult diagnosis for women to accept, and a carefully planned and sensitive approach is required when informing the patient of the diagnosis. A dedicated multidisciplinary clinic separate from the routine menopause clinic will provide ample time and the appropriate professionals to meet the needs of these emotionally traumatized patients. At the West London Menopause Service we have restructured our services and created dedicated clinics for the POI patients. Counselling should include explanation that remission and spontaneous pregnancy can still occur in women with spontaneous or medical POI. Specific areas of management include the provision of counselling and emotional support, diet and nutrition supplement advice, HRT and reproductive healthcare, including contraception and fertility issues. In the UK, the Daisy Network, a voluntary support network for women with POI, provides excellent support and information for POI sufferers.

As a minimum, the initial investigation of patients presenting with erratic periods, for which pregnancy should be excluded, includes measurement of serum FSH, estradiol and thyroid hormones. If FSH is in the menopausal range (>40 IU/L), the test should be repeated 4–6 weeks later for confirmation, as levels can fluctuate. Young women with spontaneous POI have pathologically low oestrogen levels compared with their peers who have normal ovarian function. The NICE [2], British Menopause Society [23], International Menopause Society [24] and ESHRE [21] guidelines state that in women with POI, systemic hormone therapy is recommended at least until the average age of the natural menopause (51 years). Hormone treatment with HRT, or the contraceptive pill if pregnancy is not desired, is required not only to control vasomotor and other menopause symptoms, but also minimize risks of cardiovascular disease, osteoporosis and dementia, as well as to maintain sexual function. Three small prospective randomized trials thus far have compared HRT with the combined contraceptive pill in POI. Limited data suggest that both options are effective but HRT appears to be superior in increasing bone mineral density and in its beneficial effects on cardiovascular risk markers. There is an urgent need for large-scale long-term randomized prospective studies to determine the optimum routes and regimens of hormone replacement in POI. Outcome measures should include vasomotor, urogenital, quality of life and psychosexual health and the long-term effect on cardiovascular, cognitive and skeletal health.

In the absence of such long-term trials, a POI registry, funded by Imperial College London, has been developed to collate good-quality prospective data from healthcare professionals globally [25–27]. There is an unmet need to determine long-term response to interventions such as the contraceptive pill and HRT and in those not receiving treatment. This is particularly important in women with rare causes and hormone-sensitive cancers where randomized trials are unlikely to be ever performed. The registry will be used to create a global genetic biobank for genetic studies, with an ultimate goal of defining the specific pathogenic mechanisms involved in the development of POI. The database has the potential to define and characterize the various presentations of POI along the lines of the STRAW + 10 guidelines for natural menopause [1]. It could also be used to further refine the role of biomarkers such as AMH to precisely predict the course and timing of natural and early ovarian insufficiency.

Interventions

Lifestyle measures

The modern approach to optimizing health in the menopause should start from public education in school and the workplace. Common-sense lifestyle and dietary approaches instituted well in advance of the menopause will maximize that chances of good health through midlife and beyond. As recommended by the British Menopause Society position statement [28], every woman should be encouraged to take plenty of regular

exercise in addition to having a well-balanced diet, avoiding smoking and minimizing alcohol consumption. Data suggest that women who are more active tend to suffer less from the symptoms of the menopause and have higher bone mineral densities compared with sedentary controls. There is also evidence for reduction in bone loss by ensuring adequate calcium (1000 mg) and vitamin D_3 (800–1000 IU) in the diet. However, excessive calcium intake can increase the risk of adverse events such as myocardial infarction [29]. Routine supplementation with calcium is not now recommended unless deficiency has been detected. Ensuring adequate vitamin D_3 levels will not only improve calcium absorption but may also have a beneficial effect on general well-being and musculoskeletal symptoms. A reduction in alcohol and caffeine intake can also reduce the severity and frequency of vasomotor symptoms.

Hormone replacement therapy

Oestrogen

Dose

There is a general consensus that the minimum effective dose of estradiol should be prescribed and the dose increased if required to alleviate symptoms. However, it is important that the dose is high enough to fully alleviate symptoms. Although there is little evidence that higher doses of exogenous oestrogen are associated with increased risk of breast cancer, there are dose–response effects with venous thromboembolism and stroke. Lower doses of oestrogen are less likely to cause breast tenderness and bleeding problems (due to less endometrial stimulation), which will encourage continuation of therapy.

The recommended starting doses of currently available systemic oestrogen are as follows:

- 0.3 mg oral conjugated equine oestrogens;
- 1 mg oral micronized estradiol or estradiol valerate;
- 25–50 μg transdermal estradiol;
- two metered doses of estradiol gel or 0.5–1.0 mg estradiol sachets;
- 25–50 mg implanted estradiol (note that estradiol implants are currently unlicensed for commercial reasons).

Data suggest that in many women the benefits of estradiol for symptom relief and bone protection can be achieved with a 0.5-mg dose when combined with progestogen [30]. Side effects such as bleeding problems are minimized by this dosage and a neutral effect on breast symptoms and mammographic density is possible [31]. Women who suffer POI or early menopause need higher doses of oestrogen to reproduce the physiological hormone levels which would have been present if the ovaries had not failed early.

Summary box 50.2

The dose and route of administration of estradiol should be tailored to the requirements of the woman in order to optimize benefits and minimize side effects and risks.

Route of administration

Prior to the menopause the physiological state consists of an estradiol/estrone ratio of 2 : 1. This can only be achieved if estradiol is delivered transdermally, thus avoiding first-pass hepatic metabolism. Oral estradiol preparations are partially metabolized to estrone by hepatic first-pass metabolism and therefore do not fully restore this ratio. There are now observational and case–control data showing that the thromboembolic risk is neutralized by avoidance of first-pass stimulation of coagulation factors, even in women who are obese and thrombophilic [32]. This is particularly important in women who are obese or smokers and are therefore at increased risk of venous thromboembolic disease.

There are twice-weekly or once-weekly transdermal systems containing both oestrogen and progestogen that can be used either sequentially or as continuous combined HRT. The hormone is adsorbed onto the adhesive matrix and this avoids the skin reactions caused by the old alcohol reservoir patches. Dot matrix patches are the smallest and best-tolerated patches, with a very low incidence of skin irritation. Estradiol gel is also available either dispensed from a pump or as a low-volume daily sachet. It is hoped that non-oral estradiol development will resume to produce commercially available nasal and sublingual tab/wafer products that also avoid first-pass hepatic metabolism. An expanded product armamentarium facilitates individualized hormone replacement.

Vaginal oestrogen

The most effective treatment for VVA is local application of oestrogen. This can be achieved through the use of creams, tablets and rings delivering estriol and estradiol. There is no significant systemic absorption of oestrogen from these products and therefore do not lead to endometrial hyperplasia or bleeding problems. Long-term endometrial biopsy data are limited but 1-year data are consistently reassuring. Endometrial protection with progestogens is not required. The British and International Menopause Societies recommendations [23,24] and recent NICE guidelines [2] highlight the importance of identifying VVA symptoms, which can be very distressing and are easily and safely alleviated with vaginal oestrogen. The regulatory authorities in the UK have granted an 'indefinite use' licence to 10-μg estradiol vaginal tablets. These were developed with the aim of providing the minimum effective dose for

relief of urogenital symptoms; a year of use will expose the user to only 1.4 mg of estradiol in total. However, some women require higher doses to fully alleviate their symptoms. The NICE menopause guidelines [2] recognize this and indicate the possibility of higher doses being used judiciously.

Options for local vaginal oestrogen are as follows:

- 0.01% estriol cream and pessaries;
- 0.1% estriol cream;
- 10 μg per 24 hours estradiol vaginal tablets;
- 7.5 μg per 24 hours estradiol-releasing silicone ring.

Summary box 50.3

Local application of oestrogen is highly effective for VVA but the benefits only last whilst the preparations are used.

New options for treating VVA

Ospemifene is an orally active selective oestrogen receptor modulator that has oestrogen-type activity in the urogenital tract [33]. It is licensed in a few countries, such as the USA and Italy, for treatment of moderate to severe dyspareunia and has recently been made available in the UK. The avoidance of oestrogen may be of advantage in women with a past history of hormone receptor-positive malignancy whose menopause symptoms are often compounded by the use of tamoxifen or aromatase inhibitors.

CO_2 laser and erbium laser technology is being used to rejuvenate atrophic vulval and vaginal tissue by facilitating the regeneration of collagen and elastin through improved blood flow [34]. Although the preliminary data are promising, longer-term randomized placebo-controlled studies are required to confirm the benefits and duration of effect.

Progestogens/progesterone

Regimens

Progestogens or progesterone are required in women using systemic oestrogen to minimize the risk of endometrial hyperplasia and carcinoma. If the last menstrual period occurred less than 1 year prior to starting HRT, a sequential combined regimen is recommended (i.e. continuous oestrogen with progestogen for 12 days per cycle). A progestogen challenge should be considered after 3 months of oestrogen alone in women who have had a subtotal hysterectomy to test for residual endometrium. An ultrasound scan could also be performed to check for residual endometrium. Low-dose continuous progestogen should also be used after endometrial ablation and pelvic radiotherapy and should also be considered in women following hysterectomy for severe endometriosis.

The typical dosages of the more commonly used progestogens are shown in Table 50.1.

Bleeding problems

If bleeding is heavy or erratic, the dose of progestogen can be doubled or duration increased to 21 days. Persistent bleeding problems beyond 6 months warrant investigation with an ultrasound scan and/or endometrial biopsy. After 1 year of therapy (2 years in POI) women can switch to a continuous combined regimen that aims to give a bleed-free HRT regimen, which will also minimize the risk of endometrial hyperplasia. Alternatively, women can be switched to the tissue-selective agent tibolone. Both these regimens may be associated with some erratic bleeding to begin with but 90% of those that persist with these treatments will eventually be completely bleed-free. If starting HRT *de novo*, a bleed-free regimen can be used from the outset if the last menstrual period was over a year ago.

Progestogenic side effects

One of the main factors for reduced compliance is that of progestogen intolerance. Progestogens have a variety of effects apart from the one for which their use was intended, that of secretory transformation of the endometrium. Symptoms of fluid retention are produced by the sodium-retaining effect of the renin–aldosterone system which is triggered by stimulation of the aldosterone receptor. Androgenic side effects such as acne and

Table 50.1 Minimum doses of progestogen given orally in HRT as endometrial protection.

Progestogen type	Sequential combined daily dosage	Continuous combined daily dosage
Testosterone-derived progestogens		
Norethisterone	5 mg	0.1 mg
Levonorgestrel	75 μg	N/A
Levonorgestrel intrauterine system	N/A	20 μg
Norgestrel	150 μg	50 μg
Progesterone-derived progestogens		
Cyproterone*	2 mg	1 mg
Medroxyprogesterone acetate	5 mg	2.5 mg
Micronized progesterone	200 mg	100 mg
Cyclogest pessaries	400 mg	200 mg
Crinone gel (8%)	Alternate days/12 days per cycle	Twice weekly
Spironolactone-derived progestogens		
Drospirenone	N/A	2 mg

*Not available in the UK at these dosages.

hirsutism are a problem of the testosterone-derived progestogen due to stimulation of androgen receptors. Mood swings and premenstrual syndrome-like side effects result from stimulation of the central nervous system progesterone receptors.

Minimizing progestogen side effects

The dose can be halved and duration of progestogen can be reduced to 7–10 days. However, this may result in bleeding problems and hyperplasia in a few cases (5–10%) so there should be a low threshold for performing ultrasound scans and endometrial sampling in these women. Natural progesterone has fewer side effects due to progesterone receptor specificity and is now available in an oral micronized form, vaginal pessaries and gel (see Table 50.1). HRT regimens containing natural progesterone can minimize the metabolic impact and reduce the risk of thromboembolism [35]. The levonorgestrel intrauterine system, recommended for endometrial protection for up to 5 years, minimizes systemic progestogenic side effects by releasing the progestogen directly into the endometrium with low systemic absorption. Drospirenone, a spironolactone analogue, has been incorporated with low-dose oestrogen in a continuous combined formulation. It is not only progesterone receptor specific but also has anti-androgenic and anti-aldosterone effects, the former making it useful for hirsutism and the latter for fluid retention. It is also mildly antihypertensive [36]. A new product which may be the ideal solution to the progestogen intolerance problem is a combination of conjugated oestrogens with bazedoxifene (BZA), a member of the tissue selective oestrogen complex [37]. In this product, the progestogen has been replaced by BZA, a selective oestrogen receptor modulator, which protects the endometrium against endometrial hyperplasia and carcinoma. Not only is the endometrium protected but there may also be some protection against breast cancer; this requires confirmation from long-term randomized controlled trials.

Bio(body)-identical HRT

Bio-identical hormones are precise duplicates of estradiol, progesterone and testosterone as synthesized by the human ovary. They are manufactured from plant sources in the laboratory and are available as micronized oral tablets, transdermal patches, implants and gels. Regulated bio-identical products must not be confused with unregulated products from compounding pharmacists. In order to avoid confusion, regulated products should be referred to as body-identical rather than bio-identical [38]. The regulatory authorities are attempting to bring the compounding pharmacies under the same regulation as standard hormone therapy products. Compounded bio-identical hormones are not recommended by the British Menopause Society or by NICE in the recent menopause guideline [2].

The published data thus far suggest that differential effects can be achieved by the use of body-identical hormones in comparison with synthetic non-body-identical HRT. The E3N cohort study, part of the European Prospective Investigation into Cancer and Nutrition (EPIC), showed that oestrogen/progesterone combination HRT was associated with a significantly lower relative risk (neutral for 'ever use' of HRT) than for other types of combined HRT (RR 1.7–2.0) [39]. There are also data now indicating that micronized progesterone has a modulating effect on venous thromboembolism (VTE). The risk of VTE appears to be lower with micronized progesterone than it is with more androgenic progestogens when combined with oral oestrogen. The metabolic neutrality of progesterone has been seen as an advantage in avoiding attenuation of the benefits of oestrogen in cardiovascular disease prevention. This is discussed later in the chapter in connection with the new pilot studies which have been performed recently and the need for further major prospective randomized controlled trials will be highlighted.

Androgens

Women with distressing low sexual desire and tiredness should be counselled about the possibility of using androgen supplementation [40]. In the past, 100 mg implanted testosterone pellets were licensed for female testosterone replacement. These are currently only available as unlicensed preparations as the licensed implants were withdrawn for commercial reasons. The 300-μg testosterone transdermal system was developed to treat hypoactive sexual desire disorder, the American Psychiatric Association's definition of distressing low sexual desire. A series of randomized controlled trials showed a significant improvement in the number of satisfying sexual episodes in women with surgical menopause and also in women with natural menopause. Benefits were seen in women using concomitant oestrogen and in those using testosterone alone. Similar to the testosterone implants, the licence for the patches was also withdrawn for commercial (profitability) reasons.

These developments have restricted the available options for female androgen replacement. Testosterone male gel (Tostran 2% gel) can be used at lower doses off label on an alternate day basis to achieve female physiological levels. Alternatively, 1% testosterone cream (AndroFeme) marketed for female use in Australia, can be accessed internationally, but is only available for private use at time of writing. In my clinical experience, if the free androgen index [(testosterone × 100)/sex hormone-binding globulin] is kept within the physiological range (<5.0%), there are rarely any side effects such

as hirsutism and acne. Scalp hair loss and virilizing effects are rare, and this has been shown in recent meta-analyses of the data [41,42]. Cardiovascular and breast safety data have been reassuring thus far, although the regulators would like to see further long-term studies before licensing further female androgen products. A 5-year study on cardiovascular and breast safety has been completed in the USA but analysis of the data (more than 7000 women-years of use) has not yet been carried out due to lack of funding.

Dehydroepiandrosterone (DHEA) is a weak androgenic steroid produced by the adrenal gland that has androgenic properties. It is mostly produced in a sulfated form (DHEA-S), which may be converted to DHEA in many tissues. Blood levels of DHEA drop dramatically with age. This had led to suggestions that the effects of ageing can be counteracted by DHEA 'replacement therapy'. DHEA is being increasingly used in the USA, where it is classed as a food supplement, for its supposed anti-ageing effects. Some studies have shown benefits on the skeleton, cognition, well-being, libido and the vagina but these data require confirmation [43].

Benefit–risk balance of HRT

Coronary heart disease and overall mortality

Concerns about the risks of HRT were raised by the Women's Health Initiative (WHI) study [44] and the Million Women Study (MWS) [45]. The WHI study claimed that there was an excess risk of cardiovascular disease, stroke and breast cancer in women regardless of age group. However, these studies were heavily criticized due to their design, particularly the WHI study where the average age of recruitment was 63 years and with an excess of obesity, hypertension and pre-existing cardiovascular disease. There is now strong and consistent evidence that oestrogen therapy may be cardioprotective if started around the time of menopause (referred to as the 'window of opportunity' or 'timing' hypothesis) and may be harmful if started more than 10 years after menopause.

In the 13-year follow-up of women in the WHI study, the cumulative data in the 50–59-year-old age group showed a reduction in CHD (hazard ratio, HR 0.65, 95% CI 0.44–0.96) [46]. The risk of myocardial infarction was also significantly decreased (HR 0.60, 95% CI 0.39–0.91). Women less than 10 years since menopause who received conjugated oestrogens plus medroxyprogesterone acetate showed a non-significant reduction in CHD (HR 0.90, 95% CI 0.56–1.45), suggesting a potential attenuation of the coronary benefit with this particular regimen using a continuous progestogen. Meta-analyses of randomized controlled trials, including data from the WHI study, have shown a significant reduction in CHD as well as mortality in women treated with oestrogen under the age of 60. In the WHI study, the cumulative results showed a reduction in all-cause mortality in the 50–59-year-old age group with oestrogen alone and oestrogen–progestogen. When mortality data for conjugated oestrogens and conjugated oestrogens plus medroxyprogesterone acetate from the two WHI trials were combined, the reduction in all-cause mortality was significantly reduced by 30%.

In the most recent Cochrane analysis [47], women within 10 years of menopause had a reduction in all-cause mortality of 0.70 (95% CI 0.52–0.95) and in cardiovascular mortality of 0.52 (95% CI 0.29–0.96). An observational study from Finland [48] recently reported that estradiol products (oral and transdermal) with and without progestogen decreased coronary and all-cause mortality significantly (12–54%); of note in this study, while longer duration of use decreased mortality, age of initiation did not make a difference.

A number of recent randomized controlled studies (DOPS, KEEPS and ELITE) have shown that cardiovascular risks can be minimized and benefit maximized using HRT in younger populations. The Danish Osteoporosis Prevention Study (DOPS) [49] studied younger women at the onset of menopause who prospectively received standard doses of estradiol and norethisterone in an open-label fashion or no treatment for 10 years and had 16 years of follow-up. There were significant reductions in mortality and in hospitalizations for myocardial infarction and congestive heart failure.

The Kronos Early Estrogen Prevention Study (KEEPS) [50] showed no difference between conjugated oestrogens 0.45 mg, transdermal estradiol 0.05 mg and placebo for intermediate end-points: carotid artery intima–media thickness and coronary calcium. These young healthy women had virtually no coronary artery disease and it is possible that there was insufficient progression over 4 years to detect differences between the groups.

The Early versus Late Intervention Trial with Estradiol (ELITE) (oral estradiol 1 mg and placebo in two groups of women, <6 years from menopause and the other >10 years) showed a reduction in carotid intima–media thickness over time in the younger women, and no change in the older population, confirming that the timing of oestrogen treatment is important in influencing the progression of coronary disease [51].

Summary box 50.4

There appears to be a 'window of opportunity' in the early menopause transition when treatment with HRT confers cardiovascular benefits.

Stroke

Stroke is a rare event before age 60. Stroke incidence may be increased when HRT is initiated in women over 60 years of age, but this is not common practice. Initiation of HRT in women less than 60 years of age or less than 10 years since menopause has no effect on the risk of stroke according to data from the 13-year follow-up data from the WHI study [46] and the Cochrane analysis [47]. The risk of ischaemic stroke with HRT may be related only to standard-dose oral therapy, with lower doses having a smaller risk and no significant risk occurring with standard and low-dose transdermal therapy, according to the large GP research database in the UK.

Venous thromboembolism

The incidence of VTE is higher during the first year of oral oestrogen use, with or without progestogen. The initiation of menopausal hormone therapy in older women and, to a lesser extent, the continued use of such therapy is associated with an increased risk compared with non-users. In the WHI study [46] in the 50–59-year-old age group, the excess risk of pulmonary embolism was six additional cases per 10 000 woman-years for oestrogen–progestogen therapy, and four additional cases with oestrogen. Both are far less than the risk of VTE in normal pregnancy. Meta-analyses of these epidemiological studies have shown that transdermal oestrogen does not increase the risk of VTE.

Cognitive function and dementia

HRT initiated after the onset of dementia symptoms does not benefit cognitive function or slow disease progression. HRT initiated and used after midlife increases risk of dementia whereas when initiated during midlife is associated with a reduced risk of Alzheimer's disease and dementia. As with CHD, the prevention of Alzheimer's disease seems to be dependent on commencing HRT in the 'window of opportunity' [15]. Most data are from observational studies as extremely long-term randomized trials would have to be conducted to prove primary prevention benefits conclusively.

Breast cancer

The degree of association between breast cancer and HRT remains debatable. Most longer-term studies largely reflect the use of one combination of HRT, oral conjugated oestrogens and medroxyprogesterone acetate. These suggest a possible increased risk with increasing duration of usage. The WHI oestrogen and progestogen trial and several large observational studies have reported an increased risk after at least 5 years of use, suggesting a possible promoter effect on existing tumours. When adjusted for risk factors, significance was no longer reached [46]. The recent meta-analysis of data by the NICE guideline group stated that the degree of risk for oestrogen and progestogen combined HRT was an extra five cases per 1000 women over a 7.5-year period (i.e. approximately one extra case per 1000 women per annum) [2]. HRT using oestrogen alone is associated with a neutral impact on breast cancer risk in most studies and even possibly a reduction in risk [24].

Ovarian cancer

Controversy exists as to whether HRT increases the risk of ovarian cancer. A recent meta-analysis of data from 52 studies suggested that for women aged 50–54 years the absolute risk was about 1 per 10 000 women per year of use, with a base rate of 1.2 per 1000 per 5 years and an absolute excess of 0.55 per 1000 per 5 years [24,52]. Further good-quality data are needed to allow definitive statements about ovarian cancer risk and HRT.

Osteoporosis

The goal of osteoporosis treatment is the prevention of fractures and the choice of therapy should be based on a balance of effectiveness and safety. HRT decreases the incidence of all fractures, including vertebral and hip fractures, even in women not at high risk of fracture. HRT is the only therapy available with proven efficacy of fracture reduction in patients with osteopenia. Although HRT prevents fractures at any age after the menopause, age at initiation of menopausal hormone therapy is important. In the age group 50–60 years or within 10 years after menopause, the benefits of HRT generally outweigh risks and can be considered as first-line therapy [23,24]. In women over 60 years of age, alternatives to HRT such as bisphosphonates should be considered as first-line therapy. If HRT is to be considered in this age group, the minimum effective dose should be used, with oestrogen ideally delivered transdermally.

Contraindications to HRT

Generally speaking, HRT is contraindicated in women with a history of active cardiovascular disease or recent stroke. Data from one pilot study suggest that there can be beneficial effects in women post myocardial infarction or acute coronary syndrome but this requires confirmation. Although contraindicated in venous thromboembolic disease, there is some evidence that transdermal preparations are safer through avoidance of first-pass hepatic metabolism [32].

When transdermal oestrogen is given to normotensive or hypertensive women it does not elevate blood pressure, and when given in combination with oral natural progesterone or drospirenone may actually lower blood pressure [36]. There is therefore little justification for withholding appropriate HRT from controlled hypertensive women and this is reflected in the recent NICE menopause guidelines [2].

Use of HRT in patients with early-stage endometrial cancer does not seem to increase the risk of recurrence according to observational data and one randomized study [53]. A recent meta-analysis of two randomized and four cohort trials in women with a past history of epithelial ovarian cancer has not indicated an increased risk of recurrence but more data are required, particularly on the role of hormone receptor status and influence on outcome [54]. Squamous cell carcinoma of the cervix is not thought to be oestrogen sensitive but good data are lacking. Women with a past history of these malignancies are usually offered HRT if they wish to use it. Data are lacking on the influence of HRT on vaginal and vulval carcinoma but it is not thought to have an adverse effect due to lack of hormone sensitivity.

Women with a past history of severe endometriosis should be treated with continuous combined therapy even after hysterectomy to prevent recurrence of the endometriosis.

Hormone receptor-positive breast cancer is regarded as the principal contraindication to oestrogen treatment, but high-risk women with a strong family history of breast malignancy or those with benign breast disease should not necessarily be denied treatment. Some women may continue to have intractable menopausal symptoms despite all the recognized alternatives having been tried in which case they should be helped to make an informed choice regarding the use of HRT to restore their quality of life.

It is unclear what the precise risk of breast cancer recurrence is with HRT use. The HABITS study [55] showed an increased risk whereas the Stockholm trial [56] did not; both studies were stopped early due to the WHI study findings. In the Stockholm study a greater proportion of women were using tamoxifen. A large randomized placebo-controlled study (LIBERATE) in breast cancer survivors using tibolone demonstrated a marginal increase in recurrence rates (RR 1.4) [57]. Patients with the *BRCA1*/*BRCA2* genes who undergo prophylactic bilateral salpingo-oophorectomy are usually offered HRT if they are young and have not had breast cancer. The many benefits of HRT on quality of life and primary prevention in early menopause and POI are thought to outweigh risk of possibly attenuating the benefits of the bilateral salpingo-oophorectomy.

There is a pressing need for more research in breast cancer survivors, as indicated in the NICE guideline research recommendations [2]. These women often have the most severe symptoms, not just because of menopause but because their endocrine therapy often makes symptoms worse.

Duration of therapy

Advice from the menopause societies almost universally states that the advantages outweigh the disadvantages for treatment to continue whilst symptoms persist. It is now accepted that symptoms last on average for 5–7 years, while in approximately 10% of women symptoms persist for life. If the underpinning principle of HRT is that it should be used to improve and maintain a good quality of life, arbitrary time limits should not be applied but should be individualized. Although the risks of breast cancer appear to be duration dependent, evidence suggests that overall mortality is actually reduced in women commencing HRT before the age of 60 [47,48]. Thus, duration of therapy requires careful judgement of the benefits and risks to each woman, who should be facilitated to make a fully informed choice. The decision to continue should be reviewed on an annual basis. If therapy is to be discontinued, the dose should be reduced in a stepwise fashion over a minimum of 6 months to reduce the risk of immediate severe symptom resurgence, although this does not change the incidence of symptom persistence in the long term.

Summary box 50.5

Arbitrary limits should not be placed on duration of treatment with HRT: women should be given individualized information about the benefits and risks.

Official prescribing advice

It is still recommended by the regulatory authorities in the UK (Medicines and Healthcare products Regulatory Agency or MHRA) that HRT should be used primarily for symptom relief in the short term at the lowest effective dose and that alternatives should be considered in the long term for prevention of osteoporosis. Annual reappraisal of HRT use should be carried out, with weighing up of the pros and cons on an individual basis. Recent consensus statements advise that HRT can be prescribed as a first-line agent in women at risk of osteoporosis-related fractures. Primary prevention of cardiovascular disease and dementia with HRT is not advised at this stage except for women who have undergone POI.

Alternatives to HRT

Women seeking advice about managing their menopause should always be informed how to optimize their lifestyle and diet and given information about complementary and other alternative therapies as well as hormonal options. An integrated approach to the management of vasomotor symptoms should be considered in women wanting to consider alternatives to (or contraindicated to) HRT [58]. A possible algorithm drawn up by a consensus group of international

experts integrating lifestyle, complementary and pharmacological interventions is shown in Fig. 50.2. The algorithm is not intended for women with premature menopause or for those with other risk factors such as osteoporosis. The network meta-analysis in the NICE menopause guideline recommended St John's wort and isoflavones as possible evidence-based therapeutic options which are better than placebo [2].

Non-pharmacological alternatives

Gels for vaginal symptoms

Vaginal bioadhesive moisturizers and lubricants are a more physiological way of replacing vaginal secretions than with preparations such as KY jelly. Moisturizers are hydrophilic and actually rehydrate the vaginal tissues. Lubricants should be pH and concentration balanced to prevent drying and irritation of the vaginal tissues [59].

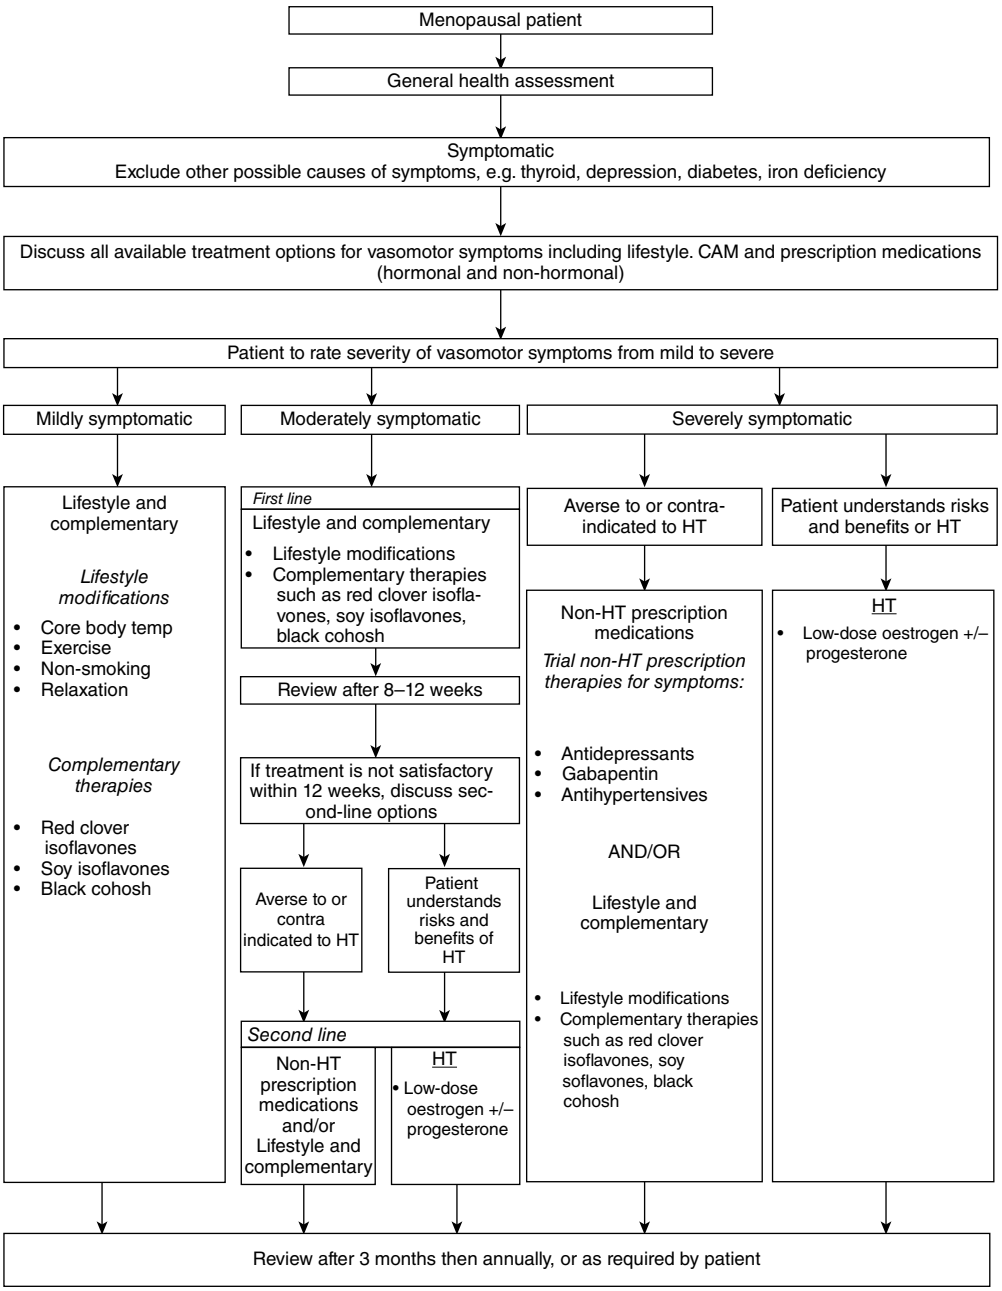

Fig. 50.2 Vasomotor symptom treatment algorithm: a conservative clinical approach. CAM, complementary and alternative medicine; HT, hormone therapy. *Source:* adapted from Panay [58].

Women in whom vaginal oestrogen is contraindicated (e.g. those on aromatase inhibitors) or those wishing to avoid oestrogen can derive some relief from these preparations.

Pharmacological alternatives

Alpha-2 agonists

Clonidine, a centrally active α_2-agonist, has been one of the most popular alternative preparations for the treatment of vasomotor symptoms. A recent meta-analysis of the few randomized controlled trials has shown a marginal benefit of clonidine over placebo. However, this preparation has been largely superseded by the selective noradrenaline reuptake inhibitors (SNRIs) and gabapentin [60].

Selective serotonin reuptake inhibitors and selective noradrenaline reuptake inhibitors

Although the NICE network meta-analysis did not show conclusive evidence of benefit with these preparations, a significant amount of evidence exists for the efficacy of selective serotonin reuptake inhibitors (SSRIs) and SNRIs in the treatment of vasomotor symptoms. Most of these data are derived from small studies in breast cancer patients. The best data are for the SNRI venlafaxine at a dose of 37.5 mg twice daily [60]. SSRIs such as fluoxetine and paroxetine should be avoided in patients using tamoxifen as they can interfere with its metabolism [2]. The key effect with these preparations appears to be stimulation of the noradrenergic as opposed to the serotonergic pathways, hence the preferential effect of SNRIs. Desvenlafaxine succinate, a derivative of venlafaxine, is licensed in a few countries as a way of maintaining the benefits of the parent molecule but minimizing side effects.

Summary box 50.6

SSRIs and SNRIs should not be used routinely to treat vasomotor symptoms in women who do not have contraindications to HRT.

Gabapentin

Gabapentin, a neuropathic analgesic, has been shown in some studies to be superior to placebo for vasomotor symptoms. In a study using gabapentin at a dose of 900 mg/day, a 45% reduction of hot flush frequency and a 54% reduction in symptom severity was demonstrated [60]. Further work is being conducted to confirm the efficacy and safety of this preparation but for the moment its use is restricted to specialist centres. Its use is limited by side effects such as drowsiness and somnolence, particularly at high doses.

Complementary therapies: phytoestrogens

The evidence for efficacy and safety of some of these complementary therapies can be extremely limited or non-existent [61]. In order to enable women to make a fully informed choice, it is important that when a recommendation is made regarding a specific complementary therapy, it should focus on preparations for which a significant dataset exists for efficacy and safety and in which there is ongoing research and development.

The Traditional Herbal Registration (THR) scheme [62] was introduced in 2009. Where a herbal medicine carries the certification mark, this means that the MHRA has assessed the product to ensure that is acceptably safe when used as intended, is manufactured to good quality standards, and is accompanied by reliable and accurate product information for the public and patients. The authorized usage and dosage of the medicine is based on evidence of its traditional use. The effectiveness and safety of the product has not otherwise been assessed by the MHRA.

Data from some phytoestrogen-containing preparations appear to demonstrate benefits, not only for symptom relief but also on the skeleton and cardiovascular system. Efficacy for vasomotor symptom relief is lower than with traditional HRT (maximally 60–70% symptom reduction compared with 90–100% with traditional HRT). Beneficial effects have been shown on cardiovascular risk markers such as lipids and arterial compliance and on bone markers/density, with possible selective oestrogen receptor modulator (SERM)-type effects. There are still no hard data on major outcome measures such as CHD and fractures. Laboratory data suggest avoidance of stimulation of oestrogen receptors in the endometrium and breast and safety in observed populations but, once again, sufficiently powered randomized controlled trial data on endometrial and breast cancer incidence are absent.

Summary box 50.7

Alternatives to HRT relieve symptoms by up to 60% maximally; recommendations for usage should be confined to those preparations that have an evidence base for efficacy and safety and the THR kite mark.

Future research

In order to optimize benefits and minimize side effects and risks, targeted agents are being developed that are able to switch on receptors in tissues where this is

desirable and avoid receptors in tissues such as the breast and endometrium. For example, the ideal SERM would be agonistic in the bone, cardiovascular system and urogenital tract and antagonistic in the endometrium and breast, while at the same time alleviating vasomotor and other menopause symptoms. This does not yet exist. Understanding the processes that regulate the activity of different oestrogen receptor co-regulator complexes is a key next step in the development of SERM/oestrogen receptor ligands with improved functional selectivity.

Pharmacogenomic approaches may help identify women with different oestrogen dose requirements based on identification of genetic variants in enzymes involved in hormone/drug metabolism and impacting hormone/drug targets. The goal of pharmacogenomics is to use genetic information to predict how an individual will respond to a drug, with the ultimate objective of enabling healthcare professionals in selecting the right drug, in the right dose, at the right time, for each individual patient in order to maximize effectiveness and minimize side effects. Environmental and biological factors also impact menopause symptoms, including BMI, tobacco, alcohol or caffeine, stress and anxiety. Further work is required to understand the mechanisms by which these environmental and biological factors affect symptoms. They may be independent variables or may be intertwined with variation in gene–environment interactions.

One might argue that the ideal solution to menopause-related problems is to reverse the process. This was not thought to be possible due to irreversible loss of follicles/oocytes. However, recent research has demonstrated the presence of oogonial stem cells in adult ovaries, and work is ongoing to try to initiate replication in these stem cells with a view to producing new oocytes [63]. This would be a particularly welcome breakthrough in young women with POI.

Conclusions

Effective management of the menopause is taking on ever-increasing importance in view of our ageing population, which is increasing both the health and economic burden on society. Economic expenditure to optimize health in the menopause and beyond has not kept pace with the ageing population. Many of our doctors and nurses have become de-skilled in managing the menopause over the last decade and menopause services have been withdrawn due to the media scares of the early 2000s. There are six key action points that require urgent implementation if we are to reverse this process.

1) Health departments/regulators/politicians: encourage a change of negative policy towards menopause and HRT.
2) The prescribers: expand education and training for healthcare professionals to optimize menopause management and achieve consensus among all menopause societies as detailed in the recent Revised Global Consensus Statement on Menopausal Hormone Therapy [64].
3) Media: engage positively, highlighting favourable data and putting risks into perspective.
4) Pharma industry: reverse negative commercial research and development decisions and encourage the exploration and development of novel regimens.
5) The menopausal woman: improve access to information to allow informed choice and increase proactive confidence to maintain menopausal health.
6) HRT: clarification of differences in action/risk profiles to maximize benefits and minimize adverse effects.

Summary box 50.8

Key points for effectively managing menopause

1) Discussion of lifestyle measures, HRT and alternatives should take place from the outset.
2) Management should be individualized, taking into account risks and benefits.
3) The main indication for use of HRT should be for symptom relief but there may also be primary prevention opportunities.
4) HRT should generally be commenced at a low dose and increased if necessary to achieve effective symptom relief, except in POI where higher doses are physiological.
5) Androgen therapy should be offered to women with persistent low libido and energy levels.
6) Rigid cut-offs in duration of therapy should be avoided, with regular reappraisal (at least annually) of the benefits and risks for each individual.
7) Delivery of menopause services should ideally be from a multidisciplinary team in primary care with close liaison with allied specialties and menopause experts.

Part 11

Reproductive Problems

51

Subfertility

Nick Raine-Fenning[1,2]

[1] *Division of Child Health, Obstetrics and Gynaecology, School of Medicine, University of Nottingham, Nottingham, UK*
[2] *Nuture Fertility, The Fertility Partnership, Nottingham, UK*

Importance

Infertility is the second most common reason for women of childbearing age to visit their general practitioner. As approximately one in seven heterosexual couples have problems conceiving, infertility affects around 3.5 million people in the UK. There has been a small but steady increase in the prevalence of fertility problems and a greater proportion of people now seek help for such problems.

Infertility is associated with significant psychological morbidity for both partners and, where there is underlying pathology, physical morbidity too both through the conditions associated with infertility and their associated treatment. If left untreated, infertility can result in stress, depression and emotional distress. However, investigation and treatment is also associated with psychological and physical trauma that is often exacerbated by the length of treatment and the multidisciplinary approach that is involved.

Infertility is regarded as an upsetting and difficult life experience for some women, resulting in anxiety and depression comparable to those associated with other serious medical conditions such as heart disease, cancer, hypertension and HIV infection.

Definition: what is infertility?

Infertility is rarely absolute. Unless the male partner has suffered testicular failure and/or does not produce sperm or the woman is menopausal and/or does not have a uterus, conception is usually still possible. It is the chance of conception that really defines fertility and this is very much dependent on how long the couple have been trying, female age and the underlying cause. Subfertility is therefore a more appropriate term for most couples. It is defined by the duration a couple have been trying to conceive without success after which formal investigation is justified and treatment, where indicated, implemented.

A woman of reproductive age, who has not conceived after 1 year of unprotected vaginal sexual intercourse, in the absence of any known cause of infertility, should be offered further clinical assessment and investigation along with her partner. Single women and same-sex couples should be offered formal investigation after six cycles of unsuccessful artificial insemination. Couples should be referred earlier where the woman is 36 years or over or if there is a known clinical cause of infertility or a history of predisposing factors for infertility, including amenorrhoea, oligomenorrhoea, pelvic inflammatory disease or undescended testes.

Aetiology

The main causes of infertility in the UK are shown in Table 51.1. Male factor is now the most common cause of primary subfertility closely followed by ovulatory disorders. In about 40% of cases, fertility disorders are found in both the man and the woman. Tubal disease is the most common cause of secondary infertility.

There are no identifiable factors in one in four couples. This does not mean there is no underlying problem and a significant proportion of women will be shown to have low ovarian reserve or other problems if they go on to have assisted conception treatment, which is not only an effective treatment but also provides an informative assessment.

Ovulatory disorders

The World Health Organization (WHO) categorizes ovulation disorders into three groups based on serum

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 51.1 Causes of infertility in the UK.

	Prevalence (%)	
Cause	**Primary**	**Secondary**
Unexplained	25	20
Ovulatory disorders	25	15
Tubal disease	20	40
Male factors	30	20
Uterine or peritoneal disease	10	5

measurements of follicle stimulating hormone (FSH), luteinizing hormone (LH) and estradiol.

Group I ovulation disorders

Group I ovulation disorders (10%) are caused by hypothalamic–pituitary dysfunction or failure, which results in hypo-oestrogenic amenorrhoea. They are characterized by low gonadotrophins, a normal prolactin and low oestrogen levels. Three conditions are included: hypothalamic amenorrhoea, hypogonadotrophic hypogonadism and hypopituitarism.

Hypothalamic amenorrhoea is characterized by secondary amenorrhea with low or normal gonadotrophins and hypo-oestrogenism. It is often caused by excessive exercise, lean body mass, weight loss, severe dietary restriction, anorexia or bulimia nervosa or chronic illness. The treatment must be aimed at the underlying cause.

Hypogonadotrophic hypogonadism is caused by gonadotrophin-releasing hormone (GnRH) deficiency. Kallmann's syndrome is congenital and thought to result from the disruption of embryonic migration of GnRH neurones. Acquired causes include central nervous system (CNS) or pituitary tumours, infiltrative diseases, infection, brain/pituitary radiation, pituitary apoplexy, head trauma, and drugs such as glucocorticoids, narcotics and chemotherapy.

Hypopituitarism is typically caused by a pituitary tumour or its treatment by surgery and/or radiotherapy but may be due to extra-pituitary tumours, sarcoidosis, haemochromatosis and Sheehan's syndrome. The clinical manifestations depend on the cause and both the type and degree of hormonal insufficiency. Patients may be asymptomatic or present with symptoms related to hormone deficiency or a space-occupying lesion.

Group II ovulation disorders

Group II ovulation disorders (85%) are defined as dysfunction of the hypothalamic–pituitary–ovarian axis. They are characterized by normal oestrogen levels, normal or low FSH levels, and normal or high LH levels. This group of disorders results in anovulatory oligomenorrhoea, predominantly involving women with polycystic ovaries, which are present in about 80–90% of women with oligomenorrhoea and 30% of women with amenorrhoea. Women with polycystic ovaries often have associated clinical symptoms such hyperandrogenism presenting as hirsutism, acne or androgen-dependent alopecia.

Group III ovulation disorders

Group III ovulation disorders (5%) are caused by ovarian failure, or ovarian insufficiency as it is now called. They are characterized by raised levels of FSH and LH and a low oestrogen. Ovarian insufficiency is often unexplained but may be associated with gonadal dysgenesis, including Turner's syndrome, or be subsequent to bilateral oophorectomy or treatment with chemotherapy or radiotherapy.

Tubal disease

The incidence of tubal disease is very dependent on whether the woman has primary or secondary infertility. Primary infertility refers to a woman who has never conceived whilst secondary infertility relates to any previous pregnancy irrespective of whether that resulted in a live birth or not. Women with secondary infertility, especially those who have had an ectopic pregnancy, have a much higher incidence of tubal disease.

Uterine and/or peritoneal disorders

Uterine and/or peritoneal disorders are the least common cause of infertility but this may, in part, relate to the difficulty in identifying and defining pathology.

Endometriosis does not necessarily cause infertility but there is an association with fertility problems, although the cause is not fully established. Even with severe endometriosis, natural conception is still possible and up to 70% of women with mild to moderate endometriosis will conceive without treatment. However, up to 30–50% of women with endometriosis may experience infertility irrespective of the severity of the disease and infertile women are six to eight times more likely to have endometriosis than fertile women. Endometriosis is thought to influence fertility in several ways, including distorted pelvic anatomy, adhesions, pelvic inflammation, altered immune system functioning and impaired implantation. Women with endometriosis may also have endocrine and ovulatory disorders, including luteinized unruptured follicle syndrome, impaired folliculogenesis, luteal phase defect, and premature or multiple LH surges.

Adhesions are reported to be the leading cause of secondary infertility in women and are thought to be

responsible for approximately 22% (15–40%) of all infertility cases [1]. Adhesions cause infertility by distorting adnexal anatomy and the tubo-ovarian relationship and/or by preventing or impairing the ability of the fallopian tube to pick up the oocyte at ovulation and then transport it. This may be due to the ovary being encapsulated by adhesions or by adhesions that limit tubal/fimbrial movement. The American Fertility Society classification for adnexal adhesions [2] can be used to quantify the severity of the adhesions, which is predictive of term pregnancy rates. Of patients who have undergone major gynaecological surgery, 60–90% will develop adhesions.

Fibroids have been associated with infertility. Intracavity and intramural fibroids are thought to exert a mechanical effect leading to cavity distortion. However, recent data suggest that fibroids may still have a negative effect on fertility even if the cavity appears hysteroscopically normal due to effects on uterine blood flow, impaired embryo implantation or abnormal sperm migration. Despite this, many women with relatively large fibroids conceive without difficulty.

Intrauterine adhesions reduce conception. When associated with amenorrhoea, they are referred to as Asherman's syndrome. The adhesions lead to partial or complete obliteration of the uterine cavity and/or the cervical canal, resulting in menstrual abnormalities and/or recurrent pregnancy loss. Secondary infertility is seen in 43% of women with intrauterine adhesions and may be due to obstruction of sperm into the cervix or prevention of embryo migration and/or implantation.

Male factor

In the UK, seminal fluid analysis is found to be the only cause of infertility in about 20% of couples, and is a contributory factor in a further 25% of couples. However, impaired semen quality, azoospermia and inadequate coitus are contributing factors in nearly 50% of infertile couples.

Abnormal semen characteristics are usually idiopathic and occur in 26% of infertile men. The spermatozoa are mostly dysfunctional and unable to fertilize an oocyte but a proportion are often functionally normal. Sperm function may also be impaired by anti-sperm antibodies.

Azoospermia may be due to hypothalamic–pituitary failure, primary testicular failure (non-obstructive azoospermia) or obstruction of the genital tract (obstructive azoospermia). Primary testicular failure is the most common cause of male infertility due to azoospermia or severe oligozoospermia and may be the result of cryptorchidism, testicular torsion or trauma, orchitis, chromosome disorders (Klinefelter's syndrome, Y-chromosome microdeletions), systemic disease, or follow radiotherapy or chemotherapy, although in the majority of cases (66%) the cause is unknown. Obstructive azoospermia is uncommon, with a prevalence of less than 2%. It is often associated with congenital bilateral absence of vas deferens, which itself is commonly associated with cystic fibrosis mutations or renal tract abnormality.

Anejaculation and retrograde ejaculation are relatively uncommon but may result from spinal cord injury, prostatectomy, retroperitoneal lymph node dissection, diabetes mellitus, transverse myelitis, multiple sclerosis, or be of psychogenic origin.

Varicoceles are more common in men with abnormal semen than men with normal semen (25.4% vs. 11.7%) and are associated with decreased ipsilateral testicular volume. It is unclear if, or why, varicoceles impair fertility and spermatogenesis but any effect is likely to be due to elevated scrotal temperature and impaired semen quality.

Principles of management

Given the various causes and presentations of infertility, it is essential that patients are managed as individuals from their initial referral through to their ultimate treatment. Investigations must be directed on the basis of a critical consideration of clinical features and used to inform patient management and counselling. All healthcare practitioners working in fertility must therefore have a comprehensive understanding of tests and treatments and be able to give patients and couples advice on their personal chances of natural and/or assisted conception so that they can make an informed decision as to how to proceed.

For the remainder of this chapter I shall refer to the typical management of a heterosexual couple for the simple reason that this reflects most referrals to secondary care. However, same-sex couples and single women are increasingly seeking advice and treatment and their assessment and management, save the obvious need for donor sperm, is comparable in most instances. Please substitute 'no partner' or 'second female partner' where relevant when referring to your own clinical practice.

Take a critical history

Couples who experience problems in conceiving should be seen together because both partners are affected by decisions surrounding investigation and treatment. Furthermore, women have been shown to be more satisfied when seen with their partners.

The consultation should start with an understanding of the duration of infertility and the age of the woman or couple. It is important to specifically enquire about

sexual history, including the frequency and timing of intercourse. Without this information it is not possible to define 'subfertility' and therefore the need for investigation or treatment.

Other key factors that influence assessment and treatment include previous pregnancies in the female partner and whether the couple have children together or through a previous relationship. The former influences the tests offered to the woman and her prognosis, while the presence of children invariably has implications for funding. It is also important to assess the couple's lifestyle as this impacts on their chance of natural conception and influences the success of treatment. Finally, consider any religious or ethical objections the couple may have in respect of their potential treatment. This information is often volunteered and does not require direct questioning.

Primary care physicians generally have a good understanding of fertility and in most cases will have performed some tests prior to, or in conjunction with, their referral. Make sure these are available and confirm the couple are aware of the results. Missing a diagnosis of severe oligospermia or azoospermia or failing to realize this until the end of the consultation will mean that much of the conversation was meaningless and will not reassure the couple. Make sure you gather all clinically relevant information and any test results before you see the couple and share these with them at the appropriate time depending on what they show and what the couple know.

It is, of course, important to finish by taking a general history from both partners to establish their current and past health, any medications they are using and any known allergies.

Female

Having already ascertained the woman's age and parity, the history should now focus on identifying or excluding an underlying cause of subfertility.

Cycle regularity gives an indication of ovulation. Most women (95%) who menstruate every 23–35 days are ovulating. Those with irregular menstrual cycles or who are amenorrhoeic are not ovulating or, if they are, ovulate infrequently.

Women with severe premenstrual pain are more likely to have endometriosis or chronic pelvic infection. These conditions may also be associated with chronic pelvic pain and/or deep dyspareunia. All of these symptoms are consistent with pelvic pathology and, in most cases, warrant pelvic and ultrasound examination followed by laparoscopy.

Heavy periods may reflect dysfunctional uterine bleeding but could be due to fibroids, adenomyosis, endometriosis or endometrial polyps, all of which may impair implantation. Similarly, intermenstrual or post-coital bleeding could be hormonal or reflect local or endometrial pathology. Again, these symptoms would be an indication for pelvic and ultrasound examination possibly followed by hysteroscopy and/or laparoscopy depending on the findings.

The history should then focus on risk factors for tubal disease and abdomino-pelvic adhesions. This influences the test of tubal patency that you will offer. Tubal disease and adhesions that may impair the tubo-ovarian relationship are more common after pelvic infection, sexually transmitted infection, abdomino-pelvic surgery, particularly that involving the pelvic organs, and ectopic pregnancy irrespective of how it was managed. They may also occur in women with endometriosis.

Male

The male history is often redundant, as most couples will be referred with the results of a seminal fluid analysis. Providing this is normal and shows a good number of motile, morphologically normal sperm, there is little value in taking a detailed history from the male partner. However, a specific enquiry regarding any psychosexual problems including erectile or ejaculatory dysfunction is essential.

For men who have not had a seminal fluid analysis or those who have been shown to have abnormal results, a more detailed history is indicated. A history of problems with testicular descent, puberty, trauma or surgery, mumps, and past local infection or inflammation may provide a reason for a low sperm count or impaired motility but do not influence current management.

Questions about current health, medications and lifestyle are more relevant as they can be modified where necessary in most cases. No cause will be identified in approximately 30–50% of men with poor semen quality.

Perform a relevant examination

Just like the clinical history, examination of the male and female partner is often unremarkable. It may not even be indicated in some cases and should only be performed if it will influence management. General inspection, both during the consultation and at examination, also provides an opportunity to consider lifestyle issues such as smoking and obesity, which may be readily evident. As a minimum, weight and body mass index (BMI) should be calculated and recorded. This influences management and has implications for funding. Where relevant, a general inspection should be conducted to look for signs of systemic disease, such as thyroid dysfunction, acromegaly and other endocrine disorders, and phenotypic abnormalities.

Female

Polycystic ovary syndrome (PCOS) and other causes of hyperandrogenism may manifest with acne and hirsutism. More rarely, insulin resistance may lead to acanthosis nigricans. Virilism can lead to male pattern baldness and clitoromegaly. Breast examination is often not indicated but when performed should include Tanner's staging.

Abdominal examination may reveal scars from previous abdominal surgery. Large pelvic masses including ovarian cysts and fibroids, palpable abdominally, clearly influence management and may militate against a laparoscopic approach if surgery is indicated. However, it is rare to find an unexpected mass or demonstrate abdominal tenderness.

Pelvic examination should be considered for women with menstrual dysfunction. Inspection of the vagina and cervix may reveal local pathology that is responsible for irregular or post-coital bleeding and therefore provides reassurance as this is unlikely to affect fertility or influence management. It also provides an opportunity to take swabs for microbiological assessment if there is a history of sexually transmitted infection or signs and symptoms of current infection. A cervical smear should not be performed opportunistically or if cervical pathology is evident; the latter requires referral for colposcopic examination.

Bimanual examination can provide critical information that impacts on investigation and management. A fixed, tender, retroverted uterus is highly suggestive of adhesions and the presence of chronic pelvic inflammation or endometriosis. Such findings warrant an ultrasound scan and, in most cases, an operative laparoscopy with intention to treat any disease and divide any adhesions. In more severe cases, where nodules of endometriosis are visible or palpable or there is evidence of thickening and induration of the uterosacral ligaments, consideration should be given to pelvic MRI to assess the rectovaginal septum and exclude superficial or full-thickness bowel involvement.

Male

Most men do not need to be examined, but where it is considered essential the key examination is that of the genital organs. The scrotum and its contents should be gently palpated to identify the vas deferens and exclude any masses or local pathology. The volume of each testicle should be assessed using an orchidometer and recorded. A prostate examination is rarely needed but if indicated is probably best performed by a urologist.

Perform directed investigations

People who experience fertility problems should be treated by a specialist team because this is likely to improve the effectiveness and efficiency of treatment and improves satisfaction.

The female partner

Serum FSH and LH should be checked in the early follicular phase between days 2 and 5 of the menstrual cycle. The levels of these hormones cannot be interpreted in the absence of serum estradiol and all three tests are needed to assess hypothalamic–pituitary–ovarian function. Most women have normal FSH, LH and estradiol levels.

Low FSH and LH levels in conjunction with a low estradiol suggest hypogonadotrophic hypogonadism and type I anovulation. Thyroid function and prolactin should be checked along with other hormones depending on the clinical picture. Elevated serum LH or a raised LH/FSH ratio are no longer used to diagnose PCOS but may provide prognostic information so should be noted and recorded.

An early follicular phase FSH level above 15 IU/L is very suggestive of impaired reserve whilst levels persistently above 30 IU/L are consistent with ovarian failure. The National Institute for Health and Care Excellence (NICE) [3] states that the FSH should be less than 9 IU/L and that levels above this cut-off indicate impaired ovarian reserve. However, there are more accurate tests for ovarian reserve, namely antral follicle counts and serum anti-Müllerian hormone (AMH) levels. These have been used to triage treatment as they provide some information about egg quality. However, this requires more research and, at present, there is insufficient evidence to preclude treatment or fast-track patients on the basis of an ovarian reserve test. NICE suggests that a total antral follicle count of four or less, AMH level of 5.4 pmol/L or less, and FSH level above 8.9 IU/L are predictive of a low response. Age, although not an independent factor, must always be considered under such circumstances as many younger women conceive naturally or after treatment despite having seemingly poor ovarian reserve.At present, NICE suggests any of the three tests may be used but most fertility experts rely on antral follicle counts and serum AMH and not FSH unless the latter is significantly raised.

Women with a regular cycle should have a mid-luteal progesterone to confirm ovulation, but a day 21 progesterone is only relevant for women with a 28-day cycle. There is little value in measuring serum progesterone in a women with amenorrhoea or oligomenorrhoea and it is better to assume anovulation. Thyroid function and prolactin should be checked under such circumstances along with tests to exclude PCOS. Thyroid function and prolactin are not indicated in women with a regular cycle unless there are associated clinical features. The use of basal body temperature charts to confirm ovulation does not reliably predict ovulation and is not recommended.

Current rubella immunity should be checked and the woman immunized where necessary. Treatment should

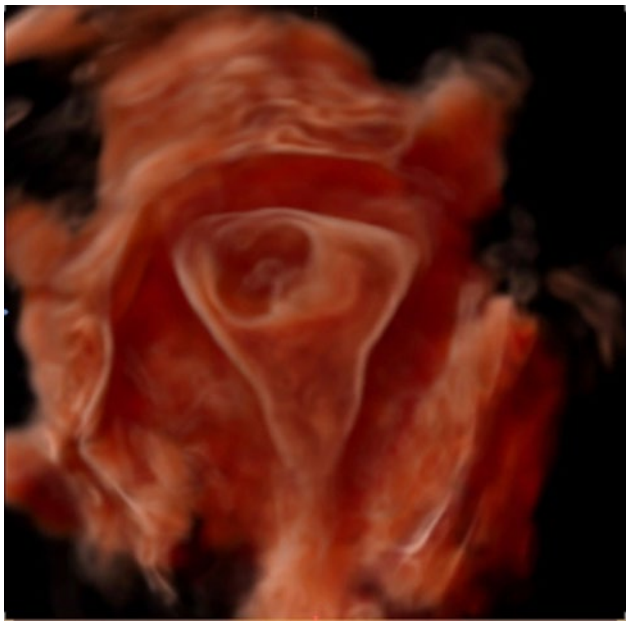

Fig. 51.1 Rendered three-dimensional ultrasound scan showing a type 0 fibroid in the endometrial cavity. (*See also colour plate 51.1*)

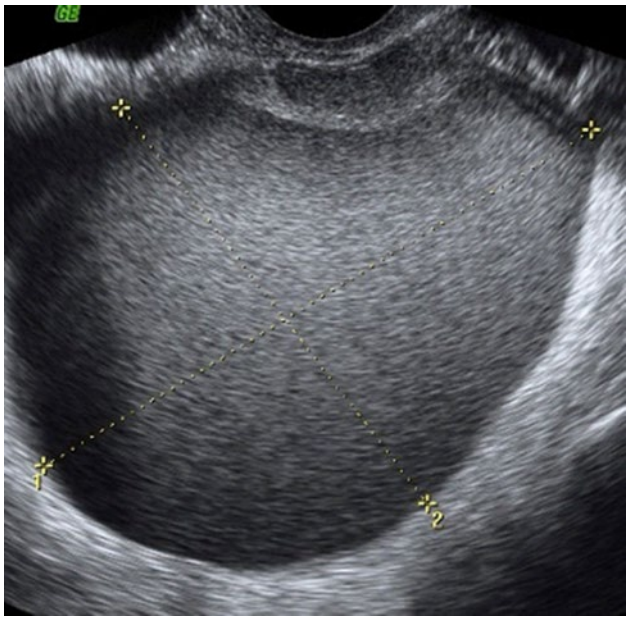

Fig. 51.2 Typical unilocular cyst with 'ground glass' contents consistent with an endometrioma.

be delayed for at least 1 month during which time the couple should avoid intercourse or use appropriate contraception. Immunity should be rechecked and treatment then offered. Some women do not mount an immune response despite repeated immunization.

Ultrasound is not indicated for all patients at initial assessment. It should be reserved for women with menstrual dysfunction, abdominal or pelvic pain, dysmenorrhoea or dyspareunia or where pathology is suspected on examination. In such cases, it may reveal fibroids (Fig. 51.1), adenomyosis, endometrial polyps, hydrosalpinges, or ovarian cysts including an endometrioma (Fig. 51.2), which provides a non-invasive diagnosis of endometriosis.

Ultrasound can also be used to diagnose the polycystic ovary and should be performed in any woman with an irregular cycle and/or hyperandrogenism, along with serum testosterone and sex hormone-binding globulin to allow the free androgen index to be calculated. Women with high levels and those with signs of virilism should also have other androgens checked, including androstenedione and dehydroepiandrosterone sulfate as well as 17-hydroxyprogesterone if relevant.

Ultrasound can also be used to count the number of antral follicles, as outlined above, and provide an objective assessment of ovarian reserve but this is typically reserved for women considering assisted conception as it provides information about the likely response to controlled ovarian stimulation.

The last investigation, but arguably one of the most important, is a test of tubal patency. The results of semen analysis and assessment of ovulation should be known before a test for tubal patency is performed. Hysterosalpingography (HSG) and laparoscopy with dye are the two most widely used methods to test for tubal pathology. Both are invasive procedures but HSG is less so. However, laparoscopy is more accurate and therefore the gold standard. When HSG suggests the presence of tubal obstruction this is confirmed by laparoscopy in only 38% of women. HSG is therefore not a reliable indicator of tubal occlusion. However, when HSG suggests that the tubes are patent, this will be confirmed at laparoscopy in 94% of women, and so is a reliable indicator of tubal patency.

Women who are not known to have comorbidities should therefore be offered HSG to screen for tubal occlusion because this is a reliable test for ruling out tubal occlusion and it is less invasive than laparoscopy. Women who are thought to have comorbidities should be offered laparoscopy and dye so that tubal and other pelvic pathology can be assessed at the same time [3]. Comorbidities include pelvic inflammatory disease, previous ectopic pregnancy, pelvic adhesions, and endometriosis. Hysterosalpingo-contrast ultrasonography is an alternative to HSG for women who are not known to have comorbidities since it is as effective but requires appropriate expertise.

Chlamydial antibody testing is comparable to HSG in the diagnosis of tubal pathology [4]. Elevated titres of chlamydial antibodies are significantly associated with tubal disease, with higher titres predicting more severe tubal pathology. Negative titres do not justify avoidance

of a test of tubal patency but support HSG as opposed to laparoscopy unless there are clinical features or a history suggestive of past sexually transmitted infection or pelvic inflammatory disease. Women undergoing HSG or any procedure requiring instrumentation of the uterus must be screened for *Chlamydia* or offered prophylactic antibiotics. Women who are screened and found to have chlamydial infection, and their sexual partners, should be referred for appropriate management with treatment and contact tracing before proceeding with further investigation.

Women with no risk factors for tubal disease can be offered ovulation induction or intrauterine insemination without a test of tubal patency. Tubal assessment should be performed after three cycles if treatment has been unsuccessful. Women with a history suggestive of tubal damage should be offered tubal assessment before treatment. However, all women may choose to have a test of tubal patency prior to treatment if they prefer this approach.

Women should not be offered hysteroscopy on its own as part of the initial investigation unless clinically indicated because the effectiveness of surgical treatment of uterine abnormalities on improving pregnancy rates has not been established. The routine use of post-coital testing of cervical mucus in the investigation of fertility problems is no longer recommended because it has no predictive value on pregnancy rate.

The male partner

Semen analysis is the primary assessment tool for male fertility and outweighs all other tests, and should be compared with the WHO reference values [5] (Table 51.2). Variations in laboratory techniques significantly influence the reliability of the results of semen analysis and so the accuracy of the result is dependent on following accredited methods of analysis that should be regularly audited and subject to quality control. Screening for anti-sperm antibodies should not be offered, as there is no evidence of effective treatment to improve fertility.

Table 51.2 World Health Organization reference values for seminal fluid analysis.

Semen volume: ≥1.5 mL
pH: ≥7.2
Sperm concentration: ≥15 million per mL
Total sperm number: ≥39 million per ejaculate
Total motility (progressive and non-progressive motility): ≥40% motile or ≥32% with progressive motility
Vitality: ≥58% live spermatozoa
Sperm morphology: ≥4% normal forms

Oligospermia is used to describe seminal fluid analyses where the concentration of spermatozoa is below the lower reference limit. Asthenozoospermia and teratozoospermia refer to the percentage of progressively motile and morphologically normal spermatozoa, respectively. Oligoasthenoteratozoospermia therefore refers to seminal fluid analyses showing a low number of spermatozoa with reduced progressive motility and normal morphology. Azoospermia refers to the total absence of spermatozoa in the ejaculate.

However, the reliability of the WHO reference values and their ability to predict conception has been questioned and, unless there is azoospermia, the predictive value of subnormal semen variables is limited. No functional test has yet been established that can unequivocally predict the fertilizing capacity of spermatozoa, including sperm function tests such as computer-assisted semen analysis.

If the result of the first semen analysis is abnormal it should be repeated. The repeat test should be undertaken 3 months after the initial analysis to allow for a cycle of spermatogenesis unless there is azoospermia or severe oligozoospermia, when it should be repeated as soon as reasonably possible. This is important because a single-sample analysis will falsely identify about 10% of men as abnormal. Repeating the test reduces this to 2%.

Male infertility due to severe oligozoospermia and azoospermia has been associated with a number of genetic factors, including numerical and structural chromosomal abnormalities, microdeletions of the Y chromosomes and mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene, commonly associated with congenital vas deferens abnormalities. Men with severe oligozoospermia and azoospermia should be offered genetic testing and counselling before undergoing fertility treatment.

Men with azoospermia or severe oligozoospermia should should also have a full endocrine profile to exclude testicular failure or hypothalamic–pituitary–testicular dysfunction. As a minimum, it is essential to check serum levels of FSH, LH and testosterone along with thyroid function and prolactin. More detailed assessments may be needed depending on the result of these tests but should be performed in conjunction with an endocrinologist.

Men with severe oligozoospermia should consider freezing sperm for subsequent use provided they have been shown to have an apparently normal karyotype.

Treat patients as individuals

Choice is an integral part of any decision-making process. Patients should have access to evidence-based information that they can use to inform decisions regarding their

care and treatment. Verbal information should be supplemented with written information or audio-visual media and provided in a form that is accessible to people who have additional needs and those who do not speak or read English.

The NICE quality standard [6] describes a concise set of statements that summarizes what the best possible care should comprise, states that previous children, sexual orientation and relationship status should not be a factor in determining eligibility for treatment, and that counselling should be available throughout treatment.

Lifestyle measures

People who are concerned that it is taking longer than expected to conceive should be given advice on the impact that lifestyle can have on their chances of getting pregnant. Both partners should be informed that the effects of caffeinated beverages (tea, coffee and carbonated drinks) on fertility is unclear. Some prescription, over-the-counter and recreational drugs may interfere with male and female fertility and so should be disclosed to the healthcare practitioner. The same is true of occupations, especially those that involve exposure to chemicals or excess heat.

Patients should be offered lifestyle advice and access to specialist services and consultation, where appropriate, to address factors that influence fertility and the success of treatment such as body weight, smoking, drinking and drug use.

- Women who have a BMI of 30 or over should be informed that they are likely to take longer to conceive and that weight loss is likely to increase their chance of conception if they are not ovulating. Men who have a BMI of 30 or over should be informed that they are likely to have reduced fertility. Group programmes involving exercise and dietary advice increase the chance of pregnancy more than weight loss advice alone.
- Smoking, both active and passive, may reduce male and female fertility. Smokers should be offered referral to a smoking cessation programme.
- Women should drink no more than 1 or 2 units of alcohol once or twice per week and avoid episodes of intoxication as this reduces the risk of harming a developing fetus. Consumption of 3–4 units per day for men is unlikely to affect their semen quality.
- Men should be informed that there is an association between elevated scrotal temperature and reduced semen quality. It is uncertain whether wearing loose-fitting underwear improves fertility.
- Women should take 0.4 mg of folic acid per day before conception and up to 12 weeks' gestation as this reduces the risk of having a baby with neural tube defects. Women who have a previously affected infant, who take antiepileptic medication or who have diabetes should take 5 mg/day.

The relationship between psychological stress and fertility problems is complex and the individual response to stress situations is variable. Work-related stress may reduce conception rates and psychological stress can negatively affect a couple's relationship and libido, which may impact on their chance of conception. Couples undergoing fertility tests and treatment have been shown to experience a higher frequency of male sexual disturbances, including loss of libido and a decrease in the frequency of sexual intercourse. Both partners should therefore be informed that stress in the male and/or female partner can affect the couple's chance of conception and their relationship. All efforts should be made to limit stress wherever possible.

The effectiveness of complementary therapies, for both men and women, has not been properly evaluated and further research is needed before such interventions can be recommended.

Reassurance

Women with unexplained subfertility should not be offerred oral ovarian stimulation agents such as clomifene citrate, anastrozole or letrozole. Clomifene citrate, as a stand-alone treatment, does not increase the chances of a pregnancy or a live birth. Rather, they should be reassured and given advice on natural conception and the timing and frequency of sexual intercourse. They should be offered *in vitro* fertilization (IVF) treatment if they have not conceived after 2 years, including up to 1 year before their fertility investigations, of regular unprotected sexual intercourse. Couples with mild male factor infertility and minimal and mild endometriosis should be treated in exactly the same way.

Treat the cause

While it is possible to adopt a generic approach to fertility treatment, it is paramount to individualize care and consider the underlying cause. Women who are not ovulating should be managed according to the likely problem. The management of women with hypothalamic hypogonadism is totally dependent on whether there are issues with weight, stress, thyroid disease or hyperprolactinaemia. They should not be offered ovulation induction until these issues are addressed as it is unlikely to work. Furthermore, correction or moderation of the underlying cause often leads to resumption of ovulation, mitigating the need for treatment. This is a safer and more practical approach.

Male factor

A specific male factor should be identified and corrected where possible.

- The term 'mild' male factor infertility is used to describe two or more semen analyses that have one or more variables which fall below the 5th centile and where the effect on the chance of pregnancy occurring naturally through vaginal intercourse within a period of 24 months would then be similar to people with unexplained infertility or mild endometriosis. Mild male factor infertility should therefore be treated in the same way and couples encouraged to have regular sexual intercourse for a maximum of 2 years.
- Men with mild to moderate oligozoospermia may conceive naturally but the chances are lower than for men with normal seminal fluid analyses. They can continue to try naturally but intrauterine insemination does not appear to increase the chance of conception. They should not be offered anti-oestrogens, gonadotrophins, androgens, bromocriptine or kinin-enhancing drugs because they have not been shown to be effective. Men with leucocytes in their semen should not be offered antibiotic treatment unless there is an identified infection because there is no evidence that this improves pregnancy rates.
- Men with severe oligozoospermia and azoospermia are unlikely to conceive naturally. The most effective treatment is assisted reproduction. While IVF is feasible in mild to moderate oligozoospermia, intracytoplasmic sperm injection (ICSI) is usually required to achieve fertilization, especially in moderate to severe oligozoospermia, asthenozoospermia or teratozoospermia.
- Men with obstructive azoospermia should be offered surgical correction of epididymal blockage, as an alternative to surgical sperm recovery and IVF, because it is likely to restore patency of the duct and improve fertility. In non-obstructive azoospermia there are foci of spermatogenesis in about 50% of cases. Lifestyle measures may return sperm to the ejaculate but most cases are managed by surgical sperm recovery from the epididymis or testis followed by ICSI because of the number and immaturity of the recovered sperm.
- Men with hypogonadotrophic hypogonadism should be offered gonadotrophin drugs in a similar manner to women.
- Men should not be offered surgery for varicoceles because it does not improve pregnancy rates.
- Treatment of ejaculatory failure can restore fertility without the need for invasive methods of sperm retrieval or the use of assisted reproduction procedures and is recommended. A variety of options is available and the choice will depend on individual circumstances.

Ovulation induction

Where indicated, ovulation induction should be offered. The aim is to induce a monofollicular response to insure this occurs, and a multifollicular response is avoided, all patients undergoing ovulation induction should have ultrasound monitoring through their first cycle of treatment. This ensures they are taking a dose that minimize the risk of multiple pregnancy. Differentiating between the three causes of Group I ovulation disorders is essential as it governs the approach to ovulation induction and is prognostic of treatment outcome. Treatment may involve lifestyle modifications (normalizing weight and exercise regimes), pulsatile GnRH, or gonadotrophin therapy with human menopausal gonadotrophin (hMG). Lifestyle modifications are more appropriate for hypothalamic amenorrhoea while pulsatile GnRH is recommended for patients with hypothalamic hypogonadism as it is more physiological and induces monofollicular ovulation. However, neither of these strategies is appropriate for patients with hypopituitarism. In this circumstance, gonadotrophins need to be directly replaced and this requires the administration of both FSH and LH. This is usually achieved through the use of hMG, which contains both hormones in a ratio of 1 : 1. This approach is very successful in women with hypogonadotrophic hypogonadism and hypothalamic amenorrhoea, resulting in cumulative conception rates of 82.1% and 65.4% and cumulative live-birth rates of 95.0% and 85.3%, respectively, over the course of a year.

Women with Group II ovulation disorders should be offered clomifene citrate, metformin or a combination of these. Clomifene citrate should not normally be continued for longer than 6 months as there are more effective treatment options. Women prescribed metformin should be informed of the side effects associated with its use, such as nausea, vomiting and other gastrointestinal disturbances. These can be lessened by reducing the dose, taking the medication with food, or through the use of a slow-release formulation. Women with a Group II ovulation disorder and BMI over 30 should be encouraged to lose weight as this alone may restore ovulation; if it does not, it will improve their response to ovulation induction agents and have a positive impact on pregnancy outcomes. Women who prove resistant to increasing doses of clomifene citrate should be offered laparoscopic ovarian drilling, combined treatment with clomifene citrate and metformin if not already offered as first-line treatment, or gonadotrophins. Concomitant treatment with GnRH agonist, pulsatile GnRH, growth hormone and/or hMG during ovulation induction in women with PCOS who do not respond to clomifene citrate is not recommended because there is no evidence they improve pregnancy rates. Tamoxifen and aromatase inhibitors may be used as alternatives to clomifene.

Women with Group III ovulation disorders require treatment with donor eggs. The use of donor oocytes is also effective for certain cases of IVF treatment failure, where there is evidence of poor oocyte quality or poor

response to ovarian stimulation, and where there is a high risk of transmitting a genetic disorder to the offspring.

Tubal disease and adhesions

Tubal surgery has largely been replaced by IVF. It still has a role in select cases and in women who do not want IVF or who are unable to self-fund treatment. It should only be offered in centres where appropriate expertise is available.

For women with mild tubal disease, tubal surgery may be more effective than no treatment. For women with proximal tubal obstruction, selective salpingography plus tubal catheterization, or hysteroscopic tubal cannulation, may improve the chance of pregnancy.

In women undergoing IVF, the presence of hydrosalpinx is associated with early pregnancy loss and poor implantation and pregnancy rates. Hydrosalpinges large enough to be visible on ultrasound are associated with the poorest outcome, including increased miscarriage rates. Women with hydrosalpinges should therefore be offered treatment before IVF because this improves the chance of a live birth. Various surgical treatments including salpingectomy, salpingostomy, proximal tubal ligation or clipping, and transvaginal aspiration have all been used to improve IVF outcome. Laparoscopic salpingectomy has been shown to increase ongoing pregnancy rates following IVF by about 50% and is therefore the current standard treatment, although laparoscopic proximal tubal ligation/clipping has a similar effect. Transvaginal aspiration does not improve outcome. The hysteroscopic placement of Essure® intratubal devices to occlude the fallopian tube and prevent leakage of fluid back into the uterine cavity is not effective and is associated with lower ongoing pregnancy rates (26.2%) than after laparoscopic salpingectomy (55.8%). A hysteroscopic approach may still be valid in women who cannot undergo laparoscopic salpingectomy as there is no alternative, but there is no evidence to show benefit.

Fertility can be improved by the division of adhesions. Pregnancy rates increase by 38–52% in previously infertile patients following laparotomy with adhesiolysis. In women with infertility as a result of adnexal adhesions, pregnancy rates of 32 and 45% at 12 and 24 months, respectively, have been reported following adhesiolysis, compared with 11 and 16% at corresponding time intervals in untreated women. Higher pregnancy rates (12% vs. 29%) have also been reported 3 years after tubal surgery. Division of adhesions around the ovary has also been shown to increase pregnancy rates by over 50%.

Adhesions re-form in most patients (mean 85%) regardless of the method of adhesiolysis used or the type of adhesion being lysed. Women must be made aware of this and, even when successful, that fallopian tubes may become blocked again. If natural conception does occur in women with tubal disease and/or adhesions, there is a higher risk of that pregnancy being ectopically located. This is also true after tubal surgery and adhesiolysis. The risk is thought to be around 10% but will vary depending on individual circumstances. Any woman with tubal disease or adhesions who does conceive should seek early referral and an ultrasound scan around 7 weeks' gestation or sooner in the event of any symptoms of ectopic pregnancy, of which they should be fully informed.

Uterine factors

Infertile women with large fibroids or submucosal/intramural fibroids that affect the uterine cavity are often offered myomectomy. However, there is no robust evidence to show this is effective. Women may decide to avoid myomectomy and this is reasonable. Uterine artery embolization has been used but its effects on fertility are unclear and it can lead to premature menopause or impaired ovarian reserve and persistent amenorrhoea. These complications are unpredictable but more common in older women and may result from non-target embolization.

Whilst endometrial polyps are likely to negatively impact on fertility and impair implantation, the evidence for this is far from clear and there are no randomized controlled trials to show polypectomy is beneficial. However, polypectomy is a relatively straightforward procedure with minimal risks that can often be performed as an outpatient procedure and should be offered to all women with a polyp prior to treatment. Broad-based polyps often recur and may need to be formally resected rather than simply avulsed or blindly curetted to reduce this happening.

Women with amenorrhoea and intrauterine adhesions should be offered hysteroscopic adhesiolysis because this is likely to restore menstruation and improve the chance of pregnancy. However, the key to intrauterine adhesions is their prevention rather than their subsequent treatment. They most commonly occur following uterine instrumentation of a pregnant uterus. Women of childbearing age who wish to preserve their fertility should be made aware of the risk at the time of evacuation of retained products and offered alternative management, especially if they require repeated procedures.

Hysteroscopy provides a minimally invasive way to remove polyps and submucosal fibroids and divide intrauterine adhesions. There is no robust evidence to show this improves fertility but their presence does impair implantation and there is a biological rationale as to why their removal may improve fertility.

There are no treatments for adenomyosis that improve fertility. Treatment should be based on symptom control. GnRH agonists can be used but there are no data to show

they lead to an increase in spontaneous pregnancy or improve the outcome of IVF.

Endometriosis and peritoneal disease [7–9]

Suppression of ovarian function to improve fertility in minimal–mild endometriosis is not effective and should not be offered for this indication alone. There is no evidence of its effectiveness in more severe disease. Indeed, more harm than good may result from treatment, because of adverse effects and the lost opportunity to conceive.

Ablation of endometriotic lesions plus adhesiolysis to improve fertility in minimal–mild endometriosis is effective and improves ongoing pregnancy and live-birth rates but the role of surgery for moderate–severe disease is uncertain and there are no randomized controlled trials or meta-analyses to inform management. When surgery is performed, laparoscopy is preferred to laparotomy as it is associated with pregnancy rates of 54–66% compared with 36–45% after laparotomy in women with moderate and severe endometriosis.

Women with ovarian endometriomas should be offered laparoscopic cystectomy because this improves the chance of pregnancy. Laparoscopic cystectomy for ovarian endometriomas is better than drainage and coagulation as it reduces symptoms and the risk of recurrence. Excision of the endometrioma capsule increases the postoperative spontaneous pregnancy rate, compared with drainage and electrocoagulation of the endometrioma wall. Nevertheless, both techniques carry potential risks for ovarian reserve, either by removal of normal ovarian tissue during excision or by thermal damage to the ovarian cortex during ablation. It should also be noted that there is no evidence that cystectomy prior to treatment with assisted reproductive technologies improves pregnancy rates in infertile women with endometrioma larger than 3 cm. In this case, cystectomy should only be considered to improve endometriosis-associated pain or the accessibility of follicles.

IVF is appropriate treatment, especially if tubal function is compromised, there is also male factor infertility and/or other treatments have failed. Whilst IVF pregnancy rates are lower in women with endometriosis than in those with tubal infertility, endometriosis does not appear to adversely affect pregnancy rates. Treatment with a GnRH agonist for 3–6 months before IVF in women with endometriosis may increase the rate of clinical pregnancy.

The complete surgical removal of endometriosis may also improve live-birth rate in infertile women with AFS/ASRM stage I/II endometriosis undergoing laparoscopy prior to treatment with assisted reproductive technologies although the benefit is not well established.

Intrauterine insemination

Intrauterine insemination, with or without ovarian stimulation, is no longer recommended for people with unexplained infertility, mild endometriosis or mild male factor infertility who are having regular unprotected sexual intercourse. Intrauterine insemination may be considered in exceptional circumstances such as when people have social, cultural or religious objections to IVF. Unstimulated intrauterine insemination may benefit couples who are unable, or would find it very difficult, to have vaginal intercourse because of a clinically diagnosed physical disability or psychosexual problem.

Unstimulated intrauterine insemination with donor sperm, often referred to as donor insemination, is the recommended treatment for men with azoospermia due to testicular failure or severe deficits in semen quality who do not wish to undergo ICSI. Donor insemination may also be considered where there is a high risk of transmitting a genetic disorder or infectious disease to the offspring or the latter to the woman from the man. It may also be used for couples with severe rhesus isoimmunization. Donor insemination is the treatment of choice for people in same-sex relationships and single women. However, as these individuals invariably have to self-fund their treatment, some elect to have IVF with donor sperm.

People who have not conceived after six cycles of donor or partner insemination, despite evidence of normal ovulation, tubal patency and semen analysis, can be offered IVF or a further six cycles of unstimulated intrauterine insemination.

Assisted conception

NICE recommends that women under 40 who have been trying to get pregnant for 2 years should be offered three full cycles of IVF. Women aged between 40 and 42 who have been trying for two or more years and have not previously received IVF or have low ovarian reserve should be offered one full cycle of treatment. The overall chance of having a live birth after IVF treatment falls with rising female age and also decreases as the number of unsuccessful cycles increases. ICSI is indicated and should only be offered if there are severe deficits in semen quality, obstructive azoospermia, non-obstructive azoospermia or if previous IVF treatment resulted in failed or very poor fertilization.

Counselling and support

People experiencing fertility problems should be offered counselling because fertility problems themselves, and the investigation and treatment for fertility problems, can cause emotional stress. Counselling should be offered before, during and after investigation and treatment.

People who experience fertility problems should be informed that they may find it helpful to contact a fertility support group. There are several patient organizations and support groups available throughout the UK that offer general or specific advice. Fertility Fairness, formerly the National Infertility Awareness Campaign, has campaigned for people to have comprehensive and equal access to a full range of appropriate NHS investigations and treatments for infertility, including the right to access up to three full cycles of IVF treatment free on the NHS [10].

Welfare of the child

The welfare of the child who may be born as a result of fertility treatment, including the need of that child for supportive parenting, and of any other child who may be affected by the birth must be considered prior to offering treatment in accordance with Human Fertilisation and Embryology Authority (HFEA) regulations [11]. Each patient should be assessed to decide whether there is a risk of significant harm or neglect to any child.

Prognosis

Natural conception

Over 80% of couples will conceive within 1 year if the woman is aged under 40 years and they have regular sexual intercourse every 2–3 days. Half of the couples who do not conceive in the first year will conceive in the second year such that the cumulative pregnancy rate over 2 years is over 90%.

A prospective cohort of women aged 35–39 years, from the European Fecundability Study, suggested even higher rates of conception after 2 years (Table 51.3). Pregnancy rates did decrease with increases in female age. Men aged 40 years having intercourse twice per week have approximately 10% lower cumulative success rates compared with men aged 35 years over the same time period. All subfertile patients should therefore be made aware that female fertility and, albeit to a lesser extent, male fertility decline with age [12].

Coital frequency also influences conception rates. At least 94% and 77% of fertile women aged 35 years and 38 years, respectively, conceive after 3 years of trying if they have intercourse two or three times per week. Conception rates within 12 months fall from 92% for women aged 19–26 years to 86% for women aged 27–34 years and 82% for women aged 35–39 years for couples having intercourse twice per week. Conception rates fall further to 85%, 76% and 71%, respectively, for couples having intercourse once per week. Furthermore, sperm motility is highest in semen emission every 3–4 days on average. Coitus every 2–3 days is therefore likely to maximize the overall chance of natural conception, as spermatozoa survive in the female reproductive tract for up to 7 days after insemination.

In terms of timing, most pregnancies can be attributed to sexual intercourse during a 6-day period starting 5 days before ovulation and including the day of ovulation, with the highest estimated conception rates associated with intercourse 2 days before ovulation.

Table 51.3 Cumulative probability of conceiving a clinical pregnancy by number of menstrual cycles based on female age.

Age (years)	Pregnant after 1 year (12 cycles) (%)	Pregnant after 2 years (24 cycles) (%)
19–26	92	98
27–29	87	95
30–34	86	94
35–39	82	90

Assisted conception

NICE suggests that most women typically achieve success rates of 20–35% per cycle with a cumulative success of 45–53% after three full cycles of IVF, which is why it recommends three IVF cycles as it is both the most cost-effective and clinically effective number for women under the age of 40. Patient and public engagement has shown that many patients think that an 80% chance of getting pregnant through IVF is excellent and anything less than 50% is poor. However, these figures need to be considered and directly compared with natural fecundity as young healthy couples only have around a 20% chance of conceiving naturally in a month.

Funding

Although NICE has made its recommendations clear, funding for fertility treatment and assisted conception is ultimately determined by clinical commissioning groups (CCGs). Different CCGs use different eligibility criteria, with female age, BMI, previous children, relationship status and sexuality all deciding factors. Most CCGs do not offer funding for women who are overweight (BMI >30 kg/m^2) and all have an upper age cut-off that varies from 35 to 43 years. Most CCGs will not support couples who have children irrespective of whether these were conceived together or with a different partner.

Summary box 51.1

- Infertility is the second most common reason for women of childbearing age to visit their GP and affects one in seven heterosexual couples.
- Infertility is defined by the duration a couple have been trying to conceive without success, after which formal investigation is justified and treatment, where indicated, implemented. For most couples this will be after 1 year of unprotected vaginal sexual intercourse but couples should be referred earlier where the woman is 36 years or over or if there is a known clinical cause of infertility or predisposing factors for infertility.
- Male factor is now the most common cause of primary infertility closely followed by ovulatory disorders. There are no identifiable factors in one in four couples. Tubal disease is the most common cause of secondary infertility.
- Patients must be managed as individuals, from their initial referral through to their ultimate treatment. Investigations should be directed on the basis of a critical consideration of clinical features and used to inform patient management and counselling.
- Choice is as an integral part of any decision-making process. Patients should therefore have access to evidence-based information that they can use to inform decisions regarding their care and treatment.
- All patients should be given advice on the impact that lifestyle can have on their chances of getting pregnant, both naturally and following treatment.
- Couples with unexplained subfertility, mild male factor infertility and minimal to mild endometriosis should be reassured and given advice on natural conception and the timing and frequency of sexual intercourse. They should be offered IVF treatment if they have not conceived after 2 years, including up to 1 year before their fertility investigations, of regular unprotected sexual intercourse.
- While it is possible to adopt a generic approach to fertility treatment, it is paramount to individualize care and treat the underlying cause.
- People experiencing fertility problems should be offered counselling because fertility problems themselves, and the investigation and treatment of fertility problems, can cause emotional stress. Counselling should be offered before, during and after investigation and treatment.
- The welfare of the child who may be born as a result of fertility treatment must be considered prior to offering treatment in accordance with HFEA regulations.
- Over 80% of couples will conceive within 1 year if the woman is aged under 40 years and they have regular sexual intercourse every 2 –3 days. Half of the couples who do not conceive in the first year will conceive in the second year, such that the cumulative pregnancy rate over 2 years is over 90%. However, all subfertile patients should be made aware that female fertility and, albeit to a lesser extent, male fertility decline with age.

Assisted conception is the facilitation of natural conception by some form of scientific intervention. It has been available for many years, but one of the first recorded and possibly best-known instances of assisted conception was that performed by the eminent surgeon John Hunter in London in 1785. The husband, in this infertile couple, had hypospadias and artificial insemination of ejaculated sperm was performed on the wife. This resulted in a successful pregnancy and subsequent birth. This basic assisted conception continued until scientific techniques improved in the middle of the twentieth century. The advent of improved techniques, particularly in the form of ovulation induction and controlled ovarian stimulation, has allowed the successful treatment of the anovulatory female. The purification and use of human menopausal gonadotrophins (hMGs) in the 1960s led to multiple follicular development allowing *in vitro* fertilization (IVF). Over the last 40 years there have been dramatic improvements in the treatment of both the infertile female as well as the male. There is now a full panoply of techniques with acronyms ranging from the more well known such as IUI, IVF, ICSI and PGD, through to ones that have now become more esoteric due to lack of success rates such as DOT, PROST and even DIPI (Table 52.1). With these advances it is possible to treat the vast majority of subfertile men and women successfully and give them the child they so desire.

Investigations prior to assisted conception

Even though the diagnosis may have been made and the most appropriate form of treatment decided upon, there are a few essential investigations that should be performed prior to any form of assisted conception. These will not only ensure the best results when the assisted conception is performed, but also reduce the chance of any diagnosis being missed before multiple cycles are embarked on with the subsequent emotional and financial cost to the patient if they are unsuccessful.

Female

Tests of ovarian reserve have been utilized for many years; previously an early follicular phase follicle- stimulating hormone (FSH) level was used and is still the mainstay in most countries. The use of anti-Müllerian hormone (AMH) is now more widespread and gives a more accurate assessment of ovarian reserve. It has better intra- and inter-cycle variability and has a better correlation with ovarian response to superovulation and better success rates than any other blood test. Indeed it is often used to assess the patient's suitability for techniques such as IVF prior to treatment. A very low level (<3 pmol/L) would suggest a live-birth rate of less than 2% and hence IVF using the patient's own eggs would rarely be successful. Conversely, a high level (>50 pmol/L) would suggest very sensitive ovaries and a higher chance of developing ovarian hyperstimulation syndrome (OHSS) if the dose of FSH is not reduced and an antagonist protocol used.

Most forms of assisted conception, excluding egg donation, require normal ovarian reserve to have any significant chance of success. If the patient has irregular periods, then prolactin, thyroid function and, if appropriate, testosterone and sex hormone-binding globulin (SHBG) levels should also be measured.

If the patient is undergoing a licensed form of assisted conception under the 1990 Human Fertilisation and Embryology Act, then both the male and female partner have to be screened for hepatitis B, hepatitis C and HIV. If either partner

Table 52.1 Assisted contraception abbreviations.

Acronym	Definition
IVF	*In vitro* fertilization
IUI	Intrauterine insemination
ICSI	Intracytoplasmic sperm injection
PGD	Pre-implantation genetic diagnosis
PGS	Pre-implantation genetic screening
DOT	Direct oocyte transfer
PROST	Pronuclear stage transfer
DIPI	Direct intraperitoneal insemination
MESA	Microepididymal sperm aspiration
PESA	Percutaneous epididymal sperm aspiration
TESE	Testicular sperm extraction
GIFT	Gamete intrafallopian transfer

is positive for the above conditions this does not preclude them from being treated but unless specific embryo cryopreservation facilities are available, embryo freezing of surplus embryos cannot be performed because of the theoretical risk of cross-infectivity between the patient's embryos and unaffected embryos from other patients.

Ultrasound

Virtually all ultrasound scanning in assisted conception is performed transvaginally. The initial scan assesses several areas.

- Ovarian morphology: if there are underlying polycystic ovaries, they may be hyperresponsive to stimulation with gonadotrophins.
- Presence of ovarian cysts: if present, suitable treatment should be arranged.
- Many centres now also measure the antral follicle count (AFC) as this is also used in the dose calculation of FSH for the stimulation phase of IVF.
- The ovaries are assessed for accessibility, not just for the monitoring itself but also if transvaginal oocyte retrieval (TVOR) is planned in order to ensure that this can be performed without undue difficulty. Sometimes in patients who have abdominal adhesions due to iatrogenic causes, previous pelvic inflammatory disease or endometriosis, then gentle abdominal pressure can be applied during the screening ultrasound to ensure that the ovary can be moved down to a more accessible position for egg collection.
- The uterus is also assessed for the presence of abnormalities such as uterine fibroids to ensure the endometrium appears normal and there are no other abnormalities.
- The rest of the pelvis is also screened in a systematic fashion to exclude other pathology.

Uterine cavity and tubal patency

Both the uterine cavity and the fallopian tubes should be examined prior to all forms of assisted conception. For techniques such as IUI, where either one or both fallopian tubes are required to be patent, it is obvious why both the cavity and the tubes should be checked. Less obviously, the fallopian tubes require inspection for techniques such as IVF, even though they are not required for the actual procedure. We know from grade A evidence [1] that the presence of hydrosalpinges can significantly reduce the implantation rate due to reflux of the hydrosalpingeal fluid into the uterine cavity. The integrity of the uterine cavity should be evaluated as various forms of pathology, including intrauterine adhesions, congenital abnormalities such as large septate uterus, submucous fibroids and intrauterine polyps, can all significantly reduce the implantation rate and hence the subsequent live-birth rate from all forms of assisted conception. If a significant problem is noted in the uterine cavity, this would normally be corrected prior to the assisted conception cycles being performed. The uterine cavity and the fallopian tubes can be investigated using the following methods.

Hysterosalpingography

Hysterosalpingography (HSG) has been used for many decades but had a reputation for being painful. With newer techniques, and in particular the advent of suction caps and small balloon catheters, the need for unnecessary trauma is obviated. It allows assessment of both the uterine cavity and the fallopian tubes and it is an extremely useful screening test that can be performed with a high degree of accuracy without the need for a general anaesthetic. It is recommended that chlamydial screening be performed beforehand, preferably as part of the initial work-up of the female partner, and antibiotic cover for the procedure should be used.

Hystero-contrast sonography

Several ultrasound techniques have been developed to try to assess tubal patency. In most an echogenic fluid is instilled inside the uterine cavity and into the fallopian tubes, which can be tracked by transvaginal ultrasound. This can be a good method for assessing tubal patency, but due to the high echogenicity of the fluid it can sometimes miss uterine cavity lesions such as mild intrauterine adhesions and the subtle distortions caused by submucous fibroids [2]. This can be avoided by initially using sterile saline to outline the endometrial cavity before using ultrasound contrast medium, which by design is relatively echogenic.

Laparoscopy and hysteroscopy

These are commonly performed infertility investigations, particularly if the patient has other presenting complaints, especially pelvic pain.

If a screening test such as HSG has been performed and an intrauterine lesion found, then hysteroscopy would also be performed. If the diagnosis is confirmed the lesion is removed, for example intrauterine adhesions can be divided hysteroscopically, or submucus fibroids can be extracted by transcervical resection.

Male partner

A comprehensive semen analysis should be performed on all males referred for assisted conception to ascertain the most appropriate technique suitable for the patient. Most assisted conception units look at the normal World Health Organization (WHO) sperm criteria including sperm morphology; generally, IVF is used if the parameters are good and intracytoplasmic sperm injection (ICSI) if there is a problem with any of the parameters. The presence of other problems, such as anti-sperm antibodies within the ejaculate, are also ascertained and, if present, further samples can be obtained with the patient ejaculating directly into culture medium to try to lessen the impact of these antibodies on sperm function. This can sometimes mean that a sample severely affected by anti-sperm antibodies only deemed suitable for IVF can sometimes be 'upgraded' to techniques such as IUI if ejaculation into medium is performed. Overall, the proportion of IVF and ICSI procedures performed worldwide is roughly equal, although the popularity of ICSI is increasing.

Important coexistent pathologies

There are several other coexistent pathologies that can significantly reduce the successful outcome of assisted conception or increase the complication rates associated with it.

Uterine fibroids

Uterine fibroids are very commonly detected by transvaginal scanning of the infertile woman. It has always been difficult to ascertain the causality between these fibroids and the patient's infertile status, but the presence of fibroids does not necessarily mean there is a direct causal link between fibroids and infertility. On the other hand, there are a number of reported case series where removal of fibroids resulted in subsequent improved conception rates of between 30 and 80% [3]. It was previously thought that fibroids only significantly reduced implantation rates if the uterine cavity was distorted. Two series examined the effect of fibroids in other locations on implantation in IVF cycles. In the first of these, Eldar-Geva [4] showed that intramural fibroids significantly reduced implantation rates; this was then confirmed by Hart *et al.* [5]. Both of these studies confirmed the impact of fibroids that do not distort the uterine cavity but this appears to be only true for fibroids above 3 cm in size. Therefore, any patient who has fibroids larger than 3 cm, and in particular who has recurrent implantation failures, should be considered for myomectomy prior to further assisted conception. Although treatment of these fibroids does appear to have an impact on implantation rates, in a randomized trial Surrey *et al.* [3] failed to demonstrate improved live-birth rates.

Hydrosalpinges

There have been several studies that have shown the adverse effect of hydrosalpinges on IVF outcome. Indeed, three randomized controlled trials were included in the Cochrane review [6] to see if salpingectomy would be useful for patients with hydrosalpinges prior to undergoing IVF. Surgical treatment of these hydrosalpinges versus non-surgical treatment increased the odds of live birth plus ongoing pregnancy (odds ratio, OR 2.13, 95% CI 1.24–3.65) and of pregnancy (OR 1.75, 95% CI 1.07–2.86). It has now been shown that removal of these diseased tubes by salpingectomy prior to IVF leads to the implantation rates that would be expected in patients unaffected by hydrosalpinges. Whether these hydrosalpinges should be removed or blocked in the proximal portion (by clipping or coagulation) will depend on several factors such as degree of damage and whether the patient has pain associated with the hydrosalpinges. Salpingectomy used to be the routine recommendation but more units are now coagulating the proximal portion because of the worry that salpingectomy may compromise ovarian vasculature and reduce subsequent response to stimulation [7 6]. Most practitioners would individualize the treatment of hydrosalpinges and take all other variable parameters into consideration, ranging from any male factor present through to degree of tubal disease, as well as the known ovarian function of the patient prior to removing them.

Polycystic ovaries

Polycystic ovaries as seen by ultrasound are an extremely common finding in women of childbearing age and can occur in about 30% of patients. Patients with polycystic ovaries can be more difficult to stimulate with gonadotrophins for either IUI or IVF. Initially there can be a degree of resistance at lower doses but then a very narrow therapeutic window before the patient hyperstimulates, and this can quite often lead to cycle cancellation. In view of the severe complications resulting from OHSS, one should always start with a low dose and then increase in small increments until the appropriate therapeutic window is achieved. Some have advocated the use of laparoscopic ovarian drilling to try to improve this

therapeutic window, as well as the pre-cycle administration of insulin-sensitizing agents such as metformin. There is now evidence that metformin does not improve the success rate but can improve the safety of the cycle.

Endometriotic cysts

Endometriosis is a common coexistent pathology in patients undergoing assisted conception. Although there is little evidence that the routine treatment of peritoneal endometriosis results in a significant improvement in assisted conception cycles, there can be benefit in treating large endometriomas (>44 cm) prior to IVF. It is thought this may benefit the cycle in several ways, including the ovarian response itself and overall number of eggs obtained (particularly in the ovary containing the endometrioma). The second concern with ovarian endometriomas is that these can be inadvertently punctured during TVOR and there is a significant increase in ovarian abscess formation if this occurs. Pre-cycle drainage by needle aspiration can also be a cause of ovarian abscesses and this is generally not advised. If the size of the ovarian endometrioma is felt to be significant so that it may adversely affect cycle outcome or increase the chance of inadvertent needling, then it is better for the endometrioma to be surgically treated prior to initiation of the cycle. Prolonged downregulation with GnRH analogues can shrink the cysts and also improve the overall success rates.

Smoking

Patients should be advised that smoking significantly reduces the effectiveness of all forms of assisted conception and that they should therefore quit smoking.

Obesity

It is recommended that a patient should have a body mass index (BMI) of between 19 and 30. Outside this range success rates of assisted conception are reduced. If the BMI is above 30, not only are success rates lower but miscarriage rates higher and complications such as OHSS increased. It is therefore recommended that the female partner should be encouraged to lose weight.

Types of assisted conception

There are many types of assisted conception available in the modern unit. These range from less invasive procedures such as IUI through to the widely known IVF, with or without ICSI. The use of other procedures such as gamete intrafallopian transfer (GIFT) has reduced due to the improving success rates of IVF. Other techniques associated with assisted conception cycles such as pre-implantation genetic diagnosis (PGD) and pre-implantation genetic screening (PGS) are also performed in a few specialized centres.

Intrauterine insemination

Intrauterine insemination (IUI) is where a prepared sample of sperm (normally produced by masturbation) is inseminated into the uterine cavity at the appropriate time of the patient's menstrual cycle. Approximately 2 weeks later a pregnancy test is performed to see if the cycle has been successful.

Protocols

IUI can be performed in a natural cycle, with Clomid alone, with Clomid and then FSH injection, or purely with FSH. If any form of ovulation induction has been used, it is also quite common to use a single human chorionic gonadotrophin (hCG) injection approximately 36 hours prior to the insemination to ensure optimal timing with ovulation.

Monitoring

Although for unstimulated cycles it is possible just to perform urinary luteinizing hormone (LH) monitoring using home dipstick methods, this does not give the best success rates. If any form of ovulation induction has been used, then it is recommended that more accurate monitoring is performed. This is normally achieved by transvaginal ultrasound and has benefits of not only deciding the best time to give the dose of hCG and hence the timing of the insemination, but also ensuring that ovulation induction is having the desired effect, i.e. one (or at most two) developing follicle(s) over 18 mm. If there are more than two follicles, this can be detected by ultrasound, the cycle cancelled and the patient advised against having unprotected intercourse due to the increased risk of higher-order multiple pregnancies.

The overall success rate, as with any subfertile couple, depends on multiple factors, most importantly female age and, with IUI, the quality of the sperm. Though IUI can be used for mild male factor problems, it is not recommended for anything more severe. Success rates of around 5% per cycle have been quoted for unstimulated IUI, increasing to 8–10% per cycle for stimulation with Clomid and 12–18% per cycle when FSH is used in the protocol. Although success rates of 35% have been quoted in literature, these tend to be highly selective series and not necessarily representative of a general case mix of patients across a wider age range [8].

Complications

The main complication of IUI is higher-order multiple births and occurs when FSH has been used. Most centres would expect a twinning rate of 10–15% and a triplet rate

of less than 1%. If the triplet rate is higher than 1%, and in particular if there are even higher numbers than this, then this is normally due to inadequate monitoring and inadequate numbers of cycles being cancelled when an over-response of the ovaries has been seen.

Although ovarian hyperstimulation can occur, particularly in the protocols where FSH is used, this would normally be mild to moderate at most, and it is very unusual to get a case of severe hyperstimulation in IUI cycles. If this happens it tends to be when an inappropriate starting dose of FSH has been used and again when inadequate monitoring has been performed.

The patient should also be warned about the possibility of ectopic pregnancies, and most clinics would offer an early ultrasound scan in the patients who have had a positive pregnancy test at between 6 and 7 weeks' gestation.

Advantages

IUI is a relatively simple technique that is cost-effective and can be offered by both secondary and tertiary fertility centres. It is not as invasive as IVF and allows fertilization to occur within the fallopian tubes and therefore it is generally acceptable to most religious groups.

Disadvantages

The success rates are lower than those with IVF, and if the cycle fails less information is obtained than with an IVF cycle, particularly pertaining to possible egg or subsequent embryo quality. It also requires at least one healthy fallopian tube and reasonable sperm parameters. If monitoring is suboptimal, then there can be a significant increase in higher-order multiple births, with the expected sequelae.

Indications

- Unexplained infertility.
- Mild male factor.
- Ejaculatory problems.
- Cervical problems.
- Ovulatory disorders.
- Mild endometriosis.
- To optimize the use of donor sperm.

In vitro fertilization

In vitro fertilization is where the mature oocyte is surgically removed from the ovary and then fertilized with sperm in the laboratory. The world's first successful IVF baby was delivered by Patrick Steptoe in 1978 after a number of years collaborating with Robert Edwards. Over the last 25 years the success rates and types of IVF have greatly improved and at present there are well over 2 million babies born throughout the world by this technique.

Indications

- Severe tubal disease: tubal blockages.
- Severe endometriosis.
- Moderate male factor.
- Unexplained infertility.
- Unsuccessful IUI.

Protocols

Initially, simple forms of ovulation induction using Clomid and hMGs were used. Over the last 20 years protocols have been refined and these are now classified into three main categories:

1) natural cycle;
2) long protocol (agonist cycles);
3) short protocol (antagonist cycles).

Although there are other short protocols using agonists, these are now less used due to poorer success rates.

Agonist cycles

Long protocols are still at present the most widely used protocols throughout the world. They involve the use of a GnRH agonist that can be taken nasally on a daily basis (e.g. buserelin, nafarelin) or as a daily subcutaneous injection (e.g. buserelin, leuprorelin) or as a depot preparation (goserelin, leuprorelin). The agonist is given continuously and initially increases the production of gonadotrophins (FSH and LH) from the pituitary gland. If this continuous administration is maintained, then downregulation of the GnRH receptors is achieved. This causes a reduction in LH and FSH levels and thus a reduction in stimulation of the ovary. As a result folliculogenesis is suppressed and blood estradiol levels fall to menopausal levels within 3 weeks. As long as the agonists are continued then the ovary is suppressed unless exogenous gonadotrophins are given. The start of agonist administration can be on either day 2 of the menstrual cycle or, more commonly, day 21. The rationale behind using these long protocols is to create a temporary menopause from which the ovaries can then be stimulated by the daily use of FSH/hMG injections.

In a mid-luteal start (normally around day 21), the patient is reviewed when her period starts approximately 7–10 days after the agonist is initiated. A scan and often a blood estradiol level are performed to ensure the patient is adequately suppressed. If this is the case, then gonadotrophins are started the following day and continued until an adequate ovarian response is gained.

An early follicular, or day 2, start can also be used and the patient bought back for her scan and blood test on average 2 weeks later to see if she is suppressed. As in the luteal start, if adequate suppression is obtained, then exogenous gonadotrophins are started and then continued until satisfactory ovarian response is obtained.

Antagonist protocols

Antagonists (ganirelix and cetrorelix) have been in common use for the last 10 years. The antagonist has an almost immediate effect on the pituitary and, unlike agonists, does not need several days to achieve menopausal levels of the pituitary-derived gonadotrophins. Therefore the patient is prevented from having a premature LH surge and ovulating spontaneously within an hour of the start of the antagonist. A daily dose of 0.25 mg is normally given and there is also a 3-mg dose of cetrorelix that can last for several days. The drugs are given subcutaneously and are started either on a fixed day of FSH stimulation (normally on the 5th day of stimulation) or when the lead follicle is a certain size by ultrasound monitoring (normally 14 mm). The antagonists are continued alongside the gonadotrophin stimulation until an adequate response is achieved and then stopped prior to the hCG injection.

The benefits of antagonists over agonists are:

- no menopausal side effects;
- no cyst formation from the initial gonadotrophin surge;
- shorter cycle duration;
- less gonadotrophin required per cycle, therefore lower drug costs;
- antagonist cycles should be used in patients with polycystic ovaries as they have a lower incidence of OHSS which allows the use of an agonist trigger.

Monitoring

It is essential that adequate monitoring is performed during stimulation of the ovaries with exogenous gonadotrophins. Serial transvaginal ultrasound to assess follicular growth should be used. A decreasing number of units continue to use serial estradiol levels to add to the information obtained from the ultrasound. The use of serial estradiol can be useful in some patient groups, particularly if an under- or over-response is anticipated. An under-response can sometimes be anticipated in the older patient or the patient with previously raised FSH levels. An over-response can sometimes be anticipated if there has been a previous over-response or if the patient has polycystic ovarian morphology on her initial diagnostic ultrasound. There seems to be no value in routine estradiol monitoring.

Monitoring during the stimulatory phase allows the dose to be increased or decreased, if appropriate, as well as the timing of the hCG injection.

hCG injection

This is used to induce final maturation of the oocytes prior to oocyte retrieval. Generally, recombinant hCG 250 μg subcutaneously in a prefilled pen is used. If urinary hCG is used, then a dose of 10 000 IU is given, although in patients with an over-response this can be decreased to 5000 IU. hCG should be given when either one or two lead follicles have reached 18 mm. The injection is normally given around midnight to allow for oocyte retrieval approximately 35 hours later prior to physiological ovulation occurring. If the hCG injection is incorrectly administered, then either very few or no eggs are obtained at the egg collection.

Agonist trigger

If the patient is at significant risk of OHSS then, rather than using an hCG trigger with a prolonged half-life and subsequent prolonged stimulation of the corpora lutea, an agonist trigger can be used. This gives a more normal LH surge with a shorter half-life. This has been shown to significantly reduce the rates of severe OHSS. If an agonist trigger is used, then the luteal phase support is often modified (see section on luteal phase support). Agonist triggers are also used in egg donor cycles where the risk of OHSS has to be lower and the embryos are nor replaced in the donor herself.

Oocyte retrieval

Originally, this was done laparoscopically but the advent of real-time ultrasound has allowed a less invasive oocyte retrieval by ultrasound-directed needling of the ovaries. Smaller and better-quality ultrasound probes, particularly with the advent of transvaginal scanning, has allowed both the monitoring of the ovary during stimulation and the actual retrieval itself to be performed transvaginally. Virtually all oocyte retrievals are performed by this transvaginal ultrasound-directed route. The laparoscopic route is still occasionally used if the ovaries are inaccessible transvaginally. This can occasionally occur in frozen pelvises or when the ovaries have been moved out of the pelvis prior to pelvic irradiation.

TVOR can be performed under general anaesthesia or, more commonly, local anaesthesia or some form of intravenous sedation. The procedure generally takes 20–30 min, depending on how many follicles are present. Either a single-use disposable needle is used or a double-channel needle that allows 'flushing' of the follicle if the egg is not obtained on simple aspiration. The needle is inserted under ultrasound control directly into the follicles of one ovary and the fluid aspirated and given directly to the embryologist. If the egg is not found after all the fluid has been aspirated, then the follicle is flushed and re-aspirated to try to find the egg, as well as using gentle needle agitation (Fig. 52.1). After all the follicles have been exhausted from one ovary, the needle is then withdrawn and reinserted under ultrasound control into the other ovary and the process repeated. After the ultrasound probe is removed, the vaginal vault is checked for

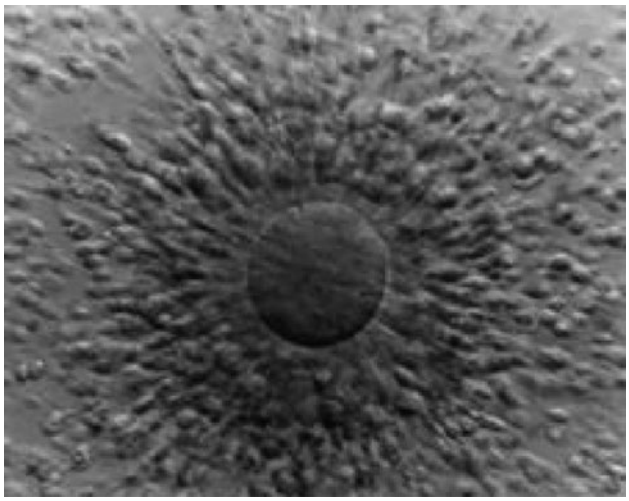

Fig. 52.1 Human oocyte with cumulus cells.

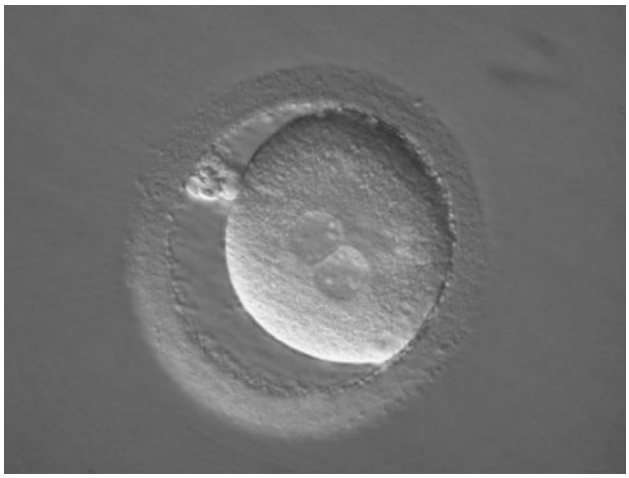

Fig. 52.2 Human embryo 2 pronuclear (PN) stage day 1, normal fertilization.

bleeding; although bleeding is usually not a problem, occasionally an absorbable suture has to be inserted under direct vision for a specific bleeding point. Most patients go home a few hours after the procedure has been completed.

Embryo transfer

Eggs are fertilized either by routine insemination with a concentration of approximately 100 000 normally motile sperm per millilitre or by ICSI (see later section). They are incubated in a commercially prepared culture medium under strict laboratory conditions. The temperature within the incubators is carefully controlled, as are the gas content, humidity and pH.

Traditionally, most embryos were transferred at day 2 or 3 following egg collection. There is now good evidence that if embryos are left in extended culture conditions and transferred on day 5 (at the blastocyst stage), higher pregnancy rates can be achieved [9]. Indeed, day 5 or blastocyst transfer is the default position in most units. Approximately 55–60% of all mature eggs fertilize normally and these are graded by the embryologist on day 2 (Fig. 52.2). At present, the guidelines in the UK from the Humam Fertilisation and Embryology Authority (HFEA) state that only two embryos should be transferred in people under the age of 40, unless exceptional circumstances are present, but over the age of 40 three embryos can be transferred. With increasing success rates and concerns over multiple births, many units now electively transfer one embryo if the patient is under 38 years old, unless she has had multiple previous failed cycles. Although this may have a slight effect on success rates, the other normal embryos are frozen and hence if a cycle is unsuccessful, the patient can undergo repeated single embryo transfers from frozen embryo replacement cycles. Evidence from elective single embryo transfer programmes in Scandinavia and Belgium has shown that twin rates can be virtually eliminated whilst maintaining acceptable overall pregnancy rates [10].

The potential benefits of a day 2 transfer are that a single-stage culture medium can be used and also that the majority of normal embryos survive to this stage. After two or three embryos have been replaced, there may be surplus embryos of a satisfactory quality that are suitable for cryopreservation. The potential downside of a day 2 transfer is that in a normal menstrual cycle, the day 2 embryo is still in the fallopian tube and not in the uterine cavity. Also it is much more difficult to accurately grade a day 2 or 3 embryo. The benefit of a day 5, or blastocyst, transfer is that the embryo has been replaced when it would physiologically be in the uterine cavity –this may have some benefits regarding certain growth factors that can improve embryo development. Blastocyst transfer also allows better selection of embryos as some abnormal embryos perish between day 2 and day 5 (Figs 52.3–52.6).

Embryo transfer is performed without anaesthetic. A Cuscoe's speculum is generally used to visualize the cervix, which is cleaned carefully, and a sterile single-use embryo transfer catheter is carefully inserted through the cervical canal. Where in the uterine cavity the embryos are replaced is a topic of great debate, but it is not uncommon for them to be placed in the mid-cavity portion and generally to stop insertion of the catheter before the fundus where it could potentially cause some slight trauma and bleeding. Evidence suggests that embryo transfer should be performed under ultrasound guidance as this allows more accurate placement of the embryos in the uterine cavity and has been shown to significantly improve success rates [11].

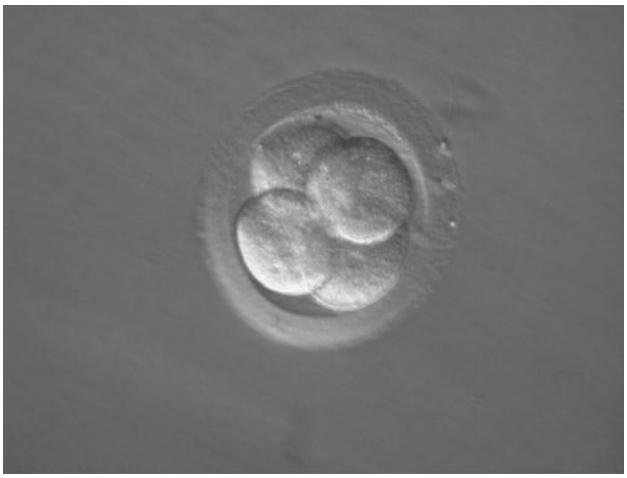

Fig. 52.3 Four-cell stage, day 2.

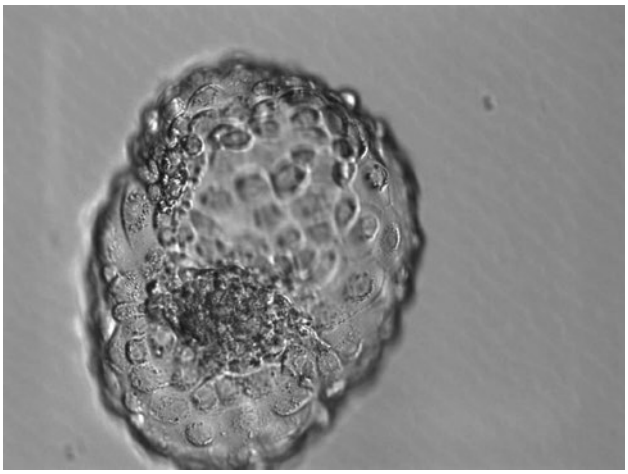

Fig. 52.6 Blastocyst, day 5.

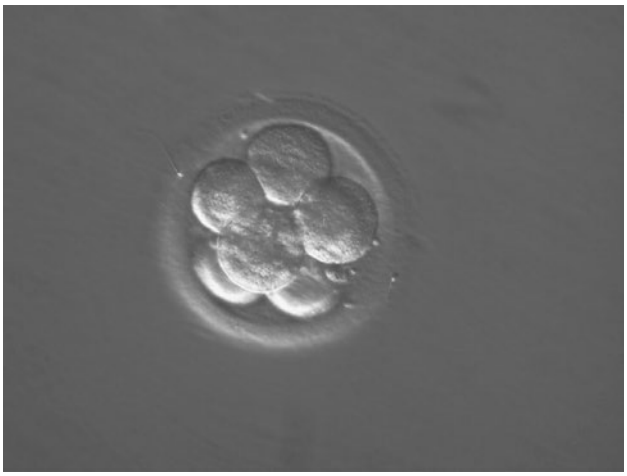

Fig. 52.4 Eight-cell stage, day 3.

Fig. 52.5 Morula, day 4.

After the outer sheath has been inserted in the correct location, an inner catheter containing the embryos is inserted into the outer sheath. When it is in the correct position a very small aliquot of fluid is used to emit the embryos from the end of the catheter. The inner catheter is then removed and handed back to the embryologist to confirm that no embryos have been retained in the inner catheter. If the catheter is clear, the outer sheath is gently withdrawn and the speculum removed.

Although there is no chance that the embryos can 'fall out', many patients are not surprisingly very cautious at this stage and quite often are allowed to rest in a supine position for up to 2 hours before being allowed to leave the hospital. There has been no evidence that leaving the patients in a supine position increases pregnancy rates, but it may help the patients psychologically.

Luteal phase support

With modern assisted conception utilizing either agonist or antagonist protocols, some form of luteal phase support (LPS) is necessary. Although natural cycle IVF does not need this, superovulation may impair normal corpus luteal function and the use of LPS has been shown to improve success rates [12]. The use of LPS with antagonist cycles is more debatable, but pregnancy rates without it are generally thought to be significantly lower [13]. LPS is broadly divided into three types: (i) use of luteotropic preparations such as hCG, (ii) use of progestogens or progesterone and (iii) use of more intense regimens when there has been an agonist trigger. hCG is given by subcutaneous injection in small aliquots that stimulates the patient's own ovaries to produce more progesterone. It has been shown to be as efficacious as progesterone

but does require an injection and also increases the risk of OHSS in some patients.

The use of progesterone is more common and it can be given as tablets, injections, vaginal gel or vaginal pessaries/rectal suppositories. Intravaginal or rectal use of progesterone achieves extremely good tissue levels very rapidly. It is known that LPS should be given for a minimum of 2 weeks, but some clinics routinely offer it up to 12 weeks or even later. However, there is little good evidence that continuing it beyond 2 weeks significantly improves pregnancy rates. The minimum dose is 200 mg/day but the most commonly prescribed dose is 400–800 mg/day.

The more intense regimens utilize injectable intramuscular progesterone with estradiol supplementation, normally in the form of tablets. The progesterone and estradiol are both routinely continued if the pregnancy test is positive. It is not uncommon for the injectable progesterone to be changed to a vaginal preparation at around 8 weeks of gestation because of the pain caused by the repeated deep intramuscular injections required for the oil-based progesterone preparation.

Pregnancy test

The wait between the embryos being replaced and the pregnancy test is the most psychologically stressful time for the majority of patients. Some patients can start bleeding early, prior to the pregnancy test. Progesterone supplementation can also delay bleeding, even if the pregnancy test is negative. Generally, pregnancy tests are performed around 14 days from embryo transfer and can either be done at home with a urinary pregnancy test or at the clinic with a serum pregnancy test. A home pregnancy test is more convenient for the patient, and the currently available kits have excellent levels of sensitivity down to detection rates of 25 IU. If the pregnancy test is positive and in the normal range, then it is usual to offer the patient a transvaginal scan 2–3 weeks later to ensure that the pregnancy is intrauterine and also to assess its viability. If the initial hCG level is low, then this is often repeated 48 hours later to assess the rise; it if it is suboptimal, then the possibility of an ectopic pregnancy or miscarriage has to be considered and appropriate follow-up organized.

Results

All assisted conception treatment cycles in the UK have to be reported to the national regulator, the HFEA. Details of all these treatments can be accessed by both patients and professionals on the HFEA website (www.hfea.gov.uk). The latest consolidated figures are from 2013 and show that 49 636 women had 64 600 cycles of IVF or ICSI, and 4452 cycles of donor insemination were performed; 14 062 pregnancies were reported as a result of this treatment. There has been a significant increase in the number of patients having an elective single embryo transfer, and as a result multiple pregnancy rates have fallen significantly while overall pregnancy rates have shown a small increase (Table 52.2). This table also reflects the very significant impact that female age has on the chance of a successful pregnancy outcome. In comparison, male age has very little impact.

Treatment cycle numbers are increasing at approximately 3.9% per annum, with 13 839 babies born as a result of IVF treatment using fresh eggs. Over recent years there has been a proportionately greater increase in the number of treatments using frozen and thawed embryos compared with treatment cycles using fresh embryos. In 2013, 12 320 cycles using frozen embryos were performed (10% annual increase). The age-stratified pregnancy rates are presented in Table 52.3, where it can be seen that age has less of an impact because the embryos transferred were collected when the woman herself was younger.

Table 52.2 Pregnancy rates (%) per embryo transfer for IVF using the patient's fresh eggs.

Age (years)	2012	2013
18–34	41.5	41.8
35–37	35.9	38.3
38–39	29.7	30.2
40–42	21.6	23.1
43–44	10.6	12.4
≥45	3.4	7.0
All ages	34.6	35.5

Table 52.3 Pregnancy rates (%) per frozen embryo transfer.

Age (years)	2012	2013
18–34	30.0	33.4
35–37	28.3	30.9
38–39	25.0	29.1
40–42	22.7	25.2
43–44	14.2	13.0
≥45	9.3	13.0
All ages	27.5	30.6

Summary box 52.1

Latest trends in IVF and ICSI in the UK

- Numbers of treatment cycles using 'fresh' eggs have stabilized.
- Numbers of treatment cycles using thawed frozen embryos has significantly increased.
- Treatment cycles using donor gametes are increasing.
- Pregnancy and live-birth rates show a modest increase.
- Multiple pregnancy and live-birth rates continue to decline.
- The percentage of blastocyst transfers continues to grow.
- Rapid increase in the number of egg freeze cycles.

Intracytoplasmic sperm injection

Intracytoplasmic sperm injection is where individual morphologically normal sperm are immobilized and injected into a mature oocyte that has had its surrounding cumulus and corona cells removed. An inverted microscope with a heated stage and micromanipulating equipment is used (Fig. 52.7). The oocyte is carefully positioned using a holding pipette under gentle suction. A very sharp glass injecting pipette is slowly inserted to rupture the oolemma, and the immobilized sperm injected into the oocyte with a very small volume of the medium. The injecting pipette is then carefully removed and the oocyte incubated under the usual stringent laboratory conditions.

Indications

- Severe male factor including azoospermia and subsequent surgical sperm retrieval by MESA, TESE or PESA (see Table 52.1).
- Severe oligoasthenoteratozoospermia.
- Poor or total non-fertilization from previous IVF cycles.
- Pre-implantation genetic diagnosis cycles.

Most IVF units would have approximately 40–60% of their total IVF cycles using ICSI. Studies have been performed to determine if ICSI with normal sperm improves pregnancy rates, but there is no evidence for this strategy [14]. Despite this, the incidence of ICSI appears to be increasing, with one of the driving factors the desire to avoid failure of fertilization at IVF.

Results

Pregnancy rates of 36.5% per transfer are reported [15] with live-birth rates of 30.4% per transfer based on over 28 800 cycles.

Safety

ICSI has been in clinical use since the early 1990s and all the results of the follow-up studies are generally reassuring. Many centres will also recommend male karyotype screening if sperm concentrations are below 5 million/cm^3. Some centres also advocate the use of Y chromosome microdeletion screening, although this is not routinely offered. Cystic fibrosis screening is essential in cases of azoospermia, particularly if it is related to the

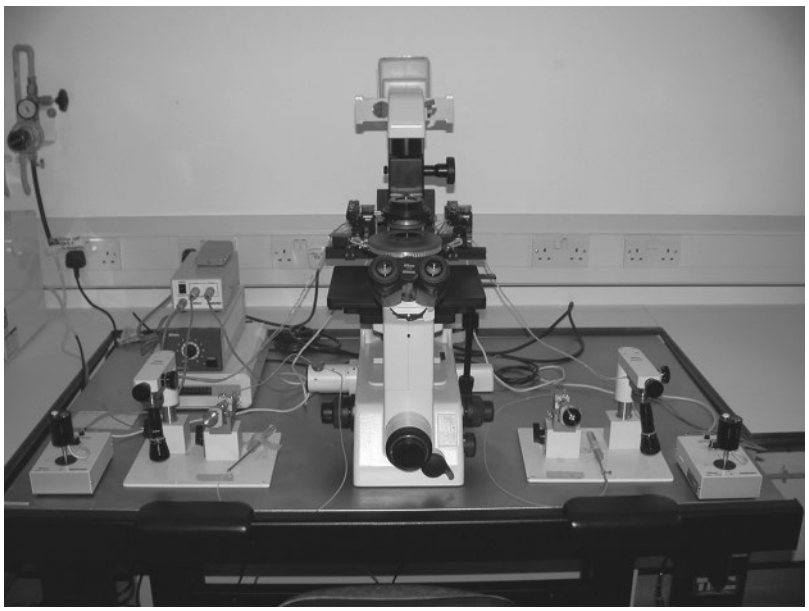

Fig. 52.7 Intracytoplasmic sperm injection micromanipulator.

condition of congenital bilateral absence of the vas deferens, as a significant proportion of these patients will be carriers of the cystic fibrosis mutations. Being a carrier does not preclude them being treated as a couple, but the female partner is then offered screening, and if she also is found to be a carrier, then they should be referred for consideration of IVF–ICSI with PGD.

If all the above results are normal, patients should be counselled carefully that there is a slight increase in genetic abnormalities in the offspring. Most of these abnormalities are thought to be minor and the major congenital malformation rate is generally thought to be similar to that of the general population.

Gamete intrafallopian transfer

Gamete intrafallopian transfer was first used around 1984 and here the eggs are collected laparoscopically, identified by the embryologist and then placed back in the fallopian tube, again laparoscopically, with a small aliquot of specially prepared highly motile sperm. The use of GIFT reached a peak in the early 1990s and has been diminishing since then.

Advantages

GIFT was initially developed to increase the availability of assisted conception due to the scarcity of suitable laboratory facilities and embryological skills. As the eggs did not have to be cultured outside the body, few of the usual laboratory facilities were needed. It appears to be very physiologically sound as both the egg and sperm are in the appropriate place at the appropriate time. The embryo travels physiologically down into the uterine cavity and hence there is no disruption of the endometrial environment, as there would be with normal embryo transfer from IVF.

Disadvantages

It is more invasive than IVF as a laparoscope is used to replace the embryos and sperm through the fimbrial end of the fallopian tube. The eggs are generally collected by transvaginal egg collection as it has been shown that more eggs are obtained by this route. As part of good clinical practice, only a limited number of eggs are replaced, even though it is not known whether these will fertilize normally by the sperm that is added. Therefore less information is obtained than with an IVF cycle. At least one fallopian tube should be healthy. Normal sperm parameters are also optimal, although GIFT can be used in cases of mild male factor disease.

The place of GIFT in the third millennium is often debated and its routine use is now very limited. Most European centres would only use it in cases where IVF is not allowed for religious reasons. Since conception occurs within the body, GIFT is often acceptable even though IVF is not. In some cases of totally unexplained infertility, where there has been repeated IUI and IVF failures, GIFT may also have a small place.

Success rates

These vary enormously depending on patient selection, but success rates in appropriate circumstances can be 30% live birth per transfer [13]. Apart from a few advocates, the use of GIFT in most large clinics accounts for less than 0.5% of all their assisted reproductive technology cycles.

Frozen embryo replacement cycle

The first pregnancy resulting from a frozen human embryo was in 1985 and since then the use of frozen cycles has increased dramatically. Freezing surplus morphologically normal embryos allows the use of those embryos that otherwise may have been wasted. Freezing surplus good-quality embryos is now routine, and this allows a significantly increased cumulative chance of pregnancy per egg collection. Normally, embryos are frozen on day 5 after the selected ones have been replaced fresh, but can be frozen any time from day 1 through to day 5. The use of day 1 freezing is normally confined to elective freezing of all embryos when there is a high risk of OHSS occurring. Slow freezing protocols of embryos have now generally been replaced by ultra-rapid vitrification protocols. The increased use of blastocyst culture and the highly successful warming rates post vitrification are both leading to increased success rates with cryopreserved embryos. Some centres believe that elective freezing of all embryos might improve both efficacy and safety for mother and fetus, and prospective randomized controlled trials are currently underway to assess this.

Transfer of frozen embryos

There are two main ways to transfer frozen embryos: first, replace them in a spontaneous menstrual cycle or, second, suppress the patient's own menstrual cycle with GnRH agonists and then supplement with oestrogen to thicken the endometrium prior to embryo replacement.

Natural cycle

The patient has to have regular menstrual cycles for this to be a feasible option and the patient's cycle is then monitored by serial ultrasound scan as well as hormone profiling, including estradiol and LH measurements. As long as there are no adverse factors noted on these measurements, the embryos are thawed and replaced approximately 6 days after the LH surge has been detected (if the embryo is vitrified at the blastocyst stage). Approximately 80% of frozen blastocysts survive the

thaw process and, depending on the age of the patient, one, two or three embryos are replaced. No LPS is required as the ovaries are not downregulated, and sufficient natural progesterone is produced from the patient's own corpus luteum.

Medicated cycles

The majority of frozen embryo replacement cycles (FERC) employ suppression of the patient's own menstrual cycle as this gives better control, although there is some controversy as to whether this gives better results. A GnRH agonist is used for suppression of the menstrual cycle and is normally started on day 21. If the patient is menopausal, then this is not required and only oestrogen supplementation is used. After adequate suppression has been achieved, hormone supplementation in the form of oestrogen is used. This is generally an increasing regimen with either tablets or patches until sufficient endometrial thickness has been achieved. The embryos are replaced in a similar fashion to IVF and, because of ovarian suppression, LPS is required. If the patient is pregnant this is continued up to approximately 12 weeks of pregnancy.

All IVF units should have a frozen embryo replacement programme and it is not only generally accepted as a safe and effective means of treatment but also one that is cost beneficial, maximizing the use of the patient's fresh cycle.

Summary box 52.2

Frozen embryo replacement cycles

- There is a significant increase in the use of thawed frozen embryos.
- Vitrification has become the main technology for cryopreservation.
- Both natural cycle and medicated frozen cycle treatments remain popular.
- Shorter GnRH antagonist medicated cycles are available.
- The concept of 'freeze-all' embryos is currently being evaluated in prospective randomized controlled trials.
- Elective freezing or 'segmentation' of treatment cycles may reduce the incidence of OHSS.

Egg donation

Oocyte donation is where a donor oocyte obtained from a fresh IVF cycle from a suitable screened donor is fertilized with the sperm from the recipient's partner and the fertilized embryo replaced in the recipient. The first successful pregnancy from an egg donation cycle was in 1983.

Procedure

Unfertilized mature oocytes are obtained from a donor who, in the UK, should be less than 37 years old, healthy and preferably of known fertility. The donor is screened for hepatitis B, hepatitis C and HIV as well as for appropriate genetic diseases. It is generally recommended that both the donor and recipient undergo counselling with regard to the implications of egg donation and the possible outcome. A routine IVF cycle is then performed and, depending on the sperm parameters of the male partner of the recipient, the eggs fertilized either routinely or with ICSI. The resultant embryos can be replaced fresh or in a frozen cycle.

The recipient is prepared in a similar way to FERC. If the menstrual cycle is regular, the embryos can be replaced in a natural cycle (although this is unusual as recipients rarely have normal menstrual cycles). More often than not, they are replaced as in a suppressed FERC with the use of oestrogen to produce an optimum endometrium for implantation.

Indications

- Ovarian failure, either premature or physiological.
- Patients with very poor ovarian function where previous IVF has repeatedly failed.
- Patients over the age of 45 and with severe male factor disease necessitating ICSI.
- Patients with hereditary genetic disease where using the patient's own gametes is not advisable.

Benefits

The recipient adopts the success rate corresponding to the age of the donor. Therefore success rates with egg donation are generally high. Any resultant offspring have the aneuploidy rates of the age of the donor as well. Therefore for a patient who is over the age of 40, the success rates are far greater and the risks of genetic disease, such as Down's syndrome, significantly lower.

Problems

The main problem with oocyte donation is obtaining eggs. In the UK it is illegal at present to pay donors for their eggs and they are only allowed to be compensated minimally for their time and inconvenience. Since 1 April 2005, anonymity for the donors has also been repealed and any resultant offspring can trace their genetic mother from the age of 18. At present, demand for donor eggs in the UK outstrips supply, and this has led to many patients seeking cross-border reproductive care in countries where legislation differs and donors are more plentiful.

Egg share programmes can be used where a person requiring IVF for personal reasons agrees to donate half

her eggs to an unknown recipient in lieu of having a reduced cost for her own IVF cycle.

Surrogacy

Surrogacy is used when a patient's uterus is either absent or unable to maintain a pregnancy, and a surrogate or host uterus is used to carry the pregnancy. Generally this procedure is used where a young patient has lost her uterus to cancer or to uncontrollable bleeding, for example postpartum haemorrhage or following a difficult myomectomy. The patient's own eggs are obtained as in an IVF cycle, fertilized by her partner's sperm and the resultant embryos replaced within the surrogate. Counselling is obligatory for both the patients and the surrogate. Generally, surrogates are women who have already had children themselves and are recruited either by the patients or through charitable organizations. Surrogacy is legal in the UK and the surrogate can be compensated for time lost away from employment during the pregnancy. However, the child's legal mother is the woman who delivers the child and therefore the patient and the husband have to undergo formal court order procedures to become the legal parents of their genetic offspring which the surrogate has delivered. The laws governing surrogacy vary widely from country to country.

Egg freezing

Egg freezing is where eggs are obtained from an IVF cycle, but rather than being fertilized with sperm are left unfertilized and then frozen for future use. Unfortunately, using slow-freezing techniques unfertilized eggs did not survive the freeze–thaw process anywhere near as well as an embryo due to the large size of the unfertilized eggs and the high water content. This caused problems during the freezing process as ice crystals can form within the egg, disrupting the delicate structures and resulting in its demise when thawed. Egg freezing programmes using conventional slow-freezing techniques are associated with low pregnancy rates of under 10% per transfer. As a result of these poor results such treatment was usually only recommended for young patients with cancer facing treatments such as chemotherapy, radiotherapy or sterilizing surgery. Recently, an alternative approach to cryopreservation called vitrification has been attempted. Improvements in thaw rates are seen (>80%) and pregnancy rates of up to 35% per transfer have been reported [16]. This new technology may justify an expansion of the indications of egg storage from fertility preservation in oncology patients who have no partner to the so-called 'social' egg freezing that may be popular with professional women trying to delay the impact of age-related decreases in ovarian function and egg quality.

Pre-implantation genetic diagnosis

Pre-implantation genetic diagnosis is a form of very early prenatal diagnosis. It combines the techniques of assisted conception with molecular genetics and cytogenetics to detect genetic disease in embryos at the pre-implantation stage. It allows couples who carry serious genetic disorders to have embryos free of these diseases transferred into the uterus, allowing the woman the secure knowledge that she is starting off the pregnancy with an unaffected embryo. This prevents the need for invasive prenatal diagnosis and the difficult decision on whether to terminate an affected pregnancy. The technique was pioneered at the Hammersmith Hospital in the early 1990s [17], and can now be applied to almost all hereditary conditions where the mutation is known.

Indications

- Single gene defects such as cystic fibrosis, thalassaemia or sickle cell disease.
- Chromosomal rearrangements such as translocations.
- HLA matching for donor sibling stem cell transplantation.
- Predisposition genes, e.g. *BRCA*.

Procedure

The embryos are obtained as with any routine IVF procedure, although generally ICSI is now used to minimize the potential for genetic contamination. Biopsy may be of the polar body (at the MII oocyte phase), at the cleavage stage of development on day 3, or more commonly at the blastocyst stage on day 5. The zona pellucida of the embryo is opened by using either acid-tyrodes or special lasers, and several trophoblast cells are removed for the specific test itself. The genetic material is amplified and a variety of different approaches are used to make the genetic diagnosis, including comparative genomic hybridization (CGH) and, most recently, next generation sequencing (NGS). Unaffected embryos are then transferred to the uterus.

Pre-implantation genetic screening

Chromosomal aneuploidy in human embryos is one of the commonest reasons for failure of implantation following IVF. These aneuploidies may be age-related aneuploidies in the egg (meiotic) or related to early cell division in the embryo (post-zygotic). Pre-implantation genetic screening is the use of PGD techniques to detect these aneuploidies in an attempt to ameliorate the impact of female age on IVF. Initial indications for the technique were advanced maternal age, recurrent IVF failure at the

stage of implantation, previous aneuploid pregnancies and recurrent miscarriage. The technique originally used multicolour fluorescence *in situ* hybridization and was controversial not because of its attractive self-evident hypothesis but its lack of a robust evidence base. Eventually, following prospective randomized controlled trials it was shown to be ineffective. Advances such as whole genome amplification, CGH and NGS have led to a renewed interest in PGS and these novel exciting approaches are currently under evaluation.

Surgical sperm retrieval

In cases where there is either azoospermia or necrozoospermia, surgical sperm retrieval can be performed to obtain sperm directly from the epididymus (MESA) or the testis (TESE or PESA). A biopsy should always be taken from each testis and sent to histopathology, as carcinoma *in situ* can be found in approximately 1% of subfertile men.

These techniques can be performed under either local anaesthetic or a light general anaesthetic. The patient should be screened for cystic fibrosis and karyotyping prior to the procedure. There are major chromosomal abnormalities in just over 2% of infertile men, which is three times the normal incidence. In the case of azoospermia this increases to over 15%. If semen results are in the normal range, then chromosomal abnormalities are significantly lower. An FSH level is also beneficial: if in the normal range, then the chance of obtaining usable spermatozoa is much higher (around 90% if testicular volumes are normal); if FSH is markedly raised, then the chance is significantly lower (less than 10% if testicular volumes are reduced).

Any sperm obtained through these techniques is then cryopreserved for future use. The sperm can be used fresh if the operation is timed to coincide with the oocyte retrieval on the female side. ICSI has to be used in all cases of surgical sperm retrieval as there are inadequate motile sperm for normal fertilization.

Donor sperm

If no usable sperm are obtained from surgical sperm retrieval or from ejaculation, then the use of donor sperm is generally offered. Donor sperm is obtained by masturbation from healthy screened donors. All donor sperm in the UK has to be quarantined, and then the donor screened again. Sperm can then only be released for use after both sets of screening have been found to be negative.

Indications

- Azoospermia.
- Carriers of severe genetic disease.
- Lesbian/single women.

Use

Donor sperm used to be inseminated around the cervix using an unprepared specimen close to what was thought to be the fertile time. Now a prepared sample of sperm is used and inseminated directly into the uterine cavity as part of an IUI programme. The patient has the usual screening tests, including a test of tubal patency, and as long as the menstrual cycle is regular, the cycle is monitored and at the appropriate time, around ovulation, the prepared sample is inseminated directly into the cavity. If the patient has irregular cycles or unstimulated IUI has been unsuccessful, then stimulated IUI can be performed and success rates are generally higher. If the fallopian tubes are severely damaged or blocked, then the donor sperm has to be utilized with techniques such as IVF. Success rates are almost entirely dependent on the age of the patient.

Complications of assisted conception

Multiple births

The most common complication of assisted conception is that of multiple births. Of all the patients that have become pregnant through IVF programmes, approximately 24% have twins when two or three embryos are transferred. Triplet rates vary depending on the percentage of embryo transfers that are three embryos or more. In the UK a maximum of three embryos can be transferred, but only under exceptional circumstances or if the patient is 40 years old or greater. The majority of embryo transfers in the UK at present are two-embryo transfers. Even with a twin pregnancy, the risk of cerebral palsy is up to eight times greater than that of a singleton pregnancy. In triplet pregnancies, the rate can be as high as 47 times greater. The offspring also are at risk of all the other multiple sequelae of prematurity [18].

To try to reduce the rate of multiple births, the HFEA has made strong recommendations to move towards elective single embryo transfers. As clinical and laboratory techniques improve, this should maintain acceptable pregnancy rates and reduce the twin rate to monozygotic twins only. Indeed in some Scandinavian countries, if the patient is 35 years old or under, then elective single embryo transfer is the only route allowed. One embryo is transferred fresh and all the other embryos are frozen, and the patient undergoes repeated single embryo transfer until the desired outcome or all the embryos are used up. Although there is increasing evidence to support the advocacy of elective single

embryo transfer, it can be difficult to persuade patients as many see a twin pregnancy as a desirable outcome. There has been tremendous progress in reducing the incidence of multiple pregnancy through elective single embryo transfer strategies.

Ovarian hyperstimulation syndrome

Ovarian hyperstimulation syndrome is an iatrogenic condition that can occur in any IVF cycle, but usually is only mild to moderate. It is characterized by an excessive ovarian response resulting in multiple follicular growth and large numbers of eggs collected. Severe OHSS can be life-threatening and is associated with intravascular fluid depletion and thrombosis, ascites and pleural effusion. It generally occurs in specific at-risk groups, in particular young patients who have polycystic ovaries. In these situations the starting dose of gonadotrophins should be lowered to take account of the increased sensitivity of the polycystic ovaries. Even in the best centres with adequate monitoring there can be a surprisingly brisk ovarian response and the ovaries can hyperstimulate. In these situations several options are available. The cycle can be abandoned and then restarted at a lower dose or the eggs collected, fertilized and all the embryos electively frozen as severe hyperstimulation tends to be most serious in patients who become pregnant from a fresh transfer. Lastly, if the risks have been fully considered and still thought acceptable, the embryos can be transferred and the patient very carefully monitored. If OHSS develops, admission to hospital is essential for monitoring fluid balance and plasma protein levels. Human albumin solution should be given if hypoproteinaemia develops. If the patient develops tense ascites, it can be drained on a daily basis, limited to 1 L in multiple aliquots, as this often gives great relief and increases urinary output but avoids abrupt hypoproteinaemia. If the patient develops pleural effusions, these also can be tapped, although draining the ascites helps these as well. Because of the increased risk of thromboembolism, patients should also receive thromboprophylaxis in the form of antithrombotic stockings and low-molecular-weight heparin daily. Generally the condition is self-limiting but the patient should be kept in hospital and closely monitored until the OHSS has resolved. The condition does not appear to adversely affect the fetus and the subsequent pregnancy is generally successful. On the rare occasions where the situation is deteriorating and the patient's life is at risk, the pregnancy may need to be terminated. New strategies involving the use of GnRH antagonist protocols, GnRH agonist triggers and elective cryopreservation of embryos have now made severe OHSS a very rare occurrence.

Ectopic pregnancy

Ectopic pregnancy can occur with any of the assisted reproductive techniques, and not only in patients with tubal disease – any patient undergoing any form of assisted conception is at a greater risk. In IVF programmes the generally accepted rate is between 2 and 5%, even though the embryos are transferred directly into the uterine cavity. This may be due to uterine contractions and it is probable that embryos move into the fallopian tubes at some stage but return to the uterine cavity. Patients successfully pregnant following assisted conception should always be offered an early scan to ensure that the pregnancy is intrauterine. If the pregnancy is found to be extrauterine, then the full range of treatment options should be discussed with the patient. With the increasing number of salpingectomies performed for hydrosalpinges, it is hoped that the incidence of ectopic pregnancy with IVF will reduce.

Transvaginal oocyte retrieval

There are always accepted risks of complications from ultrasound-guided oocyte retrieval, and these can range from infection of the ovaries causing ovarian abscess, through to damage to the bowel. These are generally quoted at 1% or less, and all patients should be counselled about them prior to starting their treatment [19].

Summary

More than 5 million babies have now been born following IVF. Assisted conception treatments continue to grow internationally and in some developed countries they now account for more than 2% of live births. There has been a steady improvement in success rates due to scientific advances, despite the increased age of patients accessing treatment. IVF treatments are becoming safer and there have been significant reductions in the rate of OHSS, principally through the introduction of GNRH agonist triggers. Multiple pregnancy rates following IVF are also reducing through the use of elective single embryo transfer. Cryopreservation is proving to be an increasingly important part of assisted conception treatment, with fertility preservation becoming ever more popular for medical and non-medical reasons as oocyte vitrification techniques improve.

Pelvic Pain

53

Endometriosis

Neil P. Johnson[1,2,3]

[1] *Robinson Research Institute, University of Adelaide, Adelaide, Australia*
[2] *University of Auckland and Repromed Auckland and Auckland Gynaecology Group, Auckland, New Zealand*
[3] *World Entometriosis Society (2017–2020)*

The contemporary definition of endometriosisis is an inflammatory disease associated with pelvic pain or infertility that is characterized by lesions of endometrial-like tissue outside the uterus [1]. It is thus more than the presence of endometrial glands and stroma outside the uterus, the experience of pelvic pain or infertility by women with the disease being the important defining features. It is preferable to take a patient-centred approach to endometriosis, with a focus on patient-centred outcomes, rather than the lesion-based approach that has been the hallmark of much clinical research in recent decades.

Endometriosis affects approximately 176 million women of reproductive age worldwide [2]. While its underlying cause is uncertain, it is likely to be multifactorial including genetic factors with epigenetic influences, and perhaps promoted through environmental exposures [3]. Endometriosis has elements of a pain syndrome with central neurological sensitization [4], and is a proliferative, oestrogen-dependent disorder with growing evidence of progesterone resistance [4]. There is overlap with other conditions characterized by pelvic/abdominal pain and infertility. Some symptomatic women with pelvic pain who do not have diagnosed endometriosis may benefit from similar treatments.

Epidemiology

Aetiology

The oldest proposal for the formation of endometriosis is Sampson's theory of *retrograde menstruation* [5] or, more aptly, retrograde passage and implantation of endometrial tissue. Menstrual material containing viable cells is transported into the peritoneal cavity in a retrograde direction along the fallopian tubes and the refluxed endometrium then implants onto the surface of exposed tissues, principally the peritoneum. The amount of menstrual backflow seems important as higher prevalence rates occur in women with increased menstrual exposure due to (i) obstructed outflow associated with Müllerian anomalies, (ii) short menstrual cycles, (iii) increased duration of bleeding, and (iv) decreased parity [6]. In addition, endometriosis is found more commonly on the left side of the pelvis, thought to be due to the cleft created by the sigmoid colon's peritoneal reflections. However, Sampson's theory does not explain all endometriosis since it can occur before menarche, in women with amenorrhoea, despite menstrual suppression, at the umbilicus, and (incredibly rarely) in men. Hence the theory of *coelomic metaplasia*, the pluripotential of coelomic epithelium to develop not only into the more appropriate normal tissue but also, through a programming defect, into endometriotic tissue. Furthermore, despite the ubiquitous occurrence of retrograde menstruation, which gynaecologists often view at the time of laparoscopy during menses, endometriosis occurs only in a minority of women, and this is explained by the third theory, the contribution of *immunologic surveillance defects* (which also explains the association of endometriosis with other autoimmune diseases). The expression of factors such as cell adhesion molecules, proteolytic enzymes and cytokines affecting the adherence, implantation and proliferation of tissue within the peritoneal cavity may differ between women, as may clearance of endometrial cells from the pelvis, and altered systemic humoral immunity (altered B-cell function and antibody production) has also been implicated. It is unclear whether such abnormalities are truly a cause or a result of the disease. Finally, *embolic transport* of endometrial cells through the blood and lymphatic stream may contribute to the very rare

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

occurrences of endometriosis at sites distant from the pelvis, including lungs, brain and nasal tissues (responsible for the rare case reports, so loved by journal editors, of catamenial pneumothorax and haemoptysis, catamenial epilepsy and catamenial epistaxis).

Risk factors include age, increased peripheral body fat and greater exposure to menstruation (short cycles, long duration of menses and reduced parity), whereas smoking, exercise and oral contraceptive use (current and recent) may be protective [6]. However, there is no evidence that the natural history of the disease can be influenced by controlling these factors. There is clear genetic predisposition: endometriosis is six to nine times more common in the first-degree relatives of affected women than in controls; and in an analysis of more than 3000 Australian twin pairs, over 50% of the variance of the latent liability to the disease was attributable to additive genetic influences [7]. Stage 3–4 disease has a stronger genetic linkage than stage 1–2 disease [8]. Endometriosis is inherited as a complex genetic trait, similar to diabetes or asthma, meaning that a number of genes interact to confer disease susceptibility, but the phenotype probably only emerges in the presence of environmental risk factors. (Other than the known risk factors outlined above, specific promoting environmental agents have proven elusive. One of the most appealing environmental exposure theories, that the environmental pollutant dioxin might be an underlying cause of the disease [9], was ultimately difficult to confirm.) Genome-wide association studies (GWAS) [8,10–12] have confirmed genetic associations and nine genome-wide significant genetic susceptibility loci have been reported in at least one dataset. However, there is no indication of high-risk mutations, such as the *BRCA* mutation in breast cancer. The logarithm of the odds (LOD) score for the genetic loci on chromosome 7 [13] and chromosome 10 [14] is between 3 and 4, compared with the LOD score of over 20 for the *BRCA1* gene. The currently recognized nine endometriosis gemetic loci explain only 3.5% of the heritability of endometriosis, compared with the *BRCA1* gene which is considered to account for 60–70% of cases of familial breast cancer.

Prevalence

The prevalence is estimated to be 8–10% in women in the reproductive years [6]. Reported rates of endometriosis have long been recognized to be highly variable in different populations of women (Summary box 53.1).

Summary box 53.1

Prevalence rates at laparoscopy for different indications

	Number of studies	Number of patients	Number with disease	Percent with disease (range)	Percent with stage I–II disease (range)
Pelvic pain	15	2 400	688	24.5 (4.5–62.1)	69.9 (61.0–100)
Infertility	32	14 971	2812	19.6 (2.1–78.0)	65.6 (16.3–95.0)
Sterilization	13	10 634	499	4.1 (0.7–43.0)	91.7 (20.0–100)

Natural history of endometriosis and associated comorbidities

Whilst endometriosis occurs most commonly in the reproductive years, it should also be considered in adolescents with suggestive symptoms; in fact most women with endometriosis date the onset of symptoms to their teens [15]. Women with endometriosis appear to have a higher risk of obstetric complications, including preterm delivery, antepartum haemorrhage, pre-eclampsia and need for caesarean section, with rare occurrences of intra-abdominal bleeding from endometriotic lesions requiring urgent surgery [1]. Even though 97% of women with endometriosis become pain-free after menopause [16], symptoms of endometriosis may also persist after natural or surgical menopause. If hormone replacement treatment (HRT) is required for women with a history of endometriosis, it is wise to use a combined oestrogen/progestin preparation. Evidence is emerging regarding comorbidity for women with endometriosis. There may be subtle associations with ovarian and breast cancers, cutaneous melanoma, asthma and some autoimmune, cardiovascular and atopic diseases, and women with endometriosis appear to be at decreased risk of cervical cancer [17]. Endometriosis has been recently shown to have a significant association with coronary heart disease (relative risk, RR 1.62, 95% CI 1.39–1.89) [18]. There is an association between endometriosis and clear-cell,

low-grade serous and endometrioid ovarian cancer [19], but the overall risk of ovarian cancer among women with endometriosis remains low, with a relative risk ranging from 1.3 to 1.9 [20]. This equates with an increased lifetime risk of ovarian cancer of no more than 1 in 100, which is not considered sufficient to mandate routine ovarian cancer screening for women with a history of endometriosis. Much more rarely, endometriosis may present as an invasive disease while remaining histologically benign, with ascites, sometimes even pleural effusions, and invasive lesions affecting not only the pelvis but also the diaphragm, bowel and abdominal side-walls, and thus may be impossible to distinguish clinically and on imaging from intra-abdominal malignancy.

Endometriosis phenotypes at laparoscopy

Although a stronger focus on the symptoms experienced by women and their outcomes is currently needed, it is also important to retain an understanding of endometriosis lesions, as this features prominently in the literature. It is also of practical importance, as endometriotic lesions that are not absolutely typical often remain unrecognized by less experienced laparoscopists (Fig. 53.1).

Peritoneal (or typical) endometriosis

Peritoneal endometriosis comprises superficial lesions scattered over the peritoneal, serosal and ovarian surfaces. The appearance has been described as 'powder-burn' or 'gunshot' deposits.

Cystic ovarian endometriosis (endometriomas)

Endometriomas develop as cystic lesions within the ovary, classically forming 'chocolate cysts' due to the degradation of blood over time to a thick haemosiderin-rich fluid. Several variants on the implantation and metaplasia theories have been proposed to account for ovarian endometriomas. Thus, it has been suggested that superficial lesions on the ovarian cortex become inverted and invaginated, and that endometriomas are derived from functional ovarian cysts or metaplasia of the coelomic epithelium covering the ovary. Endometriomas have features in common with neoplasia such as clonal proliferation, which is consistent with the endometriosis disease theory. They are statistically associated with subtypes of ovarian malignancy, such as endometrioid and clear-cell carcinoma. However, it still remains uncertain whether such cancers arise from malignant transformation of benign endometriotic tissue.

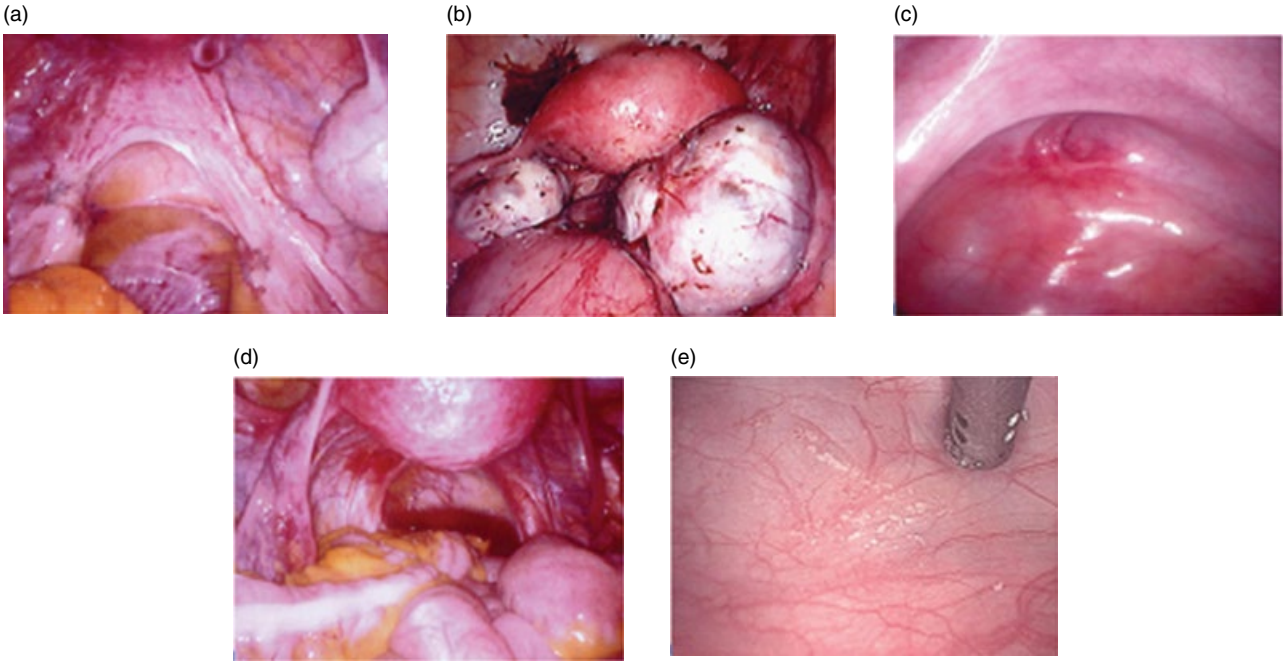

Fig. 53.1 Laparoscopic appearances of different endometriosis phenotypes: (a) peritoneal (typical) endometriosis adjacent to deep endometriosis of the left uterosacral ligament; (b) endometrioma of the right ovary; (c) peritoneal pocket in the anterior pouch of Douglas; (d) uterine adenomyosis and flame endometriotic lesion of left broad ligament; (e) subtle endometriosis vesicular lesions of the peritoneum. Images (a), (b), (d) and (e) kindly contributed by Dr Michael East, Gynaecologist, Oxford Women's Health, Christchurch, New Zealand. (*See also colour plate 53.1*)

Deep endometriosis

Now defined as lesions extending deeper than 5 mm under the peritoneal surface or those involving or distorting bowel, bladder, ureter or vagina [21], recognition of deep endometriosis may pose substantial difficulties for the inexperienced surgeon. Donnez *et al.* [22] suggested that these are a form of adenomyosis arising in Müllerian rests in the rectovaginal septum, and it has been proposed that deep endometriosis should be redefined as adenomyosis externa on pathological grounds [23]. However, deep endometriosis can be more widespread than this location. Numerous subtypes of deep endometriosis have even be described (Fig. 53.2), but such subclassifications become esoteric, as there is little consensus about the best treatment approaches for deep endometriosis [1] and more research focus needs to go into defining subtypes that actually predict response to different treatments, both surgical and medical.

Other phenotypes

Koninckx *et al.* [24] added three more lesion phenotypes to the three traditionally recognized phenotypes described. These were adenomyosis, peritoneal pocket lesions and subtle endometriosis. *Adenomyosis* is characterized by ectopically placed endometrial glands and stroma within the wall of the uterus itself, usually distributed through the endometrium and sometimes forming discrete myomas known as ademomyomas. *Peritoneal pocket lesions* were formerly assumed to reflect 'scarring from old endometriosis' but excision of such lesions usually reveals active endometriosis in the pocket margins. More recently recognized *subtle or atypical endometriosis* comprises red implants, polypoid lesions, and serous or clear vesicles. It remains unclear, however, whether these subtle lesions should be considered early disease, or whether they are transient physiological events without any clinical significance [25]. The 'most subtle' of all endometriotic lesions would be microscopic endometriosis [26], in other words the histological finding of endometriosis in macroscopically normal peritoneum. The significance of microscopic endometriosis is unclear but it seems likely that most endometriotic lesions would need to pass through this stage as they progress to macroscopic lesions.

Classification systems

The World Endometriosis Society consensus [21] identified three classification systems of value (from many proposed), although these still have limitations. There is an argument that all women with endometriosis undergoing surgery should have a Revised American Society of Reproductive Medicine (r-ASRM) score and stage completed [27], women with deep endometriosis should have an Enzian classification completed [28], and women for whom fertility is a future concern should have an Endometriosis Fertility Index (EFI) completed [29], and documented in the medical/surgical records (Fig. 53.3); that is, until better classification systems have been validated.

The most widely used classification is the r-ASRM classification [27], in which points are allocated for endometriotic lesions, periovarian adhesions and pouch of Douglas obliteration (Fig. 53.3a). The total score is then used to describe the disease as minimal (stage I), mild (stage II), moderate (stage III) or severe (stage IV). Stages I and II consist mainly of superficial lesions, and stages III and IV of endometriomas. The limitations of the r-ASRM classification system are that it does not describe deep endometriosis adequately, has poor correlation with fertility outcomes and very poor correlation with pain symptoms and quality of life, gives poor prognostic information, and has poor predictive accuracy with respect to treatment outcomes [21]. The main forces that perpetuate the r-ASRM classification system are its longevity, its widespread clinical use, its prevalence in the literature describing the operative appearance of endometriosis, and its incorporation into other classification systems of potentially greater value.

If the r-ASRM classification is to be used, the Enzian classification system [28] should be employed when deep endometriosis is also present to give a complete description of the operative findings (Fig. 53.3b). Enzian may also be used preoperatively based on findings on clinical examination, transvaginal ultrasound and MRI in order to assist planning of surgery by predicting the extent of deep endometriosis and the time required for surgery. However, the Enzian classification also has poor correlation with symptoms and infertility, and limited prognostic value for the

Endometriosis fertility index surgery form.

ENDOMETRIOSIS FERTILITY INDEX (EFI) SURGERY FORM

LEAST FUNCTION (LF) SCORE AT CONCLUSION OF SURGERY

Score	Description		Left	Right
4	= Normal	Fallopian Tube		
3	= Mild Dysfunction			
2	= Moderate Dysfunction	Fimbria		
1	= Severe Dysfunction			
0	= Absent or Nonfunctional	Ovary		

To calculate the LF score, add together the lowest score for the left side and the lowest score for the right side. If an ovary is absent on one side, the LF score is obtained by doubling the lowest score on the side with the ovary.

Lowest Score: Left + Right = LF Score

ENDOMETRIOSIS FERTILITY INDEX (EFI)

Historical Factors			Surgical Factors		
Factor	Description	Points	Factor	Description	Points
Age			LF Score		
	If age is ≤ 35 years	2		If LF Score = 7 to 8 (high score)	3
	If age is 36 to 39 years	1		If LF Score = 4 to 6 (moderate score)	2
	If age is ≥ 40 years	0		If LF Score = 1 to 3 (low score)	0
Years Infertile			AFS Endometriosis Score		
	If years infertile is ≤ 3	2		If AFS Endometriosis Lesion Score is < 16	1
	If years infertile is > 3	0		If AFS Endometriosis Lesion Score is ≥ 16	0
Prior Pregnancy			AFS Total Score		
	If there is a history of a prior pregnancy	1		If AFS total score is < 71	1
	If there is no history of prior pregnancy	0		If AFS total score is ≥ 71	0

course of symptoms, quality of life and infertility, with an uncertain capacity to detect a woman's likely response to treatment for pain and/or infertility [21].

Adamson and Pasta [29] developed the EFI as a simple, robust and validated clinical tool that predicts fertility outcome for women following surgical staging of endometriosis (Fig. 53.3c) and it may have considerable utility in developing treatment plans for infertile women with endometriosis, now with extensive external validation [21]. It would be logical to develop an endometriosis classification system for pain and/or quality of life using a similar methodology to the EFI in order to combine the factors most predictive of pain and quality-of-life outcomes.

Symptoms of endometriosis

Endometriosis-associated pain symptoms

Severe dysmenorrhoea, deep dyspareunia, chronic pelvic pain, ovulation pain, cyclical or perimenstrual

symptoms – often bowel or bladder related, causing dyschezia or dysuria – with or without abnormal bleeding, and chronic fatigue have all been associated with endometriosis. Dyspareunia is the symptom that women often find most distressing and which usually has the biggest negative impact on their quality of life [30]. This is probably because, whilst other symptoms such dysmenorrhoea occur only for a limited time each cycle and are thus more manageable, dyspareunia can be present throughout the cycle and it may also have profound effects on a woman's relationship with her partner. The predictive value of any single symptom or set of symptoms is limited as each symptom can have other gynaecological or non-gynaecological causes. Interestingly, the symptom complex that most accurately predicts endometriosis from a woman's medical history is menstrual dyschezia and a history of benign ovarian cysts [31]. There is little correlation between disease stage and the type, nature and severity of pain symptoms, underscoring that the current classification systems are inadequate for women with pain related to endometriosis. It has long been accepted that typical lesions can cause moderate pain (although around half of all women with such lesions are pain-free), ovarian endometriomas tend to be associated with more severe pain (even though 10–20% of women are pain-free), and deep endometriosis can be associated with very severe pain (although, again, women sometimes have no pain at all). The association of other endometriosis phenotypes, including subtle lesions, with pain is less clear. The suggested causes for endometriosis-related pain include tissue damage and distorted anatomy, peritoneal inflammation, activation of nociceptors, and nerve irritation/invasion in deep endometriosis. If pain is persistent, it may become chronic and, through central sensitization, develop the hallmarks of a chronic pain syndrome [32]. Pain symptoms are usually assessed in clinical trials using a four-point verbal rating scale for three symptoms (dysmenorrhoea, dyspareunia and pelvic pain) and two examination signs (pelvic tenderness and induration). More recently, health-related quality of life has also been evaluated, as traditional outcome measures may not adequately assess what the patient considers important. The most useful patient-generated, disease-specific tool is the Endometriosis Health Profile (EHP)-30, a 30-item questionnaire that covers five dimensions: pain, control and powerlessness, emotional well-being, social support and self-image [33].

Endometriosis-associated subfertility

Endometriosis is associated with subfertility. The infertility associated with the anatomical distortion of fallopian tubes and ovaries, ovarian damage through endometrioma formation and tubal damage consequent on endometriosis is obvious. Most women do not have such severe endometriosis, but there is even an association between minimal/mild endometriosis and subfertility, with cohorts showing that fecundity is approximately halved and time to pregnancy doubled for women with these so-called milder forms of endometriosis [34,35]. Even women undergoing medically assisted reproduction, including *in vitro* fertilization (IVF), have poorer outcomes if they have endometriosis [36] or adenomyosis [37]. Numerous mechanisms have been proposed, including negative effects on ovarian reserve, ovulation dysfunction, sperm survival in the female genital tract and egg quality (and thus embryo quality). Potentially subtle effects on egg quality have variously been ascribed to abnormal folliculogenesis: the follicular fluid of women with endometriosis has been found to have increased levels of interleukin (IL)-6 and progesterone, and decreased levels of cortisol and insulin-like growth factor binding protein (IGFBP)-1; and granulosa cells express increased levels of tumour necrosis factor (TNF)-α, soluble Fas ligand and corresponding apoptotic activity. Intraperitoneal inflammation is also a feature of endometriosis, including evidence of increased phagocytosis of sperm by peritoneal macrophages, as well as inflammatory, proteolytic and angiogenic activity of the peritoneum and peritoneal fluid, involving IL-6, other growth factors (including vascular endothelial growth factors), cytokines and haptoglobins. Other proposed mechanisms have included reduced sexual frequency due to dyspareunia, luteinized unruptured follicle syndrome, luteal insufficiency and recurrent miscarriage. Whilst traditionally the biggest negative impact of endometriosis on a woman's fertility was thought to be mediated through egg quality, it is becoming more apparent that endometrial dysfunction, with the possibility of reduced endometrial receptivity, also seems likely. Women with endometriosis have reduced expression of integrins, the key receptivity molecules, in their endometrium at the time of the implantation window; they also overexpress osteopontin, a ligand that binds integrins.

Diagnosis

Diagnostic delay

The average delay of around a decade between symptom onset and a definitive diagnosis is well recognized. The key to avoiding diagnostic delay is improved education and awareness. This education and a willingness to consider endometriosis as a diagnosis extends not just to girls and young women and their families, but to

health professionals in primary care as well as gynaecologists. In the past, even the gynaecological community has been guilty of paternalistic attitudes regarding menstrual health and endometriosis. While a definitive laparoscopic diagnosis carries great importance for many women, many others would prefer to avoid a laparoscopic procedure if possible. Although a diagnosis is important, it is not a key end-point and can be viewed as an interim stage for a woman to regain wellness. What is crucial is that a possible diagnosis of endometriosis is considered at an early stage and that the woman (or adolescent) is offered appropriate management with that possibility in mind.

History and clinical examination

Making a diagnosis on the basis of symptoms alone is difficult as the presentation is so variable and other conditions such as irritable bowel syndrome, pelvic inflammation and pelvic congestion syndrome mimic endometriosis. Eliciting pelvic tenderness, a fixed retroverted uterus, tender uterosacral ligaments or enlarged ovaries on examination is suggestive of endometriosis, although examination findings can be normal. The diagnosis is likely if nodules are palpable in the uterosacral ligaments and pouch of Douglas, and is confirmed if lesions (which can be biopsied) are visualized on vaginal speculum examination.

Laparoscopy

Laparoscopic visualization of endometriotic lesions has long been held as the gold standard for diagnostic purposes, and this remains the case. However, Wykes *et al*. [38] showed in a systematic review including four studies with a total of 433 participants that, when compared with histological evaluation of visualized lesions, laparoscopic visualization alone has limited accuracy (94% sensitivity and 79% specificity). Histological confirmation of lesions seen at laparoscopy is therefore ideal, and mandatory if deep endometriosis or an endometrioma is present. The entire pelvis should be inspected systematically, and the findings documented in detail, preferably with the aid of standardized laparoscopic photographs or a video recording [39]. Whilst it has long been considered best practice to surgically remove endometriosis at the time of diagnostic laparoscopy (provided that adequate consent has been obtained and the surgeon's expertise is sufficient to deal with the extent of endometriosis diagnosed), Vercellini *et al*. [40] have made a yet stronger call to avoid 'low value care' (meaning interventions with uncertain benefits and/or defined harms, or whose effectiveness is comparable with less expensive alternatives). Hence they have argued that the concept of 'diagnostic laparoscopy' should disappear, with laparoscopy being reserved for those women likely to benefit from laparoscopic removal of their endometriosis.

Low-invasive tests

A low-invasive diagnostic test for endometriosis, through imaging or biomarkers (in urine, blood, endometrium or other body fluids or tissues) or some combination of these, has long been sought. This is partly related to the recognition that not all women who might have endometriosis will have a laparoscopy. In low-resource settings, access to laparoscopy may not be feasible. Even in developed countries, the availability of gynaecologists in relation to the number of women with endometriosis means that not all women with endometriosis can have a laparoscopic procedure, while some women elect to avoid laparoscopy. The concept of avoiding low-value care is inextricably interlinked to the aspiration of an accurate and reliable method of diagnosing endometriosis non-surgically.

Until recently, there was a dogma that laparoscopy was the only acceptable accurate method of diagnosing endometriosis and that imaging and biomarker tests were insufficiently accurate. In the case of many low-invasive tests this remains true, but we now have a comprehensive set of systematic reviews of low-invasive diagnostic tests for endometriosis [41–45]. Summary box 53.2 summarizes the evidence regarding the potential value of the low-invasive tests. A low-invasive diagnostic test might be considered suitable as a replacement test for laparoscopy if it equates to the accuracy attained by laparoscopic visualization itself (≥94% sensitivity and ≥79% specificity). Other tests might have utility as triage tests: those with very high sensitivity which, if negative, rule out endometriosis (so-called SnOUT triage tests); or those with high specificity that, if positive, can raise the suspicion of, or rule in, endometriosis (so-called SpIN triage tests).

Imaging tests have shown promise in diagnosing certain subtypes of endometriosis, such as endometriomas and deep endometriosis, and in mapping deep endometriosis to various sites (Summary box 53.2), although do not prove so accurate in making the actual diagnosis of endometriosis. Regarding biomarkers (measured in urine, blood and endometrial tissue), the accuracy of any one test has not been found to be sufficiently accurate to be a reasonable replacement, or even triage, diagnostic test. This is also true for the most widely used biomarker to date, serum CA125. The detection of endometrial nerve fibre antigens (protein gene product, PGP-9.5) showed promise as a replacement test in most studies but could not be reliably detected in all settings.

Summary box 53.2

Summary of evidence for low-invasive diagnostic tests for endometriosis [41–45].

	Candidate replacement tests	Candidate SnOUT triage tests	Candidate SpIN triage tests
Imaging	MRI for endometriomas, deep endometriosis and mapping deep endometriosis to various sites Multidetector CT enema for rectosigmoid and other bowel endometriosis*	–	Transvaginal ultrasound for endometriomas, deep endometriosis and mapping deep endometriosis to various sites (and almost for endometriosis) MRI for pouch of Douglas and rectosigmoid endometriosis Transrectal ultrasound for rectosigmoid endometriosis
Biomarkers			
Urine	–	–	–
Blood	–	–	–
Endometrium	PGP9.5 for endometriosis (but reliability of detection not confirmed in all settings)	–	–
Combined tests	Serum IL-6 + endometrial PGP9.5 for endometriosis Vaginal examination and transvaginal ultrasound for rectal endometriosis	–	Urine vitamin D-binding protein level corrected for creatinine (VDBP-Cr) × serum CA-125 (>2755) for pelvic endometriosis History (length of menses) + serum CA-125 (>35 U/mL) + endometrial leucocytes for pelvic endometriosis Transvaginal ultrasound + serum CA-125 or CA-19.9 (at various cut-offs) for ovarian endometrioma Vaginal examination + transvaginal ultrasound for mapping deep endometriosis at various sites

* Despite diagnostic utility, multidetector CT enema is not advised owing to its invasiveness and unacceptable radiation exposure.

The most promising approach for an accurate low-invasive diagnosis appears to be a combination of low-invasive tests. The diagnostic test accuracy research to date suggests utility of the combination of serum IL-6 with endometrial PGP9.5 to diagnose endometriosis, and of the combination of transvaginal ultrasound with serum CA-125 level (at cut-off >35 IU/L) to diagnose endometriomas. It should now be possible to develop a combination of the low-invasive diagnostic tests (including clinical history, examination findings, imaging and/or biomarkers) that most accurately diagnoses endometriosis. This would allow laparoscopy to be reserved for women most likely to benefit from laparoscopic removal of endometriosis.

General treatment issues

Patient participation in the decision-making process is essential, as multiple management options exist and endometriosis is potentially a chronic problem. Choosing which treatment to have will depend on a number of factors (Summary box 53.3). Summarizing how these factors influence decision-making is difficult because each patient is different and the decisions are often complex. Some women with endometriosis require long-term individualized care and their priorities may change over time consequent on the type and severity of their symptoms, the impact of those symptoms, current and future fertility wishes, and lifestyle factors. Hence there is value in an endometriosis centre of excellence, although this framework is now more appropriately considered as a network of expertise [1], as the concentrated locality of all facilities in a single centre is not mandatory. Through this, patients benefit from a multidisciplinary network of experts that typically includes gynaecologists, fertility specialists, gastroenterologists, colorectal surgeons, urologists, physiotherapists, psychologists and nutritionists. Networks of expertise require an adequate case mix with frequency of complex cases, a dedicated theatre team that facilitates management based on the best available knowledge, implemented by professionals with extensive experience and transparent records of outcome data [1]. An important link for a network of expertise is with an endometriosis organization (part of the function of which is a patient support group), which promotes education and information-sharing for women with endometriosis about the condition and its management [1].

Summary box 53.3

Factors influencing choice of treatment

- Woman's age.
- Fertility status.
- Nature of symptoms.
- Severity of disease.
- Previous treatments.
- Priorities and attitudes.
- Resource implications.
- Costs and side-effect profile.
- Risks of treatment.
- Other subfertility factors.
- Intended duration of treatment.
- Best available evidence.

Summary box 53.4

Treatment aims

- What are you treating (disease, symptoms or both)?
- Why are you treating?

Possible reasons to treat

- Improve natural fertility.
- Enhance chances of success at assisted reproductive technology.
- Pain relief as an alternative to surgery.
- Pain relief while awaiting surgery.
- Adjunct to surgery.
- Prophylaxis against disease occurrence.
- Symptom recurrence.

Treatment aims

The treatment aims should be agreed with the patient (Summary box 53.4). For surgery, the intended benefits and the major risks and complications should be explained and documented on the consent form. When medical treatment is initiated, ideal practice would be to document in the medical notes, and/or in a letter to the patient, what options were discussed, why the decision to treat was made, as well as the treatment aims and side effects/risks. Treatments may divided broadly into those designed to improve symptoms (primarily pelvic pain) and those designed to improve fertility. It is important to emphasize that a 30% placebo effect is common in endometriosis studies, hence the need for appropriately controlled randomized controlled trials (RCTs). The information on effective treatments which follows is drawn primarily from analysis of RCTs and systematic reviews of RCTs. Current information that is up to date is readily available in the Cochrane Library (http://www.cochranelibrary.com/), where an overview of all Cochrane reviews of endometriosis treatments is available, including 14 Cochrane reviews that examine pain outcomes and eight reviews that examine fertility outcomes in women with endometriosis [46], as well as key guidelines, such as the European Society for Human Reproduction and Embryology (ESHRE) guideline [47] and consensus statements such as the World Endometriosis Society consensus statement on current management [1].

Treatment for women with symptoms such as pain related to endometriosis

Lifestyle and dietary interventions

Women report positive effects from lifestyle and dietary interventions in managing their endometriosis, but few well-designed studies have examined lifestyle factors. RCTs have not been used to assess counselling and/or psychological support, cognitive–behavioural therapy, different types of exercise including yoga, and exclusion diets (especially gluten-free diets), all reported to have beneficial effects. Even in the context of positive RCT results, it has been difficult to establish consensus around the benefit of fish oil (omega-3 fatty acids) for dysmenorrhea, or of dietary intervention following endometriosis surgery in the form of vitamins, minerals, salts, lactic ferments and fish oil [1].

Empirical medical treatment

Many clinicians support empirical medical treatment of endometriosis either prior to or without laparoscopic confirmation of endometriosis. Time to surgery may delay appropriate treatment, there is a false-negative rate in laparoscopic diagnosis, and surgery is invasive, expensive compared with empirical therapies and carries a risk of morbidity. A full clinical evaluation that includes consideration of other causes of the symptoms and assessment of the disease impact for the individual woman is

required prior to empirical treatment. Management of pelvic pain should not be delayed in order to obtain surgical confirmation of endometriosis. First-line empirical treatment options that should be considered include non-steroidal anti-inflammatory drugs (NSAIDs), other analgesics (paracetamol and opioids, although most clinicians would reserve opioid analgesics for second-line treatment), the combined oral contraceptive pill (OCP), traditional progestins such as medroxyprogesterone acetate and norethisterone, or newer progestins such as dienogest. Second-line medical treatment with gonadotrophin-releasing hormone (GnRH) agonists with add-back HRT, oral GnRH antagonists, the levonorgestrel-releasing intrauterine system (LNG-IUS) or opioid analgesics are sometimes also considered for empirical treatment for women who are not optimally treated with first-line empirical therapy whilst awaiting laparoscopic surgery (and some women successfully treated with second-line empirical medical treatment might not proceed to surgery). It is unclear whether medical treatment prior to laparoscopy might mask the diagnosis by reducing the appearance of endometriotic implants and hence may make endometriosis more difficult to diagnose and treat surgically. It is important to highlight that NSAIDs have important side effects, including peptic ulceration and an adverse impact on ovulation, and that analgesics, particularly opiates, if used inappropriately and without medical monitoring, carry a risk of abuse and/or addiction. All women receiving medical treatment should be carefully monitored for beneficial and harmful effects with regular follow-up consultations [1].

Surgical treatment

Crucial aspects in planning laparoscopic surgery are that surgery should be carried out in the most appropriate setting which can ensure adequate preoperative counselling, appropriate surgical expertise, adequate technical resources, and postoperative support care. Whenever possible, laparoscopic surgery should always be undertaken in preference to laparotomy for improved surgical visualization and for the benefits of speedier postoperative recovery. Laparoscopic surgical removal of endometriosis (through excision and/or ablation of endometriosis) is an effective first-line approach for treating pain related to endometriosis. The odds of overall pain reduction were significantly higher at 6 months following laparoscopic removal of endometriosis compared with diagnostic laparoscopy (OR 6.6, 95% CI 3.3–13.1, three RCTs, $N = 171$, $I^2 = 0\%$) (Fig. 53.4), an impact that was sustained at 12 months [48].

Although RCTs have failed to demonstrate benefit of excision over ablation for most endometriosis, there is unanimous consensus over the recommendation to excise lesions where possible, especially deep endometriotic lesions, which gives a more thorough removal of disease [1,49]. It is also acknowledged that, even after expert removal of endometriosis, there may be a recurrence rate of symptoms and endometriotic lesions that varies from 10 to 55% within 12 months [50], with recurrence affecting approximately 10% of the remaining women each additional year [51]. The risk of requirement for repeat surgery is higher in women younger than 30 years at the time of surgery [52]. First operations tend to produce a better response than subsequent surgical procedures, with pain improvements at 6 months in the region of 83% for first excisional procedures compared with 53% for second procedures [53]. Excessive numbers of repeat laparoscopic procedures should therefore be avoided.

It has been suggested that there may be an increased recurrence rate for surgery undertaken in the luteal phase (through reimplantation of retrograde-passing endometrial tissue at subsequent menses whilst the sites of surgically removed lesions are still healing). However, there remains insufficient evidence to necessitate the planning of surgery for a particular time of the cycle, although surgery in the follicular phase avoids the complicating factor of the presence of a haemorrhagic corpus luteum [1].

There is no place for adding laparoscopic uterine nerve ablation to laparoscopic removal of endometriosis. Although presacral neurectomy might provide benefit for a small number of women with central dysmenorrhoea, the benefits are likely to be outweighed by the potential for harmful effects (including presacral haematoma and dysfunction of bladder and/or bowel) and the technique is not usually recommended.

Laparoscopic excision (cystectomy) for endometriomas reduced the recurrence rate of the symptoms of dysmenorrhoea (OR 0.15, 95% CI 0.06–0.38), dyspareunia (OR 0.08, 95% CI 0.01–0.51) and non-menstrual pelvic pain (OR 0.10, 95% CI 0.02–0.56) compared with laparoscopic ablation (drainage and coagulation) (Fig. 53.5), and was also associated with a reduced rate of recurrence of the endometrioma (OR 0.41, 95% CI 0.18–0.93) [54]. Laparoscopic excision for ovarian endometriomas has therefore been preferred to ablation where possible to minimize recurrence of symptoms and of the endometriomas, although care must be taken to minimize damage to surrounding normal ovarian tissue. Endometrioma surgery is technically difficult and demanding owing to the risks of damaging the vasculature and surrounding ovarian tissue. For women with large endometriomas in whom ovarian reserve is a concern, there may be some value in a multiple-step procedure (with interval surgery that utilizes intervening medical suppressive treatment).

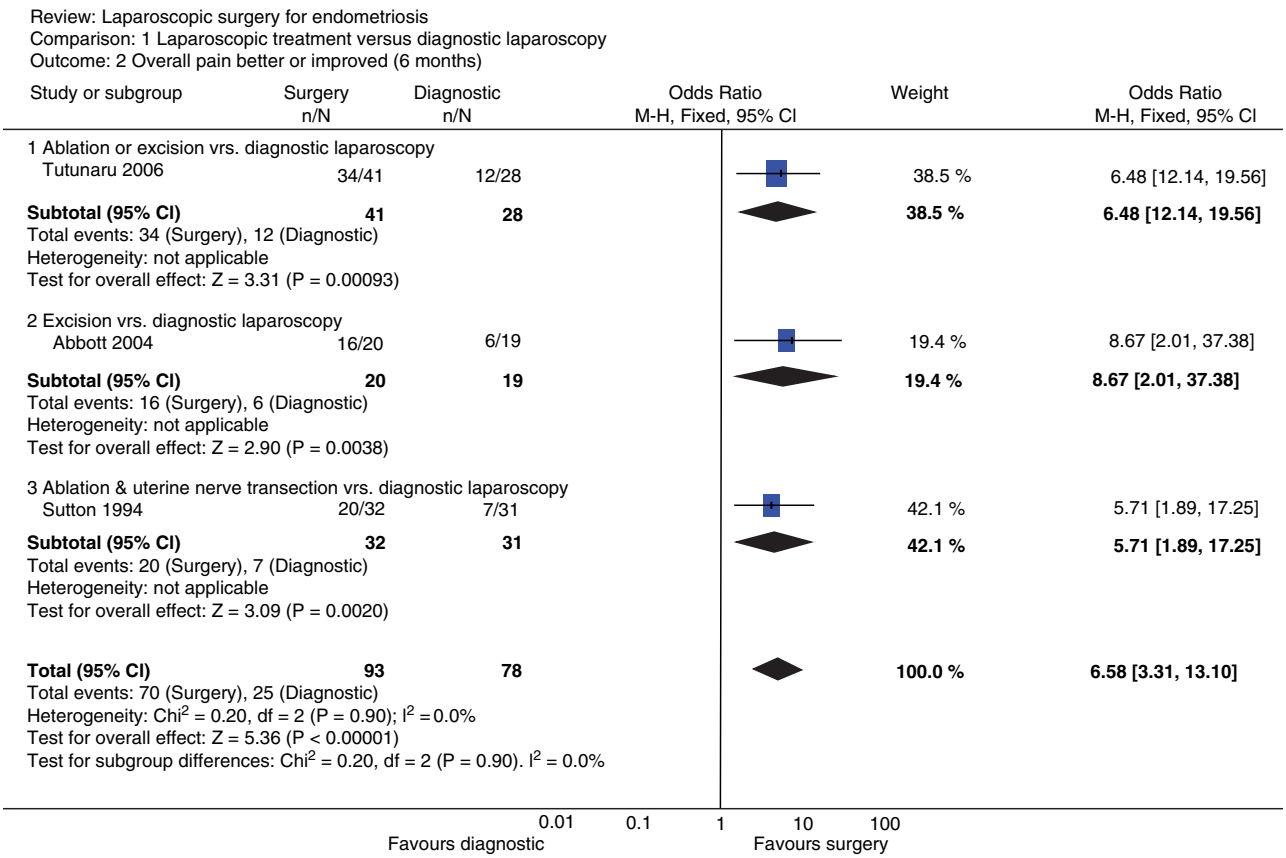

Fig. 53.4 Pain outcomes at 6 months after laparoscopic removal of endometriosis. *Source:* Duffy JM, Arambage K, Correa FJ *et al*. Laparoscopic surgery for endometriosis. *Cochrane Database Syst Rev* 2014;(4):CD011031. Reproduced with permission of John Wiley & Sons.

The OCP reduces the recurrence rate of endometriomas after ovarian cystectomy. Otherwise, evidence does not support the use of short-term preoperative or postoperative medical treatment in association with laparoscopic removal of endometriosis for improving pain outcomes or recurrence rates [1].

Different approaches have been taken in surgery for deep endometriosis. This surgery is among the most challenging in gynaecology. The dilemma is that incomplete resection may impact negatively on symptomatic outcome [55], but that radical interventions increase the risk of major complications such as ureteric and rectal injuries. Evidence is still lacking to guide the best surgical approach to deep endometriosis [1]. If the disease includes bowel endometriosis, the surgical options for the bowel include shaving, disc excision, or segmental excision and re-anastomosis. The low recurrence rates after shaving and disc excision suggest that, in most cases, it is possible to avoid removal of large segments of bowel, as segmental excision and re-anastomosis is associated with the highest complication rates, including post-anastomotic leak with the life-threatening complication of faecal peritonitis. Rather than undertake bowel surgery initially, the optimal approach is to first consider medical treatment. Bowel surgery should only proceed on the basis of shared decision-making after thorough consideration of risks versus benefits, ideally following multidisciplinary consultations that include provision of information for women on potential complications of surgery. Only then should bowel surgery be performed laparoscopically by expert surgeons, avoiding laparotomy whenever possible. What is clear is that highly specialized surgical expertise is required for excision of deep endometriosis and it should be undertaken only in centres of expertise. Evidence is emerging that triage of women due to undergo endometriosis surgery will allow almost all of them to receive appropriate treatment at their first surgical procedure. Triage methods include transvaginal ultrasonography, especially with the emergence of advanced gynaecological ultrasound [56], and MRI [57], which can predict the type of severe endometriosis that may involve ureters, bladder or bowel and which demands high-level surgical expertise.

Debate continues over the role of hysterectomy and of concurrent oophorectomy, with little reliable evidence to inform practice, but if such surgery is undertaken it

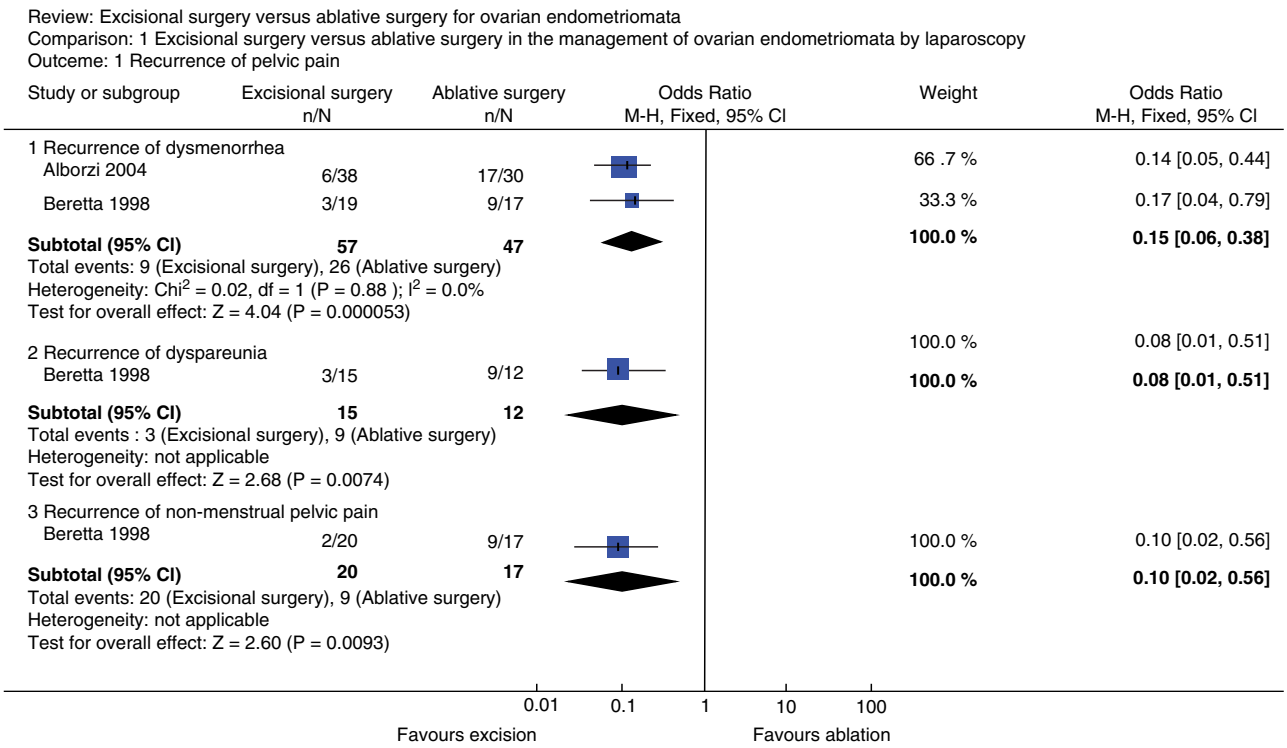

Fig. 53.5 Pain outcomes (dysmenorrhoea, dyspareunia and non-menstrual pelvic pain) following excisional versus ablative surgery for endometriomas. *Source:* Hart RJ, Hickey M, Maouris P, Buckett W. Excisional surgery versus ablative surgery for ovarian endometriomata. *Cochrane Database Syst Rev* 2008;(2):CD004992. Reproduced with permission of John Wiley & Sons.

should be performed laparoscopically where possible. Observational studies have suggested improved pain outcomes for women who undergo hysterectomy for r-ASRM stage IV endometriosis, but this may also be related to associated pathology such as adenomyosis. For young women who have undergone bilateral oophorectomy, it is wise to use HRT to avoid menopause symptoms and prevent loss of bone mass, preferably in a combined regimen including oestrogen and progestin, considering the possibility of unopposed oestrogen reactivating endometriosis that has not been fully removed. There is no evidence to justify delaying the start of HRT [1].

Medical management

Medical treatment may be given routinely as an adjunct to surgery preoperatively or postoperatively (although this is not recommended as discussed under surgical management), as a defined course of treatment remote from surgery, or as a longer-term strategy designed to prevent recurrence of endometriosis or endometriomas [58]. Hormonal treatments typically induce atrophy and/or decidualization of peritoneal deposits by suppressing ovarian function. Endometriomas rarely decrease in size with medical therapy and adhesions will be unaffected. Hypothetically, medical maintenance therapy might be an effective treatment option that could, in some cases, control the denervation and reinnervation changes that are believed to precede central sensitization and the development of a chronic pain syndrome. Whilst use of medical treatments such as OCP may be long term, specific studies are needed to investigate whether medical intervention may prevent development of a chronic pain syndrome. However, most medical agents are only effective for the duration of their use and symptoms often recur after treatment ceases.

As with empirical medical treatment, NSAIDs, other simple analgesics and OCPs can be considered for use as first-line medical treatment of laparoscopically proven endometriosis. Progestins with a proven effect in RCTs and with a specific indication for the treatment of endometriosis, such as medroxyprogesterone acetate, norethisterone and dienogest, can also be considered first-line treatments taking into consideration their different side-effect profiles. It is important to discuss potential side effects with the woman before treatment commences, and careful follow-up is required.

Second-line medical treatments could include GnRH agonists, which should be used with add-back HRT routinely (to alleviate hypo-oestrogenic side effects and prevent the loss of bone mass associated with GnRH agonist treatment), LNG-IUS (which is effective also for many

women with adenomyosis or deep endometriosis), orally active GnRH antagonists (elagolix) [59], depot progestins (although the side-effect profile and thus treatment burden is high), and opioid analgesics. Other possible second-line medical treatments include non-oral combined hormonal contraceptives such as transdermal patches and vaginal rings [60].

Danazol and gestrinone should not be used owing to the high treatment burden of androgenic side effects, other than for women established on these treatments in the absence of side effects for whom other treatments have proven ineffective.

Despite different modes of action, these hormonal medical treatments all appear to relieve symptoms even if deep endometriosis or endometriomas are present. Treatment response tends to be idiosyncratic, with women often responding to some medical treatments and not to others. There are no known markers that predict response to one agent rather than another, so treatment choice usually hinges on acceptability, likelihood of side effects and cost. If one hormonal treatment is ineffective, another may prove effective.

Emerging medical treatments

Preliminary studies have shown value from new orally active GnRH antagonists (relugolix), selective progesterone receptor modulators (ulipristal, mifepristone, asoprisnil and megestrol), melatonin, aromatase inhibitors (anastrozole, fadrozole, formestane, exemestane, letrozole), the thiazolidinedione rosiglitazone, and valproic acid, and further evaluation of these agents is ongoing. For the immunomodulator pentoxifylline and the anti-TNF-α agent infliximab, RCTs have not shown benefit to date. The selective oestrogen receptor modulator raloxifene was not found to be beneficial. As angiogenesis is a crucial activity for the normal processes of the reproductive tract and other organ systems, it is doubtful whether agents used for their anti-angiogenic properties (including cabergoline, endostatin, sirolimus, thalidomide and vascular endothelial growth factor inhibitors) will be useful clinically [1].

Complementary therapies

Complementary therapies may help women to cope better with their endometriosis and its treatment and are supported by some evidence from RCTs. Acupuncture appears to be moderately effective and safe but requires repeated treatments. High-frequency transcutaneous electrical nerve stimulation (TENS) has some effectiveness for short-term pain management. There is limited evidence in favour of Chinese herbal medicine that may be difficult to apply outside of the traditional Chinese medicine setting. For women with dysmenorrhoea only, there is limited evidence of benefit for vitamins B_1 and B_6 (with safety concerns associated with higher doses of vitamin B_6) and magnesium, and topical heat may be effective for low back pain, but there are no studies specifically examining endometriosis [1].

Treatment for women with endometriosis-related infertility

Surgery

The principles of laparoscopic surgery for subfertility are similar to those for other symptoms of endometriosis. Appropriate surgical training is again the key to the best outcomes. It is very important to consider ovarian reserve prior to laparoscopic surgery in the woman experiencing infertility, as evidence is growing that surgical treatment of endometriomas contributes to reduced ovarian reserve. The coexistence of pain will be an important factor to consider that will impact on the decision whether to proceed with surgery, although surgery and assisted reproductive techniques should be considered as complementary strategies.

Laparoscopic surgical removal of endometriosis is recognized as being effective in improving fertility in stage I and II endometriosis. The clinical pregnancy rate was significantly improved following laparoscopic removal of endometriosis compared with diagnostic laparoscopy (OR 1.9, 95% CI 1.3–2.9, three RCTs, $N = 528$, $I^2 = 0\%$) (Fig 53.6), which translated into a significantly increased live-birth rate in meta-analysis of two of these RCTs [48].

There is no RCT evidence to support excision over ablation, but it is recommended to excise lesions where possible, especially deep endometriosis where pain is present [1]. No RCTs have yet assessed whether surgery improves fertility in women with stage III and IV endometriosis and those with deep endometriosis. The functional appearance of the fallopian tubes and ovaries at the end of the laparoscopic procedure, gauged by the EFI, gives prognostic information that is helpful in counselling women postoperatively [29].

Laparoscopic excision (cystectomy) whenever possible for endometriomas greater than 4 cm in diameter improves fertility more than ablation comprising drainage and coagulation (spontaneous pregnancy OR 5.2, 95% CI 2.0–13.3) (Fig 53.7) [52]. However, much care needs to be taken in correct identification of tissue planes and careful dissection of the endometrioma to avoid damaging or removing normal ovarian tissue and thus impacting ovarian reserve. There is now also clear evidence that laparoscopic suturing for haemostasis

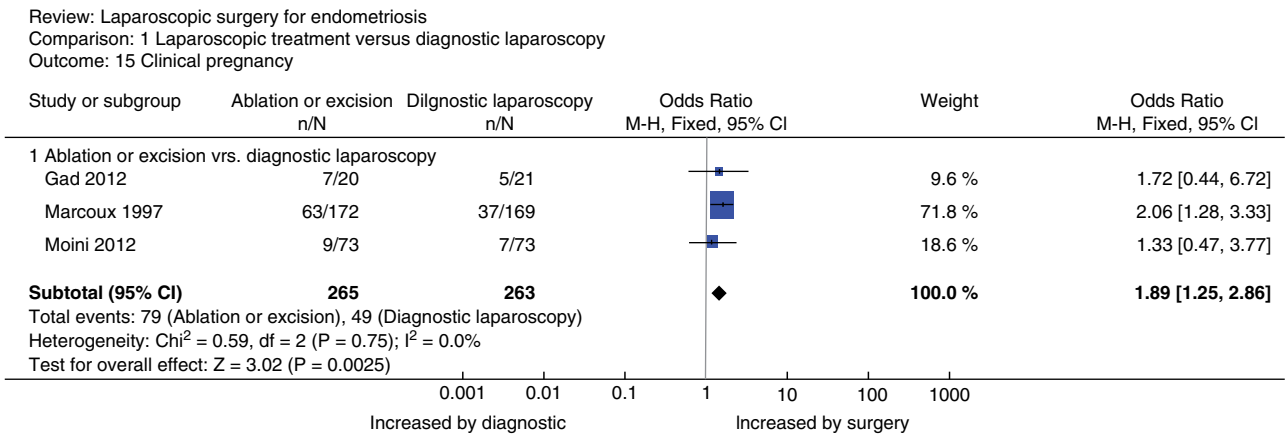

Fig. 53.6 Clinical pregnancy rate after laparoscopic removal of endometriosis. *Source:* Duffy JM, Arambage K, Correa FJ *et al.* Laparoscopic surgery for endometriosis. *Cochrane Database Syst Rev* 2014;(4):CD011031. Reproduced with permission of John Wiley & Sons.

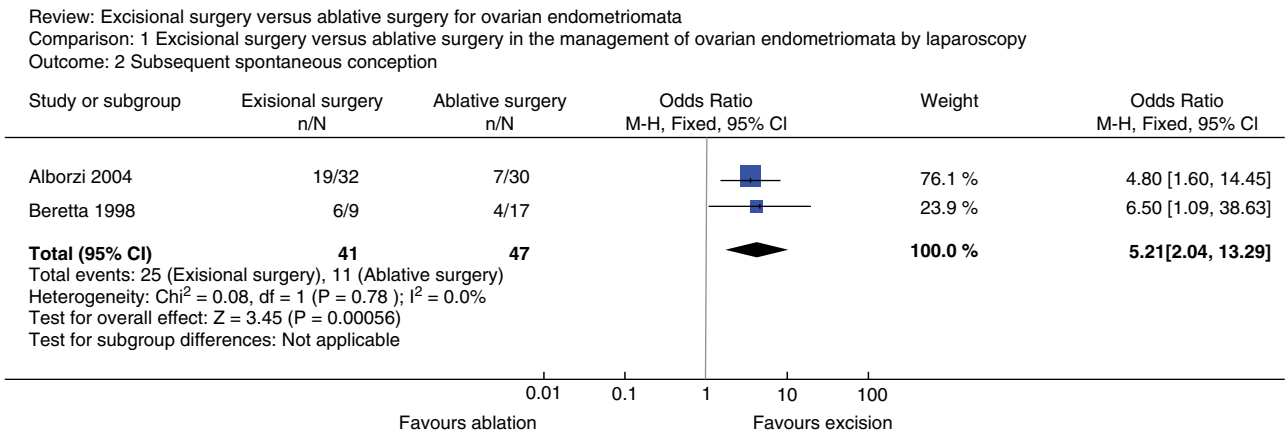

Fig. 53.7 Pregnancy rates following excisional versus ablative surgery for endometriomas. *Source:* Duffy JM, Arambage K, Correa FJ *et al.* Laparoscopic surgery for endometriosis. *Cochrane Database Syst Rev* 2014;(4):CD011031. Reproduced with permission of John Wiley & Sons.

preserves ovarian reserve more effectively than electrosurgical haemostasis [61] and thus minimal use of energy modalities in haemostasis is imperative. Young women for whom fertility is a consideration should have the benefit of discussion of the option of egg freezing prior to undergoing ovarian endometrioma surgery, especially if bilateral.

The best surgical approach for deep endometriosis in the context of endometriosis-related infertility remains unclear. Whilst observational studies suggest good fertility results in women who undergo laparoscopic excision [55,62], laparoscopic shaving [63] and colorectal excision [64,65], these data are far from confirmatory. These surgical approaches have not been assessed in RCTs and carry a high risk of complications. Laparoscopic surgery for deep endometriosis is usually considered a second-line treatment option after failed IVF (unless IVF is not feasible or the patient has severe pain symptoms).

The pregnancy rate after repeat surgery is lower, approximately half that after first surgery [50], and two cycles of IVF might be more effective in achieving pregnancy. However, surgery should be considered for women with endometriosis-related infertility who continue to be symptomatic, have enlarging endometriomas, or those who decline IVF and those for whom IVF is repeatedly unsuccessful.

Medical adjunct therapy in conjunction with laparoscopic surgery has not been shown to benefit fertility and is not recommended since postoperative medical adjunct therapy may delay pregnancy at a time when fertility has been improved by surgery [1].

Assisted conception for endometriosis-associated infertility

In terms of medically assisted reproduction, intrauterine insemination (IUI) combined with ovarian stimulation is

an effective option for women with minimal to mild endometriosis, if the fallopian tubes are normal. IUI plus ovarian stimulation is more effective than unstimulated IUI, gonadotrophin stimulation appears more effective than that with clomifene, and the role of unstimulated IUI is uncertain for women with endometriosis. Multiple pregnancy is a key hazard of ovarian stimulation and all reasonable steps should be employed to avoid this outcome. No consensus could be established over double insemination for IUI. However, IVF is commonly offered first line in preference to IUI when endometriosis is more severe, tubal function is impaired, or in the context of advanced female age and/or reduced sperm quality. It is unclear whether controlled ovarian stimulation alone provides fertility benefit for women with endometriosis and whether gonadotrophins provide benefit over, for example, letrozole [1].

The presence of endometriosis has a negative impact on IVF success rates compared with other causes of infertility [36]. Nonetheless, IVF is recommended as a fertility treatment for women with endometriosis, especially if fallopian tube function is compromised or if there are other infertility factors such as male factor. The chance of success is similar for GnRH antagonist versus GnRH agonist protocols [1]. IVF does not appear to increase the risk of recurrence of endometriosis [66].

Adjuvant therapy to assisted conception for endometriosis-associated infertility

Medical treatment (including GnRH agonists) and laparoscopic surgical treatment prior to IUI plus controlled ovarian stimulation is not recommended, since there are insufficient data demonstrating benefit [1].

The most dramatic improvement in the outcome of IVF appears to be through treatment with GnRH agonists for 3–6 months prior to IVF, as the systematic review of three RCTs showed a substantial benefit of this treatment in improving the chance of pregnancy (OR 4.3, 95% CI 2.0–9.2) (Fig 53.8) [67]. GnRH agonist treatment not only suppresses endometriosis, but the mechanism for fertility improvement in this case appears to be via the promotion of endometrial integrins, the expression of which is known to be much reduced in the endometrium of women with endometriosis.

There are insufficient data to recommend the use of OCP prior to IVF/ICSI and no data to compare the approach of pretreatment with OCP versus GnRH agonist. There is concern that the presence of an endometrioma may damage the ovary yet, on the other hand, ovarian response to stimulation in IVF might be reduced in some women who have had an endometrioma removed. The benefit of laparoscopic removal of endometriosis and/or endometriomas prior to IVF is unclear with respect to IVF outcome, although it may improve access to the ovaries and even reduce the chance of infection related to the egg collection procedure [1]. Whilst laparoscopic surgery following repeat failure of IVF treatment may improve the chance of natural conception, its role as an adjunct to IVF is unclear. Any decisions to perform surgery for endometriomas or deep endometriosis before assisted reproductive techniques should be made only after fully informed consent by surgeons with appropriate expertise. There should be discussion about the option of prior egg freezing with women contemplating such surgery.

Medical therapy

There is no evidence of fertility benefit from medical treatment – ovulation suppression may delay pregnancy and this is not recommended [1].

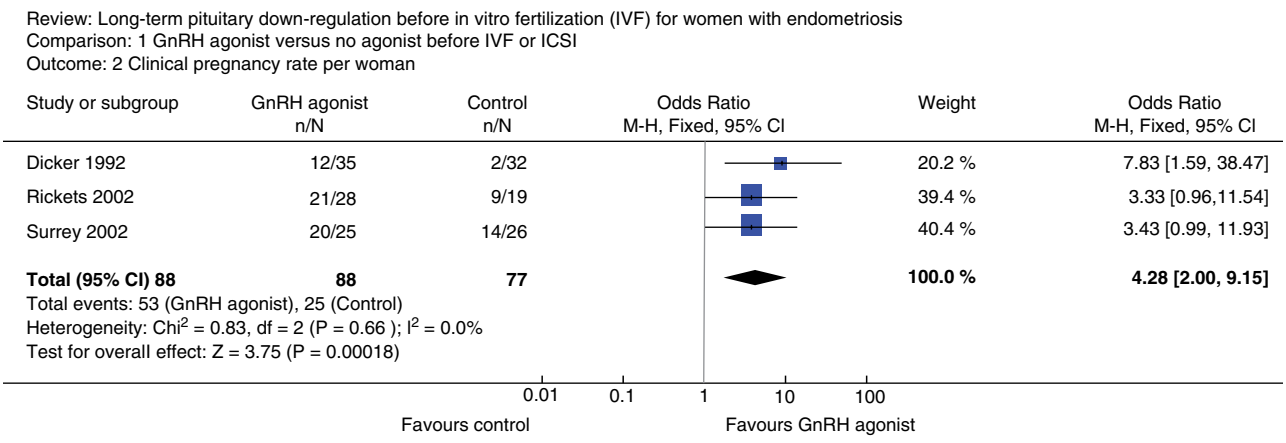

Fig. 53.8 Pregnancy rates following 3–6 months of GnRH analogue downregulation prior to IVF. *Source:* Sallam HN, Garcia-Velasco JA, Dias S, Arici A. Long-term pituitary down-regulation before in vitro fertilization (IVF) for women with endometriosis. *Cochrane Database Syst Rev* 2006;(1):CD004635. Reproduced with permission of John Wiley & Sons.

Emerging therapies

The most promising innovative fertility treatment for women with endometriosis-related infertility is lipiodol uterine bathing and tubal flushing. In an RCT evaluating fertility outcome from lipiodol among women with unexplained infertility attempting natural conception, a small subgroup of 62 women with endometriosis showed a dramatic significant improvement in pregnancy rate (RR 4.4, 95% CI 1.6–12.2) and live-birth rate (RR 3.7, 95% CI 1.3–10.5) following a lipiodol hysterosalpingogram versus no intervention [68]. The mechanism may be through an effect of lipiodol enhancing endometrial expression of uterine natural killer cells and downregulating endometrial osteopontin [69]. There is insufficient evidence to recommend the use of the following as fertility treatments: pentoxifylline, traditional Chinese medicine, vitamin C and E, mifepristone, rosiglitazone and valproic acid [1].

Ongoing research

The World Endometriosis Research Foundation (WERF) has evolved the Endometriosis Phenome and Biobanking Harmonisation Project (EPHect), a global initiative aimed at facilitating and improving research in endometriosis. Publication of four papers recommending global standardization of data collection [39,70] and sample collection [71,72] in endometriosis research is intended to foster many new collaborations among existing centres and encourage other endometriosis centres that have not yet embarked on research to join. It is hoped that this endeavour will aid in the quest to improve the quality of life of millions of women affected by endometriosis worldwide.

Chronic Pelvic Pain

Janesh Gupta

Centre for Women's and Newborn Health, Institute of Metabolism and Systems Research (IMSR), University of Birmingham, Birmingham Women's Hospital, Birmingham, UK

Pain perception is subjective, multifactorial and involves complex physical, biochemical, emotional and social interactions. Somatic pain is usually sharp and unilateral whereas visceral pain is duller, aching, bilateral or localized to the midline.

Chronic pelvic pain (CPP) is defined as non-cyclical pain lasting for more than 6 months, localized to the anatomical pelvis and anterior abdominal wall, at or below the umbilicus, or to lumbo-sacral back and buttocks of sufficient severity to cause functional disability or lead to medical intervention [1]. CPP is a broad term with varied presentations and has a significant impact on quality of life. It may present as dysmenorrhoea, dyspareunia, vulvodynia, non-specific pelvic pain, musculoskeletal pain, intestinal cramps or dysuria [2]. CPP is associated with long-standing mental health problems, with reported increased rates of anxiety, depression, somatic disorders, disturbed concentration and insomnia [3]. In primary care settings, CPP has a similar prevalence to migraine, back pain and asthma [4] and postmenopausal women have also reported a substantial burden of CPP [5]. In the literature the incidence and prevalence of CPP are reported in an inconsistent manner which makes comparison and discussion difficult. It is recognized that in England it can take several years for a patient's persistent chronic pain condition to be recognized and even longer before management is provided in a secondary care setting [6].

Chronic post-surgical pain may develop after any surgical procedure, and is a common feature after abdominal and pelvic surgery, with a prevalence varying between 10 and 40% [7].

CPP is a symptom and not a diagnosis but it has to be regarded as a disease in its own right and requires attention accordingly. This involves multidisciplinary care, which differs from the organ-centred view. Pain associated with a well-described disease process requires that the disease be treated as a priority. Pain management is therefore a vital component and may reduce chronicity.

In most instances the diagnosis is derived from clinical history rather than relying upon examination and investigations. An empathic consultation and acknowledging the presenting complaints can in themselves be therapeutic; furthermore, a comprehensive neurological, myofascial and postural assessment should be carried out. Overall, pain relief, though paramount, is not the only goal of treatment. Improvement in quality of life is also equally important.

Summary box 54.1

- Pain is a complex phenomenon.
- CPP is 6 months or more of non-cyclical pain in the pelvis.
- CPP is as common as migraine, back pain and asthma.
- CPP is a symptom and not a diagnosis.

Clinical history

Clinical history is an integral part of management as it not only helps to find the possible cause or predisposing factor but also helps in understanding the impact on quality of life and the patient's expectations from treatment. Table 54.1 presents a classification of causes of CPP that should be borne in mind while undertaking the clinical assessment.

Clinical history needs to include the onset and duration of symptoms, the location and radiation of pain, factors associated with exacerbation and relief, and the relationship of pain to the menstrual cycle. Dysmenorrhoea may be a separate or related symptom. The intensity of dysmenorrhoea can sometimes warn of the possibility of

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 54.1 Classification of the causes of chronic pelvic pain.

Inflammatory, infective: chronic salpingitis
Inflammatory, non-infective: endometriosis, vulvodynia with dermatosis
Mechanical: uterine retroversion, adhesions
Functional: pelvic congestion, irritable bowel syndrome
Neuropathic: post-surgical, dysaesthetic vulvodynia, vulval vestibulodynia ('vestibulitis')
Musculoskeletal: pelvic floor myalgia, abdominal and pelvic trigger points, postural muscle

specific pathology such as endometriosis. Dyspareunia may include pain during intercourse, but for many women a particularly unpleasant symptom is post-coital pain and a specific enquiry about this should be made.

One should also explore the temporal relationship of pain with events like labour and delivery, which could have damaged the pelvic floor, or surgery which could have caused adhesions or nerve damage leading to pain. A history of subfertility hints at a diagnosis of endometriosis. Earlier studies showed a history of sexual abuse in more than half of patients with CPP [8].

Many women with chronic abdominal or pelvic pain will turn out to have irritable bowel syndrome (IBS) as their primary problem [9]. These patients do not have good outcomes following (inappropriate) gynaecological referral and investigation [10]. Therefore, it is particularly important that a detailed history is taken of bowel symptoms. The Rome II criteria [11] for the clinical diagnosis of IBS in those with chronic pain include at least two of:

- relief of pain with defecation;
- change in the frequency of stool; and
- change in the appearance or form of stool.

Abdominal bloating in association with acute exacerbations of pain is indicative, but needs to be distinguished from menstrual cycle-related bloating. While dyspareunia is not likely to be due solely to IBS, bowel spasm may account for the experience of those patients who describe an interval between the end of intercourse and the onset of acute pain associated with the urge to defecate and abdominal distension [12].

Bladder symptoms also form an important part of the systems review. Urinary frequency and urgency, but most importantly exacerbation of pain associated with a full bladder, may indicate the presence of interstitial cystitis, a neurogenic inflammatory condition of the bladder associated with chronic pain. As with IBS, it has been suggested that a proportion of women with CPP seen by gynaecologists are in fact suffering from unrecognized interstitial cystitis on the basis of potassium chloride sensitivity testing [13].

As pain is subjective, attempts to quantify can be made using a number of validated pain assessment measures, such as a 10-cm visual analogue scale (VAS) where one end is marked 'no pain' and the other end is the 'worst imaginable pain' [14]. There are also specific questionnaires available from the International Pelvic Pain Society (https://pelvicpain.org/home.aspx).

Health-related quality of life can be measured using a generic instrument such as EuroQoL EQ-5D (measured on a scale of –0.59 to 1 based on responses to five questions about life quality) or the EQ-VAS scale (measured on a 0–100 scale) [15]. Other generic quality-of-life measures such as the SF-36 (http://www.sf-36.org/tools/sf36.shtml) or the shorter SF-12 can also be used.

Examination

Observing how a patient walks into the consulting room can provide a clue to the diagnosis. Pelvic pain that is predominantly secondary to musculoskeletal origins can lead to the typical pelvic pain posture, with lordosis and concomitant kyphosis. On examination, musculoskeletal symphysial tenderness may be noted in such women. Abdominal wall pain has been proposed as a defining new test, where there is abdominal wall tenderness with a positive Carnett test (i.e. tenderness that worsens or remains the same with abdominal wall contraction). The prevalence in women with pelvic pain was 67% and was independently associated with CPP (odds ratio, OR 13.8, 95% CI 3.71–51.2; P <0.001) but not with other symptoms including dysmenorrhoea, deep and superficial dyspareunia, or bowel and bladder symptomology. The women with abdominal wall pain were more likely to require opioids or pain adjuvants than women without it (P = 0.015 and P <0.001) [16].

Careful inspection of the abdomen can reveal previous surgical scars, which could suggest pain from adhesions or nerve entrapment. 'Trigger point' tenderness elicited by palpation with one finger suggests a nerve entrapment, often involving the ilioinguinal or iliohypogastric nerves. Hernial sites should be examined carefully. On palpation, abdomino-pelvic masses may be noted. It is useful to ask the patient to point to the area of maximum pain and encircle the area where the pain spreads. The diagnosis is confirmed by infiltration of local anaesthetic such as bupivacaine into the tender area. Interestingly, the duration of relief is often much longer than the action of the local anaesthetic, perhaps because surrounding muscles are induced to relax and are no longer pulling on the sensitive area.

Local examination of the perineum should be carried out after obtaining verbal consent and in the presence of a chaperone. Vulval erythema may suggest infection, whilst thinning is suggestive of lichen sclerosus. In cases of vulvar vestibulitis, there can be local redness near the vestibular gland. The presence of vulval or lower limb varicosities is associated with pelvic vein incompetence. During vaginal examination, tenderness on palpation of the pelvic floor muscles could suggest myofasciitis of the pelvic musculature, whereas deep fornicial tenderness with nodularity on palpation could suggest chronic inflammatory disease or endometriosis. The uterus should be palpated for size, mobility and tenderness. Palpation of the adnexa may reveal masses like endometriomas or there can be tenderness in the adnexa due to pelvic congestion syndrome (see later).

Investigations

Investigations largely depend on the diagnosis suggested by history and examination. A few basic tests may be required, such as urine microscopy and sensitivity to rule out infection and a full blood count to rule out anaemia and infection. Culture swabs to exclude sexually transmitted infections such as *Chlamydia* are useful. If symptoms suggest, tests may be required to rule out diabetes or hypothyroidism. An ultrasound examination may be useful in identifying uterine or adnexal pathology and has been shown to be an effective means of providing reassurance [17,18].

Laparoscopy has commonly been undertaken as the primary investigation for CPP. The aims are to give a diagnosis but also to provide 'one-stop' treatment for endometriosis and adhesions where these are identified. This approach is cost-effective for endometriosis treatment, as the expense of a second procedure or hormonal treatment is obviated [19]. This method is being challenged by a current study to assess if MRI can replace or triage the need for laparoscopy in women presenting with CPP (MEDAL study: http://www.nets.nihr.ac.uk/projects/hta/092250). The results are awaited.

Conscious pain mapping by laparoscopy has been used at some centres and found useful in cases where examination and imaging were inconclusive, with a majority of patients showing some improvement in VAS pain scoring [20–22]. However, these studies have been small and there are no randomized controlled trials to suggest that this technique should be implemented into routine practice.

Summary box 54.2

- A detailed comprehensive clinical history should differentiate between gynaecological and non-gynaecological pelvic pain.
- Cyclical pelvic pain is likely to be associated with endometriosis.
- Irritable bowel syndrome is a common non-gynaecological cause of CPP.
- Trigger points can indicate nerve entrapment.
- Ultrasound is a useful tool for excluding gross pelvic pathology and for providing reassurance.
- Laparoscopy is not recommended as a first-line investigation.

Management

Medical therapy

Medroxyprogesterone acetate (MPA) has been used extensively but is only effective after 4 months' treatment as reflected in pain scores (OR 2.64, 95% CI 1.33–5.25; $N = 146$] and a self-rating scale (OR 6.81, 95% CI 1.83–25.3; $N = 44$), but benefit was not sustained 9 months after treatment [23,24]. MPA plus psychotherapy was effective in terms of pain scores (OR 3.94, 95% CI 1.2–12.96; $N = 43$) but not the self-rating scale at the end of treatment. Benefit was not sustained following treatment. Venography scores, symptom and examination scores, mood and sexual function were improved to a greater extent 1 year after treatment with the GnRH analogue goserelin compared with progestogen [25].

No improvement in pain scores was seen in women taking the selective serotonin reuptake inhibitor sertraline compared with placebo. The SF-36 subscale 'health perception' showed a small improvement in the sertraline arm, while the 'role functioning–emotional' subscale showed a large fall in the sertraline arm [26].

Surgical therapy

Previously, laparoscopic uterosacral nerve ablation (LUNA) was commonly performed for the treatment of CPP. However, a large and well-designed randomized controlled trial showed that this technique did not lead to any improvement in pain, dysmenorrhoea, dyspareunia or quality of life [27].

Adhesiolysis

Intraperitoneal adhesions can form *de novo* or following a surgical procedure. Diamond *et al.* [28] distinguished

two types of postoperative peritoneal adhesions. Type 1, or *de novo* adhesion formation, involves adhesions formed at sites that did not have previous adhesions, and includes type 1A (no previous operative procedure at the site of adhesion) and type 1B (previous operative procedures at the site of adhesion). Type 2 involves adhesion reformation, with two separate subtypes: type 2A (no operative procedure other than adhesiolysis at the site of adhesion) and type 2B (other operative procedures at the site of adhesions). Each surgeon defines adhesions on an individual basis contingent on the surgeon's own experience and capability. A peritoneal adhesion index has been described and is based on the macroscopic appearance of adhesions and their extent in the different regions of the abdomen. The abdomen is divided into nine quadrants and bowel-to-bowel adhesions are also noted. Each area is given a grade: grade 0, no adhesions; grade 1, flimsy adhesions requiring blunt dissection; grade 2, strong adhesions requiring sharp dissection; and grade 3, very strong vascularized adhesions requiring sharp dissection with damage hardly preventable. Using specific scoring criteria, clinicians can assign a peritoneal adhesion index ranging from 0 to 30, thereby giving a precise description of the intra-abdominal condition [29].

There is no definite relationship between adhesions and pain. Usually, peritoneal adhesions, or flimsy adhesions which allow movement between two structures, cause little pain [30]. Traditionally, laparoscopy has been the only way of diagnosing and treating adhesions. Recently, transvaginal ultrasound has been suggested for the diagnosis of adhesions based on ovarian mobility [31,32].

It is controversial to surgically treat adhesions to decrease pain as adhesiolysis itself has an inherent risk of adhesiogenesis. A large Dutch trial randomizing both men and women to adhesiolysis or no treatment found no difference between the groups. There was a small possible difference in those undergoing adhesiolysis with dense vascular adhesions but the sample size was small for conclusive results [33]. A recent systematic review examining the efficacy of adhesiolysis for the treatment of chronic pain showed that the benefit of intervention varied from 16 to 88%, with the majority of studies reporting pain relief in more than 50% of cases. However, there was a high risk of bias in most of the studies [34,35]. Therefore, it is important to take steps to minimize adhesion formation in the first place. The use of hyaluronic acid derivatives, polyethylene glycol (PEG)-based derivatives and solid barrier agents derived from oxidized regenerated cellulose (Interceed) during laparoscopy or laparotomy in benign gynaecological surgery is supported by only limited evidence and their use should perhaps not be continued [36,37].

Summary box 54.3

- Progestogens and selective serotonin reuptake inhibitors are not useful for treating CPP.
- GnRH analogues have better efficacy but should only be used in the short term.
- LUNA and adhesiolysis should not be performed.

Other treatments

Despite all the options available, there are still thousands of women suffering from CPP. The experience of pain necessitates the involvement of the central nervous system (CNS) and there is increasing evidence that pain, no matter where it is perceived to originate from, can be both generated and perpetuated by the CNS itself. Currently, a double-blind, multicentre, randomized controlled trial (GaPP2) is evaluating the efficacy and mechanism of action of gabapentin for the management of CPP; 300 women with more than 3 months of pelvic pain, with no pathology found at laparoscopy within 36 months of trial entry, will be randomized to gabapentin and placebo. This treatment approach has already shown promise in a pilot study on 47 patients [38] which suggested that there is a central component to CPP that can be suppressed by the use of gabapentin.

While there are few data supporting the efficacy of treatments targeting the CNS in CPP specifically, there is good evidence to suggest that the underlying pain mechanisms and central changes associated with chronic pain are similar no matter where the pain is perceived to originate from and it is therefore reasonable to consider these treatment options for all women with CPP. Medical options such as antidepressant and anticonvulsant drugs are well tolerated and could therefore be started by a gynaecologist or primary care physician. Other more novel or invasive therapies are likely to require referral to a pain management team. However, it is important that gynaecologists are aware that such options exist so that referral can be considered for patients who are refractory to standard treatments prior to performing radical or fertility-removing surgery [39].

Acupuncture and Chinese herbal medicine may have roles to play in the treatment of CPP associated with dysmenorrhoea, endometriosis, IBS and pelvic inflammatory disease, either as an adjunct or as an alternative to conventional treatments. Unfortunately, the current evidence lacks rigour and the available trials are frequently small, poorly designed and inadequately reported [40].

Pelvic congestion syndrome

Pelvic congestion syndrome (PCS) is described as chronic pelvic pain arising from dilated and refluxing incompetent pelvic veins. The majority of studies cite pelvic pain, dilated ovarian veins and venous reflux or congestion as the principal features of PCS. There is no generally accepted, well-defined criteria for diagnosing PCS. It is predominantly observed in multiparous women of reproductive age, suggesting a mechanical and/or hormonal mechanism. The pain is typically described as dull pelvic pain that radiates to the upper thighs and is aggravated by prolonged standing and walking.

CPP affects 24% of women worldwide, and the cause cannot be identified in 40% despite invasive investigation. Pelvic vein incompetence is thought to be a possible cause of CPP. Taylor in 1949 first described how incompetent and distended pelvic veins might cause symptoms of pain/dyspareunia and menstrual dysfunction. There is some evidence to tentatively support this hypothesis, as there are data to suggest that women with pelvic vein incompetence experience more lower abdominal and pelvic pain than age-matched women with varicose veins or healthy controls [41]. The proportion of women found to have pelvic vein incompetence who report CPP varies from 39 to 91% [42]. Transvaginal Doppler and magnetic resonance venography are useful screening tools but the definitive diagnosis is made by venography.

Recent systematic reviews for evaluating pelvic vein occlusion in women suffering from CPP or PCS have shown that transvenous occlusion of the ovarian and internal iliac veins can be technically successful in 98–100%. The procedure is generally safe, with subjective improvement in pelvic pain frequency, dysmenorrhoea and dyspareunia lasting up to 5 years [43] (Figs 54.1–54.4). However, as there are significant methodological flaws with most of these studies, there is an urgent need for well-designed randomized controlled trials. A current study (Transvenous occlusion of pelvic vein incompetence, http://www.isrctn.com/ISRCTN15091500) is being conducted and the results are awaited. Until then, this procedure should not be routinely implemented in clinical practice.

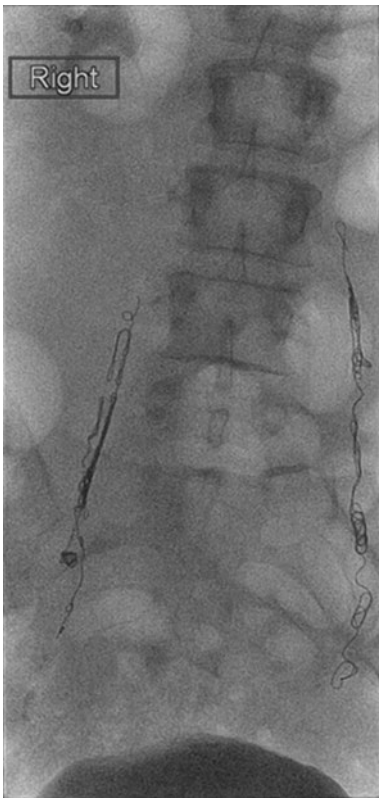

Fig. 54.4 Post-embolization of both ovarian veins. Note the parallel channels on the right side. In this case no reflux could be seen from injection into the internal iliac veins, therefore they were not embolized in this case. *Source:* Dr Rob Jones. Reproduced with permission of Dr Rob Jones.

Hysteroscopic sterilization

It is reported that women suffer from CPP after hysteroscopic sterilization. Patients with previous diagnoses of any chronic pain (CPPP, chronic low back pain, chronic headache and fibromyalgia) are more likely to report both acute pain (OR 6.81, 95% CI 2.95–15.73) and chronic pain (OR 6.15, 95% CI 2.10–18.10) after the procedure [44].

Myofascial pain

Myofascial pain usually arises from a trigger point, which is formed due to a metabolic crisis within the muscle. It is palpable as a taut, ropy band. Pain is movement related, aggravated by specific movement or activity and relieved by certain positions. Adjacent to the trigger point is a referral zone where the involved muscle displays weakness and restricted stretch. Trigger points involving the levator ani muscle and other pelvic floor muscles can cause CPP. Current guidelines by the Royal College of Obstetricians and Gynaecologists [39] and Cochrane database [45] suggest trigger point injections with local anaesthetic, corticosteroids and botulinum toxin A to treat myofascial CPP. Botulinum toxin A inhibits the release of acetylcholine from cholinergic nerve terminals, preventing the activation of muscle contraction and causing transient hypotonia and muscle weakness. It also provides long-term analgesia by retrograde axonal spread and blockade of neurotransmitter release from spinal cord. Studies have shown that botulinum toxin type A may be a useful agent in women with pelvic floor muscle spasm and CPP who do not respond to conservative physical therapy [46]. Self-limiting adverse effects like *de novo* urinary

Summary box 54.4

- Pelvic congestion syndrome is still being assessed as a potential cause for CPP.
- Treatment of pelvic vein incompetence with embolization has not been evaluated and should not be routinely performed until clinical trials have been completed.
- Myofascial pain arises from trigger points and can be treated with local anaesthesia, corticosteroids or botulinum toxin.

retention, faecal incontinence, and constipation and/or rectal pain have been reported with no obvious long-term adverse effects [47].

Conclusions

Chronic pelvic pain is a debilitating and distressing condition as in many cases diagnosis is uncertain and treatments unsatisfactory. A comprehensive clinical history and thorough examination can provide a diagnosis in many women. When no diagnosis can be reached, a treatment goal should be established. Some women are relieved by the fact that there is no sinister pathology and do not want further investigations and treatment, whereas pain relief is of paramount importance for others. A multidisciplinary team approach should evaluate such cases, especially in liaison with a chronic pain team. New avenues of research are ongoing in the field, such as assessment of the effects of pelvic vein occlusion, use of neuromodulators and complementary therapies.

Uterovaginal Prolapse

Mark Slack

Addenbrooke's Hospital, University of Cambridge Teaching Hospital, Cambridge, UK

Pelvic organ prolapse (POP) is defined as the downward displacement of pelvic organs from their original position into or beyond the vagina. An enormous variation exists in the clinical presentation, from minimal descent to complete eversion of the vagina along with the uterus, bladder and rectum. It can also occur in patients who have previously experienced a hysterectomy.

POP will affect a substantial number of women. Although it is a benign condition it can have a major impact on the quality of life. Skilful assessment and management is required to ensure appropriate treatment and improved outcome. Inappropriate treatment can leave women worse off than when they started.

Incidence and epidemiology

The lifetime risk of surgery for POP is 12–19%, with more than 300 000 women undergoing surgery a year in the USA. Approximately 8% of women in the UK report symptoms of prolapse [1–4].

On routine examination, loss of vaginal or uterine support will be seen in up to 30–70% of women who present for routine gynecological care. However, only a small proportion of these will report symptoms. Of this cohort, only about 3–6% will have descent beyond the hymenal margin and it is this group that will tend to be symptomatic [5]. In one large epidemiological study in the USA called the United States (US) National Health and Nutrition Examination Survey (NHANES), in response to the question 'Do you experience bulging or something falling out?', only 2.9% of women responded in the affirmative [6].

The most common form of prolapse is that of the anterior wall of the vagina (cystocele). Prolapse of the posterior wall (rectocele) is far less frequent and apical prolapse (descent of the uterus or vaginal vault if the patient has had a hysterectomy) the least common. Patients can present with one or more of the forms and in any combination.

The natural history of prolapse is not well known as long-term epidemiological studies are extremely rare. One study found that the incidence of prolapse to or beyond the hymen was 26% after 1 year of observation and 40% after 3 years. Over the same time period spontaneous remission rates at 1 and 3 years were 21% and 19% [7,8].

Summary box 55.1

- Most pelvic organ prolapse is asymptomatic.
- Anterior prolapse is the most common presentation.
- The natural progression of the condition is poorly understood.

Aetiology

The aetiology is poorly understood. Predisposing risk factors for the development of prolapse include vaginal childbirth, obesity, previous hysterectomy and age [9,10].

Vaginal birth is probably the principal risk factor, with avulsion injury to the levator ani during childbirth along with pudendal neuropathy and fascial damage the most common causes. There is no evidence that instrumental delivery increases the risk of developing POP [11–13]. Nulliparous women may also develop prolapse and a range of other conditions may contribute to the development of the disease [14]. Of these, age is the most significant contributor, with the incidence of prolapse doubling with every decade of life [5,8].

The genetic predisposition is less clear. There does seem to be an ethnic influence, with lower rates of POP reported in Black and Hispanic women compared with white women [5,15]. Twin studies have also

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

demonstrated a genetic component [16] and a familial association has been clearly identified [17]. Because of the protean nature of collagen diseases, it is more difficult to establish a clear link between collagen disorders and POP.

The influence of body mass index (BMI) is well established, which is of some concern given the 20% rise in obesity in the last 20 years [18]. There is no clear consensus that a prior hysterectomy (unless it was performed for prolapse) is a risk factor for subsequent vault or vaginal prolapse [19]. Conditions associated with chronically increased intra-abdominal pressure, such as chronic cough and heavy lifting, are also considered to be risk factors [15].

Pelvic anatomy

The bony pelvis provides the architectural framework for the supports of the organs of the pelvis. The organs are supported by the fibres of the paracolpium (direct support) and by the levator plate (indirect support). The fibres of the paracolpium arise from a broad area on the pelvic side wall over the fascia of the piriformis muscle, sacro-iliac joint and lateral sacrum. They insert into the lateral upper third of the vagina, with some fibres inserting anteriorly and posteriorly. These fibres are condensations of the endopelvic fascia and are composed of perivascular connective tissue and smooth muscle and contain blood vessels, lymphatics and nerves. They run in a predominantly vertical direction and their upper borders are continuous with the cardinal and uterosacral ligaments.

The levator ani comprises the pelvic diaphragm muscles: the pubococcygeus, iliococcygeus, puborectalis and coccygeus muscles. Together they form a thin broad muscle arising anteriorly from the posterior aspect of the pubic bone just lateral to the symphysis pubis and laterally from the white line of the obturator internus muscle fascia and ischial spine. The right and left muscle bellies swing backwards and downwards to fuse together behind the anal canal and anterior to the coccyx to form the levator plate between these two structures. The anal canal, lateral vagina and urethra gain some attachment of the medial margins to the levator ani. The levator plate provides indirect support for the vagina by acting as a platform against which the upper vagina and cervix are compressed during episodes of raised intra-abdominal pressure. Narrowing of the urogenital hiatus also occurs with rises in intra-abdominal pressure.

The supports of the vagina are divided into three zones: the upper, middle and the lower. The fibres in the upper are largely vertical in orientation while the fibres supporting the middle section are attached to the side wall. The fibres surrounding the lower third are almost fused with the surrounding structures [20]. This reflects the different embryological origins of the vagina and determines the surgical approach to the repair of each level.

Clinical presentation

The most consistent and specific symptom of POP is a feeling of a bulge in the vagina or a sensation of protrusion of tissue out of the vagina. In more advanced cases the prolapse can be seen and palpated outside the vagina with the patient complaining of a 'lump'. It is not uncommon for women to be asymptomatic in the early morning and then for the symptoms to develop or worsen throughout the day with activity and be relieved by lying down. While some women may present with a single symptom of prolapse, they typically have a more complex presentation that can include urinary symptoms of incontinence, frequency, nocturia and voiding dysfunction; faecal symptoms of incontinence and obstructed defecation; and sexual dysfunction. While these symptoms present commonly in association with prolapse, they are not usually caused by it and therefore are unlikely to be resolved by the surgery aimed at correcting the POP.

In a large study of women with symptomatic vaginal prolapse, 87% reported urinary frequency and urgency, 73% reported urinary incontinence and 50% had symptoms of voiding dysfunction [21]. As stated above this may be because of shared aetiological factors and may not be a direct causal link.

Bowel symptoms include the sensation of incomplete emptying and the need to manually assist defecation. The latter can include putting digital pressure on the perineum or splinting the posterior wall with the fingers during evacuation. Splinting is a mechanical means of improving defecation. In these cases obstructed defecation may be improved by surgery. Pressure on the perineum obviously has a different mechanism of action and there is no evidence that correction of a posterior wall prolapse in these cases will resolve the symptoms of obstructed defecation.

Sexual dysfunction is a common symptom in women attending a urogynaecology clinic [22]. A high percentage are not sexually active but cite the reason as lack of desire and arousal. Pain and discomfort only affect a small number.

The best way to record symptoms is with a validated quality of life (QOL) instrument. The pelvic floor distress inventories (PFDI-20, PFIQ-7) are well studied and validated [23]. The use of validated QOL instruments will help provide a more accurate reflection of the symptoms that bother a patient the most. One such system (e-PAQ, http://www.epaq.co.uk/) can be administered before the patient sees the doctor in clinic. Not only will this help with understanding what worries the patient most but can also be used for assessment of outcomes.

Summary box 55.3

Symptoms of POP

Symptoms likely to correlate with POP

- Bulge.
- Fullness.
- Dragging and deterioration with activity.
- Symptoms relieved by rest.

Symptoms unlikely to correlate with POP

- Backache.
- Pain.
- Urinary and/or bowel dysfunction.
- Sexual dysfunction.

Validated QOL instruments improve the accuracy of the history.

Evaluation

Patients presenting with a complaint of POP need to have a comprehensive history taken. This should include a full urinary, bowel and sexual history. It is also essential to establish which are the most worrisome symptoms and to clarify which symptoms the patient hopes will be corrected. The use of an objective QOL instrument can be very useful in establishing which symptoms are the most bothersome [24]. Because of a lack of understanding of the longitudinal history of prolapse, counselling about the need for intervention can be extremely difficult.

Because of the high incidence of asymptomatic POP, patients presenting to their practitioner with primary bladder or bowel dysfunction are often then referred on for management of the prolapse due to the mistaken belief that their bladder or bowel symptoms are the result of the prolapse noticed during the routine physical examination. Treatment of the prolapse in isolation will very often lead to disappointment with the outcomes achieved. This is a failure of expectation more than a failure of treatment and is a much-underestimated problem in the management of POP. Similarly, sexual dysfunction is seldom the result of POP in isolation. Other symptoms misappropriated to POP are backache and pelvic pain syndrome.

All women presenting with symptoms of POP should have a thorough examination. This should begin with palpation of the abdomen before proceeding to the pelvic examination to exclude an abdominal mass or ascites. For the pelvic examination the women should ideally be examined in the dorsal lithotomy position with Valsalva. This has been shown to be as effective as an examination in the standing position [25]. In cases where the symptoms do not correlate with the physical findings it may be worthwhile bringing the patient back for a late afternoon clinic and to perform the examination in the standing position [26]. A Sim's speculum is used to systematically identify each component of the prolapse. To assess for anterior prolapse the blade is used to retract the posterior wall while inspecting the degree of prolapse of the anterior wall. Conversely, for the posterior wall the blade is used to retract the anterior wall while assessing the degree of prolapse of the posterior wall. During this examination the position of the cervix, or in a post-hysterectomy patient the vault, is determined. The final part of the assessment is a bimanual pelvic examination. There are a range of methods that have been described to classify prolapse. Of these, the POP-Q method is the internationally accepted standard. The POP-Q system is the POP classification system of choice of the International Continence Society (ICS), the American Urogynecologic Society (AUGS) and the Society of Gynecologic Surgeons. It has proven inter-observer and intra-observer reliability and is the most commonly cited system in the medical literature (Fig. 55.1). Alternatively, the Baden–Walker Halfway Scoring System, which has five degrees/grades, is another commonly used POP staging system but it lacks accredited reproducibility (Table 55.1). The degree, or grade, of each prolapsed structure is described individually (e.g. grade 1 anterior vaginal wall prolapse or grade 3 uterine prolapse). The grade/degree is defined as the extent of prolapse for each structure noted on examination while the patient is straining. Because there are no clear demarcations among the cut-off stages, the Baden–Walker system lacks the precision and reproducibility of the POP-Q system.

There is no need for a routine rectal examination or a barrier test to look for urinary incontinence.

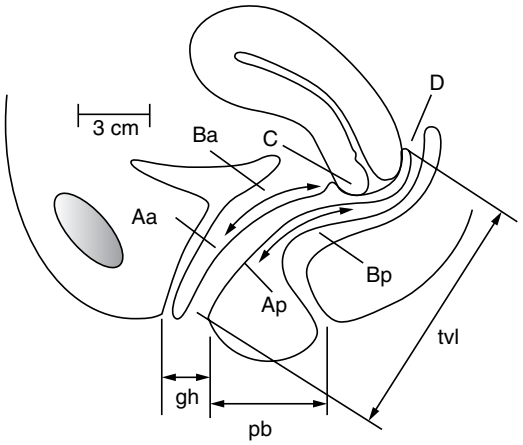

Fig. 55.1 The POP-Q system. Aa, anterior wall; Ap, posterior wall; Ba, anterior wall; Bp, posterior wall; C, cervix or cuff; D, posterior fornix; gh, genital hiatus; pb, perineal body; tvl, total vaginal length.

Table 55.1 Baden–Walker Halfway Scoring System.

0	Normal position for each respective site
1	Descent halfway to the hymen
2	Descent to the hymen
3	Descent halfway past the hymen
4	Maximum possible descent for each site

Investigation

Lower urinary tract symptoms should be evaluated independently with urinalysis, a urinary flow rate and assessment of the residual urine volume. In selected cases, where there are significant urinary symptoms, urodynamic testing may be helpful. Coexistent urinary incontinence should be investigated in the same way that it would be if the patient did not have POP.

The need to identify the patient at risk of developing urinary incontinence prior to surgery is more debatable. Women with POP without significant urinary incontinence have a 10–20% chance of developing incontinence after prolapse surgery. Because of this, some advocate the use of urodynamics after reduction of the prolapse to try to identify those at risk. They support the view that these patients should have an associated anti-incontinence operation at the time of their POP operation. This view is supported by the CARE study, which concluded that a prophylactic operation to prevent stress urinary incontinence was necessary at the time of sacrocolpopexy [27]. In an earlier study, researchers felt that preoperative testing overestimated the risk and resulted in a high proportion of women undergoing additional surgery when only a minority would develop the problem [28].

An anti-incontinence procedure should not be offered routinely. Patients are counselled about the risk and reassured that in the group that develop incontinence, spontaneous resolution will occur in more than 50% of the patients by 6 months. Only the remainder (5–8%) will need an additional incontinence procedure. A substantially lower number will undergo additional surgery than if one follows the CARE study protocol [27]. Because of the uncertainty surrounding this subject, very careful counselling of the patient is essential before embarking on surgery.

Patients with severe symptoms of bowel dysfunction, including obstructed defecation and faecal incontinence, should be seen by the colorectal team ahead of any surgical intervention.

There is little place for radiological investigations such as dynamic MRI and transperitoneal ultrasound (TPUS) in the routine management of POP. Dynamic MRI gives outstanding images but it is unlikely that it offers any advantages over a detailed clinical examination in the management of these patients. Likewise, TPUS does not seem to offer any advantages to clinical evaluation [29].

Investigations

Essential
- Urinalysis.
- Flow study and measurement of residuals.

Unsure
- Urodynamics and barrier testing.

Of no value in routine management
- Radiological imaging.

Management

Conservative

It is always preferable to seek a conservative solution ahead of a surgical one. The condition is bothersome and can restrict normal activities but it is seldom life-threatening. The surgeon must be mindful that all surgical procedures carry inherent risks and should not proceed with a surgical procedure without first offering a trial of conservative treatment.

It is important to counsel the patient that progression is not inevitable. Unfortunately, a precise profile of risk factors for progression does not exist, further compounding the difficulties with counselling. An even more difficult group of patients to counsel are those who

present soon after pregnancy. The majority of them can expect to experience spontaneous resolution as time elapses from the delivery. Too hasty a recourse to surgical intervention is to be avoided and the patient should be encouraged to persist with conservative measures for at least 18 months before considering surgery.

Options for conservative therapy include pelvic floor muscle training (PFMT) and pessary use. Lifestyle advice such as weight loss and smoking cessation should be advised when relevant. The evidence supporting the role of weight loss in POP is limited. The Women's Health Initiative (WHI) study confirmed a higher rate of progression in women with raised BMI but did not demonstrate an improvement of POP after weight loss [7]. However, if the conservative measures fail, weight loss will improve their general health and reduce perioperative complication rates should surgery become an option. Weight loss will also reduce the risk of stress urinary incontinence.

Although PFMT has been recommended for the management of urinary incontinence, there is disagreement about its value for the management of POP, especially the more advanced stages. This was partly due to the paucity of literature in the area [30]. However, more recent studies have shown that PFMT can result in improvement in both POP symptoms and POP stage. Randomized trials have supported the benefit of PFMT especially when involving individualized training and supervision. In one study it was shown that symptom control was better than in controls but by 12 months there was no difference in the number of women who needed surgery [31]. The efficacy of PFMT beyond 12 months in unknown. However, as PFMT carries no risk to the patient, it should be offered to all patients who present with POP.

Vaginal pessaries are devices which are inserted into the vagina for the management of POP. They have been in use in various forms for hundreds of years. They offer an excellent non-surgical option for women with prolapse and there are virtually no contraindications to vaginal pessary use. A significant number of women express a preference for a non-surgical management of their prolapse. Pessaries can be used as a long-term solution or as a semi-diagnostic test to evaluate which symptoms are removed with reduction of the pessary. They can also be used as a temporary measure in women who want to delay surgery until they have completed their family or while waiting for surgery.

Patient acceptance of pessaries is variable ranging from 40 to 100%. The rate of acceptance is influenced by counselling and the enthusiasm of the healthcare practitioner. Patients who decline pessary use are usually younger, nulliparous and have severe symptoms of prolapse or incontinence. Women who have had prior prolapse surgery, more severe prolapse and more bothersome symptoms, especially those relating to bowel, bladder and sexual function, are more likely to choose surgical management. This is not surprising as this group will be desperate for a resolution of their problems. They need encouragement to try the pessary and be reminded that if it does not alleviate the symptoms, surgical treatment is still an option [32,33]. There are no direct contraindications apart from a possible allergy to the materials.

A wide variety of pessaries in a range of materials, shapes and sizes is available. They can be divided into support pessaries and space-filling pessaries. Support pessaries are further subdivided into those without a diaphragm (Fig. 55.2) (ring, Smith, Hodge, Gehrung) and those with (Falk and Schaatz). There is also a wide variety of space-occupying pessaries (Shelf, Gelhorn, Donut, Cube) although little to recommend one over another (Fig. 55.3).

The most commonly used pessary is the ring [34]. This has been shown to be very successful, with resolution of symptoms in a high percentage of patients. Ring pessaries have a smaller surface area than space-occupying pessaries and patients using rings are mostly able to have normal sexual intercourse. They are easily removed and inserted by the patient, which reduces the need for repeated pessary changes in the surgery. The common feature of all the pessaries is that they lack an evidence base for their use. Much of what we know is anecdotal and based on personal experience.

Fitting the pessary takes place after a careful examination. Using the length of the vagina (measured from

Fig. 55.2 Mediplus ring pessary. *Source:* Mediplus Ltd.

Fig. 55.3 Other types of vaginal pessary. *Source:* Mediplus Ltd. Reproduced with permission of Mediplus Ltd, United Kingdom.

behind the symphysis pubis to the pouch of Douglas) as a guide, an estimate is made of the size of pessary. The pessary should be the largest size that fits into the vagina without the patient being able to feel it. Immersion of the pessary in hot water ahead of insertion will make it more malleable and easier to insert. Removal can be uncomfortable as it is difficult to alter the diameter ahead of extraction. Fitting the pessary is usually a process of trial and error. It is not uncommon to try two or three different sizes before getting the best fit. A ring pessary is usually trialled in the first instance. If this does not remain in place and there are no contraindications, a space-occupying pessary should be tried. Women must be counselled that the pessary may fall out, usually within the following 24 hours. This occurs most commonly in association with straining at stool. They are then advised to return for review. Patients are encouraged to remove their pessary fortnightly for cleaning and then reinsert. If the patient is unable to practise self-management, she should be seen for review every 3–6 months for a pessary change. Pessary changes can be very uncomfortable and this often becomes a greater problem with advancing age and progressive tightening of the introitus. Use of topical oestrogen can reduce this difficulty. Unless there is a contraindication to its use, patients should be encouraged to use topical vaginal oestrogen as a way of facilitating changes but also as a means of reducing discharge, granulation and bleeding. After an initial 2-week spell of daily insertion it is maintained with a twice-weekly regimen. There will be a group of patients unable to retain a pessary and the exact reasons for treatment failure remain elusive [35].

The most common side effects, which are also the major reasons for discontinuing use of a pessary, are vaginal discharge and the development of granulation tissue in the vagina. Granulation tissue can exacerbate the discharge and can lead to bleeding. The discharge is often anaerobic in nature, which suggests it occurs secondary to a change in the natural microbiome of the vagina or from the biofilm which can develop on the pessary. The change in pH in the vagina in association with the menopause, and further exacerbated by the presence of the pessary, may predispose to the development or recurrent urinary tract infections [36]. The discharge can be treated with the addition of intermittent courses of vaginal antibiotics usually containing metronidazole. Vaginal bleeding in postmenopausal patients is particularly bothersome and needs to be managed as for any other postmenopausal bleed. A transvaginal ultrasound will usually be able to rule out endometrial pathology. Persistence of discharge,

granulation tissue and bleeding are usually indications to consider surgical management.

Resolution of symptoms is experienced in a majority of women in the short term. However, there is a gradual reduction in satisfaction rates over time [35]. A study in Australia reported that pessary use dropped to 14% over 14 years [37].

There is no evidence that either systemic or topical oestrogen is effective therapy for POP. There is histological evidence that local oestrogen increases the development of mature collagen along with vaginal wall thickness but the clinical correlation is lacking [38]. However, the use of topical oestrogen may offer the patient some relief of symptoms caused by vaginal atrophy. Patients might otherwise have incorrectly attributed the hypo-oestrogenic symptoms to the presence of the prolapse. There is some evidence that use of the selective oestrogen receptor modulator raloxifene may reduce the need to undergo surgery [39], but the vasomotor side effects associated with this treatment are likely to preclude its use in clinical practice.

Summary box 55.5

Conservative management

Appropriate measures
- Weight loss.
- Pelvic floor muscle training.
- Vaginal pessary placement.

Invalid measures
- Hormone replacement therapy.

Surgery

Women with symptomatic POP who decline conservative treatment or experience no improvement with it may require surgical treatment. The aim of surgery is to restore anatomy, relieve symptoms and restore function. Before proceeding with surgery it is essential to understand the patient's expectations are. The surgeon must be convinced that the proposed procedure is appropriate and must also ensure that the patient knows what can be achieved with surgery and, more importantly, what cannot. Surgery should be reserved for patients who have at least stage 2 POP on examination and have bothersome symptoms attributable to the POP.

Surgery can be undertaken using vaginal or abdominal approaches. The abdominal approach can be through open abdominal surgery or minimal access surgery (MAS) undertaken either laparoscopically or robotically. There is no consensus on which approach is superior. Despite the major advances achieved in the field of MAS, the majority of surgeries are carried out via the vaginal approach. This may reflect the fact that MAS is technically more challenging. Comparison of different surgical procedures for POP is made more difficult by the lack of agreement on objective outcome measures. MAS has been shown to have significant advantages over open surgery, with a reduction in wound complications, postoperative pain, convalescent time and return to normal activity. Despite this only a minority of procedures are done in this fashion [40]. The increased adoption of robotically assisted surgery will enable more surgeons to utilize minimal access techniques for pelvic floor surgery. The da Vinci system is already available but other more versatile robotic platforms are under development by Transenterix, Medtronic and Cambridge Medical Robotics (CMR). The newer robots, like the CMR Versius, have a more versatile modular form that suits reconstructive pelvic surgery (Fig. 55.4).

Very few patients require surgery to a single compartment and will usually need some combination of the various approaches.

Surgery for apical prolapse

The abdominal approach usually involves sacrocolpopexy which involves suspending the vaginal apex to the anterior longitudinal ligament of the sacrum with a synthetic mesh. This can be carried out as an open procedure using a Pfannenstiel incision but more recently the majority are performed either as a laparoscopic sacrocolpopexy or a robotically assisted sacrocolpopexy.

Transvaginal apical support can also be achieved with a sacrospinous fixation. This involves suspending the vaginal vault to the sacrospinous ligament with sutures. Typically this is a unilateral extraperitoneal approach. There are descriptions of a bilateral approach, although this is often not possible in patients with reduced vaginal volume.

The uterosacral colpopexy also has good results but some series have reported high ureteric injury rates. The results after uterosacral suspension are similar to those achieved with a sacrospinous fixation. The 2013 Cochrane meta-analysis of randomized controlled trials on apical suspending surgery concluded that the abdominal approach was superior to vaginal-based sacrospinous colpopexy, with reduced recurrent vault prolapse, postoperative stress incontinence and dyspareunia. This was at a cost of longer operating time, longer time to recovery and greater expense. It would seem therefore that the abdominal supporting procedures should be reserved for the younger, fitter and more active patients while the vaginal procedures should be reserved for older and frailer patients.

Surgery for anterior compartment prolapse

Anterior vaginal wall defects rarely occur in isolation and are often accompanied by descent of the vaginal apex (cervix or vaginal vault) or posterior wall. The need to repair other anatomic sites should usually be decided under anaesthesia when the patient is fully relaxed and a detailed examination can be carried out. The apical support must be very carefully evaluated as it is increasingly believed that anterior compartment prolapse rarely occurs in isolation. This is borne out by significantly better surgical outcomes when an anterior repair is performed concurrently with an apical support repair [41].

Traditionally, the anterior repair involves the midline plication of the vaginal fascia followed by excision of the redundant vaginal wall epithelium and then suture of the epithelium. Repair of the anterior wall may also involve correction of lateral wall defects. This can be performed vaginally or abdominally and has similar success rates to the midline technique.

Anterior wall surgery has success rates in the range of 40–60% [42]. Because of these poor results, surgeons have started to use artificial grafts to try to improve outcomes. In a study of 2756 women it was shown that the addition of an apical supporting procedure to an anterior repair significantly reduced the need for reoperation from 20% to 11% [43]. Native tissue repair is the dominant method of repair; perhaps the addition of apical support procedures will lead to improved outcomes.

Surgery for posterior compartment prolapse

Posterior repair is associated with much higher rates of anatomical success, with outcomes as high as 80–95% [44]. The operation involves a midline plication of the rectovaginal fascia, excision of redundant epithelium and reconstruction of the epithelium. The use of mesh has never been shown to have advantages over native tissue repair. Improvement in bowel symptoms has been demonstrated in the majority of women after posterior colporrhaphy [45].

Patients who present with significant prolapse of the anterior and posterior walls often have concomitant loss of apical support. Some believe that if the apex or uterus is poorly supported, there is a lower chance of supporting the anterior and posterior wall defects.

Obliterative surgical procedures

Obliterative procedures are reserved for women who have failed conservative therapy but who have significant comorbidities and are therefore not candidates for extensive surgery and who do not plan for future vaginal intercourse. The most common procedure is a colpocleisis. This can be done in women who have had a hysterectomy and those who have not.

The procedure involves removal of strips of vagina from the anterior and posterior vaginal epithelium, leaving a small strip of lateral epithelium on each side. The anterior and posterior walls are then sutured together. The main purpose of the side strips is to allow for vaginal or uterine secretions to be discharged. The procedure is associated with excellent results and very low complications [46].

Role of synthetic materials

Grafts may be biological (allograft, autograft or xenograft) or synthetic. Synthetic materials are further defined according to the type of polymer (absorbable or non-absorbable, monofilament or multifilament), pore size and weight. These features will determine how the graft will behave in the body, especially the way these various materials will integrate in the tissues. The best grafts are monofilament, with a pore size greater than 75 µm. Microporous and multifilamentous grafts cause an over-exuberant inflammatory reaction with subsequent tissue damage [47].

Early data suggested that traditional repair was associated with more postoperative prolapse as seen on examination and also as reported by patients [44]. This led to a rapid introduction of multiple operations (kits) utilizing mesh and tools for the insertion of the mesh. These were marketed very aggressively and with little regard to whom they were being sold. Consequently, reports soon appeared with mesh complications, including extrusion, infection, shrinkage and fibrosis.

Multiple law suites materialized all over the world, which led many manufacturers to withdraw their products from the market. In 2016, the US Food and Drug Administration (FDA) reclassified surgical mesh for transvaginal POP as a class III device, requiring manufacturers to submit premarket approval applications to support the safety and effectiveness of the synthetic mesh [48]. Consequently, the use of mesh in transvaginal surgery has dropped from a high of 27% of surgeries in 2008 to less than 2% by 2011.

Summary box 55.6

Surgical options

Restorative

Vaginal

- Anterior colporrhaphy.
- Posterior colporrhaphy.
- Vaginal hysterectomy.
- Sacrospinous fixation.
- Sacrospinous hysteropexy.
- Uterosacral plication.

Abdominal

- Sacrocolpopexy (open/laparoscopic/robotic).
- Sacrohysteropexy (open/laparoscopic/robotic).

Obliterative

- Colpocleisis.

The future

With an ageing population with an increasingly sedentary lifestyle and endemic levels of obesity, the number of patients presenting for treatment is likely to rise. Investment in POP research is required so that we can better delineate the problems and hopefully develop more effective solutions. There needs to be more effort directed towards the accurate measurement of outcomes. This will involve the monitoring of operative morbidity as well as long-term functional outcomes. Improved outcome data will allow us to understand the natural history of the condition, which in turn will help us counsel our patients and so hopefully better manage expectations.

The urogynaecology community must learn from the lessons of the mesh debacle and ensure that we always demand evidence ahead of fashion and fad. Hopefully there will be newer and better graft materials to help augment surgical repair. These may or may not include a contribution from stem cell technology.

Urinary Incontinence

Vik Khullar

Queen Charlotte's and Chelsea Hospital, Imperial College London, London, UK

Urinary incontinence has a major impact on the quality of life of women and urgency incontinence has been found to be associated with increased mortality [1]. Through ignorance, embarrassment and a belief that loss of bladder control is a 'normal' result of childbirth and ageing, many women suffer for years before seeking help [2]. An accurate diagnosis can be made and many women can be cured or improved by the use of various management strategies.

Urinary incontinence is defined as the complaint of any involuntary loss of urine [3], whereas continence is the ability to retain urine at all times except during micturition. Both continence and micturition depend on a structurally and functionally normal lower urinary tract.

Urinary incontinence is best classified according to aetiology, as shown in Table 56.1. There are a number of additional causes of urinary incontinence in elderly woman (Table 56.2), many of which can be reversed by appropriate intervention.

Clinical presentation of urinary incontinence

Symptoms of lower urinary tract dysfunction fall into three main groups: (i) incontinence; (ii) overactive bladder (OAB) symptoms; and (iii) voiding difficulties.

Stress urinary incontinence (SUI) is the most common complaint. It may be a symptom or a sign but it is not a diagnosis. Apart from stress incontinence, women may complain of urge incontinence, dribble or giggle incontinence, or incontinence during sexual intercourse. Nocturnal enuresis (bed wetting) may occur on its own or in conjunction with other complaints. Symptoms of voiding difficulty include hesitancy, a poor stream, straining to void and incomplete bladder emptying.

Apart from the symptoms of lower urinary tract dysfunction, it is important to take a full history from all women who present with urinary incontinence. Other gynaecological symptoms such as prolapse or menstrual disturbances may be relevant. A fibroid uterus may compress the bladder and can cause urinary frequency and urgency. There is an increased incidence of stress incontinence amongst women who have had large babies, particularly following instrumental vaginal delivery, so an obstetric history may be helpful. Information regarding other urological problems, such as recurrent urinary tract infections, episodes of acute urinary retention or childhood enuresis, should be sought.

Urinary incontinence is sometimes the first manifestation of a neurological problem (such as multiple sclerosis) so it is important to enquire about neurological symptoms. Endocrine disorders such as diabetes may be responsible for symptoms of lower urinary tract dysfunction and should therefore be recorded.

Some drugs affect urinary tract function, especially diuretics, which increase urine output. In older people they may cause urinary incontinence where only urgency existed previously. Other drugs that affect detrusor function include tricyclic antidepressants, major tranquillizers and α-adrenergic blockers.

Unfortunately, clinical examination is usually unhelpful in cases of female urinary incontinence. General examination should include the subject's mental state and mobility as well as the appearance of local tissues. Excoriation of the vulva will indicate the severity of the problem and atrophic changes may reveal long-standing hormone deficiency. A gynaecological/urological examination should be carried out and although stress incontinence may be demonstrated, this will only confirm the patient's story; it will not actually indicate the cause. If a neurological lesion is suspected, then the cranial nerves and sacral nerve roots S2–S4 should be examined.

The bladder has been described as an 'unreliable witness'. The correlation between clinical diagnosis and

Restricted mobility
Depression
Drug therapy (e.g. diuretics)
Endocrine disorder (e.g. diabetes)
Limited independence

urodynamic diagnosis is poor, and therefore it is unusual to be able to make an accurate diagnosis based on history and examination alone. Urodynamic stress incontinence is the commonest cause of urinary incontinence in women and detrusor overactivity is the second most common cause. These two diagnoses account for over 90% of cases of female urinary incontinence. As their treatment differs it is important to make an accurate initial diagnosis.

Summary box 56.1

Urinary incontinence

- Defined as the complaint of any involuntary loss of urine.
- Often under-diagnosed and under-treated.
- The incidence increases with age.
- Known to have a significant effect on quality of life.
- Stress urinary incontinence, overactive bladder (with or without incontinence) and mixed incontinence are the commonest types of urinary incontinence.

Investigations

Investigations range from the very simple to the highly sophisticated and complex and are outlined in Table 56.3.

GP/outpatient tests

Midstream urine sample

A midstream urine (MSU) specimen should always be sent for culture and sensitivity prior to further investigation. Although the patient's symptoms are unlikely to be caused by a urinary tract infection, they can be altered by one.

Frequency–volume charts

It is often helpful to ask women to complete a frequency–volume chart or urinary diary (Fig. 56.1). This is informative for the doctor as well as the patient and may indicate excessive drinking or bad habits as the cause of lower urinary tract symptoms. The frequency–volume chart (urinary or bladder diary) provides an objective assessment of a patient's fluid input and urine output.

As well as the number of voids and incontinence episodes, the mean volume voided over a 24-hour period can also be calculated, as well as the diurnal and nocturnal volumes. Frequency–volume charts have the advantage of assessing symptom severity in the everyday situation.

Pad test

Incontinence can be confirmed (without diagnosing the cause) by performing a pad weighing test. Many different types of pad test have been described based on the method for filling the bladder or length of the test.

	Day 1			Day 2			Day 3			Day 4			Day 5

Urodynamics

Urodynamic studies comprise several investigations that are employed to determine bladder function.

Uroflowmetry

Uroflowmetry, the measurement of urine flow rate, is a simple test that can exclude the presence of outflow obstruction or a hypotonic detrusor, but on its own will not differentiate between the two. In order to obtain a flow rate, the patient is asked to void onto the flowmeter, in private, when her bladder is comfortably full. The maximum flow rate and volume voided are recorded. In women, the normal recording is a bell-shaped curve with a peak flow rate of at least 15 mL/s for a volume of 150 mL of urine voided (Fig. 56.2a). A reduced flow rate in an asymptomatic woman may be important if she is to undergo incontinence surgery as she is more likely to develop voiding difficulties in the postoperative period (Fig. 56.2b).

Cystometry

Cystometry, which measures the pressure–volume relationship within the bladder, can differentiate between

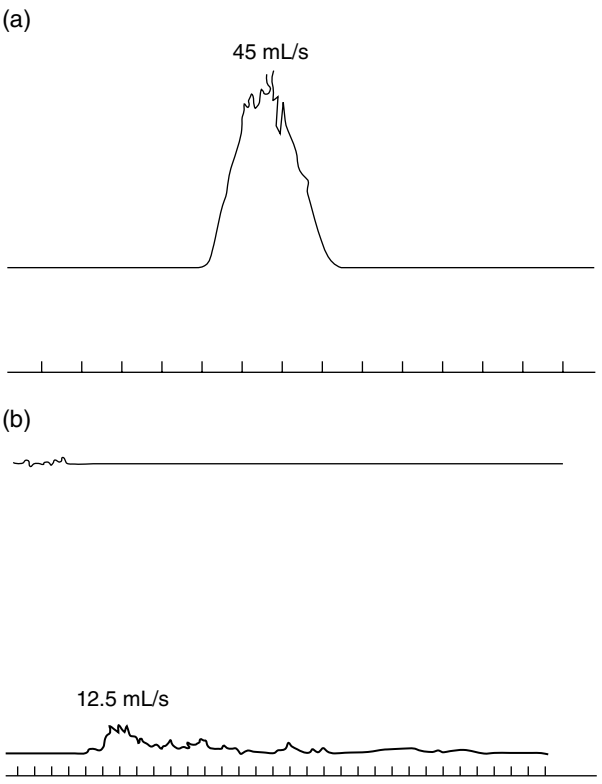

Fig. 56.2 (a) Normal uroflowmetry (maximum flow 45 mL/s, voided volume 330 mL); (b) reduced flow rate (maximum flow rate 12.5 mL/s, voided volume 225 mL).

urodynamic stress incontinence and detrusor overactivity in the majority of cases. The bladder is filled with physiological saline via a urethral catheter. During bladder filling the intravesical (total bladder) pressure and the intra-abdominal pressure are measured. The rectal (or vaginal) pressure is recorded to represent intra-abdominal pressure and this is subtracted from the bladder (intravesical) pressure to give the detrusor pressure. This is called subtracted cystometry (Fig. 56.3).

The information obtained from a subtracted cystometrogram includes sensation, capacity, contractility and compliance (Fig. 56.4). The urinary residual volume is normally less than 50 mL, the first sensation of desire to void is normally at 150–250 mL and the cystometric bladder capacity is normally 400–600 mL. Under normal circumstances, the detrusor pressure does not rise by more than 0.03 cmH_2O for 1 mL of bladder volume and there are no detrusor contractions during bladder filling. Ideally, the bladder is filled with the woman sitting or standing and the filling catheter removed once capacity is reached. She is asked to cough several times and to heel bounce and any rise in detrusor pressure or leakage per urethram is recorded. She is then asked to pass urine and the detrusor pressure is measured and any urinary residual volume can be noted (Fig. 56.5).

Videocystourethrography

Videocystourethrography with pressure and flow studies, which combines cystometry, uroflowmetry and radiological screening of the bladder and urethra, can be a most informative investigation (Fig. 56.6). It is relatively expensive and time-consuming and is only available in tertiary referral centres. Abnormal bladder morphology can be assessed as well as the presence of vesico-ureteric reflux, trabeculation or diverticula. Occasionally, a urethral diverticulum or vesicovaginal fistula may be identified (Fig. 56.7).

Special investigations

Urethral pressure profilometry

The resting urethral pressure profile (UPP) is a graphical record of pressure within the urethra at successive points along its length. Of particular interest are the maximum urethral closure pressure and functional urethral length (Fig. 56.8). In addition, stress pressure profiles can be performed if the patient coughs repeatedly during the procedure. This enables the pressure transmission ratio (the increment in urethral pressure, on stress, as a percentage of the simultaneously recorded increment in intravesical pressure) to be calculated. Urethral instability or relaxation can also be identified. Although urethral pressure profilometry is not useful in the diagnosis of urodynamic stress incontinence, it is helpful in women whose incontinence operations have failed and also in those with voiding difficulties [4].

Imaging of the urinary tract

Imaging of the urinary tract is mainly through ultrasound, X-rays or MRI [5]. Intravenous urography has now largely been replaced by ultrasound of the upper urinary tract. However, a CT urogram is important in cases of haematuria (Fig. 56.9). Additional pathology may be diagnosed, such as the presence of a ureteric fistula, a transitional cell carcinoma or calculi.

Ultrasound is now routinely used for assessing bladder volumes [6] and assessing the upper urinary tracts. Transvaginal ultrasound does allow clear visualization of the urethra and urethral diverticula. Bladder wall thickness of an empty bladder can be measured transvaginally giving a reproducible and sensitive method of screening for detrusor overactivity (a mean bladder wall thickness >5 mm gave a predictive value of 94% in the diagnosis of detrusor overactivity) [7]. Measurement of bladder wall thickness has also been shown to have a role as an adjunctive test in those women whose lower urinary tract symptoms are not explained by conventional urodynamic investigations [8].

MRI is useful in diagnosing urethral diverticula and imaging the pelvic floor muscles [9].

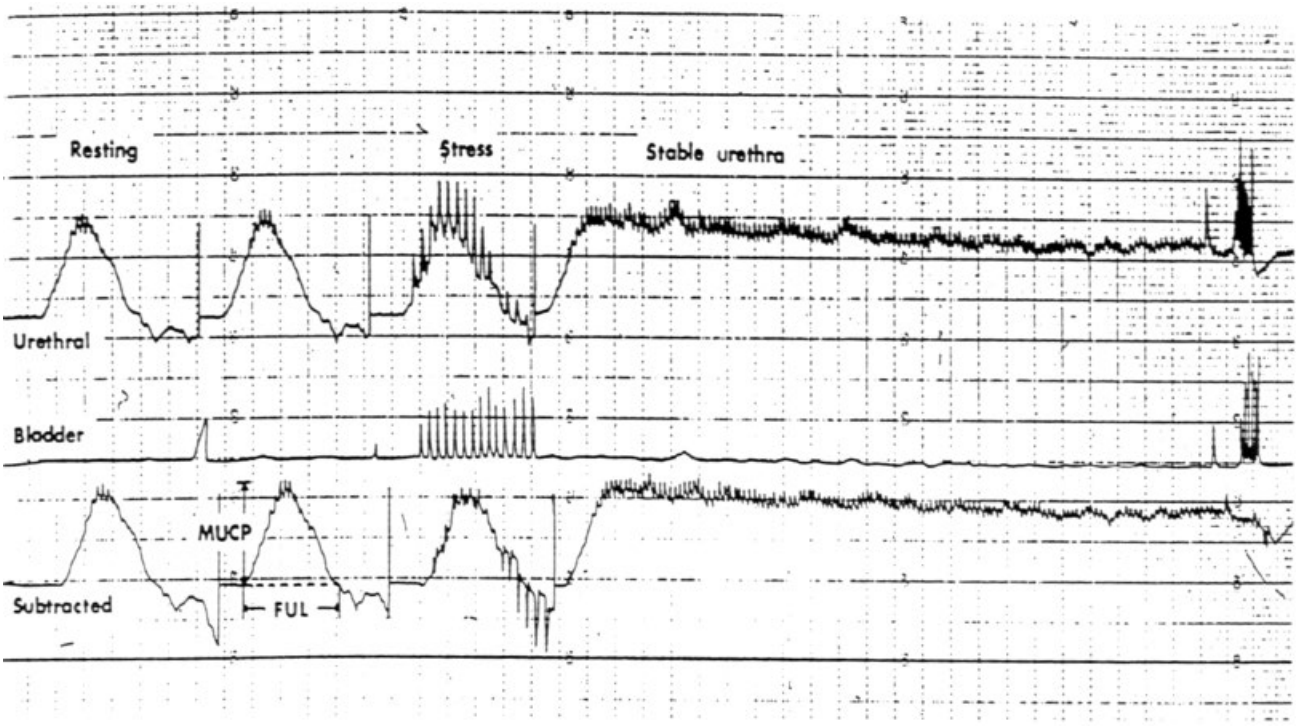

Fig. 56.8 Urethral pressure profilometry: normal trace.

Fig. 56.9 Intravenous urogram showing a right duplex ureter.

Electromyography

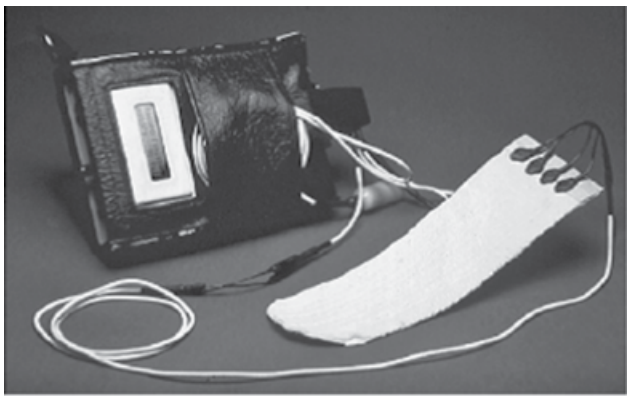
Electromyography can be employed to assess the integrity of the nerve supply to a muscle [10]. The electrical impulses to a muscle fibre are measured following nervous stimulation. Two main types of electromyography are employed in the assessment of lower urinary tract dysfunction. The pudendal nerve is stimulated and potentials measured via the electrode. This is inaccurate as the muscular activity of the levator ani is not necessarily representative of that of the rhabdosphincter urethrae [11]. Single-fibre electromyography is more accurate as it assesses the nerve latency within individual muscle fibres of the rhabdosphincter. Electromyography may be useful in the assessment of women with neurological abnormalities or those with voiding difficulties and retention of urine [12].

Ambulatory urodynamics

All urodynamic tests are unphysiological and most are invasive. Various authors have suggested that long-term ambulatory monitoring may be more physiological as the assessment takes place over a prolonged period of time and during normal daily activities. Ambulatory urodynamics is defined as a functional test of the lower urinary tract utilizing natural filling and reproducing the subject's everyday activities [13].

Ambulatory urodynamics is useful in cases where the clinical and conventional urodynamic diagnoses differ,

(a)



(b)

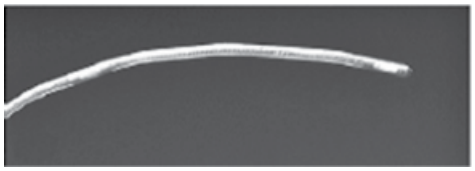


Fig. 56.10 Ambulatory urodynamic equipment demonstrating (a) the digital recording unit and Urilos pad and (b) microtip pressure transducer.

or when no abnormality is found on laboratory urodynamics [14] (Fig. 56.10). Ambulatory urodynamics has been shown to be more sensitive than laboratory urodynamics in the diagnosis of detrusor overactivity but less sensitive in the diagnosis of urodynamic stress incontinence [14], although its role in clinical practice remains controversial [15].

Summary box 56.2

Investigation of urinary incontinence

- Diagnosis may be based on symptoms or urodynamic studies.
- All women should have a full history and clinical examination.
- Frequency–volume charts are useful in making a diagnosis.
- Infection and voiding difficulties should be excluded.
- Subtracted cystometry should be considered in those patients who fail conservative therapy.
- Women with recurrent incontinence or who may have neurological problems should be investigated with videocystourethrography.
- Ambulatory urodynamics may be useful in women with symptoms not explained by conventional cystometry.
- All women with haematuria and bladder pain require cystoscopy.

Causes of urinary incontinence

Urethral incontinence will occur whenever the intravesical pressure involuntarily exceeds the intraurethral pressure. This may be due to an increase in intravesical (or detrusor) pressure or a reduction in urethral pressure or a combination of the two. Thus, the fault which leads to incontinence may lie in the urethra or the bladder or both.

Urodynamic stress incontinence

Urodynamic stress incontinence is defined as the involuntary leakage of urine during increased abdominal pressure in the absence of a detrusor contraction [3]. There are various different underlying causes that result in weakness of one or more of the components of the urethral sphincter mechanism (Table 56.4).

Urodynamic stress incontinence is associated with vaginal delivery due to denervation of the urethral sphincter mechanism or damage to the urethral sphincter [16,17]. Snooks *et al.* [18] employed electromyography to reveal evidence of pelvic floor denervation in women who had delivered vaginally but not in those who had undergone caesarean section. A long active second stage of labour was the only factor associated with severe damage.

If a woman complains of stress incontinence as her sole symptom and stress incontinence can be demonstrated on coughing, there is a 95% chance that the diagnosis is urodynamic stress incontinence. However, Haylen *et al.* [19]

Pelvic floor muscle training (PFMT)
Perineometry
Vaginal cones
Maximum electrical stimulation
Duloxetine

have shown that only 2% of women who present for urodynamic assessment fall into this category.

Conservative treatment

Types of conservative treatment for urodynamic stress incontinence are listed in Table 56.5. Conservative treatment is indicated as first-line therapy if the patient is medically unfit for surgery or does not wish to undergo an operation, or in women who have not yet completed their families.

Pelvic floor muscle training

Pelvic floor muscle training (PFMT) and pelvic floor physiotherapy remain the first-line conservative measures since their introduction in 1948 [20]. PFMT appears to work in a number of different ways:

- women learn to consciously pre-contract the pelvic floor muscles before and during increases in abdominal pressure to prevent leakage ('the knack');
- strength training builds up long-lasting muscle volume and thus provides structural support; and
- abdominal muscle training indirectly strengthens the pelvic floor muscles [21].

Cure rates varying from 21 to 84% have been reported [22,23]. Success appears to depend on the type and severity of incontinence treated, the instruction and follow-up given, the compliance of the patient and the outcome measures used. However, the evidence would suggest that PFMT is more effective if patients are given a structured programme to follow rather than simple verbal instructions [24] and it appears that pelvic floor exercises increase the size of the urethral sphincter on three-dimensional ultrasound measurement [25]. The results are not superior to continence surgery [26].

Weighted vaginal cones

These are currently available as sets of five or three [27], all of the same shape and size but of increasing weight (20–90 g). When inserted into the vagina, a cone stimulates the pelvic floor to contract to prevent it from falling out and this provides 'vaginal weight training'. A 60–70% improvement rate has been reported using this technique [27] and two studies have shown that cones are as effective as more conventional forms of pelvic floor re-education and require less supervision [28].

Maximal electrical stimulation

Maximal electrical stimulation can be carried out using a home device that utilizes a vaginal electrode through which a variable current is passed. The woman is able to adjust the strength of the stimulus herself and is instructed to use the device for 20 min daily initially for 1 month. Maximum electrical stimulation has been employed in both the management of urodynamic stress incontinence and detrusor overactivity, although it has not gained popularity [29].

Vaginal devices

There are many women who, for various reasons, are not suitable for, or who do not wish to undergo, active treatment of their incontinence. However, they do require some sort of 'containment' of their leakage and vaginal devices may be suitable for use during exercise on a short-term basis [30].

Medical therapy

Although various agents such as α_1-adrenoceptor agonists, oestrogens and tricyclic antidepressants have all been used anecdotally in the past for the treatment of stress incontinence, duloxetine is the first drug to be specifically developed and licensed for this indication.

Duloxetine is a potent and balanced serotonin (5-hydroxytryptamine) and noradrenaline reuptake inhibitor (SNRI) that enhances urethral striated sphincter activity via a centrally mediated pathway [31]. Duloxetine was associated with significant and dose-dependent decreases in incontinence episode frequency. Reductions were 41% for placebo and 54, 59 and 64% for the 20, 40 and 80 mg groups, respectively. Discontinuation rates were also dose dependent: 5% for placebo and 9, 12 and 15% for the 20, 40 and 80 mg groups, respectively; the most frequently reported adverse event was nausea [32].

Surgery

Surgery is usually the most effective way of curing urodynamic stress incontinence, and a 90% cure rate can be expected for an appropriate, properly performed primary procedure. Traditional surgery for urodynamic stress incontinence aims to support the bladder neck and proximal urethra and in some cases to increase the outflow resistance. Undoubtedly, the results of suprapubic operations such as Burch colposuspension or the Marshall–Marchetti–Krantz procedure are better than those for the traditional anterior colporrhaphy with bladder neck buttress [33–35]. Numerous operations

Urinary diversion

have been described and many are still performed today. Common operations for urodynamic stress incontinence are listed in Table 56.6.

Anterior colporrhaphy

Anterior colporrhaphy is only rarely performed for urodynamic stress incontinence. Although it is usually the best operation for a cystourethrocele, the cure rates for urodynamic stress incontinence are poor compared with those from suprapubic procedures [36]. As prolapse is relatively easier to cure than stress incontinence, it is appropriate to perform the best operation for incontinence when the two conditions coexist.

Marshall–Marchetti–Krantz procedure

The Marshall–Marchetti–Krantz procedure is a suprapubic operation in which the paraurethral tissue at the level of the bladder neck is sutured to the periostium and/or perichondrium of the posterior aspect of the pubic symphysis. This procedure elevates the bladder neck but will not correct any concomitant cystocele. It has been largely superseded by Burch colposuspension because its complications include osteitis pubis in 2–7% of cases.

Colposuspension

The Burch colposuspension has been the operation of choice in primary urodynamic stress incontinence as it corrects both stress incontinence and a cystocele. The operation is performed via a low transverse suprapubic incision. The bladder, bladder neck and proximal urethra are dissected medially off the underlying paravaginal fascia and three or four pairs of non-absorbable or long-term absorbable sutures are inserted between the fascia and the ipsilateral iliopectineal ligament. Haemostasis is secured and the sutures are tied, thus elevating the bladder neck and bladder base (Fig. 56.11). Postoperatively, a suction drain is left in the retropubic space and a suprapubic catheter is inserted into the bladder. Colposuspension is now well recognized as an effective procedure for stress incontinence but complications include detrusor overactivity, voiding difficulties or exacerbated recto-enterocele. There have been studies comparing open and laparoscopic colposuspension, with similar results if surgeons are trained adequately [33].

Sling procedures

Sling procedures are normally performed as secondary operations where there is scarring and narrowing of the vagina. The sling material can be either biological (autologous rectus fascia, porcine dermis, cadaveric fascia) or synthetic (Prolene® and Mersilene®, Ethicon, Somerville, NJ, USA). The sling may be inserted either abdominally or vaginally, or by a combination of both. Sling procedures are associated with a higher incidence of side effects and complications, especially after the insertion of inorganic material but mid- to long-term continence outcomes are superior to open colposuspension [33] but there are increased rates of irritative symptoms [37].

Retropubic mid-urethral tape procedures: tension-free vaginal tape

The tension-free vaginal tape (Gynecare®, Ethicon, Somerville, NJ, USA), first described by Ulmsten in

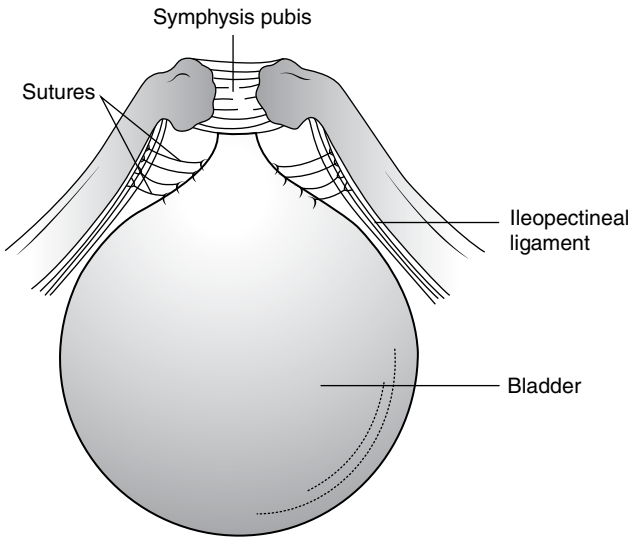

Fig. 56.11 Suture placement for the Burch colposupension between the paravaginal tissue and the ileopectineal ligament.

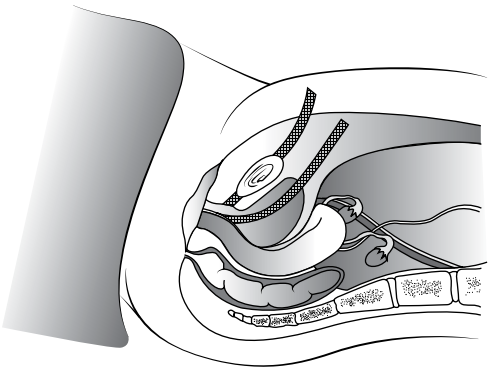

Fig. 56.12 Tension-free vaginal tape *in situ* under the mid-urethra and exiting suprapubically.

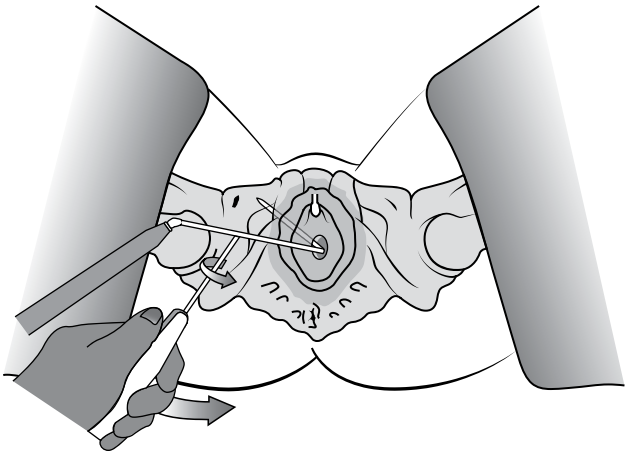

Fig. 56.13 Transobturator tape: 'inside out' procedure.

1996 [38], is now the most commonly performed procedure for SUI in the UK, and more than 2 million procedures have been performed worldwide. A knitted 11 mm × 40 cm polypropylene mesh tape is inserted transvaginally at the level of the mid-urethra, using two 5-mm trocars (Fig. 56.12). The procedure may be performed under local, spinal or general anaesthesia. Most women can go home the same day, although some do require catheterization for short-term voiding difficulties (2.5–19.7%). Other complications include bladder perforation (2.7–5.8%), *de novo* urgency (0.2–15%) and bleeding (0.9–2.3%) [34]. It has comparable outcomes to Burch colposuspension [33].

Transobturator mid-urethral sling procedures

The transobturator route for the placement of synthetic mid-urethral slings was first described in 2001 by Delorme [39] (Fig. 56.13). However, the transobturator route may be associated with damage to the obturator nerve and vessels; in an anatomical dissection model, the tape passes 3.4–4.8 cm from the anterior and posterior branches of the obturator nerve, respectively, and 1.1 cm from the most medial branch of the obturator vessels [40]. Consequently, nerve and vessel injury, in addition to bladder injury and vaginal erosion, remain a potential complication of the procedure. Also the success rate has been found to be lower than retropubic tape in randomized studies [41].

Bladder neck suspension procedures

Endoscopically guided bladder neck suspensions [42–44] are simple to perform but are less effective than open suprapubic procedures and are now seldom used.

Urethral bulking agents

Urethral bulking agents are a minimally invasive surgical procedure for the treatment of urodynamic stress incontinence and may be useful in the elderly and those women who have undergone previous operations and have a fixed, scarred and fibrosed urethra.

Although the actual substance injected may differ, the principle is the same. It is injected either periurethrally or transurethrally on either side of the bladder neck under cystoscopic control, and is intended to 'bulk' the bladder neck and mid-urethra in order to stop premature bladder neck opening, without causing outflow obstruction. The procedure may be performed under local, regional or general anaesthesia. There are now several different products available (Table 56.7). The use of minimally invasive

Table 56.7 Urethral bulking agents.

Urethral bulking agent	Application technique
Glutaraldehyde cross-linked bovine collagen (Contigen*)	Cystoscopic
Polydimethylsiloxane (Macroplastique†)	Cystoscopic MIS implantation system
Pyrolytic carbon-coated zirconium oxide beads in β-glucan gel (Durasphere‡)	Cystoscopic
Ethylene vinyl copolymer in dimethyl sulfoxide (DMSO) gel	Cystoscopic
Calcium hydroxylapatite in carboxymethylcellulose gel (Coaptite§)	Cystoscopic
Copolymer of hyaluronic acid and dextranomer	Cystoscopic Implacer system
Polyacrylamide hydrogel (Bulkamid¶)	Cystoscopic

implantation systems (Fig. 56.14) has also allowed some of these procedures to be performed in the office setting without the need for cystoscopy. Long-term follow-up studies give a greater than 50% objective cure rate at 2 years but a subjective improvement rate of about 70% [45–47].

Although success rates with urethral bulking agents are generally lower than those with conventional continence surgery, they are minimally invasive and have lower complication rates, meaning that they remain a useful alternative in selected women.

Artificial urinary sphincter

An artificial sphincter is a device that may be employed when conventional surgery fails [48]. It is implantable and consists of a fluid-filled inflatable cuff that is surgically placed around the bladder neck. A reservoir containing fluid is sited in the peritoneal cavity and a small finger-operated pump is situated in the left labium majus. The three major components are connected via a control valve. Under normal circumstances the cuff is inflated and thus obstructs the urethra. When voiding is desired the pump is utilized to empty the fluid in the cuff back into the balloon reservoir so that voiding may occur. The cuff then gradually refills over the next few minutes. Artificial sphincters are associated with many problems [49]: they are expensive, the surgery required to insert them is complicated and the tissues around the bladder neck following previous failed operations may be unsuitable for the implantation of the cuff. In addition, mechanical failure may occur, necessitating further surgery. However, there is a place for these devices and their technology is likely to improve in the future.

National Institute for Health and Care Excellence guidelines

In the UK, the management of SUI has recently been reviewed by the National Institute for Health and Care Excellence (NICE) [50]. A trial of supervised PFMT of at least 3 months' duration should be offered as first-line treatment to all women with stress or mixed urinary incontinence.

Retropubic mid-urethral tape procedures using a 'bottom-up' approach with macroporous (type 1) polypropylene meshes are recommended as treatment options for SUI in cases where conservative management has failed. Open colposuspension and autologous rectus fascial sling procedures are recommended alternatives where clinically appropriate. Synthetic slings using materials other than polypropylene that are not of a macroporous (type 1) construction are not recommended for the treatment of SUI.

Intramural bulking agents (glutaraldehyde cross-linked collagen, silicone, carbon-coated zirconium beads} should be considered for the management of SUI if conservative management has failed, although women should be made aware that repeat injections

may be required and that efficacy diminishes with time and is inferior to that of a retropubic suspension or sling.

Laparoscopic colposuspension is not recommended as a routine procedure for the treatment of SUI in women and should only be performed by an experienced laparoscopic surgeon. Anterior colporrhaphy, needle suspension procedures, paravaginal defect repair and the Marshall–Marchetti–Krantz procedure are not recommended.

Conclusions: stress incontinence

It is important to remember that the first operation for stress incontinence is the most likely to succeed. Most suprapubic operations in current use produce a cure rate in excess of 85–90% in patients undergoing their first operation for correctly diagnosed urodynamic stress incontinence. The colposuspension has long been recognized as the 'best' first operation, although mid-urethral tape procedures would now appear to be as efficacious. Repeat continence surgery is often less efficacious than primary surgery and subsequent surgery may have to be performed on a vagina that is less mobile and in which there is fibrosis of the urethra. In such cases, insertion of a urethral bulking agent may be easier to perform and more effective. Ultimately, it is important that the operative procedure performed is tailored to the needs of the individual.

Summary box 56.3

Stress urinary incontinence

- SUI is a symptom.
- Urodynamic stress incontinence is a urodynamic diagnosis.
- SUI is the commonest form of incontinence in women.
- All women should be treated conservatively with PFMT initially.
- Duloxetine may be useful in addition to PFMT.
- Women who fail to improve with conservative measures may be suitable for surgery.
- Mid-urethral tapes are currently the most commonly performed operation for SUI.

Detrusor overactivity

Detrusor overactivity is defined as a urodynamic observation characterized by involuntary contractions during the filling phase that may be spontaneous or provoked [3]. It is the second commonest cause of urinary incontinence in women and accounts for 30–40% of cases. The incidence is higher in the elderly and after failed incontinence surgery. The cause of detrusor overactivity remains uncertain and in the majority of cases it is idiopathic, occurring when there is a failure of adequate bladder training in childhood or when the bladder escapes voluntary control in adult life. In some cases detrusor overactivity may be secondary to an upper motor neurone lesion, especially multiple sclerosis. In such cases it is known as neurogenic detrusor overactivity. In men, detrusor overactivity may be secondary to outflow obstruction and may be cured when the obstruction is relieved. However, outflow obstruction in women is rare.

Low compliance is said to exist when there is a sustained rise in detrusor pressure without actual detrusor contractions during bladder filling. There is a variety of causes, including radical pelvic surgery, radiotherapy, recurrent urinary tract infections and interstitial cystitis, but the symptoms associated with phasic detrusor overactivity and with low compliance may be indistinguishable without cystometry (Fig. 56.15).

Detrusor overactivity and overactive bladder

The symptoms of OAB are due to involuntary contractions of the detrusor muscle during the filling phase of the micturition cycle (termed detrusor overactivity). However, OAB is not synonymous with detrusor overactivity as the former is a symptom-based diagnosis whereas the latter is a urodynamic diagnosis. It has been estimated that 64% of patients with OAB have urodynamically proven detrusor overactivity and that 83% of patients with detrusor overactivity have symptoms suggestive of OAB [51].

Clinical symptoms

Most women with an OAB exhibit a multiplicity of symptoms, including urgency, urgency incontinence, stress incontinence, enuresis, frequency and especially nocturia and sometimes incontinence at orgasm [52]. There are no specific clinical signs and the diagnosis can only be made urodynamically when there is a failure to inhibit detrusor contractions during cystometry.

Treatment for detrusor overactivity aims to re-establish central control or to alter peripheral control via bladder innervation (Table 56.8). The fact that so many different types of treatment are available for this condition shows that none is universally successful. Various behavioural interventions (habit retraining) have been successfully

used to treat idiopathic detrusor overactivity and have been shown to improve symptoms in up to 80% of women [53,54]. Unfortunately, these types of therapy are time-consuming and require the patient to be highly motivated. However, it is always appropriate to instruct patients with detrusor overactivity regarding the use of bladder drill, which is timed voiding, often as an adjunct to drug therapy.

Drug therapy

Drug therapy is the most widely employed treatment for detrusor overactivity (Table 56.9). From the number of preparations studied it is clear that there are no ideal drugs and very often the clinical results have been disappointing, this being partly due to poor efficacy and side effects [55].

Drugs that have a mixed action

Oxybutynin The effectiveness of oxybutynin in the management of patients with detrusor overactivity is well documented. A double-blind placebo-controlled trial found oxybutynin to be significantly better than placebo in improving lower urinary tract symptoms, although 80% of patients complained of significant adverse effects, principally dry mouth or dry skin [56]. Similar results have also been demonstrated in further placebo-controlled trials [57,58]. These can be mitigated by slow-release preparations or alternative methods of administration (e.g. topical or intravesical).

Propiverine Propiverine (Detrunorm, Amdipharm UK Ltd, London) has been shown to combine anticholinergic and calcium channel blocking actions [59]

and may be useful in women who have troublesome adverse effects with other antimuscarinic agents. An extended-release preparation has also recently been launched. In a study by Stohrer *et al.* [60], dry mouth was experienced by 37% in the treatment group as opposed to 8% in the placebo group, with drop-out rates being 7% and 4.5%.

Antimuscarinic drugs

Tolterodine Tolterodine is a competitive muscarinic receptor antagonist with relative functional selectivity for bladder muscarinic receptors [61] and although it shows no specificity for receptor subtypes, it does appear to target the bladder over the salivary glands [62]. The drug is metabolized in the liver to the 5-hydroxymethyl derivative, which is an active metabolite having a similar pharmacokinetic profile and is thought to significantly contribute to the therapeutic effect [63].

Several randomized, double-blind, placebo-controlled trials on patients with both idiopathic detrusor overactivity and neurogenic detrusor overactivity have demonstrated a significant reduction in incontinent episodes and micturition frequency [64–66]. Further studies have confirmed the safety of tolterodine and at the recommended daily dosage the incidence of adverse events was no different to that in patients taking placebo [67].

Trospium Trospium chloride (Specialty European Pharma, London, UK) is a quaternary ammonium compound that is non-selective for muscarinic receptor subtypes and shows low biological availability [68]. It crosses the blood–brain barrier to a limited extent, and hence would appear to have few cognitive effects [69]. Overall, trospium chloride was associated with a significant improvement in urinary frequency, incontinence episodes, urgency severity and volume voided when compared with placebo. The most common side effect was dry mouth (trospium 8.7% vs. placebo 3%) and constipation (trospium 9.4% vs. placebo 1.3%).

Solifenacin Solifenacin (Astellas, Chertsey, Surrey, UK) is a potent M_3 receptor antagonist that has selectivity for the M_3 receptors over M_2 receptors and has much higher potency against M_3 receptors in smooth muscle than it does against M_3 receptors in salivary glands [70].

The evidence would appear to suggest that solifenacin may offer superior efficacy to the other currently available antimuscarinic agents and that switching from tolterodine to solifenacin offers improved efficacy rates [71]. Pooled data from the phase III studies have demonstrated equal efficacy in the elderly [72] while phase IV studies have shown little cognitive effect, a synergistic effect with conservative therapy [73] and improvement in quality-of-life and patient-reported outcome measures [74].

Darifenacin Darifenacin (Warner Chilcott, Rockaway, NJ, USA) is a tertiary amine with moderate lipophilicity and is a highly selective M_3 receptor antagonist that has been found to have a fivefold higher affinity for the human M_3 receptor relative to the M_1 receptor [75].

A review of the pooled darifenacin data from three phase III, multicentre, double-blind clinical trials in 1059 patients with OAB has been reported [76]. Darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week. Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation.

Fesoterodine Fesoterodine (Pfizer, Sandwich, Kent, UK) is a derivative of 3,3 diphenylpropylamine, which is a non-selective antimuscarinic agent that has recently been developed for the management of OAB. It is rapidly and extensively converted by ubiquitous esterases to its active metabolite 5-hydroxymethyl tolterodine (5-HMT) [77]. The pharmacokinetic profile of 5-HMT is dose proportional at doses up to 12 mg, and thus allows for flexible dosing [78]. Although tolterodine is also converted to 5-HMT, this occurs primarily in the liver via cytochrome P450 (CYP) 2D6, and hence is more dependent on the metabolizer status of the patient. Consequently, the potential benefit of fesoterodine over tolterodine is that it allows a more predictable dose–effect relationship. The current evidence would suggest that fesoterodine may offer some advantages over tolterodine in terms of efficacy and flexible dosing regimens.

Antidepressants

Imipramine Imipramine has been shown to have systemic anticholinergic effects and blocks the reuptake of serotonin. Some authorities have found a significant effect in the treatment of patients with detrusor overactivity [79], although others report little effect [80]. In light of this evidence and the serious adverse effects associated with tricyclic antidepressants, their role in detrusor overactivity remains of uncertain benefit, although they are often useful in patients complaining of nocturia or bladder pain.

Antidiuretic agents

Desmopressin Desmopressin (1-desamino-8-D-arginine vasopressin; DDAVP) (Ferring Pharmaceuticals, Copenhagen, Denmark) is a synthetic vasopressin analogue. It has strong antidiuretic effects without altering blood pressure. The drug has been used primarily in the treatment of nocturia and nocturnal enuresis in children [81] and adults [82]. Desmopressin is safe for long-term use; however, the drug should be used with care in the elderly owing to the risk of hyponatraemia.

Intravesical therapy

Botulinum toxin Botulinum toxin interferes with neural transmission by blocking the calcium-dependent release of the neurotransmitter acetylcholine, causing the affected muscle to become weak and atrophic. The affected nerves do not degenerate, but as the blockage is irreversible only the development of new nerve terminals and synaptic contacts allows recovery of function.

The role of botulinum toxin has been established in the treatment of neurogenic and idiopathic detrusor overactivity using 200 units and 100 units of botulinum toxin A respectively. The main complications are urinary retention and the need for intermittent self-catheterization and urinary tract infection [83].

At present, the evidence would suggest that cystoscopic administration of botulinum toxin may offer an alternative to surgery in those women with intractable detrusor overactivity, although the effect lasts for up to 9 months.

Neuromodulation

Peripheral neuromodulation

Stimulation of the posterior tibial nerve in patients with urge incontinence was first reported in 1983 [84] and has also been proposed for pelvic floor dysfunction [85]. The tibial nerve is a mixed nerve containing L4–S3 fibres and originates from the same spinal cord segments as the innervation to the bladder and pelvic floor. Consequently, peripheral neuromodulation may have a role in the management of urinary symptoms.

Peripheral neuromodulation may offer an alternative therapeutic option for those patients with intractable OAB who have failed to respond to medical therapy, although it remains less cost-effective than treatment with antimuscarinic agents.

Sacral neuromodulation

Stimulation of the dorsal sacral nerve root using a permanent implantable device in the S3 sacral foramen has been developed for use in patients with both idiopathic and neurogenic detrusor overactivity (Fig. 56.16). The sacral nerves contain nerve fibres of the parasympathetic and sympathetic systems providing innervation to the bladder as well as somatic fibres providing innervation to the muscles of the pelvic floor. The latter are larger in diameter and hence have a lower threshold of activation, meaning that the pelvic floor may be stimulated selectively without causing bladder activity. Prior to implantation, temporary cutaneous sacral nerve stimulation is performed to check

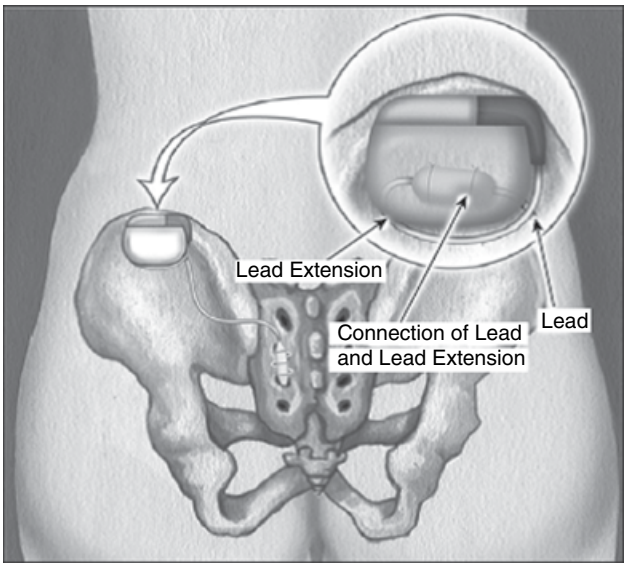

Fig. 56.16 Sacral neuromodulation.

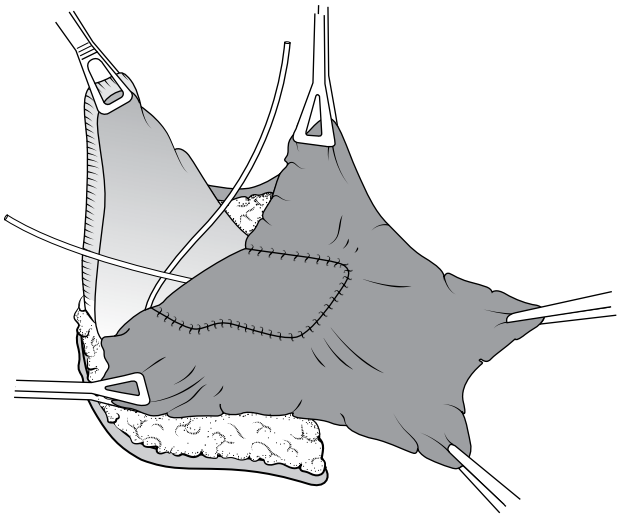

Fig. 56.17 Clam ileocystoplasty.

for a response and, if successful, a permanent implant is inserted under general anaesthesia. Initial studies in patients with detrusor overactivity refractory to medical and behavioural therapy have demonstrated that, after 3 years, 59% of 41 urinary urge incontinent patients showed a greater than 50% reduction in incontinence episodes, with 46% of patients being completely dry. However, up to 50% of implanted patients will require reoperation and the stimulators need replacing after 10 years.

Although neuromodulation remains an invasive and expensive procedure, it offers a useful alternative to medical and surgical therapies in patients with severe intractable detrusor overactivity.

Surgery

For those women with severe detrusor overactivity that is not amenable to simple types of treatment, surgery may be employed.

Clam cystoplasty

In the clam cystoplasty [86] the bladder is bisected almost completely and a patch of gut (usually ileum) equal in length to the circumference of the bisected bladder (about 25 cm) is sewn in place (Fig. 56.17). This often cures the symptoms of detrusor overactivity [87] by converting a high-pressure system into a low-pressure system, although inefficient voiding may result. Patients have to learn to strain to void, or may have to resort to clean intermittent self-catheterization, sometimes permanently. In addition, mucus retention in the bladder may be a problem, but this can be partially overcome by ingestion of 200 mL of cranberry juice each day [88] in addition to intravesical mucolytics such as acetylcysteine. The chronic exposure of the ileal mucosa to urine may lead to malignant change [89]. In addition, metabolic disturbances such as hyperchloraemic acidosis, vitamin B_{12} deficiency and occasionally osteoporosis secondary to decreased bone mineralization may occur.

Urinary diversion

As a last resort for those women with severe detrusor overactivity or neurogenic detrusor overactivity who cannot manage clean intermittent catheterization, it may be more appropriate to perform a urinary diversion. Usually this will utilize an ileal conduit to create an abdominal stoma for urinary diversion. An alternative is to form a continent diversion using the appendix (Mitrofanoff) or ileum (Koch pouch), which may then be drained using self-catheterization.

National Institute for Health and Care Excellence guidelines

The medical management of OAB has been reviewed by NICE [50]. In the first instance, bladder retraining lasting for a minimum of 6 weeks should be offered to all women with mixed or urge incontinence. In those women who do not achieve satisfactory benefit from bladder retraining alone, the combination of an antimuscarinic agent and bladder retraining should be considered.

When considering drug therapy, immediate-release non-proprietary tolterodine should be offered to women with OAB or mixed urinary incontinence as first-line drug treatment if bladder retraining has been ineffective. If immediate-release tolterodine is not well tolerated, darifenacin, solifenacin, trospium or an extended-release

formulation of tolterodine should be considered as alternatives. In addition, women should be counselled regarding the adverse effects of antimuscarinic drugs.

Propiverine should be considered as an option to treat frequency of micturition but is not recommended for the treatment of urinary incontinence. Flavoxate, propantheline and imipramine should not be used for the treatment of OAB. Although desmopressin may be considered specifically to reduce nocturia in women, it is currently outside marketing authorization and hence informed consent must be obtained.

When considering the role of oestrogens, systemic hormone replacement therapy should not be recommended, although intravaginal oestrogens are recommended for the treatment of OAB in postmenopausal women with urogenital atrophy.

Summary box 56.4

Overactive bladder and detrusor overactivity

- OAB is a symptomatic diagnosis.
- Detrusor overactivity is a urodynamic diagnosis.
- All women benefit from conservative measures and bladder retraining.
- Antimuscarinics are the most commonly used drugs.
- Patients refractory to drug therapy may benefit from botulinum toxin.
- Neuromodulation may be useful in refractory cases.
- Reconstructive surgery should only be considered when all other therapy has failed.

Mixed incontinence

Those women with both detrusor overactivity and urodynamic stress incontinence pose a difficult management problem. The detrusor overactivity is initially treated with antimuscarinic agents but if there is persistent SUI once the urgency and urgency incontinence is treated, then continence surgery is performed. However, if urge incontinence still predominates, surgery may aggravate the woman's symptoms.

Retention with overflow

In women, chronic retention with resultant overflow incontinence is uncommon and often no cause can be found. It is one manifestation of the wide range of voiding difficulties which may occur, the major causes of which are shown in Table 56.10.

Table 56.10 Causes of voiding difficulties leading to overflow incontinence in women.

Urethral distortion due to large cystocele
Myogenic
Atonic detrusor secondary to over-distension
Functional
Anxiety

Women with overflow incontinence present in a variety of ways. They may complain of dribbling urine or of voiding small amounts at frequent intervals, or of stress incontinence. Alternatively, they may notice recurrent urinary tract infections. The diagnosis is usually made by the discovery of a large bladder on clinical examination. This can be confirmed by a post-micturition ultrasound scan to assess the residual urine volume or by catheterization, which will reveal a residual volume of more than 50% of bladder capacity. There may, in addition, be a reduced peak flow rate of less than 15 mL/s.

Clinical examination will rule out many of the causes, such as a pelvic mass or a cystocele. It is important to investigate cases of urinary retention thoroughly in order to exclude any treatable underlying pathology. An MSU specimen should be sent for culture and sensitivity, and the appropriate swabs (urethral, vaginal and cervical) should also be sent. Radiological investigations should include intravenous urography, an X-ray of the lumbosacral spine and an MRI scan where indicated. It is particularly important to identify diabetes so that treatment can be undertaken before permanent damage occurs.

Treatment for overflow incontinence will depend on the underlying pathology. If the detrusor is hypotonic, cholinergic agents such as bethanechol 25 mg three

times a day may be helpful. If there is outflow obstruction, urethral dilatation or urethrotomy may be required. In cases where no cause can be found, clean intermittent self-catheterization is the best long-term method of management for these patients.

Fistulae

Urinary fistulae may be ureterovaginal, vesicovaginal, urethrovaginal or complex, and can occur following pelvic surgery or in cases of advanced pelvic malignancy, especially when there has been radiotherapy. The most common varieties in the UK are lower ureteric or bladder fistulae occurring after an abdominal hysterectomy. In developing countries, poor obstetrics with obstructed labour resulting in ischaemic necrosis of the bladder base is more likely to be the cause of a vesicovaginal or urethrovaginal fistula.

Fistulae give rise to incontinence that is continuous, occurring both day and night. They are usually visible on speculum examination but cystoscopy and intravenous urography may be required to confirm the diagnosis.

Treatment is surgical. Ureterovaginal fistulae should be repaired as quickly as possible to prevent upper urinary tract damage. Vesicovaginal fistulae are usually treated conservatively, initially with bladder drainage and antibiotics, during which time some will close spontaneously. Abdominal or vaginal repair is normally performed 2 or 3 months after the initial injury, although there is now a trend towards earlier repair; if a fistula is detected within a very short period of time after the initial operation, it can often be closed immediately.

Urethral diverticulum

Urethral diverticula are becoming more common, presumably because of the increased incidence of sexually transmitted infections. They are found in women of any age and lead to various complaints including pain, particularly after micturition, post-micturition dribble and dyspareunia. Diagnosis can be made either radiologically on a micturating cystogram or videocystourethrogram or by urethroscopy. In addition, MRI may be useful. Urethral diverticula should be managed conservatively, initially with intermittent courses of antibiotics if necessary; if there are severe symptoms, then surgical excision of the diverticulum may be required. It is usual to perform a subtotal diverticulectomy in order to avoid urethral stricture formation, and following the procedure a urethral catheter is left in place for 2 weeks, acting as a stent to allow the urethra to heal.

General conservative measures

All incontinent women benefit from simple measures such as the provision of suitable incontinence pads and pants. Those with a high fluid intake should be advised to restrict their drinking to 1 L a day, particularly if frequency of micturition is a problem. Caffeine-containing drinks (such as teas, coffee and cola) and alcohol are irritant to the bladder and act as diuretics, so should be avoided if possible. Anything that increases intra-abdominal pressure will aggravate incontinence, so patients with a chronic cough should be advised to give up smoking, and constipation should be treated appropriately.

Women with long-standing severe incontinence, especially the elderly, may be more comfortable and easier to manage with a regularly changed indwelling suprapubic catheter; for the young disabled, urinary diversion should be considered earlier rather than later. It is not always possible to cure urinary incontinence but it is usually possible to help the sufferer and thus improve her quality of life.

Oestrogens in the management of incontinence

From the available evidence oestrogen alone does not appear to be an effective treatment for SUI. There was some evidence suggesting that the use of local oestrogen therapy may improve urgency incontinence (relative risk, RR 0.74, 95% CI 0.64–0.86) and overall there were one or two fewer voids in 24 hours and less frequency and urgency [90]. The authors concluded that local oestrogen therapy for incontinence may be beneficial, although there was little evidence of long-term effects. The evidence would suggest that systemic hormone replacement using conjugated equine oestrogens may make incontinence worse. In addition, the authors comment that there are too few data to comment reliably on the dose, type of oestrogen and route of administration.

Other lower urinary tract disorders

Urethral lesions

Urethral caruncle

A urethral caruncle is a benign red polyp or lesion covered by transitional epithelium usually found on the

posterior aspect of the urethral meatus. It is commonly seen in postmenopausal women and although usually asymptomatic, it may cause pain, bleeding and dysuria. The cause is unknown. Treatment is by excision biopsy and local vaginal oestrogens.

Urethral mucosal prolapse

Prolapse of the urethral mucosa also occurs in the postmenopausal woman but, in addition, is sometimes seen in girls (usually Black) between the ages of 5 and 10 years. It is a reddish lesion that encompasses the whole circumference of the external urethral meatus, thus differentiating it from urethral caruncle. Urethral mucosal prolapse is not painful but may cause bleeding, dysuria or urethral discharge. It may be treated by excision or cautery.

Urethral stenosis or stricture

Outflow obstruction due to urethral stenosis or stricture is rare in women. Such lesions usually present after the menopause and are found in the distal urethra. They are often the result of chronic urethritis or may follow fibrosis from repeated urethral dilatations or other surgery to the urethra. The most common symptoms are of voiding difficulties, but recurrent urinary tract infections may occur. Diagnosis can be made using uroflowmetry in conjunction with cystometry or by videocystourethrography. Urethral pressure profilometry or cystourethroscopy will help to localize the lesion. Urethrotomy, either Otis or open, is the treatment of choice, and local oestrogen therapy may be helpful in postmenopausal women.

Urinary frequency and urgency

Definitions [2]

- *Diurnal frequency*: the complaint that micturition occurs more frequently during waking hours than previously deemed normal.
- *Nocturia*: the complaint of interruption of sleep one or more times because of the need to micturate. Each void is preceded and followed by sleep.
- *Urgency*: the complaint of a sudden compelling desire to pass urine, which is difficult to defer.
- *Urgency incontinence*: the complaint of involuntary leakage accompanied by or immediately preceded by urgency.

Causes and assessment

There are many different causes of frequency and urgency of micturition; the more common ones are shown in Table 56.11.

Clinical examination will exclude many of the causes. This is important before expensive time-consuming investigations are undertaken. As one of the commonest causes of frequency of micturition is a lower urinary tract infection, it is important to send an MSU specimen for culture and sensitivity. If negative in persistent symptomatic women, then fastidious organisms such as *Mycoplasma hominis* and *Ureaplasma urealyticum* or *Chlamydia trachomatis* should be tested for. If there is a history of haematuria, loin or groin pain, and a urinary tract infection cannot be identified, intravenous urography and cystoscopy should be performed.

The investigations performed should be organized around the patient's precise symptomatology. However, a frequency–volume chart is often useful as it may identify excessive drinking as the cause of urinary frequency or diagnose nocturnal polyuria. For women with incontinence in addition to frequency with or without urgency, it is best to organize urodynamic studies prior

to cystoscopy as the latter is usually unrewarding. Subtracted cystometry detects detrusor overactivity, which is a major cause of urgency and frequency and also reveals chronic retention of urine with an atonic bladder, which may lead to frequency or recurrent urinary tract infections. For women with frequency, urgency and dysuria without incontinence, a cystourethroscopy may be more helpful than a urodynamic assessment.

Treatment

As for detrusor overactivity, treatment should be directed to the underlying cause if one has been identified.

Painful bladder syndrome

Painful bladder syndrome is the complaint of suprapubic pain related to bladder filling accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology [3]. A cause of painful bladder syndrome in women is interstitial cystitis.

Interstitial cystitis

Interstitial cystitis produces severe symptoms that include frequency, dysuria and lower abdominal and urethral pain. It affects individuals of both sexes, although only about 10% of sufferers are men. The peak age is 30–50 years [91]. There is growing evidence that interstitial cystitis is an autoimmune disease. Histological changes in bladder wall biopsies are consistent with a connective tissue disorder. The most common marker is mast cell infiltration of the muscularis layer of the bladder.

Diagnosis

The diagnosis of interstitial cystitis can be difficult. Pain is the most common presenting complaint and occurs in 70% of sufferers. This is usually suprapubic, although urethritis, loin pain and dyspareunia are also frequently encountered. A long history of a combination of frequency, urgency and dysuria in the absence of proven infection is often present. Other urinary complaints may coexist. Many of the women have previously undergone hysterectomy, although it is difficult to know if this represents a true relationship or just reflects desperate attempts on the part of the doctor to relieve the patient's symptoms.

Clinical examination is usually unrewarding and the diagnosis is often based on the finding of sensory urgency (painful catheterization, urgency and the absence of a rise in detrusor pressure and a bladder capacity of less than 300 mL) at dual-channel subtracted cystometry. Cystoscopy needs to be undertaken under general anaesthesia in order to obtain a good-sized bladder biopsy. Terminal haematuria at either urodynamic investigation or cystoscopy is suggestive of interstitial cystitis (Fig. 56.18). Characteristically, the cystoscopic findings include petechial haemorrhages on distension, especially with a second fill, reduced bladder capacity and rarely Hunner's ulcers. There is still confusion because of the lack of conformity in diagnostic parameters commonly used. Table 56.12 lists the criteria for excluding a diagnosis of interstitial cystitis.

Treatment

Interstitial cystitis is the final common pathway of a multifactorial disease process and therefore many different types of treatment have been proposed. Many patients benefit from simple self-help measures and the avoidance of caffeine-containing compounds (tea, coffee and cola) and dietary changes.

Both non-steroidal and steroidal anti-inflammatory agents such as azathioprine, sodium cromoglycate and chloroquine have been tried [91]. Sodium pentosan polysulfate is believed to decrease the bladder wall permeability, and variable success rates have been quoted, from 27% [92] to 83% [93]. Heparin, which is thought to reduce the available cations and have a similar effect to sodium pentosan polysulfate, has also been employed [94].

Those who prefer an infective hypothesis of causation have employed long-term antibiotics. Norfloxacin can be given 400 mg nightly for 3 months or, alternatively, a bladder antiseptic such as hexamine hippurate may be used.

Dimethyl sulfoxide (DMSO) has also been instilled into the bladder with some success [95] and recent randomized studies have shown a superior outcome using iAluril over DMSO. Tricyclic antidepressants are used in low doses as an adjunct to treatment to help relieve pain [96].

Although bladder distension has been used for the treatment of sensory bladder disorders, there is no evidence to support the use of this technique in interstitial cystitis. Short-term benefit may be reported, but repeated distensions can lead to an exacerbation of symptoms. There is still a place for either substitution cystoplasty or urinary diversion in severely affected patients but augmentation cystoplasty is rarely effective as pain continues to be a problem.

The majority of women who suffer with interstitial cystitis do so for many years until they either find ways of coping with their symptoms or eventually undergo surgery. Fortunately, the symptoms tend to wax and wane and it is often possible to provide support and intermittent therapy until a remission occurs [97].

For postmenopausal women, failure of adequate lubrication during sexual intercourse may be a problem so a

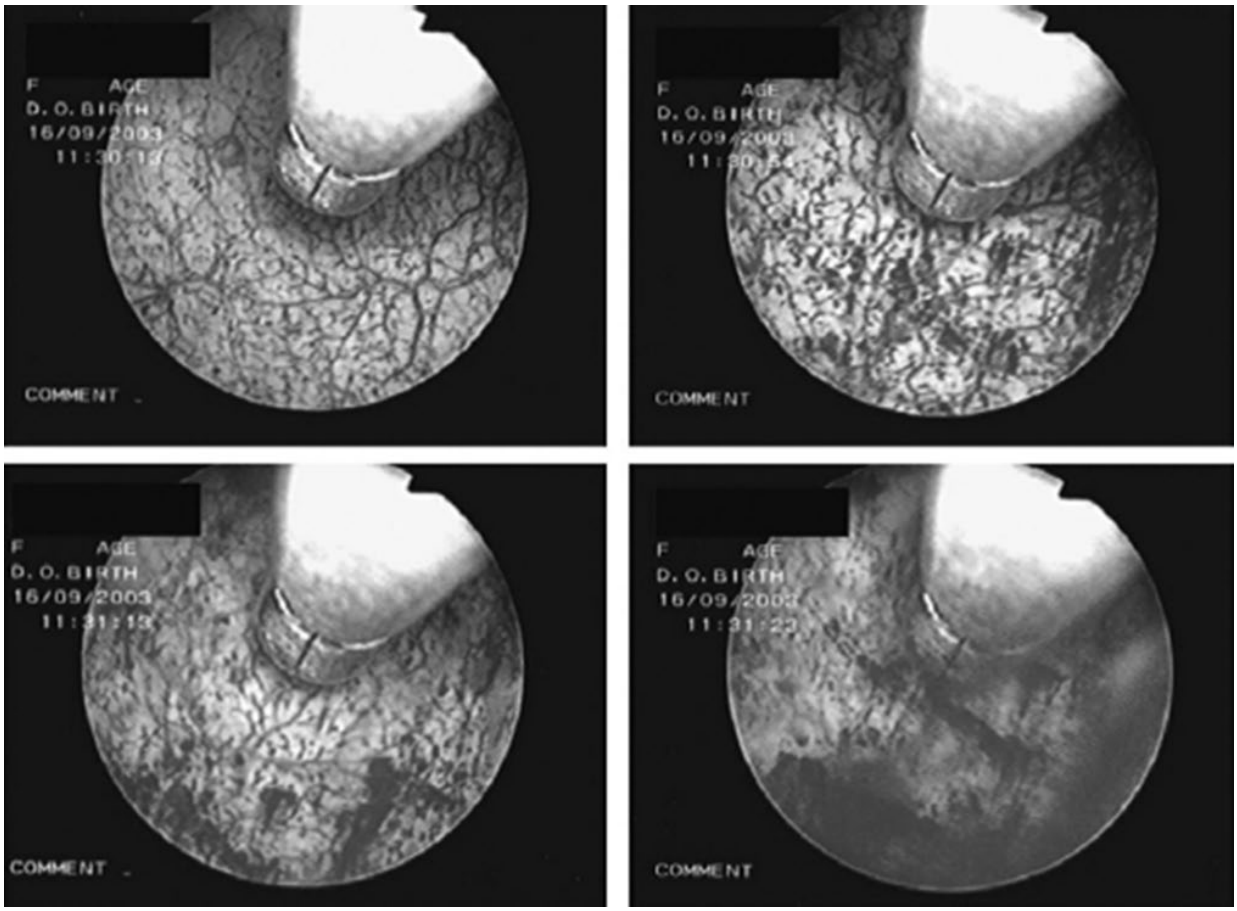

Fig. 56.18 Series of cystoscopic images showing gradual cystodistension with haemorrhage in a young woman with interstitial cystitis.

Table 56.12 Criteria for excluding a diagnosis of interstitial cystitis.

Bladder capacity >350 mL on awake cystometry
Absence of an intense desire to void at 150 mL during medium-fill cystometry (30–100 mL/min)
Demonstration of phasic involuntary bladder contractions on cystometry
Symptomatology of <9 months' duration
Absence of nocturia
Symptoms relieved by antimicrobials, urinary antiseptics, antimuscarinics or antispasmodics
Urinary diurnal frequency <9 times
Diagnosis of bacterial cystitis within the last 3 months
Bladder calculi
Active genital herpes
Gynaecological malignancy
Urethral diverticulum
Chemical cystitis
Tuberculosis
Radiation cystitis
Bladder tumours
Vaginitis
Age <18 years

lubricant gel or preferably vaginal oestrogen replacement should be prescribed [98]. For premenopausal women who develop recurrent urinary tract infections associated with sexual intercourse, post-coital antibiotic prophylaxis with trimethoprim, nitrofurantoin or cephalexin has been shown to be highly effective.

Conclusion

Urinary incontinence is common and, though not life-threatening, is known to have a significant effect on quality of life. Appropriate investigation and management allow an accurate diagnosis and avoid inappropriate treatment. Although many forms of conservative therapy may be initiated in primary care, continence surgery, and the investigation of more complex and recurrent cases of incontinence, should be performed in specialist secondary and tertiary referral units. Ultimately, an integrated pathway utilizing a multidisciplinary team approach including specialist nurses, continence advisers, physiotherapists, urologists and colorectal surgeons will ensure the best possible outcomes in terms of 'cure' and patient satisfaction.

Benign Diseases of the Vulva

Fiona M. Lewis[1,2]

[1] *St John's Institute of Dermatology, Guy's and St Thomas' NHS Trust, London, UK*
[2] *Frimley Health NHS Trust, Slough, UK*

Many women who present with vulval symptoms may have a dermatological problem rather than an infective or gynaecological complaint. It is therefore important that all healthcare professionals who see these patients learn to recognize the common skin conditions that affect the vulva and to refer for dermatological advice and management appropriately. Many clinics with a multidisciplinary team have been established to provide a specific service for women with vulval disorders.

This chapter gives an overview of the common skin problems that affect the vulva and the basic principles of initial management.

History-taking

A good history is the initial step in making an accurate diagnosis in any patient who presents with vulval symptoms. A clear method of history-taking should be used, and a proforma can be helpful to ensure that the key areas are covered.

The interview should take place in a sympathetic environment and it is often helpful to enquire about the general history initially before moving on to the more personal questions related to vulval disease.

The following areas should all be covered, but sometimes more detail is required about specific symptoms depending on the presenting problem.

- Presenting symptoms: is it itch or pain? Patients may report 'irritation' but this should always be qualified, as irritation is not always synonymous with itching. It is helpful to ask if they want to scratch to alleviate the symptoms, as if they say no, then itch is not the problem. Is the itching constant or intermittent and are there any provoking or alleviating factors?
- Previous treatments: what has been used (prescribed and over-the-counter medication) and what was the response? What regimen was used?
- Dermatological history: ask about a personal and family history of atopy and psoriasis. Ask about any other skin problems, either past or present, and also specifically about oral and ocular symptoms. Do they have any known allergies?
- Gynaecological history: is there any relationship of the symptoms with menstruation? If the patient has been pregnant, were deliveries straightforward or complicated resulting in trauma to the vulva? The history relating to cervical smears and any abnormalities or treatment is important, particularly in patients with vulval intraepithelial neoplasia, where cervical intraepithelial neoplasia is frequently associated.
- Sexual history: is there any history of sexually transmitted infections, vaginal discharge or dyspareunia? If appropriate, ask about risk factors for HIV infection. Loss of libido is common with any dermatological condition of the vulva, and psychosexual factors frequently complicate vulval conditions.
- General medical history: underlying medical conditions can be relevant to some vulval problems, i.e. inflammatory bowel disease, other autoimmune conditions.
- Medication: some drugs can be associated with vulval ulceration, e.g. nicorandil, foscarnet.
- Social history: details on the smoking history, alcohol intake and travel history where appropriate.

Examination

The examination should always be carried out with a trained chaperone present. Good lighting and appropriate magnification is essential. The vulva can be adequately

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

examined with the patient in the dorsal and left lateral position. Again, the examination should be approached systematically. The vulva is first examined overall but the labia majora need to be separated in order to adequately visualize the internal structures of the vulva.

General view

- Hair
- Skin colour, texture and surface.

Specific areas to be inspected

- Mons pubis
- Labia majora
- Labia minora
- Interlabial sulci
- Clitoris
- Vestibule
- Hymen
- Perianal skin.

The vagina and cervix should be examined in all patients with erosive disease (e.g. erosive lichen planus, autoimmune bullous disease) and vulval intraepithelial neoplasia, as well as in patients complaining of a vaginal discharge. An examination of the skin at extragenital sites will often give valuable diagnostic information and inspection of the oral mucosa, eyes, scalp, nails and other flexural sites is important.

Normal variants

There are some very common and important normal variants seen on examination of the vulva. These should be easy to recognize and the patient reassured. There are also physiological changes that vary with age and hormonal status.

Angiokeratomas

These are common and are usually seen on the labia majora. They are often multiple and appear as small red or purple vascular lesions with overlying hyperkeratosis (Fig. 57.1).

Hart's line

This demarcates the junction of the keratinized and non-keratinized epithelia of the labia minora and vestibule, respectively (Fig. 57.2). It can be very prominent in some women.

Vestibular papillae

A common finding is the presence of tiny filiform projections on the inner labia minora and vestibule (Fig. 57.3).

Fig. 57.1 Angiokeratomas: dark-red papules seen on the labia majora. (*See also colour plate 57.1*)

Fig. 57.2 Hart's line demarcating the junction between the keratinized skin of the labia minora and the non-keratinized mucosa of the vestibule. (*See also colour plate 57.2*)

Originally, it was thought that these were related to human papillomavirus (HPV) but there is good evidence that this is not the case. They are a normal variant and do not require any treatment.

Fordyce spots

These are small sebaceous papules found on the inner surfaces of the labia minora (Fig. 57.4). They can be very prominent in some women and may also be seen on the buccal mucosa.

Fig. 57.3 Vestibular papillae: filamentous projections of the vestibular epithelium. (*See also colour plate 57.3*)

Fig. 57.4 Fordyce spots: tiny yellow papules on the inner labium minus. (*See also colour plate 57.4*)

Normal physiological changes

Childhood

In the first few weeks of life, the vulva is under the influence of maternal hormones. The clitoral hood and labia minora are relatively prominent and may be seen without separation of the labia majora. Labial adhesions are common and usually resolve with time. Topical oestrogens may be helpful.

Puberty

Deposition of fat increases the size of the labia majora and mons pubis, and pubic hair appears. The rims of the labia minora may become pigmented. The clitoris enlarges and the vestibular glands become active.

Pregnancy

The vulva can be engorged and varicosities are common. Hyperpigmentation can be significant.

Post menopause

The labia majora become less prominent and there is a reduction in hair growth.

Investigations

In some cases, a firm diagnosis can be made on the clinical appearances alone, but in others a variety of investigations are needed to confirm the diagnosis.

Biopsy

This is a very simple procedure that can be performed in the outpatient clinic under local anaesthesia. A 4–6 mm punch biopsy is taken after infiltrating the area with lidocaine. Topical EMLA (lidocaine 2.5%, prilocaine 2.5%, Astra Zeneca, London, UK) may be used before injecting the lidocaine but care must then be taken in interpreting the histological appearances as subepidermal cleavage can be induced by this agent [1]. Clinicopathological correlation is vital in all cases of vulval dermatoses, and review by a dermatopathologist is very helpful. In cases where an autoimmune bullous disorder is suspected, a biopsy should also be taken for direct immunofluorescence.

Microbiological investigation

Appropriate swabs and transport media for bacterial, yeast and viral culture may be needed. If a sexually transmitted infection is suspected, the patient should be referred to a genitourinary clinic for full investigation and contact tracing.

Skin scrapings to look for fungi can be taken in the clinic and direct examination of the skin under Wood's lamp may be helpful to confirm erythrasma, where the affected skin will fluoresce pink.

Patch testing

This is performed where an allergic contact dermatitis is suspected, either as a primary problem or where it is a secondary phenomenon caused by an allergy to treatment. Patients need to be referred to a dermatologist for these tests, which should include specific allergens that may cause problems on the vulva.

Inflammatory diseases of the vulva

Lichen sclerosus

Lichen sclerosus is an inflammatory dermatosis with a predilection for the anogenital skin [2]. It is significantly more common in women than men. Extragenital lesions may be seen in about 10% of women with genital involvement. They present as ivory white plaques, often at sites of trauma or friction (Fig. 57.5).

Aetiology

The aetiology remains unclear but it is thought that it is mediated by a lymphocyte reaction. Immunohistochemical alterations of the epidermis and dermis support an autoimmune cause and circulating IgG antibodies to extracellular matrix proteins have been demonstrated. There is an association in both the patient and their first-degree relatives with other autoimmune diseases, particularly thyroid disorders.

Fig. 57.5 Extragenital lichen sclerosus: 'white spot disease'. Flat white lesions which can coalesce into plaques. Follicular plugging may be seen. (*See also colour plate 57.5*)

Clinical features

There are two peaks of presentation: in childhood and around or after the menopause. The predominant symptom is that of pruritus but soreness and dyspareunia will be experienced in the presence of ulceration, erosions and fissures. In children, constipation is a frequent feature if the perianal area is affected.

The early lesions are white ivory papules that may coalesce to form plaques. Ecchymosis due to rupture of dermal vessels is common, as is oedema (Fig. 57.6). Ecchymosis is common in children and often leads to the erroneous diagnosis of sexual abuse. Extension of disease around the perianal area presents as a 'figure of eight' pattern. As the disease progresses, scarring occurs with loss of the labia minora, which become fused to the labia majora. The clitoral hood can seal over and the clitoris may be buried (Fig. 57.7). Introital narrowing can lead to difficulties with intercourse and dyspareunia if the skin splits. The vagina is not involved in lichen sclerosus and this may be a useful distinguishing feature from lichen planus. The only exception to this is where there is a significant vaginal prolapse, where the epithelium becomes keratinized and lichen sclerosus can then develop on this vaginal mucosa.

Fig. 57.6 Vulval lichen sclerosus: early established disease showing rubbery oedema of labia minora and clitoral hood and stark whitening extending to perianal skin. Note currently healing fissure at 6 o'clock position. (*See also colour plate 57.6*)

Fig. 57.7 Advanced vulval lichen sclerosis: white sclerotic change, complete burying of the clitoris and total replacement of architecture with 'plastering' down and resorption of labia. Gross ecchymoses and narrowing of vaginal introitus. (*See also colour plate 57.7*)

Histology shows a thinned epidermis overlying a homogenized band of collagen in the upper dermis with a lymphocytic inflammatory cell infiltrate underlying this (Fig. 57.8).

Lichen sclerosus and malignancy

Squamous cell carcinoma (SCC) is a rare complication of lichen sclerosus, occurring in about 4% of patients [3]. This may present as a small persistent erosion or ulcer, a hyperkeratotic area or fleshy friable papule or nodule (Fig. 57.9). Any suspicious lesions must be biopsied. If vulval intraepithelial neoplasia (VIN) is found in association with lichen sclerosus, it is usually the differentiated form where there is basal atypia but normal maturation of the epidermis. It is less common to have undifferentiated VIN.

Treatment

There is good evidence that the treatment for lichen sclerosus, in adults and children, is a super-potent topical steroid such as clobetasol propionate 0.05% ointment [4,5]. This is applied once daily for a month, on alternate days for the second month and then twice weekly for the third month. Emollients are used as a soap substitute. Ongoing treatment may be required by some patients to maintain control. Patients whose disease is difficult to control or those with any history of VIN or SCC need long-term follow-up in specialized clinics.

There is no role for the use of topical testosterone. Surgery is only required to treat the scarring complications

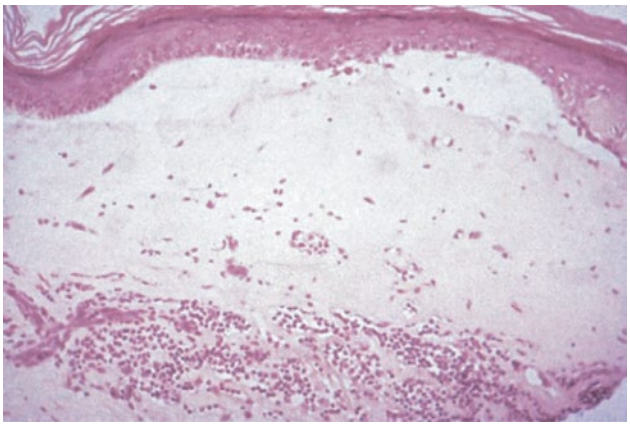

Fig. 57.8 Histology of lichen sclerosus: an atrophic epidermis is seen over the homogenized band of collagen and, below this, a lymphocytic infiltrate. Haematoxylin and eosin × 40. (*See also colour plate 57.8*)

Fig. 57.9 Lichen sclerosus complicated by squamous carcinoma. Note the classical cigarette-paper scarring and background whitening. Here the squamous cell carcinoma presents as a fleshy nodule, but persistent erosion should also prompt biopsy. (*See also colour plate 57.8*)

or if there is neoplastic or pre-neoplastic change. Topical calcineurin inhibitors are increasingly popular but should not be used first line as there are concerns about their long-term safety in relation to the development of malignancy.

In those with resistant symptoms, it is important to exclude an allergic contact dermatitis to treatment, irritant dermatitis due to urinary incontinence, or an additional problem such as herpes simplex or candidiasis. A proportion of patients will develop vulvodynia after their lichen sclerosus is well controlled. Treatment must be targeted at this rather than increasing the use of topical steroids.

Summary box 57.1

Lichen sclerosus

- Lichen sclerosus is an inflammatory dermatosis that commonly affects the anogenital skin.
- There are two peaks of presentation: prepubertal girls and postmenopausal women.
- It presents with itchy, white, atrophic lesions, often with ecchymosis and oedema.
- Scarring will occur if untreated.
- An ultra-potent topical steroid is the first-line treatment.
- Patients require long-term follow-up as there is a small risk of malignancy developing.
- Any resistant areas, ulcers or hyperkeratotic lesiors should be biopsied.

Lichen planus

Lichen planus (LP) is an inflammatory disorder, which can affect both skin and mucous membranes. The characteristic cutaneous lesions are small purplish papules, which may exhibit a fine lace-like network over their surface known as Wickham's striae. These can also be seen on mucosal lesions. The papules commonly occur on flexor surfaces and can koebnerize at sites of trauma. The nails can show pterygium formation and scalp lesions can result in a scarring alopecia.

Histology shows irregular acanthosis with a saw-toothed pattern, basal cell degeneration and a dense band-like dermal infiltrate of lymphocytes. There is often pigmentary incontinence, which is responsible for the marked hyperpigmentation sometimes seen clinically (Fig. 57.10).

Aetiology

The cause is unknown but it is likely that it is a T-lymphocyte-mediated inflammatory response to some form of antigenic insult. Lichenoid eruptions can be seen in graft-versus-host disease and secondary to medications such as non-steroidal anti-inflammatory drugs (NSAIDs). Although there has been interest in the association of hepatitis C infection and LP, there is only evidence for this in certain populations and it is not relevant in northern Europe. There is an association of LP and other autoimmune disorders.

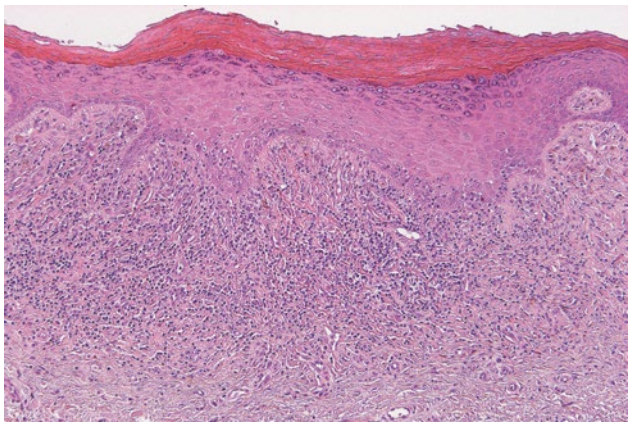

Fig. 57.10 Histology of lichen planus showing saw-toothing of the epidermis, with a dense lymphocytic infiltrate and liquefactive degeneration of the basement membrane. *Source:* Eduardo Calonje. Reproduced with permission of Eduardo Calonje. (*See also colour plate 57.10*)

There are three major clinical patterns of LP affecting the anogenital skin: erosive, classic and hypertrophic. These may occur in isolation without the presence of disease at other sites.

Erosive lichen planus

Erosive LP is the commonest form to affect the genital skin [6]. There is a specific subtype of erosive mucosal LP, the vulvovaginal–gingival (VVG) syndrome affecting the vulva, vagina and gingival margins [7], with specific genetic associations. The lacrimal duct, external auditory meatus and oesophagus can also be involved and disease at these sites needs a multidisciplinary approach to management.

The vulval lesions mainly affect the inner labia minora and vestibule where erythema and erosions occur (Fig. 57.11). A lacy white edge is seen and this is the best site for a confirmatory biopsy (Fig. 57.12). There may be marked scarring with significant architectural change, which can be impossible to differentiate from lichen sclerosus in some cases. Symptomatically the condition is itchy and painful and dyspareunia is a common feature. If there is vaginal involvement, there may be a blood-stained discharge and episodes of post-coital bleeding. It is important to recognize vaginal disease as scarring at this site can result in complete vaginal stenosis. Glazed erythema and erosions occur on the gingivae (Fig. 57.13), buccal mucosa and also the tongue.

The disease tends to fluctuate with a relapsing and recurring pattern.

Fig. 57.11 Erosive lichen planus: there is scarring with loss of the labia minora. Wickham's striae are seen at the edge of the erosions. (*See also colour plate 57.11*)

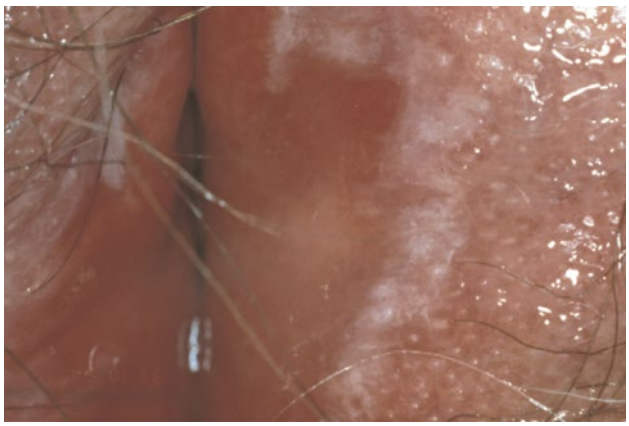

Fig. 57.12 The lacy white edge of the eroded area is seen. This is the best site for biopsy. (*See also colour plate 57.12*)

Fig. 57.13 Erosive lichen planus with gingival involvement. Erythema and erosions are seen at the gingival margins. Similar lesions may be seen on the buccal mucosa and tongue. (*See also colour plate 57.13*)

Fig. 57.14 Papular lichen planus: typical coalescing flat-topped papules showing white Wickham's striae. They are violaceous in colour and are usually also found on the inner wrist and elsewhere. (*See also colour plate 57.14*)

Classic lichen planus

Papules, very similar to the cutaneous lesions, are found on the vulva (Fig. 57.14) and perianal skin. They may be asymptomatic in over 50% of patients [8]. Wickham's striae can also be seen associated with the lesions. Flexural hyperpigmentation can be significant even many months after the disease has resolved.

Hypertrophic lichen planus

Hypertrophic lesions are less common and mainly affect the perineum and perianal skin. They can become ulcerated and painful. They can be resistant to topical treatment.

Lichen planus and malignancy

Squamous cell carcinoma and SCC *in situ* have been reported in classic and hypertrophic types but not in the VVG syndrome. In studies of patients with vulval malignancy, LP has been seen in the surrounding epithelium [9].

Management

The main treatment is a super-potent topical steroid ointment. In general, clobetasol propionate 0.05% ointment is applied in a similar regimen to that used for lichen sclerosus for 3 months, then reducing to be used as needed. Bland emollients can be helpful as a soap substitute. Petroleum jelly used as a barrier will help symptomatically. For vaginal disease, some of the foam preparations used in inflammatory bowel disease can be useful, for example hydrocortisone acetate. This is inserted via the applicator into the vagina at night. Dilators may also be required to keep the vagina patent.

There is some evidence for the use of the topical calcineurin modulators tacrolimus and pimecrolimus in the treatment of LP. There are small case series that support their use but there is also concern with long-term safety, particularly with regard to the development of malignancy. It is therefore recommended that they are not used as first-line treatment but for short periods in those who do not respond to potent topical steroids. They are not tolerated well on the anogenital skin, which also limits their use.

Several systemic treatments have been used in LP but no controlled trials exist [10].

Summary box 57.2

Lichen planus

- Lichen planus can affect the skin and oral and genital mucosae, but also the scalp and nails.
- The erosive subtype, VVG syndrome, can also involve the lacrimal ducts, oesophagus and external auditory meatus. These sites should be examined.
- Scarring can occur with marked functional sequelae.
- The management should be multidisciplinary and it is very important to involve other specialties early, e.g. for oesophageal involvement.
- The first-line treatment is an ultra-potent topical steroid.
- There is a small risk of SCC in the classic and hypertrophic types.

Eczema

The terms 'eczema' and 'dermatitis' are used synonymously for an epidermal inflammation that has many forms. It is characterized histologically by spongiosis where the keratinocytes lose cohesion and vesicles may form. Many different inflammatory cells infiltrate the dermis. The skin becomes scaly secondary to parakeratosis and fluid may ooze onto the surface and dry to a crust. In chronic cases, the skin becomes thickened and lichenified. Vulval eczema is often over-diagnosed and there is a significant overlap with vulval psoriasis, which is much more common.

Seborrhoeic eczema

This is a common type of eczema, with peaks in childhood (cradle cap and nappy rash) and early adulthood. There is evidence that it is caused by the yeast *Pityrosporum ovale*. The lesions are erythematous with a greasy scale and particularly affect the naso-labial folds, eyebrows, forehead, scalp and behind the ears. The anogenital skin may be involved together with other flexural sites, including the inguinal folds and gluteal cleft. The skin shows erythema and a build-up of keratinous debris.

It is often very difficult to distinguish seborrhoeic eczema from flexural psoriasis. Characteristic lesions at other sites may help and the histology may be similar. The management of seborrhoeic eczema is the same as that of psoriasis.

Irritant eczema

The anogenital skin is very susceptible to an irritant eczema as it is a site that is occluded and often exposed to many irritant substances. There is diffuse erythema and fissuring and the skin may become thickened and macerated in areas. Deodorants, bubble baths, soaps and irritant topical treatment (e.g. wart preparations) are common causes. It is a particular problem in those suffering from urinary or faecal incontinence.

Allergic contact dermatitis

Allergic contact dermatitis is a delayed type IV hypersensitivity reaction and in the genital area is much more likely to occur on perianal skin than on the vulva. Relevant positive patch-test reactions are found and the most common culprits are topical medicaments, local anaesthetics, cosmetics and fragrances [11]. Dermatological advice on patch testing should be sought. In addition to the standard patch-test series, extended testing is often necessary to find the causative allergen.

Lichen simplex

'Lichenification' is the term used to describe a thickening of the skin with accentuation of the skin markings. It is a response to chronic scratching and rubbing of the skin and is usually seen on a background of eczema or psoriasis. 'Lichen simplex' is the term used to describe an isolated area of lichenification without an obvious background dermatitis. It is common in areas that the patient can easily reach. The thickened plaques may be

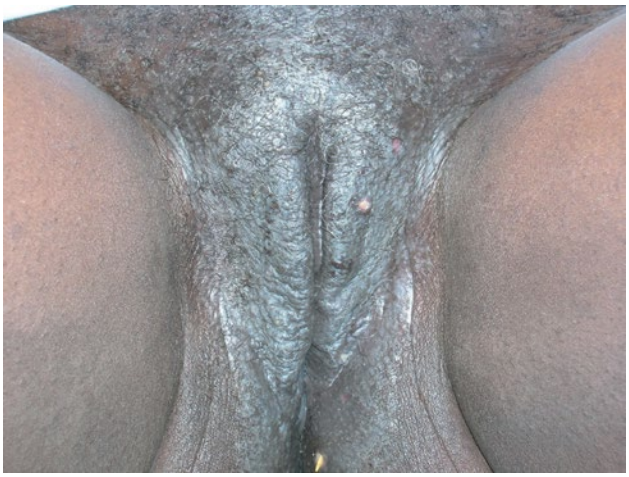

Fig. 57.15 Vulval lichen simplex: the outer labia majora are significantly lichenified with accentuated skin markings and loss of hair from rubbing. (*See also colour plate 57.15*)

hypopigmented or hyperpigmented and the common sites are the outer labia majora and mons pubis. There may also be loss of hair from rubbing (Fig. 57.15). A potent topical steroid applied on a reducing regimen over a 3-month period can be very helpful and in many cases will resolve the problem. However, in others, it is considered to be a sensory problem and treatment needs to be directed towards breaking the itch–scratch cycle.

Management of vulval eczema

The management of all eczematous processes is similar. All potential irritants and allergens should be withdrawn. Bland emollients (e.g. emulsifying ointment) are used as a soap substitute. A topical steroid, combined with an antimicrobial if appropriate, can be used once daily initially and then as needed as the problem improves. If the eczema is acute and the skin is oozing and wet, then potassium permanganate soaks (1 in 10 000 dilution) are helpful. Gauze is soaked in the solution and applied to the affected areas for 15 min once or twice a day. Patients with lichen simplex may require a potent topical steroid to gain control of their symptoms. The frequency of application can slowly be reduced as the lichenification resolves. Antihistamines may help at night to reduce scratching.

Psoriasis

Psoriasis is one of the commonest skin conditions, affecting about 2% of the population in some form. The characteristic lesions are silvery white scaly plaques on the extensor aspects of the limbs, but generalized disease may occur with scalp and nail involvement. The aetiology is unknown but there is a genetic predisposition and the disease may be triggered by streptococcal infection and trauma (Koebner phenomenon). Psoriasis may also be exacerbated by some drugs, for example beta-blockers, lithium and chloroquine.

Histology shows marked epidermal thickening (acanthosis) with deep epidermal ridges projecting into the dermis. Spongiosis with a neutrophil infiltrate of the epidermis may be seen.

Genital flexural psoriasis is common and may occur in isolation [12]. There is little scaling because of the moist occluded environment of the anogenital skin. The lesions present on the inner and outer aspects of labia majora as well-demarcated erythema or salmon-pink patches that are usually symmetrical (Fig. 57.16). The genito-crural inguinal folds may also be affected. Perianal involvement is common with extension into the gluteal cleft (Fig. 57.17). Itching and burning are common symptoms but as maceration and fissuring is often seen, women

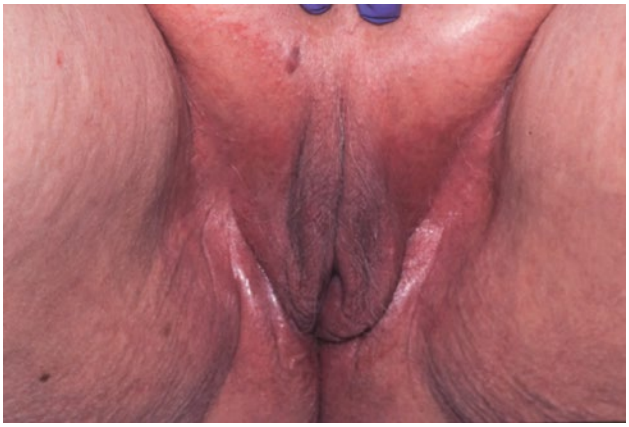

Fig. 57.16 Vulval psoriasis: erythema and maceration with extension into the inguinal folds. The edge is still well defined. (*See also colour plate 57.16*)

Fig. 57.17 Perianal psoriasis: well-demarcated erythema with extension into the natal cleft. (*See also colour plate 57.17*)

may also complain of soreness. It is helpful to examine the rest of the skin to look for other signs: the scalp may show scaling and the nails in psoriasis display thimble pitting, onycholysis and subungual hyperkeratosis.

The use of an emollient as a soap substitute is helpful. The traditional treatments for psoriasis (e.g. tar, dithranol, calcipotriol) are too irritant to be used in the flexures and therefore a mild to moderately potent topical steroid is used. This can be applied once daily and then reduced in frequency to be used as needed. In patients with severe disease, systemic treatment may be required but these patients should be under specialist dermatological supervision. Oral therapy with methotrexate, cyclosporin and acitretin can be used and the new biological therapies may be considered in very extensive, resistant cases.

Reiter's disease is an inflammatory response to an enteric or lower genital tract infection, with arthritis, uveitis and skin lesions that are very similar to those of psoriasis. The vulva may be affected with a circinate ulcerative vulvitis similar to the balanitis that commonly occurs in men with this syndrome. The histology is similar to that of pustular psoriasis.

Hidradenitis suppurativa

Hidradenitis suppurativa is an inflammatory disorder affecting areas where apocrine glands are present. The basic pathology is not in the gland itself but in the follicular epithelium, where an infundibular inflammation, possibly triggered by antimicrobial peptides produced after injury, leads to abscess formation and deep sinus tracts [13].

Anogenital involvement is common, with painful nodules, sinuses and scarring (Fig. 57.18). Bridged comedones are characteristic. SCC has been reported in chronic disease.

Fig. 57.18 Hidradenitis suppurativa: oozing inflamed lesions are seen on the mons publis with bridged comedones. (*See also colour plate 57.18*)

The management of this condition can be difficult. Topical antibiotics can be used in mild disease together with other measures such as stopping smoking and weight reduction. In moderate to severe disease, long-term oral tetracyclines are the first-line treatment. Oral clindamycin has been used in some cases with success. Second-line treatments include surgery, anti-androgen therapies and, now, anti-tumour necrosis factor (TNF) biological agents.

Bullous diseases

Genetic causes

Epidermolysis bullosa

Epidermolysis bullosa is used to describe a group of inherited conditions (dominant or recessive) characterized by skin fragility and bullae. The junctional and dystrophic types involve the vulva and scarring may result. These children must be cared for in specialist centres with access to expert nursing care.

Benign familial chronic pemphigus (Hailey–Hailey disease)

This is rare autosomal dominant condition where moist red plaques in the flexures and genital areas develop in the second to fourth decades. Friction worsens the problem and the plaques may fissure and become secondarily infected. Histology shows extensive intraepidermal acantholysis described as a 'dilapidated brick wall'. Treatment is unsatisfactory but topical steroids and prompt treatment of any infection can be helpful. Photodynamic therapy has had limited success in a few patients.

Bullous drug eruptions

Fixed drug eruption

Fixed drug eruptions occur at the same cutaneous or mucosal site each time the causative drug is ingested. Vulval involvement usually presents with swelling that may then form blisters and erode. As this is intermittent, the patient rarely associates it with medication and challenge tests may be needed. There are many drugs that can cause this problem, the most relevant for the vulva being co-trimoxazole, fluconazole, aciclovir and NSAIDs. Resolution frequently results in post-inflammatory hyperpigmentation.

Erythema multiforme

Erythema multiforme is an acute reaction pattern where mucosal erosions and ulcers occur, often with

cutaneous 'target' lesions. Stevens–Johnson syndrome is a severe form of erythema multiforme where bullous lesions occur which may scar. Vaginal involvement can lead to stenosis and it is important to perform a vaginal examination and treat this site if it is involved, otherwise permanent stenosis can occur secondary to the inflammation and erosion. Erythema multiforme and Stevens–Johnson syndrome may be induced by herpes simplex infection or medications, especially antibiotics and NSAIDs. However, no cause is found in up to 50% of cases.

Toxic epidermal necrolysis (Lyell's syndrome)

This is a dermatological emergency where severe and widespread epidermal loss occurs. It carries a significant mortality. Drug hypersensitivity is the usual cause (most commonly antiepileptics, NSAIDs and antibiotics), but idiopathic cases may be seen.

There is sudden onset of painful areas of erythema which rapidly become eroded or blistered, usually of the genitalia, mouth and eyes. Vulvovaginal scarring and stenosis may occur as erosions heal. The triggering drug must be stopped and the patient transferred to a specialist dermatology centre or burns unit experienced in the management of these cases. Treatment is mainly supportive, with the role of steroids and immunoglobulin still undecided. In the early stages, the differential diagnosis is that of staphylococcal scalded skin. In this latter condition, there is very superficial desquamation caused by staphylococcal exotoxins. Treatment is with high-dose antibiotics such as flucloxacillin.

Autoimmune bullous disorders

Bullous pemphigoid

Bullous pemphigoid is the commonest autoimmune bullous disorder and mainly affects the elderly, although cases have been reported in children. IgG antibodies are directed against the basement membrane and these are demonstrated in a linear fashion on direct immunofluorescence studies. Circulating IgG antibodies may be found. Histology shows subepidermal blisters. The mucous membranes may be involved with tense blisters which rupture to form superficial erosions.

These patients need to be managed by a dermatologist. Potent topical steroids may be used but systemic steroids and immunosuppressive drugs are usually required.

Mucous membrane pemphigoid (cicatricial pemphigoid)

This is a rare autoimmune bullous disorder but mucosal involvement is prominent, with the vulva, vagina, eyes, mouth and larynx being affected. Scarring is common and can cause problems with the vulva and eyes. It generally affects older women. The histological and immunofluorescence findings are similar to those of bullous pemphigoid, but there are often less eosinophils present. Treatment can be difficult but steroids, mycophenolate and other immunosuppressive treatments are used [14]. These patients are at risk of ophthalmological and oesophageal complications and management should involve dermatologists and any other relevant specialists. These patients share many of the clinical features of the VVG form of lichen planus.

Pemphigus

Pemphigus vulgaris is a rare bullous disorder affecting the skin and mucous membranes. IgG antibodies are directed against keratinocytes. The bullae are flaccid and erosions are more commonly seen. The patients are often younger and cases have been reported in children. Histology shows intraepidermal bullae. IgG is seen in the intercellular spaces on direct immunofluorescence and circulating IgG antibodies are found.

This disease carries a high degree of morbidity and patients should always be under the care of a dermatologist. Treatment includes high-dose systemic steroids, azathioprine cyclophosphamide and mycophenolate mofetil.

Vulval ulceration

Aphthous ulcers

Oral aphthae are common but similar lesions can occur on the vulva and are frequently mistaken for herpetic infection. The vulval ulcers measure a few millimetres and have a yellow base surrounded by an erythematous rim, but major aphthae may be larger than this. Histology is non-specific. Treatment is difficult but topical steroids, tetracyclines and local anaesthetic agents can be helpful.

Acute ulcers associated with infection

Lipschutz described acute painful ulcers in young women in 1913. They are now known to be a reaction to systemic infection and have been reported most commonly in association with Epstein–Barr virus infection [15]. They typically occur in teenagers and present as rapidly enlarging painful ulcers, often occurring in apposition in a 'kissing' pattern. They usually heal without scarring after a few weeks but a short course of prednisolone can speed resolution if severe. Topical steroids and local anaesthetic agents such as 5% lidocaine ointment are helpful symptomatically.

Manifestations of underlying disease

Inflammatory bowel disease

Although anogenital lesions can occur in ulcerative colitis, they are rare. They are commoner in Crohn's disease, affecting up to 30% of patients, and they may precede the onset of bowel disease by some years [16]. Where there is no continuity with bowel disease or distant sites are involved, the lesions are termed metastatic and most vulval lesions are of this type. Typical presentation includes unilateral or bilateral oedema (Fig. 57.19) lymphangiectasia and classic 'knife-cut' fissures in the interlabial sulci (Fig. 57.20). Sinus tracts and fistulae may also occur. Perianal ulceration or oedematous tags are also often present.

Histology shows granulomatous inflammation but may be non-specific. The main differential diagnosis is hidradenitis suppurativa and the two may coexist.

Treatment can be challenging and ideally should involve a multidisciplinary team. Potent topical steroids are used initially but systemic treatment is often needed and include steroids, immunosuppressive agents, antibiotics, especially metronidazole, and the biological TNF-α blockers; these may be successful in improving the condition [17].

Fig. 57.19 Unilateral vulval oedema: Crohn's disease. Sometimes vulval oedema, usually unilateral, can accompany Crohn's disease of the gastrointestinal tract. (*See also colour plate 57.19*)

Fig. 57.20 Vulval Crohn's disease: deep 'knife-cut' fissures are seen in the inter-labial sulci. (*See also colour plate 57.20*)

Pyoderma gangrenosum

Pyoderma gangrenosum is an aggressive ulcerative disorder of unknown aetiology but with a strong association with an underlying inflammatory disease such as rheumatoid arthritis, inflammatory bowel disease and myeloproliferative disorders.

Purulent ulcers with a prominent violaceous edge are most commonly seen on the lower limb but the vulva may be involved. The initial lesion is sometimes pustular, which then ulcerates rapidly to form single or multiple ulcers with an indurated edge.

Histology is inflammatory but non-specific and the diagnosis is usually clinical. Early recognition is important as there is often a prompt response to systemic steroids or cyclosporin. Other agents such as dapsone, azathioprine or minocycline may be needed. Surgery should be avoided at all costs as the lesions koebnerize and so debridement is often followed by disease progression.

Behçet's syndrome

The original description by Behçet was a triad of oral and genital ulceration with uveitis. It is now known as a multisystem disorder and the diagnostic criteria have been refined [18]. The diagnosis is made on the clinical

features, with a score of 4 or more points when a patient has recurrent oral ulceration (2 points), recurrent genital ulceration (2 points), ocular lesions (2 points), cutaneous lesions (erythema nodosum, folliculitis, pyodermatous plaques, all scoring 1 point), vasculitis (1 point) and a positive pathergy test (where pustulation occurs at the site of minor skin trauma, such as venepuncture).

The syndrome usually starts before the age of 50. The oral ulcers are similar to common aphthae but the vulval ulcers are usually larger, more painful and tend to heal with scarring. The labia minora are most commonly affected (Fig. 57.21). The histology is rather non-specific but thrombosed arterioles may be seen.

The management of these patients should be multidisciplinary as many organ systems may be involved. Neurological and ophthalmological complications can be serious and must be actively treated. Several drugs are used including steroids, colchicines, dapsone and thalidomide. Topical steroids may be used for the genital ulcers. There may be a role for the use of biological agents.

Necrolytic migratory erythema (glucagonoma syndrome)

This is a rare syndrome, of unknown cause, where cutaneous changes are seen secondary to a pancreatic islet cell tumour. The eruption is erosive and can migrate with a spreading serpiginous edge. The perineum is most severely affected but perioral lesions may also be seen. Glossitis and diabetes are usually associated. The diagnosis is made by finding a raised glucagon level. The rash often responds well to surgical removal of the primary tumour.

Fig. 57.21 Behçet's syndrome. Extensive deep ulcers, here penetrating the labia in a 45-year-old Turkish woman. (*See also colour plate 57.21*)

Acrodermatitis enteropathica

This is related to zinc deficiency and may be inherited as an autosomal recessive condition or acquired secondary to parenteral nutrition, malabsorption, severe eating disorders or penicillamine. The erythematous and pustular lesions affect the genitalia and also the perioral skin. Diagnosis is made on a low zinc level and treatment is with oral supplementation.

Disorders of pigmentation

The pigmentation of the vulval skin can vary widely with ethnicity and hormonal status. Dark areas can result from deposition of haemosiderin or melanin. Haemosiderin pigmentation tends to be red/brown and occurs after an inflammatory dermatosis such as lichen planus. Melanin pigmentation is usually darker brown or black and any new pigmented areas where the diagnosis is not clinically obvious must be biopsied.

Hyperpigmentation

The most common cause of pigmented patches on the vulval skin is post-inflammatory hyperpigmentation. It most frequently occurs after lichen planus but can be seen after other inflammatory dermatoses and fixed drug eruptions.

Vulval melanosis

Areas of pigmentation may be seen without any preceding history of inflammation (Fig. 57.22). These can be very irregular and must always be biopsied to confirm their benign nature. Histology shows an increased number of melanocytes and some pigmentary incontinence. Similar lesions may be found in the oral cavity and there is no evidence that they become malignant at either site.

Acanthosis nigricans

Velvety, thickened and hyperpigmented plaques are seen symmetrically spreading form the labia majora to the inguinal folds and may extend perianally. Similar lesions can be seen on the neck and in the axillae. Multiple skin tags are often seen on the surface of the plaques. The condition is most frequently seen in overweight individuals and it is associated with insulin resistance. Some cases, particularly those of sudden onset and in thin patients,

Fig. 57.22 Vulval melanosis: irregular areas of pigmentation without any preceding inflammation. (*See also colour plate 57.22*)

Fig. 57.23 Vitiligo, showing symmetrical loss of pigmentation. (*See also colour plate 57.23*)

can be associated with an underlying malignancy and appropriate investigations should be performed.

Hypopigmentation

Hypopigmentation can occur as a post-inflammatory change and is most clearly seen in darker skin. It resolves spontaneously after the inflammation is treated.

Vitiligo

This is a common autoimmune disorder where complete depigmentation of the skin occurs. It is patchy but symmetrical and peri-oroficial sites including the genitalia are often involved. The main differential diagnosis is lichen sclerosus and indeed the two diseases may coexist. However, in vitiligo there is no ecchymosis or architectural change and the texture of the skin is normal (Fig. 57.23). There is no effective treatment, and ultraviolet phototherapy that is occasionally helpful at other sites is not suitable for use on the vulval skin.

Pigmented lesions

Benign pigmented lesions can occur on the vulva. However, any pigmented lesion should be subjected to histological examination to exclude pigmented variants of VIN or malignant melanoma of the vulva.

Seborrhoeic keratoses

These may be heavily pigmented and have a 'stuck-on' appearance. They are usually found on the outer labia majora and in the groins. No treatment is generally required but cryotherapy or curettage and cautery are effective if they become troublesome. If there is any suspicion of HPV infection or cervical intraepithelial neoplasia, the lesions should be biopsied to exclude undifferentiated VIN.

Melanocytic naevi

Vulval naevi are not common. Some have atypical features and are regarded as atypical genital naevi [19] rather than variants of 'dysplastic' naevi. The unwary pathologist may report a malignant melanoma as there is cytological atypia but the lesions are symmetrical with normal cellular maturation. Naevi seen with lichen sclerosus can also mimic malignant melanoma clinically and histologically but there are case reports of true malignant melanoma developing in association with lichen sclerosus.

Benign tumours

Skin tags (acrochordia)

These small lesions are very common, particularly at flexural and frictional sites such as the axillae, eyelids

and groins. No treatment is needed but if they enlarge and become painful, they can be removed by cryotherapy or cautery.

Cysts

Epidermoid cysts are the most common type of cyst found on the vulva and are usually seen on the labia majora. They present as small, painless, yellow lumps. No treatment is needed but surgical excision is effective if they become symptomatic (Fig. 57.24).

Bartholin's cysts occur due to an obstruction in Bartholin's ducts and are therefore seen on the lower third of the inner labia majora. They can become infected and enucleation is the treatment of choice. Rarely, a carcinoma of Bartholin's glands can present as a cyst and any recurrent lesions should be excised to exclude this.

Hidradenoma papilliferum

These arise from anogenital mammary glands and are therefore usually found in the inter-labial sulcus or on the perineum. They are painless but excision is needed for histological examination.

Syringomata

Syringomata are eccrine duct tumours that are most commonly found on the face. They present as small papules which may be itchy on the genitalia. They occur on the labia majora most frequently but the labia minora can be involved. Treatment is unsatisfactory but laser ablation is used in those who are highly symptomatic.

Fig. 57.24 Multiple epidermoid cysts on outer labia majora. These are usually asymptomatic. (*See also colour plate 57.24*)

Vascular lesions

Angiokeratoma

See section Normal variants.

Haemangiomas

Capillary haemangiomas are present at birth and do not fade. They are asymptomatic and cause no functional problems. Although laser treatment can be used, this is only done to improve the cosmetic appearance.

Cavernous haemangiomas (strawberry naevi) develop within the first few weeks of life and may grow rapidly. When present on the vulva, the labia majora are the most common sites involved but the perianal area and buttocks may also be affected. Occasionally, they break down and cause painful areas of ulceration that often become infected. Early assessment by a paediatric dermatologist is helpful, as propranolol is now commonly used to treat the lesions. They do spontaneously resolve over a period of years but, if troublesome, may require ablative treatment such as laser or excision.

Varicosities

Vulval varicosities are common during pregnancy and some thrombose spontaneously after delivery. They are usually associated with varicosities on the lower limbs, but if isolated to the genitalia the patient should be further investigated to exclude an obstructive pelvic lesion.

Disorders of lymphatics

Acute lymphoedema

Some swelling may occur in diseases such as candidiasis or acute eczema but resolves quickly with appropriate treatment of the condition. Urticaria and angioedema may involve the vulva. The history is that of acute swelling, sometimes related to intercourse where it may be pressure induced.

Type I hypersensitivity contact urticarial reactions to latex are an increasing problem. There is immediate swelling of the labia after using latex condoms and it can also occur if healthcare workers wear latex gloves for examination. In severe cases, the reaction may be life-threatening if full anaphylaxis follows. Contact urticaria to seminal fluid has also been described but is rare. The symptoms are completely abolished if condoms are used. Desensitization may be successful and a

successful pregnancy can be achieved by artificial insemination after removing the allergenic components of the seminal fluid.

Chronic lymphoedema

Lymphoedema may follow chronic inflammation (such as hidradenitis suppurativa or Crohn's disease), infection, malignancy, surgery or radiotherapy. The vulva becomes thickened and indurated and may be more prone to attacks of cellulitis. Prophylactic penicillin may be required.

Lymphangiectasia

Small lymphatic vesicles (lymphangiectasia) may develop on a background of chronic lymphoedema. They may be primary, due to an inherited defect, or secondary, due to Crohn's disease or following radiotherapy for cervical or vaginal cancer. The lesions have a verrucose appearance and are often incorrectly diagnosed as viral warts.

Treatment with CO_2 laser can be used in symptomatic cases where there is leakage of lymph. Congenital lesions may need imaging studies to identify if there are deeper lymphatic abnormalities.

Benign Diseases of the Vagina, Cervix and Ovary

D. Keith Edmonds[1,2]

[1] *Imperial College London, London, UK*
[2] *Queen Charlotte's and Chelsea Hospital, London, UK*

Vagina

The vagina is the lowest part of the female internal genital tract. Clinical examination of the vagina is often limited as it is obscured during the use of a speculum and digital examination does not allow assessment. It is therefore only examined in detail in circumstances where there are specific symptoms to prompt vaginal examination.

The vagina consists of a non-keratinized squamous epithelial lining supported by connective tissue and surrounded by circular and longitudinal muscle coats. The muscle is attached superiorly to the fibres of the uterine cervix, and inferiorly and laterally to the pubococcygeus, bulbospongiosus and perineum. The lower end of the epithelium joins, near the hymen, the mucosal components of the vestibule and superiorly extends over the uterine cervix to the squamocolumnar junction. The vaginal epithelium has a longitudinal column in the anterior and posterior wall, and from each column there are numerous transverse ridges or rugae extending laterally on each side. The squamous epithelium during the reproductive years is thick and rich in glycogen. It does not change significantly during the menstrual cycle, although there is a small increase in glycogen content in the luteal phase and a reduction immediately premenstrually. The prepubertal and postmenopausal epithelium is thin or atrophic.

The vagina has a varied bacterial flora in oestrogenized women, and knowledge of what is normal and abnormal is important for determining infection. The main organisms are listed in Table 58.1.

Vaginal infection

Between puberty and the menopause the vaginal lactobacilli maintain a pH between 3.8 and 4.2 which protects against infection. Before puberty and after the menopause, the higher pH level and urinary and faecal contamination increase the risks of infection. Vaginal atrophy may also occur in the postpartum period with the hypo-oestrogenic state during lactation. Normal physiological vaginal discharge consists of a transudate from the vaginal wall, squames containing glycogen, polymorphs, lactobacilli, cervical mucus and residual menstrual fluid, as well as a contribution from the greater and lesser vestibular glands. Vaginal discharge varies according to oestrogen levels during the menstrual cycle and is a normal physiological occurrence. Vaginal discharge does not normally have an unpleasant odour, and if this occurs in the presence of change in colour or copiousness, then it may indicate infection. Non-specific vaginitis may be associated with sexual trauma, allergy to deodorants or contraceptives, and chemical irritation from topical antimicrobial treatment. Non-specific infection may be further provoked by the presence of foreign bodies, for example ring pessary, continual use of tampons and the presence of an intrauterine contraceptive device.

Bacterial vaginosis

Bacterial vaginosis has been previously associated with the organism *Gardnerella vaginalis* but a wide range of organisms, including *Mobiluncus* spp., *Bacteroides* spp. and *Peptostreptococcus*, are also implicated. Some 50% of infected women are asymptomatic and the vagina is not usually inflamed, and therefore the term 'vaginosis' is used rather than vaginitis [1]. Examination will reveal a thin grey–white discharge and a vaginal pH increased to greater than 5. A Gram stain of collected material will show 'clue' cells, which consist of vaginal epithelial cells covered with microorganisms and the absence of lactobacilli. The diagnosis can also be confirmed by adding a drop of vaginal discharge to saline on a glass slide and adding one drop of 10% potassium hydroxide. This

releases a characteristic fishy amine smell. Bacterial vaginosis may be associated with increased risk of preterm labour [2], pelvic inflammatory disease and postoperative pelvic infection [3,4]. The treatment of bacterial vaginosis is with metronidazole, either as 200 mg three times a day for 7 days or as a single 2-g dose. Alternatively, clindamycin can be used as a vaginal cream.

Trichomoniasis

Trichomoniasis is a sexually transmitted disease caused by the parasite *Trichomonas vaginalis*. Symptoms usually appear 5–28 days after exposure and include a yellow–green vaginal discharge, often foamy, with a strong odour, dyspareunia and vaginal irritation. Of women infected, 10% also manifest a 'strawberry' cervix on examination (Fig. 58.1). *Trichomonas vaginalis* is a flagellated organism that can damage the vaginal epithelium, increasing a woman's susceptibility to infection by human immunodeficiency virus (HIV). This is caused by lysis of the epithelial cells. Treatment is with metronidazole 400 mg three times daily for 7 days or tinidazole 2 mg as a single dose. As this is a sexually transmitted disease, diagnosis should prompt the gynaecologist to refer the patient to a genitourinary medicine clinic for contact tracing.

Vaginal candidiasis

This is a fungal infection commonly referred to as 'thrush'. It is caused by any of the species of *Candida*, of which *Candida albicans* is the most common. This is an infection that causes vaginal irritation and vaginitis, which leads to itching, burning, soreness and a classic

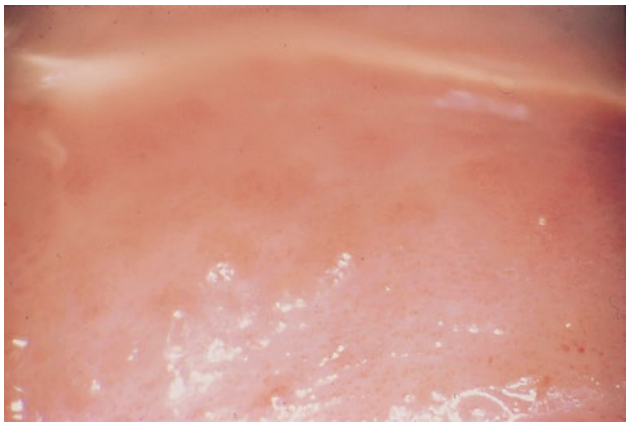

Fig. 58.1 Trichomoniasis with 'strawberry' vaginitis. (*See also colour plate 58.1*)

whitish or whitish-grey cottage cheese-like discharge. The irritation and inflammation spreads across the vulva and may also involve the perianal skin. *Candida* can be transmitted to a sexual partner, in whom it can cause red patchy sores near the head of the penis or on the foreskin, causing a severe itching and burning sensation. *Candida albicans* usually causes infection when production of lactic acid by lactobacilli is disturbed, resulting in a change in the pH in the vagina and subsequent overgrowth of *Candida*. Diabetics and patients using antibiotics for other infections have an increased incidence of candidiasis. This, in conjunction with other treatments (e.g. steroids) or conditions including HIV, leads to a weakening in the immune response, allowing *Candida* to thrive. *Candida* is frequently found in the vagina but it may also be part of the intestinal flora. The diagnosis is usually made on inspection, but a swab from the infected area will confirm the diagnosis in culture. Treatment for vaginal candidiasis is primarily with antifungal pessaries or cream inserted high into the vagina. Single-dose preparations offer the advantage of compliance, and imidazole drugs (clotrimazole, econazole and miconazole) are effective in short courses of 1–14 days according to the preparation. Oral medication is also available in the form of fluconazole or itraconazole and these treatments are usually extremely effective at eradicating the disease. Some 10% of women who contract candidiasis will develop recurrent disease – this is particularly likely if there are predisposing factors, such as pregnancy, diabetes or oral contraceptive use. It is important to consider partner treatment in those patients who suffer recurrent disease and in those patients who are resistant to two courses of imidazoles. If bacteriological confirmation of recurrent disease is made, a number of long-term treatments can be prescribed. These include fluconazole 100 mg orally every week for 6 months, clotrimazole 500-mg pessary weekly for 6 months or itraconazole

400 mg every month for 6 months. There is extensive alternative medicine literature on the treatment of *Candida* but there is very little scientific evidence to prove its efficacy.

Summary box 58.1

Vaginal infection

- It is important to differentiate between infection and normal flora in diagnosing vaginal infection.
- Bacterial vaginosis may be associated with preterm labour.
- Recurrent vaginal candidiasis needs systemic investigation prior to long-term treatment.

Syphilitic lesions of the vagina

Syphilis is uncommon among women in the UK. However, unusual vaginal lesions must raise suspicion, particularly if the patient or partner has recently travelled overseas.

The primary lesion may be in the vagina or on the vulva or cervix. There is usually a single, painless, well-demarcated ulcer with indurated edges, associated with lymphadenopathy. Secondary lesions include condylomata lata, mucous patches and snail-track ulcers.

Diagnosis is based on identification of the causative organism, *Treponema pallidum*, on dark-ground microscopy, or by serological examination for syphilis, for example using enzyme-linked immunosorbent assay (ELISA). For further details and specifics of treatment with Bicillin (i.e. procaine penicillin with benzylpenicillin sodium), see Chapter 64.

Gonococcal vaginitis

Gonorrhoea may infect the cervix or Bartholin's gland but not the vaginal epithelium, except in prepubertal girls or postmenopausal women. If there is suspicion of sexual abuse in a young child with a vaginal discharge, a swab for culture for *Neisseria gonorrhoeae* (see Chapter 64) should be taken.

Bartholin's gland diseases

These paired glands close to the introitus are responsible for mucus secretion that keep the vagina moist and lubricated during sexual arousal. If the duct becomes blocked, mucus is unable to escape and therefore a cyst will form. If this becomes infected, abscess formation occurs and this can be extremely painful. The most common organisms causing this are *Staphylococcus* and *Escherichia coli*, although other organisms may be encountered including *Neisseria gonorrhoeae* or *Chlamydia*. Bartholin's cysts or abscesses occur in about 3% of women, most commonly between the age of 20 and 30 years.

Bartholin's cysts may require no treatment unless troublesome, but abscesses almost always do. These may spontaneously rupture and resolve but recurrence rates are high. There are a number of surgical options, including incision and treatment with silver nitrate, marsupialization (which involves wide excision, drainage and eversion of the cyst mucosa to the vaginal skin), fistulization (incision, drainage and insertion of a catheter for 2–4 weeks), carbon dioxide laser incision and drainage, and needle aspiration of cysts.

A meta-analysis in 2009 failed to identify a best treatment approach [5]. Recurrence rates vary but are around 5%.

Viral infections

Lesions due to human papillomavirus (HPV) and herpes simplex virus can be seen in the vagina. Further information is given in Chapter 64.

Vaginal atrophy

This is seen not only following the menopause, but also prior to puberty and during lactation. Examination shows loss of rugal folds and prominent subepithelial vessels, sometimes with adjacent ecchymoses. The patient may present with vaginal bleeding, vaginal discharge or vaginal dryness and dyspareunia but also with urinary symptoms including frequency, nocturia, dysuria and recurrent urinary infection. Superficial infection, with Gram-positive cocci or Gram-negative bacilli, may be associated. Vaginal atrophy is symptomatic in 45% of postmenopausal women.

Treatment requires oestrogen to restore the vaginal epithelium and pH level. This is usually by topical oestrogen cream, and some of the oestrogen will be absorbed systemically. The endometrial safety of long-term use is uncertain. Preparations vary in length of recommended treatment, but this is usually for 3 months and then the effect is assessed. Repeated applications over time may be needed depending on symptoms returning. Alternatively, in postmenopausal women hormone replacement therapy can be used.

Vaginal trauma

This may follow coitus, with damage to the epithelium or less frequently the vaginal muscle wall, or the breakdown of adhesions at the vault following vaginal surgery (Fig. 58.2). It may be associated with parturition or be iatrogenic, for example ulceration associated with the use of a ring pessary. Trauma may be associated with significant haemorrhage and occasionally will leave vesical or rectal fistulae.

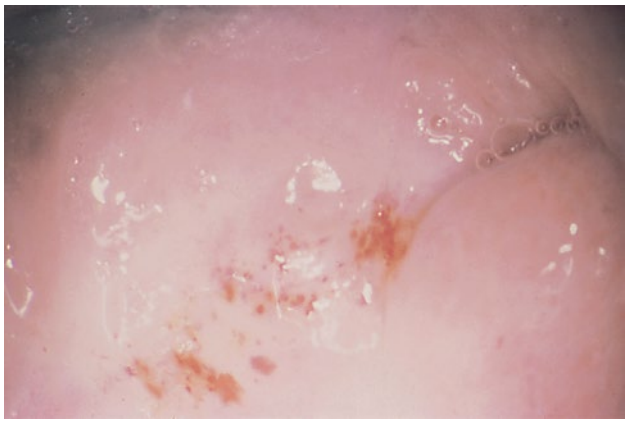

Fig. 58.2 Bleeding and adhesions at the vaginal vault. (*See also colour plate 58.2*)

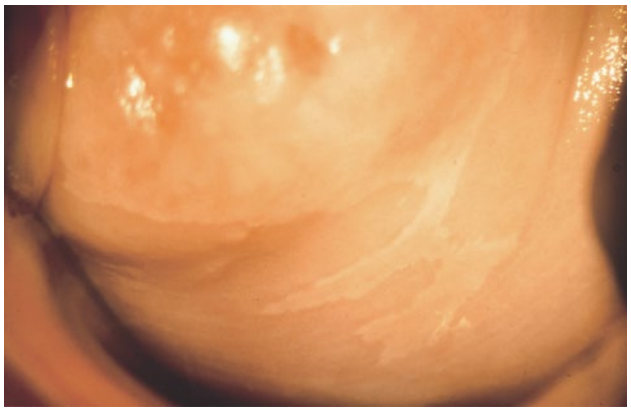

Fig. 58.3 Vaginal intraepithelial neoplasia as an extension of a cervical lesion. (*See also colour plate 58.3*)

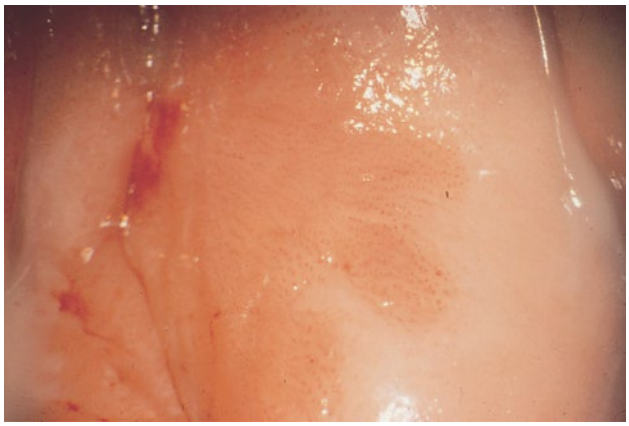

Fig. 58.4 Vaginal intraepithelial neoplasia in post-hysterectomy vaginal angle. (*See also colour plate 58.4*)

Fistula

A fistula may result from trauma, as described in the previous section, or it may be due to carcinoma or Crohn's disease. Fistula of the anterior wall is now uncommon in association with childbirth, but rectovaginal fistula may follow an obstetric tear or extension of an episiotomy, and an incomplete or inadequate repair. Fistulae involving ureter, bladder or rectum may follow gynaecological surgery.

Endometriosis

Occasionally, deposits of endometriosis can be found beneath the vaginal epithelium in patients with rectovaginal endometriosis or following surgery or episiotomy. They may cause abnormal vaginal bleeding or pain. They are most easily identified while bleeding but have a blueish appearance at other times. Treatment can be by laser vaporization or excision, or by drug therapy as for endometriosis elsewhere.

Vaginal intraepithelial neoplasia

Vaginal intraepithelial neoplasia (VAIN) is seen in about 10% of patients with cervical intraepithelial neoplasia (CIN) (Fig. 58.3). It is almost always in the upper vagina and confluent with the cervical lesion [6]. It is uncommon to find VAIN in the presence of a normal cervix, but Lenehan *et al.* [7] reported that 43% of their patients with VAIN after hysterectomy had a history of negative cervical smears and benign cervical pathology. VAIN may be present in the vaginal vault or suture line after hysterectomy (Fig. 58.4) (this may be residual after CIN has been treated) or may be distant from the vault and associated with multicentric intraepithelial neoplasia. Hummer *et al.* [8] reported a series of 66 patients with VAIN and showed that one-third of cases had developed within 2 years of treatment of the previous cervical lesion. The longest time interval between the diagnosis of CIN and VAIN was 17 years; the age of patients with VAIN in that series ranged from 24 to 74 years, with a mean age of 52 years.

The aetiology of VAIN is similar to that of CIN, with HPV found in 98% of cases and HPV-16 being found in 68% [9]. Extension of the transformation zone into the fornices would seem to be responsible, even though no abnormality was recognized when the cervical lesion was treated. A higher incidence of VAIN has been noted in patients on chemotherapy or immunosuppressive therapy. The role of radiotherapy for carcinoma of the cervix some 10–15 years prior to the development of VAIN has been noted, particularly when a subsequent lesion is in the lower vagina. It is thought by some [10] that a sublethal dose of radiation may induce tumour transformation and that VAIN or vaginal sarcoma may result.

As for cervical lesions, VAIN I is equivalent to mild dysplasia, VAIN II to moderate dysplasia and VAIN III to severe dysplasia or carcinoma *in situ*. The disease is normally recognized as a result of abnormal cytology seen in a vaginal vault smear specimen. Townsend [11] recommended that vault smears should be performed annually for women after hysterectomy performed for CIN, and every 3 years if the hysterectomy was for benign disease. Current teaching discourages the need for any subsequent smears in this latter group but recommends follow-up of patients who have had hysterectomy for cervical lesions. Gemmell *et al.* [12] recommend that vault smears should be taken 6 months, 12 months and 2 years after hysterectomy; the patient should then return to 5-yearly screening.

Colposcopic assessment of patients with abnormal vault smears will delineate areas of aceto-white epithelium. Punctuation may be apparent in more than 50%, and areas of abnormality will often fail to stain following the application of Lugol's iodine solution (Fig. 58.5). However, atrophic changes within the vagina may lead to extensive areas of non-Lugol's staining and difficulty in defining the limits of lesions. A preliminary 2-week course of oestrogen cream to correct oestrogen deficiency and then colposcopic examination 2 weeks following this will improve the definition of lesions. Problems may be encountered in interpreting or gaining access to areas of change disappearing into post-hysterectomy vaginal angles or suture line. Vaginal biopsies from the vault can usually be taken without anaesthesia, but occasionally difficult access into vaginal angles may require the use of general anaesthesia and appropriate vaginal retractors.

No adequate study on the progression of VAIN to invasive disease has been reported. Among the series of patients reported by McIndoe *et al.* [13] were patients who had abnormal smears following hysterectomy; some of these patients were followed up for almost 20 years before developing invasive carcinoma while others progressed more rapidly.

There has been a wide variety of treatments for VAIN. Surgical excision remains the mainstay of treatment, including excision biopsy for smaller lesions, partial vaginectomy for mutifocal disease and, rarely, total vaginectomy for extensive or persistent high-grade VAIN. The difficult patient to treat is the one who has already undergone a hysterectomy for a cervical lesion and returns with an area of abnormality in the suture line. Whether leaving the vault open at the time of hysterectomy avoids sequestration of the vaginal mucosa above the usual suture line has not been proven. Ireland and Monaghan [14] found that 9 of 32 patients with VAIN had invasive carcinoma in the area of the suture line, and they emphasized both the difficulty in assessing the vaginal vault and the need for obtaining adequate tissue for histological examination. They therefore advocated partial vaginectomy whenever abnormal epithelium is seen at the angles or suture line of the vault. This procedure requires an abdominal approach after packing the vaginal vault and involves the mobilization of the ureters down to their insertion into the bladder, dissection of bladder and rectum from the vagina, and sufficient mobilization to allow removal of the upper 1–2 cm from the top of the vagina. The definition of just how much to remove is usually best achieved by commencing a mucosal dissection from below prior to packing the vagina. Occasionally, more extensive disease will require total vaginectomy followed by either skin grafting or mobilization of a loop of bowel to reconstruct the neovagina. There are some who advocate a vaginal approach [15], but access may not be easy and occasionally brisk bleeding from vaginal arteries may be encountered.

Use of the carbon dioxide laser is more likely to be successful in treating those women who have not had

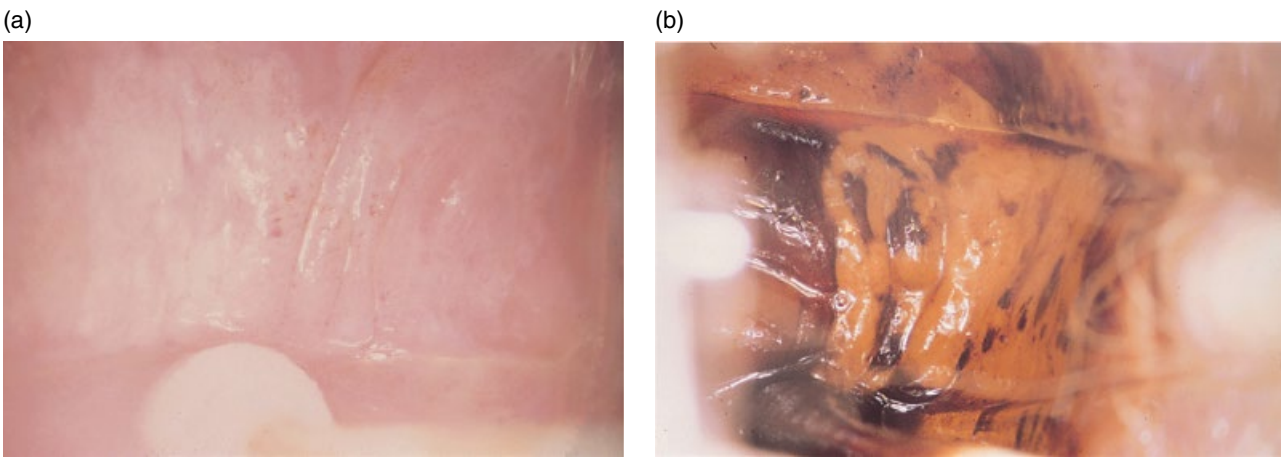

Fig. 58.5 (a, b) Area of vaginal intraepithelial neoplasia before and after the application of iodine solution. (*See also colour plate 58.5*)

hysterectomy and where the full extent of the lesion can be demarcated. It must be noted that the vaginal wall may be thin in postmenopausal women and the bladder and rectal mucosa less than 5 mm away. The advantage of the carbon dioxide laser over other forms of selective ablation, for example diathermy or loop excision, is that there should be greater control of the area and depth of laser vaporization. Techniques using high-power density and rapid beam movement minimize carbonization and adjacent thermal necrosis to allow recognition of tissue architecture with removal of lesional epithelium down to the underlying stroma, thereby reducing the risk of bladder or bowel damage [16].

Medical treatment has also been used. Imiquimod 5% cream is commonly used and a recent review reported complete response rates in VAIN I–III of 57–86% [17]. Experience with the use of 5-fluorouracil has been less extensive in the UK than in the USA. Caglar *et al.* [18] claimed that the subsequent denudation of epithelium was specific for only abnormal epithelium. However, sometimes epithelial ulceration is extensive, accompanied by severe vaginal burning, and subsequent healing may take several months. Treatment failure is common. A recent study by Rhodes *et al.* [19] examined the role of intravaginal oestrogen alone and in combination with other therapies. In the group treated with oestrogen alone, 90% had regression or cure; of those who had combined therapy, a cure rate of 81.3% was reported. In contrast, those treated without oestrogen had a cure rate of only 71%.

The other option is to use radiotherapy by the intravaginal approach [20]. Such treatment may produce vaginal narrowing and interfere with coitus, and so this should be reserved for highly selected difficult cases and in older women in whom sexual activity has ceased. Local damage to the bladder and rectum are risks of brachytherapy.

Summary box 58.2

- VAIN coexists with CIN in up to 6% of patients.
- Colposcopic assessment and follow-up is mandatory.
- Treatment is either by excision or local ablative therapy.

Diethylstilbestrol and related vaginal lesions

Diethylstilbestrol (DES) was used from the mid-1940s for the treatment of recurrent or threatened abortion and unexplained fetal loss late in pregnancy, predominantly in the north-eastern states of the USA (where it is estimated that 2 million women were treated) and also in Canada, Mexico, Western Australia and western Europe.

Herbst and Scully [21] reported seven cases of clear cell adenocarcinoma of the vagina seen and treated in Massachusetts General Hospital, Boston, in young women aged between 14 and 22 years. A retrospective study by them linked these carcinomas with the intrauterine exposure of the patients to DES given to their mothers during pregnancy. The more extensive survey [22] looked at 346 cases of clear cell adenocarcinoma of the cervix and vagina. The maternal history was available in 317 patients and it was found that two-thirds of the patients had been exposed *in utero* to DES or a similar non-steroid oestrogen given to the mothers during pregnancy. In a further 10%, drugs of doubtful origin were given but in 25% no history of maternal hormone therapy could be obtained. The authors found that the age incidence for clear cell adenocarcinoma of the vagina in young women began at 14 years, peaked at 19 years and then subsequently declined. They estimate that the probable risk of development of clear cell carcinoma in women exposed to DES *in utero* is 0.14–1.4 per 1000 women. DES produced various other vaginal and cervical lesions. Vaginal adenosis was often seen in combination with cervical eversion or ectropion. The patients often had a ridge between the vaginal and cervical tissue referred to as a collar, a rim or a 'cock's comb cervix'. Such appearances occurred in approximately 25% of exposed patients. The adenosis can affect the anterior and posterior vaginal walls and lateral vaginal fornices, but is usually restricted to the upper third of the vagina. Sometimes there will be cytological abnormality, extensive immature metaplasia and CIN. Originally it was recommended that women who were known to have been exposed to DES *in utero* should be screened from the age of 14 years with both cytology and colposcopy. DES exposure was uncommon in the UK and associated vaginal changes will be seen infrequently. Such patients should be managed by annual cervical and vaginal cytological surveillance and colposcopic assessment. It is still not known if the risk of adenocarcinoma persists, for example after the menopause.

Benign vaginal tumours

These are uncommon but occur within the vaginal wall and include myoma, fibromyoma, neurofibroma, papilloma, myxoma and adenomyoma.

Cystic lesions may be found within the vagina, usually laterally and occasionally extending from the fornix down to the introitus. These are usually of Gartner's or Wolffian duct origin. They may increase to such a size as to interfere with coitus or tampon use. They can usually be managed by de-roofing, but care must be taken in the fornices to avoid large uterine and vesical vessels.

Cervix

Benign lesions

Position of the squamocolumnar junction and changes within the transformation zone

It is known that the uterine cervix increases in size in response to oestrogens; because the cervix is anchored at the fornices, the end result of any enlargement is eversion to expose the columnar epithelium of the endocervical canal. This occurs dramatically in the neonate and under the influence of maternal oestrogens, at puberty under the influence of rising oestrogen levels, during the use of the combined oral contraceptive pill and during the first pregnancy (Fig. 58.6). Ectopy is the preferred term for this display of columnar epithelium (rather than 'erosion'); colposcopic examination demonstrates the folding of the epithelium into villi (Fig. 58.7). Upon withdrawal of oestrogen, for example in the puerperium or at the menopause, the squamocolumnar junction approaches the external os once more and indeed may be found within the endocervical canal.

In approximately 5% of women there will be extension of the squamocolumnar junction into the anterior and posterior fornices so that on subsequent examination an extensive area of change will be noted, the so-called congenital transformation zone. The presence of this may not be apparent to the naked eye but can be demonstrated following the application of iodine. Biopsy will show no evidence of intraepithelial neoplasia but delayed or immature metaplasia.

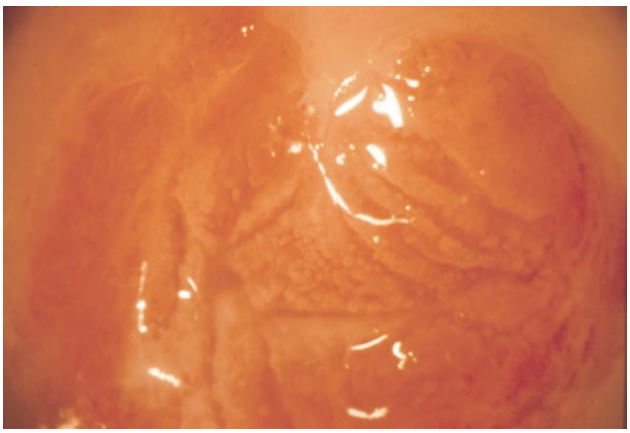

Fig. 58.6 Eversion of the cervix during pregnancy. (*See also colour plate 58.6*)

Cervical metaplasia

Exposure of the columnar epithelium to low pH as found within the vagina promotes a series of physiological changes, known as metaplasia. It is believed that reserve cells lying within the monolayer of columnar epithelium will proliferate, producing a multilayered epithelium with the columnar cells left exposed on the surface (Fig. 58.8). These cells will initially appear immature and undifferentiated, but with the passage of time will show the usual differentiation to resume a squamous epithelium with glycogenation of the superficial squamous cells. This process occurs at the squamocolumnar junction, or transformation zone, starting in the neonate and continuing until well after the menopause. Examination of the endocervix will show a series of longitudinal ridges with columnar cells lining both the tops of the ridges and extending down into the depths or crypts (Fig. 58.9). Metaplasia usually occurs initially in the ridges and may well bridge over these, leaving a squamous cover with columnar epithelium remaining within the crypts. If a crypt cannot expel the mucus produced from the columnar epithelium, a retention cyst or Nabothian follicle will occur (Fig. 58.10); sometimes these follicles are large and

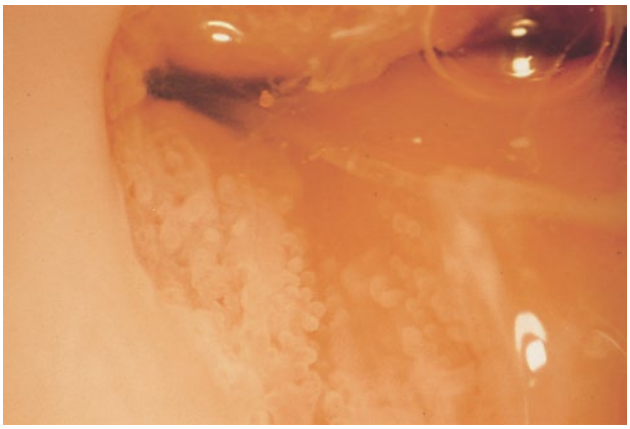

Fig. 58.7 Columnar villi at the squamocolumnar junction. (*See also colour plate 58.7*)

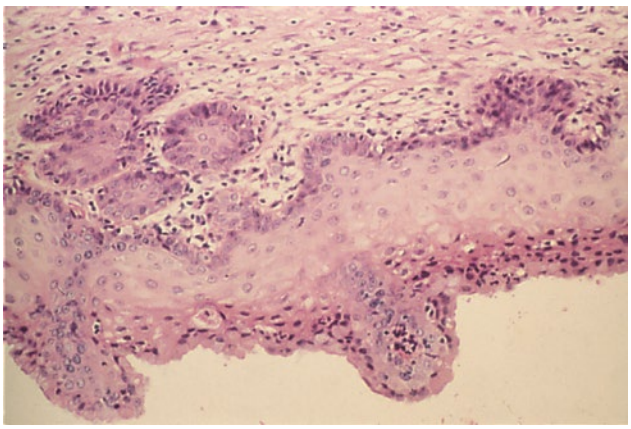

Fig. 58.8 Photomicrograph of columnar and multilayered immature metaplastic epithelia. (*See also colour plate 58.8*)

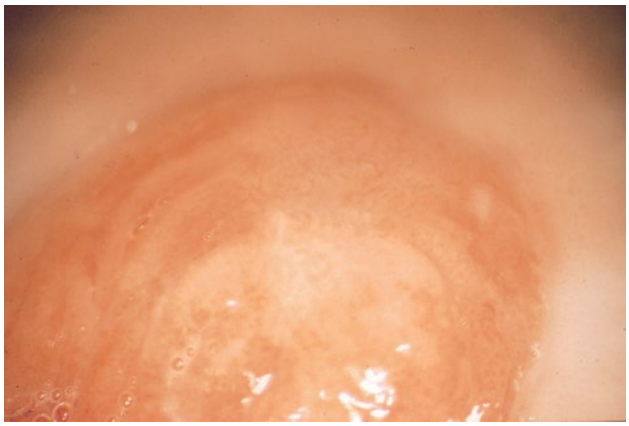

Fig. 58.9 Squamous metaplasia of the cervix. (*See also colour plate 58.9*)

Fig. 58.11 A small endocervical polyp. (*See also colour plate 58.11*)

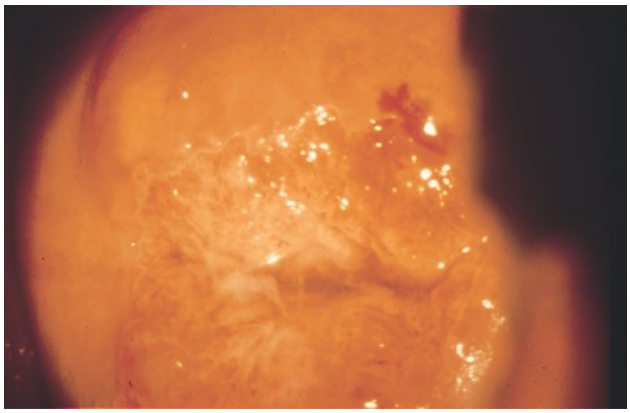

Fig. 58.10 A typical transformation zone with a mucus-filled Nabothian follicle at 11 o'clock. (*See also colour plate 58.10*)

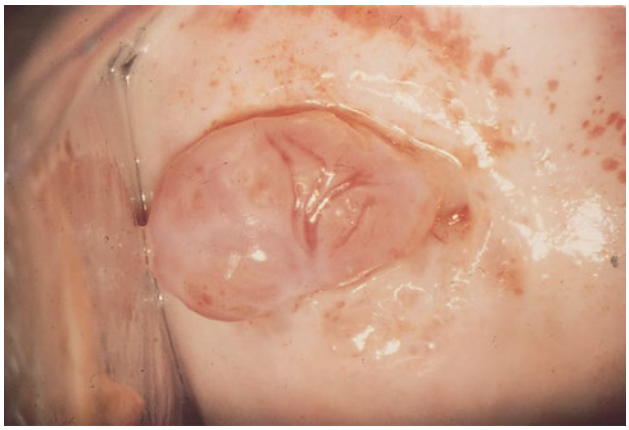

Fig. 58.12 A large polyp with adjacent atrophic epithelium and ecchymoses. (*See also colour plate 58.12*)

extensive across the transformation zone. They are entirely benign and are not associated with infection, i.e. they are not a sign of cervicitis and require no treatment.

Endocervical polyps

The recognition of endocervical polyps at the time of taking a cervical smear is common and usually increases with age up to and beyond the menopause (Figs 58.11 and 58.12). Occasionally these polyps will be symptomatic, producing some increase in vaginal discharge or bleeding on coital contact. Histology of these polyps will show that they consist of columnar epithelium, sometimes with metaplastic squamous epithelium across the tip. Malignant change is most unusual. However, if these polyps are removed, for example by polypectomy, tissue should be sent for histology, recognizing that some 15% of uterine tumours will be polypoidal and occasionally will extrude through the external os.

Chronic cervicitis

There was previous enthusiasm for treating by cautery or diathermy those patients who complained of chronic watery vaginal discharge and were found to have an 'erosion'. As already explained, these areas of ectopy or everted columnar epithelium are not pathological and the term 'cervicitis' is not appropriate.

However, some women with *Chlamydia trachomatis* (and rarely with *Neisseria gonorrhoeae*) will present with symptoms of discharge and an abnormal cervix will be noted. Brunham *et al.* [23] described 'mucopurulent cervicitis' in association with *Chlamydia*, and Hare *et al.* [24] described the colposcopy appearances of 'follicular cervicitis'. Providing these organisms have been excluded by appropriate microbiology, 'cervicitis' does not require treatment except by increasing vaginal acidity to promote squamous metaplasia.

Summary box 58.3

Cervical disease

- The squamocolumnar junction can be found in a number of clinical sites across the cervix and occasionally reaches the vault of the vagina.
- Cervical metaplasia is a normal phenomenon.
- Endocervical polyps can be removed in an outpatient setting.
- Chronic cervicitis requires no treatment.

Ovaries

Benign disorders

Anatomy

The ovaries are attached to the lateral pelvic side walls by the suspensory ligament containing the ovarian vessels, and to the cornua of the uterus by a ligamentous condensation of the broad ligament. Each ovary is $3 \times 2 \times 1$ cm in size in the resting or inactive state, but will increase in size during physiological stimulus; they shrink after the menopause. The surface is covered by a flattened monolayer of epithelial cells, and beneath this are the ovarian follicles, with oocyte, granulosa layer and surrounding theca. Beneath this cortical layer are a stromal medulla and a hilum where the vessels enter through the mesovarium. The events associated with follicular development and ovulation are described in Chapter 46. The size and position of the ovaries varies between puberty and menopause – the mean volume, as assessed by transvaginal ultrasound scan of a premenopausal ovary, is 6.8 cm^3 (upper limit of normal 18 cm^3) compared with a mean postmenopausal size of 3 cm^3 (upper limit 8 cm^3).

Ovarian enlargement

Ovarian enlargement will occur in response to follicle stimulating hormone and luteinizing hormone. Follicular and luteal cysts can occur, and theca lutein cysts up to 15 cm in size will develop in response to very high levels of chorionic gonadotrophin, as occurs with trophoblastic disease. Hyperstimulation syndrome can occur, with massive enlargement of the ovaries and development of ascites, in response to therapeutic gonadotrophin stimulation during fertility treatment (see Chapter 52).

Polycystic disease

Polycystic enlargement of the ovaries has been described under a variety of names. Stein and Leventhal [25] described seven cases of amenorrhoea or irregular menstruation with enlarged polycystic ovaries demonstrated by 'pneumoroentgenography' and restoration of normal physiological function after wedge resection. Judd *et al.* [26] demonstrated that the mildly elevated androgen levels found in this syndrome were of ovarian origin. The changes in gonadotrophin ratios and androgen levels are not always consistent with the appearances of the ovaries, and increasingly the diagnosis of polycystic ovarian disease is based on ultrasound findings of peripheral distribution of 10 or more follicles of 2–8 mm in diameter, with increased ovarian volume and associated endocrine criteria (see Chapter 47).

Ovarian pregnancy

Ovarian ectopic pregnancy is uncommon, with an estimated incidence of 1 per 25 000 of all pregnancies. Patients usually present with features of an extrauterine pregnancy or bleeding from a corpus luteum. Preoperative diagnosis is difficult.

Treatment is surgical removal, which may require removal of the ovary. This can usually be achieved laparoscopically (see Chapter 43).

Ovarian endometriosis

Ovarian enlargement may be found secondary to endometriosis (i.e. endometriomas). Endometriomas vary in size considerably and although medical management is possible with smaller cysts, larger endometriomas require surgical treatment (see Chapter 53).

Ovarian tumours

There are five main groups of ovarian tumour as classified by the World Health Organization. However, the benign tumours are as follows:

- Epithelial: serous cystadenoma, mucinous cystadenoma, Brenner tumour.
- Germ cell: teratoma (Fig. 58.13).

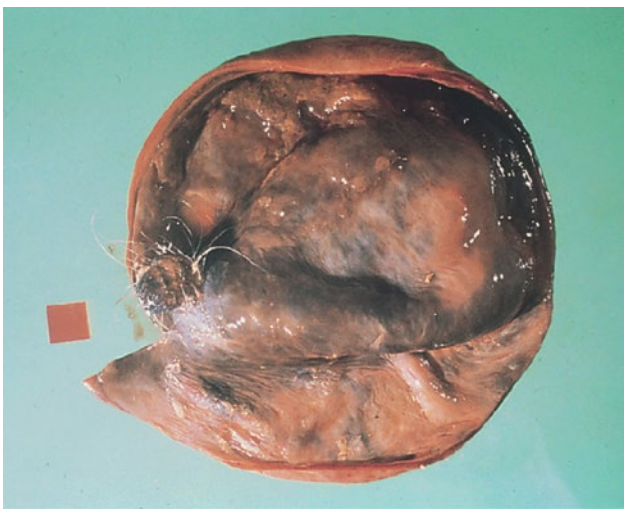

Fig. 58.13 A benign cystic teratoma of the ovary showing hair and skin. (*See also colour plate 58.13*)

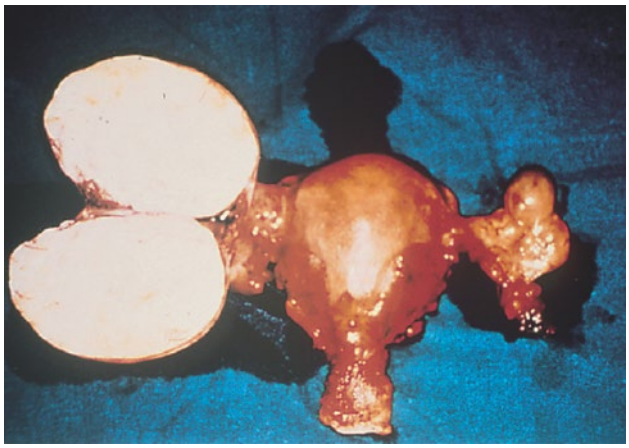

Fig. 58.14 An ovarian fibroma. (*See also colour plate 58.14*)

Benign tumours comprise about 85% of all ovarian neoplasms, mucinous cystadenomas contributing 50% and serous 25%, with teratomas occurring in about 10%. There are other soft tissue tumours that are not specific to the ovary, such as fibromas (Fig. 58.14).

Corpus luteum

The corpus luteum is a physiological development following ovulation, and in a normal menstrual cycle may reach 3 cm in diameter. Occasionally, the corpus luteum may persist in the absence of pregnancy and may increase in size to up to 5 cm in diameter. It is usual at this point that regression begins and the corpus luteum cyst spontaneously resolves. These cysts are often seen incidentally on ultrasound in asymptomatic women or in women who have mild abdominal pain. The management is conservative. In 95% of cases, repeat ultrasound at 6–8 weeks will show that the structure has disappeared and normal ovarian function ensues. It is extremely important that a conservative approach is adopted in these circumstances and these cysts only need to be removed laparoscopically if they persist or increase in size over time.

Mature cystic teratomas (dermoid cysts)

Dermoid cysts are cystic teratomas that contain elements of ectoderm, endoderm and mesoderm which may include skin, hair follicles and sweat glands; occasionally, hair can be quite prolific. There can also be pockets of sebum, blood, fat, bone, nails, teeth and cartilage and occasionally thyroid tissue. Dermoid cysts usually present with abdominal discomfort or acute pain due to torsion, in women between the ages of 18 and 25 years. Diagnosis may be made on ultrasound, where there are classic features (see Chapter 36), and if there is any doubt as to the aetiology, an MRI scan can be performed although is rarely necessary. Dermoid cysts can vary in size and grow over time until diagnosis is made. Occasionally, dermoid cysts may be diagnosed for the first time during pregnancy and here clinical decisions – about whether to adopt a conservative approach with management of the cyst postnatally – need to be made in the light of clinical symptoms and size. Dermoid cysts are bilateral in 10–15% of cases.

The management of dermoid cysts is surgical in cases where the patient is symptomatic. Ovarian cystectomy can be performed by laparotomy or laparoscopy. With larger cysts (i.e. >6 cm), the preferred method is laparotomy; smaller cysts may be removed laparoscopically. There is some controversy about the laparoscopic approach due to the risk of spillage of the contents leading to chemical peritonitis. The risk is small (0.2%) but it is a serious complication when it does occur [27]. Spillage has been reported as occurring in 13–100% of cases [28,29]. There is also debate about the incidence of recurrence after laparoscopic surgery. There would seem little doubt that the recurrence rate is higher in the laparoscopic group, probably about 10%, compared with 0.1% in the laparotomy group [28].

Ovarian cystectomy is always the preferred surgical option as most of these patients will not have tested their fertility. In the majority of cases, the finding of a dermoid cyst is incidental and so expectant management may be an option, particularly if the cyst is small. Data on this strategy are lacking at present but this would seem a logical approach.

Serous cystadenomas

These account for approximately 25% of all benign ovarian neoplasms and their peak incidences are in the fourth and fifth decades of life. Symptoms are usually rather non-specific but can include pelvic pain or discomfort or occasionally a pelvic mass is discovered at routine examination. Approximately 20% of cystadenomas are bilateral and they are benign. Treatment is by either salpingo-oophorectomy or ovarian cystectomy depending on whether the patient is keen to preserve her fertility. Recurrence is extremely rare.

Mucinous cystadenomas

These comprise 50% of benign ovarian epithelial neoplasms and tend to occur most often between the third and sixth decades of life, with a mean age of around 50 years. Small tumours are often found incidentally, whereas the larger tumours present as an obvious pelvic or abdominal mass. They are rarely bilateral. Treatment

is by ovarian cystectomy or oophorectomy, which may be performed either laparoscopically or by laparotomy.

Ovarian cyst accidents

Ovarian cysts may present acutely, and here pain may be severe following rupture, haemorrhage or torsion of the cyst. Haemorrhage can be dramatic and severe bleeding can cause hypovolaemia and a haematoperitoneum. Patients present in a collapsed state and the differential diagnosis is often of a ruptured ectopic pregnancy. Treatment is by emergency laparotomy to stop the bleeding, followed by assessment and salvage of the ovary if possible. Torsion of an ovarian cyst presents as intermittent acute abdominal pain, usually in the iliac fossa associated with the ovary. The pain is colicky in nature and the pain may be referred to the sacro-iliac joint or to the upper medial thigh. It is important that ultrasound imaging, including Doppler assessment for blood flow, is performed although torsion will only be diagnosed in 60% of cases. Episodes of torsion may be spread over quite long periods of time and it is important for the clinician to recognize the pattern of symptoms of acute presentation if multiple torsion is to be avoided or it will result in ovarian ischaemia. Sadly, failure to recognize this sequence of events may lead to an acute situation with surgery resulting in salpingo-oophorectomy as salvage of the ovary is not possible. However, treatment is usually by detorsion even if the ovary appears necrotic, with removal of the ovarian cyst either at the time or as an interval procedure. Detorsion alone is insufficient as rates of recurrent torsion are high [30].

Summary box 58.4

Benign disease of the ovary

- Cysts of the corpus luteum should be monitored and will resolve spontaneously in 95% of cases.
- Mature cystic teratomas should be removed surgically.
- Cyst accidents are common and careful diagnosis and management will avoid loss of an ovary.

Benign Disease of the Uterus

Thierry Van den Bosch

Department of Development and Regeneration, University Hospitals KU Leuven, Leuven, Belgium

Benign disease of the uterus includes uterine fibroids, adenomyosis and endometrial polyps. These pathologies may remain asymptomatic or cause considerable morbidity. Uterine fibroids are the most prevalent benign lesions of the uterine corpus. Benign focal intracavitary lesions are present in-one third of premenopausal women and in almost half of postmenopausal women with abnormal uterine bleeding. In premenopausal women, focal intracavitary lesions, including intracavitary fibroids and endometrial polyps, become more prevalent with advancing age [1].

This chapter discusses each of these conditions and considers their aetiology, pathogenesis, presenting symptoms, diagnosis and treatment with inclusion of new developments, particularly in the treatment of symptomatic fibroids.

Adenomyosis

Definition

Adenomyosis is defined as the presence of endometrial tissue, including endometrial glands and stroma, in the myometrium and is associated with smooth muscle proliferation in the inner myometrium [2]. It may be either diffuse or focal. Adenomyosis typically results in uterine enlargement and an irregular endo-myometrial border or junctional zone. The histological definition of adenomyosis usually includes a depth of penetration between 2.5 and 5 mm [3].

Incidence

The reported incidence of adenomyosis in hysterectomy specimens varies considerably, ranging from 9 to 62% [4]. This wide range is likely to reflect the varying diagnostic methodologies used by different pathologists.

Aetiology

The ectopic endometrium is responsive to steroid hormones. In addition, gene polymorphisms have been identified in the oestrogen receptor, with mutations of oestrogen receptor alpha [5]. This ectopic tissue may respond to the cyclical hormone changes of the menstrual cycle, contributing to the symptoms of heavy menstrual bleeding (HMB) and dysmenorrhoea. Abnormal prostaglandin production also occurs and this could exacerbate both pelvic pain and heavy bleeding.

Clinical presentation

The commonest presentation is HMB and dysmenorrhoea, the latter being worse in deep infiltrating disease [6]. However, adenomyosis is often diagnosed in women without bleeding or pain symptoms, leading Weiss *et al.* [4] to challenge the causative relationship between adenomyosis and symptoms. The condition is reportedly characteristic of the fifth decade of life, with 45 years being the commonest age of presentation. It is uncommon in nulliparous women and occurs less frequently in smokers [7].

Diagnosis

The diagnosis is made on histological examination of the uterus after hysterectomy but the preoperative diagnosis may be suggested on ultrasound examination. Typical ultrasound features of adenomyosis include an asymmetrical thickening of the myometrium or a globular uterus, myometrial cysts, myometrial echogenic islands, fan-shaped shadowing, subendometrial echogenic lines and buds, translesional vascularity and an irregular or interrupted junctional zone [8,9] (Fig. 59.1).

On MRI, adenomyosis has historically been linked with a thickened junctional zone [10]. According to Brosens

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

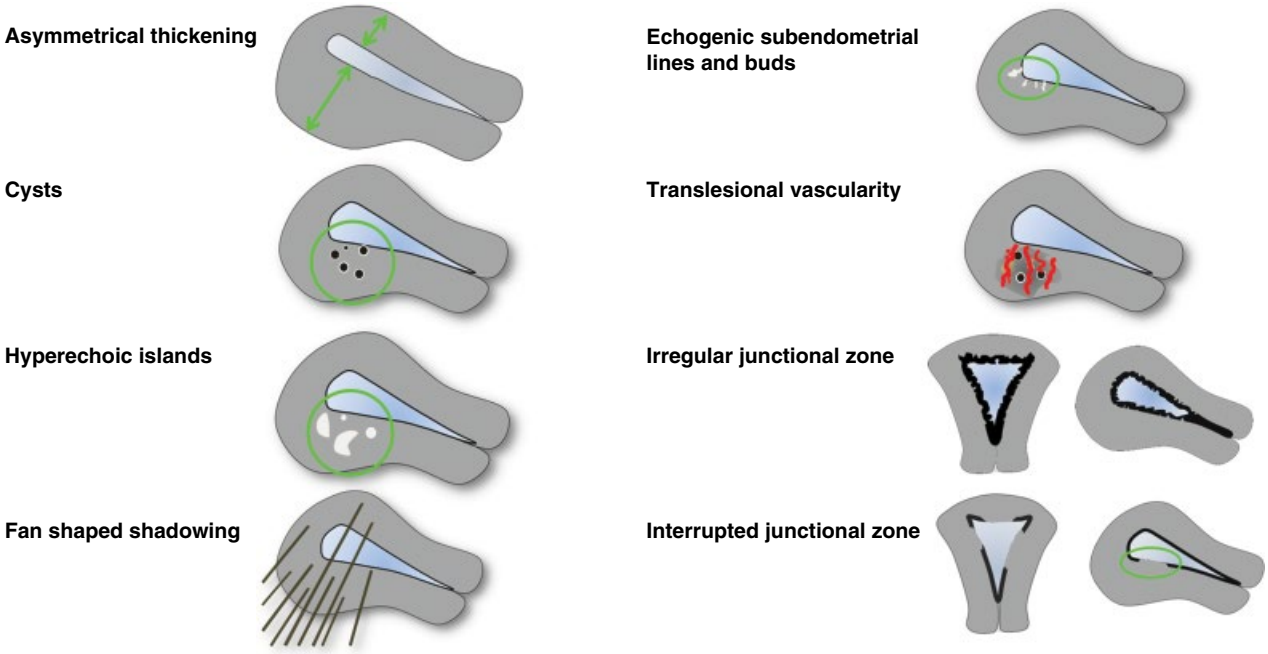

Fig. 59.1 Ultrasonographic features of adenomyosis. *Source:* Van den Bosch T, Dueholm M, Leone FP *et al.* Terms, definitions and measurements to describe sonographic features of myometrium and uterine masses: a consensus opinion from the Morphological Uterus Sonographic Assessment (MUSA) group. *Ultrasound Obstet Gynecol* 2015;46:284–298. Reproduced with permission of the International Society of Ultrasound in Obstetrics and Gynaecology.

et al. [11], the thickening seen on MRI relies on the disruption of the inner myometrial architecture secondary to smooth muscle hyperplasia but, unlike the ultrasound features, does not evidence mucosal invasion of the myometrium.

Treatment

The treatment is mainly symptomatic, and aims to relieve HMB and dysmenorrhoea. Various medical and minor surgical techniques have been shown to be of some benefit in the short term. Antifibrinolytics, non-steroidal anti-inflammatory drugs, the oral contraceptive pill and progestins may be considered as first-line methods of treatment. The levonorgestrel-releasing intrauterine system (LNG-IUS) has been shown to be effective for reducing uterine volume and relief of adenomyosis-related symptoms at 1 year, but the efficacy of this device declines with time [12]. Endometrial ablation is not used as a first-line treatment of adenomyosis as it fails to remove deeply infiltrating endometrial glands. It has been shown to improve menorrhagia and dysmenorrhoea in some women, and those with superficial disease have good results from this treatment option. Those with deeply infiltrating disease, however, tend to have persistent symptoms and, if conservative therapy fails, should be offered hysterectomy if fertility is not an issue [13].

The minimally invasive radiological technique of uterine artery embolization (UAE) is used in some centres for the treatment of symptomatic adenomyosis. It has been shown to be effective in the short term, but there is a high rate of symptom recurrence within 2 years of treatment [14].

Summary box 59.1

- Adenomyosis is a cause of menorrhagia, dysmenorrhoea and uterine enlargement.
- Its true prevalence is unknown, but it has been reported in 9–62% of hysterectomy specimens.
- Transvaginal ultrasonography is the primary diagnostic tool.
- Symptomatic medical treatment is the first-line management.
- Hysterectomy is the definitive treatment.

Endometrial polyps

Definition

Endometrial polyps are discrete outgrowths of the endometrium containing a variable amount of glandular tissue, stroma and blood vessels. Polyps may be pedunculated

or sessile, single or multiple. They are relatively insensitive to cyclical hormonal changes and thus are not shed at the time of menstruation. Hyperplastic or malignant foci within a polyp are infrequent. The incidence of cancer in asymptomatic women and in women with postmenopausal bleeding diagnosed with a polyp is 0.1–1.5% and 1.0–4.5%, respectively [15,16].

Epidemiology

In symptomatic women the prevalence of polyps is reported as ranging between 6 and 32% [17]. In the general population aged 20–74 years, Dreisler *et al.* [17] reported the presence of endometrial polyps in 7.8%, the occurrence being very low below age 30. In their study they did not find an association between the presence of polyps and abnormal bleeding.

Presentation

Postmenopausal uterine bleeding, HMB, intermenstrual bleeding, dysmenorrhoea and subfertility have been related to endometrial polyps.

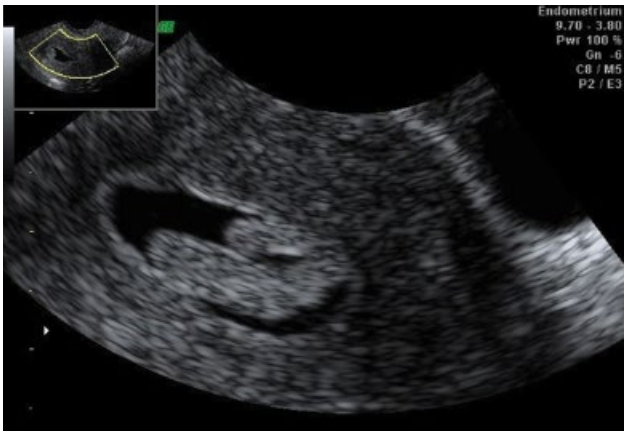
Diagnosis

Both fluid instillation sonography and hysteroscopy have a comparable diagnostic accuracy in detecting focal intracavitary lesions [18].

On transvaginal ultrasound examination a polyp typically is a relatively hyperechogenic lesion with or without small and regular internal cysts. The interface between the endometrium and the lesion often appears as a bright echogenic edge. On colour imaging a dominant vessel is often visible [19]. In a premenopausal woman with a spontaneous menstrual cycle, an echogenic polyp is more readily detected in the proliferative phase of the cycle, when the endometrium is more hypoechogenic (three-layer pattern). In women on hormonal therapy or who are postmenopausal, where timed examination is not feasible, instillation of fluid into the uterine cavity will create a negative contrast against which focal intracavitary lesions are easily visualized (fluid instillation sonography) (Fig. 59.2). Both saline infusion sonography and gel instillation sonography may be used [20].

Hysteroscopy enables direct visualization of the uterine cavity and is often considered the reference test. On hysteroscopy, polyps can be distinguished from pedunculated fibroids as they have fewer vessels over their surface. Malignant polyps are more likely to be irregular, vascular and/or friable. Hysteroscopic-guided biopsy

(a)



(b)

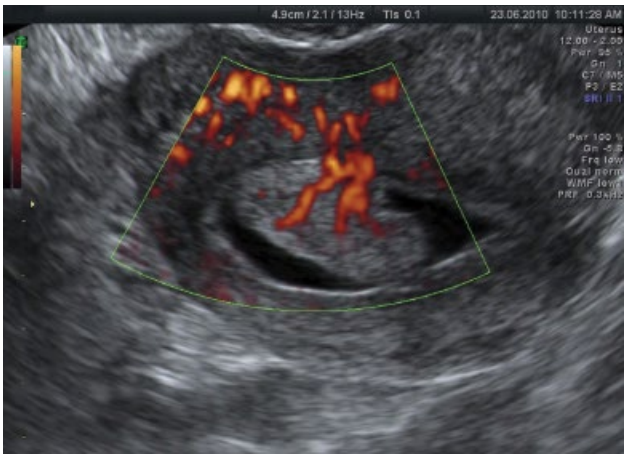


Fig. 59.2 (a, b) Fluid instillation sonography demonstrating endometrial polyps. On power Doppler imaging (b) the vascular pedicle is visible. (*See also colour plate 59.2*)

(preferably total excision of the lesion) and pathological analysis confirm the diagnosis, as visual appearance alone is insufficient.

Endometrial polyps are frequently missed with blind endometrial sampling, including dilation and curettage. There is no place for blind sampling without imaging in modern gynaecology [21,22].

Treatment

There is consensus that symptomatic women with endometrial polyps should undergo hysteroscopically guided removal under direct vision. In the vast majority this will result in cessation of the abnormal uterine bleeding [23]. The resection may be performed either under general anaesthesia or in an outpatient setting with or without local anaesthesia or sedation [24].

Summary box 59.2

- Endometrial polyps occur in about 25% of women who present with unscheduled vaginal bleeding.
- The most accurate tests for diagnosing polyps are fluid instillation sonography and hysteroscopy.
- There is no place for blind sampling in the diagnosis of focal intracavitary lesions.
- Treatment involves excision under direct vision (using hysteroscopy).

Uterine leiomyomata (fibroids)

Definition

Uterine leiomyomata or fibroids are the most common benign tumours of the female genital tract, arising from neoplastic transformation of single smooth muscle cells of the myometrium. They usually appear as well-circumscribed firm tumours with a characteristic white-whorled appearance on cross-section. Fibroids are paler than the surrounding myometrium and there is usually a very sharp line of demarcation between the tumour and the normal uterine muscle (Fig. 59.3).

Histologically, they are typically composed of varying proportions of spindled smooth muscle cells and fibroblasts. The size of fibroids varies greatly. The vast majority of fibroids are found in the corpus (body) of the uterus, but they may also occur in the cervix, uterine ligaments and ovary. Fibroids may be single but are commonly multiple and should be reported using the FIGO classification [25] (Fig. 59.4):

0 pedunculated intracavitary;
1 submucosal, <50% intramural;
2 submucosal, ≥50% intramural;
3 100% intramural, but in contact with the endometrium;
4 intramural;
5 subserosal, ≥50% intramural;
6 subserosal, <50% intramural;
7 subserosal pedunculated;
8 other (e.g. cervical, parasitic).

Incidence

The incidence of fibroids increases with age: it has been reported to occur in 20–40% of women during reproductive life and in as many as 70% of uteri removed at the time of hysterectomy [7]. Especially in postmenopausal women, conservative treatment including myomectomy, myoma morcellation, UAE or endometrial ablation [26] should be considered only after malignancy has been excluded [27,28].

The incidence of malignancy (leiomyosarcoma) is 0.64 per 100 000 women per year and is extremely uncommon in women below the age of 40. Unlike a fibroid, which consists of spindled cells arranged in fascicles with abundant eosinophilic cytoplasm and uniform nuclei, a leiomyosarcoma is hypercellular and consists of atypical smooth muscle cells with hyperchromatic enlarged nuclei and shows increased mitotic activity and tumour cell necrosis [29]. However, the pathogenesis of leiomyosarcomas remains unclear and no evidence exists to suggest that fibroids undergo neoplastic change.

There are significant racial differences in the incidence of fibroids, with Afro-Caribbean women having a twofold to ninefold greater risk. In addition, they tend to present at a younger age compared with Caucasian women and have multiple fibroids and higher uterine weights and are more prone to both anaemia and severe pelvic

pain [30,31]. Reproductive factors also influence the risk of fibroids, with a reduction in incidence with increasing parity (beyond 24 weeks' gestation) and the prolonged use of the oral contraceptive pill [31,32]. Environmental factors also influence the risk of fibroid development. Independent of body mass index, smoking appears to decrease the risk of fibroid development [33,34].

Aetiology

The pathophysiology of fibroids remains poorly understood. Clonality studies using the homozygosity of glucose 6-phosphate dehydrogenase forms show that multiple tumours in the same uterus are derived from individual myometrial cells rather than occurring through a metastatic process. This, together with their high prevalence, suggests that initial development arises from a frequently occurring event, the nature of which is currently unknown. Growth of fibroids is partly dependent on the ovarian steroids that act through receptors present on both fibroid and myometrial cells. It is likely that the control of growth is due, in part, to alterations in apoptosis. Bcl-2, an inhibitor of apoptosis, is significantly increased in cultured leiomyoma cells. It is also influenced by the steroid hormone milieu.

Cytogenetic abnormalities occur in 40% of uterine fibroids. Most commonly, these involve translocation within or deletion of chromosome 7, translocations of chromosomes 12 and 14, and occasionally structural aberrations of chromosome 6 [35]. These cytogenetic abnormalities are not observed in normal myometrial tissue and may not be present in all the fibroids in a single uterus [36]. Abnormalities in uterine blood vessels and angiogenic growth factors are also involved in the pathophysiology of uterine fibroids. The myomatous uterus has increased numbers of arterioles and venules and is also associated with venule ectasia or dilatation. It has been noted that there are no mature vessels running through uterine fibroids despite the fact that they have a well-developed blood supply.

Control of growth

More information is available on the control of uterine fibroid growth than on the aetiology of these benign tumours. Growth factors are of importance in controlling the growth of fibroids and their composition. Higher concentrations of the angiogenic fibroblast growth factor have been found in fibroids than in the surrounding myometrium. In addition, the functions of transforming growth factor-β, granulocyte–macrophage colony-stimulating factor and epidermal growth factor (EGF), amongst others, have been shown to differ between fibroid and normal myometrial tissue [36].

As fibroids have not been identified in prepubertal girls and usually shrink at the time of the menopause, it has long been assumed that these lesions are dependent on the presence of the sex steroids, oestrogen and progesterone. The sex steroids act via receptors. The steroid combines with the receptor, which is then translocated to the nucleus of the cell. Studies have identified that steroid receptors are present in higher concentrations in fibroids than in the surrounding myometrium and that the concentration of receptors is significantly affected by the administration of agents which alter circulating estradiol concentration. Further work has centred on the relationship between steroid hormones and growth factors, such as EGF and insulin-like growth factor (IGF), which would appear to be important, possibly as mediators for oestrogen action. The number of progesterone receptors is greater in fibroids than in the surrounding myometrium. Like oestrogen, it has an impact on EGF receptor content and also suppresses apoptosis. Progesterone stimulates and inhibits fibroid growth, the former by upregulating EGF and Bcl-2 and downregulating tumour necrosis factor-α expression, the latter by downregulating IGF-1 [37].

Symptoms associated with uterine fibroids

It is estimated that only 20–50% of women with one or more fibroids will experience symptoms that are directly attributable to them. However, it is not always clear why some produce symptoms and others do not [7]. In the case of small fibroids, it is often the assumed that only those impinging on the uterine cavity cause symptoms. This may be a result of the presence of surface vessels on the fibroid and/or the resultant increased surface area of the uterine cavity.

Symptoms associated with fibroids may be variable, ranging from mild to severe, causing distress and impinging significantly on health-related quality of life. Women commonly present with menstrual problems, particularly HMB [38]. Dysmenorrhoea may be an additional problem leading to a further negative impact on a woman's health. Not all women will present with a menstrual problem, some experiencing symptoms related purely to the size of the fibroid. This may be a dragging sensation or feeling of pressure in the pelvis, abdominal swelling or urinary symptoms. Table 59.1 highlights the commonly encountered symptoms associated with fibroids. The relationship between fibroids and fertility is discussed in Chapters 51 and 52.

Diagnosis

The uterus is often found to be enlarged and presents as a pelvic mass (often central and mobile) on both abdominal and vaginal examination. However, it may

Table 59.1 Presenting symptoms of uterine fibroids.

Menstrual upset: menorrhagia and/or dysmenorrhoea
Abdominal discomfort
Sensation of pelvic pressure or backache
Abdominal distension
Urinary frequency, difficulty in micturition, incomplete bladder emptying or incontinence
Bowel problems such as constipation
Reproductive dysfunction: difficulty in conceiving, pregnancy loss, postpartum haemorrhage

be difficult to distinguish between an enlarged uterus and an ovarian mass and so further imaging is mandatory. Ultrasonography, especially transvaginal, is very useful as a first-line diagnostic test (Fig. 59.5). Fibroids are typically well-defined round or lobulated myometrial lesions. The echogenicity is highly variable: it may be uniform hypoechogenic, isoechogenic or hyperechogenic as compared with the surrounding myometrium, or non-uniform due to mixed echogenicity, internal hyperechogenic spots or calcifications. These calcifications may cause intense shadowing. On colour Doppler a fibroid typically has circumferential vascularization, and sometimes some internal vascularization.

Abdominal ultrasound and MRI may be of additional value in the case of larger fibroids. MRI is useful for examining large fibroids or in obese women where adequate imaging on transvaginal or transabdominal ultrasonography is precluded, or in cases of suspected malignancy. There are no pathognomonic features for a leiomyosarcoma on any imaging technique. A large (≥8 cm), solitary, oval-shaped, heterogeneous myometrial tumour, with strong and irregular vascularization, central necrosis/degenerative cystic changes and absence of calcifications should raise the suspicion of a leiomyosarcoma. Rapid increase in size has been reported in leiomyosarcoma. MRI with gadolinium enhancement gives an indication of the vascularity and may prove helpful in differentiating between a leiomyosarcoma and a fibroid. Total lactate dehydrogenase (LDH) and LDH isozyme 3 are reportedly elevated in leiomyosarcoma. Elevated CA125 levels are seen in advanced-stage leiomyosarcoma only [27,28].

Treatment of uterine fibroids

The management of fibroids depends on the symptoms, the type and size of the fibroid, the patient's age and the desire to preserve fertility. Surgical treatment includes hysterectomy and myomectomy. Medical treatments do not eradicate fibroids but are designed to provide symptomatic relief.

Medical treatment

Gonadotrophin-releasing hormone agonists

The most established medical option is administration of a gonadotrophin-releasing hormone (GnRH) agonist. These drugs lead to the downregulation of pituitary receptors that result initially in stimulation of gonadotrophin release, followed by gonadotrophin output reduction and consequent reduction in ovarian steroid production within 2–3 weeks of commencing treatment. The decreased output of ovarian steroids continues while treatment is ongoing. These analogues are given as 1- or 3-monthly depot injections or as nasal spray. Fibroid shrinkage occurs rapidly in the first 3 months but then tends to slow down with little further decline. Most studies suggest a fibroid volume reduction of 40% [39]. The principal disadvantages of GnRH analogue administration are that the fibroids regrow when treatment has stopped. In addition, they are associated with postmenopausal side effects consisting of hot flushing, vaginal dryness and, with prologed use, significant bone loss. An 'add-back' therapy by administering low-dose oestrogen replacement therapy counteracts these side effects without inducing fibroid regrowth.

GnRH agonists have a licence for use in the UK in women with severe anaemia. Their administration results in amenorrhoea, which is associated with a significant increase in haemoglobin. Agonists are also useful prior to surgery [40,41], for example enabling a hysterectomy to be carried out vaginally, with or without laparoscopic assistance. GnRH agonists have also been used prior to myomectomy for similar reasons. However, it is important to note that the plane of cleavage between the fibroid and the surrounding myometrium can be masked after preoperative use, making the surgery significantly more difficult.

Selective progesterone receptor modulators

Selective progesterone receptor modulators (SPRMs) are effective in reducing pain, bleeding and fibroid size, and are associated with an improvement in quality of life [37,42]. Unlike GnRH analogues, SPRMs do not lead to oestrogen deficiency and do not cause hot flushes, nor osteoporosis. Short-term administration appears to be safe and these preparations may influence the way we treat symptomatic fibroids in the future [43].

The SPRM ulipristal acetate reduces the proliferation of leiomyoma cells and induces apoptosis [44]. Moreover, it inhibits neovascularization, cell proliferation and cell survival in the fibroid but not in the normal surrounding myometrium. Side effects include headache and breast tenderness. The progesterone antagonist action may lead to unopposed oestrogen stimulation of the endometrium. Administration for a longer period may lead to endometrial thickening. Progesterone

(c)

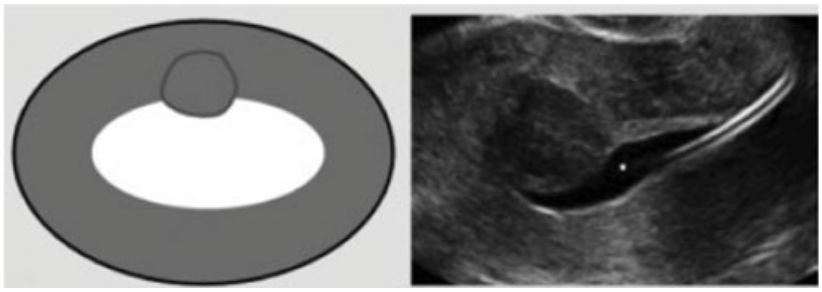

Fig. 59.5 Fluid instillation sonography showing an intrauterine fibroid [44]. Reproduced with permission of John Wiley and Sons. (*See also colour plate 59.5a*)

receptor modulator-associated endometrial changes (PAEC) characterized by cystic glandular dilatation should be distinguished from endometrial hyperplasia. Long-term studies are needed to evaluate outcomes after prolonged use.

Levonorgestrel-releasing intrauterine system

LNG-IUS has revolutionized the treatment of dysfunctional uterine bleeding and may be one of the reasons why the hysterectomy rate has declined over recent years. However, the use of this system in women with fibroids is considered to be a relative contraindication, partly because the device is more likely to be expelled during a very heavy bleeding episode and because the presence of a distorted uterine cavity may make insertion of the device more difficult and increase the expulsion risk.

Intuitively, if the cavity is regular, a trial with an LNG-IUS system may be appropriate. However, coil placement should be checked after a very heavy bleeding episode to exclude expulsion.

Other medical treatments tending to reduce menstrual bleeding without effect on fibroid size include progestogens, the oral contraceptive pill and tranexamic acid.

Surgical treatment

Hysterectomy

Hysterectomy remains the most common surgical treatment option for uterine fibroids. It ensures immediate and definitive resolution of fibroid-associated symptoms. However, it also guarantees infertility, which may not be an appropriate option for some women. Moreover, it is associated with significant morbidity, a relatively long inpatient hospital stay and prolonged recovery period. Major complications occur with hysterectomy and data from a large UK audit (the VALUE study) suggest that complications are all increased in the presence of uterine fibroids [46].

Myomectomy

In women who wish to retain their fertility, uterine-sparing options must be considered. The first of these is myomectomy, which involves the selective removal of the fibroid. This can be carried out as an open/abdominal, laparoscopic or hysteroscopic procedure. Intracavitary fibroids (FIGO type 0, 1 and some type 2) lend themselves to hysteroscopic removal, which decreases blood loss and improves fertility. The feasibility of hysteroscopic resection depends on fibroid location (FIGO classification), size and number and on the surgeon's skills. Complications during hysteroscopic myomectomy include uterine perforation and the associated potential for visceral damage, haemorrhage, infection and fluid overload.

Some of these issues are likely to be even more significant when laparoscopic myomectomy is performed. Rupture of the uterus in labour is also a risk after myomectomy if the cavity is breached during the myomectomy.

Uterine artery embolization

UAE is a minimally invasive radiological technique. Pelvic arterial embolization has been used in the treatment of massive obstetric haemorrhage for more than three decades, and was first reported by the French gynaecologist Ravina [47]. UAE involves the cannulation of the common femoral artery with a small plastic tube that is fed around the aortic arch, through the iliac vessels and thereafter into the contralateral internal iliac artery and corresponding uterine artery. Multiple particulate material (usually in the form of polyvinyl alcohol) is then injected into the circulation to effect embolization and thus cease flow beyond the level of the uterine artery. Visualization of the latter is facilitated by the use of a contrast medium and digital fluoroscopy. The procedure may be performed under local anaesthesia, or under intravenous conscious sedation. Opiate analgesia is usually required up to 24 hours following treatment and most women are managed thereafter with oral analgesia, returning to normal activities within 2 weeks of the procedure.

For poorly understood reasons, the blood supply to the normal myometrium renews itself via the rich pelvic collateral circulation, with contributions from ovarian and vaginal arteries. However, the fibroids do not usually revascularize to a significant extent. This leads to shrinkage of the fibroids and subsequent relief of fibroid-related symptoms. In contrast to the effects of GnRH agonists, where shrinkage of fibroids is maintained only as long as treatment continues, embolization results in sustained shrinkage.

There has been much discussion in the literature regarding the pros and cons of UAE [48]. Observational data suggest that there is a significant beneficial effect on menstrual blood loss and bulk-related symptoms [48,49]. Patient satisfaction rates following the procedure are also high and comparable to those found after hysterectomy. More recent data suggest that in addition to the shorter hospital stay and recovery period associated with UAE, improvements in health-related quality of life are also sustained in the long term after UAE [51]. Another significant benefit of embolization is uterine conservation, and thus preservation of fertility.

The average uterine shrinkage is 40%, although in some instances this can be greater. A cervical or submucosal fibroid may also pass vaginally in the weeks or months following treatment, resulting in an anatomically normal uterus. However, variable recurrence rates for fibroids have been reported after embolization as occurs with myomectomy [52]. Unlike hysterectomy, there is no

guarantee that the procedure will eliminate all menstrual symptoms and revascularization with subsequent regrowth of fibroids does occur in some women. Nonetheless, most case series report improvements in HMB of 85–88% at 1 year [52]. More recently, longer-term data from randomized trials have been published, stating that health-related quality-of-life measures improve significantly and remain stable at 5-year follow-up evaluation [53].

Some women may require further treatment with hysterectomy, myomectomy, endometrial ablation or a repeat embolization. Importantly, with increasing long-term follow-up, it appears that such reinterventions associated with UAE occur more often than previously suggested, with rates of 28% being reported at 5 years [53].

A number of complications (Table 59.2) may be associated with embolization and these may be serious, particularly if severe sepsis occurs.

In approximately 10% of women, the post-embolization syndrome occurs 7–10 days after the procedure. It consists of a flu-like illness and is characterized by general malaise and pelvic pain in association with a mild pyrexia and raised white cell count. This is not as a result of infection but is thought to be due to cytokine release at the time of necrosis of the fibroid. The syndrome is often very difficult to distinguish from infection and is treated with a combination of analgesia, adequate hydration, prophylactic antibiotics and reassurance.

Another significant problem resulting from embolization is infection. Most women require a simple course of antibiotics but, rarely, sepsis may occur, a complication that may lead to the patient's death.

There is a radiation penalty to the ovaries associated with the procedure which occurs during digital fluoroscopy. This, in combination with disruption of uterine blood flow and with non-target embolization, may increase the risk of premature ovarian failure. Reassuringly, however, recent studies demonstrate that there is no evidence for UAE accelerating a decline in ovarian function at 1 year following treatment when compared with surgery, irrespective of age [54,55].

Table 59.2 Complications of uterine artery embolization.

Groin injury: haematoma, infection
Contrast allergy
Radiation exposure to ovaries
Non-target or mis-embolization: ovary, bowel or bladder
Fibroid expulsion
Persistent vaginal discharge
Amenorrhoea: secondary to premature ovarian failure, endometrial atrophy or intrauterine adhesions
Ovarian failure
Post-embolization syndrome
Infection
Sepsis requiring emergency hysterectomy (occurs in <1%)
Death (rare)
Treatment failure: failed cannulation, revascularization or regrowth of fibroids

There are some studies reported in the literature of pregnancies. While some suggest that the outcome is not adversely affected [56], others report increased rates of miscarriage, intrauterine growth restriction, preterm delivery, malpresentation and postpartum haemorrhage following embolization [57].

While a few non-randomized studies have assessed UAE versus myomectomy [58], a randomized study suggests that of the two treatment options, myomectomy is associated with superior reproductive outcomes in the first 2 years after treatment in terms of miscarriage, pregnancy and labour rates. Perinatal outcomes were similar [59].

The cost-effectiveness of UAE versus surgery has been studied. Short-term data reported embolization to be more cost-effective at 1 year [60], but more recent unpublished studies suggest that owing to reintervention and return visits to hospital after UAE, both embolization and surgery are cost-neutral in the long term.

Ablation procedures

Endometrial ablation may be performed with or without myomectomy and is associated with a high rate of amenorrhoea. Provided that the uterine cavity is not too enlarged or distorted, ablation appears to be a successful option. It would seem that microwave and bipolar radiofrequency endometrial ablation may be the best of the second-generation techniques, although randomized data looking at fibroids in particular are not available [61].

A new transcervical device (VizAblate®) is currently available, allowing radiofrequency ablation of fibroids under real-time sonographic guidance. The first reports have shown a significant reduction in fibroid size, together with symptomatic relief in the first 12 months after the procedure [62].

High-intensity focused ultrasound

With high-intensity focused ultrasound (HIFU), an extracorporeal source of focused ultrasonic energy is used to induce coagulative necrosis in the fibroid, without damaging the surrounding tissues. The procedure is MRI-guided to monitor the exact anatomical location of the target lesion and the temperature within the lesion as well as in the surrounding tissues [63]. Recently, sonographically guided HIFU has also been introduced [64]. HIFU of the target lesion causes tissue destruction by a thermal effect, cavitation and direct damage to the lesion's blood vessels. Unlike UAE, HIFU

is not associated with an infarction-like syndrome. Quality-of-life symptom severity scores are similar to those associated with UAE, but the impact of treatment on HMB is less than for embolization [65]. This modality is neither suitable for large fibroids nor large numbers of fibroids, and its impact on the recurrence rate of these benign tumours is unclear.

Summary box 59.3

- Fibroids occur in 25% of women during reproductive life.
- Aetiology is poorly understood.
- Symptoms include menorrhagia, bulk-related problems and reproductive dysfunction.
- Diagnosis is by clinical examination and transvaginal ultrasound.
- Abdominal ultrasound and MRI may be of additional value in the case of larger fibroids.
- GnRH analogues with add-back therapy or SPRMs may be used in the short term or as a useful adjunct to surgery in the presence of large fibroids or associated anaemia.
- The LNG-IUS or endometrial ablation may considered in the presence of a fibroid uterus which is no more than 14 weeks in size in the absence of significant uterine cavity distortion.
- Myomectomy permits uterine conservation but is associated with fibroid regrowth and subsequent adhesion formation.
- Hysterectomy remains a good treatment option for some women but is associated with significant morbidity, a prolonged hospital stay and recovery, and induces infertility.
- UAE is an alternative to surgery for symptomatic fibroids.

Conclusions

Benign gynaecological disease is common and may cause women many problems, some of which can have a significant impact on quality of life. The treatment options for uterine fibroids include hysterectomy, myomectomy, minimally invasive modalities (e.g. UAE, ablation techniques, HIFU) and medical treatment (e.g. GnRH analogues, SPRMs). The treatment choice will be made together with the patient according to fibroid characteristics, the symptoms, the patient's age and the wish to preserve fertility.

Gynaecological Cancer

60

Malignant Disease of the Vulva and the Vagina

David M. Luesley[1,2]

[1] *Division of Reproductive and Child Health, University of Birmingham, Birmingham, UK*
[2] *Birmingham Women's Healthcare NHS Trust, Birmingham, UK*

Background

Vulval carcinoma is uncommon. In 2013, just over 1300 cases were registered in the UK, making it the twentieth most common malignancy (Table 60.1). The lifetime risk of developing vulval cancer is now estimated at 1 in 275. Age-specific incidence rates rise gradually from around age 35–39, and more sharply from around age 65–69, reaching the highest rates in the 90+ age group [1]. The age-standardized incidence of vulval squamous cell carcinoma is 2.5 per 100 000 women per year in England and 2.4 per 100 000 in the USA [2].

There appears to be an association between vulval cancer incidence and social deprivation. The estimated deprivation gradient in vulval cancer incidence between females living in the most and least deprived areas in England has widened in the period 1996–2010 [1]. It has been estimated that there would have been around 240 fewer cancer cases each year in England during 2006–2010 if all females experienced the same incidence rates as the least deprived [1].

Vulval cancer mortality rates have decreased in the UK, an observation noted since the early 1970s. European age-standardized mortality rates decreased by 43% between 1971–1973 and 2010–2012, with most of this decline occurring before the late 1990s. This trend can mainly be attributed to improvements in treatment and earlier diagnosis [3,4]. Over the last decade (between 2001–2003 and 2010–2012), European age-standardized mortality rates have remained stable [5]. The West Midlands Cancer Registry UK, which covers a population of 5.6 million, has reported rates for cases registered between 2001 and 2005, with a 5-year relative survival of 80.5% in women aged under 65 at diagnosis and 61.6% in older women; the corresponding figures from the SEER programme for cases diagnosed in the USA in 2004 were 81.6% and 70.6% [6]. In neither dataset is there evidence of an increase in relative survival over time in these age groups.

There has been a significant increase in rates of vulval cancer in younger women. The proportion of cases diagnosed in those under the age of 50 years rose from 6% in 1975 to 15% in 2006 [1]. A similar trend has been documented in other countries [7,8]. These tumours appear to be more frequently associated with vulval intraepithelial neoplasia (VIN), human papillomavirus (HPV) infection, and immunosuppression. In older women they are more frequently associated with non-neoplastic epithelial disorders such as lichen sclerosus. This suggests that there are at least two oncogenic pathways for the development of this cancer.

The overall increase in vulval cancer might be explained by the rise in the average age of the female population and possibly because of an increase in HPV infection in younger women.

Risk factors

The following are recognized as risk factors for developing vulval cancer.

- Lichen sclerosus: 4–7% risk of developing cancer [9,10].
- Vulval cancer develops in 9% of women with untreated high-grade VIN, 1–8 years after their VIN diagnosis, a systematic review suggested [11].
- Paget's disease [12].
- Melanoma *in situ* [13–15].
- Smoking [16].
- Immunosuppression.
- Advanced age.
- Cohort studies have shown that vulval/vaginal cancer risk is four to eight times higher in cervical cancer survivors [17–19]. Other cohort studies have shown

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 60.1 Vulval cancer (C51), number of new cases, crude and European age-standardized incidence rates per 100 000 population, females, UK, 2013 (Cancer Research UK).

	England	Wales	Scotland	Northern Ireland	UK
Cases	1061	78	142	32	1313
Rate per 100 000	3.9	5	5.2	3.4	4
Age-standardized rate per 100 000	4 (3.7–4.2)	4.8 (3.7–5.8)	5.1 (4.3–5.9)	3.8 (2.5–5.2)	4.1 (3.9–4.3)

that vulval cancer risk is two to six times higher in women with previous cervical intraepithelial neoplasia (CIN) [20].
- A cohort study showed that vulval cancer risk is higher in women whose sister or mother has/had cervical squamous cell carcinoma [21]. The association between cervical and vulval cancers is probably mainly due to shared risk factors (e.g. HPV).

Aetiology

The aetiology of vulval cancer remains unknown. However, oncogenic HPVs are strongly associated with some vulvar cancers [22] and non-neoplastic epithelial disorders (lichen sclerosus) with others. Currently available data suggest two hypotheses. First is the classic *de novo* neoplasm in the elderly that is frequently seen in association with conditions such as lichen sclerosus. The second type is more often associated with VIN, particularly multifocal disease and disease elsewhere in the lower genital tract. This 'infectious-like' type is presumed to be linked to HPV.

Recently it has been suggested that non-HPV VIN or differentiated VIN might be the precursor lesion associated with lichen sclerosus and therefore non-HPV squamous cell cancers. Previously it had been thought that differentiated VIN was found only in association with established cancers, but it has now become clear that this type of VIN can and does occur without contemporaneous cancers but usually with lichen sclerosus. This observation provides additional support for the two oncogenic pathways hypotheses [22]. Recent studies have focused on the genetic, epigenetic and molecular changes in vulval squamous cell carcinoma and associated lichen sclerosus [23]. Many studies have reported significantly higher incidences of somatic mutations in HPV-negative tumours compared with their positive counterparts, *TP53* being the most frequent. Epigenetic changes have also been identified and hypermethylation appears to be a common event in lichen sclerosus [24].

An understanding of premalignant epigenetic changes offers the opportunity of either reducing or even reversing the dysplastic process in vulvar epithelium.

Histology

The majority of vulvar cancers are squamous in origin. The various histotypes include:

- squamous cell carcinomas;
- malignant melanoma;
- Paget's disease;
- Bartholin's gland carcinoma;
- adenocarcinomas;
- sarcomas (dermatofibrosarcoma protuberans, Kaposi's sarcoma); and
- metastatic malignant disease and lymphomas.

Verrucous cancer and basal cell cancer are variants of squamous cell carcinomas. Non-squamous cancers of the vulva account for 10% of all vulval cancers. Histology does have a bearing on management, largely because of the different risks of nodal metastases and the predilection for distant spread (Fig. 60.1 and Table 60.2).

Summary box 60.1

- Vulval carcinoma is an uncommon tumour that is most common in the elderly.
- There is evidence suggesting a gradual increase in the number of younger women with this disease.
- There are likely to be two distinct carcinogenic processes, one linked to oncogenic papillomaviruses and the other to conditions such as lichen sclerosus.
- The majority of vulval cancers are squamous.

Presentation

Most squamous cancers primarily involve the medial aspects of the labia majora, with the labia minora being involved only one-third as often. Other sites of predilection include the clitoral and periurethral areas. Small lesions may be asymptomatic and go unnoticed by the patient, and even now there would appear to be excessive delay in diagnosis for some women. A recent review of practice in the West Midlands suggests that up to one- third of patients apparently report symptoms for over a year.

Fig. 60.1 Histological variants of vulval cancer.

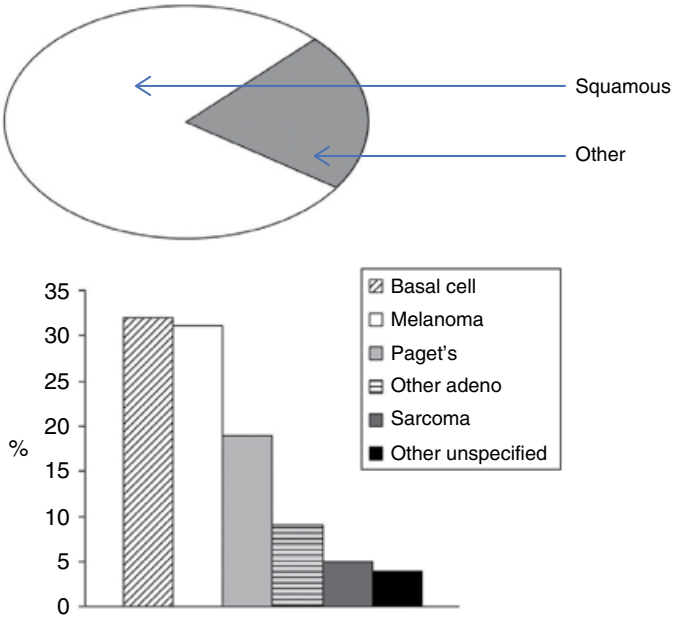

Table 60.2 Summary of histological variants.

Histotype	Comments
Squamous cell carcinomas	Account for 90% of malignant vulval neoplasms
	Metastasize to the local lymph nodes, primarily the superficial and deep inguinal nodes, and they may be involved bilaterally. The risk of nodal disease varies with location and degree of invasion
	Usually present with a nodule or ulcer and may cause pruritus or soreness and pain. Bleeding and an offensive odour may be present with larger lesions
Veruccous and basal cell carcinomas	Squamous variants and rarely, if ever, metastasize locoregionally
	Verrucous carcinomas present as slow-growing wart-like lesions with a tendency to recur locally after excision
	Basal cell carcinomas usually present as an ulcerated nodule on the labia. They do not metastasize and can be managed by local excision or radiation. Up to 20% recur locally after treatment
Malignant melanoma	Has a poor prognosis and is generally managed as for cutaneous melanomas at other sites
	The overall 5-year survival ranges between 8 and 50% and appears to be worse than for cutaneous melanomas elsewhere
	Three patterns of vulval melanoma are identified: mucosal lentinginous (commonest), superficial spreading and nodular. Breslow's thickness of invasion (invasion >1.75 mm has a high risk of recurrence), ulceration and amelanosis are significant prognostic factors. Surgical excision of the lesion with wide margins remains the mainstay of treatment. c-Kit expression another valuable predictor of prognosis and survival
Adenocarcinomas	Exceedingly rare and are more likely to represent metastases from another site. There is an association with vulval Paget's disease
Carcinoma of Bartholin's gland	Also rare and may be squamous, adenocarcinoma or an adenoid cystic carcinoma. They occur more often in younger premenopausal women and overall have a survival rate of about 35% at 5 years
	They usually present as a solid mass in the region of Bartholin's gland with intact overlying skin. Surgical management is similar to that for squamous cell carcinoma
Sarcomas	Very uncommon and in general are biologically similar to soft-tissue sarcomas at other sites. Generally there is poor prognosis after the appearance of regional or distant relapse. Wide local excision appears to offer the best chance of preventing local recurrence. Elective treatment of the regional nodes is not indicated and there is no advantage in resecting metastatic nodes. The role of adjuvant radiation and chemoradiation has not been assessed, largely because of its rarity
Metastatic tumours	Rare and account for about 8% of all vulval neoplasms. Cervix, endometrium and renal carcinomas have been the most frequently documented primary sites
Paget's disease	Presents as a crusty, erythematous, dark pink/red eczematous 'glazed' area on the vulva. It is an intraepithelial malignancy in 90%. Up to 10–15% of vulval Paget's disease is associated with underlying adenocarcinoma, which may be of the breast, stomach, bowel and bladder. Fluorescein dye has been used to detect the lateral extent of disease spread. Wide local excision with closure of large defects with advancement flaps is required to manage this condition

Table 60.3 Presenting symptoms in vulval carcinoma.

Symptoms	Frequency (%)
Pruritus	71
Vulval lump or swelling	58
Vulval ulceration	28
Bleeding	26
Pain or soreness	23
Urinary tract symptoms	14
Discharge	13

This may reflect patients' attitudes in seeking medical attention or, as suggested by Stroup *et al.* [25], a lack of awareness of the disease in both patients and clinicians. This study also suggested that older patients were more likely to be diagnosed with advanced disease. A more recent US-based study [26] came to similar conclusions, with advancing age and social deprivation both being associated with more advanced stage at diagnosis.

As squamous cell carcinoma of the vulva often progresses slowly, early disease presentation should be feasible and could enable diagnosis to be made at a less advanced stage. Both younger patient age and early disease stage are associated with favourable disease outcome. Therefore, efforts should be considered that improve both patient and primary care awareness. This observation is not new – Monaghan reported that 32 of 335 patients delayed seeking medical attention for more than 24 months, and only 35 of 335 presented within 3 months of noticing symptoms [27]. Similar delays ranging from 1 to 36 months, with a mean of 10 months, were noted by Hacker *et al.* [28]. Whether this is due to fear or ignorance on the part of the patients or to delay in clinical examination by the primary carer is unknown. A recent study, based on the first English National Audit of Cancer Diagnosis in primary care, analysed the patient and primary care interval in 10 953 patients covering 28 different cancer sites, including vulval cancer. The mean patient referral interval (patient time to present to GP) was 59 days, the fifth longest for the study cohort. The mean interval from consulting a GP to referral was 16 days, the third shortest referral interval [29]. These data imply that a significant burden of the delay lies in women not presenting to their GPs and thus a fairly robust case can be made for improved lay education. The reasons for presenting have been analysed by Podratz *et al.* [30] (Table 60.3).

Other indications for suspecting malignancy include pigmentation disorders relating to potential melanoma and melanoma *in situ*. This appears to be increasing although evidence so far is only anecdotal, but could reflect the growing awareness by the public of moles and other pigmented skin lesions and their association with malignant melanoma.

Assessment

There are two phases of investigation. First, confirming the diagnosis and histotype. The initial disease assessment should also include the clinical and histopathological extent of disease (stage). Second, the patient's fitness needs to be assessed, as does the possibility of concurrent disease, which might influence management. Although not disease focused the second phase is equally important, as the age range of patients with this disease makes comorbidity and frailty important variables when designing management strategies.

Examination

The clinical assessment of a vulval malignancy should document both the size and location(s) of all the lesions and the characteristics of the adjacent skin. Care should be taken to assess any involvement of the vagina, urethra, and base of bladder or anus. Palpation is important with large tumours to determine whether the tumour is infiltrating deep to the pubic and ischial bone. The integrity of the anal sphincter can only be reliably assessed by a combined rectal and vaginal examination.

Discomfort and tenderness are often associated with large tumours, necessitating examination under general anaesthesia. The presence or absence of groin lymphadenopathy or discrete skin metastases should also be noted.

Diagnosis

Diagnosis is based on a representative biopsy of the tumour that should include an area where there is a transition of normal to malignant tissue. Biopsies should be of a sufficient size to allow differentiation between superficially invasive and frankly invasive tumours and orientated to allow quality pathological interpretation. Occasionally an alternative strategy might be considered. In certain situations where the clinical diagnosis is apparent and the patient is very symptomatic (i.e. experiencing heavy bleeding and/or pain), definitive surgery to the vulval lesion may be performed. However, biopsy with frozen section is recommended before performing any radical procedure.

Because of the potential for other genital tract malignancy, the vagina and cervix should also be thoroughly assessed and biopsied as necessary.

Spread

The major histotype will determine, to a certain extent, how the tumour invades and metastasizes. The following comments relate to the most common squamous variant.

The tumour spreads both locally and via the lymphatics to the regional lymph nodes. Local spread may involve the vagina, perineum and anal canal, urethra and clitoris and, in

Fig. 60.2 Large anterior vulval cancer with satellite skin deposits. (*See also colour plate 60.2*)

late disease, involvement of bone may occur. The sites and extent of spread as well as the involvement of structures where function may be impaired (anal sphincter, urethra, clitoris, etc.) are of extreme importance when planning treatment. Skin beyond the vulva may also become involved (Fig. 60.2), particularly over the mons onto the lower abdominal wall and laterally to involve the skin of the thighs. Lymphatic drainage of the vulva is initially to the superficial inguinal nodes, thence to the deep inguinofemoral chain and on to the pelvic (iliac) nodes. In general, central vulvar structures are believed to drain bilaterally whereas lateral structures drain to the ipsilateral nodes primarily. Deep pelvic node involvement in the absence of inguinal node disease is rare. Overall, about 30% of operable patients have nodal spread, 10–15% with tumours measuring 4 cm or less in diameter and more for higher-stage tumours [31–33]. Haematogenous spread can also occur but is uncommon and tends to be associated with large tumours that have already involved the regional nodes.

Premalignant and malignant change in the vagina and cervix is not infrequently seen in association with vulvar cancers. This is not necessarily a metastatic process but may indicate a common aetiological event such as oncogenic HPV infection that can render the whole lower genital tract vulnerable to neoplastic transformation.

Staging

Vulval cancer is staged surgico-pathologically using the FIGO staging system, last updated in 2009 [34]. FIGO staging employs the familiar four categories with substages but now takes into account the number of positive nodes and type of nodal positivity. It also recognizes that tumour size on its own has little discriminatory value in terms of survival, large node-negative tumours having almost as good an outcome as small node-negative tumours (Table 60.4). An alternative is the tumour node metastasis (TNM) system, which is a composite of primary tumour, nodal and metastatic status (Table 60.5). Both systems employ nodal status to allocate stage.

Table 60.4 International Federation of Gynecology and Obstetrics (FIGO) staging of vulval cancer (2009).

Stage I	Tumour confined to the vulva
Ia	Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm. No nodal metastasis
Ib	Lesions >2 cm in size or with stromal invasion >1 mm confined to the vulva or perineum. No nodal metastasis
Stage II	Tumour of any size with extension to adjacent perineal structures (lower third of urethra; lower third of vagina; anus) with negative nodes
Stage III	Tumour of any size with or without extension to adjacent perineal structures (lower third of urethra; lower third of vagina; anus) with positive inguinofemoral nodes
IIIa	With one lymph node metastasis (≥5 mm), or one or two lymph node metastases (<5 mm)
IIIb	With two or more lymph node metastases (≥5 mm), or three or more lymph node metastases (<5 mm)
IIIc	With positive nodes with extracapsular spread
Stage IV	Tumour invades other regional (upper two-thirds of urethra; upper two-thirds of vagina) or distant structures
IVa	Tumour invades any of the following: upper urethral and/or vaginal mucosa; bladder mucosa; rectal mucosa or fixed to pelvic bone; or fixed or ulcerated inguinofemoral lymph nodes
IVb	Any distant metastasis including pelvic lymph nodes

Groin node assessment

Given that most surgically managed vulval cancers will not have metastatic involvement of the lymph nodes and that surgical exploration of the groin will be associated with short- and long-term morbidity, it is understandable that continuing efforts are being made to identify node-positive and node-negative cases prior to surgical intervention. The more accurate the prediction, the more that unwanted morbidity can be avoided. The last 10 years has seen considerable effort in this area, initially with imaging but also with selective node resection. Table 60.6 lists the various methodologies that have been assessed in this role.

Sentinel lymph node biopsy

This technique has quickly become the most adopted as an adjunct to surgical treatment, particularly in earlier cancers. The sentinel node is defined as the first node in the lymphatic chain draining an anatomical area. If the sentinel node from the suspected lesion is negative for disease, then the remainder of the nodes should also be

Table 60.5 TNM classification system.

Primary tumour (T)	
Tis/0	Pre-cancer stage: carcinoma *in situ* or vulval intraepithelial neoplasia (VIN)
T1	There is a tumour and it is confined to the vulva and/or perineum
T1a	Tumour has grown no more than 1 mm into underlying stromal tissue and no more than 2 cm wide
T1b	Tumour is >2 cm wide or it has grown more than 1 mm into stromal tissue
T2	Tumour is any size and is growing into the lower third of the vagina or urethra or anus
T3	Tumour is any size and cancer is spreading to the upper urethra, rectum, bladder or pubic bone
Regional lymph nodes (N)	
N0	Cancer has not spread to lymph nodes
N1	One to two lymph nodes have become infected in the groin area. Either:
N1a	One or two lymph nodes affected and area of cancer spread in both <5 mm
N1b	One lymph node is affected and area of cancer spread >5 mm
N2	Cancer has spread to the lymph nodes in the groin with one of the following features:
N2a	Three or more lymph nodes affected but each area of spread <5 mm
N2b	Two or more lymph nodes affected, all with area of spread 5 mm or more
N2c	Cancer has spread to lymph nodes and has started to grow through the outer covering of a least one node (known as extracapsular spread)
N3	Cancer has spread to the lymph nodes causing the development of open sores (ulcerations). The lymph nodes become stuck to the tissue near it
Distant metastasis (M)	
M0	Cancer has not spread to distant sites (no metastasis)
M1	Cancer has spread to distant sites, metastasis. This includes spread to pelvic lymph nodes

Table 60.6 Imaging techniques for groin node assessment and sensitivities.

Technique	Sensitivity	Reference
Magnetic resonance imaging	40–50%	Barton *et al.* [35]
Magnetic resonance lymphography	55–89%	Sohaib & Moskovic [36]
Ultrasonography*	58%	Heaps *et al.* [37]; Moskovic *et al.* [38]
Computed tomography scan	Poor	Lin *et al.* [39]; Andersen *et al.* [40]
Positron emission tomography	Poor	Kamran *et al.* [41]

*With and without fine needle aspiration.

free of the disease (Fig. 60.3). The sentinel node for vulval lesions can be identified by injecting methylene blue dye into the tumour edge and/or using immunoscintigraphy where a radiolabelled marker (technetium-99) is injected into and around the margins of the lesion. A hand-held gamma camera is used to identify the radioactive tracer uptake in the regional lymph nodes [42,43]. Identification during surgery is further enhanced by the use of blue dye, which, along with the raised radiation count, allows the sentinel node to be clearly seen (Fig. 60.4).

Three recent systematic reviews [44–46] all indicate that the sentinel node technique using the combined method (technetium-99 and blue dye) is sufficiently sensitive and specific to be regarded as the standard of care for women with unifocal tumours measuring 4 cm or less where there is no evidence of clinically enlarged nodes. The technique may be enhanced using preoperative SPECT/CT imaging, which might also help in the identification of aberrant sentinel nodes [47]. Data are still required as to the effectiveness of the technique when the primary lesion has been removed (post excision biopsy). In one study of 32 women, slightly more sentinel nodes were identified when performed after diagnostic biopsy when compared with those following excision biopsy [48]. In a cohort of 106 patients in whom one-third had undergone primary excision with a secondary resection of the nodes performed on average 30 days later, no compromise in accuracy was noted [49]. Our own data and those of others indicate that surgical morbidity is significantly reduced, with shortened length of hospital stay, reduced wound breakdown, and reduced lymphoedema and lymphocyst.

Table 60.7 compares the most frequently seen complications in a routine audit comparing women who had complete lymphadenectomy versus sentinel node. Both groups had similar tumours in terms of size and stage. Importantly, patient-reported outcomes are favourable as well [49] and the technique has been shown to be significantly cost-effective when compared with complete lymphadenectomy [50].

As with inguinofemoral lymphadenectomy, there is a risk of a false-negative outcome (2–3%). However, the difference between the false-negative rates is not significant and given the potential huge benefit in morbidity avoidance is a small risk outweighed by benefit.

One observer has raised a potential negative effect of this technique: although based on the observation of only two patients, there was concern that in patients who are node positive, the technique might increase the risk of extranodal metastasis by a direct effect on the lymphatics [51].

Summary box 60.2

- Most vulval cancers present with soreness, pruritus or the presence of a mass or ulcer.
- All suspicious lesions should be subjected to a diagnostic biopsy.
- Primary spread is both local and to the inguinofemoral nodes.
- The status of the lymph nodes has a major bearing on clinical outcome.
- Invasion >1 mm in depth is associated with increasing rates of lymph node involvement.
- Clinical examination of the lymph nodes is unreliable.
- Staging of vulval cancer is surgical and clinical.
- Sentinel node sampling is proving to be the most accurate method of assessing lymph node spread.

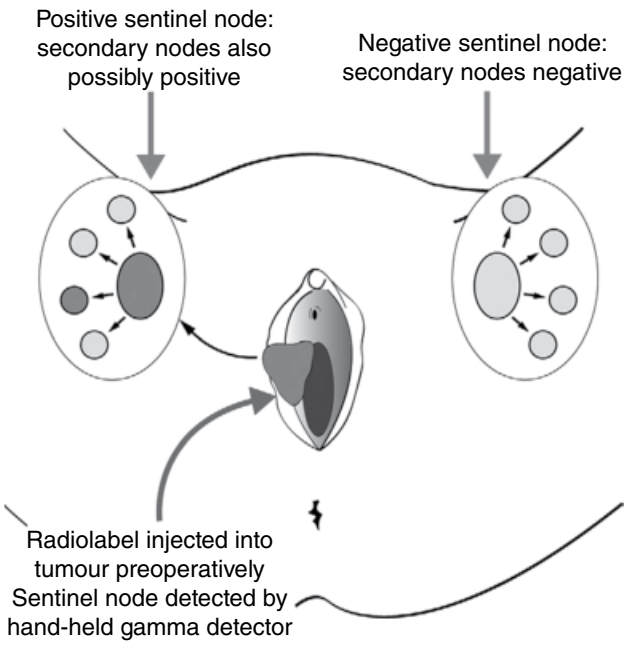

Fig. 60.4 Schematic demonstrating the rationale of sentinel lymph node sampling.

Table 60.7 Complication rate by groin node dissection type.

	Sentinel lymph node only (*N* = 89)	Sentinel lymph node biopsy plus full groin node (*N* = 18)
Lymphocyst	5.5%	44%
Lymphoedema	2.7%	33%
Recurrence	2%	0%
Average length of stay	2 (1–17) days	7 (5–25) days

Surgical management of the primary vulvar lesion

The site, size and relation of the lesion to important functional structures will determine the most appropriate method for treating the vulvar lesion. Similarly, the clinical presence or absence of nodal or distant disease will affect the management strategies. It would, for instance, be illogical to embark upon radical local treatment for the primary cancer in the presence of distant untreatable metastases unless there was no other suitable form of palliation. Two broad categories of patient can be identified at the outset:

1) those who have small unifocal vulvar lesions with no clinical evidence of nodal involvement;
2) those who have more advanced vulvar disease and/or have clinical evidence of nodal involvement.

For the purposes of further discussion, these will be termed as early and late disease, respectively.

Surgical management of early vulvar cancer

Radical vulvectomy is excessive treatment for the majority of unifocal and early cancers. Wide local excision is usually sufficient for the majority of lesions between 1 and 10 mm in depth. Until recently the general consensus was that the most important factor governing local recurrence was the margin of excision. Two publications have underpinned this management principle for 20 years [37,52]. Current guidance from the Royal College of Obstetricians and Gynaecologists (RCOG) still endorses the principle of wide resection margins in order to guarantee a post-fixation maximum clearance of 8 mm on all margins. One large single institution retrospective cohort has recently questioned this approach [53]. This cohort contained 102 consecutive patients and the authors did not find any significant increased risk of recurrence in relation to the margin of excision, as long as the tumour was completely excised. A similar but larger cohort from the West Midlands [54] has reached similar conclusions. The latter included over 200 patients followed up for over 5 years. In addition, the histopathology of the adjacent epithelium and HPV status was also included in the multivariate analysis. There would appear to be ample evidence to revisit the concept of wide excision margins as this could have a significant impact on local surgical morbidity.

The excision should be taken to the depth of the fascia lata, which is coplanar with the fascia of the urogenital diaphragm. Even when adequate excision has been achieved, there may be other variables identified after examination of the specimen that some have suggested indicate a high risk of relapse. These include tumour thickness (or invasiveness) and capillary lymphatic space involvement, and perineural infiltration [55]. In addition the adjacent epithelium, which may reflect the underlying oncogenic process, may influence recurrence. Differentiated VIN appears to have a higher rate of recurrence than basaloid or warty VIN, although this is based on a very small case series [56].

As one would expect, the local recurrence rate for wide local excision compares favourably with that following radical vulvectomy. Hacker and van der Velden [52] have collated data from 12 published series including 530 patients, of whom 165 were treated by radical local excision and 365 by radical vulvectomy. The local recurrence rates were 7.2% and 6.3%, respectively.

Surgical management of advanced vulvar lesions

The reader should appreciate that 'advanced' in vulvar terms indicates that wide local excision would either be a radical vulvectomy and/or would compromise function. The same principles apply here as with the smaller unifocal lesions in that the objective is to obtain adequate clearance on all the resection margins. As subsequent function and cosmesis are more likely to be affected, consideration should also be given to adjunctive treatment. It is important to consider the woman and her feelings when constructing the management plan. An elderly woman with extensive or multifocal disease with an associated symptomatic non-neoplastic epithelial disorder such as lichen sclerosus may well gain an overall benefit from radical vulvectomy with subsequent grafting. Conversely, a young woman with a clitoral cancer may be managed initially by radiotherapy, reserving surgery for failed local control. These types of cases form the basis for local management of advanced vulvar lesions. The prime objective is to maximize local control, closely followed by consideration of further function and cosmesis in that particular woman.

Lymph node disease

Patients with superficially invasive vulval cancer are at minimal risk of nodal disease (Table 60.8). This is defined as a depth of invasion of less than 1 mm. Depth of invasion is closely related to the risk of nodal disease, and should be measured from the most superficial dermal papilla adjacent to the tumour.

Overall, about 30% of vulval cancers will have inguinofemoral nodal disease and about one-fifth of those with positive inguinofemoral nodes will have positive pelvic nodes (i.e. about 5% overall). It has been known for many years that pelvic nodes are rarely, if ever, involved if the inguinal nodes are negative. The low frequency of pelvic node involvement and the doubts surrounding the ability of surgery to control disease at this site have led most to conclude that the routine application of pelvic node dissection in vulval cancer should be discontinued.

The following clinical factors can predict for the presence of lymph node disease, although clinical examination of the nodes themselves is unreliable:

- lesion size;
- whether or not the nodes are clinically suspicious; and

Table 60.8 Relationship of depth of invasion to risk of nodal disease.

Invasion depth (mm)	Per cent node positive
<1	0
1.1–2	7.7
2.1–3	8.3
3.1–5	26.7
>5	34.2

Source: Hacker *et al.* [28].

- disease that involves both the labia minora and labia majora has a 50% chance of nodal involvement, whereas when only one of these structures is involved the risk is approximately 20% – Stehman and Look [57] have also suggested that clitoral or perineal siting of the tumour carried an increased risk of nodal disease.

Other risk factors depend on histopathological assessment of the primary lesion. Not surprisingly, these are similar to the general prognostic factors for outcome, and include:

- tumour grade;
- capillary lymphatic space involvement;
- degree of invasion (tumour thickness); and
- perineural invasion.

Management of the lymph nodes

Types of lymph node dissection

The primary lymphatic drainage of the vulva and distal vagina is to the inguinal (superficial femoral) and the nodes lying along the femoral vein. Efferent vessels from the superficial inguinal nodes drain to the deep inguinal or femoral nodes. The most cephalad femoral lymph node is the node of Cloquet. This is not a constant anatomical finding and has been noted to be absent in 54% of cadavers. The femoral nodes also receive some direct afferents, particularly from the clitoris and anterior vulva, thus explaining the observation of involved femoral nodes with uninvolved inguinal nodes. One prospective study [58] has suggested that superficial lymphadenectomy alone may be associated with a higher risk of groin relapse, although the relatively low relapse rate in early disease renders any conclusion somewhat unreliable.

Laterality

Extensive crossover of lymphatic channels of the vulva may result in nodal involvement of the contralateral groins in addition to the ipsilateral groin nodes. Because of this, bilateral groin node dissection is usually required. However in small (<2 cm) lateral tumours, only an ipsilateral groin node dissection need initially be performed. A lateralized lesion, agreed by the European Organization for Research and Treatment of Cancer (EORTC) Vulva Group consensus, is defined as one in which wide excision, at least 1 cm beyond the visible tumour edge, would not impinge upon a midline structure. If the ipsilateral nodes are subsequently shown to be positive for cancer, the contralateral nodes should also be excised or irradiated, as the nodes are more likely to be positive in this scenario.

Andrews *et al.* [59] noted that this was also the case for T2 lesions despite a relatively high ipsilateral positivity rate of 34%. However, exceptions have been reported. For larger lateralized lesions the picture is more confused and, until further data become available, bilateral node dissection (or selective sentinel node biopsies) would be advisable.

En bloc and separate groin incisions

The need for en bloc removal of the lymph nodes has received much attention, largely because it has been felt that this type of procedure accounts for a significant proportion of the morbidity (Fig. 60.5) and that the technique employing separate groin incisions (Fig. 60.6) results in a better cosmetic outcome. The triple incision technique was first described in 1965, although it only became popular in the 1980s. Those who have reported

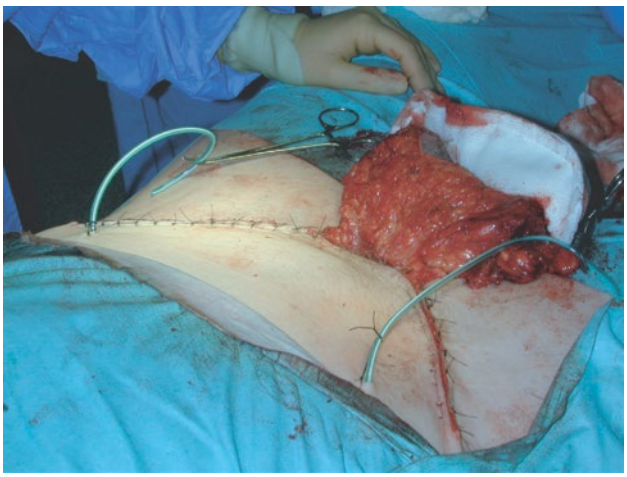

Fig. 60.5 En bloc dissection of the inguinofemoral lymph nodes. (*See also colour plate 60.5*)

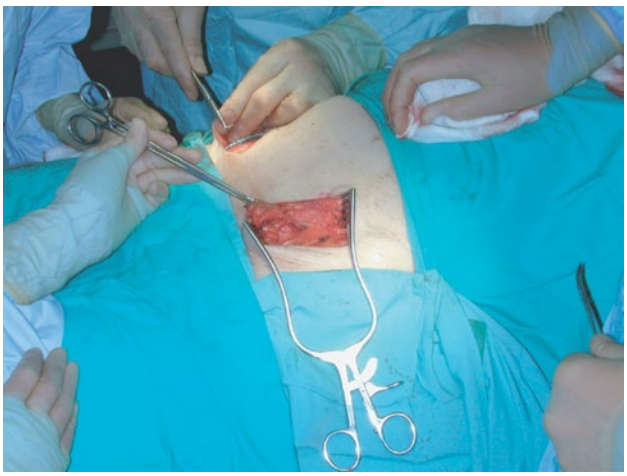

Fig. 60.6 Separate groin incisions. (*See also colour plate 60.6*)

Fig. 60.7 Clinically suspicious left groin nodes. (*See also colour plate 60.7*)

on its use have not shown any disadvantages in terms of survival or local relapse for early-stage carcinomas, and there have been quite marked improvements in the morbidity.

The anxiety relating to the triple incision is the possibility of relapse in the bridge of tissue left between the vulvectomy or local excision and the groin nodes. This tissue will contain lymphatic channels, but whether lymphatic metastasis is an intermittent or embolic event or a continuous or permeation event remains uncertain. Certainly if the lymphatic channels contain malignant cells at the time of resection, then recurrence would seem to be a real possibility.

Current consensus would suggest that en bloc dissection of the nodes is probably best retained for large vulvar lesions and in situations where there is gross involvement of the groin nodes (Fig. 60.7). It would seem more logical to address the increased morbidity of the procedure with more attempts at reconstruction rather than undertreating with less than adequate primary surgery.

Management of involved lymph nodes

Resection of the groin lymph nodes provides prognostic information and might also confer some survival benefit. There are varying degrees of positivity, from microscopic deposits in one of many nodes to gross extracapsular spread in the entire group of nodes. As with the overall stage, this spectrum is also associated with a spectrum of outcomes (Table 60.9) and requires different approaches to management. The most important variable influencing survival is extracapsular spread from the lymph nodes; for patients who have only one node involved, the most important prognostic factor is the greatest dimension of the metastasis within the node (Table 60.10).

Table 60.9 Survival in relation to nodal status and size of vulval lesion.

Nodal status	Primary size	Survival (%)
Negative ($N = 385$)	≤2 cm	97.9
	2–3 cm	90.5
	>3 cm	75–80
	All	90.9
Positive ($N = 203$)	All	57.2
1 or 2 positive nodes	–	75
3 or 4	–	36
5 or 6	–	24
7 or more	–	0

Source: Homesley *et al.* [61].

Table 60.10 Management in relation to lymph node status.

Groin nodes negative	No further treatment
Groin nodes positive after surgery	–
One node only involved*	Observation only
Two or more nodes involved	Inguinal and pelvic radiation
Clinically positive before surgery	Resection followed by radiation
	Radiation followed by resection
	Radiation only

*In the situation where there is only one node involved but the node is either completely replaced by tumour or there is extracapsular spread, the author feels that adjuvant radiotherapy is justifiable.

These observations explain and underpin the 2009 revisions in FIGO staging.

In the past, pelvic lymphadenectomy was considered to be appropriate if the inguinofemoral nodes were involved. This practice has become increasingly uncommon, as it has been well demonstrated in Gynecologic Oncology Group protocol 37 [60] that in this situation pelvic radiation confers a better outcome than pelvic node dissection. Interestingly, the survival difference appeared to reflect better control of disease in the groin than pelvic or distant disease.

A final observation with regard to the lymph nodes is that all the available data are based on what is considered to be standard pathological evaluation of the groin nodes (standard sections stained with haematoxylin and eosin). In other tumour systems it has been possible to define a group of patients with micrometastases by using complete serial sectioning and immunohistochemical staining. These nodes positive for micrometastases would

have been negative on standard assessment. There are no studies available as yet indicating what, if any, clinical significance of such findings might be in vulval cancer.

Complications of surgical treatment

The complications of vulval and groin surgery are listed in Table 60.11. Any major cancer procedure carries immediate morbidity risks such as haemorrhage, thromboembolism and infection, and vulvar procedures are no exception to this. Prophylactic antiembolic strategies are of value and should be used in all cases. Reducing the length of hospitalization and early mobilization indirectly enhances such prophylaxis and may result from modifications of the radical approach.

Radical en bloc dissection (radical vulvectomy and bilateral node dissection) results in lymphoedema in between 8 and 69% of cases. Wound breakdown is very common, occurring in 27–85% of cases, and can become secondarily infected, resulting in cellulitis. The average hospital stay for this radical procedure varies from 17 to 33 days. The triple incision technique has yielded significant improvements in operative blood loss and length of stay, although high breakdown rates continue to be reported (22–52%) [62,63]. The occurrence of lymphocyst (Fig. 60.7) and lymphoedema does not seem to be significantly less than that with the radical en bloc technique. Unilateral groin dissection does appear to lower the incidence of morbidity, but there is no significant difference in morbidity when superficial is compared with deep groin node dissection. Van der Zee *et al.* [64] have reported significant reductions in wound breakdown, cellulitis, length of hospital stay and lymphoedema when sentinel node sampling is compared with inguinofemoral lymphadenectomy.

Less radical approaches to the vulva have certainly improved cosmesis and subsequent function. Other surgical modifications [65] to reduce morbidity include sparing the saphenous vein at the time of surgery to reduce wound and lower limb complications, although the data on outcome in terms of lymphoedema are inconclusive [66,67]. It has also been suggested that the tissues most lateral in the groin need not be resected. Sartorius transposition to cover the femoral vessels in thin and emaciated patients also helps to reduce wound morbidity [67]. Wound healing is also improved by avoiding undermining of the skin edges, performing tension-free closures, using wound drainage and administering prophylactic antibiotics. Increasingly, surgeons have employed grafting techniques either at the time of initial surgery or as a second-stage procedure. The grafts successfully employed have been the gracilis and rectus muscle myocutaneous flaps and rotational full-thickness skin flaps taken from the inner thigh or buttock (Fig. 60.8). The use of these flaps to fill considerable defects and a more conservative approach to excision have resulted in less scarring and more functional vulvas. As yet it has not been possible to demonstrate that this translates into improved psychological well-being, although the psychological trauma of radical excision without reconstruction is well documented [68].

Management of complications

For lymphoedema, compression hosiery is prescribed along with rest and exercise, avoidance of trauma (skin care), simple gravity drainage and manual lymphatic drainage. For lymphocyst, a conservative approach is adopted and drainage under antibiotic cover is recommended only for symptomatic cases, but they tend to re-form.

Wound healing can be promoted with manuka honey dressing [69]. Recently, there have been anecdotal reports of using tissue sealant to promote healing in groin wounds that have broken down [70].

Radiotherapy and chemotherapy

The role of radiotherapy and chemotherapy in the treatment of vulvar cancer is less defined than that for surgery. However, there are data quite clearly indicating that squamous vulvar cancers are sensitive to both radiotherapy and chemotherapy.

Basal cell cancers are well recognized as being radiosensitive, and radiotherapy may be the treatment of choice if surgery is likely to result in either functional or cosmetic impairment. Melanomas have not been shown to respond and verrucous cancers have been reported as becoming much more aggressive as a result of radiotherapy.

Adjuvant radiotherapy

The factors influencing the need for adjuvant radiotherapy are (i) surgical margins and (ii) groin node positivity. There is insufficient evidence to recommend adjuvant local therapy routinely in patients with suboptimal surgical margins (<8 mm). Adjuvant treatment for positive margins is associated with improved survival when compared with observation alone [71]. A more recent multicentre retrospective study of 257 patients concluded that in patients with close or positive margins the addition of adjuvant radiotherapy improved overall survival from 29% to over 60% [72]. As with most retrospective studies, selection bias is a cause for concern.

Adjuvant radiotherapy should be considered when two or more lymph nodes are involved with microscopic metastatic disease or there is complete replacement and/or extracapsular spread in any node [58,73,74]. Treatment should be to the groins and the pelvic nodes, although there is no evidence to show whether treatment should be directed at both sides or to the involved side only. The increasing use of the sentinel node technique may require a re-evaluation of this strategy.

A large multicentre retrospective cohort study from Germany evaluated 1618 patients of whom 1249 had surgical groin staging and known lymph node status. Node-positive patients receiving adjuvant radiation ($N = 189$) fared better than 61 patients who did not receive adjuvant radiotherapy (progression-free survival 39.6% vs. 25.9%). This difference is significant and the authors concluded that the addition of chemotherapy would be likely to improve outcome further given the incremental improvements seen with other squamous cancer [75]. A subsequent study appears to lend weight to this assumption where, in a large retrospective cohort of patients eligible for adjuvant treatment, the addition of chemotherapy resulted in a 38% reduction in the risk of death [76].

Primary treatment

Radiotherapy with or without concurrent or sequential chemotherapy is being used more frequently in the management of advanced vulval cancer. Radiotherapy may, in certain circumstances, be the sole treatment, but more usually it is used preoperatively with a view to allowing for sphincter-preserving surgery.

Encouraging results were reported by Beriwal *et al.* [77] who were able to demonstrate a complete pathological response in 16 of 33 patients receiving preoperative chemoradiation. All but one remained disease-free at 26 months. In the remaining 17 patients, who had only a partial response, eight developed recurrence locally within 8 months.

Radiotherapy may also be of use in place of surgery for histologically proven involved groin lymph nodes. Whether such irradiated nodes require removal after treatment remains unknown.

Radiotherapy and chemotherapy schedules

Radical treatment usually requires that a prophylactic dose (45–50 Gy) is delivered to the primary and nodal sites and the tumour is then boosted by a second phase of treatment using electrons, conformal radiotherapy or brachytherapy to a total dose of 65 Gy. The total prescribed dose is determined by the clinical context.

A Cochrane review suggests that there is no evidence that prophylactic groin irradiation should be used in preference to surgery [78]. With regard to the use of concurrent chemotherapy and radiation therapy, there are no robust prospective data. Several retrospective studies have suggested that there may be some improvement in local control with regimens employing cisplatin and 5-fluorouracil, mitomycin C and 5-fluorouracil, and 5-fluorouracil alone.

When there is no obvious macroscopic disease and the sole intention is adjuvant treatment, the total dose is 45–50 Gy with no concurrent chemotherapy.

Complications of radiotherapy

The reason for the limited application of radiotherapy in this disease lies in the poor record of tolerance and high levels of complications reported in the older series. This almost certainly relates to the type of treatments and techniques available in these series. More modern equipment and a greater understanding of its potential and applications have resulted in a marked improvement in tolerance and morbidity [79].

Most women will note erythema and some moist desquamation as a result of radiotherapy. With appropriate care and attention to local hygiene, such problems rarely

result in premature discontinuation of treatment. Radiation-induced cystitis requires bladder irrigation and treatment of any infection. Proctitis is managed with prednisolone (Predfoam), Normacol and loperamide.

More severe side effects include necrosis of bone (symphysis and femoral heads) and fistula formation. Careful planning of field sizes, dose and fractionation minimize such risks.

Recurrent disease

Between 15 and 30% of cases will develop recurrence. The most common site is the residual vulva (70%), with the groin nodes accounting for almost 20% and the remainder of relapses occurring in the pelvis or as distant metastases. In a large prospective cohort of well-characterized unifocal cancers in the Groins V2 study, local recurrence was 27.2% at 5 years and 39.5% at 10 years after primary treatment [80].

Most recurrences occur 2 years after primary treatment, and close surveillance every 3 months in the first 2 years is usually practised. This is reduced to 6-monthly surveillance for a further 2–3 years and annually thereafter. Additionally, patients are encouraged to self-inspect and report any symptoms of pain, bleeding or discharge. It should be stated that this schedule for follow-up is empirical and not evidence based.

Survival is poor following regional relapse, hence the efforts to prevent this at the outset. Skin bridge recurrence has been reported to be more likely to occur in patients with positive lymph nodes [81].

In vulval cancer, disease can recur several years following presumed adequate treatment of the primary cancer. Furthermore, some features of the original disease seem to be associated with this late type of recurrence, to such an extent that other terms employed include 're-occurrence' or 'second field tumours'. Rouzier *et al.* [82] were the first to document this late recurrence potential with tumours associated with lichen sclerosus in the adjacent epithelium. In a large retrospective cohort [54] we have also documented this phenomenon. The Birmingham cohort comprised 201 patients extensively classified in terms of pathology, HPV status and treatment modality. Furthermore, the minimum follow-up was 5 years. It appeared from an in-depth analysis that both local recurrence and re-occurrence were significantly more likely in women who had evidence of lichen sclerosus when compared with usual-type VIN. Lymph node positivity was also a significant predictor for local relapse. As long as the primary tumour was completely excised, the excision margin was not a predictor of relapse. This hypothesis-generating cohort study proposes that local relapse in completely excised tumours occurs as a result of persisting bio-instability of the adjacent epithelium (second field tumour) or as a direct result of tumour emboli in the associated skin lymphatics. Further work is in progress to develop a clearer understanding of the bio-instability of adjacent epithelium and with it the potential for prophylaxis to reduce local recurrence risk.

Treatment

The management of relapsed disease will depend on the site and extent of the recurrence [83]. Wide excision of local recurrences can result in a 5-year survival rate of 56% if the inguinal nodes are negative [84]. If excision would risk sphincter function, radiotherapy should be considered as the first choice. If radiotherapy has already been given to maximum dose, then excision should be considered.

Groin recurrence has a much poorer prognosis and is difficult to manage. In patients who have not been treated previously with groin irradiation, radiotherapy (with or without additional surgery) would be the preferred option. The options are much more limited in those who have already been irradiated and palliation, which may include surgery, should be considered. There is no standard chemotherapy or other systemic treatment effective in patients with metastatic disease.

Summary box 60.3

- The current consensus is that radical excision of the primary lesion(s) should aim to achieve disease-free margins of at least 8 mm after fixation.
- All lesions with invasion greater than 1 mm should be considered for either ipsilateral or bilateral lymph node dissection.
- Adjuvant radiotherapy or re-excision should be considered if the excision margins are suboptimal.
- One lymph node replaced or breached by a tumour or two with microscopic deposits should prompt adjuvant radiotherapy.
- Advanced tumours or tumours where excision may cause functional compromise should have treatment individualized (surgery, radiotherapy and chemotherapy) to maximize cure and minimize functional compromise.
- Local recurrence may be managed by either re-excision or radiotherapy, whichever would be associated with the least functional compromise.
- Groin recurrences are difficult to treat and the outcome is poor.

Vaginal cancer

Background

Vaginal cancer is rare and accounts for only 1–2% of all gynaecological malignancies. They arise as primary squamous cancers or are the result of extension from the cervix or vulva. Most authors report a wide age range (18–95 years), with the peak incidence in the sixth decade of life and a mean age of approximately 60–65 years. There would appear to be no relationship with race or parity.

A systematic review of the treatment of vaginal cancer revealed only 26 publications [85].

Aetiology

The cause of vaginal cancer is unknown, although several predisposing and associated factors have been noted:

- previous lower genital tract intraepithelial neoplasia and neoplasia (mainly CIN and/or cervical carcinoma);
- HPV infection (oncogenic subtypes); and
- previous gynaecological malignancy.

Several authors report that approximately one in four or as high as one in three patients have had a previous gynaecological malignancy. Large case–control studies have not been able to confirm pelvic radiotherapy, previous hysterectomy, long-term use of a vaginal pessary and chronic uterovaginal prolapse as causative factors.

Presentation

The symptoms will depend on the stage of tumour at presentation. The most common presenting features are:

- vaginal bleeding, which accounts for more than 50% of presentations;
- vaginal discharge;
- urinary symptoms;
- abdominal mass or pain; and
- asymptomatic (approximately 10% of tumours will be asymptomatic at the time of diagnosis).

Vaginal tumours may be overlooked during vaginal examination, particularly when a bivalve speculum is used. Careful inspection of the vaginal walls while withdrawing the speculum is necessary to avoid this, otherwise the blades of the speculum may obscure a tumour on the anterior or posterior vaginal wall.

Pathology

Between 80 and 90% of tumours in the larger series are squamous. Other carcinomas include adenocarcinomas, adenosquamous carcinomas and clear cell adenocarcinomas. Other rare primary vaginal cancers are discussed separately.

Site and size

Tumours can occur at any site in the vagina. The upper third of the vagina is the site most frequently involved, either alone or together with the middle third in approximately two-thirds of cases. Approximately one in six will be found to involve the entire length of the vagina. There is no predilection for any particular wall of the vagina. Figure 60.9 demonstrates a well-localized lesion in the lower vagina that does not originate from the vulva.

As with site, the size of tumour shows great variation at presentation, ranging from small ulcers less than a centimetre in diameter to large pelvic masses, although the majority of tumours are a maximum of 2–4 cm in diameter.

Staging and assessment

Any tumour classified as a primary vaginal carcinoma should not involve the uterine cervix. There should be no clinical evidence that the tumour represents metastatic or recurrent disease. Staging should be carried out according to the FIGO classification. This classification is summarized in Table 60.12.

The staging process itself can present problems since it may be difficult to differentiate one stage from another. This applies particularly to stage I and II disease, which may be hard to separate clinically; similarly, it is difficult to separate stage IIa and IIb on purely clinical grounds. Differences also exist in interpretations of the significance of positive inguinal nodes and their effect on staging. The current staging does not indicate in which group such patients should be placed, and some authors would

Fig. 60.9 Vaginal cancer. (*See also colour plate 60.9*)

Table 60.12 FIGO clinical staging of primary vaginal carcinoma.

Stage	Definition
0	Vaginal intraepithelial neoplasia III (carcinoma *in situ*)
I	Invasive carcinoma limited to vaginal wall
IIa	Carcinoma involves subvaginal tissue but does not extend to parametrium
IIb	Carcinoma involves parametrium but does not extend to pelvic side wall
III	Carcinoma extends to pelvic side wall
IVa	Involvement of mucosa of bladder or rectum (bullous oedema does not qualify for stage IV) or direct extension beyond true pelvis
IVb	Spread to distant organs

assign these patients to stage III with others preferring IVa or IVb.

The majority of series report that stage II disease is most commonly found at presentation (approximately 50% of all cases). Stages I and II combined consistently constitute 70–80% of cases.

Assessment

The assessment is best performed under general anaesthesia.

- The site and limits of the tumour can be accurately determined and a full-thickness biopsy taken for histological analysis.
- Combined rectal and vaginal examination is helpful to determine whether there is any extension of the tumour beyond the vagina and the extent of any spread.
- Cystoscopy and sigmoidoscopy are required to exclude or confirm the involvement of bladder or rectum.
- Chest X-rays or intravenous urograms can be used for the assessment.
- More complex radiological investigations such as rectal ultrasound scanning or MRI may be helpful in selected instances to define the dimensions and extension of the tumour.

Treatment

The majority of cases of vaginal carcinoma are treated using pelvic radiotherapy, although surgical excision is an appropriate form of management in selected cases. Experimental chemotherapeutic regimens are being developed both alone and in conjunction with radiotherapy for advanced cases or recurrent disease.

Radiotherapy

The proximity of the bladder and rectum means that, except in early cases, salvage of normal bladder and rectal function can only be achieved using radiotherapeutic techniques. Radiotherapy is certainly effective in treating vaginal cancer and survival rates have improved throughout the century as techniques have developed and improved. Techniques utilized have included:

- external beam radiotherapy (teletherapy);
- brachytherapy (e.g. interstitial implants, intravaginal cylinders or vaginal ovoids); and
- a combination of the two.

There is little place for using external beam therapy alone and the majority of tumours should be treated in combination with brachytherapy, with small early-stage tumours being suitable for treatment by brachytherapy alone. The optimal dose remains unclear but the mid-tumour dose should be at least 75 Gy. Above this dose any survival benefit must be weighed against the increased toxicity of therapy, and doses of 98 Gy or more have been shown to cause a higher incidence of severe side effects. Complication rates reported for radiotherapy vary according to dosage and techniques used and to the different grading systems used by different authors. Most report complications as occurring in 10–20% of patients. Life-threatening complications have been reported to occur in 6% of those undergoing radiotherapy for gynaecological malignancies, and vaginal carcinoma is no exception.

Acute complications include:

- proctitis;
- radiation cystitis; and
- vulvar excoriation or ulceration and even vaginal necrosis.

Significant long-term complications reported include:

- vesicovaginal or rectovaginal fistulae;
- rectal stricture; and
- vaginal stenosis.

In younger women, vaginal stenosis may be a long-term complication of great significance.

Surgery

There are relatively few reports of the use of surgery in vaginal cancer. Given what little information does exist, there are three general situations where surgery might be considered as first-line management.

1) Patients presenting with a stage I tumour in the upper third of the vagina, particularly on the posterior wall where resection may be technically straightforward. These patients can be treated with radical hysterectomy (if uterus *in situ*), pelvic lymphadenectomy and vaginectomy.

2) Patients with small mobile stage I tumours low down in the vagina, which if amenable to excision can be treated by vulvectomy with inguinal lymphadenectomy.
3) Bulky lesions that are unlikely to be cured by primary radiotherapy may be considered for exenteration in a few carefully selected cases.

It is undoubtedly possible in many instances to remove a vaginal carcinoma by surgical means, and there is little evidence to suggest that survival is improved following any of the treatment modalities. The choice of treatment will depend on the potential toxicity of the proposed treatment in relation to an individual patient and an individual tumour. Surgery is problematic in this respect because, to achieve adequate margins around the tumour, important structures (e.g. bladder or rectum) may be compromised.

The addition of lymphadenectomy would appear important as Stock *et al.* [86] reported that 10 of 29 patients (34%) undergoing pelvic node dissection and all three of their patients subjected to inguinal lymphadenectomy had positive nodes. High rates of metastasis to inguinal nodes from tumours of the lower third of the vagina have been noted. Early reports suggested that morbidity after surgical treatment of vaginal cancer was both frequent and serious.

However, the majority of complications were seen in patients undergoing surgical management of post-irradiation recurrence or following exenterative surgery for advanced disease. Serious complications include urinary problems (stress and/or urge incontinence) and fistulae. Lastly, any procedure requiring removal of the entire vagina will render the patient apareunic, although lesser degrees of vaginal excision usually allow subsequent sexual function.

Chemotherapy

There is little published work regarding the use of chemotherapy in vaginal cancer. Reports that exist concern combined chemoradiation as first-line treatment of advanced disease and the palliative use of chemotherapy for recurrent disease. In squamous vaginal cancer the use of chemotherapy should still be regarded as experimental.

Survival

Overall 5-year survival rates are now in the region of 50%, with rates of 39–66% reported. Survival is much higher in early-stage disease. However, there is some inconsistency in the allocation of cases to stages I and II. Survival rates for stage I disease are consistently reported at between 70 and 80%.

Prognostic factors

Stage, size, site and histological grade and type have all been proposed as factors that may influence survival. Only tumour stage and site, however, are consistently reported as being directly related to survival.

Recurrence

Recurrence occurs locally or within the pelvis in most instances, with about 20% relapsing with distant metastasis. The majority of relapses occur soon after primary therapy. Stock *et al.* [86] found a median time to relapse of 0.7 years. The outlook after failure of primary therapy is poor and in the majority further treatment is unlikely to be successful. As with cervical carcinoma, those patients with purely pelvic recurrence are sometimes suitable for salvage surgery by exenteration.

Uncommon vaginal tumours

Sarcomas

Leiomyosarcomas are most frequently diagnosed, with other types reported including adenosarcoma and angiosarcoma. Primary therapy is surgical involving wide local excision of the tumour with free margins. Adjuvant radiotherapy has been advocated for high-grade tumours or in recurrent disease. Adjuvant chemotherapy has been utilized by some but has not been shown to confer a survival advantage in soft-tissue sarcomas of the extremities. The majority of women present with discomfort or bleeding.

Rhabdomyosarcoma (sarcoma botryoides)

Rhabdomyosarcoma accounts for less than 2% of vaginal sarcomas. It is the most common soft-tissue tumour in the genitourinary tract during childhood. About 90% of cases occur in children under 3 years of age and almost two out of three occur in the first 2 years of life, although rare cases are reported in older women. Presentation is classically with a vaginal mass composed of soft 'grape-like' vesicles, but others may present with vaginal bleeding, discharge, a single small polyp or, occasionally, a black haemorrhagic mass.

Treatment involves conservative surgery (aimed at preserving function of the female pelvic organs) but depends largely on combination chemotherapy using vincristine, actinomycin-D and cyclophosphamide. Adjuvant surgery or radiotherapy may be added depending on response to chemotherapy. Survival has been greatly improved by the advent of combination chemotherapy and over 90% of individuals have been reported to survive following treatment.

Clear cell adenocarcinoma

As suggested by its name, it displays characteristic histological features that include the presence of solid sheets of clear cells, or of tubules and cysts lined by hobnail cells. The median age at diagnosis is 19 years (range 7–42 years) and approximately 61% of patients have documented exposure to diethylstilbestrol (DES) or to a chemically related non-steroidal oestrogen *in utero*. Although the risk of developing a clear cell adenocarcinoma following exposure to such drugs *in utero* was thought to be considerable, it is now appreciated that the risks are in fact very low (0.014–0.14%). Highest risks are for exposure that occurs early in pregnancy, the risk after exposure in the first 12 weeks' gestation being threefold that at 13 weeks. The majority occurs in the upper third of the anterior vaginal wall. Treatment is either by radical surgery or radiotherapy dependent on stage, in a fashion akin to the management of cervical carcinoma.

Although the peak incidence of DES-associated clear cell carcinoma in the USA was in 1975, a recent report suggests that there may also be an association with the development of non-clear cell adenocarcinomas occurring in older DES-exposed women [87].

Melanoma

Primary malignant melanoma of the vagina is an aggressive and rare gynaecological malignancy. Fewer than 200 cases have been reported worldwide to date but it is known that this disease has the worst prognosis of all gynaecological malignancies. Malignant melanoma of the vagina is 100-fold less common than melanoma of non-genital skin. The behaviour of this tumour also differs from that of melanomas found in other sites in that it is more aggressive than cutaneous melanomas (including vulvar melanoma) and that there is no difference in incidence between different races or skin types. The median age at presentation is around 66 years and the incidence increases with advancing age. The commonest presenting complaint is vaginal bleeding, but presentation may also be with a pelvic mass, vaginal discharge or dyspareunia. The optimal mode of treatment remains unclear, but whatever method is used the outlook is bleak. Prognostic factors that have been proposed include age, stage, tumour diameter, depth of invasion and mitotic rate. As with squamous vaginal carcinoma, the choice of treatment lies between surgery, radiotherapy or a combined approach. A number of recent articles support the use of radical surgery as a primary approach [88]. Radical surgery refers to either anterior or complete exenteration and it is suggested that although a 5-year survival is not necessarily increased by such measures, the median and disease-free survival may be prolonged.

Endodermal sinus tumour

Endodermal sinus tumours, which more commonly arise in the ovary or testis of infants, are also recognized in the vaginas of very young girls. Approximately 50 cases have been reported, with no patients aged over 3 years. Presentation will usually follow an episode of vaginal bleeding or discharge in a young girl who at examination is found to have a friable polypoid exophytic tumour.

Immunohistochemistry will reveal positive staining for α-fetoprotein, and in some cases serum α-fetoproteinlevels are elevated.

The behaviour of the tumour is locally aggressive but metastasis will also occur via haematogenous or lymphatic spread. Most tumours arise on the posterior vaginal wall and, if untreated, patients are known to die within 2–4 months of diagnosis.

The emphasis for treatment has moved towards limited excisional surgery combined with preoperative or postoperative chemotherapy. Multiagent chemotherapy is employed and is the same as that used for the successful treatment of ovarian endodermal sinus tumour.

Summary box 60.4

- Vaginal cancer is rare and most are squamous cancers.
- Superficial disease in the upper third may be managed similarly to cervical cancer.
- Superficial disease in the lower third may be managed as for vulval cancer.
- Deeply invasive disease and any disease whose excision would result in functional compromise should first be treated with radiotherapy with or without chemotherapy.
- Stage and tumour site are the most important prognostic variables.

Conclusions

The rarity of vaginal cancer means that many questions regarding its management remain unanswered. Many cases are amenable to treatment by more than one method, with comparable results in terms of survival. Choice of treatment may therefore often be made in relation to the potential toxicities of different treatments and should be tailored to each individual patient.

Premalignant and Malignant Disease of the Cervix

Maria Kyrgiou[1,2]

[1] *Department of Surgery and Cancer, Imperial College London, London, UK*
[2] *West London Gynaecological Cancer Centre, Queen Charlotte's & Chelsea – Hammersmith Hospital, Imperial Healthcare NHS Trust, London, UK*

Premalignant disease of the cervix

Cervical cancer is largely preventable through treatment of screen-detected cervical lesions. It has a long natural history with a prolonged precancerous phase that is easily detectable and treatable. Exfoliative cytology has been the mainstay for screening of cervical pre-invasive disease (cervical intraepithelial neoplasia or CIN). Assessment of women with abnormal cervical cytology and the selection of those requiring treatment relied mainly on colposcopic impressions of the cervical transformation zone and the histological appraisal of directed punch biopsies. Local treatment for cervical pre-invasive disease is highly successful. The recognition that persistent infection with oncogenic human papillomavirus (HPV) causes cervical cancer has led to the development of HPV DNA test, other molecular biomarkers and prophylactic vaccines against HPV.

Epidemiology

Cervical cancer remains the most common female malignancy in virtually all developing countries and the seventh most common in women worldwide. Globally in 2012, an estimated 528 000 women developed cervical cancer and almost 266 000 died from this disease. Of all cervical cancers, 83% occur in the less developed world due to the absence of screening [1] (Fig. 61.1).

The trends in the incidence of cervical cancer in different countries relate largely to the availability, quality and coverage of screening programmes, as well as exposure to HPV and other risk factors, which reflect sexual habits and cultural and socioeconomic influences. The comparatively low incidence of cervical cancer in affluent societies is largely related to the implementation of population–based screening programmes and their coverage. This has led to a dramatic decrease in the incidence and mortality from invasive disease, as cancers are prevented or detected at an early stage (Fig. 61.2).

In the UK, it is estimated that cervical screening saves approximately 5000 lives every year. Although the overall age-standardized incidence of cancer increased by 3% in women during the 10-year period from 1993 to 2002, the corresponding data for cervical cancer showed a decrease of approximately 30%. The incidence of cervical cancer has fallen in the UK by 44% since 1975, and mortality from 7.1 per 100 000 in 1988 to 2.4 per 100 000 in 2007. The benefits became more obvious since the reorganization of the service in 1988 and the increase in coverage (from 35% in 1988 to 85% in 1998).

HPV infection, risk factors and natural history

Several risk factors for cervical cancer have been investigated over the years. There is now a strong and consistent body of evidence demonstrating that persistent infection by oncogenic high-risk HPV subtypes is responsible for instigating the neoplastic process and that this might be potentiated by other cofactors (Fig. 61.3). With more than 200 HPV subtypes recognized today, it is only a fraction of these that has been found to have carcinogenic potential. Of these, subtypes HPV-16 and HPV-18 are most commonly associated with invasive cancers and are thought to cause approximately 65–75% of cases, depending on the continent. The most frequent low-risk subtypes are HPV-6 and HPV-11, which also lead to the development of anogenital warts. The commonest types are classified according to their oncogenic potential as follows:

- low-risk subtypes HPV-6, HPV-11;
- high-risk subtypes HPV-16, HPV-18, HPV-31, HPV-33, HPV-45, HPV-56.

Lyon, France: International Agency for Research on Cancer; 2013. Available at http://globocan.iarc.fr, accessed 4 August 2016.

The lifetime risk of acquiring any HPV infection probably exceeds 80%. With more sensitive testing available, studies show that HPV infection is more commonly the rule, not the exception. HPV types associated with the alpha species predominate in the anogenital area but other HPV types such as the beta and gamma HPV types, once thought to be predominantly cutaneous only, can also be commonly detected. Since the lifetime risk of developing invasive cervical cancer is much lower at 0.6%, cervical cancer should be regarded as a rare complication of a very common infection by HPV.

One of the early observations in most epidemiology studies was the high frequency of detection of the viral DNA. The more HPV types tested, not surprisingly, the higher the frequency of detection. In most studies, but not all, age influenced prevalence with young age being associated with higher rates, some as high as 45% in Western societies. This vulnerability is thought to be due

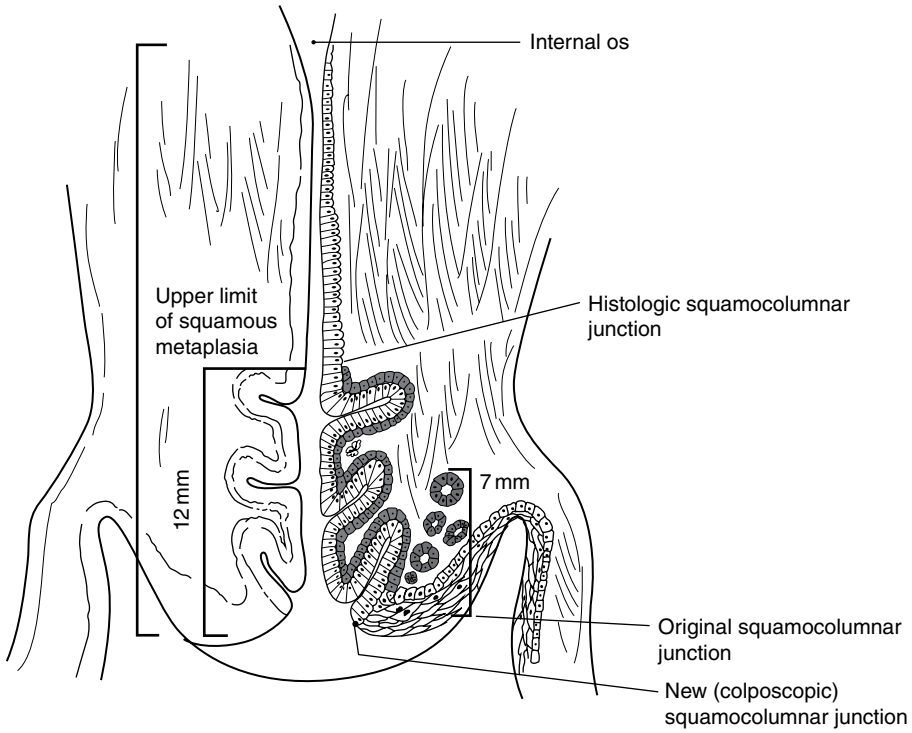

Fig. 61.3 The cervical epithelium and transformation zone.

to immature or naive immune responses as well as the biological vulnerability of the immature cervical epithelium seen in adolescents. The prevalence of HPV infection declines to about 5% in women above the age of 30.

Most HPV infections are transient. Approximately 60–80% clear spontaneously within 1–2 years, although the rest may result in CIN lesions within 2–4 years. The progression rate of CIN in women with high-risk HPV positivity is about 5% per year. In women over 30 years with high-risk HPV positivity and a normal cytology sample, the risk of developing CIN 3 is 116 times higher than in women with HPV but cytology negative. Even for women who develop CIN, the regression rates are high and depend, amongst other factors, on the grade of CIN and the woman's age. Above the age of 30 years, the regression rate is lower. Taken together, in the absence of intervention, roughly one-third of early precursor lesions disappear spontaneously, one-third persist and one-third progress to CIN 3 or invasive cancer.

HPV is a non-lytic infection, so that the inflammatory response to HPV is much more subtle than other mucosal infections, such as *Chlamydia trachomatis*. The initial immune response to acute HPV infections is most likely mediated by the local innate immune system, probably involving mechanisms such as activation of Toll-like receptors and natural killers cells. Persistent infections are cleared by the development of adaptive immune responses, which are dependent on antigen-presenting cells. HPV-16 is thought to downregulate both innate and adaptive immune responses. Final pathways to cancer result in interference with telomerase activity and viral integration, although a proportion of cancers are found to have episomal HPV DNA only. HPV E6 and E7 are known oncoproteins that control fundamental carcinogenic events including proliferation, senescence, and apoptosis. Cellular targets include p53, E6AP, CBP, p300, Bak, hTERT, MAGUK, cIAP, survivin, p107, pRB and p130.

Observational data show that the estimated time from infection to the development of invasive disease is approximately 15 years, although there may be swift progression in rare cases (Fig. 61.4). Cervical carcinogenesis normally has a lengthy precancerous phase that has been well defined through different grades of cervical preinvasive disease, although the continuum of the carcinogenic process has been questioned in some cases. Despite these major advances in our current understanding of the disease, the exact factors that determine infection and/or disease that will persist, progress or, conversely, spontaneously resolve are incompletely understood.

Several other risk factors of cervical disease have been described previously and have been correlated with heightened or reduced risk of cervical cancer in epidemiological studies. These include:

- low socioeconomic status;
- tobacco smoking (twofold);
- oral contraceptives (2.5-fold);
- early sexual debut;

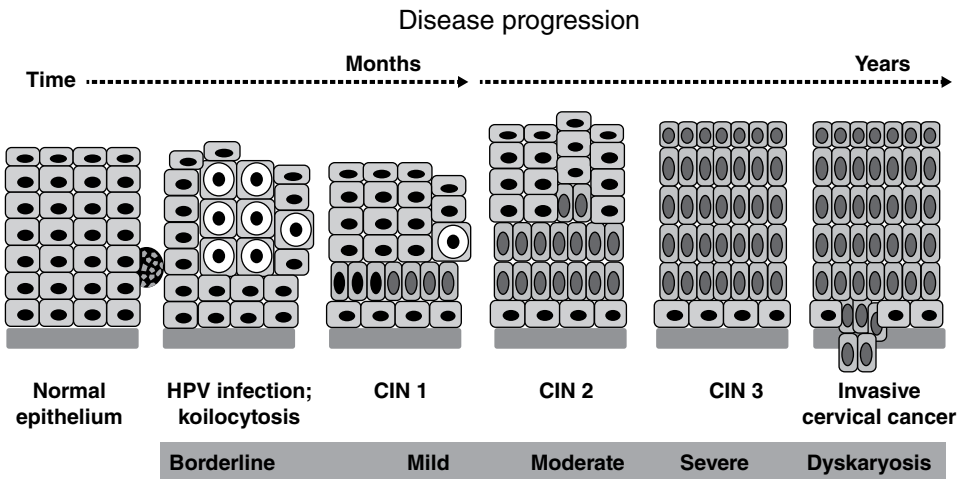

Fig. 61.4 Natural history of HPV infection and disease progression.

- multiple sexual partners (of woman or of the partner);
- other sexually transmitted infections (e.g. herpes simplex virus, *Chlamydia*) and bacterial vaginosis might influence HPV persistence and the probability of progression of HPV infection to dyskaryosis;
- immunocompromise, including HIV (fivefold).

The most consistent factors are tobacco smoking, oral contraceptive use and parity. All have biological plausibility. Nicotine and its carcinogenic metabolites can be detected in cervical mucus and smoking has been associated with a dampening of local immune markers. Both oestrogen and progesterone increase cell proliferation and hence vulnerability to DNA damage. Higher parity may be associated with high levels of hormone exposure and/or repeated trauma.

Most of the risk factors reporting a positive association are surrogates for sexual activity. They relate to increased risk for HPV infection and do not have a causal independent relation to cervical cancer. Others are potentially determinants of progression rather than prime aetiological agents.

Classification of cervical intraepithelial neoplasia

Squamous lesions

The Bethesda system for classification is widely used internationally. This was introduced in the USA in 1988 and was modified in 2001 [5]. This classifies abnormalities into:

- atypical squamous cells of undetermined significance, or ASCUS;
- atypical squamous cells cannot exclude high-grade squamous intraepithelial lesion (HSIL), or ASC-H;
- low-grade squamous intraepithelial lesion (LSIL), encompassing HPV and CIN 1;
- HSIL (encompassing CIN 2 and CIN 3) and squamous cell carcinoma.

The CIN classification introduced by Richart in 1967 for histological classification of cervical precancerous lesions has generally replaced the World Health Organization (WHO) classification and reflects the depth of epithelial involvement.

In the UK, cervical cytology was previously classified into mild, moderate and severe dyskaryosis, with borderline nuclear abnormalities used for changes that fall short of dyskaryosis. The previous terminology for cytology results used by the British Society of Clinical Cytology in 2001 was replaced by a new version introduced by the British Association for Cytopathology (BAC) and the NHS Cervical Screening Programme (NHSCSP) in 2013 (Table 61.1).

Table 61.1 Cervical cytology: classification of squamous lesions according to Bethesda and BAC/NHSCSP nomenclature.

Cytology		Histology
Bethesda 2001	*BAC/NHSCSP 2013*	
ASCUS, ASC-H	Borderline changes in squamous cells	HPV
LSIL	Low-grade dyskaryosis	CIN 1
HSIL	High-grade dyskaryosis (moderate)	CIN 2
HSIL	High-grade dyskaryosis (severe)	CIN 3
HSIL, SCC	High-grade dyskaryosis/?invasive SCC	SCC

ASCUS, atypical squamous cells of undetermined significance; ASC-H, atypical squamous cells cannot exclude HSIL; CIN, cervical intraepithelial neoplasia; LSIL, low-grade squamous intraepithelial lesion; HSIL, high-grade squamous intraepithelial lesion; SCC, squamous cell carcinoma.

Glandular lesions

Although the natural history and biology of glandular lesions is less clear, attempts have been made to mirror the range of cellular changes of the squamous into the glandular mucosa (cervical glandular intraepithelial neoplasia or cGIN). The Bethesda 2001 [5] system classifies glandular cytological abnormalities into four subcategories: atypical glandular cells (AGC); AGC, favour neoplastic; endocervical adenocarcinoma *in situ* (AIS); and adenocarcinoma. The BAC/NHSCSP 2013 classification system divides the glandular lesions into two groups, borderline changes and glandular neoplasia (Table 61.2).

Cervical cancer screening

Traditionally, cytology relied on the assessment of exfoliative smears on glass slides under the microscope, as first described by Papanicolaou in the 1940s. Liquid-based cytology has largely replaced conventional cytology in recent years. The technique has many advantages. It is semi-automated, creates a uniform spread of epithelial cells that are easier to read by cytotechnicians and cytopathologists, and reduces the rate of unsatisfactory samples. The fluid can also be used for reflex testing for HPV DNA and other biomarkers.

It is expected that cervical screening based on HPV DNA tests will replace cytology-based screening in the future, at least in women above the age of 30. Large randomized controlled trials and a meta-analysis of these documented the superiority of HPV-based screening when compared with cytology, with a 60–70% better protection against invasive disease. The optimal way of triaging women that test positive for high-risk HPV remains to be determined and some options include reflex cytology, HPV-16/HPV-18 genotype positivity or newer biomarkers. The use of HPV mRNA tests in primary screening has also been suggested but longitudinal data are required.

The age of screening initiation and the frequency of screening intervals vary across countries [2,4]. In the UK, for example, screening starts at the age of 25. Screening does not start earlier as the risk of invasive cancer at younger ages is small, while many lesions spontaneously regress without treatment in this age group [3]. Sentinel pilot sites are testing the introduction of HPV-based screening with reflex cytology for those that test positive for HPV. This may allow further extension of the screening interval to 5 years if women test negative (Table 61.3).

The current indications for referral for colposcopy in the UK are:

- one cervical sample showing borderline nuclear changes in squamous cells that are high-risk HPV positive;
- one cervical sample showing mild dyskaryosis changes in squamous cells that are high-risk HPV positive;
- one cervical sample showing mild dyskaryosis changes in squamous cells with unreliable, inadequate or no results for HPV test;
- three cervical samples showing borderline nuclear changes in squamous cells with unreliable, inadequate or no results for HPV test;
- one cervical sample showing borderline nuclear changes in endocervical cells;
- one cervical sample showing moderate or severe dyskaryosis;
- one cervical sample showing possible invasion;
- one cervical sample showing glandular neoplasia;
- three consecutive inadequate cervical samples;
- any grade of dyskaryosis following treatment for CIN;

Table 61.2 Cervical cytology: classification of glandular lesions according to Bethesda and BAC/NHSCSP nomenclature.

Bethesda 2001	BAC/NHSCSP 2013
AGC NOS	Borderline changes in endocervical cells
Endocervical	? Glandular neoplasia
Endometrial	Endocervical type
Glandular	Non-cervical
AGC favour neoplastic	
Endocervical	
Glandular	
Endocervical AIS	
Adenocarcarcinoma	
Endocervical	
Endometrial	
Extrauterine	
NOS	

AGC NOS, atypical glandular cells, not otherwise specified; AIS, adenocarcinoma *in situ*.

Table 61.3 Screening intervals in the UK proposed by the National Institute for Health and Care Excellence.

Age (years)	Screening interval recommended
Under 25 s	No screening
25	First invitation
25–49	Three yearly
50–64	Five yearly
Over 65 s	No screening

- three abnormal cervical samples of any grade over a 10-year period;
- suspicious symptoms and abnormal cervix.

Colposcopy

Hinselman first introduced colposcopy early in the last century (1925). Colposcopy comprises low-power magnification and illumination of the lower genital tract after application of various stains: acetic acid (3–5%) and Lugol's iodine. Apart from refinements to the optical and illumination systems and the introduction of a green filter that can enhance the vascular appearance, there has been little technological advancement since. New technologies (such as DySiS and Zedscan) are being assessed and have potential to improve the accuracy and reproducibility of the colposcopic assessment.

The objectives of colposcopic assessment are to:

- assess the presence and severity of the abnormalities detected on cytology;
- guide colposcopically directed biopsies from the area with the most severe changes;
- exclude invasive disease;
- aid in outpatient management and treatment of CIN;
- assist follow-up after treatment.

Colposcopy is deemed satisfactory when the entire squamocolumnar junction is visualized and the upper limit of any lesion is seen. The size and topography of the lesion should be ascertained, especially if there is any extension of the lesion into the cervical canal or onto the vagina. Both of these clinical scenarios are important in relation to appropriate treatment. Colposcopic abnormalities maybe graded according to a variety of indices, such as the appearance of the aceto-white epithelium, iodine negativity and vascular patterns such as mosaic, punctation and atypical vessels. The area between the original and the new squamocolumnar junction after replacement of the columnar epithelium after puberty by metaplastic squamous epithelium is called the transformation zone and should be described as type I, II or III [6].

The colposcopic assessment is subjective and prone to intra-observer variability, particularly in the diagnosis of low-grade as opposed to high-grade lesions. The predictive accuracy improves with the increased severity of the anticipated lesion. Agreement between the colposcopic impression and histology is achieved in only 37% of cases, while agreement within one grade is 75%. Formal training and a period of apprenticeship leads to certified expertise in this technique.

Management and treatment

One in ten women in the UK have an abnormal result at screening. Of these, 2–3% will present with high-grade findings at cytology and the remaining 7% with cervical samples classified as ASCUS or LSIL or their British terminology equivalents of borderline and mild dyskaryosis [7].

The management of the minor cytological abnormalities that are common in young women has challenges. Although the majority represent clinically insignificant lesions, some can harbour high-grade disease. Their management consumes a disproportionate amount of health resources, although their significance remains debatable. An HPV DNA test has recently been introduced in many countries to assist the selection of women with these minor abnormalities that should be further investigated with colposcopy. Women who test negative for high-risk oncogenic HPV types return to routine recall. Further management of confirmed CIN 1 lesions varies and depends on the woman's age, the length of persistence of the disease and her fertility wishes. Young women who have not yet completed their families are usually managed conservatively with surveillance. Older women or women at high risk of non-compliance with persistent disease may undergo treatment.

Most women with histologically high-grade lesions (defined as CIN 2+) will undergo treatment and CIN 2 on a biopsy is often considered the clinical threshold to proceed to treatment. Exceptions may apply in selected cases of young women with small CIN 2 lesions. Increasingly, clinicians manage carefully selected cases with close surveillance, as the regression rate in young women with small lesions is high.

Local conservative cervical treatment for CIN aims to remove or ablate the entire transformation zone and lesion with a cone-shaped part of the cervix to a depth of more than 7 mm to ensure eradication of CIN that may involve the gland crypt. The majority of the techniques are easy to perform, of low cost and are usually performed under local anaesthesia in an outpatient setting. The peak age of CIN is similar to the mean age of having the first child in Western societies. It is therefore important that the proposed treatment will eradicate the preinvasive disease with the minimum disruption in cervical function.

The treatment methods are divided into excisional and ablative (Table 61.4). Both have high cure rates of over 90% and have similar treatment failure rates, with the exception of cryotherapy for high-grade disease. The choice of technique relies on patient characteristics, the colposcopic appearance, the depth, severity and size of the lesion, the type of transformation zone, the age and fertility wishes, the clinician's experience/preference and the equipment available.

The need to maximize clinical resources, achieve quicker and more effective management of patients, limit postoperative complications and preserve reproductive function has led to the popularity of local

Table 61.4 Excisional and ablative treatment techniques.

Excisional
Large-loop excision of the transformation zone (LLETZ), Europe; loop electrosurgical excisional procedure (LEEP), USA
Needle excision of the transformation zone (NETZ); straight wire excision of the transformation zone (SWETZ)
Laser conization
Cold knife conization
Hysterectomy
Ablative
Cryocautery
Radical electrodiathermy
Cold coagulation
Carbon dioxide laser ablation

excisional methods for cervical premalignancy. Most centres use large loop excision of the transformation zone (LLETZ), as this is quick, easy to learn, of low cost and well tolerated. Excisional techniques provide a histological sample that allows the precise grading of the lesion, assessment of the excision margins, and the ability to confirm with certainty the absence of microinvasive or glandular disease. This further allows clinicians to adopt a 'see and treat' approach in appropriate cases at the initial visit. In contrast, ablative techniques destroy the cervical epithelium and demand pretreatment biopsies at a separate initial visit with the risk of noncompliance. Furthermore, punch biopsies under-diagnose the severity of the lesion in 20% of cases compared with the histology of the large loop.

Excisional techniques

The use of excisional methods only is indicated in cases of repeat conization, unsatisfactory colposcopy, suspected invasion, glandular epithelium involvement, and when there is discrepancy between cytology, colposcopy and biopsy. The specimen should ideally be removed as a single sample. After treatment, women should avoid intercourse, insertion of menstrual tampons and use of swimming pools for 4–6 weeks.

- *LLETZ/LEEP* using low-voltage apparatus is now the most widely practised technique. It is performed under local anaesthesia. There are different available sizes of loops. There should be minimal artefactual damage to the specimen and the cervix, and roller ball can be used for haemostasis.
- *NETZ/SWETZ* is a recent modification that uses a straight wire rather than a loop. This technique allows shaping of the excision, which can be particularly useful in asymmetrical lesions.
- *Laser conization* follows the same principle as LLETZ and NETZ, but can be technically more demanding, takes longer to perform and requires equipment that is expensive to buy and maintain.
- *Cold knife conization* is used rarely but particularly in cases of suspected invasion and glandular disease. The lack of diathermy minimizes the thermal artefact and allows accurate assessment of the excision margins. However, there is a comparatively increased risk of haemorrhage and reproductive morbidity, and the procedure can only be done under general anaesthesia and requires hospitalization.
- *Hysterectomy* still retains a place in the management of CIN in women who have other gynaecological conditions such as fibroids, menorrhagia or prolapse. It may also be used in cases of glandular lesions where fertility does not need to be spared, especially in cases of treatment failure or incomplete excision. It is important to ensure complete excision of the cervix, the transformation zone and any vaginal lesion; the preferential route is vaginal hysterectomy or laparoscopically assisted vaginal hysterectomy preceded by colposcopic assessment.

Ablative techniques

Ablative treatment may be an option in selected cases when the transformation zone and the lesion are fully visible, the colposcopy satisfactory and there is no discrepancy between cytology, colposcopy and histology. These techniques are contraindicated in women with glandular lesions, suspicion of invasion or history of a previous cone and where pretreatment biopsies are required.

- *Cryotherapy* destroys tissue by freezing using probes of various shapes and sizes, and is probably best reserved for small low-grade lesions as the rates of clearance of CIN 3 are poor in comparison to other techniques. The duration of freeze is 2 min from the appearance of the ice ball. A freeze–thaw–freeze technique is advocated as this increases the cure rate. Despite these reservations, the technique is worthy of consideration, especially in low-resource settings as cryoprobes are cheap and widely available.
- *Electrodiathermy* requires general, regional or local anaesthesia. Under colposcopic control it is possible to destroy up to 1 cm depth using a combination of needle and ball electrodes. The apparatus required is cheap and easy to maintain but thermal necrosis may be considerably more than anticipated and more difficult to control.
- *Cold coagulation*: in this technique, heat at 100–120 °C is applied to tissue using a Teflon-coated thermosound for 30 seconds. The procedure is easy and does not usually require analgesia.
- *Laser ablation*: a micromanipulator attached to the colposcope is used to manipulate the laser and treatment

is conducted under direct vision. As the technique is precise, it gives good control over depth of destruction, good haemostasis and excellent healing, with minimal damage to the adjacent tissue. The technique is particularly useful in lesions that extend to and involve the vagina. The vaginal epithelium does not have gland crypts and, as a result, a depth of destruction of about 2–3 mm is usually sufficient. Despite these benefits, the cost of the equipment and maintenance is high and not readily available in most units.

Complications of treatment

The complications of CIN treatment are rare, and are divided into early and late complications.

Early

- Perioperative pain.
- Primary haemorrhage (<1%) that is usually easily controlled with the use of ball diathermy, nitrate sticks and Monsel's solution. Haemostatic sutures may be required in difficult cases.
- Secondary haemorrhage usually presents within 2 weeks from treatment and is usually related to infection. This generally settles with a course of broad-spectrum antibiotics.

Late

- Cervical stenosis and, consequently, inadequate colposcopy. This is more common in cases of cold knife conization, in deep or repeat excisions and especially in cases where haemostatic sutures were required. Difficulties in obtaining sufficient cytological samples and unsatisfactory colposcopy reduce accuracy of follow-up and fertility problems may also occur.
- Reproductive morbidity: although treatment does not appear to adversely affect fertility and ability to conceive, all techniques have been correlated with an increased risk of second-trimester miscarriage and preterm birth. The risk appears to increase with increasing cone depth and is higher for excisional compared with ablative techniques [8–10]. Clinicians should therefore balance the risk and benefits of treatment for different lesions and minimize the removal of healthy tissue.

Follow-up after treatment

After CIN treatment women remain at higher risk of recurrent/residual disease and invasive cervical cancer as compared with the general population. Several risk factors have been associated with high risk of recurrence and these include positive margins for disease, particularly in the endocervix, glandular disease, large lesions, age over 40 and grade of the disease. Although the risk for high-grade recurrence is substantially increased in women with involved as opposed to clear margins (18% vs. 3%), repeat conization is not recommended, with the exception of women over 50 who have positive endocervical margins for high-grade disease [11].

The majority of therapy failures (90%) are detected within 24 months from treatment. Traditionally, women with a history of treatment were followed up closely for 10–20 years after their treatment. More recently, HPV DNA test with or without cytology has been introduced in most countries as a 'test of cure' and allows early discharge of women who test negative back to routine recall and better detection of those at high risk of recurrence.

Cytology after treatment is less accurate and sampling should ensure good representation of endocervical cells, particularly when treatment was conducted for glandular disease. In the case of HPV positivity or cytological abnormality, a colposcopic assessment should be undertaken. Colposcopic assessment is technically more difficult in women who have undergone treatment. Foci of CIN and/or invasive disease may be buried under an apparently normal epithelium. The transformation zone may be difficult to visualize in its entirety due to scarring and because it often retracts deep in the endocervical canal.

Challenging clinical groups

Glandular disease

The incidence of glandular disease is increasing and the epidemiology of invasive adenocarcinoma is changing, with a higher incidence now recorded in women under 35. Of cervical tumours, 20–30% are now classified as adenocarcinoma or adenosquamous carcinoma. These lesions have a more aggressive course than their squamous counterparts and a poorer prognosis that may partly reflect frequent delays in diagnosis. HPV-18, in particular, has been associated with glandular lesions. The evidence on how to best manage these relatively uncommon lesions is rather limited.

Atypical glandular cytology may be suggestive of invasive cervical adenocarcinoma or adenocarcinoma *in situ*. Other conditions often seen on this cytology include CIN and endometrial pathology. If endometrial cells are seen on the cytology report in a postmenopausal woman not taking hormone replacement therapy, this may indicate endometrial disease and should be investigated appropriately. If borderline glandular changes (AGC) are present, colposcopic assessment with appropriate cervical biopsies and selective endometrial biopsy are indicated. Colposcopic findings are usually non-specific

(e.g. stark aceto-whiteness in fused villi) but colposcopy is always essential, as a high percentage of these women have concomitant CIN. Punch biopsy in the setting of atypical glandular cytology is unreliable, as the lesions are often small and may occur in the base of gland crypts. Excisional conization for diagnosis and treatment is recommended.

The majority (90%) of these lesions are located within 1 cm of the squamocolumnar junction and coexist with CIN, although they can be found potentially anywhere in the endocervical canal. Women with glandular lesions can be managed conservatively with local excision provided adequate close surveillance is possible. The excision margins should be free from disease; if involved, further excision is recommended. If the family is complete, the option of hysterectomy can be considered. Hysterectomy should be also considered if the disease recurs and if surveillance with cytology is compromised by cervical stenosis.

Cervical pre-invasive disease in pregnancy

Women who have an indication for colposcopy and are pregnant should undergo the procedure. The aim of this examination is to exclude invasion, while biopsy and/or treatment should be postponed until the postnatal period. Colposcopy should be performed by an experienced clinician as more pronounced aceto-white changes due to increased vascularity can often lead to over-diagnosis. If invasive disease is suspected, a suitably sized biopsy is required. This can be a cone, a wedge or LLETZ and is diagnostic rather than therapeutic. All these may be associated with a risk of haemorrhage and miscarriage and suitable facilities to deal with this situation should be available in a theatre setting. Punch biopsy is not a reliable method of excluding invasive disease.

HPV vaccines

The discovery that HPV is causally associated with cervical cancer led to the development of HPV vaccines. The introduction of prophylactic vaccination is the latest important landmark in the history of prevention of cervical cancer. To date, two vaccines have been developed and clinically evaluated, the quadrivalent vaccine (HPV 16/18/6/11, Gardasil) and the bivalent vaccine (HPV 16/18, Cervarix). Results from trials indicate that the vaccine is safe, well tolerated and highly efficacious in HPV-naive women. The optimal target age is the prepubertal woman before coitarche, while it will remain an individual decision for older women. The first country to introduce a national HPV immunization programme was Australia in both males and females in 2007. In the UK, this was initiated in September 2008 in females only. Data from Australia, Denmark and other countries that implemented the vaccination revealed an 80–90% reduction in the incidence of anogenital warts (for quadrivalent vaccine). More recently, vaccinated populations were found to have significant reduction in the incidence of HPV infection and high-grade pre-invasive disease. The nonavalent vaccine (Gardasil 9) that includes a further five high-risk subtypes in the vaccine cocktail (31, 33, 45, 56, 58) was launched in 2016. Several studies are exploring the use of therapeutic vaccines in women with existing high-grade disease.

Vaccination and screening are complementary strategies and synergy in a cost-effective manner will be required for the next few decades. Further research to assess screening strategies in vaccinated cohorts is needed. The introduction of vaccination is especially important in the developing countries, but affordability remains a major issue.

Summary box 61.1

- Persistence of oncogenic HPV infection appears to be the necessary but not sufficient cause of cervical cancer.
- For the local treatment of cervical precancerous lesions, a depth of at least 7 mm is recommended to ensure eradication of CIN from gland crypts.
- Women should be aware that CIN and its treatment increase the risk of reproductive morbidity in a subsequent pregnancy.
- The incidence of glandular lesions of the cervix is increasing. Their natural history is less understood. Treatment should be balanced against the woman's age and fertility wishes. Close follow-up is necessary; the cytology should include endocervical cells.
- HPV DNA test has been introduced as a 'test of cure' in the follow-up after treatment and as a triage tool for women with ASCUS or LSIL findings at screening in many countries.
- HPV DNA has better accuracy than cytology in primary screening and will replace cytology; the optimum way of triaging women who test positive for HPV in primary screening is still unclear.
- The introduction of prophylactic vaccination is the latest important landmark in the history of prevention of cervical cancer.

Malignant disease of the cervix

Cervical cancer remains the second commonest female malignancy worldwide. Three-quarters of affected women live in developing countries that experience the major burden of disease. The disease primarily affects

younger active women and therefore the total years of life lost is proportionately higher than that for most other cancers with a later onset.

Countries with established screening programmes face different challenges, including improving the outcome for women with advanced disease, preserving fertility in younger women who increasingly bear the greatest burden of disease, and incorporating advances in medical technology such as positron emission tomography (PET) and minimal access surgery. The realization that persistent infection with oncogenic high-risk HPV is causally associated with cervical cancer has undoubtedly been the most significant advance globally that led, more recently, to the development of prophylactic vaccines.

Epidemiology

Cervical cancer is the seventh most frequent cancer worldwide, with an estimated 528 000 new cases leading to 266 000 deaths in 2012. The mortality is substantially lower than the incidence; worldwide, the ratio of mortality to incidence is 55%. Cervical cancer still remains an important public health issue in Europe, with more than 66 000 new cases and 29 000 deaths annually. The majority of these cases are diagnosed in eastern European countries where there are no screening programmes. In the UK in 2006, there were 2873 registrations, and 941 deaths in 2007. The incidence rate for cervical cancer peaks between 30 and 40 years of age, declines in incidence in older age groups but peaks again in the over-80 age group [12,13].

Pathological subtypes

The majority of cervical cancers are squamous in origin, but adenocarcinomas appear to be increasingly common, accounting for approximately 10–20% of all primary cervical cancers. This increase partly reflects an increased awareness of the disease. Adenocarcinoma is more likely to be diagnosed in younger women and has a largely poorer prognosis in comparison with cervical squamous carcinoma, which partly reflects the delay in diagnosis. Cytology screening programmes were designed to detect squamous lesions and, as a result, the endocervical distribution of glandular abnormalities reduces their accuracy. Specific oncogenic HPV types, in particular HPV-18, have been related to adenocarcinoma. Primary screening with HPV DNA test has been shown to improve the detection of glandular intraepithelial neoplasia and allows significantly better prevention of adenocarcinomas than cytology-based screening.

The rare but aggressive small-cell neuroendocrine-type squamous carcinoma typically behaves like similar disease arising from the bronchus. Adenocarcinomas can be pure, but a significant proportion (40%) have mixed adenosquamous cells, the adenosquamous carcinoma. Adenocarcinomas include many more histological subtypes than squamous cancers. About 80% are made up of cells of the endocervical type with mucin production (Table 61.5).

Clinical presentation and diagnosis

The symptoms associated with cervical cancer are common and non-specific and usually manifest in late-stage disease. Early-stage disease may be asymptomatic and suspected on a cervical cytology sample or diagnosed following treatment for cervical pre-invasive disease, commonly in the form of LLETZ. The classical signs and symptoms are irregular vaginal bleeding, especially post-coital, and abnormal appearance of the cervix. Invasive cancer is rare in women with post-coital bleeding, but assessment is merited as it is much more common in this group than in the general population. These symptoms are also common in women with *C. trachomatis* infection. Discharge and pain are often associated with more advanced disease.

Diagnosis requires a biopsy for histopathological review by an experienced gynaecological pathologist. The biopsy needs to be large enough to demonstrate stromal invasion and often an appropriately sized loop diathermy (LLETZ) may be used. The optimal biopsy site is often the edge of the tumour, which allows assessment of the transition from invasive to non-invasive tissue. Central biopsies may reveal only premalignant or necrotic material, though often there may be no alternative. The tumours may bleed briskly after biopsy and occasionally require packing. In very early disease, a cone with loop diathermy (LLETZ), knife (cold knife conization) or diathermy needle (NETZ) can be diagnostic but also curative. Biopsies in a pregnant patient are

Table 61.5 Histological subtypes of cervical cancer and frequency.

Histological subtypes	Frequency (%)
Squamous cell carcinoma	80–85
Adenocarcinoma	10–15
Adenosquamous	5
Other rare types	5
Small cell	
Primary sarcomas	
Primary and secondary lymphomas	

important if invasion is suspected, but should be performed by an experienced clinician as significant bleeding may occur.

Staging procedures and patterns of spread

Having established the diagnosis, the next step is to stage the disease, as this determines the ongoing management and helps to assess prognosis and exchange of information among health professionals.

Cervical cancer is still staged clinically using the International Federation of Gynaecology and Obstetrics (FIGO) system (Table 61.6). Traditionally, this included procedures such as pathology review, examination under anaesthesia with combined rectovaginal examination, cystoscopy, proctoscopy, chest radiography and perhaps intravenous urography. In current practice in most Western countries, all women diagnosed with cervical cancer undergo MRI and CT, while complex/advanced cases are also often offered PET-CT to determine the extent of the disease. Although the imaging results cannot change the clinical FIGO staging, they are often used to plan management. MRI has high accuracy (90%) in describing the size, stage and extent of disease and permits detailed assessment of lymph nodes; it is obviously superior to CT and has commonly made examination under anaesthesia combined with cystoscopy redundant. PET-CT seems to enhance the accuracy in diagnosing involved lymph nodes and extracervical disease but more robust studies are required.

Several studies have described the use of sentinel node biopsy, which may be assessed by open or laparoscopic surgery. Some authors have reported 100% accuracy, but this technique is assessed only in the frame of research trials at present. In more advanced cancers, retroperitoneal or transperitoneal laparoscopic staging has been used to plan the field of radiation. Although several studies have reported survival benefit following debulking of large nodes prior to radiation, the only available randomized controlled trial showed surgical staging to be negatively correlated with outcome compared with non-interventional assessment. PET-CT seems to be an alternative, accurate, non-invasive assessment tool to surgical staging.

Table 61.6 FIGO staging for cervical cancer.

Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)
Stage Ia	Invasive carcinoma which can be diagnosed only by microscopy, with deepest invasion ≤5 mm and largest extension ≤7 mm
Stage Ia1	Measured stromal invasion of ≤3.0 mm in depth and extension of ≤7.0 mm
Stage Ia2	Measured stromal invasion of >3.0 mm and not >5.0 mm with an extension of not >7.0 mm
Stage Ib	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage Ia*
Stage Ib1	Clinically visible lesion ≤4.0 cm in greatest dimension
Stage Ib2	Clinically visible lesion >4.0 cm in greatest dimension
Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
Stage IIa	Without parametrial invasion
Stage IIa1	Clinically visible lesion ≤4 cm in greatest dimension
Stage IIa2	Clinically visible lesion >4 cm in greatest dimension
Stage IIb	With obvious parametrial invasion
Stage III	The tumour extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or non-functioning kidney†
Stage IIIa	Tumour involves lower third of the vagina, with no extension to the pelvic wall
Stage IIIb	Extension onto the pelvic wall and/or hydronephrosis or non-functioning kidney
Stage IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous oedema, as such, does not permit a case to be allotted to stage IV
Stage IVa	Spread of the growth to adjacent organs
Stage IVb	Spread to distant organs

* All macroscopically visible lesions, even with superficial invasion, are allotted to stage Ib carcinomas. Invasion is limited to a measured stromal invasion with a maximal depth of 5.00 mm and a horizontal extension of not >7.00 mm. Depth of invasion should not be >5.00 mm taken from the base of the epithelium of the original tissue (superficial or glandular). The depth of invasion should always be reported in millimetres, even in those cases with 'early (minimal) stromal invasion' (~1 mm). The involvement of vascular/lymphatic spaces should not change the stage allotment.
† On rectal examination, there is no cancer-free space between the tumour and the pelvic wall. All cases with hydronephrosis or non-functioning kidney are included, unless they are known to be due to another cause.

Table 61.7 Incidence of nodal disease in cervical cancer according to stage.

Stage	Positive pelvic lymph nodes (%)	Positive para-aortic lymph nodes (%)
Ia1 (<1 mm)	0	0
Ia1 (1–3 mm)	0.6	0
Ia1 (LVSI positive)	4	0
Ia2 (3–5 mm)	4.8	<1
Ia2 (LVSI positive)	11	<1
Ib	16	2.2
IIa	25	11
IIb	31	19
III	45	30
IVa	55	40

LVSI, lymphovascular space invasion.

Cervical cancers proliferate in the following ways.

1) Direct spread into the cervical stroma, parametria and beyond, into the vagina, body of the uterus, bladder and rectum.
2) Lymphatic spread into parametrial, pelvic side wall and para-aortic nodes. The incidence of pelvic lymph node and para-aortic disease according to stage is illustrated in Table 61.7.
3) Blood-borne spread is unusual.

Management and treatment

The principles of management are:

- tertiary review of pathology;
- staging;
- establishing the aim of treatment (i.e. curative or palliative);
- consideration of patient factors, such as age, fertility wishes, obesity, surgical and medical history, health status, preference;
- treatment of local and possible metastatic disease;
- presenting the patient with suitable options.

Specialized multidisciplinary gynaecological oncology teams should assess all these factors and determine the optimum management for each woman tailored to her individual characteristics. Decisions on how best to treat early disease in young women, especially when fertility-sparing techniques are considered, require considerable experience.

In principle, treatment options vary for each stage. An excisional cone is sufficient for treatment of microinvasive disease (stage Ia1) provided the margins are clear. The management of stage Ia2 disease is more controversial. Surgery and radiation have similar survival rates for stage Ib–IIa disease, while the combination of both increases morbidity. A large randomized controlled trial reported that radiation therapy and radical hysterectomy were equally effective in terms of 5-year overall and disease-free survival rates. Surgery has obvious advantages: it permits conservation of ovarian function in premenopausal women, the preservation of fertility in selected cases, and also reduces the risk of chronic bladder, bowel and sexual dysfunction associated with radiotherapy. Surgery provides a histological sample and permits the assessment of risk factors, such as lymph node status, that influence prognosis. Complications in the hands of skilled surgeons are uncommon. Late-stage tumours (IIb–IV) should be treated with chemoradiation as this is related to improved survival but also higher short- and medium-term toxicity in comparison with radiotherapy alone. Fertility-sparing surgical techniques such as radical trachelectomy may be appropriate in selected cases.

A more detailed description of the treatment options is described in the following sections.

Stage Ia (Ia1 and Ia2)

In early cervical cancer, surgical excision alone can be curative. Correct staging and identification of early disease allows the selection of a group of women who are not at risk of lymph node disease and can be treated with less aggressive and, importantly, fertility-sparing therapy. There are two aspects to consider: adequate removal of local disease, and identification and treatment of distant disease.

In stage Ia1, the risk for lymph node involvement is virtually zero. Consequently, complete excision of the invasive and pre-invasive disease with clear margins is commonly sufficient. The options of treatment include excision with knife or diathermy/laser or simple hysterectomy depending on the woman's wishes and fertility aspirations. The knife cone is often advantageous in this setting, as the absence of thermal damage allows a more accurate assessment of the extent of invasion in comparison with a diathermy excision specimen. However, on many occasions, microinvasion is only diagnosed retrospectively as an incidental finding after loop excision for pre-invasive disease. Small adenocarcinomas can probably be treated in a similar manner. If disease is present at the margins, further excision or hysterectomy is recommended. If lymphovascular space invasion (LVSI) is present, the risk of nodal disease rises to 3.6%; although some clinicians advocate node dissection in this setting, the possible benefits must be balanced against morbidity and the risk of lymphoedema.

In stage Ia2, management of the disease is more controversial. The risk of pelvic lymph node involvement in

this stage rises to approximately 5%. A very conservative approach cannot be adopted; the pelvic lymph nodes must be surgically removed and assessed, while management of the primary tumour remains less clear. When fertility preservation is an issue, radical trachelectomy and pelvic node dissection by a vaginal, laparoscopic or abdominal approach may be considered. Laparoscopic pelvic lymphadenectomy followed by a deep cold-knife conization has also been proposed, but high-quality evidence is still lacking. If fertility is not an issue, radical hysterectomy, or possibly simple hysterectomy and pelvic lymphadenectomy, should be recommended.

Stage Ib–IIa

Patients with stage Ib–IIa disease have two options: primary surgery or chemoradiotherapy depending on the individual characteristics, comorbidities and preferences.

Surgical options

Radical hysterectomy and pelvic lymphadenectomy Radical hysterectomy and pelvic lymphadenectomy ensures complete excision of the tumour with adequate margins. There should be at least 5 mm clear margin from the tumour. The pelvic lymph node dissection should include obturator, internal, external and common iliac nodes. Para-aortic lymphadenectomy is not mandatory.

Complications, even in the hands of skilled surgeons, are significant and include haemorrhage and direct trauma to the bowel, bladder, ureter or obturator nerve. Chronic bowel and bladder problems that require medical or surgical interventions occur in up to 8–13% of women due to parasympathetic denervation secondary to surgical clamping at the lateral excision margins. Prolonged bladder dysfunction requiring long-term intermittent self-catheterization is reported in 2.6% of patients overall and can be very distressing. Lymphoedema as a late complication that usually develops in the first year after surgery occurs in up to 15% of patients and is permanent. Although it is most commonly relatively mild, symptoms can be quite severe and significantly affect quality of life in 3% of patients. Lymphocysts can also occur. Sexual function and psychological issues such as grieving over loss of fertility, altered body image and reduced vaginal size are not uncommon. The risk of fistula is about 1%.

Surgical approaches are now moving towards less aggressive, nerve-sparing techniques. The evidence reveals that more radical approaches offer no survival benefit and often lead to higher incidence of perioperative morbidity and chronic bladder and bowel dysfunction. The Piver–Rutledge classification for radical hysterectomy is widely used; newer classifications have also been proposed (Querleu–Morrow) [15] (Tables 61.8 and 61.9).

A large multicentre randomized controlled trial initiated in Canada (SHAPE) is expected to clarify whether simple as opposed to radical hysterectomy and pelvic lymph node dissection is as safe in the management of women with low-risk small-volume disease.

Table 61.8 Piver–Rutledge classification of hysterectomy for cervical cancer.

Type	Description
1	Extrafascial hysterectomy; removal of all cervical tissue
2	Modified radical hysterectomy; removal of medial 50% of the cardinal and uterosacral ligaments; uterine vessels are divided medial to the ureter
3	Equivalent to the classical Wertheim–Meigs operation; wide radical resection of the parametrium and paravaginal tissues; ureter dissected completely to bladder entry; uterosacral ligaments divided at origin; cardinals divided at pelvic side wall
4	Ureter divided from pubovesical ligament; superior vesical artery ligated and upper two-thirds of vagina excised
5	More radical procedure with possible bowel, bladder or ureteric dissection

Radical trachelectomy In other sites such as the breast and the vulva, the surgical treatment of cancer has become less radical and consists of wide local excision and regional lymphadenectomy/sentinel lymph node dissection without an adverse effect on cure rates. Gynaecological oncologists have attempted to apply the same principle for stage Ia2 and small-volume stage Ib cervical tumours by adopting more conservative fertility-sparing techniques [14]. Advanced maternal age and detection of early-stage disease as a result of screening increasingly enhance the value of these techniques.

Radical trachelectomy was first described by D'Argent in the mid-1980s and involves a radical excision of the cervix combined with either laparoscopic or open lymphadenectomy [17]. The commonest route of trachelectomy is the vaginal approach, though more recently some surgeons are favouring an abdominal or laparoscopic approach that facilitates a greater excision of the parametrium. The insertion of abdominal or vaginal suture at the level of the isthmus that can accommodate a 6-mm Hegar dilator is recommended in an attempt to prevent cervical incompetence. Intraoperative complications are rare. Postoperatively, about one-quarter of women suffer dysmenorrhoea or, less commonly, cervical stenosis, suture-related problems and dyspareunia.

Meta-analyses and case series based on the vaginal approach have demonstrated recurrence rates of around 4%, with mortality of 2.3%. Most recurrences have occurred in high-risk pathological types, with tumours over 2 cm in size and in patients with LVSI. Of those

Table 61.9 Querleu–Morrow classification of radical hysterectomy (2008).

Type A	Minimum resection of paracervix. This is an extrafascial hysterectomy. The paracervix is transected medial to the ureter but lateral to the cervix. The uterosacral and vesicouterine ligaments are not transected at a distance from the uterus. Vaginal resection is generally at a minimum, routinely less than 10 mm, without removal of the vaginal part of the paracervix (paracolpos)
Type B	Transection of the paracervix at the ureter. Partial resection of the uterosacral and vesicouterine ligaments, ureter is unroofed and rolled laterally, permitting transection of the paracervix at the level of the ureteral tunnel. At least 10 mm of the vagina from the cervix or tumour is resected
Type C	Transection of paracervix at junction with internal iliac vasculature system. Transection of the uterosacral ligament at the rectum and vesicouterine ligament at the bladder. The ureter is mobilized completely. Between 15 and 20 mm of vagina from the tumour or cervix and the corresponding paracolpos is resected routinely, depending on vaginal and paracervical extent
Type D	Laterally extended resection. Rare operations feature additional ultra-radical procedures. The most radical corresponds to the laterally extended endopelvic resection (LEER) procedure
Lymph node dissection	
Level 1	External and internal iliac
Level 2	Common iliac (including presacral)
Level 3	Aortic infra-mesenteric
Level 4	Aortic infra-renal

This classification can be applied to fertility-sparing surgery and can be adapted to open, vaginal, laparoscopic or robotic surgery.

attempting pregnancy, 70% delivered at term; the risk of premature delivery, late miscarriages and low birthweight is substantially increased.

Careful selection of patients is crucial as detailed assessment may optimize outcomes and minimize adverse events. These decisions necessitate involvement of a multidisciplinary specialized team with considerable experience.

Stage Ib2

Management of bulky Ib tumours (especially stage Ib2) is controversial as these tumours are characterized by high rates of positive nodes and close surgical margins. Most centres offer chemoradiotherapy as opposed to surgery but a few elect to operate; these centres have published equivalent survival data.

Prognostic factors

After surgery, histological examination of the specimen provides information on several prognostic factors that affect survival and these are discussed later. If the histology review suggests high risk of recurrence with positive pelvic nodes and 'close' resection margins (≤0.5 cm), women are commonly offered adjuvant chemoradiation. Many institutions use the GOG score, which assesses factors such as size of tumour, depth of invasion and LVSI and gives the combination score that facilitates clinician decision-making.

Stage IIb–IV

Surgery with curative intent is not possible in women with advanced stages of disease. The available treatment modalities that offer potential of cure are radical radiotherapy and chemoradiation. Stage IVb is treated palliatively, often with a combination of chemotherapy and targeted radiotherapy.

Radical radiotherapy

Radical radiotherapy aims to treat the primary tumour and metastatic pelvic lymph nodes. It is delivered by external-beam radiotherapy (teletherapy) that intends to treat any pelvic spread and by intracavitary treatment (brachytherapy) that targets the primary site. The challenge of optimal dose planning is to cure the primary disease and pelvic spread with the least possible morbidity to bowel, bladder and sexual function. The external-beam radiotherapy sessions to the pelvis are delivered daily, usually over 20–30 days, and are followed by brachytherapy, delivered locally to the cervix by high-dose radiotherapy technique. Extended radiotherapy involving the para-aortic nodes increases morbidity with no significant survival benefit. However, it may be appropriate in selected cases if para-aortic node involvement is indicated by PET scan and surgical staging.

Chemoradiation

There is now consensus that the use of concurrent cisplatin-based chemotherapy with radiotherapy is superior to radiation alone for the treatment of cervical cancer [16]. Five randomized phase III trials from the USA have shown an overall survival advantage with chemoradiation that decreased the risk of death by 30%. Allowing variations in exact schedule, dose of treatment and stage across different studies, they largely included women with FIGO stages Ib2–IVb cervical cancer treated with

primary radiotherapy and women with FIGO stages I–IIa disease found to have poor prognostic factors (metastatic disease in pelvic lymph nodes, parametrial disease or positive surgical margins) at the time of primary surgery. As expected, higher rates of short-term and medium-term morbidity have been reported, although long-term follow-up data that are awaited will help clarify the true morbidity of this treatment regimen.

Neoadjuvant chemotherapy

Neoadjuvant chemotherapy is the use of chemotherapy before definitive surgical treatment or radiotherapy. It has not been shown to be beneficial before radiotherapy and current evidence does not support such an approach. It has also been suggested that preoperative chemotherapy could be used to shrink disease and allow resectability of the tumour prior to radical surgery in inoperable cases and that this approach may be superior to radical radiotherapy. One randomized controlled trial suggested benefits but this has not been confirmed and inevitably the toxicity for those women who will require adjuvant radiotherapy seems unacceptable. Centres have also reported the use of neoadjuvant chemotherapy in women with bulky tumours prior to fertility-sparing techniques with good results.

Cervical cancer in pregnancy

Cancer of the cervix affects 1 in 10 000 pregnancies and represents about 1 in 34 cases of cervical cancer. Two-thirds of women diagnosed in the first or second trimester have a stage 1b tumour. Diagnosis may be delayed, as the symptoms may be attributed to the pregnancy and colposcopic assessment of the pregnant cervix is not always easy; advice should be obtained from an experienced colposcopist. If invasion is suspected, an adequate biopsy in the form of loop, knife or wedge cone should be taken. The principles of management remain the same and treatment is similar stage for stage.

The disease can be safely staged at examination under anaesthesia, with a chest radiograph and by MRI. For stage Ia1 disease, despite a high rate of positive margins, a LLETZ or knife cone is usually sufficient. Traditionally, more advanced stages presenting before 20 weeks' gestation are treated immediately, those presenting after 28 weeks are treated after delivery, while those presenting between 20 and 28 weeks remain in a grey zone. For stage I disease, diagnosed after 20 weeks, delaying treatment until after delivery is often the most favourable option. Delivery around 32–34 weeks is justified after administration of steroids to promote fetal lung maturation. Caesarean radical hysterectomy is recommended after delivery of the fetus by classical incision. Chemoradiation will cause spontaneous miscarriage or fetal death.

The management of cervical malignancy in pregnancy remains a challenge to the patient, the family and the multidisciplinary team involved. Careful and sensitive counselling is essential. Decisions on continuing or terminating the pregnancy and the modality of treatment should be made on an individual basis.

Follow-up and management of recurrent disease

The evidence on the role of post-treatment surveillance in the detection of recurrent disease is inconsistent, although follow-up enables much more than just detection of recurrent disease. It permits assessment of the complications of treatment and the psychological, physical and psychosexual morbidity and provides reassurance. There is no role for cervical or vaginal vault cytology in the follow-up period except in women who had fertility-sparing procedures.

In cases of suspected recurrence, MRI provides the most sensitive imaging modality that allows careful assessment of disease distribution and is required before considering further treatment. In confirmed cases, PET-CT is commonly required for the assessment of distant metastases and improved patient selection before planning radical treatment for apparently localized disease. The evidence demonstrates that this improves survival in operable cases and eliminates morbidity related to unnecessary interventions in unsuitable patients. Before considering further treatment, histological diagnosis is required followed by full re-staging.

The principles of the management of recurrent disease are similar to those of the primary tumour. The exact treatment depends on the primary treatment, the site and stage of the recurrence, the presence of distant disease, its resectability, treatment-related morbidity and the effect on quality of life, and the patient's general health and wishes.

Women treated initially with surgery should be considered for radiotherapy. If the disease is apparently confined to the pelvis, radical chemoradiotherapy is curative in 40–50% of cases. For those who have already undergone radiotherapy, the only potentially curative option is pelvic exenteration in some cases, provided the recurrence is central with no distant recurrence. Careful selection of cases and appropriate counselling is essential. In the hands of skilled surgeons and appropriate preoperative assessment, this surgery can result in a 5-year survival of 50%. However, up to one-third of procedures are abandoned intraoperatively; PET-CT appears to help patient selection.

Palliation

In progressive advanced cervical disease, urinary tract symptoms, fistulae and distressing pain due to infiltration

of the lumbosacral nerve plexuses are some of the common presentations. Ureteric obstruction and impaired renal function usually herald the terminal stage. Faeces and urine diversion with nephrostomies and stenting are only justified in cases where there is curative intent. Chemotherapy with cisplatin is also palliative and should be restricted to primary late stage or recurrent cases that are not considered curable with other treatment options. It may increase life expectancy by a few months, but this must be balanced against quality of life. Pain control and psychological and emotional support are of paramount importance in the terminal phase.

Survival and prognostic factors

The 1- and 5-year overall survival in patients with cervical cancer according to FIGO stage is shown in Fig. 61.5. Several prognostic factors influence survival.

- Stage of disease.
- Size, volume and depth of invasion of the tumour.
- Grade of tumour.
- Histological type: small cell tumours have clearly been shown to be associated with a worse prognosis.
- Lymphatic spread is probably the most important factor: the presence of positive nodes significantly reduces overall survival and LVSI is an additional prognostic factor.
- Parametrial invasion.
- Vascular invasion.
- Status of resection margins in cases where surgery was performed.

Psychological impact

Because cervical cancer usually affects young women, psychological morbidity is substantial and emotional support is essential, considering the significant effects of loss of fertility and early menopause. Treatment has a huge impact on the women's psychological and sexual well-being, with up to 50% of women suffering dyspareunia due to vaginal stenosis after chemoradiation. These issues often need to be addressed by clinicians and in some cases referral to a counsellor might be necessary [18].

The future

The single greatest advance in the prevention of cervical cancer during the last decade has been the development of the prophylactic vaccine against two oncogenic HPV subtypes, HPV-16 and HPV-18. It is estimated that this could reduce the incidence of cervical cancer by 70% in a high coverage population.

The use of MRI has improved the accuracy of the staging of cervical cancer. New imaging techniques such as PET-CT appear to improve the assessment of metastatic disease; this seems to be of value in the selection of the radiation field, particularly with regard to para-aortic node inclusion. PET appears also to be helpful in recurrent cases as the detection of disseminated disease influences management.

More conservative surgical approaches that can reduce morbidity might prove to be equally efficient. Research on the optimal management of early-stage, small-volume, low-risk cervical invasive disease is under investigation in a large randomized controlled trial. If this reveals no difference in outcomes, simple hysterectomy may replace the radical excision of the parametrium in selected low-risk cases. The use of conization or simple as opposed to radical trachelectomy is also under investigation in women who wish to preserve their reproductive potential. The use of neoadjuvant chemotherapy prior to fertility-sparing techniques has also been reported but further evidence is required on safety. Efforts to improve outcome for women with advanced disease, use of sentinel nodes and incorporation of medical technology advances such as PET-CT are some of the challenges of the future.

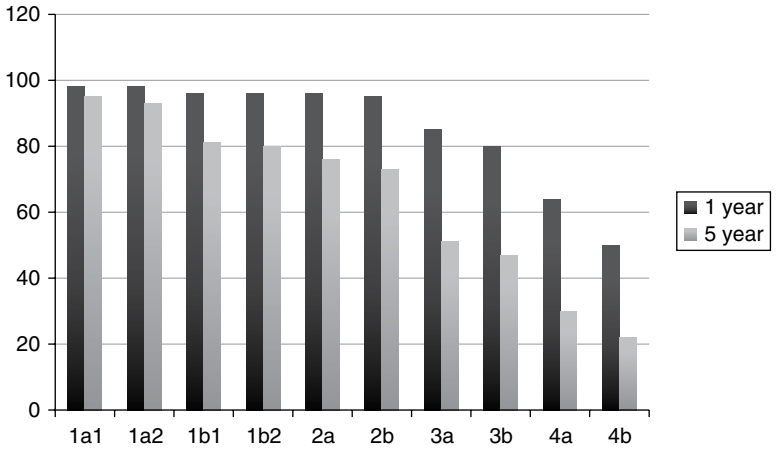

Fig. 61.5 Carcinoma of the cervix: overall survival by FIGO stage.

Summary box 61.2

- Cervical cancer is the second commonest malignancy worldwide; 75% of the cases are diagnosed in countries of the developing world that reflects the absence of screening.
- Adenocarcinomas appear to be increasingly common, accounting for approximately 20–30% of all primary cervical cancers, and have a poorer prognosis.
- Microinvasive disease can be treated by excisional cone alone.
- Surgery and chemoradiation for stage Ib–IIa disease have similar survival rates. Surgery has many advantages. Careful staging is important and allows selection of the most appropriate treatment modality as the combination substantially increases morbidity without survival benefit.
- Advances in imaging with MRI and PET-CT have improved management.
- Preservation of fertility is an option with fertility-sparing surgical techniques. Careful patient selection is required.
- The combination of chemotherapy and radiation significantly improves survival in comparison with radiotherapy but also has short- and medium-term toxicity.
- Management in pregnancy remains a challenge and decisions should be individualized.
- The disease and its treatment can have a huge physical and psychological impact on women.

Endometrial Cancer

Sean Kehoe[1,2]

[1] *University of Birmingham, Birmingham, UK*
[2] *St Peters College, Oxford, UK*

In the UK there were over 9000 cases of endometrial cancer in 2015, which means that it is now the commonest gynaecological malignancy (Fig. 62.1). Some plausible explanations include the overall increased life expectancy, obesity and also the reduction in death rates from other related malignancies, in particular breast cancer. Combined with this is the 50% reduction in the rates of hysterectomy since the early 1990s [1]. Whilst the disease affects mainly postmenopausal women, approximately 20% of cases occur in premenopausal women. The staging of endometrial cancer (using the FIGO classification) has become well embedded in practice since its introduction in 2009 [2]. Recent and ongoing randomized clinical trials continue to try to identify the optimum therapeutic approaches to care, which though primarily surgery still require an evidence base as emphasized by the international variations in care [3]. There has also been progress in understanding the genetics of endometrial cancer, and in recent years an acceptance that some tumour types, in particular serous histologies, should be considered – in surgical management terms at least – somewhat similar to serous ovarian cancers. This chapter provides some updates on the management of this disease.

Aetiology

The recognized risk factors for endometrial cancer are shown in Table 62.1. Besides these, there are other environmental factors that influence the disease, as suggested by the variation in the disease in different countries (Fig. 62.2). The main risk is excessive exposure of the endometrium to oestrogen, which has a direct association with both obesity and diabetes. Other factors such as older age and hypertension are inter-related with the factors above. Age remains the main risk factor, with the highest incidence recorded in women over the age of 50 years.

Genetics

Only one condition has been specifically identified as having a hereditary relationship with the development of endometrial carcinoma. Known as hereditary non-polyposis colon carcinoma or Lynch type II syndrome, this is an autosomal dominant condition; the main associated primary malignancy is colonic carcinoma, normally developing in women under 40 years of age. The Amsterdam criteria are used to define those families who conform to the definition of this condition, with the final diagnosis genetically determined and including a variety of mutations, of which *MSH2* and *MLH1* are the commonest [4].

In such families the lifetime risk of developing endometrial carcinoma is about 40%, and also relevant is the fact that the lifetime risk of developing ovarian cancer is 12%, nearly 10 times the population risk. At present there are no strategies except prophylactic surgery to prevent these women developing endometrial cancer. Reports on a small series of women with this condition undergoing annual scans and endometrial sampling concluded that such an approach seemed to detect earlier cancers, suggesting that screening may be beneficial. However, the paucity of cases makes this very much an assumption, though an acceptable approach in managing those women desiring to retain reproductive function. A possible alternative is the potential of the Mirena® intrauterine system in preventing the disease in such women [5,6]. A clinical trial to evaluate this failed to recruit and was abandoned. Although this is intuitively a reasonable approach, women agreeing to this therapy need to be informed of the limited evidence. When the woman's family is completed, recommending a hysterectomy is a reasonable course of action, removing any need for ongoing unproven screening systems and likely alleviating the psychological aspects associated with the potential to develop this disease. The increased risk of ovarian cancer may also justify removal of the ovaries,

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Fig. 62.1 Rates of endometrial cancer in the UK. *Source:* Cancer Research UK.

Table 62.1 Risk factors for endometrial cancer.

High levels of oestrogen/endometrial hyperplasia
Obesity/hypertension/diabetes
Polycystic ovary syndrome [5]
Nulliparity (never having carried a pregnancy)
Tamoxifen use/breast cancer
Post-menopausal
Hereditary non-polyposis colorectal cancer

though each case must be managed in accordance with the woman's needs and wishes.

Nulliparity

Nulliparity is associated with a risk of endometrial cancer. However, this may only be one of many factors involved, with some relationship to the individual's hormonal profile during life. Nulliparous women have significantly increased episodes of endometrial shedding events during their menstrual lives in comparison with parous women. In ovarian cancer, there is a direct association between the lifetime number of ovulatory cycles and the risk of ovarian cancer (the higher the number of ovulatory cycles, the greater the risk), and this could be also applied to the risk of endometrial cancer.

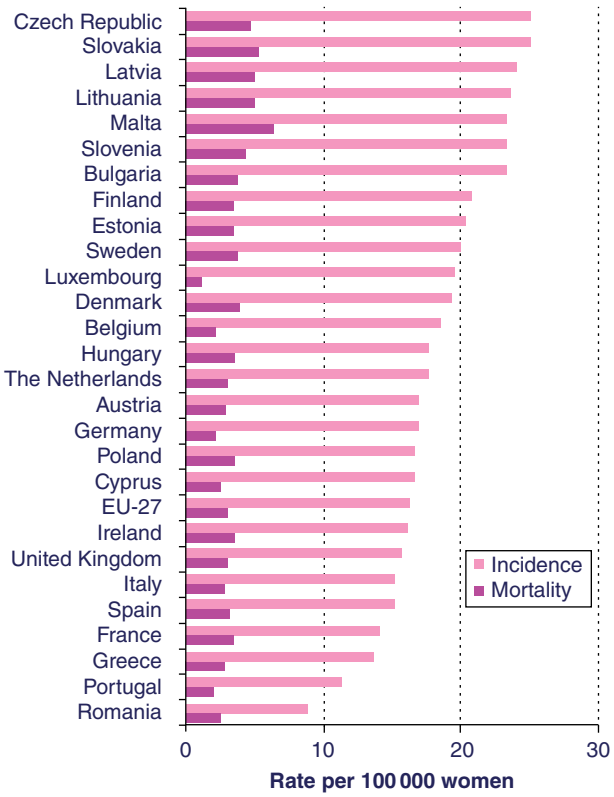

Fig. 62.2 Age-standardized (European) incidence and mortality rates, body of uterus cancer, EU-27, 2008 estimates.

The follicular phase of the cycle exhibits increasing proliferation (which increases the probability of abnormal cellular development) and strategies which reduce this may protect against abnormal mitosis. While this remains to be proven in endometrial cancer, it is a reasonable hypothesis. Of course, the use of the combined oral contraceptive, even with menstruation, affords some long-term protection (risk reduction of 50%) giving some support to the theory.

Obesity

Obesity is thought to be related to the development of about 30% of cancers in humans. In obese women, excess oestrogen is produced by the conversion of androgens in the fat, and thus the endometrial tissue has increased exposure to estrone. This is particularly pertinent considering the increased incidence of obesity in the Western world, and the concomitant increased rates of endometrial cancer.

Endometrial hyperplasia

Hyperplasia is defined as excessive proliferation of normal cells, and atypical hyperplasia is associated with a high risk of endometrial cancer. In a number of series, the risk of underlying malignancy has been shown to be higher than expected. A Gynecologic Oncology Group study in the USA of 348 women diagnosed with atypical hyperplasia on sampling were eventually found to have a frank malignancy in 46.8% of cases [7]. Similar data from the UK showed a risk of 45.9% [8]. Thus it may be preferable to consider these patients as having endometrial cancer and expedite surgery.

Clinical presentation

Postmenopausal bleeding is the commonest presentation in endometrial cancer, and up to 10% of these women will have a diagnosis confirmed. As such, their access to diagnostics must be deemed urgent. The final diagnosis is confirmed by histology. Based on the UK National Institute for Heath and Care Excellence (NICE) guidelines, all women with postmenopausal bleeding should have a transvaginal ultrasound and those with an endometrial thickness greater than 5 mm should undergo sampling of the endometrium. However, many use a cut-off of 4 mm, based on cost-efficacy and detection rates. Sampling can be undertaken in three ways: Pipelle, outpatient hysteroscopy or hysteroscopy and curettage under a general anaesthetic. All methods of sampling will miss some cancers but the rate of failure is not significantly different between outpatient sampling and hysteroscopy. Naturally, avoiding a general anaesthetic is preferable where possible and only patients in whom an endometrial sample cannot be obtained in outpatients should hysteroscopy under a general anaesthestic be considered, accepting the inevitable exceptions.

Abnormal bleeding in the premenopausal women, particularly intermenstrual bleeding in women over the age of 45, should prompt investigations including ultrasound and endometrial sampling. Whilst the overall incidence of malignancy in this group is small, nevertheless about 20–25% of all endometrial cancers occur in the premenopausal/perimenopausal age group.

Types of endometrial cancer

Endometrial cancer is categorized into type I and type II disease. The defining factors associated with these are shown in Table 62.2.

The main histological subtypes are shown in Table 62.3 and some of these may well be related to certain agents. In particular, the use of adjuvant tamoxifen in breast cancer has been proposed to be associated with some of the rarer tumours such as mixed Müllerian tumours, now called carcinosarcomas. There are no specific indicators regarding the other subtypes. Leiomyosarcomas are usually an unexpected finding following removal of a fibroid uterus. The mitotic activity of these tumours relates to their metastatic potential, with mitotic counts of less than 5 per high power field associated with a very good outcome, whereas a count above 10 per high power

Table 62.2 Endometrial cancer types.

Type I
Premenopausal and perimenopausal women
History of unopposed oestrogen exposure
Endometrial hyperplasia
Minimally invasive, low-grade endometrioid type
Good prognosis
Type II
Postmenopausal women
Not associated with increased exposure to oestrogen
High-grade tumours
Poorer prognosis

Table 62.3 Histological subtypes in endometrial cancer.

Endometrioid adenocarcinoma, 50–60%
Adenosquamous, 6–8%
Serous papillary, 18%
Sarcomas/leiomyosarcomas, 3–5%
Carcinosarcomas, 2–3%
Clear cell, 1–6%

field is associated with a worse prognosis. Other subtypes recognized as more aggressive include papillary serous and clear cell tumours, accounting for 10–15% of all tumour types. In most cases adjuvant therapies (after surgery) would be considered.

In some rare cases of sarcomas, preoperative diagnosis may be suspected when the endometrial sampling indicates this diagnosis histologically, or when a preoperative chest X-ray shows evidence of metastatic disease, normally called 'cannon-ball' metastases. The differentiation of the disease is also important, as the grade in association with other factors will influence the recommendation for adjuvant therapy.

Management

Preoperative investigations

The FIGO staging for endometrial cancer is shown in Table 62.4. This was redefined in 2009, with positive cytology, previously allocated to stage III disease, now abandoned as part of the staging process. As part of staging, there are agreed preoperative investigations which can be performed. A chest X-ray is recommended, although a CT scan may replace this. MRI/CT can be of value in some situations to ascertain if any extrauterine disease exists, which may influence the role of surgery. The value of MRI in defining the depth of tumour invasion has been examined with a view to deciding the need to excise lymph nodes but it has proved too inaccurate to be of clinical value.

Table 62.4 Carcinoma of the endometrium, FIGO staging 2010.

Stage	Description	5-year survival (%)
IA	Tumour confined to the uterus, no or less than half myometrial invasion	80–90 (I)
IB	Tumour confined to the uterus, greater than half myometrial invasion	
II	Cervical stromal invasion, but not beyond uterus	60–70 (II)
IIIA	Tumour invades serosa or adnexa	50–60 (III)
IIIB	Vaginal and/or parametrial involvement	
IIIC1	Pelvic node involvement	
IIIC2	Para-aortic involvement	
IVA	Tumour invasion bladder and/or bowel mucosa	10–20 (IV)
IVB	Distant metastases including abdominal metastases and/or inguinal lymph nodes	

Besides these investigations, cystoscopy, sigmoidoscopy and an examination under anaesthetic are all part of the staging procedure. Notably, endometrial cancer can be staged both clinically and surgically, with surgical staging being most commonly employed.

Surgical interventions

Surgery remains the primary intervention for endometrial cancer. Whilst radiotherapy is an alternative, from retrospective case–control studies it would seem that surgery affords a better survival outcome. It is unlikely that there will ever be a randomized controlled trial comparing primary radiotherapy to surgery.

The removal of the uterus and (normally) the ovaries is the recommended basic surgical procedure. This may be performed by open laparotomy or by a laparoscopic approach. Studies have shown the advantages regarding short- and long-term recovery when the laparoscopic approach is taken, which may entail either a laparoscopic-assisted vaginal hysterectomy or a laparoscopic total hysterectomy [9,10]. Robotic surgery has also become part of the surgical approach, but the consensus is that where possible the minimally invasive approach is preferable. Obviously, it is recommended not to insert any instruments into the uterine cavity during such surgery. Also, clamping/ligating the fallopian tubes at commencement of surgery would seem a reasonable action to prevent any disease dissemination when moving or handling the uterus.

In some circumstances, the procedure could be performed vaginally, and indeed this is acceptable as long as the ovaries can be removed. However, a vagina-only approach will not permit access to the pelvic lymphatics, thus limiting this type of surgery to selected patients.

Lymphadenectomy in endometrial cancer

The risk of lymphatic spread in endometrial cancer is influenced by the tumour grade, type and depth of invasion into the uterine wall (Table 62.5). Knowledge of lymphatic disease forms part of the staging process and can influence adjuvant therapy. However, debate still

Table 62.5 Lymph node metastases in endometrial cancer.

Variable	Pelvic/para-aortic nodal disease (%)
<50% uterine invasion and grade1	0–3
<50% uterine invasion and grade2/3	2–6
>50% uterine invasion and grade 1	15–18
>50% uterine invasion and grade2/3	up to 30

surrounds the value of routine pelvic and para-aortic lymphadenectomy, and randomized trials are required to resolve this issue.

There has only been one prospective randomized trial reported on lymphadenectomy in endometrial cancer. This study, called ASTEC (A Surgical Trial in Endometrial Cancer), randomized over 1400 women with clinically early-stage disease [11]. The study included two parts: (i) patients randomized to pelvic lymhadenectomy or not, and (ii) patients randomized to adjuvant pelvic radiotherapy or not in high-risk cases. The use of brachytherapy (outome reported in Blake *et al.* [12]) was permitted and the decision made locally as to whether this was used. The patient cohort receiving radiotherapy were not necessarily those recruited to the surgical aspects of the study. The conclusions were interesting in that the use of lymphadenectomy did not alter survival rates, and indeed it was suggested that it may have a negative impact on outcome, for reasons yet to be explained. Also, the number of lymph nodes retrieved did not influence outcome. Although the study was confined to patients with disease localized to the uterus (based on clinical examination and imaging in some cases), it does indicate that lymphadenectomy should not be undertaken in this group of patients.

Lymphadenectomy and non-randomized studies

There are many non-randomized reports on the role of lymphadenectomy of pelvic and para-aortic nodes in endometrial cancer. All these studies naturally suffer from the fact that there are no randomized controlled trials. Some groups suggest that, in particular, para-aortic nodal excision has a therapeutic effect, based on the fact that those who undergo this therapy have longer survival and a notable reduction in relapse disease affecting the para-aortic region [13]. Also, such resection either permits the avoidance of adjuvant radiotherapy in some cases, or identifies those where the radiotherapy field can be extended to incorporate the para-aortic region. The main problem with these debates is the lack of appropriate high-level evidence that lymphadenectomy has a real therapeutic effect on survival and indeed that extension of the field of radiotherapy influences survival. Without doubt both these procedures increase morbidity. There is an urgent need to address this issue and ensure patients are been managed in a manner whereby the morbidity of the intervention can be justified by the improved patient outcome. It can be anticipated that such trials will be undertaken in the near future.

Debulking in advanced disease

When the disease has obvious macroscopic spread beyond the uterus or indeed the pelvis, then multimodal therapy will be required, be this surgery to alleviate symptoms followed by radiotherapy with or without chemotherapy. The combination of chemoradiotherapy increases morbidity, and in endometrial cancer this poses major challenges, as many patients have other comorbidities whereby such a combination may be deemed inappropriate. Debulking surgery, an approach taken in ovarian cancer for some decades, has been reported in some small series in endometrial cancer, with a suggestion that a smaller residual tumour load correlated with a better survival outcome. This is based primarily on retrospective data or small case–control studies and the evidence for this is very poor. There is no agreement that this should be considered accepted therapy for endometrial cancer at present. However, even in advanced disease, removal of the uterus may yield immediate alleviation of symptoms such as persistent vaginal bleeding, which could justify the intervention.

Fertility-sparing surgery

As women are increasingly delaying having children, the issue of fertility-sparing options has become more common, and this is relevant to many other malignancies. There are limited publications relating to such management and the number of cases is small, making firm conclusions difficult. Longer-term outcomes are equally lacking and therefore before embarking on this therapeutic option, it is imperative to provide the patient with advice based on current information and the 'unknown' risks, particularly as this is a deviation from the normal recommended intervention that could potentially exclude the patient from a recommended curative therapy.

In those cases reported, the disease was always well differentiated and on clinical and imaging evaluations confined to the uterus (i.e. FIGO stage 1). Women were then exposed to various progestagenic agents, with careful evaluation of response by curettage at 6 weeks, 3 months and 6 months from commencement of therapy [14]. Evidence of non-response resulted in immediate surgery and in those with response some pregnancies are reported. A hysterectomy was normally performed following a successful pregnancy.

Radiotherapy

Primary

Radiotherapy can be used either as a primary or adjuvant therapy. In primary therapy, this is normally where disease spread renders surgery impossible or inappropriate. It is not considered superior to surgical intervention, with an estimated reduction in 5-year survival of about 5% when compared with surgery in early-stage disease, though this is based on retrospective series.

Adjuvant

The use of radiotherapy in an adjuvant setting continues to be modified. Original studies indicated that the use of brachytherapy with external-beam pelvic radiotherapy may be beneficial in those with high-grade disease. This original study from the 1980s by Aalders *et al.* [15] randomized 540 patients with early-stage disease to brachytherapy versus brachytherapy and external-beam therapy after undergoing surgery. The relapse rates in the latter group was reduced, although overall 5-year survival was equivalent in both groups. Further analysis suggested that patients with grade 3 tumours infiltrating greater than 50% of the myometrium might benefit from the addition of pelvic radiotherapy.

Two recent trials, the PORTEC and ASTEC trials, have changed the role of adjuvant radiotherapy [12,16]. In the PORTEC study, 715 women with stage I disease were recruited and randomized to pelvic radiotherapy versus no treatment after undergoing a hysterectomy and bilateral salpingo-oophorectomy. The 5-year survival rates were 81 and 85%, respectively. The recurrence rates were lower in the radiotherapy groups (4% vs. 14%), but in those relapsing and then receiving radiotherapy the survival was the same. Analysis showed that radiotherapy was not necessary in women with stage I endometrial cancer who were below 60 years of age with grade 1 or 2 tumours and with more than 50% myometrial invasion.

The ASTEC study had two parts where patients were randomized, the second looking at external-beam therapy to the pelvis. All had undergone surgery, consisting of at least a total hysterectomy and bilateral salpingo-oophorectomy. The conclusions were that the routine use of external beam with brachytherapy reduced the incidence of recurrent disease, and increased the disease-free survival, but did not have any positive impact on overall survival. The authors also suggested that there may be a possible survival benefit in those with high-grade disease.

Chemotherapy

When distant metastatic disease is present, systemic treatments are required. For endometrial cancer, chemotherapeutic agents or hormonal therapies are used. Cisplatin and doxorubicin are the commonest cytotoxics used, with medroxyprogesterons the most used hormonal therapy [17–19]. Many trials reporting systemic therapies are small phase II studies, and the overall response rates range from 7 to 69% depending on the study. As previously stated, the comorbidities within this patient cohort often means that hormonal therapy is the best option due to its ease of administration and lack of adverse side effects.

Many smaller series have suggested that the combination of radiotherapy with chemotherapy may improve outcome, by reducing local pelvic recurrences and also extra-pelvic disease relapse. Such effects have been proven in chemoradiotherapy as used in cervical tumours. PORTEC 3 is an ongoing prospective randomized trial that compares standard radiotherapy with combination treatment, and the results should hopefully give guidance to the best option.

Relapsed endometrial cancer

The main issues with respect to deciding the best therapy for a patient with relapsed endometrial cancer are (i) prior exposure to non-surgical interventions, (ii) the site of disease relapse, whether localized or multiple, and (iii) the patient's physical condition. Thus investigations used are similar to those within the staging system, though where available positron emission tomography (PET) can be useful in selected situations.

The commonest site of relapse is the vaginal vault and if the disease is localized and the area radiotherapy-naive, radiation is the first course of intervention. If the disease is localized but has previously undergone radiotherapy, then surgical excision (partial vaginectomy) can be performed. If there are distant metastases, then systemic therapy is necessary and depending on the patient's physical condition either chemotherapy or hormonal therapies can be used. The response rates are variable but never very high, and the effect is poorer for disease relapsed within a field of radiotherapy.

Exenterative surgery [20], when bladder, vagina and rectum are excised, is only undertaken in very carefully selected patients, and may be occasionally justifiable as a palliative procedure. In the main, many patients have such comorbidities that such surgery is generally deemed unsuitable.

Conclusion

Endometrial cancer is a disease increasing in incidence though retains a relatively good prognosis. Primary intervention is mainly surgical, with selected patients having adjuvant therapies. Advances in surgical techniques continue to reduce surgically associated morbidity, though in a population with rising obesity, maintaining morbidity rates is challenging. In some early-stage disease lymphadenectomy is unnecessary, but in higher-risk populations trials are required to

define the role of lymphadenectomy, both pelvic and para-aortic. Randomized trials are redefining the role of adjuvant therapies; in particular the role of chemotherapy in high-risk patients is awaited. Prevention is inevitably the ultimate goal, and can be partially achieved through educational health policies in reducing the incidence of obesity. In the future, screening may detect premalignant or early-stage disease and thus also improve survival rates. However, the latter still requires further research to establish the optimum modalities to employ. Inevitable, the future will also include a greater understanding of the disease and improved individualized therapy, focused more on the actual disease biology rather than based purely on the disease stage and histological subtype.

Summary box 62.1

- Endometrial cancer is now the commonest gynaecological cancer due to many factors: obesity, reduced hysterectomy rates and longevity.
- Surgery remains the mainstay of therapeutic intervention.
- Clinical trials have revealed the limited value of pelvic lymphadenectomy in early-stage disease and the outcome of trials on lymphadenectomy in high-risk patients is awaited.
- Adjuvant radiotherapy is still used, although trial results regarding its benefit in combination with chemotherapy in high-risk patients are awaited.

Surgical and Medical Management of Epithelial Ovarian Cancer

Christina Fotopoulou[1,2], Hani Gabra[1] and Sarah P. Blagden[3]

[1] *Department of Surgery and Cancer, Imperial College London, London, UK*
[2] *Queen Charlotte's and Chelsea Hospital, London, UK*
[3] *University of Oxford, Churchill Hospital, Oxford, UK*

Epithelial cancer of the ovary, fallopian tube or primary peritoneum, collectively described as 'ovarian cancer' or EOC throughout this chapter, is relatively uncommon. It represents 2% of total cancer cases in the UK (data from 2013) but is the most lethal of all gynaecological cancers. This is partly due to its insidious presentation but also because of its intrinsic histological and molecular heterogeneity [1]. EOC comprises at least five distinct histological subtypes (high-grade serous, endometrioid, clear cell, mucinous, seromucinous and low-grade serous), the most common and well studied being high-grade serous ovarian cancer (HGSOC). For the majority of patients after successful initial treatment with debulking surgery and chemotherapy, the disease will relapse and become increasingly resistant to chemotherapy with each episode of recurrence. Future treatment strategies, as well as improving response to front-line therapy, are focusing on ways to overcome chemotherapy resistance in the relapsed setting, with the judicious use of novel cytotoxic and/or targeted therapies. These options are realized with improvements in our understanding of the molecular behaviour of the disease. In this chapter, we summarize the current status quo of the surgical and medical management of ovarian cancer and present results from a number of key studies that have explored genetic, molecular and histological targeted strategies in the treatment of this disease.

Aetiology, epidemiology and genetics

EOC is diagnosed in approximately 7300 women every year in the UK and 239 000 women worldwide (www.wcrf.org). Although EOC is relatively uncommon, representing 2% of total cancer cases in the UK (data from 2013), it has a 46.2% age-standardized 5-year survival in the UK (www.cancerresearchuk.org) and the USA (www.seer.cancer.gov), indicating that more than half of patients diagnosed with the disease die within 5 years. It is generally a disease of older women, the incidence peaking at the age of 67 years [2,3]. There is geographic variation: it is more common in developed countries such as in northern Europe and in the USA, where rates exceed 9 per 100 000 women, than in developing countries such as parts of Africa and Asia [3]. As incessant ovulation is a contributing factor, the geographical variation is most likely due to differences in parity rates, with women in developed countries electing to have smaller families and therefore undergoing a higher number of ovulation events during their lifetime.

In large case–control studies, factors that interrupt ovulation like multiparity, breastfeeding, late menarche and early menopause reduce the risk of EOC [4]. The Collaborative Group on Epidemiological Studies of Ovarian Cancer conducted a re-analysis of 45 epidemiological studies and showed that 10 years of use of the oral contraceptive pill (OCP) gives a 33% reduction in risk of incidence of EOC before the age of 75. They estimate that the OCP has prevented 200 000 cases of EOC so far, and will prevent at least 30 000 cases per year in the future in developed countries [5]. Although the overall incidence of EOC has risen since the late 1970s, between 1997–1999 and 2011–2013 there has been an 8% decline in the European age-standardized incidence of the disease (www.cancerresearchuk.org). This most likely reflects the impact of the introduction of the OCP into UK family planning clinics from 1974 and its adoption by women who are now approaching their fifties and sixties. As use of the OCP has increased exponentially since then, the incidence of EOC is predicted to decline further. However, this decline may be reversed in future decades if intrauterine devices replace the OCP as the preferred method of contraception.

Factors linked to increased risk of the disease include late conception, smaller family size, obesity and use of

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

hormone replacement therapy (HRT), although the latter is still controversial, with data from a recent meta-analysis suggesting that women who use hormone therapy for 5 years from age 50 years have approximately one extra ovarian cancer case per 1000 women [6–8]. Less significant risk factors include increased height and weight (contributing to a 3% increase in the disease per decade [9]) and use of peritoneal talcum powder [10]. Interestingly, a recent analysis of epidemiological studies by histotype suggests that incessant ovulation risk factors are more predominantly linked to endometrioid and clear cell ovarian cancer [11] whilst the commonest and most lethal HGSOC has fewer associated risk factors.

Genetic factors dominate risk for 5–15% of EOCs, associated with three main inherited defects to DNA damage repair genes, *BRCA1* and *BRCA2* gene mutations (associated with site-specific ovarian cancer syndrome and breast–ovarian cancer syndrome) and mutation of mismatch repair (MMR) genes (associated with type 2 Lynch syndrome or hereditary non-polyposis colorectal cancer) [12]. The introduction of more widespread *BRCA* testing and the recent availability of commercial genomic testing kits (e.g. 23andMe) means that many women are presenting to clinicians with the knowledge they are at increased genetic risk of EOC.

It has been suggested that 50% of patients with sporadic HGSOC (i.e. who have not inherited a genetic mutation) have acquired the disease because of somatic alteration to either *BRCA* genes or other homologous recombination-associated genes such as *ATM*, *RAD51* and *FANC* [13,14]. This phenomenon is described as 'BRCAness' and is caused by a variety of mechanisms, such as somatic mutations, gene methylation or other epigenetic mechanisms, as well as downstream pathway alterations [15,16].

Summary box 63.1

- Risk of EOC (particularly endometrioid and clear cell histotypes) corresponds to number of lifetime ovulation events.
- Thus low parity, late parity, early menarche and late menopause are factors associated with increased cancer risk, whilst breastfeeding, multiparity and use of OCP are protective factors.
- Other minor risk factors include obesity, use of HRT, tall stature and use of peritoneal talcum powder.
- Between 5 and 15% of cases of EOC are caused by inherited genetic factors: *BRCA1* and *BRCA2* mutations and, less commonly, mismatch repair gene mutations.
- Tubal ligation is associated with reduced risk of endometrioid and clear cell ovarian cancer.
- Somatic aberrations to *BRCA* and other DNA repair genes have been identified in up to 50% of cases of HGSOC.

Subclassification of ovarian cancer

EOC is being increasingly recognized as consisting of a diverse group of tumours rather than a single tumour. Traditionally, it is classified by its histological features such as grade and type (e.g. high-grade serous, endometrioid, clear cell, seromucinous, low-grade serous, mucinous) and this is still the predominant information used to guide clinical care. In 2004, Shih and Kurman, pathologists from Johns Hopkins University, described a dualistic model in which EOC was further divided into two subtypes according to both its morphology and genetic features [17]. This has recently been updated by the authors [18] (Table 63.1).

Type I tumours comprise low-grade serous, endometrioid, clear cell, mucinous and transitional carcinomas. Apart from clear cell and mucinous cancers, these tumours behave in an indolent fashion, lack *TP53* mutations, are confined to the ovary at presentation and are relatively genetically stable. They are believed to originate from benign lesions such as endometriosis or a cystic ovarian neoplasm, sometimes via an intermediate step of borderline disease. In contrast, type II tumours comprise high-grade serous, undifferentiated, and malignant mixed mesodermal tumours (carcinosarcomas). These are highly aggressive and usually present at an advanced stage with a high frequency of *TP53* mutations.

The availability of genomic databases (e.g. The Cancer Genome Atlas, TCGA) has enabled further division of EOC into molecular subtypes (C1–6), four of which reclassify HGSOC into 'immunoreactive', 'differentiated', 'proliferative' and 'mesenchymal' subtypes [19]. Further analyses of these four subtypes have demonstrated association with survival outcome, the mesenchymal type having the poorest prognosis [20]. However, these subtypes are not, as yet, used to guide treatment decisions. As well as the high degree of genetic alterations, there is also a significant post-translational contribution to the ovarian cancer phenotype that is not captured in gene expression data.

Clinical presentation

EOC has often been described as a 'silent killer', with approximately 75% of patients being diagnosed at a late stage (stage III/IV). The current 5-year survival for EOC is 30–40%, but that of early-stage disease (e.g. stage I) is 84–94%, indicating a bias towards late diagnosis. This is mainly because the symptoms and signs of early-stage EOC are subtle or absent whereas those of advanced EOC include abdominal distension due to bowel gas or ascites, a pelvic mass, abnormal bowel sounds, difficulty in passing urine, palpable abdominal masses, lymphadenopathy, pleural effusion, an umbilical mass

Table 63.1 Subclassification of ovarian cancer.

Tumour type	**Type 1**						**Type 2**		
Histological classification	Endometrioid carcinoma	Clear cell carcinoma	Seromucinous carcinoma	Low-grade serous carcinoma	Mucinous carcinoma	Brenner tumours	High-grade serous carcinoma	Carcino-sarcoma	Undifferentiated carcinoma
Tissue of origin	Endometriosis	Endometriosis	Endometriosis	Fallopian tube	Germ cell/ transitional cell	Transitional cell	Fallopian tube	Fallopian tube	Fallopian tube
Features	Typically low grade, low proliferative activity, possible to identify early, slow and indolent growth						Typically high grade, high proliferative activity, good response to chemotherapy (but frequently recur), challenging to detect early, rapid and aggressive growth		
Common molecular pathway aberrations	MMR deficiency Wnt-catenin pathway activation, inactivating ARID1A, PI3K pathway activation, PTEN pathway inactivation			ERB2/KRAS/BRAF/MEK pathway activation		Unknown	Extensive genomic variations, HR DDR deficiency, P53 inactivation, CCNE1, NOTCH3 activation, Rb, NF1 inactivation	Unknown	Unknown

(Sister Joseph's nodule) and, rarely, intra-abdominal organomegaly. A number of ovarian cancer charities have championed increasing awareness of these symptoms amongst women and their primary care providers in the hope this will lead to earlier diagnosis, reduction in treatment-related morbidity and an increase in survival from the disease. The current guidance for primary care providers seeing women with symptoms suspicious of ovarian cancer recommends abdominopelvic examination, transvaginal ultrasound scan (TV-USS), serum CA125 test and, if any of these are abnormal, referral to the local gynaecology service.

Summary box 63.2

Symptoms associated with ovarian cancer

- Abdominal distension.
- Abnormal bowel sounds.
- Difficulty in passing urine.
- Dyspnoea from pleural effusion.
- Palpable lymphadenopathy.

CA125: ovarian cancer tumour marker

CA125 is a serum glycoprotein and the current gold-standard biomarker for EOC. Although it is an approved test both for the differential diagnosis of a pelvic mass and as a serial response marker in patients undergoing treatment for EOC, it has poor specificity for the disease. It is elevated in other benign and malignant ovarian and non-ovarian related conditions [21–23]. For this reason, as a stand-alone test, CA125 is neither adequate for diagnosis nor for screening (as described below). In addition, CA125 is elevated in only 80% of women with established EOC, and in only 50% of those with early-stage disease. In patients whose CA125 is elevated at diagnosis (i.e. raised above the normal range of 0–35 IU/L), serial CA125 measurement is a useful means of assessing response to chemotherapeutic treatment. The Gynecological Cancer Intergroup have developed criteria using change in CA125 as a validated measure of response to anticancer treatment. This is often used in combination with Response Evaluation Criteria In Solid Tumors (RECIST) criteria as a clinical outcome measure in EOC studies [24,25]. Levels of CA125 have been shown to have some prognostic significance [26], although other measures such as stage of disease at diagnosis are better predictors of survival outcome. Routine evaluation of CA125 (in those who express the marker) is performed in patients attending clinic for surveillance having completed treatment for front-line or relapsed EOC. An elevated CA125 is often the first warning of disease relapse, shown to precede emergence of symptoms by an average of 4.8 months [27]. Other markers have been evaluated for use in combination with CA125 to diagnose EOC, the most well-known being human epididymis 4 (HE4), a marker of proliferation in ovarian cancer cells. When used in combination with CA125 as a diagnostic, HE4 has been shown to marginally improve on the specificity of CA125 alone [28], particularly in discriminating endometriosis from malignancy. However, the lack of prospective evidence of superiority compared with existing methods of diagnosis (ultrasound, etc.) means HE4 is not approved for use as a diagnostic. However, in non-NHS settings, the HE4 test is being used in combination with CA125 calculated using the ROMA algorithm, to assist in the non-surgical evaluation of ovarian masses, even though recent evidence suggests that the combination is no better than CA125 alone [29,30]. Various studies have explored other combinations of markers but none have so far proved superior to CA125.

Summary box 63.3

CA125

- Serum CA125 is approved in the differential diagnosis of pelvic masses and as a means of monitoring response in patients receiving treatment for ovarian cancer.
- Levels of CA125 above 35 IU/L are considered abnormal.
- CA125 is relatively non-specific: it is elevated in benign conditions, but is normal in 20% of women with established ovarian cancer and in 50% of those with early-stage cancers.
- Other serum markers such as HE4 can be used to improve the diagnostic accuracy of CA125 alone.

EOC precursor lesions

Many epithelial cancers have defined precursor lesions that can be detected in coordinated screening programmes. Examples are serial Papanicolaou (Pap) smears used to detect pre-invasive cervical intraepithelial neoplasia (CIN) as precursors for cervical cancer; mammographic detection of ductal carcinoma *in situ* (DCIS) as a precursor of breast cancer; and endoscopic detection of dysplastic changes in the oesophageal epithelium (known as Barrett's oesophagus) that can precede oesophageal cancer. A similar screening programme for EOC is challenging as it has no clearly defined, or identifiable, precursor lesions. EOC was originally believed to arise from dysplastic squamous epithelial cells covering the ovary or inclusion cysts formed from invaginations of the ovarian

surface epithelium [31]. However, subsequent pathological and epidemiological studies have suggested there are distinct tissues of origin for each of the main EOC histotypes. For example, endometrioid and clear cell EOC are believed to be derived from endometriotic tissue that has migrated along the fallopian tube onto the ovary [32], consistent with the protective association between tubal ligation and reduced incidence of these (as well as serous) cancers [11]. Mucinous EOC is hypothesized to arise from Walthard nests, benign clusters of epithelial cells with morphological similarities to urothelial tissue present at tubal–mesothelial junctions [33]. The strongest precursor association has been between HGSOC cancers and fallopian tube premalignant lesions termed serous tubal intraepithelial carcinomas (STICs) located at the tubal–peritoneal junctions. This discovery came from pathological analyses of specimens collected at the time of prophylactic salpingo-oophorectomy in women with an inherited predisposition to EOC [34]. STIC lesions have also been identified in the fallopian tubes of 70% of patients with sporadic ovarian and serous peritoneal cancer, implying its association is not limited to *BRCA* carriers [35]. Whether STICs are precursors for all cases of HGSOC is still a matter of debate [36,37]. Of note, *TP53* mutations have been identified in STIC lesions and not in inclusion cysts, supporting STICs as bone-fide precursor lesions [38]. The finding of EOC precursor lesions not only facilitates preventative strategies but also provides potential screening opportunities.

Summary box 63.4

EOC precursor lesions by histotype

- High-grade EOC is believed to arise from fallopian tube STIC lesions.
- Endometrioid and clear cell EOC arise from retrograde transport of endometriotic tissue onto the ovary.
- Mucinous EOC is thought to arise from collections of urothelial-type cells called Walthard nests.

Screening and prophylactic oophorectomy

As around 75% of women with EOC present at an advanced stage, when cure rates are less than 30%, a case can clearly be made for screening women to try to identify the disease earlier and when cure is more likely. EOC screening is not currently part of routine clinical practice as it has yet to demonstrate a survival advantage in clinical trials. The two most influential studies were the Prostate, Lung, Colorectal and Ovarian Cancer Screening (PLCO) study in the USA and the UK Collaborative Trial of Ovarian Cancer Screening study (UKCTOCS) that recruited 78 000 and 200 000 women, respectively.

In the PLCO study, which completed enrollment in 2001 and extended follow-up in 2016, around 78 000 women aged 55–74 were recruited across the USA and randomized to screening versus no screening. The 28 000 women in the screening arm underwent annual TV-USS for 4 years and annual CA125 measurement for 6 years but were also screened for colorectal and lung cancers [39]. Patients then received postal follow-up questionnaires for at least 13 years from randomization. Although more ovarian cancers were identified in the screening arm (212 vs. 176 in control group), these were not early-stage cancers and there was no improvement to short- or long-term mortality [40]. Positive predictive value (PPV, which gives a percentage of true positives over the sum of true plus false positives) was low at 3.7% in the CA125 group and 1% in the TV-USS group. This reflected the high number of false positives identified. As positive findings required surgical investigation, there was an associated risk of operative complications in these patients, with a 15% incidence of serious complications (such as infection, blood loss, bowel injury or cardiovascular event) incurred in those undergoing exploratory surgery in the false-positive group.

The UKCTOCS study recruited over 200 000 postmenopausal women aged 50–74 from centres within the UK [41]. Patients were randomized to no treatment (control arm), annual CA125 with subsequent TV-USS in the multimodal screening (MMS arm) or annual TV-USS alone (USS arm). A Bayesian CA125 risk score termed the Risk of Ovarian Cancer Algorithm (ROCA) was incorporated into the MMS arm in which each CA125 was compared with the patient's preceding values, and the likelihood that the CA125 profile reflected that of ovarian cancer, even if still within the reference range. The aim of this algorithm was to improve the PPV of CA125, particularly in the detection of early-stage disease. For patients with abnormal results, CA125 and/or TV-USS were repeated within 6 weeks or 3 months, which if again abnormal resulted in referral to a gynaecologic oncologist. Patients were screened for six consecutive years and followed up for 7 years from randomization. Although the primary end-point of this study was ovarian cancer mortality at 7 years, other measured outcomes were the psychosocial, physical and economic cost of ovarian cancer screening. Final data were published in 2015, 4 years after the last patient was recruited in 2011. Although the results indicated that those in the MMS arm had more early-stage ovarian/peritoneal cancers detected than those in the screening arm and a mortality reduction of 15% (compared with 11% in the USS group), there was no significant difference in survival. Interestingly, there was

evidence of a statistical trend towards improved survival outcomes at later time points. Although the follow-up period has therefore been extended to confirm late survival benefit, the UKCTOCS results have so far failed to provide unequivocal evidence that national ovarian cancer screening should be initiated.

Confining screening to patients with higher risk of EOC (such as those with a strong family history of the disease) would theoretically increase specificity. For women at known higher risk of a genetic cancer predisposition, the UK Familial Ovarian Cancer Screening Study (UKFOCSS) evaluated annual CA125 and TV-USS tests in women at high risk of EOC. The study recruited 3563 women aged over 35 with a strong family history of breast and/or ovarian cancer and completed recruitment in March 2010 [42]. The results showed that these tests were insufficiently sensitive to detect early-stage disease and so the second part of the study was opened in which CA125 was measured 4-monthly (instead of annually) with the ROCA algorithm applied. There were 4531 women recruited to part two that again failed to show sufficient sensitivity in identifying early-stage disease. These findings again highlighted the limited sensitivity of CA125 in detecting early-stage disease and reinforced the current approach of offering risk-reducing surgery (rather than serial CA125 measurement) to women with known ovarian cancer predisposing mutations.

Risk-reducing surgery

Prophylactic oophorectomy has been shown to reduce the incidence of subsequent ovarian and breast cancer by 96% and 53%, respectively, in women known to carry *BRCA1* or *BRCA2* germline mutations [43,44]. For many women in *BRCA* families this is considered the approach of choice. In general, where it is recommended, prophylactic bilateral salpingo-oophorectomy is performed on completion of childbearing or at the age of 40 years (whichever occurs first) and HRT is commenced thereafter until a point that corresponds to natural menopause at around 50 years. However, there are no clear guidelines in place and management of these patients varies widely. The suggestion that EOC arises from STIC lesions within the fallopian tube has raised the question of whether salpingo-oophorectomy (and all its associated postmenopausal effects on cardiovascular risk and bone health) is excessive and women should undergo a two-stage procedure, with an initial prophylactic salpingectomy later followed by oophorectomy once natural menopause has occurred. This needs to be investigated prospectively, but such a study would be challenging to conduct [45]. The 'tubal hypothesis' has resulted in more routine salpingectomies being conducted alongside hysterectomies. In addition, salpingectomy is increasingly being offered as an alternative to tubal ligation for contraception in view of its cancer-protecting effects.

Summary box 63.5

Three ovarian cancer screening studies

- PLCO study: no survival improvement using annual CA125 or TV-USS versus controls in women aged 55–74 years (sample size 28 000).
- UKCTOCS: no survival improvement using annual CA125 algorithm plus TV-USS or annual TV-USS alone versus controls in women aged 50–74 years (sample size 200 000), although extended survival analysis is ongoing.
- UKFOCSS: no survival improvement in 3500 high-risk women aged over 35 using annual TV-USS and CA125.

Staging of EOC

Most ovarian cancers have serous histology reminiscent of fallopian tube origin, often with characteristic psammoma bodies. Endometrioid adenocarcinomas and clear cell carcinomas are the next commonest histological type, and mucinous carcinomas are less common still. Ovarian carcinosarcomas are epithelial tumours with sarcomatous differentiation but these are rarely encountered. There is evidence that clear cell and mucinous ovarian cancers are far less responsive to chemotherapy than serous and endometrioid ovarian cancers.

An important feature of histological classification is the grade of the cancer, ranging from well differentiated (grade 1) to moderately differentiated (grade 2) to poorly differentiated (grade 3). Borderline tumours are not regarded as cancers and in general have an excellent prognosis.

Patterns of spread of ovarian cancer

The International Federation of Gynecology and Obstetrics (FIGO) classification for ovarian cancer is based on surgical staging and was updated in January 2014 [46]. The new versus old staging is shown in Table 63.2. The principal differences in the updated version are the subclassification of IC into IC1-3, removal of stage IIC, inclusion of lymph node status into stage IIIA and B (as well as C), reclassification of splenic metastasis to stage IV (rather than IIIC) and the subdivision of stage IV into IVA and IVB according to the site of distal disease.

Table 63.2 Previous versus updated FIGO staging for ovarian, fallopian and primary peritoneal cancer.

Previous FIGO		New FIGO		
Stage I: Tumour confined to ovaries				
IA	Tumour limited to 1 ovary, capsule intact, no tumour on surface, negative washings/ascites	IA	Tumour limited to 1 ovary, capsule intact, no tumour on surface, negative washings/ascites	
IB	Tumour involves both ovaries, otherwise like IB	IB	Tumour involves both ovaries, otherwise like IB	
IC	Tumour involves 1 or both ovaries with any of the following: capsule rupture, tumour on surface, positive washings/ascites	*IC Tumour limited to 1 or both ovaries*		
		IC1	Surgical spill	
		IC2	Capsule rupture before surgery or tumour on ovarian surface	
		IC3	Malignant cells in the ascites or peritoneal washings	
Stage II: Tumour involves 1 or both ovaries with pelvic extension (below the pelvic brim) or primary peritoneal cancer				
IIA	Extension and/or implant on uterus and/or fallopian tubes	IIA	Extension and/or implant on uterus and/or fallopian tubes	
IIB	Extension to other pelvic intraperitoneal tissues	IIB	Extension to other pelvic intraperitoneal tissues	
IIC	IIA or IIB with positive washings/ascites			
Stage III: Tumour involves 1 or both ovaries with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes				
IIIA	Microscopic metastasis beyond the pelvis	*IIIA (positive retroperitoneal lymph nodes and/or microscopic metastasis beyond the pelvis)*		
		IIIA1	*Positive retroperitoneal lymph nodes only*	
			IIIA1(i)	Metastasis ≤10 mm
			IIIA1(ii)	Metastasis >10 mm
		IIIA2	Microscopic, extrapelvic (above the brim) peritoneal involvement ± positive retroperitoneal lymph nodes	
IIIB	Macroscopic, extrapelvic peritoneal metastasis ≤2 cm in greatest diameter	IIIB	Macroscopic, extrapelvic peritoneal metastasis ≤2 cm ± positive retroperitoneal lymph nodes. Includes extension to capsule of liver/spleen	
IIIC	Macroscopic, extrapelvic peritoneal metastasis >2 cm in greatest diameter and/or regional lymph node metastasis	IIIC	Macroscopic, extrapelvic peritoneal metastasis >2 cm ± positive retroperitoneal lymph nodes. Includes extension to capsule of liver/spleen	
Stage IV: Distant metastasis excluding peritoneal metastasis				
IV	Distant metastasis excluding peritoneal metastasis. Includes hepatic parenchymal metastasis	*IVA*	*Pleural effusion with positive cytology*	
		IVB	Hepatic and/or splenic parenchymal metastasis, metastasis to extra-abdominal organs (including inguinal lymph nodes outside the abdominal cavity)	

Source: Prat *et al.* [46].

Like other malignant neoplasms, ovarian cancer can disseminate along locoregional, lymphatic and blood-borne routes. However, there are patterns of dissemination that are characteristic of the different histological subtypes of ovarian cancer. In HGSOC, the dominant pattern is that of transperitoneal locoregional dissemination often resulting in bulky intra-abdominal disease particularly involving the omentum as well as other peritoneal surfaces. This is often accompanied by malignant ascites and lymph node involvement is relatively common. With the exception of malignant unilateral or bilateral pleural effusion, and involvement of the umbilicus due to tumour spread along the remnant of the umbilical vein (Sister Joseph's nodule), it is unusual for HGSOC to present with visceral metastatic disease with metastases to the liver, pulmonary, cerebral or bone that are more commonly observed in other gynaecological malignancies. An exception to this situation is the *BRCA1*/*BRCA2* familial ovarian cancers that have a very high (73%) incidence of visceral metastatic disease [47].

Histopathological diagnosis of EOC

Histopathological type, tumour grade and FIGO stage are all determined by biopsies obtained using radiological or laparoscopic guidance or during formal staging laparotomy. Cytological diagnosis, such as from a sample of ascites, is considered inadequate for definitive diagnosis. Expression of markers such as p53 and oestrogen/progesterone receptor status can be useful information for the later management of the patient. Many centres are now routinely testing *BRCA* status in all patients with ovarian cancer, although National Institute for Health and Care Excellence (NICE) guidelines recommend testing for those with a greater than 10% risk (as defined using BRCAPRO, BOADICEA and/or the Manchester scoring system) of carrying a *BRCA* mutation [48]. This is a change from the 20% threshold previously defined by NICE guidance in 2006.

Prognostic factors

Unfortunately, the majority of patients with ovarian cancer will relapse and ultimately die from their disease. While the prognosis from earlier stage, low-grade EOC is good, with a cure rate of greater than 90%, across all stages (I–IV) the prognosis is poor, with 1-year survival of 71%, 5-year survival of 40% and 10-year survival of 33% (www.cancerresearchuk.org). The main factors that predict for survival remain FIGO stage of disease, tumour grade, surgical debulking status, histological subtype and sensitivity of disease to platinum-based chemotherapy. In ongoing research, whole genome molecular profiling analyses as well as individually characterized molecular target expression is being used to develop refined predictive and prognostic models.

Treatment of newly diagnosed ovarian cancer

The standard management of stage IC–IV EOC is to perform primary debulking surgery with the explicit aim of total macroscopic clearance and to enable complete surgical staging. This is followed by adjuvant carboplatin-containing chemotherapy for all patients other than those with FIGO stage IA and IB lower-grade tumours. In these early-stage patients, surgery is probably sufficient and chemotherapy is generally omitted, although the option of giving postoperative chemotherapy to these patients is the subject of ongoing debate [49]. In those with advanced disease with poor performance status or where primary debulking surgery is predicted to be too hazardous, chemotherapy is given alone (without surgery) or as neoadjuvant treatment, the latter with the intention of allowing delayed debulking surgery once disease bulk and overall health has been optimized.

Surgical management of newly diagnosed ovarian cancer

In recent decades, there have been significant advances in the surgical management of EOC, with the refinement of extensive upper abdominal cytoreductive techniques, incorporation of refined skills like bowel resection, en bloc extraperitoneal dissection and also highly specialized anaesthetic care for optimal perioperative management [46,50–55]. Many questions remain about the ideal timing of surgery, the value of surgery at relapse and how to optimize postoperative quality of life.

Imaging modalities and their value in the surgical decision-making processes

The decision-making process for the optimal management of patients with EOC is based on a combination of clinicopathological, biochemical and radiological factors together with patient preference but also the expertise, resources and overall institutional effort of the treating team. Conventional imaging like CT and MRI are important components of the preoperative and pre-chemotherapy investigations to define extent of disease and to identify or exclude potential second malignancies or incidental findings that would change the overall management, such as the discovery of incidental pulmonary emboli. Conventional imaging has not been shown to accurately predict operability in advanced ovarian cancer [56–59]. More advanced imaging modalities such as diffusion-weighted MRI are currently the focus of investigation in various clinical trials to ascertain whether they are superior to conventional imaging in their contribution to accurate preoperative decision-making [60].

There is currently no evidence-based prognostic and predictive value for the routine use of positron emission tomography (PET)-CT in ovarian cancer surgery, apart from situations with a specific question such as the evaluation of thoracic/mediastinal lymph node involvement in stage IV disease, especially in the context of relapsed disease, where intra-abdominal debulking surgery is considered [61].

Primary surgical staging and treatment

Surgery is the cornerstone of management of EOC as it provides accurate peritoneal and lymph node staging in early-stage disease and cytoreduction in advanced-stage disease. Non-fertility-sparing surgery consists of peritoneal washings or cytology, ideally taken prior to manipulation of the tumour, bilateral salpingo-oophorectomy,

hysterectomy, multiple peritoneal biopsies from the paracolic spaces and the two subdiaphragmatic spaces, supracolic omentectomy, and pelvic and bilateral paraaortic lymph node dissection (LND) up to the level of the renal vessels. Appendicectomy should be considered in case of mucinous histology [62,63] or if there is a radiological abnormality of the appendix. Depending on the histological grade and type, up to 30% of patients with apparently early-stage epithelial EOC will be upstaged after comprehensive surgical staging [64–66].

A single prospective randomized trial by Maggioni *et al.* [67] correlated the extent of LND with outcome. The study showed that, in early EOC, systematic LND versus just lymph node sampling reveals 13% more patients with occult lymph node disease and hence will have major implications on final stage determination as well as selection of adjuvant treatment. Positive nodes were detected in 22% of patients undergoing systematic lymphadenectomy compared with only 9% of patients who underwent lymph node sampling ($P = 0.007$). Although a trend for improved progression-free survival (PFS) and overall survival (OS) was observed for the lymphadenectomy group compared with control, the study lacked statistical power. Increasing evidence shows that the rate of positive lymph nodes in stage IA mucinous cancer is extremely low, and there is no value in performing systematic LND to avoid unnecessary morbidity [68,69].

A careful discussion is required for patients with early-stage cancer who opt for fertility-sparing surgery. Patients with stage IA and favourable histology (i.e. low-grade, mucinous, serous or endometrioid EOC) have been shown to have a lower risk of relapse after fertility-preserving surgery compared with patients with higher stages or grade of disease. In a large retrospective analysis, women with G3 disease or stage IC3 with clear cell histology had a higher risk of recurrence, but mainly due to the higher incidence of extra-ovarian spread observed in grade 3 tumours, rather than to a higher relapse rate in the preserved ovary [70]. Retrospective studies showed a risk of up to 11% of positive contralateral pelvic lymph nodes in women with unilateral disease despite negative ipsilateral nodes [71,72]. For these reasons, pelvic LND staging should be bilateral.

In advanced EOC, maximal-effort cytoreduction, aiming at total macroscopic tumour clearance, is associated with a significant increase in both OS and PFS in numerous prospective and retrospective trials [73–75]. It is not yet fully clarified whether this association is causal or whether resectable tumours are biologically more chemosensitive (than those that are unresectable) and therefore associated with a better prognosis [66]. Nevertheless, there are numerous data that patients treated within institutions with higher optimal debulking rates have significantly better survival. The first meta-analysis on this subject based on a total of 53 studies comprising 6885 patients was published by Bristow *et al.* [76] and covered the time period 1989–1998. They studied the influence of surgical tumour resection on OS, not of individual patients but of patient cohorts. Patient cohorts with a high rate of 'optimal' cytoreduction (defined at that time as <2 cm) of over 75% had a median OS of 36.8 months. In contrast, patient cohorts with a maximum tumour reduction rate of less than 25% had a median OS of only 23 months. Hence, every 10% reduction in tumour was associated with a 6.3% prolongation of median OS.

In order to achieve total macroscopic tumour clearance in peritoneally disseminated disease, maximal surgical effort is required, incorporating multi-visceral resection techniques such as extensive peritoneal stripping, full-thickness diaphragmatic resection, removal of bulky pelvic/para-aortic lymph nodes, splenectomy and bowel resection. Increasingly, more extra-abdominal cytoreductive techniques are nowadays applied especially in the thoracic and mediastinal cavity with resection of cardiophrenic/paracardiac lymph nodes, pleurectomy, and supraclavicular and axillary LND in order to achieve complete tumour clearance outside the abdominal cavity. Surgical expertise and training with continuous feedback of surgical outcome, morbidity and survival have been proven to be important tools in making extensive surgery safe for the patient without unnecessarily increasing morbidity [77]. For these reasons, national and international trends focus on the specialization of such procedures in centres with adequate infrastructure, resources and training.

Pelvic and para-aortic LND is part of the debulking procedure in the presence of bulky lymph nodes. The removal of bulky lymph nodes only versus a systematic LND has been shown to be associated with a decreased 5-year PFS of 21.6% compared with 31.2% in the full LND group without any significant difference in OS in a prospective randomized phase III trial [78]. However, the caveat was that, in this study, only approximately one-third of the patient cohort were optimally cytoreduced and hence would have obtained the potential survival benefit from a full lymphadenectomy. In three prospective randomized first-line studies [79,80] evaluating 1924 patients, lymphadenectomy was associated with superior survival in patients without gross residual disease. The median survival time for patients with and without lymphadenectomy was 103 and 84 months, respectively, and 5-year survival rates were 67.4% and 59.2%, respectively ($P = 0.0166$); in multivariate analysis a significant impact of lymphadenectomy on OS was seen (hazard ratio, HR 0.74, 95% CI 0.59–0.94; $P = 0.0123$). The value of systematic pelvic

and para-aortic lymphadenectomy in the absence of bulky lymph nodes was recently evaluated in the large randomized LION trial where 650 women with stage IIB–IV advanced EOC who had achieved complete macroscopic debulk but did not have bulky lymph nodes were randomized to pelvic and para-aortic lymphadenectomy versus no lymphadenectomy. The results revealed no progression-free or OS advantage to lymphadenectomy (HR 1.057, 95% CI 0.833–1.341; $P = 0.65$) [81].

There is an international ongoing debate as to the best timing of surgery in relation to first-line chemotherapy. Two prospective randomized trials [75,82] have demonstrated lower surgical morbidity and mortality but equal survival in the neoadjuvant approach. The weakness of both studies was that the complete resection rates were very low while surrogate markers of surgical effort, such as operation time, showed an overall suboptimal setting and effort. For these reasons it is difficult to adopt the findings of these trials on patients with good performance status who can be operated until tumour-free in specialized centres. Future trials are in development that will be conducted in centres with established surgical quality to answer the question of timing and will address additional issues, such as management of fragile patients, assessment of short- and long-term quality-of-life scores, and impact of ascites and pleural effusion on haemodynamic management, and would also have an additional translational component in an attempt to identify valid biomarkers that would predict operability and clinical outcome. A recent study by Rosen *et al.* [83] showed that the long-term survival for patients undergoing primary cytoreduction was far superior to those receiving neoadjuvant chemotherapy and delayed primary surgery (9% vs. 41%, $P < 0.0001$).

Integrated multidisciplinary care of ovarian cancer

EOC is optimally managed by centralized, integrated, multidisciplinary teams. This has been shown to improve outcomes [84]. In general, the team consists of a surgical oncologist, a medical/clinical oncologist, a radiologist, a pathologist and specialist nurses. The specialist nurse acts as a conduit between the patient and the multidisciplinary team. Palliative care specialist input may be required in all phases of the disease. Increasingly, multidisciplinary teams are developing integrated care pathways for patients with EOC that bring together hospital and community services within one framework. Most recently, survivorship programmes are beginning to become integrated into standard care, with randomized studies such as OvPsych2 assessing the benefit of supportive interventions on quality of life.

Advanced ovarian cancer

Carboplatin, paclitaxel and bevacizumab as front-line therapy

The current standard of care following surgery is a combination of carboplatin and paclitaxel, given for six cycles at 3-weekly intervals. The evidence for this is based on various seminal studies. The GOG111 and OV10 studies demonstrated that cisplatin with cyclophosphamide was inferior to cisplatin and paclitaxel [85,86]. The GOG132 study showed that there was no difference in survival for cisplatin given alone when compared with cisplatin given alongside paclitaxel [87], and in the ICON3 trial carboplatin plus paclitaxel was compared with the hitherto standard treatment options of carboplatin alone or CAP (cyclophosphamide, doxorubicin and cisplatin) [88]. Although ICON3 showed no difference between PFS and OS between the single-agent carboplatin and carboplatin–paclitaxel arms, a combination of paclitaxel and carboplatin has been widely adopted in patients who are fit, lacking in comorbidities (especially those exacerbated by the treatment or its supportive therapies) and able to cope with combination chemotherapy.

The GOG218 trial explored the role of the vascular endothelial growth factor (VEGF)-targeting antibody bevacizumab given alongside front-line chemotherapy and as subsequent monotherapy maintenance. It showed a 3.8-month improvement in PFS compared with chemotherapy alone (or chemotherapy with combined but not maintenance bevacizumab) but no difference in OS [89]. Similar results were obtained from the European study ICON7, although an OS benefit of almost 5 months (log-rank $P = 0 \cdot 03$) was demonstrated in those with 'high-risk' advanced disease receiving the bevacizumab arm, albeit at a lower dose (7.5 mg/kg) than was used in the GOG218 study (15 mg/kg) [90]. For this reason, bevacizumab (7.5 mg/kg every 3 weeks for a maximum of 18 weeks) was made available by the Cancer Drugs Fund for women with high-risk stage IIIC/IV ovarian cancer although it was not approved by NICE. The Japanese Gynecologic Oncology Group (JGOG) undertook a randomized study where, in addition to standard 3-weekly carboplatin (Area Under the Curve (AUC6)), intravenous paclitaxel was given either 3-weekly (175 mg/m^2) or as weekly dose-dense therapy (80 mg/m^2). In this trial, there was a significant 11-month improvement in PFS in the dose-dense arm with significant improvement in OS also [91]. A similar question was then addressed in the European ICON8 study, in which 1485 women with newly diagnosed advanced ovarian cancer were randomized to receive standard 3-weekly carboplatin and paclitaxel (Arm1), the 'Japanese' regimen of 3-weekly carboplatin with weekly paclitaxel (Arm 2) or weekly

AUC2 carboplatin with weekly paclitaxel (Arm 3). The final results of ICON8 are pending, but it is likely to reflect the findings of the GOG-0262 study [92] in which a lack of benefit of the dose-dense Japanese regimen over standard 3-weekly carboplatin was described in a smaller cohort of 692 patients. This raises the question of why the benefit of dose-dense paclitaxel was so much greater in the Japanese population compared with the (mostly) European and North American women enrolled in the GOG and ICON8 studies.

The ICON8B study questions whether bevacizumab is advantageous when given with the Japanese regimen compared with standard 3-weekly chemotherapy. In ICON8B, women with stage III/IV EOC are randomized to 3-weekly carboplatin and paclitaxel plus bevacizumab (Arm B1), the Japanese regimen without bevacizumab (Arm B2) or the Japanese regimen with bevacizumab (Arm B3). The GOG-0262 study answered a similar question by prospectively stratifying their EOC patients according to whether they wished to have bevacizumab and then randomly assigned them to receive it in addition to either 3-weekly carboplatin and paclitaxel, or the Japanese regimen. Interestingly, in those who did not receive bevacizumab, weekly paclitaxel was associated with a 3.9 month longer PFS compared with the 3-weekly regimen (14.2 vs. 10.3 months; HR 0.62, $P = 0.03$) [92]. However, among those who received bevacizumab, the weekly paclitaxel arm had similar PFS to the 3- weekly arm (14.9 and 14.7 months, respectively; HR 0.99, $P = 0.60$). The weekly arm was associated with worse quality of life, with a higher incidence of neuropathy and grade 3/4 anaemia albeit a lower rate of neutropenia. This implies that fractionated paclitaxel is as effective as bevacizumab, perhaps because it has anti-angiogenic effects when given more frequently. However, the study was not truly randomized as the study patients self-selected bevacizumab. The results also raise the question as to whether a 3-month improvement in PFS warrants the negative impact on quality of life.

Intraperitoneal chemotherapy

Ovarian cancer is principally a disease of locoregional peritoneal dissemination within the abdominal cavity. The idea of intraperitoneal therapy is not new, having been performed since the 1950s as a means of controlling ascites. By inserting a port through the skin and into the peritoneal cavity, chemotherapy can be delivered directly to the location of the disease and at a greater localized concentration. Over the last 20 years there have been many randomized trials comparing intraperitoneal with intravenous chemotherapy for the first-line treatment of patients with stage III ovarian cancer (reviewed in Elit *et al.* [93]). The common factor is that all have included platinum, and most have added a second drug. Meta-analyses of these trials showed a significant reduction in hazards of 0.88 with confidence intervals of 0.81–0.95 and an improvement in survival (in the three largest studies) of 8, 11 and 16 months for intraperitoneal over intravenous chemotherapy beyond an expected median survival of this optimally debulked group of 4 years.

The 2006 GOG 172 study [94] showed the largest difference ever in a randomized ovarian cancer trial, with median OS of 67 months compared with the intravenous control arm of 49 months, the improvement being 17.4 months with an HR of 0.71. This regimen utilized intravenous paclitaxel on day 1, intraperitoneal cisplatin on day 2 and intraperitoneal paclitaxel on day 8, of a 21-day cycle for six cycles. However, intraperitoneal chemotherapy was associated with enhanced toxicities, including neuropathy, gastrointestinal toxicity and myelotoxicity. Despite encouragement to adopt intraperitoneal chemotherapy as standard of care by the National Cancer Institute, clinicians were reluctant to integrate it into routine practice until further randomized trials had been performed because of concerns over the complications of intraperitoneal catheters and fear of excessive toxicity [95]. Updated survival data were subsequently published in 2015 and showed median survival of 61.8 months compared with 51.4 months in the intraperitoneal arm. Interestingly, subsequent molecular analysis of those patients deriving most benefit from intraperitoneal therapy showed it was those with low *BRCA1* expression. The PETROC/OV21 study looked at intraperitoneal platinum and paclitaxel chemotherapy following suboptimal interval debulking surgery in 275 women with stage IIb/III or IV (pleural effusion only) ovarian cancer [96]. The study modified its end-points due to accrual difficulties and concluded that, of three different regimens intraperitoneal carboplatin given with intravenous and then intraperitoneal paclitaxel was (i) superior to the equivalent regimen using intraperitoneal cisplatin and (ii) gave superior 9-month progressive disease rate of 23% compared with 42% in the control arm (intravenous carboplatin and paclitaxel) ($P = 0.03$). The intraperitoneal treatment was well tolerated with low complication rates. Importantly, this study demonstrated that carboplatin was a safe and well-tolerated alternative to cisplatin when administered intraperitoneally.

The issue of whether bevacizumab adds to chemotherapy in the context of intraperitoneal treatment was addressed in the multicentre phase III GOG-252 study, in which 1560 women with stage II or III ovarian cancer were randomized to intravenous carboplatin, paclitaxel and bevacizumab (Arm 1), intravenous paclitaxel and bevacizumab but intraperitoneal carboplatin (Arm 2), or intraperitoneal carboplatin and intravenous followed by intraperitoneal paclitaxel with intravenous bevacizumab

(Arm 3). Early results demonstrated no PFS advantage of intraperitoneal therapy over intravenous therapy in sharp contrast to the findings of GOG-172.

The issue of which treatment clinicians should select for their optimally debulked advanced-stage ovarian cancer patients is complicated. Centres are divided as to whether upfront debulking or neoadjuvant chemotherapy is preferred. Intraperitoneal chemotherapy is complicated by high morbidity and is costly to arrange, bevacizumab is not approved for routine use and weekly paclitaxel has shown little advantage compared with standard 3-weekly carboplatin and paclitaxel treatment.

The *BRCA*-positive patient

Perhaps the most significant revolution in EOC management over the last 5 years has been in the management of *BRCA*-mutated cancer patients.

As well as their well-documented increased risk of breast and ovarian cancer (and to a lesser extent pancreatic and prostate cancer), cancers that have developed in *BRCA* mutation carriers are highly sensitive to poly(ADP-ribose) polymerase (PARP) inhibitors. BRCA1 and/or BRCA2 proteins are required to repair DNA double-strand breakages in a process called homologous recombination (HR). HR uses an existing DNA sequence as a template to repair the opposite broken strand. In the cancer cell that lacks both copies of *BRCA1*/*BRCA2*, repair occurs using alternate means such as non-homologous end joining or single-strand annealing. As these methods are error-prone, cells that are deficient in BRCA1 or BRCA2 demonstrate chromosomal instability and are highly sensitive to drugs or irradiation that cause double-strand breaks [97]. PARP inhibitors repair single-strand DNA breaks via the break excision repair pathway. If these breaks are left unrepaired, they can result in double-strand breaks and are reliant on the HR pathway for their recovery. In those cells without HR (i.e. BRCA-deficient cells), the HR pathway is dysfunctional and the DNA damage cannot be overcome. This causes genomic instability and apoptotic cell death.

The discovery that inhibition of PARP causes targeted cell death in cells in which BRCA1 and BRCA2 are depleted [98], a mechanism described as 'synthetic lethality', has seen the emergence of a number of PARP inhibitors into clinical practice and as part of the routine management of women with *BRCA*-mutated ovarian cancer. The front-running PARP inhibitor is olaparib that, in 2014, was granted European Medicines Agency marketing authorization for use as maintenance monotherapy in *BRCA*-mutated ovarian cancer patients who have achieved complete or partial response following platinum-based chemotherapy. In January 2016, olaparib received approval by NICE as maintenance following at least three courses of platinum-containing treatment (usually this implies at least two courses of treatment for relapsed disease), echoing the FDA approval guidelines issued in 2014. This followed a number of clinical trials in heavily pretreated relapsed ovarian cancer patients with germline *BRCA* mutations in which responses were observed (34% objective response rate, 2% complete response) and demonstrated to last an average of 7.9 months [99]. In a phase II trial, 265 patients with platinum-sensitive recurrent EOC who had received two or more prior platinum-containing regimens and achieved a partial or complete response to their most recent platinum-containing treatment were randomized to maintenance olaparib versus placebo. A superior PFS was demonstrated in those taking olaparib as maintenance therapy compared with placebo and when subset analysis was conducted, patients with *BRCA* mutations demonstrated the greatest benefit (PFS 11.2 months vs. 4.3 months in placebo arm; HR 0.18, 95% CI 0.10–0.31; P <0.0001). Interestingly, patients without *BRCA* mutations also showed a survival advantage to olaparib compared with placebo (7.4 months vs. 5.5 months) but in neither groups was the PFS advantage converted to an OS benefit [100]. Other PARP inhibitors including rucaparib and niraparib have shown benefit beyond *BRCA*-mutated patients. In the case of rucaparib a 'loss of heterozygosity (LOH) score' identified patients with defective HR but with wild-type *BRCA*. In the ARIEL2 study, 204 patients with relapsed platinum-sensitive HGSOC were given maintenance rucaparib but stratified according to their *BRCA* status and LOH score. Those who were LOH 'high' had improved response to rucaparib compared with those who were LOH 'low', but this translated to a progression-free advantage of only a few weeks, considerably less than the 12.8-month PFS observed in the *BRCA* mutant cohort [101]. The PARP inhibitor niraparib has shown benefit as maintenance therapy in women with platinum-sensitive recurrent EOC, regardless of *BRCA* mutation status. In a phase 3 study [102], patients without genomic *BRCA* mutation receiving niraparib achieved a 15.5-month PFS advantage compared with those receiving placebo. However, whether this translates to an OS improvement is as yet unknown.

Recurrent ovarian cancer

Recurrent EOC is currently an incurable clinical situation, although survival improvement can still be achieved using appropriate chemotherapy and a multidisciplinary approach. Palliation and optimization of quality of life

are important considerations in this clinical scenario, including careful symptom management and the judicious use of chemotherapy, radiotherapy and surgery. Community palliative care and hospice provision are important components in this phase of the disease. Selecting treatments with minimal toxicities is also a major aim for patients in this clinical scenario.

Chemotherapy

Depending on the time interval between primary platinum-based treatment and relapse, recurrent EOC is arbitrarily divided into platinum refractory, resistant or potentially sensitive disease. Tumour that has relapsed more than 12 months following prior treatment is defined as platinum-sensitive, between 6 and 12 months as partially platinum sensitive, less than 6 months as platinum-resistant, and during or within 4 weeks of completing treatment as platinum-refractory [103]. Platinum-refractory EOC represents disease that is primarily non-responsive to chemotherapy, and implies that it is unlikely that these patients will respond to further standard chemotherapy agents. These patients often have aggressive disease and poor prognosis. They can be considered for phase I, and some phase II trials if sufficiently fit.

Platinum-sensitive recurrence

Platinum-sensitive recurrence has several definitions. A pragmatic definition is that of recurrence of EOC requiring treatment occurring more than 6 months after last chemotherapy. Blackledge *et al.* [104] showed that those relapsing more than 18 months after previous chemotherapy have up to a 94% chance of response to subsequent platinum-based therapy (as compared with 10% response rate in those relapsing within 6 months of last platinum therapy).

Eisenhauer *et al.* [105] looked at factors predicting response to subsequent chemotherapy in platinum-pretreated ovarian cancer using data from 13 randomized trials of six chemotherapy agents (not just platinum). They found that serous histology, tumour bulk (<5 cm) and number of disease sites (less than three) were significant factors, yet treatment-free interval was not a feature at first sight at odds with Blackledge's findings. These biological predictors were the main determinants of subsequent response, with the treatment-free interval correlating closely with tumour size.

A seminal randomized clinical trial, MRC ICON4, was conducted in patients relapsing more than 6 months after last chemotherapy. This trial asked if the addition of paclitaxel to carboplatin improved survival in platinum-resistant disease. This study was extremely important because the MRC ICON3 study had shown no improvement in survival for carboplatin and paclitaxel as front-line chemotherapy in advanced ovarian cancer. In the ICON4 trial, addition of paclitaxel significantly improved survival in platinum-sensitive recurrent ovarian cancer, with an HR of 0.82, an absolute survival advantage at 2 years of 7% and an improvement to median survival of 5 months; in other words, benefit of similar magnitude to the addition of platinum to front-line chemotherapy for ovarian cancer. There were no real differences in patient-perceived toxicity and, in general, where there are not reasons to avoid paclitaxel (e.g. previous severe neuropathy, concurrent medical comorbidity especially advanced diabetes) it can be recommended for patients relapsing more than 12 months from last chemotherapy [106].

Outside the trial setting, the current NICE-approved strategy is to offer combination chemotherapy to all patients with platinum-sensitive recurrent disease if it is not medically contraindicated. Patients with platinum-sensitive or partially platinum-sensitive disease are retreated with platinum alongside paclitaxel or pegylated liposomal doxorubicin hydrochloride (PLDH), the latter following the non-inferiority study CALYPSO which compared carboplatin plus PLDH to carboplatin and paclitaxel [107]. Patients who are allergic to platinum are offered single-agent PLDH, topotecan or weekly chemotherapy with paclitaxel. Other strategies include replacing platinum with an alternative cytotoxic such as the DNA minor groove binding inhibitor trabectedin, given with PLDH in the OVA 301 trial [108]. The OCEANS study reported a PFS (but not OS) benefit of adding bevacizumab to carboplatin and gemcitabine [109]. This was followed by the results from ICON6, in which a 3-month progresson-free benefit from the small molecule VEGFR inhibitor cediranib was observed when it was given alongside, and as maintenance following, chemotherapy for patients at their first platinum-sensitive relapse. A significant improvement in OS was also observed, but at the cost of toxicities including hypertension, fatigue, nausea and diarrhoea [110]. Interestingly, a phase 2 study of cediranib given with olaparib in women with platinum-sensitive recurrent (*BRCA* mutant as well as wild-type) EOC demonstrated a PFS advantage but this trial was not powered to address OS [111]. Although toxicity of the combination was higher than in those receiving olaparib alone, this study gave an indication that the spectrum of activity of a PARP inhibitor could be enhanced by combining with an anti-angiogenic agent. The recently reported benefit of niraparib maintenance (see above) in those with a good response to chemotherapy regardless of *BRCA* status has raised the question of whether this should be offered to all patients with platinum-sensitive EOC, but is not yet NICE-approved.

Platinum-resistant recurrence

There are various definitions of platinum-resistant recurrence; however, a pragmatic definition is one of recurrent disease requiring treatment within 6 months of completing last chemotherapy. These patients appear to benefit (or fail to benefit) equally from all conventionally dosed and scheduled chemotherapeutic agents. These monotherapies all have a 10–20% overall response rate. Agents that can be considered for this indication include PLDH, topotecan, oral etoposide and weekly paclitaxel. Of these, weekly paclitaxel shows the greatest impact in terms of response rate, evident from results of the phase 3 AURELIA study in which the investigators-choice arm demonstrated that weekly paclitaxel outperformed PLDH or topotecan monotherapy [112]. In addition, this study highlighted the benefit of the VEGF inhibitor bevacizumab in the platinum-resistant setting, yielding just over a 3-month PFS advantage compared with non-bevacizumab-containing treatments. However, this did not translate to OS benefit. Feasibility is also a concern when using bevacizumab in this context as patients have to be carefully selected to minimize their risk of bowel perforation. Platinum-resistant EOC remains an area of unmet need and is the subject of a number of novel approaches, including using immunotherapy (discussed below).

Surgical treatment at relapse

Despite the established value of cytoreduction in the primary setting, the value of tumour debulking surgery for recurrent EOC remains controversial and practice varies widely, nationally and internationally. While many supporters of surgical cytoreduction at relapse advocate that complete tumour resection may result in higher survival rates, opponents argue that the high associated complication rates and longer hospitalization times are inappropriate in patients with incurable EOC, especially without evidence of benefit to quality of life. Many authors have attempted to define a preoperative algorithm which would identify optimal candidates for secondary cytoreduction as based on well-defined selection criteria. The situation is even vaguer in the tertiary setting and beyond.

In platinum-resistant or refractory EOC, there is sufficient evidence that cytoreductive attempts do not result in a survival benefit and should not be performed unless for symptom palliation [113–115]. However, the situation is different in platinum-sensitive recurrent EOC. The DESKTOP I trial was a retrospective evaluation of 267 EOC patients and demonstrated that benefit from secondary surgery was derived only when total macroscopic clearance was achieved [116]. Complete tumour resection was associated with significantly longer survival compared with surgery leaving any postoperative residual disease (median 45.2 vs. 19.7 months; HR 3.71, 95% CI 2.27–6.05; P <0.0001). These findings challenge clinicians to accurately identify those patients in whom optimal debulking can be achieved. For this reason, based on a multivariate model, three clinical factors were identified as independently predicting resectability within the so-called 'AGO score': good performance status, complete resection at primary surgery (or early FIGO stage) and absence of gross ascites at relapse. The value of the AGO score lies it its simplicity. An exploratory analysis of the DESKTOP results to evaluate the role of peritoneal carcinomatosis present in recurrent EOC clearly showed that even though it was a negative predictor for complete resection in recurrent disease, it appeared to have no negative impact on survival if total macroscopic clearance could be achieved [117,118].

A subsequent confirmation and validation of the AGO score followed within the prospective multicentre DESKTOP II trial, in which the AGO score could be confirmed as a useful and reliable tool for predicting complete tumour resection in more than two-thirds of patients with platinum-sensitive relapsed EOC. Participating centres prospectively enrolled patients with platinum-sensitive EOC at first or second relapse. The AGO score was applied to all patients, but each centre was free to decide their therapeutic management. A total of 516 patients were screened within 19 months; of these, 261 patients (51%) were classified as score positive, and 129 patients with a positive score and first relapse underwent secondary tumour debulking. The rate of complete resection was 76%, thus confirming the validity of this score regarding positive prediction of complete resectability in more than two-thirds of patients [117]. Interestingly, a poor correlation was found when comparing the number and site of lesions by preoperative imaging with the number identified at surgery.

Perioperative morbidity and mortality appeared to be acceptable within the DESKTOP series, with a mortality as low as 0.8%, an 11% re-laparotomy rate mainly due to bowel leakage or fistula (7%) and a 2% deep vein thrombosis rate, while 52% of the patients required postoperative intensive care of a median 2 days (range 1–20 days). A subsequent multicentre randomized trial, DESKTOP III (AGO-Ovar OP.4), prospectively evaluate the impact of recurrent EOC surgery in platinum-sensitive patients with positive AGO score (tumour-free initial surgery, good performance status and ascites <500 mL). This demonstrated a PFS benefit in all patients undergoing surgery of around 4 months, but the benefit was only seen in those who had a complete macroscopic debulk. Secondary debulking surgery prolonged time to later relapse, although OS data are awaited [119]. The equivalent

American trial from the Gynecologic Oncology Group (GOG213) has commenced recruiting with the addition of randomization to systemic bevacizumab 15 mg/m^2 at maintenance. There are future plans to combine results from both trials to achieve a larger cohort and more robust survival data.

In one large systematic meta-analysis by Bristow *et al.* [113], 40 cohorts of 2019 patients with recurrent EOC were identified over a period of 24 years. After controlling for all other disease-related factors, each 10% increase in the proportion of patients undergoing complete cytoreductive surgery was associated with a 3.0-month increase in median cohort survival time. Despite these encouraging retrospective data it is still not clear if the surgery itself is influencing survival or whether operability is just a surrogate marker of more 'favourable' tumour biology and therefore a better overall prognosis. The first two prospectively randomized surgical trials will definitively answer this question and may set new evidence-based standards.

The largest multicentre analysis on tertiary cytoreductive surgery (TCS) worldwide included 406 patients (median age 55 years, range 16–80) who underwent TCS between 1997 and 2011 in 12 centres across Europe, USA and Asia [120]. The majority of the patients had an advanced initial FIGO stage III/IV tumour (69%), peritoneal carcinomatosis (51.7%) and absence of ascites (72.2%), and 224 (54.1%) patients underwent complete tumour resection. The most frequent tumour dissemination site was the pelvis (73%). Median OS for patients without residual disease versus any tumour residual was 49 months (95% CI 42.5–56.4) compared with 12 months (95% CI 9.3–14.7; P <0.001). Most importantly, common clinicopathological characteristics such as tumour stage, age and histological subtype, which have been shown to be of significant predictive value at initial presentation of the disease, did not appear to be of any prognostic significance at the tertiary stage. A further clinically relevant finding was that a significant impact of third-line postoperative systemic chemotherapy on OS was identified, emphasizing the importance of combinative systemic and surgical therapy in the treatment of EOC, even in heavily pretreated patients. This may nevertheless constitute a selection bias since patients who are fit enough to tolerate chemotherapy following radical surgery may have more favourable survival rates than those for whom chemotherapy was contraindicated. Rates of major operative morbidity and 30-day mortality were 25.9% and 3.2%, respectively, and hence slightly higher than the equivalent data of secondary patients at the DESKTOP series. The most common complications were infection/sepsis (13%) and re-laparotomy (4.4%), but interestingly without any higher rates of thromboembolic events (2.5%).

Multivariate analysis identified platinum resistance, residual disease following secondary surgery and peritoneal carcinomatosis to be of negative predictive significance for complete tumour resection, whilst residual tumour at secondary and tertiary surgery, decreasing interval to second relapse, ascites, upper abdominal tumour involvement and non-platinum third line-chemotherapy were significantly associated with negative OS.

As in every surgical attempt in EOC, adequate patient selection is crucial to minimize morbidity and maximize benefit in a palliative patient cohort.

Management of bowel obstruction in the palliative setting

Patients with EOC often present with the clinical picture of impaired intestinal motility or even bowel obstruction in the advanced setting, attributed to diffuse tumour dissemination along the peritoneal layers [121]. In this context, targeted anti-angiogenic therapies are at risk of causing fistula formation or intestinal perforation [89,122]. Recurrent EOC complicated by such severe and acute events constitutes a therapeutic dilemma and surgery in these often heavily pretreated patients is highly challenging and associated with high morbidity and mortality. Surgical interventions include en bloc resection of the involved intestinal region with terminal proximal ileostomy or jejunostomy since, due to peritoneal carcinosis and inflammation, plane dissection with anastomotic and repair techniques are not feasible. This can result in short bowel syndrome requiring high institutional and physical resources and consideration of total parenteral nutrition.

In cases of acute intestinal complications such as perforation and peritonitis, therapeutic approaches are rather limited. Retrospective analyses have shown that patients operated in acute situations have significantly higher rates of anastomotic insufficiency compared with those operated electively [89,122]. In addition, rates of anastomotic insufficiency are higher at primary debulking surgery in patients with residual tumour compared to those without [122]. Benefits should be very carefully balanced with risks for each individual patient. Factors such as comorbidities, baseline quality of life, previous response to chemotherapy, treatment intervals and patient preference all need to be taken into account. Progress in endoscopic techniques, such as placement of intestinal stents and gastrostomies, have improved care of patients. However, in the case of multi-level bowel obstruction, a single stent or stoma formation is not helpful. Here, further options such as percutaneous endoscopic gastrostomy can used in highly selected cases.

Radiotherapy for relapsed disease

Radiotherapy is generally reserved for palliation of symptomatic disease, particularly symptomatic pelvic recurrence, cutaneous and intracerebral disease.

Future developments

It is likely that the future landscape of ovarian cancer treatment will be dominated by PARP inhibitors. *BRCA* testing is now being conducted in many clinical centres for HGSOC patients with or without a strong family history of the disease and patients with *BRCA* mutations will be managed with PARP-containing regimens throughout the course of their disease. It is questionable as to whether immunotherapy will also play an important role in the management of EOC. So far, checkpoint (such as PD1 or PDL1) inhibitors given alone or in combination with CTLA-4 inhibitors have transformed the management of many, hitherto lethal, cancers such as melanoma, renal cell cancer and non-small cell lung cancer. EOC has a low mutational burden, a factor that should predict lack of response to checkpoint inhibitors, but it has high levels of infiltrating regulatory T cells, believed to suppress immune activity. In a study by Hamanishi *et al.* [123] the anti-PD1 inhibitor nivolumab was given every 2 weeks to 20 patients with platinum-resistant EOC resulting in two complete responses and, across all participants, a disease control rate of 45%. In the phase IB KEYNOTE-028 study, 26 patients were given pembrolizumab and a disease control rate of 54.7% was observed. Larger randomized studies trialling immunotherapies in combination with chemotherapy, targeted therapies and other immune activators are currently underway for patients with platinum-sensitive and -resistant EOC. Enhanced understanding of the pathways underpinning chemotherapy resistance in EOC have led to a number of trials evaluating mTOR and AKT inhibitors in combination with chemotherapy in patients with platinum-resistant and -refractory disease, for example the OCTOPUS trial in which the mTOR inhibitor is given in combination with weekly paclitaxel. The greater availability and reducing costs of genomic assessment have opened the possibility of multi-armed studies in which patients are directed towards particular targeted therapies on the basis of their tumour mutational status.

Summary

The management of ovarian cancer is complex by virtue of its insidious presentation, heterogeneous histology and often rapid development of chemotherapy resistance mechanisms. Despite this, improvements have been made in 5-year survival over the last 20 years, reflecting advances in surgical technique and the use of more effective chemotherapeutic treatments, both initially and in recurrence. However, ovarian cancer still remains the most lethal of gynaecological cancers, warranting exploration into novel therapeutic strategies. These include personalization of treatment according to histology and genetic profile and the use of novel cytotoxics, targeted therapies and, perhaps also immunotherapy. Underpinning these and future developments is an ongoing commitment to unravelling the basic cellular biology of ovarian cancer. Only then can therapies be rationally designed or improved to make a significant impact on the outcome of this most deadly of cancers.

Sexual Health

64

Sexually Transmitted Infections

Peter Greenhouse

Bristol Sexual Health Centre, Bristol, UK

Sexually transmitted infections (STIs) make a substantial and often under-appreciated contribution to gynaecological and obstetric morbidity, because their covert nature and transmission efficiency ensure widespread distribution throughout the entire sexually active population. Pelvic infection (Chapter 45), tubal factor infertility (Chapter 51), ectopic pregnancy (Chapter 43), genital ulceration, vulvo-vaginal discharge (Chapter 58), genital malignancy (Chapters 60 and 61), premature labour (Chapter 28) and neonatal infection (Chapter 19) have been widely researched and described in relation to STIs. Yet the role of infections, particularly chlamydia, in such common gynaecological problems as abnormal uterine and heavy menstrual bleeding due to endometritis, and right iliac fossa pain in teenage girls due to salpingo-appendicitis, is controversial and requires further elucidation.

Given the above, a sexual contact history – so often neglected in the past – is as important a part of routine gynaecological work-up as the menstrual or contraceptive history. Risk assessment cannot reliably predict the likelihood of infection nor its location in vagina, cervix, rectum or oropharynx, as no STI causes easily recognizable signs or symptoms in more than one-quarter of women, while most are obvious in less than one-tenth, and the partner's (or partners') contact history and infection status is usually unknown.

A thorough account of STI in women requires an entire textbook [1–3], so this chapter focuses principally on those aspects of bacterial and cutaneous viral STI which have the greatest relevance to daily gynaecology practice, excluding blood-borne viruses, while emphasizing the anatomical, hormonal and immunological factors which render women more vulnerable to infection by, and present differently with, the same conditions in men.

Epidemiology

Women are typically more vulnerable than heterosexual men to acquisition of STI as, in any sexual transaction, infections are more likely to spread to the biologically receptive partner. The rate of spread (R_0) of any infectious disease depends on a combination of transmission efficiency (β), rate of change of contact or partner (c) and duration of infectiousness (D), expressed in its simplest form as $R_0 = \beta cD$ [4].

Transmission efficiency of STIs to women depends on the infecting organism load and a combination of the amount and force of frottage or penetrative friction trauma and receptor tissue vulnerability, the latter being exacerbated by poor oestrogenization during use of progestogen-only contraception [5], breastfeeding or menopause, and the former by performance-enhancing drug use and non-consensual activity. Vulnerability, particularly to HIV, is greater in the rectum than in vagina or pharynx and can be diminished at all sites or substantially prevented by lubrication and condom use. Individual immune response and organism biology determines duration of infectiousness, which is typically short – a few weeks – for epidemic infections that are either briefly overtly symptomatic, such as urethral gonorrhoea in men or where there is transient high viraemia at seroconversion such as with HIV, or longer (months or years) for endemic STIs that remain covert in both sexes.

Thus well over 50% of women who have been sexually active with more than one partner will have acquired and/or transmitted endemic STIs such as herpes simplex virus (HSV), human papillomavirus (HPV) or *Chlamydia trachomatis* without ever displaying any signs or symptoms of infection, nor sustaining any significant harm. The latter two conditions will, in most cases, have been cleared spontaneously within 1 or 2 years (in many cases,

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

sooner) by the woman's normal immunological response [6,7]. Individual genetics and frequency of exposure, allied to hormonal and immunological status, typically define the minority of women who will develop symptoms and suffer adverse sequelae.

Most analysis of epidemiological trends reflects incidence of infections diagnosed and is dependent on appropriate provision of services, contraceptive choice, clinic attendance patterns, reporting systems and advances in diagnostic technology. The UK's system of free, confidential sexual health clinics has provided consistent methodology in clinical diagnosis and collection of statistics [8]. Reported cases of gonorrhoea in women over the past 70 years (Fig. 64.1) offers an important historical perspective of how subsequent generations have experienced different rates of infection. Plotted against teenage fertility it acts as a barometer of sexual mores and partner change rates, which is directly relevant to past and future provision of gynaecological care throughout women's life stages.

The immediate post-war 'baby boom' and its associated peak of infections was followed by a rapid fall in gonorrhoea (and syphilis) with the introduction of penicillin. The late 1950s to 1960s rise was due to sexual liberalization, demographic change and the introduction of the combined oral contraceptive pill (COC). Women who were teenagers in the mid-1970s – who are now recently menopausal – experienced the highest ever recorded rates of infection, coinciding with the greatest number of COC prescriptions issued and resulting in the lowest conception rates thereto. The effect of the HIV/AIDS education campaigns of the mid to late 1980s produced a dramatic fall in all STIs which lasted throughout the 1990s, so that women born between 1970 and 1980 had the lowest recorded rates of STIs (and greatest paranoia about infection) of any generation before or since, but had higher teenage conception rates as they used condoms in preference to pills. Women born since 1990 have intermediate infection rates due to less meticulous condom use, but are the first generation to grow up with freely accessible internet pornography, triggering a rise in coercion, acceptance and practice of rectal sex [11], and mobile dating apps offering a more efficient means of finding and changing new partners quickly. Yet they also benefited from widespread use of long-acting reversible contraceptives, and consequently had much lower pregnancy rates [10].

Rates of STIs such as gonorrhoea and chlamydia are unsurprisingly highest in women in their late teenage

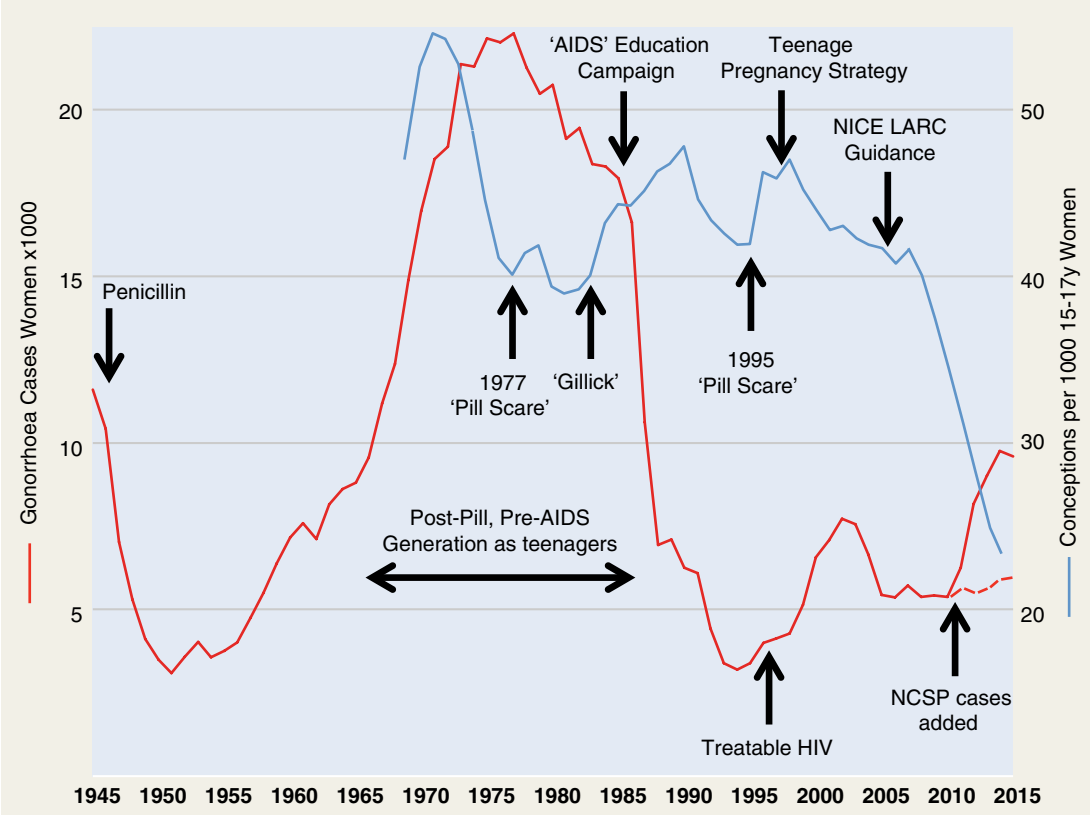

Fig. 64.1 England and Wales annual cases of gonorrhoea 1945–2015 (England only from 2010) and conception rates 1969–2014 [10]. Extrapolated from Public Health England [8] and Health Protection Agency [9] with corrections.

years and early twenties, peaking before those of young men, at the time when partner change rates are greatest and requiring repeated testing to aim for control of infections [12]. An individual's sexual behaviour and infection risk are substantially shaped by their demographic context and geographical setting [13]. Trends in STIs are broadly similar across northern European countries with similar sexual mixing patterns and the typical Western societal norm of serial monogamy with occasional infidelity. As the dating app-enabled 'half night stand' culture takes over, control of infections will become more challenging. Infection rates are already higher across entire populations where the religious cultural norm is a double-standard morality of male machismo and female virginity, as in southern Europe. STI rates are highest where poverty, drug use, economic necessity, ethnic tradition, or flight from conflict dictate that there will be large numbers of itinerant men having concurrent sexual partnerships [14] and wherever women's social, sexual and reproductive rights are least valued or respected [15].

Integrated approach to STIs in gynaecology

Any significant genital symptom, such as irritation, discharge, bleeding pattern alteration, pelvic pain or dyspareunia, should prompt enquiry and investigation as to whether the problem is due to change in hormonal milieu or a recently acquired infection, or a combination of both, given their equal contribution to these aspects of women's health (Fig. 64.2). The importance of this integrated approach [16] is particularly evident in women with recurrent pelvic pain, many of whom present to GPs and sexual health services and are presumed to have pelvic infection, when they actually have endometriosis [17,18]. These women receive antibiotics when they need hormones or surgery. The reverse occurs in women with abnormal uterine bleeding caused by chlamydial endometritis (see below): they present to gynaecologists or contraception clinics and get hormones or surgery when they need antibiotics.

Consideration of the complex interactions between a woman's hormonal status – whether due to cyclical variation, use of contraception, pregnancy, breastfeeding or life-stage changes – and their effects on systemic and local genital tract immunity is especially important for the management of recurrent genital infections (see below) and their associated symptoms. Any medical, or psychological, condition with a repeating and precisely timed cyclical fluctuation must have a hormonal cause or trigger, and might thus be amenable to hormonal treatment. Whilst biological plausibility for the latter is strong, the formal evidence base is weak due to lack of targeted research, which tends to focus purely on the infection while ignoring the contribution of luteal phase hormonally-induced immunosuppression.

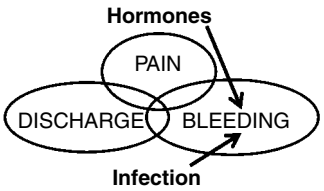

Fig. 64.2 Is it hormones or infection (endometriosis or endometritis) or both?

Sexual history-taking

This approach, and the reality of ubiquitous covert STI, requires that sexual history-taking should blend seamlessly into any routine gynaecology work-up by following on logically from menstruation details and contraceptive use. Special attention should be paid to onset of symptoms in relation to timing of hormonal or partner change. Questions do not need to be as detailed or intrusive as those typically taken in sexual health clinics [19] or following sexual assault. All that is initially required, after briefly stressing confidentiality and relevance of the questions to assisting diagnosis, is to enquire as to whether the woman is, or has been, sexually active, whether or not in a sexual relationship and, if so for how long, the interval since any previous sexual contact, be it recent or in the distant past, and whether she has had any post-coital bleeding or technical problems with sex.

By keeping questions brief, relevant and non-judgemental, sufficient useful detail should be gleaned without undue embarrassment. Clinicians should beware of making an automatic presumption of heterosexuality given the fourfold rise (to 8.7%) in experience of same-sex relationships among younger women in the most recent UK national survey [11]. Once rapport and trust in confidentiality have been established, this also represents an ideal opportunity to enquire routinely about sexual coercion or intimate partner violence [20]. Given the high prevalence and relevance of this problem, particularly during pregnancy [21], this should be considered an essential competence for any gynaecologist who supports women's human rights [22].

Relevant diagnostic tests should be taken and are discussed in Summary box 64.2. Treatment with appropriate antivirals, antifungals or antibiotics should ideally await the return of laboratory results and follow published national guidelines [23], which are regularly updated according to alterations in practice and resistance patterns, and are certain to have changed for some infections well before the next edition of this textbook (see Summary box 64.3). Immediate treatment may need to

be given, either presumptively depending on the urgency of the situation, or precisely if there is the luxury of access to accurate near-patient diagnostics [24].

Partner management

Unfortunately, immediate treatment gives less time for consideration of, and counselling about, the most neglected area of STI care in gynaecology, namely that of partner notification and treatment to prevent reinfection. Broaching the subject of sexual acquisition of infection and the need to treat the partner requires skill, discretion, privacy and accurate take-home information, and should not be rushed given the potential for misunderstanding and heightened risk of intimate partner violence [25]. Given these complexities, the minimum duty of care of a gynaecologist should be to advise abstention from intercourse until the partner or contact is treated and to seek immediate further assistance and support from health advisors and clinicians in the local sexual health clinic [26] or a nurse counsellor in their own department specially tasked with this remit. Local protocols should be established to facilitate this support, to handle confusion as results are frequently discordant and to assist the process of patient-delivered partner therapy, wherever this is part of the routine standard of care [27]. Summary box 64.1 contains some points of discussion to help reduce stigma and aid understanding.

Summary box 64.1

Discussion points on partner notification for STIs

- Any infection is likely to be asymptomatic in the partner or contact.
- There could be a long-standing pre-symptomatic phase in the woman.
- The infection could pre-date the start of the relationship.
- Given the above, an STI is not prima facie evidence of infidelity.
- Partners should be treated simultaneously to prevent reinfection, and should abstain from sexual intercourse during treatment.
- The diagnosis may not be proven and there may be other explanations for any symptoms, particularly for pelvic pain.
- Checking the partner or contact may improve the diagnosis and care of the woman.
- The partner's tests may not show infection as transmission concordance is not 100% and infections can clear spontaneously and at different rates in either partner.
- The partner should be checked and treated for their own future health.

Diagnostic advances

Much of our understanding of STI in women has changed with the introduction of highly sensitive molecular diagnostic technology, starting with polymerase chain reaction (PCR) in the mid-1990s and other nucleic acid amplification tests (NAATs) by the mid-2000s, gradually replacing the traditional methods of microscopy and culture for gonorrhoea and *Trichomonas*, viral culture for herpes, enzyme immunoassay (EIA) for chlamydia and *in situ* hybridization for HPV [28]. For these organisms, the increase in sensitivity is of a magnitude between 50 and 100% greater than previously, amplifying the epidemiological fluctuations of the past century (see Fig 64.1) and suggesting that there was far more than the recorded fourfold greater number of gonorrhoea cases among women 40 years ago than nowadays. It also emphasizes the ubiquity of endemic infections, increasing the observed proportion of symptomless carriage to over 90% for most STIs in both men and women, and has prompted a thorough re-evaluation or clarification of research into disease associations such as those of chlamydia with premature labour (Chapter 28) and HPV with genital cancers (see Chapter 61).

The benefits of the ability to detect a positive signal from, in theory, a single organism or even a fragment thereof has revolutionized genital sampling. Previously, endocervical swabs with high organism copy numbers were essential for detecting chlamydia and gonorrhoea. Now self-taken vulvo-vaginal swabs are equal to, or even more sensitive than, those taken by the clinician from the cervix [29]. This substantially reduces the need for speculum examination except in cases of post-coital or other unexplained bleeding, intractable discharge, cytology sampling and colposcopy or intrauterine procedures. Where on-site vaginal microscopy is available, women with discharge can also take their own slides for Gram staining and/or wet mount, thus fewer women are having genital examinations in sexual health clinics [30]. Indeed, without access to immediate microscopy, it is difficult to understand how gynaecologists' management of vaginal discharge can be any better than the best-guess care of a competent GP or community contraception clinic [31]. A quick and simple low-tech solution is advocated by Donders *et al.* [32], using wet mount microscopy to diagnose bacterial vaginosis (BV), aerobic vaginitis, candidiasis and trichomoniasis for immediate treatment, although this lacks sensitivity for the latter two organisms.

Near-patient and multiplex testing

The latest developments have brought laboratory-quality analysis to the bedside or outpatient clinic with the

ability to produce reliable results in less than 2 hours. Near-patient testing for chlamydia and gonorrhoea has been shown to reduce unnecessary antibiotic treatment [33], with the added benefit of allowing partners to be notified quicker, thereby reducing onward transmission. This also has potential, as yet unresearched, to improve management of the acute abdomen, particularly in young women with right iliac fossa pain, by identifying or excluding STI before surgery is contemplated or antibiotics are started.

A further recent advance is the ability to test for several organisms simultaneously. As STIs frequently coexist, a vaginal swab sample routinely tested for some 8–12 organisms circumvents the *a priori* problem of knowing or guessing what to test for while apparently sacrificing very little in the way of sensitivity, and thus fewer unsuspected infections should be missed [34]. Unfortunately, some commercially available multiplex assays include organisms (e.g. *Mycoplasma hominis*, *Ureaplasma parvum*) which most would consider commensal or which have yet to be classified as genuinely pathogenic in women, resulting in unnecessary antibiotic treatment in some women seen privately or outside the UK.

The downside of test hypersensitivity is the potential for sample contamination from surfaces in clinics [35] and the problem of persistence of dead organisms for days or weeks after successful treatment, making timing of tests of cure problematical, particularly for chlamydia and gonorrhoea (see section on individual organisms).

Routine STI testing

Minimum routine STI screening in women consists of a vulvo-vaginal swab for a combined chlamydia and gonorrhoea NAAT, and bloods for syphilis and HIV [36] (see Summary box 64.2). Clinicians are accustomed to antenatal screening for the latter two infections. This should now extend to routine gynaecological care, given the consequences of missing these treatable hidden conditions, and is essential in cases of genital ulceration or wart-like lesions, and in areas where HIV prevalence is greater than 1 in 500 of the population [37].

Summary box 64.2

Essential STI screening: genital samples and additional tests

Asymptomatic screen
- Blood tests for HIV and syphilis and vulvo-vaginal swab for chlamydia and gonorrhoea (and other sites if indicated).

Vaginal symptoms
- Basic screen *plus* high vaginal swab for microscopy/culture of *Candida* and BV, wet mount/culture or NAAT for *Trichomonas vaginalis*.

Genital ulceration
- Basic and vaginal tests *plus* herpes swab(s).

Abnormal bleeding/intrauterine device (IUD) infection
- Basic and vaginal tests *plus* deep endocervical swab culture for aerobes and anaerobes.

High-risk scenario: intravenous drug user, sex worker, swinger, woman from high prevalence area or contact/partner of same or of bisexual man
- Basic and vaginal tests *plus* blood tests for hepatitis B and C.

STI in pregnancy

STIs affect all aspects of pregnancy, from subfertility, implantation failure, ectopic pregnancy, early and mid-trimester miscarriage, premature delivery and stillbirth to fetal anomaly and neonatal infection. Yet the relatively low prevalence of epidemic STIs in developed countries means that the most severe complications are rarely encountered in obstetric practice, and the consequences of endemic STIs may pass unnoticed.

Lessons from Africa

The most substantial effect of STIs on obstetric outcome is found in developing countries, particularly sub-Saharan Africa, where untreated infection rates are highest and cofactors such as poverty, poor nutrition and other endemic infectious diseases such as malaria and tuberculosis exacerbate the problem. In this setting, even after controlling for other variables, the risk of preterm birth is doubled by gonorrhoea and *Trichomonas*, quadrupled by chlamydia, and increased sevenfold if BV is diagnosed before 16 weeks' gestation [38]. Syphilis, with an overall antenatal prevalence of between 4 and 15%, affects some 2 million African pregnancies annually, of which 1.6 million remain untreated, resulting in half a million infant deaths [39]. It is associated with one-quarter of preterm births and half of all stillbirths [38].

Recent advances in near-patient testing using simple rapid combined syphilis and HIV kits produced much higher rates of positive diagnoses, and dramatically improved the proportion of syphilis cases treated from 51.1 to 95.2% [40]. A measure of the value of treating STIs can be estimated from pragmatic trials in Rakai, Uganda of a one-off antibiotic regimen (cefixime 400 mg,

azithromycin 1 g with metronidazole 2 g) given at around 28 weeks' gestation. In the late 1990s, this combination therapy would have been simultaneously effective against gonorrhoea, chlamydia and trichomoniasis, and should have rendered syphilis non-infectious. Despite non-treatment of partners and the risk of reinfection, the relative risks of low birthweight and neonatal death were both significantly reduced, at 0.68 and 0.83 respectively [41].

Based on the above, any effort to improve screening and treatment of STIs in pregnancy in any geographical setting should be rewarded with reductions in preterm birth and neonatal death, and increases in mean gestational age and mean birthweight, although these may be difficult to measure or prove depending on absolute disease prevalence. The effects of STIs on pregnancies in developed countries is considered in the sections on individual diseases, and is further discussed in Chapter 13.

Chlamydia

'The effect of chlamydial infection in women of reproductive age is overwhelmingly underestimated' [42]. *Chlamydia trachomatis* is the most important STI affecting women's health because of its ubiquity and causal association with adverse reproductive sequelae. As some 5–10% of young women are found to be infected in screening campaigns [8,12] it is probable that at least one-third to half will have been exposed to chlamydia in a lifetime. It is an obligate intracellular bacterium with a unique quasi-viral 48-hour life cycle, transforming between its extracellular infectious state as an elementary body (EB) and the intracellular reticulate body (RB), which uses cellular material to reproduce. Tissue damage is caused partly by this process, but principally by inducing an exaggerated cell-mediated immune response in a minority of genetically predisposed individuals [43]. Some RBs can convert to persistent non-replicative forms that retain long-term viability and are thereby less susceptible to clearance with antibiotics, leading to so-called heterotypic resistance, where treatment may fail with high organism load [44]. Chlamydia is almost entirely transmitted by direct sexual contact because the organisms do not grow on or infect external skin. It can only multiply in specific types of tissues, including the columnar epithelium of the endocervix, urethra, rectum, endometrium, peritoneum, conjunctiva and pharynx, and ciliated epithelium of the fallopian tubes, nasopharyngeal sinuses and bronchi. Pharyngeal carriage of chlamydia in women genitally infected is around 12% with almost all asymptomatic [45], but oral sex is considered a relatively inefficient route of chlamydial transmission.

As with most other STIs in women, highest rates are found in the late teens and early twenties due to greatest rates of partner change, with a substantial decline from the peak at age 18–20 identified in sexual health clinic testing and by the UK national chlamydia screening programme [8,12]. Unsurprisingly, total recorded case numbers increased and overall positivity rates fell as the screening campaign rolled out to a wider proportion of the population. A better perspective on recent chlamydial epidemiology can be gleaned from Swedish data collected since the early 1980s and derived not from population screening but from widespread, low clinical threshold, diagnostic testing [46]. The sustained fall in incidence from 1986 – which was a major impetus for the UK screening initiative – occurred not because of the testing programme, but due to HIV education campaigns reducing partner change rates and increasing condom use. Since HIV became treatable in 1996, chlamydial infection rates have risen consistently.

There is increasing concern as to whether widespread screening and treatment has any realistic effect on disease prevalence, given the rate of population mixing [47]. Repeatedly exposing large numbers of individuals to antibiotics for an infection which harms only a minority contributes to the generation of resistant strains of other organisms, such as gonorrhoea and mycoplasma (see below).

Longevity of infection and spontaneous clearance

For many years it was presumed that chlamydial infection would remain present and identifiable in an infected individual until such time as they were given appropriate antibiotic treatment. It has now been shown that the majority of adolescent and adult women will eventually clear the infection from the lower genital tract via their own immune system with no apparent long-term ill effects but that a minority will retain active or quiescent chlamydial infection within their endometrium, ovarian surface and/or fallopian tubes regardless of whether the organisms are identifiable by swabs taken from the cervix [48].

The rate of spontaneous clearance in a cohort of initially infected and untreated adult women of mixed ages has been demonstrated as 50%, 80% and 95% clear after 1, 2 or 3 years respectively [49]. It has also been shown that the speed of clearance increases proportionally with increasing age so that women in their thirties are likely to have cleared the infection within a few weeks or months [50]. This explains why women in their late teens appear to have more chlamydia than those in their mid-twenties, despite the latter's increased cumulative exposure to infection. It also explains how couples are often found to

be discordant for infection, with a different speed of clearance between partners causing misunderstanding and possible recrimination [26,27].

Spectrum and sequelae of chlamydial infection

The clinical spectrum of chlamydial infection in women runs from the asymptomatic millions, who clear their infections spontaneously without suffering tubal damage [51], to the moribund few hospitalized with acute pelvic infection (see Chapter 45). Between these extremes are a range of conditions such as endometritis, menorrhagia, ectopic pregnancy and tubal factor infertility variously referred to as 'subclinical salpingitis' [52], 'atypical PID' [53] or 'subclinical PID' [54] in which the role of chlamydial infection is covert, usually unrecognized and therefore untreated.

Chlamydia and abnormal bleeding: unanswered questions

Chlamydia is one of several infections contributing to cervical friability and overt mucopurulent cervicitis [55] (Fig. 64.3), which can result in increased vaginal discharge and post-coital bleeding (PCB). Yet both the physical sign of cervicitis and the microscopic finding of leucocytes are non-specific, having a very low positive predictive value for chlamydia, but being a strong negative predictor for absence of endometritis [56]. Management of PCB in the UK is inconsistent [57], and requires definitive exclusion or treatment of chlamydia, gonorrhoea and, probably, *Mycoplasma genitalium* before any ablative surgical treatment is contemplated for benign conditions such as ectropion.

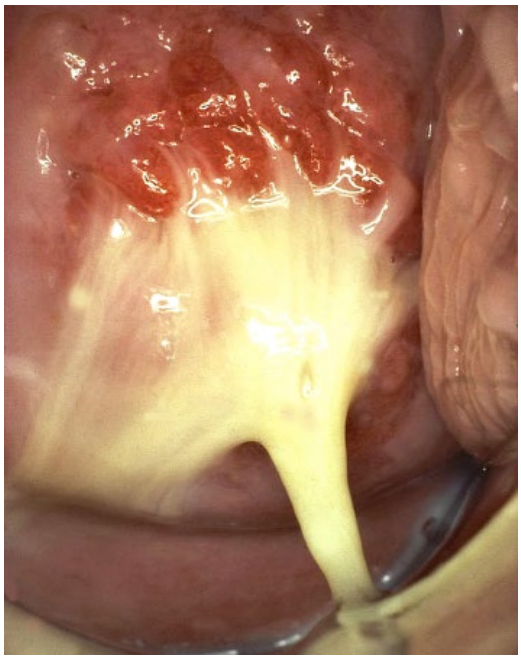

Fig. 64.3 Chlamydial mucopurulent cervicitis. Overt chlamydial mucopurulent discharge with endocervical gland oedema showing follicular cervicitis. A similar appearance is seen with gonorrhoea, but most chlamydia is covert showing little or no such obvious signs. *Source:* photograph by Peter Greenhouse FRCOG, 1992. (*See also colour plate 64.3*)

Any woman with upper genital tract infection (e.g. salpingitis, pelvic peritonitis, perihepatitis, periappendicitis) must, by definition, have a concomitant endometritis. Yet the extent to which chlamydial or other STI-related endometritis contributes to abnormal uterine bleeding (AUB) or heavy menstrual bleeding (HMB) is as yet unknown because of the paucity of specifically targeted research. Some 29% of women with recent-onset irregular intermenstrual bleeding (IMB) while taking COC pills were found to have chlamydia using a highly sensitive direct immunofluorescence test, compared with 11% who had vaginal discharge or new partners, and only 6% among new contraception clinic attenders [58]. Thus, second only to poor compliance with COC, chlamydia is the next commonest cause of IMB in young women.

Single-dose azithromycin (1 g) was shown to produce a 50% reduction in abnormal bleeding in a proof-of-concept study in predominantly African-American women attending a public sexual health clinic [59]. While histological evidence of plasma-cell endometritis reduced from 38% to 4% after treatment (P <0.001), this was not precisely linked to each case of successful resolution of bleeding.

Analysis of historical endometrial biopsies from women with unexplained AUB, who had been neither tested nor treated for chlamydia at the time of biopsy, found that some 58% had PCR evidence of chlamydia and that infection was strongly correlated (P <0.001) with the finding of macrophages, lymphocytes and plasma cells, leading the authors to make this section's opening quote on the unrecognized importance of chlamydial infection in women [42]. If this work were to be repeated prospectively and results confirmed, it would suggest that *C. trachomatis* infection could be sufficient to account for the majority of 'idiopathic' or unknown causes of AUB-E or AUB-I in the PALM-COEIN classification (see Chapter 48). Thus in the initial investigation of AUB and HMB, routine checking of pipelle or hysteroscopy samples for both plasma-cell endometritis and chlamydia, with appropriate pre-insertion treatment, might reduce the rate of persistently heavy or irregular bleeding patterns after levonorgestrel-releasing intrauterine system (LNG-IUS) insertion.

Chlamydia, periappendicitis and perihepatitis

According to Moritz in 1912, 'The causative relationships between adnexal disease and appendicitis still form

a dark area in gynaecology' [60]. The incidence of this commonest surgical emergency is significantly greater in women than in men only between the ages of 16 and 21, with a doubling in the excess rate of operation and trebling of 'negative' histology [61] coinciding with the sharp peak [8] in incidence of the commonest STI at ages 18–20. The coincident finding of chlamydia and serosal plasma cell periappendicitis [62] suggests that chlamydial 'salpingo-appendicitis' might explain this diagnostic dilemma and its ubiquity [63], necessitating chlamydia screening of all acute cases of right iliac fossa pain in young women regardless of where they present [64]. Accurate point-of-care STI tests could enhance acute management in emergency departments. If specific antibiotic regimens for chlamydial pelvic inflammatory disease (PID), such as one including high-dose ofloxacin (400 mg b.d. for 14 days), were used in future trials in this age group, this could improve the hitherto equivocal outcomes achieved [65] when comparing antibiotics with surgery, but this rationale has yet to be explored.

The association between STI and perihepatitis was first described in 1920 [66], and was originally thought to be caused by gonorrhoea. Curtis frequently found bridal veil and/or violin string adhesions between liver and diaphragm (Fig. 64.4) when performing pelvic clearance for end-stage gonococcal salpingitis [67]. The acute presentation of right hypochondrial pain, limiting deep inspiration, with positive Murphy's sign indistinguishable from that of acute cholecystitis, in association with gonococcal peritonitis was described by Fitz-Hugh [68]. Since the first isolation of chlamydia from the liver surface [69], very few cases of the Fitz-Hugh–Curtis syndrome have been described without evidence of chlamydial infection [70] or high anti-chlamydial antibody titres [71], because of the frequent coexistence of gonorrhoea with chlamydia. About 20% of PID cases have some degree of right upper quadrant pain that, in most cases, resolves rapidly with appropriate anti-chlamydial treatment, and requires adhesiolysis only in the rarest cases of persistent diaphragmatic restriction. Symptoms may present acutely without any apparent pelvic pain or other physical signs, but the association is strong enough such that any right hypochondrial pain in a young sexually active woman must be assumed to be chlamydial in origin until proven otherwise, because of the relative rarity of cholecystitis in this age group. Very rarely, women may present with pain over the left lobe of the liver or with perisplenitis.

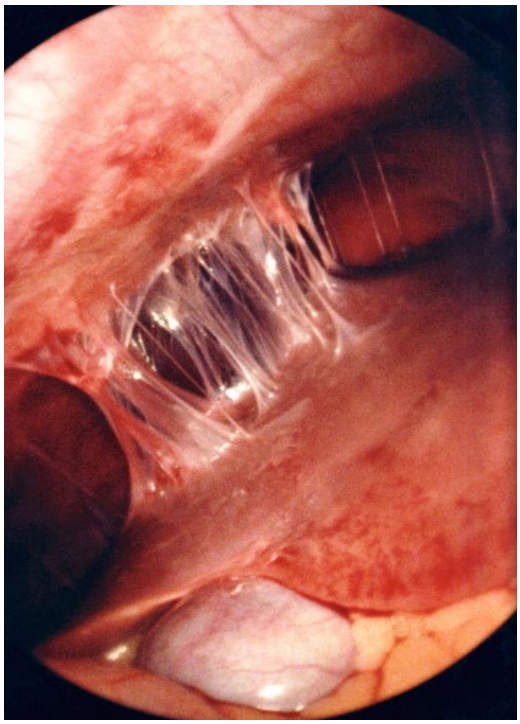

Fig. 64.4 Chlamydial perihepatitis/Fitz-Hugh–Curtis syndrome. Bridal veil and violin-string adhesions between liver and diaphragm due to chlamydial infection, causing right hypochondrial pain and restriction of respiration. Note normal gallbladder. *Source:* photography by Peter Greenhouse FRCOG, 1986. (*See also colour plate 64.4*)

Chlamydial PID and tubal factor infertility

There is a wide variety of opinion as to the proportion of women who will eventually develop tubal damage following chlamydial infection, and on the effectiveness of screening and treatment in disease prevention. Estimates range from the widely accepted 1–2% [72] to 17% in a recent thorough assessment which suggested that for every 1000 chlamydial infections in women aged 16–44 years, there would be approximately 171 episodes of PID, 73 of salpingitis, two ectopic pregnancies and five women with tubal factor infertility (TFI) by age 44 years [73]. Despite these predictions, prospective randomized studies of chlamydia screening to prevent pelvic infection report widely differing results, dependent on patient selection and data interpretation.

The Seattle PID prevention study found a relative risk of PID of 0.44 (95% CI 0.2–0.9) in screened and treated women of whom 7% had chlamydia compared with an unscreened population [74]. Yet the London Prevention of Pelvic Infection (POPI) trial found a small but non-significantly reduced number of cases in those screened and immediately treated, but the majority (79%) of incident PID cases occurred in women originally found to be uninfected [75].

As discussed in Chapter 45, the principal determinants of reproductive tract damage due to chlamydia are repeated exposure to and severity of infection [76], delayed treatment of symptomatic disease [77] and individual anti-chlamydial cell-mediated immune responses,

which are predetermined by single nucleotide polymorphisms [43] conferring enhanced susceptibility on a minority of women. These responses should theoretically become apparent at first and thus youngest exposure to infection. In contrast, some women are genetically protected against tubal damage. Those with the CCR5 Δ32 gene deletion, which also prevents infection by HIV, are four times less likely to have tubal pathology among subfertile women with anti-chlamydial IgG antibodies [78]. This raises the future prospect of being able to predict a woman's risk of infertility from genotype and chlamydial serology response [79], an approach which could be particularly useful in the investigation of 'unexplained' infertility [80].

The strongest link between TFI and chlamydial cell-mediated immune response is seen in a linear increase in anti-chlamydial antibody titre (CAT) with severity of tubal damage in subfertile women, when measured by the whole-cell inclusion immunoflourescence test [81]. As CAT is logarithmic, this fits a dose–response effect. Almost all of these women were negative on cervical NAAT screening and it is not yet known if women with high CAT would benefit from prolonged antibiotic therapy [80], though this could be an option in those with proven endometritis. Anti-chlamydial heat shock protein (HSP)-60 antibodies have been more widely studied, having highest titres in women with acute perihepatitis and salpingitis [71], and also being highly predictive of TFI when combined with markers of anti-chlamydial humoral immunity [82].

Failure of assisted reproduction techniques

Higher chlamydial HSP-60 titres are also associated with significantly greater risk of failure of assisted reproduction techniques (ART). Embryo implantation is more likely to fail [83], and early spontaneous miscarriages are more common [84]. As human HSP-60 has a similar structure to that of chlamydial HSP-60, the postulated immunopathological mechanism is either one of chronic covert endometritis preventing implantation, or a possible direct effect on early embryo development [84]. Increased expression of endometrial prostaglandin receptors has separately been proposed as a risk factor in chlamydia-infected women with recurrent miscarriage [85]. On a hopeful note, a significantly higher live-birth rate has been demonstrated in women whose chronic endometritis improved after a combination of antibiotic treatments, most of which included anti-chlamydials [86].

Chlamydia and ectopic pregnancy

Chlamydia probably contributes to the majority of ectopic pregnancies despite rarely being found on vaginal or endocervical swabbing at the time of presentation, and the range of estimated risk is a matter of dispute (see Chapter 43). Chlamydia causes suboptimal oocyte transport by partial deciliation and reduced ciliary beat frequency [87] in women who have not already suffered complete fimbrial enclosure. Over 85% of women with ectopic pregnancy have markedly raised CAT compared with women having live births [80,88]. In an ecological study, annual reduction in chlamydial incidence was directly related to a linear fall in ectopic pregnancy: among 20–24 year olds, extension of the plot line transected the zero point of the abscissa, suggesting that if there were no chlamydia in this age group, there would be little or no ectopic pregnancy [89]. The PCR finding of reverse-transcription chlamydial mRNA in fallopian tubes of women with ectopic pregnancy suggests that viable, metabolically active chlamydial infection remains present and contributing to tubal damage long after initial infection [90]. Taken together, these points suggest that young women with ectopic pregnancies may warrant extended anti-chlamydial treatment even if lower genital tract swabs are negative.

Chlamydia and arthritis

The first described example and strongest evidence of individual genetic response to chlamydia is that of HLA-B27 tissue type [91] conferring susceptibility to the triad of sexually acquired reactive arthritis (SARA), uveitis/conjunctivitis and urethritis (formerly known as Reiter's syndrome), which appears commoner in men than women [92]. SARA is an asymmetric multi-joint 'sterile' inflammation of synovium, fascia and tendons typically affecting hands, lower limbs and sacro-iliac joints, where chlamydia can be found in synovial membrane biopsy [93]. Joint involvement can occur in the absence of other features and isolated sacro-iliitis is probably frequently missed in women [94]. Treatment is by standard or extended anti-chlamydial regimens [94,95] in conjunction with anti-inflammatory drugs, and the condition is best managed jointly between sexual health clinicians and rheumatologists because of the high recurrence rate [94]. Azithromycin becomes highly concentrated in cartilage, but it is not yet proven if this regimen confers special benefit [95].

Chlamydia in pregnancy

Through the 1980s and 1990s, studies of chlamydia in pregnancy using relatively insensitive EIA testing consistently reported higher rates of spontaneous preterm labour and preterm birth (PTB) in chlamydia-infected women, but none reached statistical significance. No meta-analysis was performed, and it was assumed that chlamydial infection was not a major cause of PTB. Studies using early chlamydial DNA detection tests suggested a twofold to threefold increased risk of PTB if chlamydia was detected at 24 weeks [96].

In the treatment of women with BV in pregnancy (see Chapter 28), only systemic regimens containing recognized anti-chlamydial antibiotics (erythromycin, clindamycin) were successful in reducing PTB [97], explaining the failure of metronidazole-only regimens. Accidental treatment of chlamydial infection is probably the hitherto unexplained reason for the marked success of the only randomized antenatal trial of doxycycline (against presumed bacteriuria) yielding an odds ratio of 0.25 for PTB versus placebo [98]. Taking these facts together suggests that greater importance should be attached to antenatal screening for chlamydia [99], despite the problems of evaluating the relevance of treating an infection which can resolve spontaneously between antenatal visits in older women [49]. This is not recommended in the UK National Institute for Health and Care Excellence (NICE) guidelines [100], which merely suggest directing women under 25 years old to the National Chlamydia Screening Programme. This analysis failed to take account of the largest antenatal natural history study of untreated chlamydia, which showed adjusted odds ratios of 4.35 and 2.66 for PTB in infected women under 32 and under 35 weeks, with chlamydia accounting for 14.9% and 7.4% of premature deliveries at these gestations respectively [101].

Mother-to-child transmission of chlamydia occurs in up to 60–70% of infants born vaginally [102]. Vaginal and rectal infection in newborn girls is more likely to occur in breech deliveries, with a quoted 20% transmission efficiency [103]. Chlamydial ophthalmia neonatorum is much more common than that caused by gonorrhoea, but the incubation period is longer at around 1–2 weeks, with all infections presenting within 30 days [104]. Chlamydial pneumonitis can occur any time from 1 to 3 months after birth, with the majority presenting between 8 and 11 weeks [105].

Chlamydia treatment and prophylaxis

(see also Summary box 64.3)

Although recent UK guidelines [106] still recommend equal first-line treatment of uncomplicated chlamydia with doxycycline 100 mg b.d. for 7 days or azithromycin 1 g stat, there is increasing concern about the inadequacy of the latter regimen when assessed by test of cure (TOC) using NAAT [107,108]. Doxycycline is some 20% more effective than single-dose azithromycin for rectal infection [109], and as the rectum is a preferential site for chlamydial carriage even in women who have never had rectal sex [110], an alternative is needed. Azithromycin has a very long intracellular half-life, remaining above the MIC_{90} for chlamydia for 10 days, and is especially concentrated in uterus, fallopian tubes and bladder [111]. Yet its serum half-life is less than 24 hours, which explains its potential failure in high organism load infections [44], requiring an extended regimen prolonged over at least three and preferably five days [112]. Extended azithromycin using a total of 1.5 g minimum up to 3 g maximum (e.g. 1 g stat followed by 500 mg for 4 days) should almost certainly be used in preference to single-dose therapy when there is any suggestion of endometritis. This oral regimen was extrapolated from a successful PID monotherapy trial [113]. A further alternative for uncomplicated chlamydia is ofloxacin 200 mg b.d. (or 400 mg o.d.) for 7 days, but this must not be given to professional athletes because of the rare side effect of tendon rupture [106].

This new understanding of treatment inadequacy sheds light on, and may call into question, recommendations against antibiotic prophylaxis prior to uterine instrumentation to prevent PID, particularly before IUD insertion [114]. This analysis found no overall reduction in PID, yet a small but significant benefit with less women re-attending for pain or bleeding, in studies using a suboptimal azithromycin regimen (500 mg stat) or a homeopathic dose of doxycycline (200 mg stat). The current recommendation against routine prophylaxis [115] should be backed up by trials of an appropriately dosed anti-chlamydial regimen (i.e. extended azithromycin), particularly for young women requesting emergency IUD contraception. This is another example where near-patient high-quality diagnostics could lead to better-targeted antibiotic husbandry.

There are less therapeutic options for treatment of chlamydia in pregnancy or breastfeeding, as both doxycycline and ofloxacin are contraindicated, but are not apparently harmful in the interval between conception and first missed period. Azithromycin 1 g is recommended as first line [106] because of its safety [116] and superior tolerability to the alternative of erythromycin [117]. Amoxicillin 500 mg t.d.s. for 7 days is an alternative [118], but is not used outside pregnancy because of theoretical concerns of inducing latency. The importance of ensuring clearance of infection prior to delivery mandates a TOC, which must be performed no less than 4 weeks [119] to 6 weeks [106] after treatment has finished, because the persistence of dead chlamydial antigen can give a false-positive NAAT if taken sooner [107]. Assistance from sexual health colleagues is particularly useful in this scenario to handle sensitive relationship issues and ensure correct management of partners [106].

Further guideline-based regimens for upper genital tract chlamydia are considered in Chapter 45.

Gonorrhoea

Gonorrhoea is the second commonest bacterial STI, with less than one-tenth the prevalence of chlamydia in the UK [8], producing a similar range of gynaecological

morbidity. It is more often symptomatic because of its more direct mode of pathogenesis, but still remains unrecognized in some 70–80% of women. Gonorrhoea epidemiology, discussed in detail in Fig. 64.1, is more sensitive to changes in sexual behaviour than chlamydia. Even when cases were at their lowest in the UK in the early to mid-1990s, Black British or Black Caribbean compared with White ethnicity was associated with a 12-fold or eightfold greater risk of gonorrhoea or chlamydia respectively [120]. This was ascribed to much higher partner change rates and concurrency of relationships. This pattern is seen worldwide in other populations depending on these parameters and prevailing socioeconomic, cultural and other coercive factors.

Neisseria gonorrhoeae is a Gram-negative diplococcus which adheres via surface pili to columnar epithelial cells of moist mucous membranes of the urethra, endocervix, rectum, pharynx and conjunctiva [121]. Transmission occurs by direct inoculation of warm secretions onto a surface with near neutral pH. Although it does not infect the vagina in adolescent and premenopausal adult women, gonorrhoea causes vulvovaginitis in prepubertal girls as the hypo-oestrogenic vaginal epithelium is thin with a neutral pH and is therefore easily inflamed, with most infections being symptomatic [122]. Gonococci produce a peptidoglycan-stimulating cytotoxic tumour necrosis factor (TNF)-α [123] and a lipopolysaccharide enzyme that facilitates direct spread of the organism particularly into glandular tissues, producing damage and potential abscess formation and contributing significantly to the more severe presentation of acute gonococcal salpingitis (see Chapter 45).

The principal lower genital tract symptoms, if present, arise from an endocervicitis manifesting as excess vaginal discharge – which can often remain unnoticed because of normal cyclical changes – and increased cervical friability which predisposes to PCB [124]. Gonorrhoea is nowadays much less likely to be missed as a cause of discharge and PCB because of the routine use of dual chlamydia/gonorrhoea NAAT, such as the Aptima Combo 2 [125]. Overt gonococcal urethritis is rarely seen in women compared with men, and urethral infection is now rarely tested for other than in hysterectomized women. When previously researched using culture it was commonly found in some 80% of women with endocervical infection [1], many of whom had only mild and largely ignored dysuria. Both rectal and pharyngeal gonorrhoea are asymptomatic in around 95% of men and women. The pharynx represents a major reservoir for oral sex transmission of gonorrhoea, and fellatio is the principal route of gonorrhoea spread in those who use condoms meticulously for other forms of sex [126]. Control of pharyngeal gonorrhoea is particularly important as most antibiotic resistance develops at this site [127].

Rarely, gonorrhoea infects paraurethral tissues including Skene's glands [3], and was classically recognized as the commonest cause of Bartholin's abscesses, although chlamydia also contributes to a lesser quantity of acute and chronic Bartholin's inflammation [128].

Disseminated gonococcal infection: arthritis and septicaemia

Disseminated gonococcal infection (DGI) may occur in up to 3% of cases [129]. It usually presents without obvious genital symptoms in women, commencing with a flitting polyarthralgia, tendon pain and pyrexia. Painful pustular lesions occur in hands and feet, with infectious micro-emboli lodging in the peripheral circulation. The main feature is one or two hot swollen joints (septic arthritis), most commonly the knee and wrist, with organisms identifiable from aspiration of synovial fluid [130]. DGI is more common in women than men and often presents during pregnancy, probably because the combination of lowered immunity, increased vascular permeability and hyperdynamic circulation may facilitate haematogenous spread. Rare complications of DGI are gonococcal meningitis and endocarditis [129]. Treatment requires higher and longer doses of the first-line agents [121].

Gonorrhoea in pregnancy

Gonorrhoea is too sporadic for trial research in a European setting regarding PTB, but much of this infection will remain unrecognized in pregnancy unless vaginal discharge is copious and dual chlamydia/gonorrhoea testing is used [131]. A new diagnosis in pregnancy raises acutely sensitive issues of partner treatment [132], mutual mistrust and support needed in case of intimate partner violence. As with chlamydia, correct treatment and TOC is essential [121] to reduce the risk of PTB and prevent ophthalmia neonatorum. This was first managed with silver nitrate prophylaxis by Credé over a century ago [133], but remained the principal cause of blindness, apart from syphilis, in the UK up to the 1920s. Symptoms of discharge and eyelid oedema typically develop within 2–5 days, but occasionally present up to 2 weeks after delivery [134], and must be treated immediately as corneal scarring can occur within 24 hours [135].

Treatment of gonorrhoea (see also Summary box 64.3)

Current UK [121] and European [136] guidelines recommend ceftriaxone as the only first-line antibiotic remaining to treat gonorrhoea effectively (including in pregnancy), with a current 99.2% cure rate [127].

Ceftriaxone 500 mg i.m. stat needs to be given with azithromycin 1 g [121] or 2 g [136] stat, regardless of chlamydia test results, to reduce the chance of resistance developing to the primary drug. After initial diagnosis by NAAT, a swab must be taken for culture before treatment is given. Gonorrhoea is best managed in conjunction with a sexual health service to provide this essential antibiotic sensitivity checking, partner notification and follow-up TOC. Timing of TOC must be delayed by 2 weeks to allow for clearance of residual gonococcal DNA [137]. In the case of allergy or other contraindication to ceftriaxone, choice of antibiotic is determined by the culture result on advice from the microbiologist based on local resistance patterns. Spectinomycin 2 g i.m. stat is one of the second-line recommendations, but this is ineffective against pharyngeal gonorrhoea [138].

The most pressing problem of gonorrhoea control is the likelihood that the infection will become untreatable within the next decade [139]. The organism can evade host immune responses by having a widely variable surface structure and rapidly evolves resistance mechanisms to each new antibiotic within a few years of its introduction. Antibiotic concentrations are higher in the genitals and pelvis than in the pharynx, where gonorrhoea mixes with commensal organisms, particularly *N. meningitidis*, from which it acquires resistance genetic information. Recommended antibiotic dosage regimens will increase as resistance 'drift' increases [140]. Complete resistance to ceftriaxone is currently rare, but first occurred in pharyngeal infection of a Japanese female sex worker [141]. The pharynx was the site of all resistant strains in the last European-wide report [142]. High-level azithromycin resistance in the UK was first reported among heterosexuals [143], probably occurring due to widespread use of the drug in the chlamydia screening programme, with cases of undiagnosed gonorrhoea being missed and suboptimally treated. The first dual failure of ceftriaxone and azithromycin was recently reported from the UK [144].

While awaiting newly developed antibiotics, future management of multidrug-resistant gonorrhoea will require reuse of combinations of older antibiotics, guided by culture results and newer molecular techniques [140], necessitating ever closer working between gynaecologists, sexual health clinicians and microbiologists to achieve therapeutic success.

Untreated or untreatable gonorrhoea

For obvious ethical reasons, no modern data are available on the long-term course or duration of untreated gonorrhoea in women but, in the worst-case scenario, the possibility of untreatable infection may prompt a return to heroic surgical intervention for chronic disease. Reading from pre-antibiotic era accounts of optimal choice of timing for pelvic clearance of 'burnt out' gonococcal salpingitis, it is probable that almost all infection will have spontaneously cleared within 2 years, in many cases much sooner [67,145].

Mycoplasma genitalium

Mycoplasma genitalium (MGen) belongs to a genus of the smallest known free-living organisms, having DNA and RNA but no cell wall. It is considered to be an emerging [146] and overlooked STI [147] as it has been shown to cause some 30% of non-gonococcal urethritis in men [148], yet a thorough review could not conclusively implicate *M. genitalium* as a cause of female urethritis [146]. An equivalent contribution to other lower or upper genital tract infection in women, over and above that of gonorrhoea and/or chlamydia, has been less widely researched because of its relatively recent discovery and the limitations of diagnostic expertise confined to a small number of centres.

Mycoplasma genitalium infects genital and respiratory mucosal surfaces, and other members of the genus (e.g. *M. hominis*, *Ureaplasma parvum*) have been found to be commensal in these sites. Although progesterone is a prerequisite for establishment of infection in laboratory animals, nothing is known of the interaction of hormones and *M. genitalium* in humans. *Mycoplasma genitalium* is associated with mucopurulent cervicitis, with one group showing a 3.3-fold greater risk [149]. Yet the difficulties of standardizing a definition of cervicitis hamper accurate comparisons between studies [146], and characterizing its role in vaginal discharge has remained elusive for similar methodological reasons.

Since the original report implicating raised *M. genitalium* antibody titres in acute PID [150], substantial work has been published linking the immune response to *M. genitalium* in women with TFI [151]. Despite this, another major study showed a lack of association of *M. genitalium* antibodies with PID and ectopic pregnancy [152]. *Mycoplasma genitalium* has been found in significantly greater proportions in women with endometritis, but its low overall prevalence in women with severe PID suggests a minor role only [153]. A recent meta-analysis suggests that the association is statistically significant [154], but might be only marginally clinically relevant due to the low pooled odds ratio (POR) of 2.14 (95% CI 1.31–3.49). This suggests that only a small minority of infected women are susceptible to significant damage while most are unaffected. These issues are also considered in Chapter 45.

Mycoplasma genitalium in pregnancy

In the antenatal setting, a large London study found a low (0.7%) prevalence of *M. genitalium*, suggesting it was

'unlikely to be an important risk factor in adverse pregnancy outcome in healthy women in the community' [155]. While an authoritative review found considerable evidence for the role of *M. hominis* in postpartum and post-abortal sepsis, there was difficulty differentiating the role of *M. genitalium* from that of BV in PTB [156]. The aforementioned meta-analysis [154] reached an alternative conclusion, suggesting a POR of 1.89 (95% CI 1.25–2.85) for *M. genitalium* in PTB, but this is considerably less than the OR of 4.35 (95% CI 1.3–15.2) for chlamydia in the Rotterdam study [101].

Treatment of *Mycoplasma genitalium*
(see also Summary box 64.3)

The greatest problem in management of *M. genitalium* is the inadequacy of treatment to clear infection, and the finding that some 40–50% of the 15% who fail treatment with azithromycin 1 g will have developed chromosomally mediated resistance at the 23S site, necessitating alternative treatment with moxifloxacin [157]. The European guidelines recommend extended azithromycin regimens for 3 or 5 day as first-line choice [157]. Yet as most people are never tested for *M. genitalium*, macrolide resistance is already endemic at around 40% in countries such as the UK and Norway because of widespread exposure to single-dose azithromycin, but not in Sweden where doxycycline is used in preference to treat chlamydia [158].

The latest PID treatment guidelines have introduced specific anti-mycoplasmal regimens for the first time (see Chapter 45), but routine screening for *M. genitalium* is not recommended by the CDC [159], and few UK sexual health centres currently offer testing. However, over the next decade, the true relevance of *M. genitalium* in obstetrics and gynaecology, and the implications of its increasing resistance to macrolides in populations with widespread exposure to single-dose azithromycin treatment of chlamydial infection, will become clearer as new diagnostic techniques are standardized and used routinely in sexual health clinic practice and in cross-disciplinary research.

Summary box 64.3

Antibiotic treatment for the main bacterial STIs (all doses oral unless stated)

Chlamydia trachomatis
- First choice — Doxycycline 100 mg b.d. for 7 days.
- Second line — Ofloxacin 200 mg b.d. or 400 mg o.d. for 7 days *or* erythromycin 500 mg b.d. *or* 250 mg q.d.s. for 7 days.
- Alternative — Extended azithromycin 1 g stat *then* 500 mg o.d. for 2 days *or* 250 mg o.d. for 4 days.
- Complicated — Ofloxacin 400 mg b.d. for 14 days *or* doxycycline 100 mg b.d. for 14 days *or* extended azithromycin 1 g stat *then* 500 mg o.d. for 4 days.

Neisseria gonorrhoeae
- First choice — Ceftriaxone 500 mg i.m. stat *and* azithromycin 1 g *or* 2 g stat.
- Alternative — Consult microbiologist and/or sexual health clinician.
- Complicated — Consult microbiologist and/or sexual health clinician.

Mycoplasma genitalium
- First choice — Josamycin 500 mg t.d.s. for 10 days *or* extended azithromycin 500 mg stat *then* 250 mg o.d. for 4 days.
- Second line — (if azithromycin resistant) Moxifloxacin 400 mg o.d. for 7–10 days.
- Third line — (after azithromycin and moxifloxacin failure) Pristinamycin 1 g q.d.s. for 10 days.
- Complicated — Moxifloxacin 400 mg o.d. for 14 days.

Trichomoniasis

Trichomonas vaginalis (TV) is a sexually transmitted flagellated protozoan which can cause sudden-onset vulvitis, vaginitis, cervicitis and copious yellow or green offensive vaginal discharge accompanied by pruritis, dysuria and introital dyspareunia, but which can also be harboured symptomlessly for many months or years in some women [160]. In men it can cause overt urethritis but typically remains asymptomatic and clears spontaneously within only a few weeks. Worldwide, it is the commonest non-viral STI, yet it is substantially underdiagnosed in both sexes due to lack of appropriate testing, and the insensitivity of traditional microscopy and culture [161], which can only identify some 50% and 75% of cases, respectively. Symptoms of mild trichomoniasis may be indistinguishable from those of simultaneous candidaisis and BV, and the classic haemorrhagic spots of 'strawberry cervix' (colpitis macularis) are only rarely seen in such cases [160].

Most UK and US studies have demonstrated a much higher prevalence of *T. vaginalis* carriage in women of Black Caribbean compared with Caucasian origin [162] and especially high rates in incarcerated women [163]. Ethnically targeted screening alone would have missed over 50% of cases in a large UK community study, which

also identified deprivation as a risk factor in white British women [161]. *Trichomonas vaginalis* was more prevalent than chlamydia or gonorrhoea at all ages except among teenagers, with highest prevalence found in women aged over 40 years, in a large study of residual Aptima Combo 2 screening samples [164]. A fivefold higher prevalence of *T. vaginalis* was found in postmenopausal compared with younger women [165] as the organism thrives better in the more alkaline environment of the hypo-oestrogenized vagina. In premenopausal women with *T. vaginalis*, vaginal pH is typically raised at around 6 or 7, with absent lactobacilli making it difficult to separate from BV or aerobic vaginitis [32] on Gram-stain microscopy alone. Specific testing for *T. vaginalis* – wet mount microscopy with culture, or, if available, NAAT [24,164] – is indicated when first-line presumptive treatment of either of these conditions has failed.

Trichomoniasis in pregnancy

There is conflicting evidence from African studies that treatment of *T. vaginalis* infection may have a detrimental outcome on pregnancy and that the infection not may be associated with preterm delivery and low birthweight in HIV-infected mothers [166]. Standard doses of metronidazole are safe to use at all stages of pregnancy but, likewise, treatment of *T. vaginalis* may not improve outcome in a Western setting [167]. *Trichomonas vaginalis* infection at delivery is significantly associated with maternal postpartum sepsis [168] requiring metronidazole treatment, which will render the breast milk sour and unpalatable.

Treatment options and metronidazole resistance

Metronidazole 400 or 500 mg b.d. for 5–7 days is the standard treatment for *T. vaginalis*, having a better than 90% immediate cure rate [160]. A 2-g stat dose is less effective. TOC is recommended at 1 or 2 weeks and it is often difficult to differentiate treatment failure from reinfection. Once the latter has been excluded by simultaneous partner treatment or confirmed abstinence, some 5% of *T. vaginalis* strains show varying degrees of imidazole resistance [169]. The majority are at low level, so higher doses of metronidazole with additional intravaginal treatment or switching to tinidazole is usually successful. In cases of continued treatment failure, there are many tried, but no proven, regimens. These include intravaginal dosage of paromomycin, furazolidone, acetarsol, nonoxynol-9 or povidone-iodine. Each has had limited success in small series or individual cases [160,163,169].

Recurrent vulvo-vaginal infections

Unlike *T. vaginalis*, which is almost entirely sexually transmitted, BV and candida do not require treatment of the male partner for resolution. Yet they are more common in sexually active women and after male partner change, are initiated and exacerbated by sexual activity, increased in the presence of other STIs, and can be considered as 'sexually shared infections' among lesbian women [170,171].

The substantial overlap of vulvo-vaginal symptoms of *T. vaginalis*, aerobic/atrophic vaginitis, BV and candidiasis/candidosis requires a consistent and thorough approach to diagnosis after first-line 'best-guess' treatment has failed in primary care. While management of uncomplicated, one-off episodes of infection is described elsewhere (Chapter 58), dealing successfully with recurrent vulvo-vaginal infections demands an understanding of the vaginal microbiome [172,173], its alteration by menstruation [174], contraception [175] and/or hypo-oestrogenism [176,177], and the role of cyclical hormonal fluctuation in premenstrual suppression of systemic [178] and cutaneous immunity [179], which creates a 'window of vulnerability' to infection in the luteal phase [180]. This may need the full armamentarium of Gram stain and wet-mount microscopy, using a consistent reference standard – the Amsel method, Nugent score or Hay–Ison criteria – with culture, sensitivity assays and molecular techniques to achieve an accurate diagnosis. Further management requires an assessment of systemic immunity, and a holistic therapeutic approach combining conventional oral or vaginal antimicrobials, probiotics, reduction or ablation of menstruation, and manipulation of hormonal milieu. Most formal research has concentrated on one or other therapeutic method in isolation, whereas tailored combinations of treatment may be required to achieve individual success, making robust evidence-gathering through trial randomization more difficult.

Recurrent bacterial vaginosis

As BV represents an imbalance of the vaginal ecosystem, treatment with antibiotics is a necessarily 'flawed approach' [181]. Principal among the many alterations of the vaginal microbiome in BV is the loss of H_2O_2-producing lactobacilli [181], a consequent rise in pH, and establishment of a wide range of mostly anaerobic organsims, including *Atopobium vaginae*, *Prevotella* spp., BV-associated bacteria and *Mobiluncus curtisii*, predominant among which is *Gardnerella vaginalis*, which is maintained in a vaginal wall biofilm that persists despite metronidazole treatment [182]. Menstruation itself alters the dynamic balance of the vaginal milieu, with BV-associated

organisms at maximal concentration and lactobacilli significantly reduced during menstruation, with a subsequent fourfold rise in lactobacilli concentration into the late luteal phase [183]. This explains the finding of transient, asymptomatic, spontaneously resolving BV in healthy clinician volunteers taking daily swabs [184]. More recently, molecular techniques tracking the concentrations of some 25 intravaginal organisms have graphically demonstrated this temporary upset and spontaneous recovery of the biome during and after menstruation [174]. This explains why menstruation is one of the principal triggers for BV, but this factor is rarely taken into account in conventional treatments. For many women with recurrent BV, repeated oral or intravaginal metronidazole [185] and/or clindamycin in various regimens and combinations are their clinicians' only therapeutic strategy, metaphorically – and literally – *ad nauseam* [186].

This has prompted alternative approaches to treatment that include intravaginal lactic acid and glycerol gel, which is claimed to be as effective as metronidazole in individual BV recurrences [187], and there has also been limited success with intravaginal instillation of lactobacilli such as *L. crispatus* [188]. As with repeated metronidazole or clindamycin, after cessation none of these regimens prevents recurrence. The practice of douching and intravaginal soap washing has long been associated with BV, but stopping these practices failed to reduce symptoms or recurrence rates [189]. Thus BV causes women to douche rather than vice versa. Newer intravaginal antiseptics have also failed to disrupt the *G. vaginalis* biofilm and have been unable to prevent BV recurrence [190]. Better long-term success has been achieved with a combination of extended antibiotics and intravaginal lactobacilli capsules, with a cure rate around 65% at 1 year. This study also found that relapse was very strongly associated with taking a new sexual partner [191].

Choice of contraceptive method affects BV recurrence rates, yet few clinicians actively employ hormonal strategies in this scenario. Women using copper IUDs have more BV because they have heavier and more irregular vaginal bleeding [192], and should therefore benefit from a switch to a LNG-IUS. Conversely, women taking COC pills have significantly less recurrent BV [175,193], because they have less bleeding. Reviewing Fig. 64.2, with bleeding leading to discharge, it seems logical to propose that, in women who have BV repeatedly triggered by menstruation, anything which reduces or prevents bleeding – treatment of chlamydial endometritis [42,59], followed by continuous COC, depot medroxyprogesterone acetate (DPMA) or LNG-IUS – should reduce BV recurrences. Anectodal success has been reported with this approach [194], which attempts to treat the cause rather than the symptom, but no formal trials have been undertaken.

The role of BV in PTB and PID is reviewed in Chapters 28 and 45 respectively.

Recurrent vulvo-vaginal candidiasis

Recurrent vulvo-vaginal candidiasis (RVVC) is defined as four or more episodes occurring in a year with substantial clinical improvement between episodes [195]. Similarly to recurrent BV, the mainstay of treatment of RVVC is repeated or extended courses of systemic and/or intravaginal therapy, aided by mycological culture typing and resistance profiling [195], although the latter reveals that over 90% of RVVC is due to *Candida albicans* and that resistance to fluconazole had been, until recently, relatively uncommon despite its ubiquitous use over the last two decades [196]. After exclusion of other causes of vulvo-vaginal itch such as *T. vaginalis*, and adjustment or treatment of causes of immunosuppression such as antibiotic and steroid therapy, diabetes and late-presentation, previously undiagnosed HIV, it is clear that the majority of women with RVVC are otherwise healthy, so genetic factors are relevant: Single nucleotide polymorphism (SNP) variation in Toll-like receptor (TLR)-2 confers a threefold increased risk for RVVC [197], and TLR response varies substantially across the menstrual cycle [198].

In most women with RVVC, episodes occur repeatedly during the luteal phase of the cycle, many on a specifically predictable day each month. The luteal phase represents an entirely different immunological milieu compared with the follicular phase, with T-helper 2 domination, T-helper 1 downregulation [178] and substantial changes in cytokines such as TNF-α [199], interleukin (IL)-6 and TLRs [198], so that women are premenstrually systemically immunosuppressed [178,180,199]. A measure of the magnitude of this effect is the fact that 25% of near-fatal asthma attacks occur on the first day of menstruation [200], and at least 15 different dermatological conditions – including oral and genital herpes, candidiasis, Behçet's syndrome, hidradenitis suppurativa, acne, urticaria, eczema, autoimmune dermatitis, angioedema, erythema multiforme and lupus – recur immediately premenstrually and spontaneously recover after menstruation [201–203]. As each of these conditions, including RVVC [195], improves and stabilizes after menopause, this raises the possibility that each could be amenable to successful treatment by hormonal suppression of the menstrual cycle. Some perimenopausal women have such severe cyclical RVVC that they are symptom-free only from day 7–14, then have gross inflammation and pruritis by day 15 or 16 until gradual remission starts on the day of menstruation.

A group of six such women, managed personally, had their symptoms completely and immediately relieved by gonadotrophin-releasing hormone (GnRH) analogue therapy, and two were permanently cured by oophorectomy. Although this is a radical approach to a desperate problem, it suggests that less drastic hormonal regimens addressing the underlying cause of the problem might be beneficial, and two uncontrolled studies have reported that long-term DPMA substantially reduced or prevented RVVC [204,205]. A further encouraging finding is a proven lower candidal relapse rate when adjunctive *Lactobacillus* therapy was used with a conventional extended fluconazole regimen [206], but this has yet to reach robust guideline evidence standards.

Cyclical predictability of RVVC has led to guideline suggestions of timed monthly [207] or weekly [195,208] maintenance fluconazole therapy. Recommendations for the less common azole-resistant *C. glabrata*, and the rare, intrinsically resistant *C. krusei* are also in the guidelines [209,210], but difficulties with the treatment regimens suggest that discussion with pharmacist, microbiologist and/or sexual health clinician would be useful. As oral agents are contraindicated in pregnancy, treatment is with topical and intravaginal therapy only for 7 days [211] and is discussed further in Chapter 13.

Summary box 64.4

Recommended regimens for severe and recurrent vulvo-vaginal candidiasis [207,209,210]

Severe vulval candidiasis

- First choice — Fluconazole 150 mg p.o. three doses at 72-hour intervals.

RVVC due to C. albicans

- First choice — 'Severe' regimen followed by maintenance fluconazole 150 mg at weekly or monthly intervals.

RVVC due to azole-resistant C. glabrata or C. krusei

- Possible choice — Boric acid 600 mg p.v. o.d. for 14 days.
- Alternative — Nystatin suppositories 100 000 units p.v. o.d. for 14 days.
- Alternative — Flucytosine 17% cream with or without Amphotericin B 3% cream p.v. o.d. for 14 days.

Vulvo-vaginal candidiasis in pregnancy

- First choice — Clotrimazole 500 mg p.v. stat *then* 100 mg pv o.d. for 6 days with clotrimazole 1% cream topical prn.

Genital herpes

The four principal areas of knowledge about genital herpes of most relevance to hospital-based gynaecologists are:

1) appreciation and recognition of the ubiquity and minor nature of most genital herpes;
2) emergency management of very severe primary genital or disseminated herpes;
3) management of first presentation and previously diagnosed genital herpes in pregnancy;
4) management of frequently recurrent genital herpes in perimenopausal women.

Genital herpes is caused by HSV types 1 and 2, which exhibit neurotropism and latency similar to other members of the alpha-herpesviridae group such as the ubiquitous varicella zoster virus. The majority of adults in the UK and similarly developed countries are infected with one or other type orally and/or genitally, with combined HSV infection rates around 85% in women and 75% in men by age 40 in Australia [212] and, among European blood donors, 78% of both sexes have HSV-1, with 20% of women and 9% of men having HSV-2 by age 30 [213].

Herpes episodes are described as primary (with no previous exposure at any site), first episode/post-primary (following previous covert exposure), or recurrent. Only some one-third of those infected with HSV-2 will develop symptoms at first genital exposure [214], in many cases because past oral HSV-1 infection – acquired in childhood from being kissed by parents and/or relatives, or in adolescence from pre-sexual petting – modifies and minimizes subsequent response to HSV-2 [214]. Most will be unaware of their infection or have had such minimal symptoms that the condition has passed entirely unnoticed or is presumed to have been a transient episode of 'cystitis' or 'thrush', and may indeed be misdiagnosed as RVVC. As the natural course of recurrent genital (or oral) herpes episodes is spontaneous healing within a few days of symptom onset, women use over-the-counter remedies that appear to work successfully and thus 'confirm' the incorrect self-diagnosis. This delays or prevents accurate diagnosis, until women can be taught to recognize the associated neurological prodrome, usually within the S2 dermatome, which heralds the true cause of their recurrent symptoms [215]. The relative proportions of those infected and (un)affected by genital herpes can be simply represented (Fig. 64.5), with the minimally and entirely symptomless groups (3 and 4, i.e. 7 of 10 cases) representing the main reservoir of infection. These individuals have usually been exposed to oral HSV-1 as children and genital HSV-2 as teenagers or young adults. Given that most herpes transmissions occur from asymptomatic shedding [214,215], they may

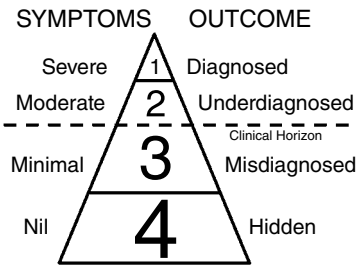

Fig. 64.5 Proportion of hidden genital herpes.

only discover their status when they take a new, previously unexposed, sexual partner who suffers a severe primary genital episode, and then wrongly blames them for knowingly spreading the infection.

Over the last three decades there has been a fall in the number of people exposed to HSV-1 in childhood, sufficient to alter the dynamic balance of those susceptible to true primary genital acquisition. At least 80% of first-episode genital herpes seen in young women is now due to HSV-1 [216], with a dramatic difference between the generations: 82% of primary anogenital herpes in the under twenties is HSV-1, compared to some 85% with HSV-2 in patients over age 50 [217]. This is relevant because genital HSV-1 is four times less likely to recur than HSV-2 [218], with less asymptomatic shedding [219], but is more likely to produce severe symptoms than HSV-2 [216] warranting hospitalization after primary genital acquisition.

Severe primary genital herpes

Most women with overtly symptomatic, true primary anogenital herpes present first with a flu-like illness, followed by genital itching similar to candidiasis and dysuria suggestive of urinary tract infection, before blistering, painful ulceration and tender inguinal lymphadenopathy become obvious. Symptoms typically commence 2–20 days after exposure, but the interval may be considerably longer if initial symptomless infection of sacral nerve ganglia is followed by delayed primary recrudescence [216]. A classic feature is sacral radiculopathy [220], mostly affecting the S2 dermatome and involving parasympathetic supply from S3 ± S4 which controls bladder and bowel function. Although the majority of women presenting to sexual health clinics can be managed as outpatients with oral aciclovir (400–800 mg t.d.s. for 5–10 days depending on severity) and topical lidocaine gel (which relieves pain within a few minutes), the 5% who experience acute retention of urine, constipation, loss of bulbocavernosus reflex and other signs of meningism [220] or cutaneous dissemination will comprise the majority admitted for gynaecological care.

As each hospital unit will see only sporadic cases with few individually published, local experience is limited and each presentation has differing individual features, with only two significant case series totalling 23 women reported in the literature [220,221]. The following account is gleaned from 40 years' clinical experience of some one or two cases per year since observing the larger initial series. Most women will be dehydrated and in severe pain, and will require rehydration, systemic and topical pain relief, attention to any systemic cause of immunosuppression, and intravenous aciclovir (10 mg/kg per 24 hours) [216] until symptoms improve or they can take oral treatment with either aciclovir 800 mg five times daily or valaciclovir 1 g b.d. Retention of urine may last from around 4 days to 3 weeks, and although in practice most women receive urethral catheters regardless of the severe pain inflicted on insertion, they would be far better served by suprapubic catheterization, as this is the only comfortable and convenient way of assessing recovery of urinary function. Subrapubic and lower abdominal pain may also be due to acute herpetic endometritis [222] or salpingitis [223], which are rarely described but probably more commonly missed. Fallopian tube lesions of acute herpetic salpingitis appear similar to cutaneous vulvo-vaginal blisters and ulcers at laparoscopy [223, and personal observation].

Severe vulval oedema and ulceration requires meticulous nursing care with saline bathing, wound separation and cool packs to prevent labial fusion, which may occur with symmetrically opposed lesions, particularly in adolescent women who may have delayed presenting for care [224]. Formal surgical separation is occasionally required [224], but has been anecdotally avoided by topical corticosteroid treatment [225] or awaiting spontaneous remission [226].

Very rarely, women may present to emergency departments with acute vulval pain – as if kicked by a horse – with a copious clear watery vaginal discharge but no external signs of ulceration, but with S2 neurology, inguinal lymphadenopathy and acute distress as above. Speculum examination (rarely performed in acute vulval herpes because of severe external pain) may reveal an acute necrotic cervicitis [227] (Fig. 64.6), and management is as above. For those women with more severe signs of meningism, frank meningitis [228] or severe cutaneous or intra-abdominal dissemination, which classically occurs in the immunocompromised, assistance from other specialists will be required and is outside the scope of this chapter.

Genital herpes in pregnancy

Management of genital herpes in pregnancy is discussed fully in the joint BASHH–RCOG guidelines [229] and in Chapter 13. One point which may be helpful in advising

Fig. 64.6 Herpetic necrotic cervicitis. Extensive cervical ulceration caused by HSV-2, associated with copious clear watery vaginal discharge and severe vulval pain. *Source:* photograph by Peter Greenhouse FRCOG, 1996. (*See also colour plate 64.6*)

the mother and her partner is that only some 15% of pregnant women are seronegative at booking for both HSV-1 and HSV-2 [230], so most mid-trimester first appearance of herpes is post-primary infection, in all but the severest presentations. This represents the first visible appearance of infection covertly acquired in the distant past, caused by maternal immunosuppression, rather than infection which has been newly acquired. In the pre-aciclovir era, true primary herpes occurring in the second trimester was usually disseminated and often fatal for the infant and mother [231]. Nowadays, even primary disseminated infection in a doubly-immunocompromised pregnant diabetic woman (Fig. 64.7) should have a healthy outcome if managed as above.

Management of recurrent herpes in perimenopausal women

Most younger women with recurrent genital herpes will be managed in sexual health clinics using standard or individually tailored suppression or episodic treatment regimens [216]. Clinics have seen a doubling in attendance of the over 45s [232] and the rate of new herpes

Fig. 64.7 Disseminated herpes in pregnancy. Second-trimester mucocutaneous and systemic dissemination of primary HSV-1 infection in a pregnant diabetic woman. Outcome after intravenous aciclovir: Complete recovery without scarring and healthy infant delivered near term. *Source:* photograph by Peter Greenhouse FRCOG, 1994. (*See also colour plate 64.7*)

diagnoses has increased faster in this than any other age group [8]. As clinic access in the UK is being restricted, gynaecologists can expect to see increasing numbers of older women with recurrent herpes requesting treatment.

The mainstay of treatment of herpes recurrences is aciclovir or valaciclovir given in a continuous regimen (see Summary box 64.5) for women with more than six recurrences per year, with long-term use of the former now extending over 35 years' experience since trials started in 1982 [233]. Less frequent recurrences can be minimized by a pre-prescribed short course, high-dose treatment, which is only effective if started immediately symptoms are recognized [216]. A combination of suppressive and episodic treatments can be offered to cover times of extra stress or holiday travel in those with less frequent episodes, provided the temporary suppression is started a few days beforehand. This allows the patient greater control and a degree of freedom from the stress of recurrence. Transmission in discordant couples can be reduced by long term suppression and condom use [234], but most seronegative partners will eventually acquire infection in the long term. Herpes antibody testing of prospective partners is an acceptable strategy, as most will be found to be unknowingly positive from previous covert infection, but the assays may occasionally give false-negative results [235].

Several women who acquired HSV-2 as teenagers or in their early twenties will have had frequent recurrences for a few years, then entered an asymptomatic phase for 5–10 years, before suffering monthly premenstrual recurrences as they become perimenopausal in their late thirties or early forties [236]. In many cases these episodes are as precisely cyclically timed as RVVC, due to

the same immunological changes [180,202]. Although there is little written in current scientific literature about catamenial herpes, it was first described over 130 years ago [237] and known as *bouton de règles*, being the commonest reason and timing for women to present with herpes. These recurrences can be successfully suppressed by giving aciclovir in the luteal phase only [236]. As many of these women appeared to have their herpes recurrences every month at the same time as their episodes of mood change in severe premenstrual syndrome (PMS), a proof-of-concept study aimed to treat the cause by using a recognized PMS treatment. Transdermal oestradiol, given during the luteal phase, or continuously in women with a levonorgestrel IUS *in situ* [238] successfully prevented almost all herpes recurrences in a series of 12 women observed over a 9-month follow-up [239].

Summary box 64.5

Recommended regimens for HSV infections (oral unless stated)

Primary genital episode

- First choice Aciclovir 400 mg t.d.s. *or* valaciclovir 500 mg b.d. for 5 days or until healed depending on severity.
- Second line Famciclovir 250 mg t.d.s. for 5 days as above.

Severe or disseminated primary episode (including pregnancy)

- First choice Aciclovir 5–10 mg/kg per 24 hours i.v. prn *then* aciclovir 800 mg five times daily until remission.

Recurrent genital episode

- First choice Aciclovir 800 mg t.d.s. for 2 days *or* valaciclovir 500 mg b.d. for 3 days.
- Second line Famciclovir 1 g b.d. for 1 day.

Suppression continuous dose

- First choice Aciclovir 400 mg b.d. *or* valaciclovir 500 mg o.d.
- Second line Famciclovir 500 mg b.d.

Suppression in pregnancy continuous dose

- First choice Aciclovir 400 mg t.d.s. from 36 weeks until delivery.

Genital warts

Around 90% of genital warts (condylomata acuminata) are caused by non-oncogenic HPV, principally types 6 and 11 [240]. Some 90% of the non-vaccinated sexually active population will have been exposed to at least one HPV type and infected by age 25, but less than 5% are ever visibly affected by overt warts. HPV infection is typically multifocal occurring over the entire anogenital area, but visible warts are seen most frequently in women at the fourchette, which is the principal area subject to friction trauma during intercourse. The lesions grow at and near the sites of healed microlacerations. Perianal warts often occur in the absence of any reported anal sex due to local inoculation by wiping. Diagnosis is by close visual inspection often aided by magnification, which can help differentiate the lesions from molluscum contagiosum or normal vulval papillae [240]. The rarest differential diagnosis is that of condylomata lata occurring in secondary syphilis, further illustrating the value of routine syphilis and HIV screening in all women with STI presentations. HPV typing and/or biopsy are rarely used in routine UK practice, but should be considered in lesions which are refractory to treatment or have a large or atypical appearance, such as the rare Buschke–Löwenstein tumour [241]. Oncogenic HPV and genital premalignancies are discussed in Chapters 60 and 61.

The incubation period for most visible warts ranges from about 3 weeks to 8 months [240], but some cases take considerably longer, appearing following sudden alteration in immune status, most commonly in pregnancy (see below). Most non-smoking immunocompetent individuals will spontaneously clear HPV within 1 year [242]. Although overt external genital warts rarely cause pain or bleeding from secondary infection, and can be considered a cosmetic nuisance, they cause substantial psychological distress by harming body image and sexual self-esteem, thus necessitating treatment at least of those lesions which are visible to the patient.

Effect of HPV vaccination

There is no evidence of cross-protection against benign HPV disease among the UK cohort of women who received the bivalent HPV vaccine (Cervarix) from 2008 to 2011 [240]. They were born between the late-1990s and mid-2000s. Slight reductions in reported cases of genital warts in UK teenagers from 2008 to 2012 [8] were due to much less genital examination being performed in asymptomatic women attending sexual health clinics [30]. This contrasts with the situation in Australia, where genital warts have been virtually eliminated since quadrivalent HPV vaccination (Gardasil) was introduced in women aged 12–26 years from 2007 [243]. This bodes well for women in the UK born from mid-2000 and vaccinated with Gardasil since 2012 but leaves a cohort of older unprotected women who may come to gynaecologists' attention.

Treatment options

Most genital warts are treated in sexual health clinics using a variety of topical modalities [240], which are chosen depending on the extent and character of the lesions. Multiple non-keratinized vulval warts are usually first treated with podophyllotoxin 0.15% cream or 0.5% solution; women with fewer or keratinized lesions are offered cryocautery with a cryoprobe or liquid nitrogen spray or, occasionally, trichloracetic acid. Second-line treatment of either may be with imiquimod 0.5% cream, the latter often being considered first choice in women with relative immunodeficiency. Diabetes, HIV, long-term steroid or other immunosuppressive therapy are three of the main contributors to the appearance, persistence, recurrence and/or unsuccessful treatment of genital warts and any high-risk HPV disease [242]. The principal avoidable cofactor is smoking, which causes Langerhans' cell depletion [244], thus preventing natural clearance of HPV [245]. Non-clearance and recurrence rates of genital warts after initial topical treatments are typically high, in the range 40–60%, thus it is important to exclude HIV and check diabetic control, and essential to advise smoking cessation [246], or at least immediate switching to vaping, as the first steps in managing any HPV-related disease.

The few women with extensive and persistent benign HPV disease who are referred to gynaecologists for formal wart excision or ablation are likely to have had many months of unsuccessful topical cream treatment and cryotherapy, and are nowadays most likely to be Cervarix-vaccinated teenagers with poorly controlled diabetes (Fig. 64.8). Assuming that all attempts to exclude or treat known causes of immunodeficiency have been made, consideration should be given to offering quadrivalent or nonavalent HPV vaccination if it has not already been used, although this approach is unlicensed. As only some one-third of individuals with overt genital warts have detectable circulating type-specific HPV antibody [247] there is a theoretical possibility that the very high antibody titres generated by vaccination might have therapeutic benefit. Several anecdotal successes have been reported, but other unseen factors may not have been excluded, and a randomized trial is currently in progress. Treatment options should be individualized, and include the very successful scissor-snip technique commonly used by colorectal surgeons for perianal warts, with further options of electrosurgical hyfrecation, local loop excision or laser ablation [248].

Fig. 64.8 Severe vulval warts. Florid warts after multiple failed treatments in a poorly controlled diabetic teenager who had received bivalent HPV vaccination 3 years previously. *Source:* photograph by Peter Greenhouse FRCOG, 2012. (*See also colour plate 64.8*)

Management of genital warts in pregnancy

Similar to herpes, many women experience their first ever episode of genital warts in the second trimester of pregnancy, which can be especially distressing for those in long-term relationships because of the automatic presumption of infidelity accompanying the diagnosis. They should be reassured that almost all such occurrences are due to previously hidden exposure to HPV in the distant past, rather than recent acquisition, and that the warts should heal spontaneously in the postpartum period because of the return of normal skin immunity. Imiquimod and podophyllotoxin are contraindicated in pregnancy [240,246]. Cryotherapy is the only commonly used treatment for cosmetic reasons, and many clinicians discourage its use as postpartum remission is the norm. Even from asymptomatic women, the risk of vertical HPV transmission varies widely from 4 to 87% [249], but almost all infant infection is covert and eventually cleared. It is exceptionally rare for vulval warts to be sufficiently large to obstruct labour but this may be an indication for caesarean section in extreme cases [250].

One study has suggested that children with juvenile recurrent respiratory papillomatosis, which is caused by HPV-6 and HPV-11, were more likely to have been delivered vaginally [251]. Its prevalence is only 1 in 100 000 [252] so the only practical prevention is via universal quadrivalent HPV vaccination.

Syphilis

Syphilis is caused by the bacterium *Treponema pallidum*, which produces a painless primary lesion within 9–90 days (average 3 weeks) of first exposure [253]. The primary chancre (see Chapter 58) presents so rarely with painless vulval ulceration that few specialists will ever have seen a case. Most acquisition is covert, with hidden vaginal, rectal or pharyngeal lesions healing spontaneously over 3–8 weeks before secondary dissemination of the infection from regional lymph nodes occurs some 6 weeks to 6 months (typically 3 months) after first exposure [254]. Only about 25% of syphilis cases have a clinically obvious secondary phase. Most remain hidden (i.e. latent) until discovered fortuitously often years later when an opportunity for screening arises. Latent syphilis is divided into early (<2 years) and late latent infection, roughly corresponding to the duration of infectivity through sexual contact. There are less than 300 cases of early infectious syphilis (primary, secondary and early latent) infection in women each year in the UK [8]. Most women present via routine antenatal screening or because of a secondary mucocutaneous skin rash, which also affects palms of hands and soles of feet, and can be easily overlooked. Among many other manifestations of secondary syphilis – including generalized lymphadenopathy, irregular alopecia, mucous patches, oro-genital ulcers, hepatitis, splenitis and rare meningitis or cranial nerve palsies – perineal and perianal lesions of condylomata lata closely resemble genital warts, and misdiagnosis is likely to occur if syphilis serology testing is omitted [254].

Thus genital wart-like lesions, or any genital ulceration, painless or otherwise, require syphilis serology. The local laboratory will offer the appropriate screening test (usually TPPA or a combined IgG/IgM assay) and then perform a full range of tests if screening is positive. The result requires discussion with and referral to a sexual health specialist [253]. However, it may be helpful to have a guide to the common patterns of serological results (Summary box 64.6), and to be aware that other rare forms of treponemal disease originating from the Caribbean, Africa and South America (yaws, bejel and pinta, respectively) produce serological results indistinguishable from those of *T. pallidum*. The panel of tests used in each laboratory differs, but the principal indicators of active syphilitic infection are the indirect antigen tests (VDRL, RPR) and the IgM assay, which becomes negative after some 18 months in untreated infection or shortly following treatment. The basic screening tests for antibody response (TPPA/TPHA and combined IgG/IgM) will remain positive after infection regardless of any treatment. A single isolated positive in any of the tests (particularly the VDRL or RPR) suggests a biological false positive, which may occur because of pregnancy, past intravenous drug use, tuberculosis, malaria, hepatitis, myeloma and connective tissue disorders such as systemic lupus erythematosus, among several other possibilities [253].

Summary box 64.6

Basic interpretation of syphilis serology results

VDRL, RPR	TPPA, TPHA	EIA-IgG/IgM, EIA-IgG	EIA-IgM	Likely diagnosis
Positive	Positive	Positive	Positive	Untreated primary, secondary or early latent syphilis
Positive	Positive	Positive	Negative	Untreated latent syphilis >18 months post acquisition *or* other treponemal infection (yaws, bejel, pinta)
Negative	Positive	Positive	Negative	Successfully treated syphilis
Positive	Negative	Negative	Negative	Biological false positive *or* very early syphilitic infection
Negative	Positive	Negative	Negative	Biological false positive
Negative	Negative	Negative	Positive	Biological false positive *or* very early syphilitic infection

Syphilis in pregnancy

Untreated syphilis is transmissible in pregnancy for up to 10 years [255] and has potentially devastating consequences for the fetus, with disease severity directly related to stage of maternal infection and showing a 'spontaneous gradual diminution of intensity' (Kassowitz's law) with time since primary acquisition [253,255]. Damage is greatest in mothers who have early syphilitic infection prior to or around conception [256]. Syphilis can be transmitted as early as 9–10 weeks, but most is thought to occur with and after syncytiotrophoblast invasion of the placental bed, between 12 and 16 weeks. The degree of placental inflammation strongly correlates with severity of infant disease [257], resulting in spontaneous miscarriage, polyhydramnios, intrauterine growth restriction, hydrops fetalis, stillbirth or early neonatal death, or severe central nervous system disease causing deafness and blindness. Lesser infection affects teeth, cartilage and bone, or causes cutaneous rashes.

The least severe infection is evidenced by positive syphilis serology in the infant only, with no physical signs. A full description of early and late congenital syphilis stigmata [258] and obstetric experience [259] has been gleaned from the extreme social deprivation and drug-related syphilis outbreak in the USA from the late 1980s to the mid-1990s.

Prevention of congenital syphilis

Early antenatal screening, with repeat screening in the third trimester for women in high-risk situations, provides a narrow window of opportunity to prevent severe congenital disease if treatment is commenced rapidly. Transmission is very rare if the rapid plasma reagin (RPR) titre is below 1 : 8 [260].

Active surveillance of congenital syphilis in the UK found that the incidence is below the World Health Organization threshold for elimination (<0.5 per 1000 live births), with only 17 cases in 5 years [261]. Since the 1996 peak of the syphilis epidemic in the former Soviet Union, congenital syphilis spread across eastern Europe to the rest of the continent. Thanks to exceptional efforts with enhanced antenatal screening, timely treatment and better control of heterosexually transmitted infection, there were only 69 cases of confirmed congenital syphilis across the entire region excluding former Soviet countries [262]. The highest incidence of cases was reported from Bulgaria, Portugal and Poland. Most recent cases have occurred in women who have defaulted much or all of their antenatal care, mostly through chaotic or coerced lifestyles, or by flight from conflict, many presenting only shortly prior to delivery.

Despite these advances, syphilis serology is positive in about 1000 pregnancies per year in UK practice, requiring a coordinated multidisciplinary team approach [261]. Of these, around 23% were false positives. Of the remaining true positives, 26% were newly diagnosed and 71% previously diagnosed, not all of whom had fully documented prior treatment. Thus some 40% required treatment according to the guideline recommendations (see below). The value of close communication between obstetric, midwifery, sexual health and neonatal teams, and the formulation of a birth plan for each case [253], was demonstrated in a UK scenario where cases were less likely to be missed as multidisciplinary care was instituted [263].

Treatment of syphilis

Uncomplicated early syphilis in non-pregnant women with or without HIV infection is currently treated with a single dose of intramuscular benzathine penicillin 2.4 mg [253]. The same regimen is first line in pregnancy up to the end of the second trimester. Two doses 1 week apart – maintaining serum levels effectively for 2 weeks – are required for adequate cure in the third trimester. In case of penicillin allergy in non-pregnant women, doxycycline 100 mg b.d. for 2 weeks is also effective. Patients should be warned about the Jarisch–Herxheimer reaction [264] which occurs in about 40% of treated cases, where an allergic reaction to toxins from dead treponemes generates an acute, transient flu-like illness that resolves within 24 hours. This can be mistaken for a penicillin allergy. Although this reaction has been reported to provoke premature labour [258], transient cardiotocographic changes were the only side effects of second- or third-trimester treatment [265], with no fetal loss following therapy.

Neither of the above regimens appears to have generated antibiotic resistance hitherto. However, no other regimens have been adequately evaluated and, as significant resistance developed rapidly to single-dose (2 g) oral azithromycin [266], treatment of penicillin-allergic women in pregnancy presents special problems, with the favoured approach being via penicillin desensitization [253,267], further emphasizing the need for a well-coordinated multidisciplinary team effort.

Conclusion

Thanks to population mobility, relationship instability, demographic change and modern digital communication technology, clinicians can no longer make a cosy automatic assumption that, regardless of age or social milieu, their patients' sexual activity is monogamous or heterosexual or volitional, an attitude which characterized paternalistic gynaecological care in the not-so-distant past. An open, non-judgemental, empathetic and inquisitive approach will identify more STIs, reduce misdiagnosis and, hopefully, answer some of the research challenges in women's sexual health posed by this chapter.

Contraception and Sterilization

Sharon T. Cameron[1,2]

[1] *Faculty of Sexual and Reproductive Healthcare, Chalmers Centre, NHS Lothian, Edinburgh, UK*
[2] *University of Edinburgh, Edinburgh, UK*

The average age of first intercourse in women is 16 years and average age of menopause is 51, so most women will need to use contraception for more than 30 years. Use of contraception in the UK is high. Despite this, unintended pregnancy is common, with abortion rates of between 11.6 and 16 per 1000 women of reproductive age in the UK in 2016 [1,2]. Around three-quarters of women presenting for abortion report having used a method of contraception around the time of conception, but the methods used are mostly of low effectiveness, or used inconsistently or incorrectly [3].

It is estimated that 30% of pregnancies ending in birth were unintended at conception [4]. Unintended pregnancies in the year following birth are also common. If a birth to conception interval is less than 12 months (short inter-pregnancy interval), then this increases the risk of preterm birth and neonatal death [5]. Obstetricians and gynaecologists should take key opportunities such as the antenatal period and routine gynaecological consultations to discuss effective contraception and provide methods where possible. The most effective methods comprise long-acting reversible contraception (LARC), including intrauterine contraception, implants and injectables. Greater uptake of LARC in the UK could prevent more unintended pregnancies, abortions and prevent short inter-pregnancy intervals for more women.

Effectiveness

The effectiveness of a method of contraception is expressed by the failure rates associated with its use. Effectiveness depends on efficacy of the method, compliance and continuation with the method. Perfect- and typical-use failure rates of methods (based on percentage of couples experiencing an unintended pregnancy during the first year of use) are shown in Table 65.1 [6]. Methods that make no demands on compliance after insertion have perfect-use and typical-use failure rates that are virtually the same. Compliance with oral contraception is not easy. In one study, almost 63% of users missed one or more pills in the first cycle, and 74% in the second cycle of use [7]. Typical-use failure rates are even higher with condoms, which rely on correct use with every act of intercourse. The progestogen-only injectable lasts 13 weeks but correct use demands the motivation and organizational skills required to receive a repeat dose. Intrauterine contraception (IUC) and implants are removed by a healthcare professional and are independent of user compliance for effectiveness.

Discontinuation rates are higher for methods which do not require removal by a provider. Data from the USA indicate that approximately 50% of women discontinue a pill or injectable within the first year of use, whereas approximately 80% of women continue the implant or IUC at 12 months [6]. Reasons for discontinuation are often associated with perceived risks and real or perceived side effects.

Pregnancy rates are still often described by the Pearl index, the number of unintended pregnancies divided by the number of woman-years of exposure to the risk of pregnancy while using the method. For long-acting methods of contraception such as IUC and implants, pregnancy rates with time (cumulative pregnancy rates) are often reported.

Medical eligibility for contraception

Most contraceptive users are young and healthy and can use all contraceptives safely. However, some medical conditions are associated with real or theoretical health risks with certain contraceptives. The World Health Organization (WHO) developed a system addressing medical eligibility criteria (MEC) for contraceptive use

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 65.1 Effectiveness of contraceptive methods: percentage of women experiencing an unintended pregnancy during the first year of use and percentage continuing use at the end of the first year (USA) [6].

Method	Typical use	Perfect use
No method	85	85
Calendar	9	
Sympto-thermal	2	
Diaphragm	16	6
Female condom	21	5
Male condom	15	2
Combined pill and progestogen-only pill	8	0.3
Combined hormonal patch	8	0.3
Combined hormonal ring	8	0.3
Injectable (DMPA)	3	0.3
IUD, copper T	0.8	0.6
IUS (Mirena)	0.1	0.1
Implant	0.05	0.05
Female sterilization	0.5	0.5
Male sterilization	0.15	0.10

(WHO MEC) [8]; this has been adapted by the Faculty of Sexual and Reproductive Healthcare (FSRH) for the UK setting (UK MEC) [9]. Using evidence-based systematic reviews, conditions are classified into one of four categories (Table 65.2). Category 1 includes conditions for which there is no restriction for use of the method, while category 4 includes conditions that represent an unacceptable health risk if the contraceptive method is used (absolutely contraindicated). Category 2 indicates that the method may generally be used. Provision of a method to a woman with a category 3 condition requires careful clinical judgement since use of that method is not recommended unless there is no acceptable alternative. The initiation and continuation of a method of contraception is sometimes distinguished and classified in the UKMEC. Initiation of a method may be appropriate in women with certain medical conditions, but if a medical condition develops while using a method, then this raises concern over continuation since use of the method may have contributed to development of the condition. It is important to note that the UKMEC categories relate to the safety of use of a method of contraception by a woman with a particular medical condition or personal characteristic. The efficacy of contraception may be affected by the condition or by a medication required for the condition but the UKMEC category does not reflect this.

Table 65.2 Definition of UK MEC categories.

UK MEC	Definition of category
1	A condition for which there is no restriction for use of the contraceptive method
2	A condition where the advantages of using the method generally outweigh the theoretical or proven risks
3	A condition where the theoretical or proven risks generally outweigh the advantages of using the method. The provision of a method requires expert clinical judgement and/or referral to a specialist contraceptive provider, since use of the method is not usually recommended unless other more appropriate methods are not available or not acceptable
4	A condition which represents an unacceptable health risk if the contraceptive method is used

For each of the personal characteristics or medical conditions considered by the UK MEC, a category 1, 2, 3 or 4 is given.

Contraceptive choice

Many factors determine the method of contraception an individual chooses. These include age, fertility intentions, perceptions of effectiveness and of safety, familiarity and experience of others, ease of use and non-contraceptive benefits. Women should be given accurate information about all methods for which they are medically eligible. Studies show that women welcome information in an audiovisual formats (DVD, tablet, phone app) and that this may enhance uptake of the most effective methods [10,11].

Intrauterine contraception

Intrauterine methods of contraception include the copper-bearing intrauterine device (Cu-IUD) and the levonorgestrel-releasing intrauterine system (LNG-IUS). IUC is amongst the most effective LARC methods (see Table 65.1). In addition, the Cu-IUD can also be used for emergency contraception. Unfortunately, IUC is unpopular in many settings. More needs to be done to improve uptake, especially amongst young women at risk of unintended pregnancy [11].

- *Cu-IUD*: most Cu-IUDs available in the UK have a plastic frame with copper wire wound around the stem with or without copper sleeves on the arms [12]. Devices containing 380 mm^2 of copper have the lowest failure rates [13]. In the UK, the Cu-IUD that contains 380 mm^2 of copper is licensed for 10 years of use, while those containing 300 mm^2 of copper are licensed for 5 years.

- *LNG-IUS*: there are three types of LNG-IUS, a 52-mg, a 19.5 mg and a 13.5-mg device. The 52-mg LNG-IUS (Mirena® and Levosert®) is licensed for 5 years for contraceptive use (Levosert is anticipated to receive a licence for 5 years). The 19.5 mg LNG-IUS (kyleena) is licensed for 5 years. The 52-mg LNG-IUS releases 14 mcg of LNG per day. The 19.5 mg LNG-IUS releases 19 mcg of LNG per day. The 13.5-mg LNG-IUS (Jaydess®) is licensed for 3 years and releases 6 μg of LNG per day. The 19.5 and the 13.5-mg LNG-IUS has a slightly narrower inserter than the 52-mg device, and a slightly thinner and shorter frame. Both the 19.5 mg and 13.5-mg LNG-IUS also have a silver band at the proximal end, which is designed to facilitate visualization by ultrasound.

Although the manufacturers have recommended durations of use for IUC, there is evidence that efficacy extends beyond these limits. The FSRH advises that any Cu-IUD inserted at or after the age of 40 can be retained until contraception is no longer required, i.e. 1 year after menopause if last menstrual period (LMP) is in fifties, or 2 years after menopause if LMP is in forties [14]. The FSRH also advises that a 52-mg LNG-IUS inserted at 45 years can be retained for contraception for 7 years or if amenorrhoeic until the menopause. If the 52 mg LNG-IUS is being used as part of hormone replacement therapy (i.e. progestogenic opposition to exogenous estradiol), then it must be replaced after 5 years. All IUC should eventually be removed.

Efficacy

A large (>61 000 women) European prospective cohort observational study (European Active Surveillance Study, EURAS) of IUC reported that the 52-mg LNG-IUS had superior efficacy to Cu-IUD, although the failure rate was low with both [15]. For LNG-IUS, the Pearl index (pregnancies per 100 woman-years) was 0.06 (95% CI 0.04–0.09) in LNG-IUS users and 0.52 (95% CI 0.42–0.64) in the Cu-IUD cohort. High efficacy is also reported for the 19.5 mg LNG-IUS which has a pearl index of 0.29 (95% CI 0.16–0.5) and 13.5-mg LNG-IUS, with a Pearl index of 0.33 (95% CI 0.16–0.60).

Mechanism of action

Both the Cu- IUD and LNG-IUS work primarily by inhibiting fertilization due to the toxic effect of copper ions on ova and sperm, and LNG also has effects on sperm penetrability and transport. Both devices also prevent implantation; the Cu-IUD exerts a local inflammatory reaction in the endometrium and the LNG-IUS induces endometrial atrophy. LNG-IUS also causes thickening of the cervical mucus, which prevents sperm entering the uterus. Effects of the 52-mg and 13.5-mg LNG-IUS on endometrium and cervical mucus are similar.

Contraindications

There are very few women for whom IUC is contraindicated. Current pelvic tuberculosis, endometrial or cervical cancer, symptomatic sexually transmitted infection (STI) or pelvic inflammatory disease (PID) are the UK MEC 4 conditions [9]. Women at risk of STIs and women with well-controlled HIV on antiretrovirals can safely use IUC with safe sex and additional condom use promoted. Unexplained vaginal bleeding should be investigated before IUC insertion and a distorted uterine cavity (due for example to fibroids) may make insertion impossible. Although providers may be reluctant to offer IUC to nulliparous women or adolescents owing to myths that insertion will be difficult or carry higher risks, the best available evidence supports safety of use of IUC in these groups, and this is reflected in the UK MEC [9].

Risks

Perforation

Rates of perforation with IUC are low (2 per 1000 insertions). Increased risks include inexperience of the clinician, breastfeeding and being less than 36 weeks' post partum [14,16]. Sometimes the clinician will suspect perforation at the time of fitting IUC and if so the procedure should be abandoned. Alternatively, women may complain of lower pelvic pain, a change in bleeding pattern or give a history of painful insertion. Others have no symptoms and the diagnosis is made due to lost threads or pregnancy.

Absent threads in an IUC user should be investigated by ultrasound. A pregnancy test should be performed and emergency contraception provided (if unprotected intercourse) and alternative contraception provided in the interim. If ultrasound confirms absence of a device within the uterus, then an abdominal X-ray should be performed. If the IUC is visible on X-ray then this indicates it must be within the abdominal cavity. In most cases the IUC can be retrieved laparoscopically as an elective procedure.

Expulsion

It is reported that 1 in 20 IUC devices will be expelled, usually in the 3 months after insertion [14]. Similar expulsion rates are reported for the Cu-IUD and LNG-IUS. With increasing use of ultrasound, it is not uncommon for an ultrasound report to state that an IUC is 'low lying' within the uterus. Unfortunately, there is no good evidence to determine if non-fundally placed IUC provides effective contraceptive cover. The clinician should manage such cases on an individual basis along with the woman's preference, taking into consideration the risks of insertion of a new device.

Infection

The overall risk of PID following insertion of IUC is low (<1%) [14]. PID is more likely in the 3 weeks following insertion, and in women at risk of STIs. FSRH guidance recommends that STI screening before insertion is only necessary for those at risk of STIs. In the absence of STI results in women deemed at high risk of infection, then prophylactic antibiotics (to cover chlamydia) can be given if insertion is required, for example. Cu-IUD for emergency contraception.

A systematic review concluded that there were no differences in outcomes in IUC users with PID who had the IUC removed or left *in situ* [16]. If the IUC is removed, then oral emergency contraception should be provided (if required) and alternative ongoing contraception.

Actimomyces-like organisms (ALOs) are commonly identified through cervical screening programmes. ALOs have rarely been associated with severe pelvic infection in IUC users. If a woman with an IUC has ALOs and has no signs or symptoms of infection, then the device can be left *in situ* or safely removed and another inserted immediately. However, if the woman has symptoms of infection, then removal of the IUC is advised along with treatment with antibiotics (and testing for STIs) [14].

Ectopic pregnancy

The overall risk of ectopic pregnancy is much reduced in women using IUC compared with women using less effective methods or no contraception. The absolute risk of ectopic pregnancy is 0.01 per 100 woman-years (95% CI 0.00–0.003) for 52-mg LNG-IUS users, 0.07 per 100 woman-years (95% CI 0.02–1.78) for Cu-IUD users and 0.10 per 100 woman-years (95% CI 0.02–0.29) for 13.5-mg LNG-IUS users [14,17,18].

However, if a pregnancy does occur with IUC *in situ*, then the relative risk of an ectopic increases. In the EURAS study approximately 20% of pregnancies in IUC users were ectopic [14]. An ultrasound scan should be conducted in pregnant women with an IUC to exclude ectopic pregnancy. IUC should be removed before 12 weeks' gestation in view of the greater risk of miscarriage, preterm delivery and chorioamnionitis if left *in situ*.

Side effects

Menstrual disturbance

The endometrial effects of the Cu-IUD tend to cause increased menstrual bleeding and dysmenorrhoea. Conversely, women can be advised that a reduction in menstrual blood loss and an increase in amenorrhoea can be expected over the first year of use with the LNG-IUS. Amenorrhoea rates with the 19.5 mg LNG-IUS and the 13.5-mg LNG-IUS are less than with the 52-mg LNG-IUS (18.9%, 12.7% vs. 23.6% amenorrhoea at 3 years, respectively) [17]. Frequent and prolonged spotting is common with the LNG-IUS, particularly in the first months of use. Careful counselling about menstrual irregularities is vital to avoid premature discontinuation.

When abnormal bleeding patterns occur with IUC, gynaecological causes should be excluded. Pelvic examination, pregnancy testing and STI testing should be considered. In addition, ultrasound and/or endometrial biopsy (especially in women over the age of 45) should also be considered if abnormal bleeding is persistent or is associated with other features such as pain/dyspareunia [19]. Addition of a non-steroidal anti-inflammatory drug (NSAID) or antifibrinolytic (tranexamic acid) may reduce menstrual blood loss with the Cu-IUD. Alternatively, Cu-IUD users may consider switching to a LNG-IUS.

Mood, weight and libido

Hormonal side effects associated with the LNG-IUS are likely to decrease with time. A systematic review failed to demonstrate any differences in side-effect profile between the 52-mg LNG-IUS and Cu-IUD. Side-effect profile of the 13.5-mg LNG-IUS is similar to that of the 52-mg LNG-IUS [20]. Effects of hormonal contraception on libido are difficult to study because of the multiple factors that influence libido. Existing evidence fails to show that the LNG-IUS has negative effects on libido. Weight gain has been reported in users of both Cu-IUD and LNG-IUS, but this does not appear to differ between these methods [20].

Timing of insertion

IUC can be fitted at any point in the cycle provided it is reasonably certain the woman is not pregnant. A Cu-IUD will be effective immediately for contraception. No additional precautions are required if the LNG-IUS is fitted on day 1–7 of the cycle, and 7 days of additional contraceptive precautions (condoms/abstinence) are recommended if fitted later than this time [14].

Postpartum IUC insertion

Insertion of IUC can take place as soon as the placenta is delivered at caesarean section or following vaginal delivery (within 10 min of delivery of placenta or up to 48 hours later) (UK MEC 1). A Cochrane review concluded that insertion at this time is safe and effective with no increased risk of perforation or infection compared with insertion weeks later [21]. Post-placental insertion of IUC can be extremely convenient for women who, due to the constraints and pressures of having a new baby, may be less likely to attend for IUC at a later date. Expulsion

rates of IUC devices after vaginal delivery may be higher than at other times (reported from 4 to 38%) [22], but this may be outweighed by advantages of insertion at this time. For women choosing post-placental insertion of a Cu-IUD, the bleeding associated with insertion can be masked by lochia; women choosing the LNG-IUS can benefit immediately from reduced menstrual bleeding [23].

Post-insertion instructions

Women who have been fitted with IUC should be provided with clear verbal and written information on what signs and symptoms would indicate a possible complication, how to conduct a self-check of threads, which device they have *in situ* and when it needs replacing. Unless pregnancy is desired, removal should only be undertaken during menstruation or if one can be reasonably certain that there is no risk of pregnancy (no unprotected intercourse within 7 days).

Summary box 65.1

- The Cu-IUD is a very effective method of contraception; most devices last for 5–10 years and the method can be used by nulliparous women.
- If a Cu-IUD is inserted after age 40, it can be left in place until contraception is no longer required.
- The commonest side effect (and commonest reason for premature removal) of Cu-IUD is heavy bleeding.
- The risk of ectopic pregnancy is enormously reduced compared with women using no contraception.
- The risk of pelvic infection has been over-emphasized and by 3 weeks after insertion is not increased. Women with risk factors for STI should be screened before insertion but the Cu-IUD is not contraindicated.

Progestogen-only contraception

Progestogen-only contraception is available in a wide variety of delivery systems including IUS (see above), implants, injectable and oral. It has been less commonly used than combined hormonal contraception and so there are fewer data on the risks associated with long-term use. All methods of progestogen-only contraception have a number of mechanisms of action. The implant, injectable and desogestrel-containing pill inhibit ovulation. Older low-dose pill formulations inhibit ovulation only inconsistently. All affect cervical mucus, reducing sperm penetrability and transport. The LNG-IUS has little effect on ovarian activity but causes marked endometrial atrophy, thus compromising implantation if ovulation and fertilization occur. Failure rates for progestogen-only methods are shown in Table 65.1.

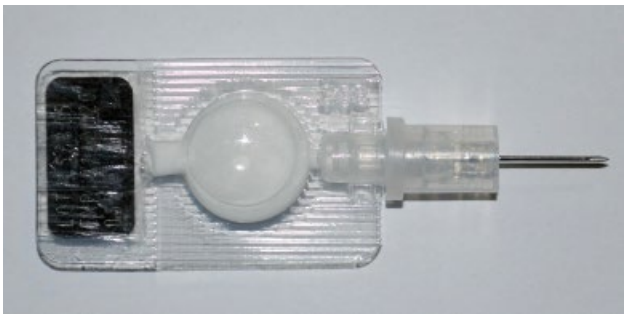

Fig. 65.1 Subcutaneous depot medroxyprogesterone acetate.

The methods

Subdermal implants

The only currently available implant in Europe (Nexplanon®) is a single rod containing 68 mg of 3-keto-desogestrel (a metabolite of desogestrel) providing contraception for 3 years. The initial release rate of 60–70 μg/day falls gradually to around 25–30 μg/day at the end of 3 years. The implant is inserted using local anaesthesia, subdermally on the inner aspect of the non-dominant arm, 8 cm above the elbow. The implant contains a small amount of barium sulfate which facilitates localization by X -ray to assist removal if not palpable. In the UK, FSRH certification of competence in insertion and removal techniques for the implant (and for IUC) is recommended [24]. Complications with insertion have been linked to subsequent difficult implant removals and rare cases of intravascular location of implants. Implants that are not palpable should be removed by someone experienced.

Up to 20% of implant users experience amenorrhoea. The remainder have regular bleeding, or irregular light unpredictable bleeding. Heavy bleeding is uncommon.

Injectable

Long-acting depot medroxyprogesterone acetate (DMPA) is available as a formulation that is given by deep intramuscular injection (150 mg) every 13 weeks (Depoprovera®) or as a micronized (104 mg) preparation that is administered subcutaneously (Sayana®) at the same interval. Both have the same efficacy and bleeding pattern, and the same effects on bone and on return to fertility after stopping [25]. The subcutaneous preparation is available in a simple delivery system consisting of a plastic reservoir filled with DMPA with an integral needle attached (Fig. 65.1) and is licensed for self-administration. Approximately 1 in 10 women may develop some lipoatrophy at the subcutaneous

injection site (dimpling or nodule of skin) and should be counselled about this.

The dose of progestogen in DMPA inhibits ovulation and by the end of 1 year of use over 50% of women will have amenorrhoea. Heavy prolonged bleeding may be a problem in around 2% of women [25].

Oral

The low dose of second-generation progestogen (levonorgestrel, norethisterone) does not consistently inhibit ovulation. A progestogen-only preparation (POP) containing the third-generation progestogen desogestrel inhibits ovulation in almost every cycle. Around 50% of women using a low-dose POP continue to ovulate and therefore menstruate regularly, while 10% experience complete suppression of follicular development and have amenorrhoea. The remainder have inconsistent ovulation and bleed irregularly. Almost 50% of women using the desogestrel POP experience amenorrhoea or infrequent bleeding periods, while the rest are likely to have irregular bleeding [26]. If a POP is taken late (>3 hours late for low-dose pill or >12 hours late for desogestrel pill), then the next pill should be taken, but additional contraceptive protection used for 48 hours (to build up contraceptive effect on cervical mucus) [26].

Indications and contraindications

Progestogen-only contraception is commonly prescribed for women in whom oestrogen is contraindicated. There are few contraindications to use of these methods. The UK MEC 4 conditions (unacceptable health risk if contraceptive is used) for use of progestogen-only methods include past breast cancer. A meta-analysis of data on use of DMPA on acquisition of HIV suggested a moderate increase in risk [27]. The biological basis proposed is a possible effect of DMPA on local immune function, or via vaginal atrophy. A WHO expert group review concluded that data were not sufficiently robust to determine if an association was causal as studies could not exclude important methodological confounders such as non-use of condoms amongst users of the injectable [28]. The use of DMPA by women at high risk of HIV is therefore a UKMEC 2 [9].

Side effects

Bleeding disturbances

The commonest side effect and cause for discontinuation of a POP is an unacceptable bleeding pattern. Inconsistent ovulation and fluctuating endogenous oestrogen production from irregular follicle growth lead to irregular bleeding. However, there is also evidence to suggest that POPs directly affect the vasculature of the endometrium, increasing the chance of bleeding. Bleeding patterns differ according to the dose of progestogen and the route of administration. It is important to ensure that women with unscheduled bleeding have no underlying gynaecological cause. In such circumstances, the FSRH guideline advises that in women using an injectable, implant or LNG-IUS may try concomitant use of the combined pill (in medically eligible women) as a short-term solution [19]. There is also limited evidence that mefenamic acid and tranexamic may reduce the duration of an episode of unscheduled bleeding in women using the injectable or implant [19].

Persistent follicles/follicular cysts

The effect of low-dose POPs on ovarian activity may result in functional ovarian cysts (persistent follicles). Usually asymptomatic, they can cause abdominal pain or dyspareunia. Most will disappear with menstruation and so treatment should be expectant management.

Other 'hormonal' side effects

Headache, nausea, bloating, breast tenderness, and weight and mood change are all common in women using and not using hormonal contraception. They often settle with time. A Cochrane review reported that injectable users had a mean weight gain of 3 kg after 2 years of use. Weight gain in adolescents who are new DMPA users is greater in those of greater baseline body mass index (BMI) [29]. Oily skin and acne can be a problem with the more androgenic progestogens such as levonorgestrel and norethisterone.

Delay in the resumption of fertility

Fertility returns rapidly after stopping low-dose progestogen-only contraception. However, it may take up to 1 year for fertility to return following cessation of DMPA which makes DMPA inappropriate for women wishing short-term contraception.

Serious side effects

Progestogen-only methods are much less widely used than the combined methods so data on long-term risks are sparse.

Cardiovascular disease

There is no evidence for an increase in the risk of myocardial infarction or stroke in association with progestogen-only contraception. Although a small number of case–control and retrospective studies suggested that DMPA may be associated with an increased risk of venous thromboembolism (VTE) compared with non-users, a causal association has not been demonstrated [30]. Use of DMPA amongst women with risk factors for VTE or a history of VTE is therefore a UK MEC 2.

Bone mineral density

Complete inhibition of ovulation by the injectable DMPA causes hypo-oestrogenism and amenorrhoea. Hypo-oestrogenism is associated with a reduction in bone mineral density (BMD). Current use of DMPA is associated with a loss of BMD compared with non-users. Prospective studies have reported statistically significant decreases in BMD over 2 years amongst DMPA users compared with non-users [31]. Limited evidence suggests that this bone loss is reversible on stopping. In spite of the effect on BMD, there is no significant association between DMPA use and risk of osteoporotic fracture after adjusting for baseline BMD. The FSRH advises that in women who wish to continue using DMPA, re-evaluation of the risks and benefits of treatment should be carried out every 2 years. In women with significant lifestyle and/or medical risk factors for osteoporosis, other methods of contraception should be considered.

Summary box 65.2

- Progestogen-only contraception is available in a wide range of delivery systems.
- The dose of progestogen determines the mode of action and side effects.
- Irregular vaginal bleeding is a common reason for discontinuation of low-dose progestogen-only contraception, which does not inhibit ovarian activity completely.
- Despite normal ovarian activity, the IUS is associated with amenorrhoea because of endometrial atrophy.
- DMPA inhibits ovarian activity completely and a high proportion of users have amenorrhoea.
- Progestogen-only contraception does not increase the risk of cardiovascular disease.
- DMPA is associated with decreased BMD.

Combined hormonal contraception

Combined hormonal methods contain both oestrogen and a progestogen and are available as oral, transdermal (patch) and vaginal preparations (vaginal ring). The mode of action (inhibition of ovulation), side effects and risks are similar. For efficacy see Table 65.1.

The methods

Oral

Most combined oral contraceptive (COC) pills in use in the UK contain ethinylestradiol in doses of 20–35 μg (so-called 'low-dose' pills). Recent developments have been COC pills containing 'natural oestrogens' such as estradiol valerate and 17β-estradiol, but these are not widely used as they have not been shown to confer any advantages over existing preparations and long-term safety data are not yet available. Risks and benefits must be assumed to be as for other COC and the same UK MEC categories apply.

Most COC pills are taken for 21 days followed by a 7-day pill-free interval when withdrawal bleeding usually occurs. COC pills are available as monophasic preparations, in which every pill in the packet contains the same dose of steroids. Phasic pills (e.g. triphasic, tetraphasic) have varied doses of steroids, but confer no advantage over monophasic pills.

Increasing numbers of women run packets of monophasic pills together, i.e. extended use. This is useful for reducing episodes of withdrawal bleeding, dysmenorhoea or headaches associated with the pill-free interval.

Transdermal

The contraceptive patch available in the UK (20 cm^2 in size) delivers 33.9 μg ethinylestradiol and 203 μg norelgestromin daily. Each patch lasts 7 days, three patches being used consecutively with a patch-free interval in week 4 when withdrawal bleeding occurs. Contraceptive protection lasts for up to 10 days, allowing for errors in changing the patch. Effectiveness is not significantly different from the COC (Table 65.1). Bleeding patterns and side effects are similar to those associated with the COC.

Vaginal

The combined contraceptive vaginal ring releases 15 μg ethinylestradiol and 120 μg etonorgestrel daily. It is made of soft ethylene-vinyl-acetate copolymer, has an outer diameter of 54 mm and a cross-sectional diameter of 4 mm. Designed to last for 3 weeks, a 7-day ring-free interval is associated with bleeding patterns that appear superior to those associated with the COC pill. In a comparison with a 30-μg ethinylestradiol COC pill, the incidence of irregular bleeding with the ring was significantly less (<5% vs. 39%). In all other respects, including efficacy, the ring is no different from COC, although there may be advantages in terms of demands on compliance.

Mode of action

The principal mode of action of combined hormonal contraception is inhibition of ovulation. Oestrogen inhibits pituitary follicle stimulating hormone (FSH), suppressing the development of ovarian follicles, while progestogen inhibits the luteinizing hormone (LH) surge. Most combined hormonal contraception is administered for 21 days followed by a 7-day hormone-free interval. The ovaries remain quiescent with seven hormone-free days, but if COC pills are missed so that

this interval is extended, then follicles can continue to develop and despite restarting contraception ovulation may occur. The FSRH advise that if two or more pills are missed, then the next pill should be taken and additional barrier methods used for 7 days. If the missed pills were after a pill-free interval, then emergency contraception is advised if unprotected sex occurred [32]. Manufacturers advise that additional barrier methods (or abstinence) for 7 days are required if a patch is applied 48 hours late or a ring is removed for more than 3 hours during the 21 days of treatment.

Additional properties of combined hormonal contraception include changes in characteristics of cervical mucus that interfere with sperm transport, a possible alteration in tubal motility, endometrial atrophy and impaired uterine receptivity.

Contraindications

The absolute (UK MEC category 4 conditions) contraindications to combined hormonal contraception (pill, patch and ring) are listed in Table 65.3.

Table 65.3 UK MEC category 4 conditions (unacceptable health risk) for use of the combined oral contraceptive pill [9].

Breastfeeding <6 weeks post partum
Not breastfeeding 0–3 weeks post partum with risk factors for venous thromboembolism (VTE)
Smoking ≥15 cigarettes/day and age ≥35 years
Multiple risk factors for cardiovascular disease
Hypertension: systolic ≥160 mmHg or diastolic ≥100 mmHg
Hypertension with vascular disease
Current or history of VTE
Major surgery with prolonged immobilization
Known thrombogenic mutations
Current or history of ischaemic heart disease
Current or history of stroke or transient ischaemic attack
Complicated valvular heart disease
Migraine with aura
Current breast cancer
Diabetes with vascular disease or nephropathy, retinopathy or neuropathy
Severe cirrhosis
Benign hepatocellular adenoma or malignant liver tumours
Positive antiphospholipid antibodies
Systemic lupus erythematosus with positive antiphospholipid antibodies
Cardiomyopathy with impaired cardiac function
Atrial fibrillation

Side effects

Contraceptive steroids are metabolized by the liver and affect the metabolism of carbohydrates, lipids, plasma proteins, amino acids, vitamins and clotting factors. Many of the reported side effects, particularly headache, weight gain and loss of libido, are also common among women not using hormonal contraception. A different dose of oestrogen or type of progestogen or a different delivery system may help. Side effects (real or perceived) often lead to discontinuation; weight gain is one of the commonest reasons for stopping.

Risks

The combined pill is extremely safe. Data from a large UK cohort study of over 46 000 women using the COC pill for up to 39 years showed that oral contraception was not associated with an increased risk of death [33]. Indeed, 'ever users' of the contraceptive pill (predominantly combined pill) had a 12% reduction in the overall risk of death for all conditions compared with 'never users' (RR 0.88, 95% CI 0.82–0.93).

Venous thrombosis

Venous thrombosis is rare in women of reproductive age. All combined hormonal contraception is associated with an increased risk of VTE compared with non-use. A number of studies have found differences in risk of VTE according to type of COC pill used. The biological mechanism is not fully understood but different progestogens appear to modify the thrombogenic effects of oestrogen to different extents. However, the absolute differences are very small. The European Medicines Agency (EMA) reviewed the risk of VTE associated with combined hormonal contraception and concluded that there was good evidence that the risk of VTE associated with different COC pills was influenced by type of progestogen, with levonorgestrel, norethisterone and norgestimate having the lowest risk (5–7 per 10 000 women) and those containing third-generation (desogestrel, gestodene) or fourth-generation (drospirenone) progestogens having the highest risk (9–12 per 10 000 women), compared with 2 per 10 000 women amongst non-users. However, the risk of VTE is low overall and is lower than the risk associated with pregnancy and the postpartum period (29 per 10 000 woman-years and 300–400 per 10 000 woman-years, respectively) [34].

Co-cyprindiol, a preparation containing ethinylestradiol in combination with the anti-androgen cyproterone acetate, is licensed for the treatment of severe acne and hirsutism. It should not be used routinely for other women, as evidence indicates that it is associated with an increased risk of VTE similar to that of COC pills containing desogestrel, gestodene or drospirenone.

The risk of VTE with combined hormonal contraception is greatest during the first year of use, possibly due to the unmasking of inherited thrombophilias such as factor V Leiden. Screening for known thrombophilias is not cost-effective. Although non-oral routes of administration avoid the first pass through the liver, thereby theoretically having less effect on clotting factors, the available evidence for the contraceptive patch and ring would indicate that the risk of VTE is no less than the COC pill and in the region of 6–12 per 10 000 woman-years.

Arterial thrombosis

The absolute risk of arterial thrombosis (myocardial infarction and ischaemic stroke) in women of reproductive age, even those with known risk factors, is extremely small (approximately 10 per 100 000 and 21 per 100 000, respectively). It is related to age, and the risk is strongly influenced by smoking. COC use has been associated with an increased risk of arterial thrombosis. A Cochrane review of 24 studies showed that women using the COC pill had a 1.6 relative risk of myocardial infarction and stroke (95% CI 1.3–1.9) compared with non-users [35]. The risks did not appear to vary according to the type of progestogen. However, increasing doses of oestrogen (>50 μg ethinylestradiol) were associated with increased risk.

Women who have migraine with aura have a higher risk of stroke than those without. In a systematic review of the limited publications, users of hormonal contraception with migraine had a twofold to fourfold risk of stroke compared with non-users [36]. Combined hormonal contraception is contraindicated in women who have migraine with aura at any age (UK MEC 4), but may be considered for women without aura. Many people describe their headaches as migraine, so it is important to make an accurate diagnosis of migraine and those complicated by aura. The UK MEC directs providers to useful websites and resources to diagnose types of migraine [9].

Malignant disease

Breast cancer

A meta-analysis of 54 studies involving over 53 000 women with breast cancer and 100 000 controls concluded that use of the COC pill was associated with a small increase in the risk of breast cancer. The increased risk persisted for 10 years after stopping the pill [37]. The relative risk for current users was 1.24; for those 1–4 years after stopping, 1.16; and for those 5–9 years after stopping, 1.07. After 10 years the relative risk was the same as that of non-users. It has been suggested that starting to use the pill may accelerate the appearance of breast cancer in susceptible women. Alternatively, women using combined hormonal contraception might have their tumours diagnosed earlier. A biological effect of combined hormonal contraception remains a possibility.

Cervical cancer

Data on the risk of cervical cancer among pill users are difficult to interpret since barrier methods confer some protection and any association identified in epidemiological studies may be the result of inadequate adjustment for sexual behaviour. A systematic review concluded that for women with persistent human papaillomavirus (HPV) infection, long-term use of the COC pill (>5 years) may increase the risk of cervical cancer. However, women should be advised that the risk can be significantly reduced through condom use, HPV vaccination (young people) and routine cervical screening.

Ovarian, endometrial and colon cancer

For ovarian cancer, epidemiological studies would suggest a 50% reduction in the risk of both epithelial and non-epithelial ovarian cancer after 5 years use of the COC pill [33]. This effect may be related to the reduction in the total number of ovulations, and therefore rupture of the ovarian capsule, experienced in a lifetime. This reduction in risk of ovarian cancer persists for 30 years after discontinuation of the COC pill. Protection is also evident for women with a family history of breast cancer. Epidemiological evidence also supports a reduction in endometrial cancer that is strongly related to the duration of COC use (20% risk reduction after 1 year, 50% after 4 years) and is sustained for 15 years after stopping the pill. There is also evidence that current or recent use of the COC pill may confer protection against colon cancer [33].

Practical prescribing

The FSRH recommends a pill containing 30 μg ethinylestradiol in combination with a second-generation progestogen for new users on the grounds that such pills are the safest and cheapest. COC pills containing other progestogens should generally be reserved for women intolerant of these and prepared to accept an increased risk of VTE.

Women should be carefully instructed how to use the pill, patch or ring and what to do when mistakes are made. Most women who stop the pill regain normal fertility after stopping. Secondary amenorrhoea is almost always the result of underlying conditions present before the method was started (such as polycystic ovarian syndrome) but regular withdrawal bleeds mask these conditions.

Drug interactions with hormonal contraception

Use of medications may increase or decrease serum levels of contraceptive hormones; likewise, hormonal contraception may alter levels of medications. This can potentially cause adverse effects. Prescribers should ask

women about all drug use and where necessary consult up-to-date and reputable internet drug interaction checkers.

Some of the commonest interactions with hormonal contraceptives are with medicines that induce liver cytochrome P450, which could reduce the efficacy of combined hormonal contraception and the progestogen-only pill and implant (e.g. some antiepileptic drugs, antifungals, antiretrovirals). These medicines are not thought to affect the efficacy of the injectable, Cu-IUD or LNG- IUS. If a woman using enzyme-inducing medication wishes to use a low-dose hormonal method, then use of condoms is also advised. Contraceptive effectiveness of the COC pill (and all other methods) is not affected by coadministration of most broad-spectrum antibiotics. While the antiepileptic lamotrigine is not an enzyme inducer, use of combined hormonal contraception increases the clearance of lamotrigine and reduces serum levels of this drug. Seizure frequency could therefore increase when initiating combined hormonal contraception and side effects may increase in the pill-free interval or when discontinuing this method of contraception.

Emergency contraception

Emergency contraception (EC) is defined as any drug or device used after intercourse to prevent pregnancy. The options for EC within the UK are the Cu-IUD or oral EC, either 30 mg of the progesterone receptor modulator ulipristal acetate (UPA) or 1.5 mg of the progestogen levonorgestrel. UPA is licensed for use up to 120 hours after unprotected sex, and LNG for up to 72 hours, although there is evidence that LNG may retain efficacy up to 96 hours.

In the UK, LNG has been available without prescription from a pharmacy since 2001; UPA has been available throughout most of Europe without a prescription since 2015. Whilst EC prevents pregnancy for individuals, there is no evidence that EC (or improved access) prevents unintended pregnancies or abortions at population level. Research has shown that women do not use EC for every act of unprotected sex. Additionally, many women have more sex in the same cycle after using EC, which increases the risk of pregnancy.

Efficacy

Effectiveness of EC is estimated by calculating the number of pregnancies that might have occurred in the absence of treatment but such estimates of efficacy are difficult to make [6]. Many women are unsure of the exact date of their LMP, many are of unproven fertility and many use it after an accident with a condom which may not in fact have resulted in the leakage of seminal fluid.

The Cu-IUD is the most effective EC, with pregnancy rates of around 1 in 1000. Copper ions are toxic to gametes and the Cu-IUD also induces endometrial effects that prevent implantation. It can be inserted for EC up to 5 days after the estimated day of ovulation (in a 28-day cycle this is interpreted as day 19, i.e. day 14 + 5 days = day 19). Although the Cu-IUD is widely used for EC, it may have limited acceptability to women because it requires an invasive procedure and the availability of a skilled provider. FSRH guidelines recommend that all eligible women should be offered a Cu-IUD for EC given its low failure rate.

The effectiveness of oral EC has been overestimated in the past. A meta-analysis of trials that compared both LNG and UPA for EC reported pregnancy rates of 2.6% and 1.8%, respectively. Since the expected pregnancy rate was calculated at 5.5%, this suggests that these methods might prevent half to two-thirds of pregnancies [38].

Mechanism of action

Both LNG and UPA work by delaying ovulation for at least 5 days (lifespan of sperm in the female reproductive tract). However, if taken in the immediate preovulatory period when the risk of conception is greatest (after the onset of the LH surge), LNG is ineffective but UPA remains able to delay ovulation. EC doses of LNG and UPA do not cause significant endometrial effects and are unable to prevent implantation *in vitro*.

Safety

Observational studies have shown no adverse effect of exposure to LNG on pregnancy outcome or subsequent infant development. Data on the effects of UPA on pregnancy are more limited. However, the available data on UPA have been consistent, with no increased risk of miscarriage, ectopic or congenital abnormality in babies compared with the general population [39].

Impact of obesity on EC

Secondary analyses of studies comparing LNG and UPA for EC suggested that obesity (BMI ≥30 kg/m^2) was associated with an increased risk of pregnancy and that failure of EC was greater amongst women with obesity treated with LNG than UPA. However, the EMA reviewed the data from published and unpublished clinical trials and concluded that the data were not sufficiently robust to conclude that obesity was associated with a decrease in efficacy of EC. The FSRH recommends that women with obesity can continue to use either UPA or LNG [39].

Starting effective contraception after EC

Given the higher risk of pregnancy if further sex occurs in the same cycle after EC, it is important that women start effective contraception as soon as possible. LNG does not interact with hormonal contraception. However, UPA is a progesterone receptor modulator and recent biomedical studies indicate that starting the POP desogestrel the day after UPA adversely affects the ability of UPA to delay ovulation, i.e. renders UPA less effective as EC. FSRH guidelines advise that after UPA for EC, women should wait at least 5 days before commencing hormonal contraception [39].

Summary box 65.3

- Ulipristal acetate is a progesterone receptor modulator that is available for emergency contraception.
- Ulipristal acetate has been shown in a meta-analysis to be more effective than levonorgestrel for emergency contraception.
- Ulipristal acetate can be given within 120 hours of unprotected intercourse.
- The most effective method of emergency contraception is a Cu-IUD.
- A Cu-IUD can be inserted up to 5 days after ovulation for emergency contraception.

Female sterilization

Female sterilization involves blocking both fallopian tubes at laparoscopy, hysteroscopy or, less commonly, laparotomy. Filshie clips are the method of choice for laparoscopic sterilization and result in immediate tubal occlusion. The Pomeroy technique, where a loop of tube is tied and excised, is the method of tubal occlusion during laparotomy. Postpartum sterilization using mechanical occlusion with Filshie clips is effective and quicker and easier to perform than partial salpingectomy. It is recommended that women wishing sterilization at caesarean section be carefully counselled, and that consent be obtained at least 2 weeks before the planned delivery [40].

Hysteroscopic sterilization has advantages of avoiding abdominal incisions and can be performed under local anaesthesia or simple analgesia in an outpatient setting. It is particularly suitable for women who present an anaesthetic or operative risk (e.g. high BMI, previous abdominal or pelvic surgery). The Essure® system uses micro-inserts that are expanding springs (2 mm diameter and 4 cm in length) made of titanium, stainless steel and nickel-containing Dacron fibres. A micro-insert is placed in the proximal section of the fallopian tube under hysteroscopy. These induce a local inflammatory response and, over the subsequent weeks, fibrosis of the intramural tubal lumen. An additional method of contraception should be used until fibrosis of the lumen has been achieved and imaging (radiography, ultrasound or hysterosalpingography) at 3 months has confirmed satisfactory placement of the inserts. In 2017, the manufacturers of ESSURE withdrew it from the European market for commercial reasons.

Efficacy

Follow-up data available for the Filshie clip suggests a failure rate of 2–5 per 1000 procedures after 10 years [40]. For sterilization by hysteroscopic micro-insert, pregnancy rates are approximately 2 in 1000. Sterilization failure may increase the risk of ectopic pregnancy, but there are no robust data on which to quantify this risk.

Risks of female sterilization

Regret rates are particularly high in women under 30 years of age (up to 30% in some studies), and so younger women should be encouraged to consider LARC. A number of failures are believed to be due to women unknowingly conceiving in the same cycle before the procedure is performed. Contraception (hormonal and IUC) should continue for at least 7 days after tubal occlusion. Risks of laparoscopic sterilization include failure and injuries to bowel, bladder and blood vessels. The risk of laparotomy as a consequence of a severe complication is 1.9 per 1000 procedures. Women considering sterilization should be advised that subsequent changes in menstrual bleeding patterns may be expected due to advancing age and stopping hormonal contraception. There is epidemiological evidence suggesting that bilateral salpingectomy may protect against developing high-grade serous ovarian cancer. It is postulated that this may be because some epithelial cancers may originate in tubal epithelium. Women should be carefully considered for removal of fallopian tubes, if their family is complete and they are undergoing pelvic surgery [41].

Although hysteroscopic sterilization can avoid the risks of a general anaesthetic, laparoscopy and abdominal scars, potential complications and adverse events include tubal perforation, infection, device migration, device expulsion and vasovagal and pelvic pain.

Vasectomy

Male sterilization is safer than female sterilization and is more commonly performed under local anaesthesia. The ability to check for efficacy (with semen analysis) is an advantage. Division of the vas deferens prevents the passage of sperm. A minimally invasive approach should be used to expose and isolate the vas deferens, as this results

in fewest complications [40]. The success of the procedure is verified by the absence of sperm on semen analysis (and contraception must be continued until this time). The time to azoospermia depends on the frequency of intercourse, but it is estimated that 20 ejaculations are required. In the UK seminal analysis is recommended at 12 and 16 weeks, although a routine second semen analysis is not required if the first confirms azoospermia.

Efficacy

Even after azoospermia has been confirmed, there is a failure rate of around 1 in 2000 procedures. In a small proportion of men, non-motile sperm will persist following vasectomy. In such cases, RCOG guidelines advise that consideration be given to stopping additional contraception when less than 100 000 non-motile sperm per millilitre are observed in a fresh semen sample after vasectomy.

Complications

Scrotal bruising occurs in almost everyone, and haematoma (1–2%) and wound infection (up to 5%) are common minor complications. The development of anti-sperm antibodies (thought to be in response to leakage of sperm) occurs in most men and appears to be harmless unless restoration of fertility is desired. Small inflammatory granulomas can form at the ends of the vas but can be effectively excised. Chronic post-vasectomy pain (testicular, scrotal, pelvic or lower abdominal) is a persistent pain of unknown cause. It has been reported in 1–14% of men after vasectomy. Concerns have been raised linking vasectomy with an increased risk of atherosclerosis, testicular cancer, prostatic cancer and other, mainly autoimmune, diseases. Several large studies have failed to substantiate these concerns and there seems to be no biological plausibility for such a link.

Assessment and counselling for sterilization

Couples sterilized at a young age, immediately after delivery or at the time of an induced abortion are more likely to experience regret. A change of partner is the commonest reason for requesting reversal. A history should be taken and scrotal or bimanual pelvic examination should be carried out either at initial consultation or before commencing the procedure.

Reversal of sterilization

Reversal of female sterilization (tubal re-anastomosis) involves laparotomy, does not always work (microsurgical techniques have around 70% success) and carries a significant risk of ectopic pregnancy (up to 5%). Reversal of sterilization with micro-inserts cannot be achieved via fallopian tube re-anastomosis, and therefore consideration should be given to *in vitro* fertilization. Reversal of vasectomy is associated with patency rates of almost 90% in some series. Pregnancy rates are much less (up to 60%), possibly due to the development of anti-sperm antibodies.

Barrier methods

Male and female condoms

The male latex condom is cheap, widely available over the counter and, with the exception of the occasional allergic reaction, is free from side effects. Polyurethane condoms offer an alternative for people with latex sensitivity. Condoms are effective in preventing STIs, including HIV. The female condom is a polyurethane sheath (single size) with flexible polyurethane ring and is placed inside the vagina. Failure rates are similar to those of the male condom (see Table 65.1).

Diaphragm and cervical cap

The diaphragm and cap are less popular than male condoms. In addition, they do not confer the same degree of protection against STIs since the vaginal mucosa is not covered. In order to select the correct size of diaphragm, a vaginal examination is conducted. Latex allergy, recurrent local vaginal infections and recurrent urinary tract infection are possible side effects. Caps fit snugly over the cervix but are seldom used.

Summary box 65.4

- All barrier methods have high failure rates when used typically.
- Male condoms reduce the risk of STIs including HIV.
- Spermicides should not be used alone and if used frequently and in large quantities may increase the risk of HIV transmission.

Fertility awareness methods

Fertility awareness methods (FAM) involve the avoidance of intercourse during the fertile period of the cycle [42]. For calendar or rhythm method, the woman calculates the fertile period according to the length of her normal menstrual cycle. The first day of the fertile period is calculated as the length of the shortest cycle minus 20 days, and the last day of the fertile period as the longest cycle minus 10 days. Therefore if cycle length varies from 25 to 30 days, the potential fertile period and days when intercourse should be avoided are days 5–20.

The mucus or Billings method relies on identifying changes in the quantity and quality of cervical and vaginal mucus. As circulating oestrogens increase with follicle growth, the mucus becomes clear and stretchy allowing the passage of sperm. With ovulation, and in the presence of progesterone, mucus becomes opaque, sticky and much less stretchy. Intercourse must stop when fertile-type mucus is identified and can start again when infertile-type mucus is recognized.

Progesterone secretion is associated with a rise in basal body temperature of about 0.5°C and so the basal body temperature method identifies the end of the fertile period. Other signs/symptoms, such as ovulation pain, position of cervix and dilatation of the cervical os, can be used to help define the fertile period. Personal fertility monitors use test strips to detect urinary metabolites of oestrogen, and LH (eg. Persona may be used by women to detect the fertile phase of the cycle); the monitor displays a green light for the non-fertile phase and a red light for the fertile phase. An increasing number of fertility apps for mobile phones, where the user inputs cycle length and/or symptoms such as basal body temperature, are being adapted for contraceptive purposes. FAM requires motivation, teaching and regular cycles. Whatever method is used, many couples find it difficult to abstain from intercourse during the fertile period. Failure rates are high (see Table 65.1).

Lactational amenorrhoea method

Breastfeeding delays the resumption of fertility after childbirth and the length of the delay is related to the frequency and duration of breastfeeding episodes. A woman who is fully or nearly fully breastfeeding and who remains amenorrhoeic has less than a 2% chance of pregnancy during the first 6 months after childbirth (lactational amenorrhoea method).

Non-contraceptive benefits of contraception

Hormonal methods of contraception in particular have many non-contraceptive benefits. When used for the management of a medical problem the risk–benefit ratio changes. The 52-mg LNG-IUS is highly effective for heavy menstrual bleeding and more cost-effective than other medical therapies and endometrial ablation. It reduces the pain of endometriosis and adenomyosis and protects against unopposed oestrogen. There is evidence that the 52-mg LNG-IUS prevents and causes regression of endometrial hyperplasia and protects the endometrium against the effects of tamoxifen (amongst women with breast cancer). The 13.5-mg LNG-IUS is not licensed for treatment of heavy menstrual bleeding, but does reduce menstrual bleeding and amenorrhoea rates improve with time.

There is good evidence that COC pills can help bleeding, acne and hirsutism, and symptoms of premenstrual syndrome. DMPA is effective in managing the symptoms of endometriosis and, given the high incidence of amenorrhoea, is also used for heavy menstrual bleeding. Hormonal contraception protects against certain gynaecological cancers, the most important being the significant reduction in ovarian and endometrial cancer with use of the COC pill. DMPA confers a high degree of protection against endometrial carcinoma and should theoretically also protect against ovarian cancer.

Conclusion

Obstetricians and gynaecologists often underestimate a woman's need for immediate effective contraception. Contraception can be started at any time if it is reasonably certain that a woman is not already pregnant. Immediately after pregnancy is a key time to provide contraception, since fertility and sexual intercourse resume quickly. Uptake of LARC at these times can prevent unintended pregnancies and short inter-pregnancy intervals that have negative consequences for maternal and child health. Hormonal methods of contraception can effectively manage a range of gynaecological conditions. It is essential therefore that obstetricians and gynaecologists can give high-quality information to women about the range of contraceptive methods and provide these for women.

Sexual Dysfunction

Kevan R. Wylie

University of Sheffield, West Bank, Sheffield, UK

Sexual activity is associated with pleasurable and enjoyable experiences potentially throughout adult life in women as well as allowing for reproductive capacity in the childbearing years. Sexual function is recognized to be associated with both psychological and physical well-being. The first principle of clinical sexuality states that 'any sexual behaviour – normal and abnormal, masturbatory and partnered – rests upon biological elements, psychological elements, interpersonal elements, and cultural concepts of normality and morality' [1] and as such conveys sexuality's inherent rich complexity.

Society has changed considerably over recent decades and the impact of sexuality as an important contributor to quality of life has been emphasized by greater numbers of women approaching gynaecologists and other clinicians seeking help for sexual (and often relationship) problems. Alongside this is an expectation to be able to raise the matter with their healthcare professional without fear of rejection or embarrassment. There is anticipation that their clinician will be willing to discuss the issues when raised by the woman, or the physician, with confidence and without judgement. Provision of clinical services for the emerging specialty of sexual medicine remains limited within the UK and is best located where multidisciplinary teams can work providing sexual medicine, sexual therapy and gynaecology services together for women and their partners.

Summary box 66.1

- Sexual activities offer both reproductive and pleasurable recreational opportunities for women.
- Healthcare professionals should offer women the opportunity to discuss any areas of concern about their sexuality or relationship.
- Sexual medicine is a multidisciplinary field of medicine incorporating gynaecology, psychology and couples' psychotherapy.

Changing attitudes towards sex

This shift in attitudes has been highlighted by the findings from the consecutive UK National Surveys of Sexual Attitudes and Lifestyles (Natsal) conducted over the last three decades. In the most recent survey of individuals aged 16–74 years who lived in Britain (England, Scotland and Wales) that was completed between 2010 and 2012, data were available for 6777 women (and 4913 men) [2]. Some of the key findings for women were that low sexual function was associated with increased age and, after age adjustment, with depression and self-reported poor health status. Low sexual function was also associated with experiencing the end of a relationship, an inability to talk easily about sex with a partner and not being happy in the relationship. Associations were also noted with engaging in fewer than four sex acts in the preceding 4 weeks, having had same-sex partners and having 10 or more lifetime partners; 51.2% of women reported one or more problems in the past year, although self-reported distress about their sex lives was much less common. For women in a sexual relationship for the past year, 27.4% (and 23.4% of men) reported an imbalance in the level of interest in sex between partners, with 17.1% of women reporting that their partner had had sexual difficulties.

Trends were reviewed over the three decades that the surveys have taken place (Natsal 1, 1990–1991; Natsal 2, 1999–2001; Natsal 3, 2010–2012). Some of the findings were as follows. The percentage of women who thought that one-night stands were 'not wrong at all' increased from 5.4% in Natsal 1 to 12.2% in Natsal 2 and 13% in Natsal 3. The percentage of women thinking that female same-sex partnerships were 'not wrong at all' increased from 27.7% in Natsal 1 to 51.5% in Natsal 2 and 66.1% in Natsal 3. The authors conclude in their review that sexual lifestyles in Britain have changed substantially in the past 60 years, with changes in behaviour seemingly greater in women than men. The continuation of sexual

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

activity into later life, albeit reduced in range and frequency, emphasizes that attention to sexual health and well-being is required throughout the life course [3].

In another recent study involving middle-aged and older UK individuals (40–80 years), 56% of women reported having sexual intercourse in the last year and 18.8% of women engaged in sexual intercourse at least weekly. The most common problems reported were lack of sexual interest (34%) and lack of pleasure in sex (25%). Of some concern, 57.7% of women took no action when they had a sexual problem and only 16.7% of women reported talking to a medical doctor, with most women (82.3%) having sought no advice from a health professional. Talking to their partner was the most common action taken by women (32.5%) [4]. Only 4.2% of women had been asked by a doctor about possible sexual difficulties during a routine visit in the previous 3 years yet 29.2% of women thought that a doctor should routinely ask patients about their sexual function.

Despite this emerging evidence of patient need, it has been reported that women may present to a gynaecology or obstetric clinic without ever being asked, or disclosing any information, about their sexual lives. One study identified that over 98% of women reported one or more sexual concerns that often changed as women aged but that most of the women had not had the topic of sexual health ever raised by their physicians [5]. The clinic environment may not be conducive to routine enquiry but this should be addressed by changes to the patient clinic space to ensure patient confidentiality.

Summary box 66.2

- Sexual problems are common within the community but persistent problems for over 6 months are much more unusual.
- The commonest sexual problem is a lack of sexual interest, fantasy and desire.
- Women are more likely to discuss their problem with a friend or their partner than with a healthcare professional.

Sexual response: models of sexual function

Humans have three primary emotion–motivation circuits and these brain systems have evolved to direct and influence sexual behaviour. These are lust (sex drive, libido), driven by androgens; attraction (passionate romantic love), driven by dopamine; and attachment (bonding), driven by oxytocin [6,7]. Evolving evidence suggests that individual differences in human sexual behaviour may be in part due to allelic variants coding for differences in DRD4 dopamine receptor gene expression and protein concentrations in key brain areas [8]. A variant of the DRD4 dopamine receptor gene (a polymorphism found on chromosome 11 in humans) has been linked with uncommitted sexual behaviour and infidelity [9].

The aetiology of unhappiness within a relationship is multiple but failing to find a partner to love may arise when psychological intimacy is unable to be reached during courtship or is lost once in a stable relationship. When this arises, couples work may be appropriate should both partners be willing to attend to explore, amongst many issues, their ways of connecting, communicating and negotiating together. Other key areas may include dealing with issues of power and trust within a relationship.

The early models of sexual response were described as linear in nature, incorporating concepts of sexual drive (endocrine), sexual desire and libido (emotional and cognitive), excitation and plateau (vascular and emotional), orgasm (neurological, muscular and emotional) and resolution (Fig. 66.1). More recently, an intimacy-based model of a women's sexual response cycle was introduced by a team of experts (Fig. 66.2). This model reflects the key roles of emotional intimacy and sexual stimuli, unlike the earlier models which tended to neglect the importance of emotional intimacy as a motivator to find or be responsive to sexual stimuli. The basis of the more cyclical model is that the goal of sexual activity in women may not necessarily be physical satisfaction (by attaining orgasm), but rather emotional satisfaction (a feeling of intimacy and connection with a partner) [10]. However, there are additional models that may be important when considering sexual function and dysfunction and the interested reader is referred to a recent review [11].

Sexual response: anatomy and physiology

The anatomy and physiology of sexual function and dysfunction is not always overtly taught at medical school or in postgraduate courses, with several obstacles preventing sexual health from being adequately addressed in health professionals' curriculum. These include low priority given to the topic and a lack of standardized objectives and means for evaluating any current curriculum. Given the raised awareness that medical conditions can result in sexual dysfunction and the fact that sexual problems may be the presenting symptom for significant underlying disease, the argument for mandatory awareness and training in the field is increasing [12].

Vaginal lubrication comprises vaginal transudate, often with secretions from the Bartholin's glands and the paraurethral Skene's glands. The process of transudation depends on both intact innervation and normal oestrogen levels. The process of parasympathetic activation via the sacral nerves S2–S4 leads to an increase in vaginal blood flow. It has been shown that the process of vasomotion occurs with the random opening and closing of the capillaries of the vaginal wall (Fig. 66.3). The normal

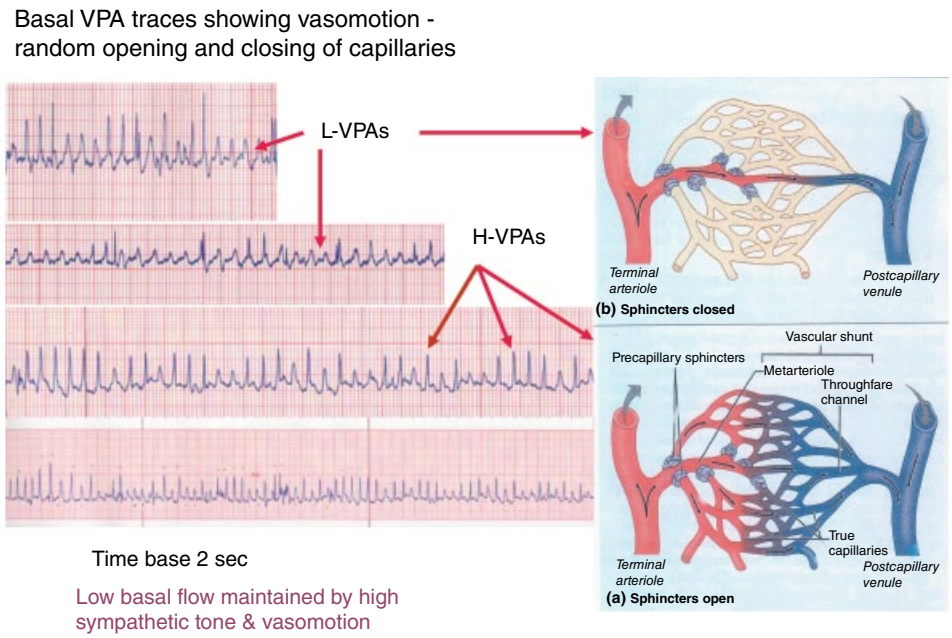

Fig. 66.3 Vaginal vasomotion.

low basal flow is maintained by both high sympathetic (T12–L2) inhibitory tone and vasomotion [13].

Concurrent with any increase in vaginal blood flow is an increase in the blood flow to the clitoris, an organ which is much hidden from routine inspection of the vulva. The perineal urethra is embedded in the anterior vaginal wall and is surrounded by erectile tissue in all directions, except posterior where it relates to the vaginal wall [14]. The erectile tissue brings about swelling and protuberance during sexual arousal. The clitoris appears to exist solely for the purpose of sexual pleasure. There has been much debate about the differences and importance (if any) between clitoral orgasm and vaginal orgasm and whether the presence of a G-spot exists to bring about sexual pleasure. In recent years a number of papers have been published with regard to the possible isolation of tissue identified to be the G-spot and the evidence and arguments are summarized in a recent commentary [15].

Sexual diversity

The gynaecologist should strive to offer a non-judgemental approach when exploring a woman's sexual identity regardless of any sexual dysfunction and this will be considered further in the following section. The principle issues involve sexual orientation, gender identity and the presence of any paraphilic patterns of sexual arousal.

Sexual orientation should be routinely enquired about with women in the clinical setting. It is difficult to be certain of the true prevalence of lesbianism but in one study, among women, 97.7% identified as heterosexual, 0.8% as lesbian or homosexual and 1.4% as bisexual. However, during this computer-assisted telephone interview, among women, 84.9% reported only opposite-sex attraction and experience. Thus, some same-sex attraction or experience was reported by 15.1% of women (compared with 91.4% of men). Of women, 8.2% reported sexual attraction and sexual experience that was inconsistent. Factors associated with this agreement or disagreement included age group, non-English-speaking background, education and socioeconomic status [16].

It is also important to distinguish and to ask about the gender that an individual may identify as. This may not always be as a binary female. The terminology and use of pronouns can be a difficult maze for the uninformed clinician and a review of the various terms has been published [17].

Trans people may transition with psychological and medical care that requires endocrinology and surgical intervention. For some trans men (i.e. woman to man), there may be a need for chest surgery and hysterectomy. If the individual has not yet decided to progress for phalloplasty, a gynaecologist may be approached, with medical recommendations and support for hysterectomy (and usually oophorectomy). Some women may present to gynaecologists having transitioned from a male gender role. These men and women should be offered the same clinical care as any women whilst recognizing there will be some differences in clinical needs during the post-perioperative care period and in the postoperative anatomy. Once transition has occurred, and where necessary, liaison with the surgeon involved in the gender confirmatory surgery may be indicated but it is not appropriate to access mental health services unless there are relevant clinical indications to do so. On some occasions, the gynaecologist may be the first person with whom a patient may raise the issue of a desire for gender transition (which if towards the male role would be as a trans man). An overview of guidelines for clinical care for trans people is available [18].

Sexual dysfunction

It is important to remember that there will be some women who do not openly share the details of their sexual life or sexual preference, even when asked about it. This can lead to some difficulties when a clinician first hears about a particular preference or practice, especially any that may be outside their own experience. An awareness of different sexual practices, particularly in the area of sexual preference as a normal part of the sexual repertoire for arousal and sexual pleasure, is considered next.

The paraphilias, or sexual preference disorders as listed in section F65 of the International Classification of Diseases (ICD-10), are a group of preferences that were considered outwith 'normal behaviour'. With the increasing acceptance of diversity over recent decades, many of the conditions historically described as 'sexual perversions' are no longer considered such and have been removed from the recent fifth revision of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) and many will most likely be removed in the forthcoming revision of the WHO classification system (ICD-11). Although paraphilias have not disappeared completely from DSM-5, there is an attempt to clearly distinguish between the behaviour itself (e.g. receiving of pain for sexual pleasure: sexual masochism) and a disorder stemming from that behaviour (i.e. sexual masochism disorder) [19].

To differentiate between an atypical sexual preference and a mental disorder, DSM-5 requires that, for diagnosis, people with such interests exhibit the following: (i) 'feel personal distress about their interest, not merely distress resulting from society's disapproval'; or (ii) 'have a sexual desire or behaviour that involves another

person's psychological distress, injury, or death, or a desire for sexual behaviours involving unwilling persons or persons unable to give legal consent' [20]. To take the example of fetishism, a fetish is an object or body part that a person must focus on to become sexually aroused and in extreme cases to achieve sexual satisfaction. The reliance on some non-living object as a stimulus for arousal and sexual gratification may arise for a number of reasons. For many people there is experimentation with fetishistic behaviour, which is not a fetish by definition. Numerous sexual aids and 'toys' are easily available from high-street shops and mail order. Some fetishes require no inanimate objects but merely non-genital parts of the body. Preference for the feet or toes (such as sucking the toes of the partner and/or having their own toes or feet licked or rubbed) was the most prevalent fetish by a considerable margin in one recent large study [21].

Likewise, in a study to try to identify 'what exactly is an unusual sexual fantasy', the themes that were most reported by women included an exotic or unusual private place for sex (such as a deserted beach or forest) with a focus on her own submissive behaviour. Around one-sixth of women mentioned involvement of a stranger and around 8% mentioned either homosexual activities or group sex. The themes were very different from those mentioned by men, where voyeurism and fetishism were the highest reported. Clearly, this matter may lead to some difficulties for partners if they were to declare these openly or try to enforce these into the sexual repertoire, especially if they were not negotiated or discussed in advance [22].

Throughout this chapter, no attempt is made to discriminate against any of these sexual choices, and for brevity reference to a partner may be made whilst recognizing that many women may be without a partner at a certain time through preference or otherwise or may have multiple partners.

Psychosocial and psychosexual factors contributing to sexual well-being

The fourth International Consultation on Sexual Medicine (ICSM) convened in Madrid in 2015. The committee reviewing psychological and interpersonal dimensions of sexual function and dysfunction made a number of recommendations that are summarized here for women presenting with sexual problems. Exploration of the attachment style of the woman, her personality, her cognitive schemas, any infertility concerns, and sexual expectations should all be noted. Assessment of depression, anxiety, stress, substance use and post-traumatic stress (and their medical treatments) should be carried out as part of the initial evaluation. Clinicians should attempt to ascertain whether any anxiety or depression is a consequence or a cause of the sexual complaint, and treatment should be administered accordingly.

Assessment of physical and mental illnesses that commonly occur in later life should be included as part of the initial evaluation in middle-aged and older persons presenting with sexual complaints [23]. Further recommendations are to assess multiple aspects of sexual functioning, including, but not limited to, subjective aspects such as sexual self-esteem and sexual satisfaction, not just sexual dysfunction. A developmental approach to assessing the onset of sexual activity is recommended, including self-focused as well as partnered activity ranging from non-genital to genital expressions, the context around those experiences, as well as any associated beliefs and emotions associated with them. Crucially, there should be an attempt to explore their possible role in the individual's current sexual function and behaviour.

Clinicians should explore sensitively childhood experiences including sexual abuse and, if this occurred, its characteristics regarding frequency, duration and whether the perpetrator was known or not.

In addition, a number of life-stage stressors are evident for women, including infertility, postpartum experiences, ageing and menopause, and these can have a specific impact on psychosocial and psychosexual experiences. The prevalence of sexual dysfunction in women reporting infertility was higher than that in the fertile control group in one study using the FSFI questionnaire [24]. The recommendation to clinicians is that during all phases of infertility diagnosis, investigation and management the clinician, whenever possible, assess sexual function and satisfaction.

Approximately half (52%) of women resume sexual activity by 5–6 weeks post partum. However, it is less clear the extent of sexual dysfunction at 2–6 months post partum, with various studies suggesting this affects 22–86% of women (see Brotto *et al.* [23] for full review].

With regards to normal ageing, a survey of 3005 respondents in the USA (ages 57–85) found that the prevalence of sexual activity was 74.8%. Women were much less likely to report being sexually active than men. Half of the women (and half of the men) reported at least one bothersome sexual problem and were concerned about the impact of ageing changes on their sexuality. The most prevalent sexual problems among women were low desire (43%), difficulty with vaginal lubrication (39%), and inability to orgasm (34%) [25].

Stressors and adverse life events that may affect sexual function and satisfaction include sexual experience throughout life, attitudes toward sex, dysfunctional sexual partner, death of partner, sexual performance issues,

impaired self-image, physical or mental fatigue, disturbed family relationships, divorce, physical illnesses and disabilities, need for special care, changes in employment and financial status [23]. A drop in testosterone levels, and increase in cognitive and depression issues with older age may also impact on sexuality. Clinicians should be aware of the relationship between symptoms of ageing and psychological health (e.g. anxiety, irritability, insomnia, memory impairment and depressed mood) in older men, and request further investigation when needed.

Menopausal status has an independent effect on reported changes in sex life and difficulties with intercourse. The results from the Study of Women's Health Across the Nation (SWAN) [26] highlight the importance of including social, health and relationship factors in the context of menopause and sexual functioning. These factors and, in particular, feelings toward one's partner or starting a new relationship have also been identified by others as highly important [27–31]. Similar to a previous study [33], Avis *et al.* [26] found declines in all areas of sexual functioning according to menopause status. Controlling only for age, the Melbourne Women's Midlife Health Project also found greater declines in sexual functioning among 197 women who transitioned from premenopause to postmenopause compared with women who remained premenopausal. Previous sexual function and relationship factors were more important determinants of libido and sexual responsiveness than estradiol level [32,33].

Finally, there are limited data on the impact of sociocultural factors on female sexual function as well as on ethical principles to follow when clinical care falls outside traditional realms of medically indicated interventions. It is recommended that clinicians evaluate their patients and their partners in the context of culture and assess distressing sexual symptoms regardless of whether they are a recognized dysfunction. There are a number of practices with complex ethical issues (e.g. female genital cutting, female cosmetic genital surgery) that may need careful reflection and discussion with the woman and within professional peer supervision for the gynaecologist [34].

Summary box 66.3

- There are a number of aetiological factors that may predispose and perpetuate sexual problems for women.
- Psychological and psychiatric morbidities are commonly associated with all the sexual problems troublesome for women.
- Encouraging women to speak about their problems during consultations may be helpful and in many cases can facilitate further discussion between the couple.

Physical factors contributing to sexual well-being

A substantial number of factors can interrupt the normal process of sexual activity and can be considered as endocrine factors (typically androgens and oestrogens), neurological factors, vascular factors and iatrogenic factors. These will be considered within each section on the various sexual dysfunctions. There are also a number of common gynaecological conditions where interruption to usual sexual function can occur, such as cervical, ovarian and other gynaecological carcinoma, prolapse, incontinence, interstitial cystitis and procedures such as hysterectomy. Dermatological conditions such as lichen sclerosus and eczematous rash can cause a number of sexual problems. Indeed, any life event may bring about a change in mood and well-being that in turn interrupt the opportunity for usual sexual activity and opportunity for pleasure.

At the 2015 ICSM consensus meeting, the expert review of the contribution of hormones, other than oestrogens and androgens, to female sexual functioning and the evidence that specific endocrinopathies in women are associated with female sexual dysfunction (FSD) identified that treating hyperprolactinaemia might lessen FSD. Polycystic ovary syndrome, obesity and metabolic syndrome could be associated with FSD, but data are limited. However, there is a strong association between diabetes mellitus and FSD [35]. Not surprisingly, the overwhelming recommendation of the experts at ICSM is that a biopsychosocial model is used to understand how these factors predispose to sexual dysfunction and that the same model is applicable for effective management thereafter.

Overview of psychosocial and psychosexual interventions

Basic sexual counselling is an integral part of all medical consultations. The clinician should always try to give the patient the opportunity to talk about her own sexuality and to listen actively so that the woman feels accepted and understood and there may follow some emotional relief. During this stage assess the woman's and her partner's concepts and knowledge of sexuality, passion, intimacy, commitment and love. Include here collecting information and details of her sexual biography and usual sexual scripts. Take the opportunity to inform her about the reality of human sexuality and to put the variety of her personal experiences into perspective. Give information about the usual frequency of problems and about differences between female and male sexuality. Encourage communication about her sexual needs with

the doctor and the partner. With knowledge comes empowerment and self-confidence around sexuality.

Education is important to dispel any myths. Some common myths are that a healthy woman always has an orgasm, that sex must lead to orgasm and that masturbation is only for single women. Time can also be used to include suggestions about use of specific sexual positions, such as the female superior position. In certain circumstances suggestions about the use of erotica and the use of specific bibliotherapy may be helpful.

Talking therapies can be helpful if indicated and specialized psychosexual therapy may be offered but this will be dependent on individual training and experience and/or access to trained psychotherapists within the service. Typically, these therapies include body awareness education, cognitive behavioural therapy (CBT) with or without relaxation therapy, couple communication training, sensate focus and, less frequently, psychodynamic individual therapy. These are described in turn.

Body awareness training includes the use of exercises to try at home. These can be provided in both verbal and written format with the opportunity to answer any questions before or after the session. Typically, these include looking at the naked body from all sides in a large mirror (and to compare it with drawings or other photographs); looking at the genitalia using a small hand mirror and exploring the genitalia with the hand; exploring the genitalia for any sensitive areas and trying to identify areas of the body that are stimulating. For this latter exercise the clinician can provide additional guidance such as to try manual stimulation (where, how and how intensive), to increase intensity and duration, to think about using a vibrator and to try manual stimulation in the presence of the partner and then involving the partner. This is probably beyond the scope of a gynaecologist.

CBT involves focusing on individual thoughts, feelings and behaviour and encourages the woman to become aware of irrational beliefs and dysfunctional thoughts. The overall aim of this brief therapy over four to six sessions is to provide help in changing the ways of thinking.

Relaxation work includes making suggestions about how to manage stress, advice on how to relax the body musculature and to recognize the value of exercise in general well-being. Mindfulness therapy may be useful in certain situations for women who are able to use this intervention [36].

Couples relationship psychotherapy has been mentioned in a previous section. There is often a reluctance to involve a partner as the woman feels that the problem belongs only to her, or due to something she has done. Often, the partner may be reluctant to attend sessions, often citing a number of reasons why they cannot attend. A simple reframe of the problem as a shared problem rather than due to the physical pain experienced by the woman or the resultant depression and medication prescribed for the depression. Whilst all of these can be contributory to the sexual dysfunction, a biopsychosocial model prefers to offer a number of explanations for a problem and so offers a number of treatment options and interventions that may include some couples' therapy together.

On some occasions, there may be sexual problems within the partner. In heterosexual partnerships these may include erectile dysfunction or early or delayed ejaculation. Depending on the aetiology, these problems may need to be dealt with alongside any interventions for the woman or the couple.

Sex therapy typically involves sensate focus (Fig. 66.4): this may start as individual work such as a 'growth programme' with genital exploration and touching and moving onto work with a partner if both parties are in agreement. Typically, there is a 'ban on sexual touching and intercourse' during the early stages of the programme. The ability to receive and also to give pleasure will open the opportunity to learn (or relearn) knowledge about the partner and offer opportunities to experience psychological and physical intimacy and to be able to say to each other that they love each other. A carefully tailored programme is usually more helpful than just providing a sheet of instructions that are often read briefly and forgotten between sessions as the detail fails to appreciate the specific circumstances and needs of the women (and her partner).

Individual psychotherapy may consider a number of issues such as of trust, intimacy, closeness, power, control, attraction, boredom and lack of pleasure. When there is evidence of concurrent depression, body image issues, sequelae of sexual abuse, personality or relationship factors, then these matters are often better addressed first with the assurance that if the sexual problems remain, these will be attended to in due course. An experienced sexual and couples' psychotherapist may feel able to continue couples sex therapy work whilst the woman has separate work on these matters with another therapist or clinician as they may take some time to resolve whilst the woman is seeking resolution or improvement to her sexual life.

Summary box 66.4

- There are a number of therapeutic approaches that may be helpful for women with sexual difficulties and dysfunction.
- As there can be multiple sexual problems described during a consultation, careful history-taking can assist the physician in prioritizing interventions to the most likely primary factors.
- Permission giving, educational bibliographies and encouraging playfulness and changes to the sexual script are time-limited interventions that may be appropriate to offer to women (and their partners).

Sexual desire disorder

A lack of sexual desire or 'sex drive' has also been termed a lack of libido. In this condition there is a lack of interest in or receptivity to sexual activity or an absence of sexual thoughts or fantasy.

The recent change to the DSM-5 classification system for sexual dysfunctions has combined desire disorder with arousal disorder to create the new diagnostic category of sexual interest arousal disorder for women (but not men). It is uncertain whether the revision to the ICD classification will follow the same direction, although there is considerable resistance to the proposal from many sexologists who consider the two processes to be separate albeit interdependent in many circumstances. The increased rejection of a linear model of sexual arousal was in part the basis for combining both disorders in DSM-5. Other changes of importance in defining a sexual disorder is that almost all DSM-5 sexual dysfunction diagnoses now require a minimum duration of 6 months as well as a frequency of 75–100%. Further, in order to make a diagnosis, the disorder must be deemed to have caused significant distress (the DSM-IV requirement of 'interpersonal difficulty' has been removed) [20].Women presenting with concerns about low sexual interest or desire and who are distressed about the situation will require a careful evaluation to identify the most likely aetiological factors. Medical factors include chronic medical conditions, cardiovascular disease, anaemia, obesity, diabetes mellitus, fatigue and chronic pain. Hormonal disorders include androgen insufficiency, Addison's disease, hypothyroidism and hyperprolactinaemia and it is also a consequence of the normal changes after pregnancy. The effects on sexual desire after bilateral oophorectomy (and surgical menopause) are well documented. Iatrogenic reasons can include

prescribed medications, such as the oral contraceptive and oral hormone replacement therapy (HRT) and tamoxifen (which all bind testosterone) and use of antidepressant or antipsychotic medication, benzodiazepines, thiazides, beta-blockers, cimetidine, steroids and lovastatin. Some psychiatric conditions may cause this problem, including anxiety, depression and substance misuse (including alcohol). Psychological experiences including environmental and life events (including work stressors), previous trauma or abuse can all influence sexual desire as can body image disorder and anorexia nervosa. As with all sexual problems, the desire problem may be secondary to other sexual problems such as dyspareunia or vaginismus. There may be problems with the way couples relate to each other, or their sexual repertoires (or 'sexual scripts') may have become mundane or boring. In some situations, there may be overt relationship problems.

Following a thorough assessment from history-taking, an effective way to exclude affective disorders is to administer the self-completed HAD questionnaire. A specific questionnaire that can be helpful in offering a measure of sexual function is the Female Sexual Function Index (FSFI). This questionnaire score can be used to assist in monitoring changes from clinical care interventions over a period of time.

Physical examination may be indicated by any comorbid conditions such as fatigue, irregular menses, pain, history of trauma or concurrent problems with sexual arousal.

To exclude endocrine disturbance, serum testosterone levels should be measured between day 8 and 20 of the monthly cycle, between 8 a.m. and 11 a.m. If these are low (<0.4 mmol/L), then the calculated free testosterone can be measured by rechecking the testosterone level and by also measuring sex hormone-binding globulin (SHBG) and albumin. The normal calculated free testosterone level is 0.4–0.8 ng/dL. It may also be prudent to measure follicle stimulating hormone (FSH), glucose and thyroid-stimulating hormone (TSH) and thyroid function as clinically indicated.

The clinical management of problems of sexual desire involves a number of options and the appropriateness of such will vary according to the findings from the assessment. Often the most reassuring factor is to normalize these experiences using data such as that available from the Natsal studies.

Herbal remedies are often enquired about by women but there has been no significant benefit identified in any recent reviews of the literature, with the exception of tribulus terrestris trialled in premenopausal married women reporting loss of libido, where a statistically significant increase in all variables, including desire, when compared with placebo (using the FSFI) was reported with only one patient out of 60 reporting any side effects [37].

If there is evidence of endocrine disturbance, tibolone or a trial of testosterone or dehydroepiandrosterone sulfate (DHEA-S) on an off-licence basis may be helpful for menopausal women. Tibolone (Livial) is often classed as a type of systemic HRT. It is a synthetic steroid with similar effects to the female hormones oestrogen and progesterone as well as testosterone. It can improve menopausal symptoms and a lack of sexual desire. Off-label prescription of bupropion is also worth trying in some cases, even in the absence of depressive symptoms.

The International Society for Sexual Medicine (ISSM) published suggested standard operating procedures for a number of sexual problems in 2013 and the reader who is interested in further details is signposted to these as well as to the reports from the ICSM 2015 [38,39]. Specific UK guidelines on the management of sexual problems in women and the role of androgens were published in 2010 [40].

The outcome of therapy is often asked about by patients before investing time and commitment to attend a number of sessions. In the review by Brotto *et al.* [23] for women with desire disorder, a meta-analysis yielded 20 controlled studies, most involving CBT approaches. Overall, a large effect size for the primary end-point of low desire and a moderate effect size on improving sexual satisfaction were reported. CBT approaches can also improve quality of sexual and marital life and sexual satisfaction. Inclusion of the male partner in CBT treatment for low desire yielded better outcomes. Two controlled studies evaluated mindfulness-based therapy compared with a wait-list control group and found that this approach led to significant improvements in sexual desire in women (strong effect size), but the research was limited by the absence of a treatment control group. Based on the meta-analysis showing strong effect sizes, it is recommended that clinicians use CBT in the treatment of women with low sexual desire and mindfulness-based therapy may be helpful. Whenever possible, use of couple- or group-based therapy over individual therapy can be helpful. Unfortunately, there is scant literature on the combination of therapies (psychological and/or biological) for women with any of the sexual dysfunctions.

Sexual arousal disorder

A lack of sexual arousal or not feeling 'turned on' is a lack of response to sexual stimulation, which can be experienced in the mind and/or the body. In the body this may include a lack of vaginal wetness (lubrication) and/or a lack of swelling, tingling or throbbing in the genital area.

Arousal may be categorized as (i) subjective sexual arousal disorder, where physical (genital) arousal can be evident but there is an absence of or markedly diminished

feelings of sexual arousal (sexual excitement and sexual pleasure) from any form of sexual stimulation; (ii) genital sexual arousal disorder; (iii) combined sexual arousal disorder or (iv) persistent genital arousal disorder (PGAD). In the rare condition of PGAD the woman may suffer from a persistent, unwanted and distressing increase in genital blood flow in non-sexual circumstances. It is characterized by involuntary genital and clitoral arousal that persists for an extended period of time and that does not go away following one or more orgasms. The genital arousal is unrelated to subjective feelings of sexual desire, feels intrusive and unwanted, and is usually highly distressing. Management is complex and the reader is referred to a recent review [41].

Aetiological factors for subjective and genital sexual arousal disorder can include medical factors such as chronic medical conditions, cardiovascular disease, diabetes mellitus, neurological disease and connective tissue disease. In postmenopausal women, the consequences of oestrogen deficiency on vaginal transudation is often marked. Iatrogenic factors include prescribed medications, especially antidepressant medications. Lactation may cause symptoms as a consequence of hyperprolactinaemia. Mental health conditions include depression, binge eating disorders and excessive dieting. Psychological issues include a history of previous abuse. Comorbid sexual problems, especially disorders of desire and pain disorders, decreased intimacy or couples' relationship problems, can also cause problems with sexual arousal.

The assessment by history-taking, questionnaires and physical examination are as listed for desire disorder. Useful blood investigations include testosterone, SHBG, free androgen index, FSH, estradiol and lipids. A measure of vaginal pH is easy to undertake during examination for measurement of acidity (normal ≤4.5). The role of specialist investigations is outside the scope of the general gynaecologist.

Treatment interventions will follow many of those listed for desire disorder. It is important to ensure adequate sexual stimulation and this can be emphasized during educational work or sensate focus therapy. Cognitive distraction is a significant contributor to sexual response problems in women and is observed more consistently for genital arousal than for subjective arousal.

Plentiful use of lubricants may be beneficial; KY Warming Liquid, Durex Warm, Durex Tingle, Zestra, Astroglide and Sylk may be useful. Clitoral vibrators may be helpful as can training about pelvic floor exercises (Kegel exercises). The clitoral therapy device Eros-CTD can be used to increase sexual arousal.

If estradiol is low, assessment for local (topical) or systemic oestrogen replacement may be helpful. If the woman wishes to try off-label medications, then after providing information and obtaining informed consent a trial of sildenafil, ephedrine, yohimbine or L-arginine may be helpful. Studies with pharmacological agents continue but are yet to progress to licenced clinical use.

A meta-analysis and a systematic review of outcome of psychotherapy for arousal disorder identified no controlled treatment outcome studies that focused on women with specifically sexual arousal complaints so no recommendations can be made [23].

The ISSM standard operating protocol is available [41].

Orgasmic disorder

When a woman has an orgasm the typical changes observed are increases in heart rate, breathing and blood pressure. The body musculature may tense, especially contraction of the genital and pelvic floor muscles, and a flush may appear on the body. There is then a period of deep relaxation. Some women may achieve multiple orgasms during a period of sexual stimulation. Problems reported with orgasm include absence of orgasm (anorgasmia), infrequent orgasms, delayed orgasm, reduction in the intensity of orgasmic sensations or painful orgasm.

Aetiological factors can include chronic medical conditions (renal or liver disease, etc.), cardiovascular disease, diabetes mellitus, neurological disease as well as the normal consequence of ageing. It is increased in endocrine situations such as post menopause and hypothyroidism. Orgasmic disorders can occur with pelvic floor weakness or damage. They commonly occur as iatrogenic consequences of medications, especially selective serotonin reuptake inhibitors (SSRIs), and are often associated with depression, high alcohol intake and use of illicit drugs. Further factors include previous abuse, age-related factors, social, cultural and religious factors, and comorbid sexual problems especially desire disorder and arousal and sexual pain disorders. Couples script or relationship problems are also associated with this disorder.

In addition to the blood tests noted for desire disorder, liver function tests and vitamin B_{12} and folate levels should be measured to exclude treatable causes of neuropathy.

Specific interventions include individual psychotherapy to consider resolution of unconscious fears about orgasm. CBT can promote changes and attitudes in sexually relevant thoughts. Couples' psychotherapy may focus on issues of trust and safety. Anxiety management may be helpful. Self-exploration work on desensitization of viewing and touching the genitals and guided masturbation exercises can be helpful. Use of vibrators including the 'rabbit', the vibrating condom ring and the Durex Play Wand can be helpful as can the Eros-CTD (alone or alongside sex therapy and sensate focus).

If the woman wishes to try medication, off-label use of bupropion (lower dose), yohimbine, sildenafil, buspirone, ephedrine, bethanecol, cyproheptadine, amantadine and oxytocin (10 IU sublingually) are all reported as valuable in selected cases within the literature or expert opinion. Topical oestrogen or testosterone may be helpful for age-related clitoral involution. The ISSM standard operating procedure guidelines are available [42].

Outcome of therapies has been reviewed by Brotto *et al.* [23]. Most treatment programmes for acquired female orgasm problems include a combination of sex education, sexual skills training, couples' therapy, directed masturbation and sensate focus. In a meta-analysis, there was a moderate effect size for the efficacy of psychological treatments on the primary end-point of anorgasmia and a moderate effect size for sexual satisfaction. In the only study evaluating the specific coital alignment technique, a significantly higher rate of orgasms during intercourse, simultaneous orgasms between partners, and satisfying orgasms was reported. Taken together, CBT is recommended for women with anorgasmia. Although the coital alignment technique is often used for women who wish to become orgasmic during vaginal penetration with intercourse, only one study evaluated the effectiveness of this method so the committee could only provide an expert opinion recommendation on this approach.

Genitopelvic pain/penetration disorder

This diagnosis replaces dyspareunia (pain felt during or after sex) and vaginismus in the previous classification system of DSM-IV. This set of problems often occurs concurrent with vulvodynia and other sexual pain syndromes. Regardless of the cause of the problem, if sex is painful then there is likely to be both physical, emotional and psychological distress.

Vaginismus is a reflexive contraction of the vaginal muscles that prevents vaginal penetration (including associated psychological associations such as trauma and abuse) and is often associated with other pelvic pain conditions. Vulvodynia is a chronic pain syndrome that affects the vulval area, may extend into the clitoris, may be burning in nature and occurs without an identifiable cause. Vulvar vestibulitis syndrome (VVS) is vulvodynia localized to the vulval region.

The aetiological factors can be considered in the following ways.

- Manipulation pain: labial pathology (infection, injury) or clitoral problems (irritation, lesions, hypersensitivity).
- Introital (often erroneously termed superficial) pain: hymenal irregularities, vulvovaginitis (e.g. candidal infection, *Trichomonas*, herpes simplex, atrophy, chemical irritation), Bartholin's cyst/infection, inadequate lubrication (including atrophic vaginitis and arousal disorders, e.g. diabetes mellitus, multiple sclerosis, spinal cord injury), traumatic factors (e.g. episiotomy scar, post radiotherapy), interstitial cystitis, urethritis, large penis size of partner.
- Mid-deep vaginal pain: may be due to a congenital shortened vagina, pelvic inflammatory disease, endometriosis, a fixed uterine retroversion, ovarian pathology, pelvic congestion, uterine contraction on orgasm (sometimes associated with low oestrogen levels), pelvic tumours, surgical adhesions, irritable bowel syndrome or constipation.

Physical examination is mandatory in women presenting with this problem, although this may have to be discussed but delayed from the assessment appointment so that the woman can prepare for the examination, which may be feared from the outset. A chaperone is essential in such circumstances [43].

Some specific interventions include education about anatomy of the vulva with mirror work. This may be helpful alongside use of biofeedback and control of pelvic musculature (including consideration of a referral to physiotherapy for specialist work). Individual therapy may include CBT that considers anticipation of pain, control of sexual encounters, managing any mood disturbance and exploring any history of abuse. Couples' therapy can also include communication training and explicit sharing of information about alternative ways of erotic stimulation and sexual activities that are consensual and enjoyable for both partners. Sensate focus can include self-massage of the vulva, sometimes alongside use of graduated vaginal trainers.

Specific medical interventions can include elimination of any micro-abrasions of the introitus using fluconazole or itraconazole; topical local anaesthetics (lidocaine) or oral agents (e.g. amitriptyline, carbamazepine, gabapentin or pregabalin) can also help manage the pain. The use of Botox for pain management is under review. Liaison with pain management services is often helpful and treatment will often involve regular psychotherapeutic work over many months.

Topical vaginal oestrogen therapy can be helpful for dystrophy, for example Vagifem® (vaginal tablet of estradiol, daily for 2 weeks then twice a week) for 3 months, Estring® (ring containing 2 mg estradiol, lasts for 90 days), Ovestin or Ortho-Gynest cream (estriol); these all require an annual pelvic review. Topical testosterone in oil/jelly (1–2%) can be helpful if there is vulval dystrophy. Topical steroids are useful for lichen sclerosus.

Lubricants such as Astroglide and Yes are helpful. In vaginismus, an oil-based and then a water-based lubricant can be used (unless a condom is used by the partner). Vaginal moisturizers include Replens, Senselle and Sylk.

The ISSM standard operating protocol is available [44].

Conclusions

Sexual problems are common in the general community and evidence suggests that they are more common in women attending gynaecology and obstetrics clinics. Clinicians should be mindful of this and be prepared to enquire about these issues using a sensitive manner and patient-based approach during routine consultations without judgement or embarrassment. Comprehensive history-taking can elicit contributions from physical, psychological and relationship perspectives to allow a biopsychosocial formulation and to propose a treatment plan. An awareness of the various interventions that may be helpful for the woman (and her partner) is valuable and the physician can assist in signposting women to the appropriate healthcare professional(s) if expertise or time does not allow direct support to the woman in the clinic where the issues have been raised and identified as requiring interventions from healthcare professionals.

Rape and Sexual Assault and Female Genital Mutilation

Catherine White

St Mary's Sexual Assault Referral Centre, Central Manchester University Hospitals, Manchester, UK

Sexual violence against girls and women is a significant public health problem across the world, with no country, community or culture immune to it. Whilst both males and females may be subjected to it, for the purposes of this chapter the focus is on female victims.

The Law

The laws around sexual offences differ from country to country. The Sexual Offences Act 2003 (England and Wales) applies to offences committed in England and Wales after 1 May 2004. Prior to that, the Sexual Offences Act 1956 would apply. The 2003 Act covers numerous different offences including the following.

Section 1 (statutory definition of rape)

1) A person (A) commits an offence if:
   a) he intentionally penetrates the vagina, anus or mouth of another person (B) with his penis,
   b) B does not consent to the penetration, and
   c) A does not reasonably believe that B consents.
2) Whether a belief is reasonable is to be determined having regard to all the circumstances, including any steps A has taken to ascertain whether B consents.

Section 5 (statutory definition of rape of a child under 13 years)

1) A person commits an offence if:
   a) he intentionally penetrates the vagina, anus or mouth of another person with his penis, and
   b) the other person is under 13 years.

Sexual activity with a child under 16 is an offence, including non-contact activities such as involving children in watching sexual activities or in looking at sexual online images or taking part in their production, or encouraging children to behave in sexually inappropriate ways.

Prevalence

A recent systematic review [1] reported that the global lifetime prevalence of intimate partner violence among ever-partnered women is 30.0% (95% CI 27.8–32.2) and the global lifetime prevalence of non-partner sexual violence is 72% (95% CI 5.3–9.1).

Reports from England and Wales [2] show that around 1 in 20 females (aged 16–59) reported being a victim of a most serious sexual offence since the age of 16. Extending this to include other sexual offences, such as sexual threats, unwanted touching or indecent exposure, increased the figure to one in five females reporting being a victim. The Crime Survey of England and Wales 2013 recorded that 2% of women and 0.5% of men had experienced some form of sexual assault (including attempts) in the previous year. The majority of victims do not report their abuse to the police.

Presentation

Given the high prevalence, it follows that any clinician having regular contact with patients will frequently encounter victims of sexual violence. Given the reluctance of most victims to disclose their abuse, the chances of the doctor discovering this important aspect in the medical history will be heavily dependent on an awareness of the scale of the problem, its potential sequelae, a natural curiosity and utilization of superior communication skills. The extent to which a patient may reveal details of abuse/violence will depend on issues particular

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

to them, the setting and the degree of confidence they have in the clinician to respond appropriately with the information. Creating an environment conducive to disclosure and a workforce that can then cope is key.

Presentations may be acute or historical. There may be a direct disclosure or the victim may present with issues secondary to the assault, such as unintended pregnancy, dyspareunia, anxiety and depression, without volunteering that they have been assaulted. The potential long-term health consequences are considerable as illustrated in Fig. 67.1.

Where a patient has either made a disclosure or the clinician has a high degree of suspicion that it has happened, a number of issues must be considered.

- What needs the patient may have (Table 67.1):
  - Medical
  - Forensic
  - Psychological
  - Social/practical
  - Safeguarding.
- What legal/statutory duties the clinician may have, such as:
  - Safeguarding referrals
  - Female genital mutilation reporting.
- What are the options for the patient and what are their ideas, concerns and expectations?
- What resources are available to assist (the patient and the clinician) and how might they be accessed?

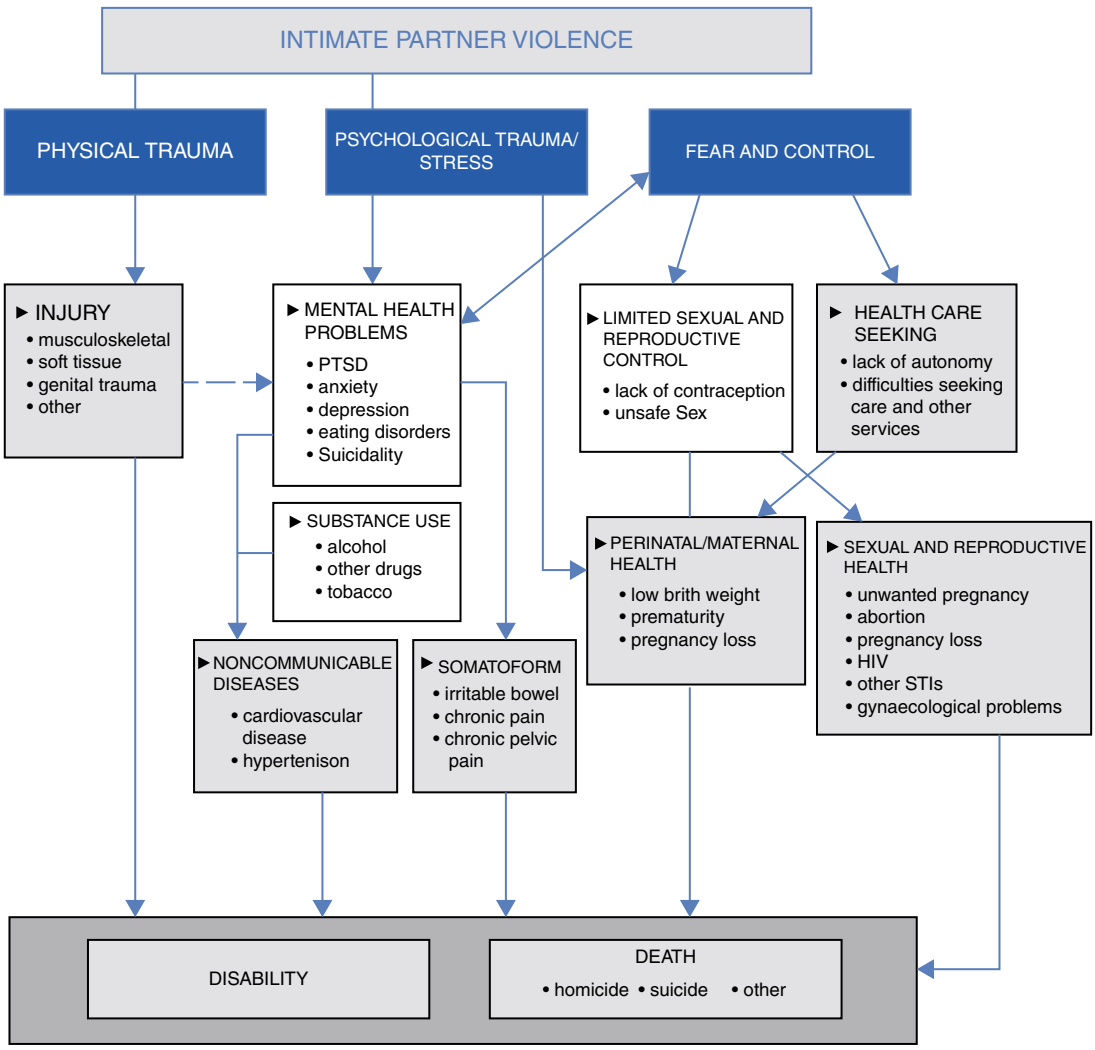

Fig. 67.1 Pathways and health effects of intimate partner violence. *Source:* World Health Organization. *Global and Regional Estimates of Violence Against Women: Prevalence and Health Effects of Intimate Partner Violence and Non-partner Sexual Violence*. Geneva: WHO, 2013. Reproduced with permission of the World Health Organization.

Table 67.1 Things to consider when someone discloses rape or sexual abuse.

Immediate safety
Are they safe now?
Are they at risk of domestic violence, honour-based violence?
Are they safe to go home?
Are there any third parties to consider, e.g. children, other dependants?
Are any safeguarding referrals required?
Are you safe?
Legal and ethical considerations
Do they have capacity to make decisions for themselves?
What are the limits to confidentiality?
Is there a statutory duty to report?
Are there any child protection or vulnerable adult concerns?
Are there public interest considerations?
What information sharing is warranted?
Medical needs
Injuries, assessment and treatment
Emergency contraception
HIV PEPSE
Hepatitis B PEPSE
Screening for sexually transmitted infections
Pregnancy testing
Forensic needs
Preservation of evidence
Documentation of injuries, including photography where necessary
Documentation of allegations
All to be done in a manner that makes evidence admissible to court
Psychological needs
Of the complainant (including risk of self-harm, suicide)
Of other witnesses
Of you

PEPSE, post-exposure prophylaxis following sexual exposure.

The clinician will need to have an understanding of the ethical issues involved in assessing a patient's capacity to make decisions, the possible limitations of confidentiality, and the potential competing duties to the patient, others possible at risk from the perpetrator and public interest. The clinician must be able to communicate all the above in a manner that allows the patient to feel empowered and start the process of regaining autonomy.

Many of these cases are complex and often made even more so by the high level of emotion that they can generate. Ideally, patients should be referred to a sexual assault referral centre (SARC) which will have the staff, including forensic physicians, with the knowledge, experience and skills to deal with these cases, providing a holistic response with ongoing support. That said, all clinicians need to be able to provide a safe initial response and have an understanding of the immediate and long-term medical issues as victims may present in a myriad of ways.

Summary box 67.1

- Sexual violence is common.
- Sexual violence may lead to multiple physical and mental health problems.
- Because of a reluctance on the part of victims to disclose abuse, clinicians need a high index of suspicion.

Management of a victim who presents acutely

Sexual violence is about control. During an assault a victim has no control over what happens to them. An important element of aiding recovery is to offer back control as soon as possible. This is best done by going at their pace, offering them information and outlining their options, and avoiding a paternalistic approach. Where possible the patient should be offered a choice of gender regarding healthcare workers. In all cases a chaperone should be used.

Capacity and consent

As with every patient encounter, the clinician has a duty to consider whether the patient has the capacity to make decisions. Whilst sexual violence can happen to anyone, there is a high preponderance of victims who are particularly vulnerable, by way of risk factors such as learning disabilities, mental health problems, and alcohol and substance misuse. Many may have a history of prior abuse, such as child abuse or domestic violence. For this reason extra care must be taken considering mental capacity.

The definition and assessment of, and responsibilities in relation to, capacity (also known as mental capacity) in England and Wales are laid out in the Mental Capacity Act 2005, which applies to all adults aged 16+. The Mental Capacity Act 2005 defines capacity as the ability to make a decision. It relates to the *process* of making a decision and not to the *outcome* of the decision. It is not limited to medical decisions, but can apply to any decision-making process (e.g. financial or social choices).

Capacity is task-specific: a person may be capable of deciding one issue but not another. Capacity is also time-specific: a person's capacity may alter with time. The Mental Capacity Act 2005 defines the lack of capacity as follows: if, at the time the decision needs to be made, patients are unable to make the decision because of an 'impairment of, or a disturbance in the functioning of, the mind or brain', they are deemed incapable. The term 'capacity' was previously used interchangeably with the

term 'competence'. Since the Mental Capacity Act 2005, 'capacity' is the preferred term.

The Mental Capacity Act 2005 lays out five statutory principles.

1) A person must be assumed to have capacity unless it is established that he lacks capacity.
2) A person is not to be treated as unable to make a decision unless all practicable steps to help him or her to do so have been taken without success. (This includes communicating in an appropriate way. In forensic practice the clinician may need to arrange for interpreters or signers to be present or use visual aids.)
3) A person is not to be treated as unable to make a decision merely because he makes an unwise decision.
4) An act done, or a decision made, under this Act for or on behalf of a person who lacks capacity must be done, or made, in his best interests.
5) Before the act is done, or the decision is made, regard must be had as to whether the purpose for which it is needed can be as effectively achieved in a way that is less restrictive of the person's rights and freedom of action.

Healthcare professionals are warned that a person cannot be judged to lack capacity simply because of age, appearance or behaviour.

Assessment of capacity

All adults are presumed to have capacity unless there is evidence to the contrary. In order to assess someone's capacity to make a valid treatment decision, two criteria have to be considered.

1) Do they have an impairment of mind or brain (temporary or permanent)?
2) Does the impairment mean that the person is unable to make the decision in question, at the time it needs to be made?

Where it is concluded that a patient does not have capacity to make the decisions in question, then an assessment of what is in their best interests should be made. Section 4 of the Mental Capacity Act 2005 contains a checklist of factors. The Code of Practice is available at https://www.gov.uk/government/publications/mental-capacity-act-code-of-practice

The Mental Capacity Act 2005 clarifies within the fourth statutory principle that any decision made, or any act performed on behalf of a person lacking the mental capacity to consent to the arrangements must be undertaken in that person's 'best interests'. Given the wide range of potential decisions covered by the Act, the term 'best interests' is not defined in the legislation. However, the Code of Practice provides, in Chapter 5, guidance on how to determine the best interests of a person who has been assessed to lack mental capacity to make the decision themselves. Using the best interests checklist as provided in Chapter 5 of the Code of Practice, the following factors need to be taken into account in determining the best interests of a person lacking capacity. In brief these comprise the following.

- Encourage participation.
- Identify all relevant circumstances.
- Find out the person's views.
- Avoid discrimination.
- Assess whether the person might regain capacity.
- If the decision concerns life-sustaining treatment:
  - Not to be motivated in any way by a desire to bring about the person's death. They should not make assumptions about the person's quality of life.
- Consult others.
- Avoid restricting the person's rights.

All the above should be taken into account, weighing up these factors to work out what is in the person's best interests.

Summary box 67.2

Sexual violence takes away power and control from the victim. Healthcare professionals can assist in addressing this by respecting the autonomy of the patient. Careful assessment of capacity and consent is vital.

History

The level of detail required in the history-taking will be dependent on the circumstances. For example, if the patient presents to a primary care clinician and there is a local SARC that the patient consents to be referred on to, then the history-taking can be limited to cover the immediate urgent needs (see Table 67.1). In broad terms, the history-taking should cover both the forensic and medical elements of the assessment (Table 67.2).

All clinicians should be mindful of the forensic aspects of the encounter and be aware that their notes are likely to form part of the evidence in any subsequent criminal justice process. Consequently, they should consider the following.

- Record keeping should be accurate, clear and contemporaneous.
- Consider what questions to ask and why. How might any information gained be relevant to the task at hand?
- Use open-ended rather than closed questions as much as possible and record responses verbatim.
- Go at the pace of the patient.
- Use language that the patient can understand.

Table 67.2 History-taking in sexual assault cases.

In broad terms questions will cover:	Examples of some of the reasons why they should be asked:
What has happened?	The nature of the assault will influence: • Assessment of need for emergency contraception • Prophylaxis in terms of blood-borne viruses such as HIV and hepatitis B • Where injuries may be found • Where forensic samples may be sought • Sites for screening for sexually transmitted infections • Subsequent criminal charges
When did it happen?	Again this will influence medical treatments such as emergency contraception, post-exposure prophylaxis, the need for forensic samples and the interpretation of subsequent results
Who was involved?	This will be of relevance to the criminal justice process. For example, where the abuser is alleged to be a child is likely to be approached differently from an adult suspect, especially where the adult is a person in a position of custody, care or control It will also influence the risk assessment of the need for HIV and hepatitis B post-exposure prophylaxis, for example a suspect who is known to be from an area with a high endemic level of HIV
Where did it happen?	This may assist in the criminal investigation. It may assist in the interpretation of injuries (or absence of injuries), for example a recent assault in a wooded area, or the importance of fibres detected on clothing
How did it happen?	This may include details such as threatened or actual violence and assist in injury interpretation (or absence of injury) Was this a drug-facilitated assault? Was there a particular modus operandi that may assist investigations?

- Explore the patient's ideas, concerns and expectations.
- Be non-judgemental in both attitude towards the patient and records made.
- Keep objective findings distinct from subjective opinion.
- There will be forensic as well as therapeutic aspects.

The history-taking will need to be modified depending on the circumstances of each case. For example, where child sexual exploitation is a possibility, the history should cover associated risk factors such as missing from home, school truancy, power imbalance in the relationship (see *Spotting the Signs: A national proforma for identifying risk of child sexual exploitation in sexual health settings* [3]).

Systems review

It is good practice to carry out a systems review as part of the history-taking. This should bring to light any problems that are a result of the sexual violence or that predate the sexual violence and may have a bearing either on examination findings or ongoing welfare of the patient.

Summary of key areas to be covered in the history

- Who gave the information and who else was present?
- History of alleged assault.
- History of actions since (such as washing, changing clothes).
- Medical history, past and present.
- Drugs and alcohol history.
- Past obstetric and gynaecological history.
- Bowel history.
- Social history.
- Discrepancies in account.
- Revisit the history if the examination findings indicate this would be helpful.
- Ongoing at-risk issues:
  - Children and adults.
  - Dependents of complainant.
  - Others at risk from alleged assailant.

Examination

As with the history-taking, the examination will have forensic as well as medical/therapeutic elements, and often there is an overlap (Table 67.3). Prior to commencing the examination, carry out the following.

- Explain to the patient what you wish to do, why you wish to do it and that you will explain any findings at the end.
- Recheck that you have consent to continue (remembering that consent is an ongoing process).
- Reassure the patient that they can halt the examination at any time.
- Ensure that a chaperone is present.

Table 67.3 Purpose of a forensic medical examination.

Therapeutic component	Forensic component
• Check for injuries or conditions that may need medical attention • Holistic assessment, particularly in child cases where other forms of abuse, apart from sexual, need to be considered • Identify medical conditions that may be mistaken for injuries • Consider and conduct risk assessment for possible medical needs: – Emergency contraception – Pregnancy testing – Post-exposure prophylaxis for blood-borne viruses, e.g. HIV and hepatitis B – Screening for sexually transmitted infection – Suicide/imminent self-harm risk	• Identify and document injuries, findings, etc. that may be of forensic significance • Identify findings, positive or negative, that may be of significance to aid the court in establishing the veracity or otherwise of any allegation • Gather forensic samples

- Ensure privacy with no unnecessary people present and no interruptions.
- Go at the pace of the patient; explain the process as you proceed using language they can understand.

The examination should be holistic, top to toe, starting with a general body examination before proceeding to an anogenital examination. Use a proforma as an aide memoire if possible. Document findings in the written notes as well as using body diagrams where necessary. Record negative as well as positive examination findings. If any aspect of the examination is not done, record this carefully as well as the reasons why. Objective findings should be clearly separated from subjective opinion.

Summary box 67.3

The history-taking and forensic examination should cover the medical, psychological and forensic elements of the assessment. It should be tailored to the circumstances of the case and done in a sensitive manner, taking into account the holistic needs of the individual.

Checklist for examination

Whilst the scope of the examination will depend on the circumstances of each case, it should be detailed and thorough (Table 67.4). The clinician's findings may be key witness in a subsequent legal process and accuracy and objectivity are therefore necessary.

Mental health examination

Every examination should include at least a brief assessment of the psychological state of the patient. The reasons for this include detection of conditions that might make the individual:

- more vulnerable to being a victim of sexual assault;
- more likely to have a history of sexual assault as a manifestation of a mental illness;
- demonstrate mental illness as a result of being a victim of sexual assault, e.g. post-traumatic stress disorder;
- at increased risk of imminent self-harm including suicide.

Table 67.5 outlines the key features of the mental health assessment. The clinician should consider the risk of imminent self-harm/suicide. Suicide risk assessment can be explored using a number of questions. Some, where answered in the affirmative, indicate a higher degree of risk (Table 67.6).

Summary box 67.4

- The examination needs to be thorough but done in a sensitive manner, with frequent checking that the patient is content to proceed.
- Sexual violence victims are at risk of self-harm and suicide and therefore all assessments should screen for this.

Anogenital examination

This is usually done after the general body examination. Again, recheck consent prior to proceeding. Go at the patient's pace and be as gentle as possible. Use of a colposcope for magnification and as a light source is often helpful. Images can be recorded as long as due regard is given to issues of consent, confidentiality and security of the images. This is not something to be undertaken

Table 67.4 Checklist for examination.

Examination component	Examples of possible features to note (this is not an exhaustive list)
1 Gait	Normal or not?
	Possible signs of intoxication, developmental problems or mechanical problems such as osteoarthritis
	Use of aids, such as wheelchair, walking stick
2 Sensory problems	Eyesight: wearing glasses
	Hearing aids
3 Clothing	Is it clean, appropriate for weather conditions?
	Any evidence of damage, e.g. torn
	Any evidence of trace material, e.g. body fluids, vegetation
4 Demeanour	Brief factual description of how patient seemed, e.g. weepy, quiet
	Take great care with choice of words. Keep descriptions objective rather than subjective
5 Signs of intoxication	For example: • Smell of breath, e.g. ketones • Blood-shot conjunctiva • Nystagmus • Slurred speech (Note: medical conditions such as hypoglycaemia or head injury may mimic or even coexist with intoxication)
6 Height	Use standardized approved equipment
	Record in metric with shoes off
7 Weight	Measure during examination rather than self-reporting by patient
	Minimal clothing to be worn
	Record in metric
8 Jewellery	Broad description rather than minute detail unless seems relevant, e.g. possible injuries associated
	Record if any jewellery absent, e.g. earring missing
	May possibly be a good source of forensic trace material, e.g. swabbing around a piercing where body fluids may have collected
9 Body markings, e.g. scars, tattoos, track marks	These may or may not be relevant to the alleged assault and it is unlikely that the doctor will know at the time of the examination. Either way they should be recorded in accordance with local policy on recording such information
10 Mental state	Document if alert, orientated in time, place and person
	If there seem to be any issues be prepared to examine and document in more detail
	See separate section on Psychological state examination
11 Hair	Is any hair missing, e.g. pulled out in the assault?
	Are there signs of infestation, e.g. with possible neglect?
	Look for debris, foreign hairs, fibres, etc.
	If hair samples are being taken at a later stage for toxicology (e.g. in suspected DFSA), document current colour, length, etc.
	If any hairs are found that may belong to possible assailant, document details of (and possibly sample) patient's hair
	See FFLM Forensic Guidelines for more details (www.fflm.ac.uk)
12 Scalp	Evidence of injuries including swelling or tenderness
13 Ears	Evidence of injuries including behind the ear
	Look for signs of perforated tympanic membrane where a history of direct blow to ear
14 Eyes	Injuries as a result of direct trauma or petechial haemorrhages from increased pressure, e.g. from strangulation
	Evidence of intoxication
	Evidence of alerted consciousness, head injury

(*Continued*)

Table 67.4 (Continued)

Examination component	Examples of possible features to note (this is not an exhaustive list)
15 Face	Evidence of injuries
	Body fluids, e.g. dry saliva from kissing, licking, biting
16 Mouth	Evidence of injuries
	Look especially for bruising on inner aspects of lips where pressure applied to outer aspect of lips has pressed them against the teeth
	Roof of mouth, especially if a history of forced oral sex
	Injuries to frenulae, especially in children
	Evidence of infection
17 Teeth	Absence of teeth due to trauma
	Dental health in cases of possible neglect
	Where bite marks present, may have to exclude possibility of them being self-inflicted
	Trace evidence (patient may have bitten alleged assailant and have trace material between teeth)
18 Neck	Injuries, in particular bite marks, love bites, bruising or swelling from strangulation
	Trace material
	Problems with swallowing
	May need to organize X-ray to exclude fracture to hyoid after strangulation
18 Nails	Length
	Presence of forensic trace material
	Missing nails (including false)
19 Upper limbs	Evidence of injuries
	Trace material
	Track marks from injecting drugs
	Scars
	Self-inflicted injuries (old or new)
	Right or left handedness
	Range of movement of joints
20 Axillae	Hair growth (as part of developmental assessment if appropriate)
	Injuries (especially bruising consistent with fingertip) if person carried/dragged
21 Breasts	Evidence of injuries
	Trace material, e.g. dry saliva from licking or kissing
	Piercings
	Tanner stage (if developmental assessment appropriate)
22 Anterior chest wall	Evidence of injuries
	Heart and chest auscultation if appropriate
23 Back	Evidence of injuries
24 Buttocks	Evidence of injuries
25 Legs	Evidence of injuries
	Restriction in range of movement of joints
26 Feet	Evidence of injuries
	Obvious trace material
27 Abdomen	Scars, masses, discomfort, etc.
	Extent of examination to be guided by the history

Table 67.4 (Continued)

Examination component	Examples of possible features to note (this is not an exhaustive list)
28 Genitalia	Position examined in
	Lighting and equipment used
	Tanner stage if applicable
	General features
	Discharge or bleeding present or not
	See Anogenital examination
29 Anal examination	Note examination position and lighting
	Injuries, tone, discharge, bleeding, etc.
	Perianal skin health
	See Anogenital examination
30 Neurological	Learning difficulties, associated communication difficulties
	Weakness, etc.
31 Musculoskeletal	Joint problems
	Mobility difficulties
32 Skin in general	Evidence of injuries
	Skin disease
	Trace evidence
	Scars, tattoos, etc.
	Colour
33 Where appropriate: (a) Cardiovascular and respiratory examination (b) Developmental examination	(a) Routine in young child examinations. In adolescents and adults, tends to be reserved where there is concern for immediate health (b) Routine for young children

DFSA, drug-facilitated sexual assault; FFLM, Faculty of Forensic and Legal Medicine.
Source: White [4].

Table 67.5 Mental state assessment.

Appearance and behaviour	General appearance	Grooming and hygiene
		Chronological and apparent age
		Physical deformities
		Height and weight
	Facial appearance	Expression
		Flatness of expression
		Dilated pupils, sweating, etc.
	Movements	Mania: may be restless, rapid and pressured movements
		Anxiety, may be tremulous and restless
		Depression: may be slow and ponderous and in extreme cases immobility and mutism (stupor)
	Social interaction	Over-familiar behaviour suggestive of mania
		Social withdrawal is associated with depression, dementia and schizophrenia
		Social disinhibition may be found in dementia and organic brain disease, e.g. frontal lobe disorder

(*Continued*)

Table 67.5 (Continued)

Speech	Volume	May be loud with mania, quiet with depression
	Spontaneity	May be delayed in depressive disorder or even absent (mutism)
		Manic patients may be uninterruptable
	Rate	Decreased in depression
		Increased in mania
	Amount	Decreased or absent (mutism) in depression
		Increased in mania
	Continuity	Loosening of associations (speech lacks logical connections, word salad)
		Flight of ideas with mania
Mood and affect	Mood is how a patient feels most days	Low or elated
	Affect is how they feel at a given moment	Labile, inappropriate
Thinking	Form	Preoccupations, including suicidal ideas. The patient can terminate these thoughts if desired
		Obsessive thoughts. These are intrusive. The patient may try to resist them. They may be distressing to the patient
		Delusions. A false belief which is both culturally unconventional and held on inadequate grounds. May be difficult to elicit as the patient either does not view them as unusual or is suspicious of the interviewer
	Content	Paranoid, persecutory or grandiose. Ideas of reference. Confabulation
		Depressive, relating to past, present or future
		Always check for suicidal content
	Flow	Flight of ideas, skipping from one topic to another in fragmented, often rapid fashion
		Perseveration: involuntary repetition of the answer to a previous question in response to a new question
		Loosening of associations
		Thought block: a sudden interruption of thought or speech
	Possession	Thought insertion, withdrawal and broadcasting are part of Schneider's first rank symptoms of schizophrenia. The patient believes that an outside agency is responsible for these events
Perception	Awareness of information from the sense organs	Illusions or distortions. These are perceptual errors or misinterpretations. Common in delirium
	Hallucinations	This is a false perception, i.e. without external stimulus. Common in schizophrenia
	Depersonalization and derealization	Subjective feelings of altered reality. May be associated with anxiety and depression
Cognition	Orientation	Orientation to time, place and person should be assessed. Patient should be asked: day, date, month and year; where he or she is; and if he or she knows who he or she is
	Concentration	Serial 7s: subtract 7 from 100 and keep subtracting 7, or spell 'world' backwards
	Memory	Short- and long-term memory should be assessed
	Intellectual ability	Ask about some recent events. Intelligence can be gauged by language. The patient can be asked to do some simple arithmetic tasks and literacy should be assessed
Judgement and insight	Insight	Assess if the patient is aware he or she has a problem, and his or her level of understanding of this
	Judgement	Assess the patient's capacity to behave appropriately. A hypothetical situation can be presented and the patient asked how he or she would behave

Table 67.6 Suicide risk assessment (high-risk indicators are in bold).

1) Do you have thoughts about harming yourself?
2) Are you thinking about suicide?
3) Do you have a specific plan to kill yourself?
4) **What methods have you considered?**
5) Do you have access to any of these methods?
6) **Do you have a date or place in mind?**
7) Have you ever self-harmed or attempted suicide in the past?
8) **Has anyone in your family died by suicide?**
9) Are you suffering from mental health problems?
10) **Have you suffered from mental health problems in the past?**
11) **Have you ever had contact with mental health services or seen your family doctor/general practitioner in relation to psychological or psychiatric problems?**
12) **Are you taking any medication for mental health problems?**
13) **Do you have a problem with drugs or alcohol?**
14) **Have you been drinking in the past few hours?**
15) **Are you experiencing particular difficulties in your life or struggling to deal with difficult past events (e.g. bereavement, divorce, running away from home)?**
16) **Do you have friends or family you can turn to for help?**
17) Do you feel that the future is hopeless and that things cannot improve?

lightly. Advice can be found in the document 'Guidance for best practice for the management of intimate images that may become evidence in court' [5].

Injuries

Whilst the majority of victims will have no injuries, any injuries must be documented accurately. The classification of injuries is as follows.

Bruise

- Due to blunt force.
- May not appear immediately.
- Under force of gravity may appear at a site distant to site of original trauma.
- Difficult to age.
- May also be called ecchymoses, contusion, haematoma.

Abrasion

- Superficial disruption of surface epithelium.
- May bleed.
- Do not extend or gravitate.
- Non-medical terms are graze or scratch.
- Document signs of healing, e.g. fresh bleeding, scab formation.

Laceration

- Full-thickness split of the skin caused by blunt trauma.
- Irregular edges and irregular division of tissue planes.
- Tissue bridges including blood vessels and nerves may be visible.
- May have abraded bruised margin.
- May contain debris.
- Often bleed.

Incision

- Due to sharp objects breaching the epithelium.
- Sometimes known as cuts.
- Edges tend to be straight with no associated bruising or abrasion.
- Tissues are cut in same plane, with nerves and blood vessels cleanly divided.
- May bleed profusely.

Burn

- Heat or chemical.
- Cigarette burns are a particular type of injury associated with abuse.

Documentation of an injury should include the following.

- Type of injury.
- Size.
- Shape.
- Depth, if possible (e.g. laceration).
- Edges, e.g. abrasion: is skin at one end?
- Laceration: is there debris or a foreign body contained in it?
- Colour: red, purple. Does it blanche with pressure? If a bruise, is there any yellow?
- Surface covering: dry or wet blood, scab, dirt.
- Swelling.
- Tenderness.

Anogenital injuries

From a medical perspective anogenital injuries tend to be minor, require little in the way of treatment and will heal rapidly, often within days. They must be considered when assessing the risk of blood-borne viruses and the need for prophylaxis. From a forensic perspective, an understanding of genital injury rates, type of injury, site and healing may assist the clinician to interpret the findings in the context of the allegations that have been made.

There are many myths and misunderstandings regarding anogenital injuries and rape and the clinician has a duty to dispel these.

Virginity testing and the myth of the intact hymen

Doctors may be asked to undertake 'virginity tests' on some girls and women. As the scientific evidence shows that it is not possible to determine with accuracy whether

or not there has been penile penetration of the vagina, *doctors should not attempt to do so*.

There are numerous issues with virginity tests.

- They have no scientific validity. A female may have been sexually active and still have an 'intact' hymen (one study of 36 pregnant adolescents showed that 34 of 36 had an 'intact' hymen [6]). Equally, a female may have some disruption to the hymen as a result of non-sexual trauma.
- They are demeaning, degrading and humiliating to the patient.
- They have significant negative social, physical and psychological impacts on the patient.
- They encourage inequality in terms of biased surveillance and control of female activity including sexuality whilst ignoring male activity.
- They treat the female body as the property and responsibility of her family and community.
- They do not address male behaviour.

Non-fatal strangulation

It is not uncommon for victims of domestic violence and sexual violence to have been subjected to strangulation. This may not necessarily be a prominent part of the history and the clinician should be proactive in seeking this information. Figure 67.2 shows the signs and symptoms of strangulation. Particularly in the context of domestic violence, it is a risk factor for subsequent homicide.

Forensic samples

There will be a number of elements to consider when deciding on the urgency of a medical examination (Table 67.7). Depending on the nature of the allegations and the time from assault to examination, forensic samples may be indicated. These would usually be taken by a forensic physician in examination conditions that minimize the risk of DNA contamination. The Faculty of Forensic and Legal Medicine has produced guidance on this which is updated every 6 months [7].

For any forensic samples to be admissible as evidence in a criminal investigation, there needs to be a clear *chain of evidence*. This is the documentation that follows any piece of evidence, from its initial retrieval up to its use in a court case. It should say what the evidence is, its source, the time and date it was taken, by whom and where and how it has been stored since.

Emergency contraception

For many female victims of rape a real concern may be the risk of pregnancy. Clinicians should undertake a risk assessment for this at the earliest opportunity and it may influence the decision regarding the timing of a medical examination given that, if required, there are time limits regarding efficacy. Guidance on emergency contraception can be found at the website of the Faculty of Sexual and Reproductive Healthcare of the Royal College of Obstetricians and Gynaecologists (www.fsrh.org).

Post-exposure prophylaxis following sexual exposure

Sexually transmitted infections including HIV and hepatitis B will be a risk for some patients as a result of the sexual assault. An individual risk assessment which takes account of the nature of the assault and details of the alleged assailant needs to be done in a timely manner. This will inform the decision as to whether or not the patient would benefit from post-exposure prophylaxis.

$$\text{Risk of transmission} = \text{risk that source is positive} \times \text{risk of exposure}$$

Time is of the essence as commencing HIV post-exposure prophylaxis is not generally recommended more than 72 hours after the assault.

The British Association for Sexual Health and HIV (BASHH, www.bashh.org) produces useful guidelines on prophylaxis after sexual assault [8]. Advice from an HIV physician should be sought where there is any uncertainty or complicating factors, such as the patient is a child, pregnant or breastfeeding.

For hepatitis B, a risk assessment is also required. Here the time frame for commencing is a more generous 6 weeks. Usually an accelerated or a super-accelerated course is recommended. In cases where the assailant is known to be hepatitis B positive, then hepatitis B immunoglobulin may be offered.

Screening for infection post assault

As a general rule, the usual advice for screening time frames is as follows.

- Bacterial infections: 2 weeks.
- Blood-borne viruses: 3 months.

Safeguarding

As previously stated, the clinician should consider whether or not the case highlights any safeguarding issues, not only for the patient presenting, but also for their dependents or other vulnerable people, for example where the patient is from a care home and the alleged assailant is a care worker in the home. Local safeguarding

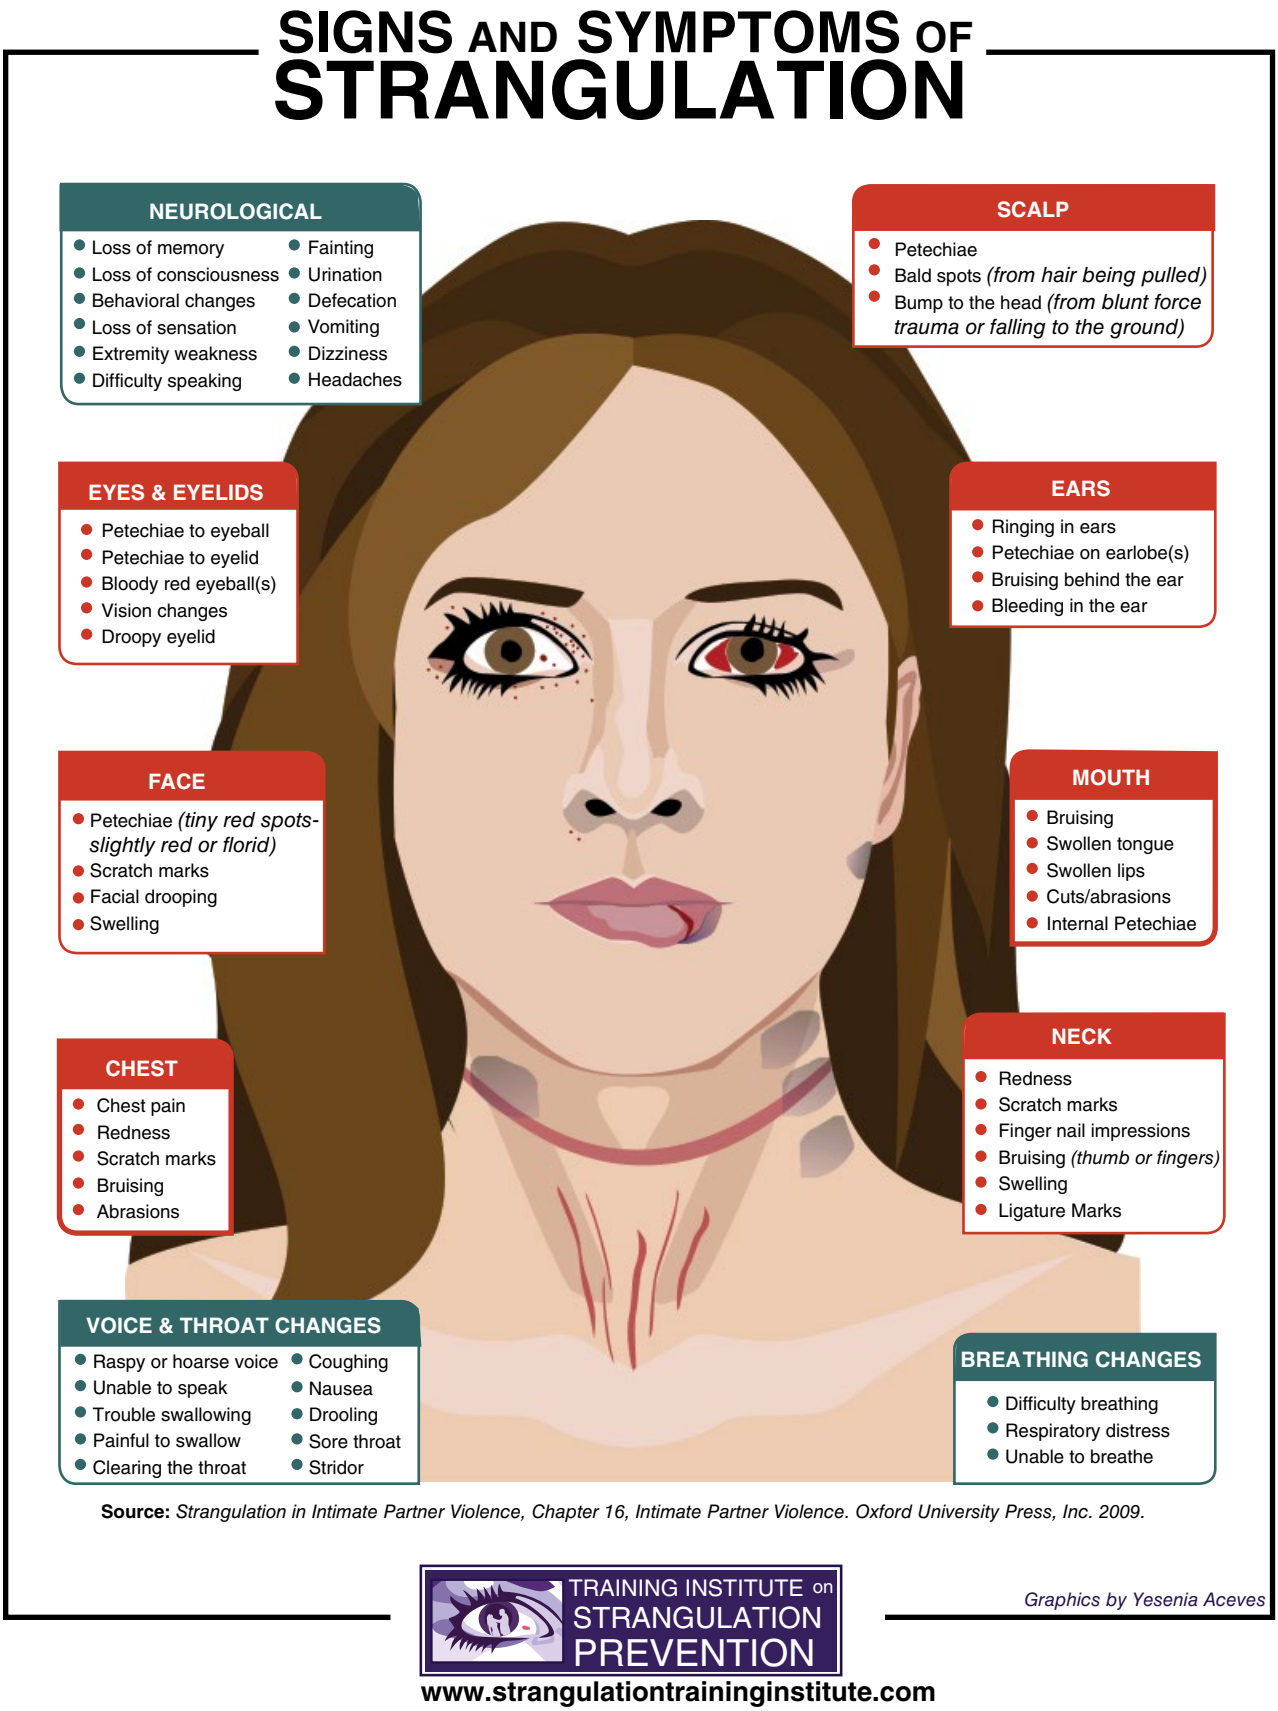

Fig. 67.2 Signs and symptoms of strangulation. *Source:* Alliance for HOPE International. Reproduced with permission of Alliance for HOPE International. (*See also colour plate 67.2*)

Table 67.7 Key time frames to consider.

Emergency contraception	Levonelle	A single oral dose of 1.5 mg as soon as possible after UPSI and within 72 hours
	Ulipristal	One tablet, orally, as soon as possible, but no later than 120 hours after UPSI
	Copper IUD (intrauterine device)	Up to 5 days after ovulation
PEPSE	HIV	Immediately, within 72 hours
	Hepatitis B	Up to 6 weeks
Forensic samples These should all be done immediately, check www.fflm.ac.uk for latest updates. Different time frames apply to some samples for prepubertal children. Times shown here are maximum rather than expected persistence	Mouth	2 days
	Female genitalia	7 days (12 hours if digital penetration)
	Male genitalia	3 days
	Anal swabs	3 days (12 hours if digital anal penetration)
	Urine for toxicology	3 days (14 days if drug-facilitated sexual assault suspected)
	Blood for toxicology	3 days
	Skin	7 days
Injuries	Most rape victims will have no or very few injuries. Some of the injuries that can be very significant forensically may be very minor in nature and heal rapidly, i.e. within days. Some examinations may be of benefit weeks, months even years post assault depending on the circumstances of the case	
Safety	Assessment of personal safety of victim and relevant third parties	Immediate

PEPSE, post-exposure prophylaxis following sexual exposure; UPSI, unprotected sexual intercourse.

policies should be followed and where there is any doubt the clinician should seek advice from safeguarding leads.

Domestic violence

Sexual abuse/violence is not unusual in the context of domestic abuse/violence. Domestic abuse should be considered in every case and be part of the routine inquiry during history-taking. Where there is a positive history, then a risk assessment should be undertaken. Resources including risk assessments are available in the document Safe Lives: Ending Domestic Abuse (http://www.safelives.org.uk/)

Honour-based crimes

Honour-based violence is a form of domestic abuse that is perpetrated in the name of so-called 'honour'. The honour code which it refers to is set at the discretion of a family or community. Those who do not abide by the 'rules' may be punished for bringing shame on the family. Infringements may include a girl or woman having a boyfriend; rejecting a forced marriage; pregnancy outside of marriage; inter-faith relationships; seeking divorce, inappropriate dress or make-up and even kissing in a public place.

Forced marriage is a component of honour-based crime. Women may present in a healthcare setting as a result. The clinician should be alert to the possibility that this is a problem and be able to deal with it sensitively and safely. More information and resources can be found at Honour Based Violence Awareness Network (http://hbv-awareness.com/). Advice regarding the law can be found at http://www.cps.gov.uk/legal/h_to_k/honour_based_violence_and_forced_marriage/#a02

Statements

The clinician may be asked to provide a statement for the courts. This is an opportunity to communicate information and the doctor should remember who the statement is intended for. In criminal cases this will ultimately be the jury. The key to writing a good statement includes:

- good contemporaneous records;
- clear simple language;
- logical approach.

The statement should include, for example:

- the qualifications and experience of the doctor;
- the circumstances in which the patient was seen;
- how the disclosure came about;
- what the details given were, who gave them, who else was present;

- the extent and findings of any examination;
- outline any care given.

It is important that the clinician writes any statement with objectivity and impartiality and within the limits of their competence.

Giving evidence in court

Most doctors find this daunting. The key to success is based on the following.

- Conducting a high-quality examination in the first place.
- Excellent contemporaneous medical notes, with a subsequent well-written report.
- Be prepared before attending court.
- Be professional and courteous.
- Communicate clearly in a manner your audience can understand.
- Stick to your area of expertise.
- Do not give opinions that are not evidence based or which are unjustifiable.
- Concede points where appropriate but do not be unduly subdued.
- Reflect and learn from each experience.

Long-term health consequences of sexual violence

Sexual violence can result in numerous health consequences with varying degrees of severity. These can be immediate, such as death or injury to more medium term and long-term problems. It can have physical, reproductive and psychological consequences.

Vicarious trauma

Most doctors will be used to dealing with distressed and distressing patients. That said, dealing with victims of sexual violence, hearing their accounts and the ramifications of the assaults can be harrowing. Doctors should be mindful of the effect this can have on them and other staff. Sometimes the effects may not be immediately obvious. Good self-awareness is essential. Clinicians have a duty to look after their mental health and should be encouraged to seek help sooner rather than later should they feel that a case has adversely impacted them.

Child sexual exploitation

Numerous myths and stereotypes regarding sexual violence exist for many reasons, some anthropological, some religious and cultural, but many through sheer ignorance. Common ones are shown in Table 67.8.

Female genital mutilation

The World Health Organization classification of female genital mutilation (FGM) is shown in Table 67.9.

FGM and the role of the healthcare professional

The clinician must be aware of the potential healthcare needs associated with FGM (see https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/525405/FGM_mandatory_reporting_map_A.pdf) as well as statutory/legal duties. Clinicians should be aware of it, appreciating what it may look like and also the possible short- and long-term health consequences, including infection, haemorrhage, vesicovaginal fistulae, and complications in pregnancy and labour.

The practice of FGM has long cultural roots. It is considered to be an abuse of human rights and a child protection issue [9] and is outlawed in many countries. In England, Wales and Northern Ireland, FGM is illegal under the Female Genital Mutilation Act 2003, and in Scotland it is illegal under the Prohibition of Female

Table 67.8 Common myths and stereotypes regarding sexual violence.

Most rapists are strangers	No. Most victims will know their abuser
Most abuse takes place outside the home	No. Most abuse takes place where the victim lives. This is especially true of child victims
Rape victims will have injuries	No. Most will not, and those injuries that do happen often heal quickly and fully leaving no scars
Rape victims will disclose the abuse at the earliest opportunity	No. Many never disclose at all. A significant number of those that do disclose will do so well after the attack and may only give partial details
Some rape victims must shoulder responsibility for the abuse	No. The rapist is responsible for his own actions
Men cannot be raped	No. Men and boys can be victims of sexual violence

Table 67.9 World Health Organization classification of FGM.

Type I	Involves excision of prepuce with or without excision of part or all of the clitoris
Type II	Excision of the prepuce and clitoris together with partial or total excision of labia minora
Type III	Excision of part or all of external genitalia and stitching or narrowing of the vaginal opening, also known as infibulations. This is the most extreme form and constitutes 15% of all cases
Type IV	Includes pricking, piercing or incision of the clitoris and/or labia; stretching of the clitoris and the labia; cauterization or burning of the clitoris and surrounding tissues, scraping of the vaginal orifice or cutting (Gishiri cuts) of the vagina and introduction of corrosive substances or herbs into the vagina

Genital Mutilation (Scotland) Act 2005. Under the 2003 Act, a person is guilty of an offence if they excise, infibulate or otherwise mutilate the whole or any part of a girl's or woman's labia majora, labia minora or clitoris, except for necessary operations performed by a registered medical practitioner or midwife (or a person undergoing training with a view to becoming a medical practitioner or midwife) on a woman who is in labour or has just given birth, for purposes connected with the labour or birth (these exceptions are set out in section 1(2) and (3) of the Act) [10,11]. The Serious Crime Act 2015 strengthened the legislative framework around tackling FGM by adding the following.

- An offence of failing to protect a girl from the risk of FGM.
- Extra-territorial jurisdiction over offences of FGM committed abroad by UK nationals and those habitually (as well as permanently) resident in the UK.
- Lifelong anonymity for victims of FGM.
- FGM Protection Orders which can be used to protect girls at risk.

In May 2016 the Department of Health updated 'Female Genital Mutilation. Risks and Safeguarding. Guidance for Professionals' [12]. This states that as FGM is a form of child abuse, professionals have a statutory obligation under national safeguarding protocols (e.g. Working Together to Safeguard Children [13]) to protect girls and women at risk of FGM. Since October 2015, registered professionals in health, social care and teaching also have a statutory duty (known as the Mandatory Reporting duty introduced through Section 5B of the 2003 Act) to report cases of FGM to the police non-emergency number 101 in cases where a girl under 18 either discloses that she has had FGM or the professional observes physical signs of FGM [14]. All cases should be dealt with under existing safeguarding frameworks, which for children under 18 who have undergone FGM would mean a referral to children's social care and the police. The guidance reminds the reader that once concerns have been raised about FGM, there should also be a consideration of potential risk to other girls in the family and practising community. Professionals should be alert to the fact that any one of the girl children amongst these groups could be identified as being at risk of FGM and may need to be safeguarded from harm.

Information sharing

In 2016 the government published multi-agency guidance on FGM [15] with an aim to provide front-line professionals with information on:

- identifying when a girl (including an unborn girl) or young woman may be at risk of FGM and responding appropriately to protect them;
- identifying when a girl or young woman has had FGM and responding appropriately to support them; and
- measures that can be implemented to prevent and ultimately end the practice of FGM.

To assist professionals regarding mandatory reporting, a two-page poster which includes FAQs and flowchart (see below) has been produced as a guide [16].

Ethical Dilemmas in Obstetrics and Gynaecology

Emily Jackson

London School of Economics and Political Science, London, UK

Obstetrics and gynaecology is one of the most ethically and legally contentious areas of medicine. Not only can it involve the creation and destruction of new human lives, but also the doctor will sometimes be faced with two possible patients, the woman and the developing embryo/fetus. At the outset, it is worth noting that the only clinical practices to which healthcare professionals have the right to refuse to participate, if they have a conscientious objection, are abortion and fertility treatment (Abortion Act 1967, section 4; Human Fertilisation and Embryology Act 1990, section 38). These rights exist as a result of the recognition that there is profound disagreement over when morally significant life begins.

This chapter will provide a broad overview of three areas of practice in obstetrics and gynaecology: termination of pregnancy, the management of pregnancy and childbirth, and the provision of fertility treatment. As well as raising complex ethical and legal issues, there is also something distinctive about the provision of abortion and fertility services in the UK. The majority of abortions in the UK are provided in the independent sector, under NHS contract [1]. Very few abortions are carried out in NHS hospitals. Most fertility treatment in the UK is provided in the private sector [2]. In contrast, the private or independent management of pregnancy and childbirth is unusual, and almost all babies born in the UK are born in NHS hospitals.

Abortion

The morality of abortion

There will never be consensus over whether abortion is morally permissible. One view, associated particularly with Roman Catholicism, is that personhood begins at conception [3]. If the fetus is a person, abortion is murder. If the fetus is a person, it makes no difference to the wrongness of killing it that it was conceived as a result of rape. Nor does its age make a difference, so on this view, termination at six weeks is morally equivalent to termination at 36 weeks. If an abortion is necessary in order to save the woman's life, then, if the fetus has an equivalent right to life, it is not self-evident that its life must be sacrificed in order to save hers.

The law is clear, however, that legal personhood is acquired only once a child has an existence independent of its mother, that is once it has been born. Of course, some might argue that birth is simply a matter of geography, and that a newborn baby is not an intrinsically different entity from a fetus immediately prior to birth [4]. But in legal terms, geography is central. While a fetus is inside the woman's body, it cannot be considered a separate legal person.

A second approach to the morality of abortion instead emphasizes the physical invasiveness of pregnancy, and the degree of self-sacrifice involved in compelling a woman to carry an unwanted pregnancy to term, and go through childbirth against her wishes. One of the most famous philosophical 'thought experiments' used to illustrate this view is Judith Jarvis Thomson's 1971 article [5], in which she invites readers to imagine that they wake up attached to a famous, unconscious violinist, who needs to be plugged into their circulatory system for the next nine months. Thomson then asks: 'Is it morally incumbent on you to accede to this situation? No doubt it would be very nice of you if you did, a great kindness. But do you *have* to accede to it?' Although this sounds extraordinarily far-fetched, Thomson's point is to jolt readers into contemplating what it might be like to be compelled to use your body to support another human life for nine months.

A third 'middle ground' position on the morality of abortion would permit abortion subject to restrictions, such as time limits. According to this view, a fetus may not have legal personhood, but it is also 'not nothing' [6].

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

As legal philosopher Ronald Dworkin [7] has explained, this view on the morality of abortion is by far the most common: most people share a belief in the sanctity of human life, but at the same time they do not believe that the fetus has the same moral status as a person, otherwise it would be impossible to justify abortion where the woman is pregnant as a result of rape. Most people also believe that the respect accorded to the fetus increases as it matures towards birth. This is often described as the 'gradualist approach': many people believe that abortion should be available as of right in the first months of pregnancy, while not believing that it should be available as of right until birth.

Abortion and the law

To the surprise of many students, abortion is still a criminal offence in the UK. A Victorian statute, passed more than five decades before women had the right to vote, continues to apply today to the termination of pregnancy. Statutory defences have existed in England, Scotland and Wales for 50 years, but under sections 58 and 59 of the Offences Against the Person Act 1861, the maximum sentence for a woman who intentionally and unlawfully procures her own miscarriage continues to be life imprisonment, and anyone who assists her could be imprisoned for up to five years.

Before abortion was partially decriminalized in 1967, a test case in 1939 established that it could be lawful to carry out a termination of pregnancy if carrying the pregnancy to term might leave the woman 'a mental wreck'. In R v Bourne [8], a distinguished obstetric surgeon, Aleck Bourne, was prosecuted for carrying out an abortion on a 14-year-old girl, who was pregnant following a violent rape. His defence was that the operation was not unlawful, because, in his opinion, the continuance of the pregnancy posed an extremely serious risk to the girl's mental health. In his direction to the jury, Macnaghten J was clear that an abortion might be carried out lawfully not only where the pregnant woman was in imminent danger of death (as had always been the case), but also where the effect of carrying the pregnancy to term might be to 'make the woman a physical or mental wreck'.

Following Aleck Bourne's acquittal, safe 'legal' abortions were available in the UK to women who could afford them, and who could find doctors who were prepared to run the risk of imprisonment. Much more commonly, women with unwanted pregnancies relied on the services of illegal abortionists It is thought that there were probably around 100 000 illegal abortions each year before the Abortion Act came into force, and mortality rates were high. Abortion had become a public health issue and by the mid-1960s there was broad public support for bringing it within the safety of medical control.

The Abortion Act 1967 provides that an abortion will be lawful in England, Scotland and Wales (the Act does not apply in Northern Ireland), and no offence will have been committed if the criteria laid out in the Act are met. These are that two doctors must be 'of the opinion, formed in good faith', that the woman's circumstances satisfy one of the four statutory 'grounds' for abortion; that the abortion is carried out by a registered medical practitioner in an approved place; and that it is notified within seven days to the relevant Chief Medical Officer.

If a termination of pregnancy does not satisfy these criteria, a criminal offence will have been committed. In 2012, Sarah Catt bought abortion pills from an internet site which she took in order to terminate her own pregnancy, shortly before she was due to give birth. She was convicted under section 58 of the Offences Against the Person Act and initially sentenced to eight years in prison [9], reduced, on appeal, to three and a half years [10].

The most commonly invoked ground for abortion, often referred to as the 'social ground', is set out in section 1(1)(a) of the Abortion Act 1967. It requires two registered medical practitioners to be 'of the opinion, formed in good faith':

> that the pregnancy has not exceeded its twenty fourth week and that the continuation the pregnancy would involve risk, greater than if the pregnancy were terminated, of injury to the physical or mental health of the pregnant woman or any existing children of her family.

In 2016, 97% of all abortions were authorized on the grounds that the pregnancy posed a risk to the pregnant woman's own health, and 99.8% of these were authorized solely because of the risk to her mental health [1].

This ground is very easily satisfied, and not only because the mental well-being of a woman who does not want to be pregnant will generally be promoted by allowing her to end her pregnancy. Through what is sometimes called the 'statistical argument', it could be argued that, because pregnancy and childbirth will almost always pose a greater risk to a woman's physical health than termination, this ground is satisfied in virtually every pregnancy.

The other three grounds for abortion are that two doctors are 'of the opinion, formed in good faith' that: under section(1)(1)(b) the termination is necessary to prevent grave permanent injury to the pregnant woman; under section (1)(1)(c) continuing the pregnancy involves a risk to her life; or under section (1)(1)(d) 'there is a substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be seriously handicapped'. None of these three grounds is subject to a time limit. In practice, however, terminations after 24

weeks are rare (fewer than 0.1%), and most are carried out because of the late detection of a grave fetal abnormality, such as anencephaly.

While the legalization of abortion is sometimes assumed to be part of the pattern of liberal law reforms that took place during the 1960s, it is important to remember that the 1967 Act does not, in any circumstances, give a pregnant woman the right to terminate her unwanted pregnancy. Even if a woman's pregnancy resulted from an act of rape or incest, she does not have the legal right to terminate it (of course, in practice doctors will invariably find that the first statutory ground is satisfied in such cases).

Instead the statute gives doctors considerable discretion over the legality of abortion. Notice, for example, that the statute does not specify that the section 1(1) grounds have to actually be satisfied. An abortion's legality depends solely upon whether two doctors have formed the opinion, in good faith, that that woman's circumstances satisfy one of the statutory grounds. So, for example, the legality of the 1% of abortions carried out under s.1(1)(d) depends upon two doctors agreeing, in good faith, that a particular handicap is 'serious', and that the risk of it materializing is 'substantial'. In deciding whether a fetus's abnormality is sufficiently serious, the Royal College of Obstetricians and Gynaecologists has recommended that doctors take into account the probability that effective treatment will be available; the probable degree of self-awareness and ability to communicate with others; the suffering that would be experienced; and the extent to which the person might be dependent upon others. There is, however, no definitive list of conditions which justify abortion, rather the test is simply whether two doctors have formed the opinion, in good faith, that there is a substantial risk that the child would be seriously handicapped.

The question of what might count as a serious handicap was raised by Joanna Jepson in 2003, following her discovery that an abortion had been carried out on a fetus with a cleft palate after 24 weeks [11]. Following her complaint, West Mercia police launched an investigation, but they decided not to prosecute the doctors who had signed the form. Ms Jepson sought and was granted leave to apply for judicial review of this decision, on the grounds that the case raised an issue of public importance, but Jackson J admitted that she would face substantial evidential and legal hurdles at the full hearing. Before this could take place, West Mercia police conceded that their initial investigation may not have been sufficiently thorough, and the case was reopened under a different team of officers. The case was then referred to the Crown Prosecution Service, which decided against prosecution because, as the Chief Crown Prosecutor for West Mercia explained [12]:

> both doctors concluded that there was a substantial risk of abnormalities that would amount to the child being seriously handicapped. The evidence shows that these two doctors did form this opinion and formed it in good faith.

An outdated statute?

There are three ways in which the Abortion Act 1967 is a poor fit with modern medical practice. First, to be lawful, an abortion must be carried out by a registered medical practitioner. This restriction made sense in 1967 when all abortions were surgical, but 62% of abortions are now medical and simply involve taking pills [1]. There is no clinical need for the pill to be provided by a doctor, and indeed nurse-led abortion services are both clinically and cost-effective. In practice, the courts have interpreted this provision in a way that facilitates nurses' involvement in medical abortions, provided that the nurse continues to be supervised by a doctor. In *Royal College of Nursing v Department of Health and Social Security* [13], the House of Lords decided that nurses could actively participate in the termination of pregnancy, provided that a registered medical practitioner is supervising the procedure.

Second, except in an emergency, 'any treatment for the termination of pregnancy' must be carried out in an NHS hospital, or in a place approved for the purposes of the Act by the Secretary of State (section 1(3)). Around two-thirds (68%) of NHS-funded terminations take place in independent clinics run by charities including Marie Stopes and the British Pregnancy Advisory Service (BPAS). Pregnancies of 24 weeks or more can only be terminated in NHS hospitals.

Once again, this restriction may be incompatible with best practice in the provision of early medical abortions. If taking mifepristone and misoprostol is 'treatment for the termination of pregnancy', then both pills must be taken in an NHS hospital or an approved place, despite the fact that it would be safe to take them in a GP's surgery, or even at home. It might be argued that it would be preferable for women to be able to take the second drug, misoprostol, at home, since this is what will usually trigger her miscarriage. Instead, in addition to the inconvenience of having to attend the clinic on two separate occasions, which may be particularly difficult for women with young children or those who live in remote rural areas, there is also a risk that the woman might miscarry while she is on her way home. There is considerable evidence that home medical abortion would be safe, and that most women would prefer it [14].

In 2012, BPAS sought, unsuccessfully, a declaration that it would be lawful to prescribe misoprostol when the woman attended the clinic to take the mifepristone, so

that she could take the misoprostol home with her, and subsequently take it at home. In *British Pregnancy Advisory Service (BPAS) v Secretary of State for Health* [15], Supperstone J held that the 'treatment', which had to take place in an approved place, was the taking of the drug, not its prescription. The irony of this is that a provision in the legislation which was intended to protect women's safety – by ensuring that surgical abortions only take place in properly equipped and staffed premises – in fact, in the case of early medical abortions, could make them *less* safe. By requiring the woman to take the second pill in a clinic, before allowing her to return home, there is a risk that she might miscarry in a public place.

Third, the provision of new birth control methods that might involve a woman taking a contraceptive pill only once her period is late, or once a month, is blocked by the Abortion Act 1967. Any method of birth control that works after implantation would involve 'procuring a miscarriage', and hence could avoid being a criminal offence only if all of the criteria in the Abortion Act are satisfied. Two doctors would have to agree that the woman's circumstances satisfy one of the statutory grounds for abortion; the woman would have to take the pill in an approved clinic or NHS hospital, while being supervised by a doctor. This would make post-implantation methods of birth control both inconvenient and expensive. As Sally Sheldon [16] explains:

> That archaic legislation, which has remained largely unconsidered for one and a half centuries, is drafted so as to block the development and use of safe, effective forms of fertility control that operate so soon after intercourse provides a compelling argument for a fundamental review of, at least, this aspect of its operation.

Sex-selective terminations

In 2012, undercover reporters from the *Daily Telegraph* filmed abortion providers allegedly agreeing to carry out terminations on the grounds of fetal sex. The reaction from the then Secretary of State for Health, Andrew Lansley, and the Chief Medical Officer, Sally Davies, was to declare that such abortions are unlawful. In 2014, the Department of Health issued *Guidance in Relation to Requirements of the Abortion Act* [17], in order 'to provide support for doctors by setting out how the law is interpreted by the Department of Health', according to which: 'Abortion on the grounds of gender alone is illegal. Gender is not itself a lawful ground under the Abortion Act'.

The assumption behind claims that abortion on the grounds of sex is illegal in the UK is that because 'fetal sex' does not appear as one of the grounds for abortion in section 1(1) of the Abortion Act 1967, abortion on the grounds of fetal sex must be unlawful. But this is to misunderstand how the Abortion Act works. It does not contain a list of legitimate reasons for abortion. As we have seen, rape does not appear as a ground for abortion in section 1(1), but this does not mean that abortion on the grounds of rape is unlawful. Instead, the Act gives two doctors considerable discretion to determine whether a woman's health would be better served by termination than by carrying the pregnancy to term.

In 2015, Fiona Bruce MP attempted to put the supposed illegality of sex-selective abortions beyond doubt through an amendment to the Serious Crime Bill. If passed, her amendment would have read: 'Nothing in section 1 of the Abortion Act 1967 is to be interpreted as allowing a pregnancy to be terminated on the grounds of the sex of the unborn child.' In the event, her amendment was defeated, not because there was support for sex-selective abortion in parliament, but because there were concerns that this provision might prevent women from terminating pregnancies where the fetus was suffering from a sex-linked disorder. Anxieties were also expressed about the use of the term 'unborn child' in legislation. Instead, an alternative amendment was passed which required research to be carried out into the incidence of sex-selective abortion in the UK. The Department of Health duly carried out this research and published its report [18] later in 2015. Its conclusion was that 'we have found no substantiated concerns of gender abortions occurring in England, Wales and Scotland'.

Termination of pregnancy in children and adults who lack capacity

Once children reach the age of 16, their consent to medical treatment is as valid as it would be if they were adults [19]. If a girl is under 16, but *Gillick*-competent – that is, she is mature enough to make the decision for herself – it is clear that she can give a valid consent to abortion, and that the termination can take place without her parents' consent or knowledge [20].

If a girl is not yet *Gillick*-competent, decisions about her medical treatment would normally be taken by her parents, subject to the possibility of being overridden by the courts if the parents' decision was not in her best interests. It is, however, hard to imagine circumstances in which it could be in the best interests of a girl who lacks capacity to terminate her pregnancy against her wishes, or, likewise, to force her to carry an unwanted pregnancy to term. Certainly this was the view of the President of the Family Division, Sir James Munby, in *Re X (A Child) (Capacity to Consent to Termination*) [21], a case involving a pregnant 13-year-old girl who was not yet *Gillick*-competent:

> I find it hard to conceive of any case where such a drastic form of order – such an immensely invasive procedure – could be appropriate in the case of a mother [*sic*] who does not want a termination, unless there was powerful evidence that allowing the pregnancy to continue would put the mother's life or long-term health at very grave risk. Conversely, it would be a very strong thing indeed, if the mother wants a termination, to require her to continue with an unwanted pregnancy.

So even if a girl lacks the capacity to make a decision about whether to have an abortion, her views will carry considerable weight.

For adults who lack capacity, the Mental Capacity Act 2005 applies, and the first question for the doctor will be whether a termination is in the patient's best interests. The Mental Capacity Act is clear that when judging what is a patient's best interests, the doctor should not just consider her clinical best interests, but also her 'past and present wishes and feelings' and 'the beliefs and values that would be likely to influence [her] decision if [she] had capacity' [22]. In *An NHS Trust* v *CS* [23], a pregnant woman who was in a violent relationship had told her sister that she did not want to 'keep the baby'. Following a further violent assault, as a result of which she now lacked capacity, Baker J decided that a termination would be in her best interests, and not only because this would promote her physical recovery: 'I consider that the clear and unambiguous views that she expressed prior to the injury are the crucial factors in this case'. Of course, deciding that a termination would be in the patient's best interests is not the end of the matter, and two doctors must additionally be of the opinion that the woman's circumstances fit within one of the statutory grounds for abortion, and the termination must be carried out by a registered medical practitioner, in an approved place.

Summary box 68.1

- Abortion is prima facie a criminal offence in the UK, but a defence exists in England, Scotland and Wales if a termination satisfies the criteria in the Abortion Act 1967.
- These are that two doctors must have formed the opinion, in good faith, that the woman's circumstances fit within the statutory grounds and that the abortion is terminated by a registered medical practitioner in an approved place.
- In practice, abortion is available 'on request' in the first months of pregnancy, and nurses are able to participate in the provision of abortion services, provided that they are under the supervision of a doctor.

The management of pregnancy and childbirth

In almost every wanted pregnancy in the developed world, the fetus makes its first 'public' appearance long before it is capable of independent life. Prenatal testing facilitates the accurate diagnosis of an expanding range of disorders, and an increasing range of conditions are treatable *in utero*. Given the ability to see, monitor, diagnose and treat the fetus, it is probably unsurprising that, even if it is established law that the fetus is not a person, there is no doubt that the fetus is now widely understood to be a patient.

Conferring 'patient' status upon a fetus presents no practical problems when the woman is a willing participant and, of course, most pregnant women will consent to any intervention in order to protect the life and health of their developing fetus. Nevertheless, fetal patienthood creates the potential for conflict if a pregnant woman wants to exercise her right to refuse unwanted treatment. Acting to save a fetus's life involves acting upon the body of the pregnant woman, and without the pregnant woman's consent, the practice of fetal medicine might amount to a battery or assault. Fetal surgery, for example, is possible only if the pregnant woman has given her consent to surgical intervention, consent that she entitled to withhold.

The right of an adult with capacity to refuse treatment that the doctor believes to be in her best interests is robustly protected by the law, and it exists even if the patient's refusal might lead to her death. If a pregnant woman has capacity, it is now clear that pregnancy does not interfere with her right to refuse unwanted medical treatment. In 1992, a judge had declared that it would be lawful to perform a caesarean section, without consent, on a woman who was refusing to consent on religious grounds [24]. That case is now of historical interest only, however. In two subsequent cases, the Court of Appeal has confirmed that pregnancy does not diminish the competent adult patient's right to refuse unwanted medical intervention.

In *Re MB (An Adult: Medical Treatment)* [25], MB lacked capacity as a result of her needle phobia, and an injection necessary to carry out a caesarean section was held to be lawful in her best interests. Nevertheless, in the course of her judgement in *Re MB*, Butler-Sloss LJ stated unequivocally that:

> a competent woman, who has the capacity to decide, may, for religious reasons, other reasons, for rational or irrational reasons or for no reason at all, choose not to have medical intervention, even though the consequence may be the death or serious handicap of the child she bears or her own death.

A year later, in *St George's NHS Trust v S* [26], the emergency caesarean section that had been performed upon S, following the granting by a judge in chambers of an *ex parte* order dispensing with her consent, was held to have been unlawful. The Court of Appeal defended the pregnant woman's right to refuse treatment that could save her fetus's life. As Judge LJ explained:

> She is entitled not to be forced to submit to an invasion of her body against her will, whether her own life or that of her unborn child depends on it. Her right is not reduced or diminished merely because her decision to exercise it may appear morally repugnant.

In practice, however, it may have been easier for the appellate court to strongly assert the primacy of the pregnant woman's autonomy, after the operation had been carried out successfully, than it was for the judge who had had to make a decision *ex parte*, when two lives were in immediate danger [27].

If the pregnant woman lacks capacity, the doctor is under a duty to treat her in her best interests, taking into account her past and present wishes and her beliefs and values. It is a fundamental principle of the Mental Capacity Act 2005 that capacity cannot be inferred just because someone makes a foolish or unwise decision [28], so the fact that a pregnant woman wants to take a decision that the doctor believes to be irrational does not justify a diagnosis of incapacity. In *The Mental Health Trust* v *DD* [29], one of several Court of Protection decisions (this one about an assessment of her capacity to decide upon future contraception) concerning DD, a pregnant woman with a complex obstetric history, learning difficulties and an autistic spectrum disorder, Cobb J explained that he had to 'review with particular care whether DD's decision making is simply "unwise" rather than evidence of her incapacity; if it were merely the former (i.e. unwise decision-making) [he] would have no right under the Mental Capacity Act 2005 to intervene'.

Summary box 68.2

- Pregnant women retain the right to refuse unwanted medical treatment throughout their pregnancies.
- If a pregnant woman lacks capacity, she can be treated in her best interests, under the Mental Capacity Act 2005.

Fertility treatment

The birth of Louise Brown, the first baby created by *in vitro* fertilization (IVF), in Oldham on 25 July 1978 undoubtedly represented one of the most important scientific breakthroughs of the twentieth century, for which Bob Edwards won the Nobel prize for medicine in 2010. As well as pioneering the development of IVF, the UK also has one of the world's most comprehensive and long-established systems for regulating fertility treatment and embryo research.

Four years after Louise Brown's birth, the government appointed Baroness Mary Warnock to chair a Committee of Enquiry into Human Fertilisation and Embryology [30]. The Warnock Report, published in 1984, formed the basis for the Human Fertilisation and Embryology Act 1990, which was substantially amended in 2008, but continues to apply today.

In 1990, babies born through IVF were called 'test tube babies' and there was considerable hostility to the provision of fertility treatment to anyone other than heterosexual couples. Times have changed, however, and it would now be unlawful for a fertility clinic to refuse to provide treatment to someone on the grounds of their sexual orientation or marital status. As well as changes in social attitudes, and in the law, there is now a great deal of high-quality longitudinal research into the well-being of families produced through different types of assisted conception. Perhaps unsurprisingly, given that these are all wanted children, the evidence is that children born as a result of assisted conception are doing at least as well, and sometimes better, on average, than children conceived naturally [31].

Regulating access to fertility treatment

Under the Human Fertilisation and Embryology Act 1990 [32], it is a criminal offence to create, store and use embryos, and store, procure, test, process or distribute gametes without a licence from the Human Fertilisation and Embryology Authority (HFEA). Centres licensed by the HFEA are inspected regularly. They must also provide the HFEA with detailed information about every treatment cycle carried out, in order that the HFEA can fulfil its duty to maintain a register of all treatments carried out in the UK and their outcomes [33].

Unlike some other countries, like France and Italy, which restrict access to fertility treatment to heterosexual couples, there are no eligibility requirements for assisted conception in the UK. Rather the only statutory restriction on access is that a woman must not be provided with treatment services 'unless account has been taken of the welfare of any child who may be born as a result of the treatment (including the need of that child for supportive parenting), and of any other child who may be affected by the birth' [34].

Although this 'welfare of the child' provision might sound uncontroversial, it has been subject to considerable criticism. For example, its logic might be questioned by invoking the 'non-identity problem': that is, it is hard

to see how a clinician could take into account a future child's welfare and decide, as a result, that it would be preferable not to bring that child into the world. There are very few would-be parents whose child's life would be likely to be so terrible that it would better for that child never to exist. The 'welfare of the child' provision has also been criticized for placing an unfair burden upon infertile people, who are no more likely to pose a risk to their children's welfare than fertile couples, who can reproduce without being vetted first [35].

In practice, this provision has been interpreted by the HFEA as a 'welfare of the child risk assessment'. The HFEA's Code of Practice instructs clinicians to consider whether there are any specific risk 'factors that are likely to cause a risk of significant harm or neglect to any child who may be born or to any existing child of the family' [36]. Examples given in the Code of Practice include previous convictions relating to harming children, previous child protection measures taken in relation to existing children, and a history of drug or alcohol abuse [37]. The Code of Practice also specifies that, in the absence of specific risk factors, all parents should be assumed to be supportive [38].

In their empirical study of how the 'welfare of the child' provision works in practice, Lee *et al.* [39] found that it was extremely rare for clinics to refuse to provide treatment on child welfare grounds. Nevertheless, the 'spectre' of the child abuser meant that clinic staff believed that it was important to be vigilant. Lee *et al.* also found an interesting distinction between would-be lesbian parents, who were often regarded as 'ideal' parents, in part, perhaps, because of their commitment to be open with their child about the circumstances of their conception, and single women, whose motivations for seeking treatment alone were more likely to be questioned.

A further practical restriction upon access to fertility treatment is that it is expensive and NHS provision is patchy at best. In 2014, NICE published a Quality Standard for Fertility Problems [40], according to which women under the age of 40 who meet the criteria for IVF should be offered three full cycles of IVF, or one full cycle if they are aged 40–42. Implementation of this quality standard is not mandatory, in the same way as NICE's technology appraisals of new medicines. In 2017 it was reported that only 12% of Clinical Commissioning Groups (CCGs) provide three full cycles of IVF to eligible women [41]; 23% offer two cycles; 61% fund one cycle only, and 3% fund no treatment at all. Access to NHS-funded fertility treatment is therefore subject to a post-code lottery. In addition, some CCGs impose further restrictions on access to treatment, such as a requirement that the woman's body mass index is below a certain threshold, or that neither would-be patient already has any children.

Consent

Unlike other more invasive medical procedures, consent to fertility treatment *must* be in writing [42]. Gametes and embryos can be used posthumously in the UK, but only where the gamete provider(s) explicitly consented to their posthumous use. In the late 1990s, there was considerable media interest in the case of Diane Blood, whose husband had had sperm samples extracted, at Mrs Blood's request, after he had lapsed into a coma. Although Mrs Blood claimed that they had discussed the posthumous use of his sperm, Mr Blood had not given written consent to the use of his sperm, and so it could not be used lawfully in treatment in the UK. Following her successful application for judicial review of the HFEA's initial refusal to permit her to export the sperm samples [43], in which the Court of Appeal was reassured that there should be 'no further cases where sperm is preserved without consent', Mrs Blood was allowed to export her late husband's sperm to Belgium where it could lawfully be used without his consent.

In 2008, the Court of Appeal's prediction that there would be no further cases in which sperm was stored without consent was proved wrong. L's husband, H, had died suddenly following routine surgery. Sperm was retrieved without H's consent after misinformation about the application of the Human Tissue Act 2004 to gametes was provided to an out-of-hours judge. When the legality of the sperm's storage and use subsequently came before Charles J [44], he concluded that the evidence that H would have wanted his sperm used posthumously by L was 'at least as compelling as that advanced by Mrs Blood'. The HFEA then permitted L to export her late husband's sperm to a clinic in the USA, where it could lawfully be used without his consent.

In 2015, the courts were first presented with a case involving the possible posthumous export of eggs, in the absence of specific written consent. AM had signed a form permitting the posthumous storage of her eggs. AM's parents believed that, before she died, AM had expressed the strong wish that one or more of her eggs should be fertilized and implanted in her mother, who would bring up the baby, along with AM's father. AM had not given specific written consent to the use of her eggs in her mother's treatment, and so they could not be used lawfully in the UK. The HFEA's Statutory Approvals Committee refused to permit the eggs' export to the USA, and AM's parents applied for judicial review of that decision. At first instance, their application for judicial review of that decision was dismissed, but the Court of Appeal allowed the parents' appeal on the grounds that there had been clear evidence that AM wanted her mother to be the surrogate mother of a child conceived using her eggs after her death [45].

A different consent issue arises if the gamete providers subsequently disagree about the use of their frozen embryos. In the UK the law is clear: the Human Fertilisation and Embryology Act 1990 allows for the variation or withdrawal of consent to the use or storage of an embryo [46]. In practice, this gives whichever partner does not want their embryos to be used in treatment a right of veto over their use. In 2007, this provision was challenged by Natallie Evans who, with her then partner Howard Johnston, had gone through one cycle of IVF, in which six embryos were created, before embarking on chemotherapy treatment for ovarian cancer. The couple subsequently split up and Mr Johnston withdrew his consent to their embryos' continued storage. Because the embryos represented her last chance to have a genetically related child, Ms Evans argued that giving her ex-partner the right to veto their storage and use was incompatible with her right to respect for her private and family life (under Article 8 of the European Convention on Human Rights). Having failed in the UK courts, Ms Evans appealed unsuccessfully to the European Court of Human Rights. While expressing considerable sympathy for her plight, the courts considered that the consent requirement in the 1990 Act served an important purpose, and that Ms Evans' right to respect for her private and family life did not take priority over her ex-partner's equivalent right to respect for his private and family life [47].

In 2008, the Act was amended to provide for a 12-month 'cooling off period' when one partner seeks to withdraw consent to their embryos' storage and use. The hope is that this will enable couples who disagree about their embryos' use or disposal to resolve their differences and come to an agreement. In practice, however, a similar case is unlikely to arise given the development of vitrification, a new and more successful technique for freezing eggs. A woman about to undergo chemotherapy treatment would now be likely to freeze her eggs, rather than embryos created with her partner's sperm. Regardless what happens to her relationship, her frozen eggs would continue to be available for her use in the future.

Gamete donation

Until 2005, most gamete donation in the UK was anonymous. Anonymity used to be thought to be in the interests of donors, recipients and children. It protected donors from unwanted contact with their genetic offspring, and it undoubtedly helped to persuade medical students to donate sperm safe in the knowledge that the children born as a result of their donations would not come back to haunt them in middle age. Anonymity was also believed to protect the privacy and security of the recipient family.

In recent years, these justifications for anonymity have been challenged, and it is now widely (though not universally) accepted that donor-conceived people's interest in information about their origins should take priority over other considerations. Regulations which came into force in 2005 prevented the use of anonymously donated gametes in treatment after 2006. Children born following this legal change have the right, once they reach the age of 18, to access identifying information about their donor. Although the abolition of anonymity has led to fewer students being willing to donate sperm, in practice, clinics have been able to recruit older donors, often with children of their own, or they have been able to import sperm from identifiable donors, most commonly from Denmark and the USA.

Of course, a child will only be able to apply to the HFEA for identifying information if she knows, or suspects, that she was conceived using donated gametes. Unless a child born to heterosexual parents is told about the circumstances of her conception, she will assume that she was conceived naturally, and will have no reason to make an application to receive identifying information about her donor. Her 'right' to information therefore exists only in theory. Of course, children born to lesbian couples or to single women will know from a relatively early age that a third party played a role in their conception, and their right to information will therefore be a real one.

Although there has undoubtedly been a trend towards openness, parents of children conceived using donated gametes do not always tell their children. All the evidence suggests that donor-conceived children who are told about the circumstances of their conception from an early age cope well, but that it is harder for children who find out later in life, or inadvertently. The HFEA's Code of Practice [48] makes it clear that patients should be strongly advised of the merits of being frank with their offspring from early childhood.

Since 2011, sperm donors have been entitled to a fixed sum of £35 per clinic visit to cover all their expenses, and egg donors to a fixed sum of £750 per cycle of donation, again to include all expenses. This sort of modest compensation is intended to be fair to donors, who undergo a series of medical tests and who have to make several visits to the clinic, and, in the case of egg donors, who also undergo an invasive surgical procedure, while not offering an incentive capable of 'overbearing their will'. A further justification for modest compensation emerged from Ravelingien *et al.*'s study [49] of Belgian recipients of sperm. They found that most recipients believed that donors should be compensated, provided that they did not receive 'too much'. Recipients were concerned that if donors received very large sums of money, clinics would attract the 'wrong kind of donor': 'lazy opportunists, people who are only interested in the money and don't

realize what is important in life'. Instead recipients wanted their sperm donors to be men with 'high moral standards', 'someone who is helpful and caring rather than egotistic and materialistic'.

Egg-sharing schemes involve women who need IVF treatment agreeing to donate half of the eggs retrieved during one cycle in return for free or much cheaper treatment. Given inadequate NHS funding, these schemes are attractive to women who struggle to afford private fertility treatment. Nevertheless, given that one cycle of IVF costs around £5000, it is clear that egg-sharing schemes involve substantial, albeit indirect, payment for egg donation, and some people [50] have argued that it does not make sense to pay egg-sharers several thousand pounds for their eggs, while limiting non-patient egg donors to £750.

Egg-sharing schemes carry no extra clinical risk, since the donor is undergoing egg retrieval for the purposes of her own treatment. Nevertheless, it has been suggested that it might be challenging for women whose own treatment fails to have shared their eggs for use in another woman's treatment. In practice, however, the assumption that women would find it difficult to come to terms with other women's successful treatment with their eggs is not supported by empirical evidence into the experience of egg-sharing [51], which instead suggests that egg sharers feel considerable empathy with the infertile women who received their eggs.

There is a limit on the number of children that may be produced from the gametes of one donor, which is expressed as 'up to ten families'. On the one hand, it could be argued that it would be sensible to set a higher limit, since this might be likely to increase the availability of sperm; on the other hand, it might be challenging for children to discover that they have an exceptionally large number of unknown half-siblings.

Unlicensed treatment

Thus far, this chapter has assumed that UK citizens receive fertility treatment services in licensed clinics, regulated by the HFEA. Two factors mean that this assumption is no longer warranted. First, it is increasingly easy for people to seek treatment overseas. They might do this for a variety of reasons [52], including cost (IVF is cheaper in the Czech Republic, for example), avoiding long waiting lists (there are more egg donors available in Spain), avoiding legal restrictions (in the UK this might mean travelling to the USA for sex selection), or a perception that treatment abroad will be better or more likely to succeed.

Treatment overseas can be safe and effective: the quality of care in Spain and the USA, for example, is often very high indeed. But there can also be risks. British women have returned from receiving IVF treatment in less well regulated countries pregnant with triplets and quads. In addition to the health risks for pregnant women and their children, higher-order multiple births impose significant additional costs on NHS neonatal care services, and because the children are more likely to suffer from disabilities, there will also be longer-term costs for the NHS and for social care services.

Secondly, the internet has produced a new phenomenon: online sperm donation. This can involve 'introduction websites', which operate in much the same way as dating websites, or donors advertising their services via Facebook. Online sperm donation will be subject to regulation only if it involves the 'procurement' of sperm, for which a licence from the HFEA is necessary. If would-be donors and would-be recipients simply get in touch with each other electronically and make their own arrangements, they are unlikely to fall foul of the prohibition on unlicensed procurement, and hence these arrangements are almost completely unregulated.

There are clearly risks associated with online sperm donation. There is no vetting of would-be donors, some of whom advertise themselves as offering 'NI [natural intercourse] only'. The sperm will not be tested for HIV and there will be no screening for common genetic disorders. There is no register of information for individuals conceived in this way, and no limit on how many families can be produced from one donor. Indeed, one Facebook sperm donor proudly advertises that he has created more than 800 children [53]. There are also legal risks. Unlike donors in licensed clinics, unless the woman is married or in a civil partnership and conception is achieved artificially, the informal sperm donor will be the child's legal father, and hence acquire the obligation to pay child support throughout the child's minority. It is thought that, in order to avoid child maintenance obligations, some online sperm donors use fake identities, meaning that they are not just anonymous but completely untraceable.

However, some women believe that there are advantages from seeking out online sperm donation, and not only because it will often be cheaper than treatment in a licensed clinic. It is clear from the profiles on these introduction websites that many would-be donors and recipients are interested in facilitating contact between the donor and his child during childhood. Jadva *et al.*'s [54] survey of members of an introduction website found that most were looking for ongoing relationships between the donor and the child. There is, however, scope for these arrangements to go quite badly wrong, and a few such cases have reached the UK courts. In one case [55], the mother was a lesbian woman who had sought an identifiable donor online, while the donor had unrealistic hopes for their future as a heterosexual family unit. In another case [56], in which the question for the court was whether the child's conception had been through artificial

insemination or sexual intercourse (the donor would be the child's legal father if conception had been through sex), the relationship between the mother and the donor had completely broken down and their dispute had cost them almost £300 000 in legal fees.

Pre-implantation genetic diagnosis

Pre-implantation genetic diagnosis (PGD) can be carried out lawfully under licence from the HFEA only where there is a significant risk that the child will have or develop a serious illness, disability or other condition [57]. Tissue typing in order to select a child who will be a good tissue match for an older sibling with a serious condition is also permissible. Although it is also possible to discover the embryo's sex through PGD, sex selection is lawful in the UK only for medical reasons: to avoid the transmission of serious conditions that affect only one sex, or which affect one sex significantly more than the other, such as haemophilia or Duchenne muscular dystrophy [58]. In 2014, the HFEA refused an application to carry out sex selection in order to avoid the inheritance of autism spectrum disorder (ASD) in a family with two 'severely affected' male children, on the grounds that PGD could not guarantee that a female child would be free from ASD [59].

Interesting ethical dilemmas arise for clinicians when a person seeks PGD for an adult-onset genetic condition which they know runs in their family, but for which they have not been tested. An obvious example is Huntington's disease. A minority of people who know that they are at risk of Huntington's have opted to be tested, with most people preferring not to know. It is, however, understandable that these people might nevertheless want to ensure that their children do not inherit the condition.

Of course, once the embryos are tested, it is likely that the clinicians will be able to tell whether the at-risk patient has the Huntington's mutation. In addition to the risk of inadvertent disclosure, it might also be difficult to preserve parental ignorance without resorting to unethical practices: if no embryos are suitable for transfer because all are affected, should the doctors fabricate an alternative reason why none are suitable (which would involve lying to the patients), or should they carry out a sham embryo transfer (which would be clinically inappropriate)? If the couple were to seek a second cycle of PGD, when the treating clinicians are sure that the at-risk patient is unaffected and that there is no risk that the child would inherit Huntington's disease, would it be unethical and perhaps even unlawful to carry out PGD? If the grandparent with Huntington's disease happens to still be alive, some of these difficulties can be resolved by instead carrying out exclusion testing, which involves excluding embryos that have inherited the relevant chromosome from the affected grandparent.

Since the 2008 amendments to the 1990 Act brought the regulation of PGD onto the face of the statute, a further use of PGD has been specifically prohibited, namely the positive selection of embryos affected by a particular condition, such as congenital deafness. No such cases had arisen under the previous legislation, but it had been anticipated that clinicians might be likely to invoke the requirement to take the future child's welfare into account in order to refuse to provide PGD to someone who wanted to screen in a genetic condition. The Act does not ban the transfer of affected embryos; rather it now provides that

> embryos that are known to have a gene, chromosome or mitochondrion abnormality involving a significant risk that a person with the abnormality will have or develop a serious physical or mental disability, a serious illness, or any other serious medical condition, must not be preferred to those that are not known to have such an abnormality' [60].

In practice, it is not clear that any deaf parents have ever sought PGD in order to guarantee that their child will also be deaf. But the deaf community was offended by the symbolism of a statutory provision which mandates that unaffected embryos must be 'preferred' to embryos affected by congenital deafness.

Summary box 68.3

- The provision of fertility services in the UK is regulated by the Human Fertilisation and Embryology Act 1990, as amended in 2008, and by the Human Fertilisation and Embryology Authority.
- Access to fertility treatment is not subject to many restrictions, but account must first have been taken of the welfare of any child to be born. As a result of a lack of NHS funding, in practice the majority of treatment is provided in the private sector.
- Consent to the use of one's gametes or embryos in treatment must be in writing, and can be withdrawn before they are used in treatment.
- All gamete donors must be identifiable, though in practice if children are not told about the circumstances of their conception, they may not know to ask for information when they reach the age of 18.
- In recent years, it has become more common for people to travel overseas for fertility treatment, or to find gamete donors online.
- Pre-implantation genetic diagnosis is available only where there is a risk of serious illness or disability, or in order to ensure that a child is a good tissue match for an existing sibling.

Conclusion

The creation and termination of new human life raises extraordinarily profound ethical and legal issues for doctors. For patients too, unwanted pregnancy and infertility are among the most intimate, private and emotionally charged reasons for seeking medical intervention. In relation to assisted conception, there has been rapid scientific progress over the past 40 years, and IVF is now a common and routine way to start a family. New developments, such as mitochondrial replacement and gene editing, along with pre-implantation whole-genome testing are going to raise important new ethical and legal questions. Does the CRISPR-cas9 gene editing technique bring the possibility of prenatal genetic enhancement a step closer, for example?

More familiar technologies, like the internet, also have an impact upon the provision of abortion services and access to fertility treatment. It is relatively straightforward to purchase abortion pills online from an offshore pharmacy, and the internet also facilitates cross-border reproductive treatment and DIY sperm donation arrangements. If, as is increasingly common, patients' first port of call when facing a new health issue is Google rather than their family doctor, it is vitally important that accessible, high-quality and evidence-based information is readily available online so that people understand the risks of bypassing regulated treatment services.

The Law and the Obstetrician and Gynaecologist

Bertie Leigh

Hempsons, London, UK

In the last edition I noted that one plausible approach to the predicament of the law in managing society's expectations of the medical profession is to see it as a by-product of clinical success. The achievements of clinicians in providing safe remedies had naturally brought with it a process of adjustment, so that where the doctor used to be deferred to by the patient because he offered a possible but unreliable bridge over hazardous surgical waters, the declining threat of many diseases led to an uncomfortable revaluation of the clinician. Paradoxically, the improvement of the service has been associated with diminished confidence in the provider. Where safe and predictable clinical excellence can be produced, the fallible human agency delivering the service is routinely weighed in the balance and frequently found wanting. The eighteenth-century apothecary had a more comfortable relationship, precisely because the expectations of the remedy on both sides were so much lower. However, even in the last few years we have seen matters taken much further: the UK Supreme Court has followed the General Medical Council (GMC) in saying that the role of the doctor must embody far more of a teacher, a guide who must explain the advantages and disadvantages of the alternative remedies available, including those that are not recommended [1]. The changes implicit in this demand have been amplified beyond the anticipations of health service providers by the requirement that detailed records must be made by the clinician of every significant element in a consultation.

Summary box 69.1

Improvements in medicine have resulted in:

- impatience with doctors;
- acceptance of risk;
- intolerance of suboptimal outcomes.

The rise of autonomy

Because the service is expected to be safe and predictable, society also demands that it be delivered on the patient's own terms. Where the survival of the parturient mother and child is a hazardous matter, the clinician responsible for the delivery may insist on defining the terms, place and means by which the delivery is to be effected. The patient who refuses to take medical advice may be regarded as eccentric; whereas if it is safe and easy to deliver a child, then it readily comes to be viewed as a 'lifestyle choice' in which the pleasure to be derived from the occasion takes a higher priority than the reduction of an already modest risk. Although society is more risk-averse than ever before, it is also predisposed to doubt risks described by experts. The first generation to embrace evidence-based medicine and to limit the ability of clinicians to introduce new therapies that have not been subjected to a double-blind trial is oddly more willing now than in the past to embrace complementary medicine and to advocate the woman's right to home birth when neither has been subjected to any such evidence-based assessment of risk. The fact that the primary care deliverer is often a midwife who may be sceptical about the role of the doctor has proved to be a complicating factor in many Western societies, whilst the rarity of any sort of competent clinical support for many in sub-Saharan Africa is a continuing source of shame in our society.

When a 2010 meta-analysis based on over 550 000 deliveries reported that home deliveries involved a significant increase in the risk of infant mortality, *The Lancet* [2] suggested that 'women have the right to choose how and where to give birth, but they do not have the right to put their baby at risk' [3]. The meta-analysis found that the risk of mortality from home birth was increased from 0.09% to 0.2% and the question that *The*

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Lancet editorial ignored was whether the increased risk of about 0.11% was reasonable or not. Nor was it clear whether the 'right' *The Lancet* was debating was legal or ethical. In law, women do have the right, broadly speaking, to do whatever they like in this regard, as the unborn child has no legally enforceable rights against its mother, in England at least. In ethics, the distinction between the right of the parent to do as she wishes before the birth and the obligation to act in her child's best interests thereafter is certainly less clear, because the parent has the same obligation to act in her child's best interests whether the child has separate legally enforceable rights or not. Legally she may smoke and drink to an extent that will put her child at risk, whilst acting unethically in the views of many.

Advances of medical understanding and the extent to which they have been shared with the public have both undermined the liberal position. In 1859 the author of *On Liberty*, John Stuart Mill, could identify such behaviour as a 'self-regarding sin' and defend himself against attacks from a renowned judge, Sir James Fitzjames Stephen, and formidable moralists such as Mathew Arnold. Today such voices are marginalized if not silent. The ethicist certainly recognizes the parental right and duty to take various decisions on their children's behalf, including the acceptance of certain risks. Thus parents have the right, for example, to take their children on a sailing dinghy provided they do not stray too far from land, that it is not too stormy and there is a life jacket. It is a question of degree, but the acceptance of risk is permissible.

What may raise more troubling ethical questions is the associated demand for an increased share of scarce resources. We already face a shortage of midwives in the UK as we enter an era of rapidly increasing austerity in the National Health Service (NHS). How far is it ethical for a woman to exercise her autonomy at the expense of her sisters who can be handled by fewer midwives in hospital? How far are the advantages of home delivery that were acknowledged by *The Lancet* editorial – shorter recovery time and fewer lacerations, postpartum haemorrhages, retained placentae and infections – attributable to more intensive one-to-one or even two-to-one care by more senior midwives in an effort to make the home birth safer?

The shortage of resources has become a more strident voice in this as in all other medical debates. UK Health Ministers used to deny that there was any rationing of resources and such suggestions were seen as political attacks on the parsimony of the Treasury. Today it is the conventional view that the British public is not prepared to pay through the Treasury for the healthcare that it demands through the press, the courts, the regulators such as the Care Quality Commission: where most OECD countries spend over 9% of gross domestic product (GDP) on healthcare, Britain is spending under 8% and the aspiration to increase this figure that was accepted in the 7 years of plenty that followed the publication of the Wanless Report in 2001 seems a distant memory. There is a striking analogy here with maternal mortality in Africa where it is accepted that 80% of maternal mortality could be avoided with a different application of the resources available within those countries.

This development spreads beyond obstetrics and gynaecology. Most aspects of medicine have become safer and more predictable, and as a consequence the relative importance of different ethical obligations upon the doctor has changed. Thirty years ago, when medical ethics was first recognized as having practical implications for mainstream clinicians, it was accepted that there were four different ethical obligations that the doctor needed to balance. The primary obligation was to do good, and that obligation preoccupied the thoughts of the clinicians of the 1970s. They might say 'first of all do not harm', but in reality that usually meant take reasonable care and the aspiration to non-maleficence took second place since it appeared to be of less practical importance in most circumstances. Third was the obligation to act justly, since it was crucial in circumstances where doctors were more responsible for the management of the NHS and therefore the allocation of resources. The modern reader of a textbook such as Ian Donald's *Practical Obstetric Problems* (1976) will be surprised by the extent of the advice on how to manage the labour ward effectively. That obligation could cause the accoucheur to hesitate before leaving the labour ward as part of what was then called the Flying Squad. The idea that the patient's autonomy should be respected came fourth. It was seen as an important part of good manners, but beyond ensuring that the patient signed the right consent form before surgery, it was hardly a fundamental aspiration of the service rendered by the doctor. Women in the 1970s took themselves to a doctor for the treatment of an ailment rather than the exercise of their autonomy.

Today, respect for the patient's autonomy has grown like a cuckoo in the nest and threatens to drive all other considerations to the margins. A vivid illustration of this was seen in the case of *Chester* v *Afshar* involving spinal surgery which came to the House of Lords in 2004 [4]. The court found that Miss Chester was not told that there was a 1% risk of significant morbidity associated with spinal surgery. The defence accepted that every reasonable surgeon would have warned of this risk, which is in itself a striking change since the *Sidaway* v *Bethlem Royal Hospitals Governors* case [5] failed on precisely that issue in 1985. Miss Chester said that if she had been

told of the risk, she might well have undergone the surgery in any event and very likely in the hands of the same surgeon, but only after obtaining a second opinion. On a conventional analysis, this meant that Miss Chester could not prove that her surgeon had caused her any damage. However, the House of Lords felt that in these circumstances the plain meaning of the English language needed some trifling adjustment. It did so on a twofold basis.

First, that it was of vital importance that Miss Chester's autonomy be respected, and in circumstances where she was contemplating spinal surgery this demanded that she must be told the risks that she was letting herself in for, otherwise she would be stripped of her dignity as a human being when she disrobed on admission. Second, that if it was not held that the erring doctor became the insurer of the patient's damage, the duty would be emptied of its content. The law would not be upholding the duty. Thus, in order to enforce the duty the law should hold that in these circumstances the doctor has caused the patient damage. Some felt that there would have been more logic about it if the House of Lords had invented a new tort of Showing Disrespect, or *Dis* as modern slang would have it, and said that in these circumstances they would order the surgeon to compensate the patient for the complete tort of advising and treating with disrespect; that would have the advantage of forcing the surgeon to compensate the patient for the insult he had rendered, whether or not she was unlucky enough to get a complication which sounded in damages. A minor solatium of £500 would uphold the duty and reflect society's real evaluation of the insult. Since he had not really caused the complication, it seems illogical to pretend that the law is enforcing a duty to advise that is equally important whether the complication results or not.

Another oddity of the case was that Miss Chester was at no less risk if she opted for conservative therapy. The evidence was conflicting, but some experts thought that she was at greater risk of long-term disability if she did not undergo surgery. As she was in significant pain preoperatively, she would need to persuade the court that she would have undergone surgery or recovered spontaneously to recover full compensation when her quantum was assessed.

Summary box 69.2

Doctors must advise their patients so that they can

- exercise their autonomy;
- even if that demands a greater share of NHS resources than they need.

The problem is more acute for obstetricians and gynaecologists than it is for other specialties for a number of different reasons. In gynaecology, apart from cancer, most procedures are designed primarily to enhance the woman's comfort or reproductive choices. They are truly elective procedures, which the woman must be free to accept or reject on her own terms. In obstetrics, the reduction of maternal mortality and the marginalization of infant mortality have meant that the woman feels that she should be put in a more powerful position. In *Montgomery* v *Lanarkshire Health Board* the UK Supreme Court has spelled out the importance of advising on the alternatives, even when no surgical intervention is planned [1].

Summary box 69.3

It is not possible to record the sort of advisory session that the law demands in a conventional outpatient clinic.

Abortion

Doctors have been in the front line of the legal control of abortion since *R* v *Bourne* in 1938 [6]. There has been thrust upon them a dual role in which they are seen as the servants of the law as well as their patients. Until the Abortion Act 1967 was passed, the doctor who performed an abortion in most circumstances committed a professional offence as well as a crime and would be struck off on conviction. The day the Abortion Act came into force, the medical abortionist ceased to be a criminal and so prosecutions before the GMC ceased. This struck no-one as odd because the law had been changed by the Queen in Parliament and if abortions were going to be performed lawfully then the GMC had to permit them. The professional offence had been to break the law. Yet the change in GMC policy as a result of the change in the law served to emphasize the fact that the GMC did not impose any distinct medical ethic or code of behaviour as had been supposed since Hippocrates, it simply reflected the law. In this respect at least there was no separate stream of doctor-made laws controlling the profession and the Oath of Hippocrates might prohibit abortion but it proved to be subordinate to the general law of the land, perhaps a litmus test for much else that has happened in medicine over the 70 years since *R* v *Bourne*.

Yet the change in abortion law went far beyond that foreseen by Parliament. When Parliament decided that it should be lawful to perform an abortion when the doctor believed that continuation of the pregnancy would be more hazardous to the health of the mother or other

children in the family than the termination of the pregnancy, few realized that this in effect legalized abortion on demand since enough doctors honestly believed that such a continuation would always be more hazardous. In 50 years, no doctor has been prosecuted before the GMC for exploring the limits of this envelope.

The predicament of the obstetrician who is asked to treat a woman for an unwanted pregnancy was made more complicated in 1990. In essence, Members of Parliament (MPs) faced a widespread doubt about the wisdom of the existing law when the new Human Fertilisation and Embryology Act was being debated. A sizeable group of MPs wished to bring down the upper limit for abortion, which was then when the fetus would be capable of being born alive. Others took a more liberal view. The compromise agreed upon was that until the pregnancy has exceeded its twenty-fourth week, abortion should be available on the existing criteria, which effectively meant abortion on demand, even where the fetus may be larger than those in the adjacent neonatal intensive care unit. Since women do not become pregnant before they ovulate, which on average is not before the fourteenth day of the cycle, this means that a doctor who believes in good faith that the social ground is satisfied may lawfully terminate a pregnancy until 26 weeks from the last menstrual period. I stress that this is untested in court and the conventional view within medicine is that the limit has been set at 24 weeks; however, to sustain that view the court would have to say that the maturity of the pregnancy referred to the time since ovulation.

After that limit, apart from where it is necessary to save the mother's life or health, abortion is lawful only when the doctor believes there is a substantial risk that the child, if born, would suffer from a serious handicap. Neither 'substantial' nor 'serious' was defined by the Act. In essence, MPs, who could not agree amongst themselves, decided to leave matters to doctors and women. The doctor was given the power to decide in consultation with the patient when it would be appropriate to perform an abortion. A substantial risk is generally speaking regarded as something of substance, to be taken into account in the organization of one's affairs. Usually this means less than the balance of probabilities. If that were right, it would be lawful at any point prior to delivery to abort a fetus who, on the balance of probabilities, would be born healthy.

Parliament did not consider such questions as whether the child had to be abnormal at birth or destined to remain handicapped permanently. So we do not know if it is lawful to terminate in the case of Huntington's chorea, which does not usually afflict a person until the fourth decade of life, or the person born with a surgically remediable lesion.

The intervening years have not been kind to a compromise based upon deference to the judgement of an individual clinician. With the rise of personal autonomy and the decline of medical authority, there is little role for a doctor to decide what is best for a patient and there is much less of a role for a doctor to tell a patient what they must and must not do. If a medical service is available, the assumption is that the doctor must provide it if the patient demands it and it is clinically appropriate. Something of a crunch point was reached in 2004 when a curate of the Church of England recognized in the statistics issued by the Department of Health that a pregnancy had been terminated at 26 weeks where the indication given was a cleft palate. If the lesion was a part of a broader syndrome, that was not apparent in the information published by the Department of Health. The curate complained to the police, who sought guidance from the Royal College of Obstetricians and Gynaecologists (RCOG). The police decided not to investigate further and an application was made for judicial review of that decision. The police agreed to reconsider matters and did investigate with a view to prosecution. Eventually they decided that the evidence available did not enable them to conclude that a prosecution would have a better than 50% chance of persuading a jury that the doctors did not have the bona fide belief that the circumstances of the Act were satisfied.

However, the case triggered a debate around several issues. The first is whether the compromise decided by Parliament was far more liberal than can be defended in view of intervening medical developments. Where advances in ultrasound have made it possible to visualize the unborn child more clearly than ever before, the difficulty in defending a decision to terminate on grounds of cleft lip and palate is harder to justify. The autonomy that the law accords the pregnant woman is based on the recognition that the unborn child is part of her body: this is challenged by the ability to visualize the fetus and watch it moving on ultrasound films that the mother carries on her mobile phone and to interact with it by performing medical procedures for its benefit. Nor does it help that advances in neonatology have brought the age of viability down still further, so that the fetus who is being killed is more often capable of being born alive and of surviving than ever before, often more mature than babies being treated in the critical care unit.

This is something about which obstetricians may provide expert advice to the legislature but must remain essentially neutral. Thus, the RCOG has published the reports of working parties on the extent to which a fetus may experience pain [7] and provided guidance on the termination of pregnancy for fetal abnormality [8], but in

neither case is it articulating a moral view to its fellows and members in the fashion in which the Hippocratic Oath bound all doctors not to procure abortion until comparatively recently. However, the RCOG does express strong views about the problems facing the service. Abortion is now the commonest procedure paid for by the NHS, almost 200 000 cases a year, and yet most cases are outsourced to commercial organizations that provide little or no training. Complex procedures are confined to the NHS, but many places expect to face problems in delivering the service when the present generation of seniors retire.

There is a second underlying debate about the role of the clinician. Is the doctor expected to exercise a judgement about whether the procedure is in the patient's best interests? If so, on what basis? If the indication for the procedure is choice, how can or should the doctor second guess the patient? When Parliament said that it wanted the decision to be taken by doctors and patients together, did it mean that the patient should have complete freedom to decide if the doctor believed that the unborn child would suffer from any recognizable handicap? What is the extent to which it is proper to expect obstetricians to be put in the guise of judges at all in such circumstances? The assessment of the degree of handicap should be undertaken by those appropriately trained for the purpose. Often they will be members of another specialty; in some places such patients are referred to paediatric surgeons for advice, and the RCOG Working Party [8] in 2010 suggested referring to a paediatrician with experience of affected children. I wonder if we will not go further in the future: sometimes the assessment of long-term handicap might be enhanced by a multidisciplinary assessment involving specialists in neurological disability, physiotherapists, speech therapists or occupational therapists. The effect of a given physical lesion will vary greatly from case to case, depending on the personality of the victim and the resources available, as well as the severity of the lesion. The difficulty is that it is hard to see how such an assessment can be organized swiftly enough when the pregnancy is advancing.

The law here has to balance society's interest in protecting the autonomy of the pregnant woman and ensuring that she is not forced to carry to term a baby which she does not want. That right has to be balanced against the right of the unborn child; since Parliament has decreed that the unborn fetus has no right, this has to be expressed as society's interest in protecting the fetus. Few think it appropriate to provide women with an unqualified right to demand the destruction of a normal third-trimester fetus. The need to balance these issues calls for a political and judicial assessment. Although doctors were placed in the front line, it is increasingly hard to understand what role society allots to them or how it expects them to perform this task. In few other areas of medicine are doctors asked to legislate between conflicting interests in this fashion; and where they have been granted a broad margin of discretion hitherto, as in end-of-life decisions, that flexibility is being curtailed.

In these circumstances the individual clinician needs to be aware of the conflicting obligations which are imposed by the law and the demands of patients. My own advice now is that, so far as possible, obstetricians should ensure that they have written objective advice from appropriate specialists on which to base their decisions. In contentious cases I suspect that we will soon advise obstetricians to transfer the decision to the place where it should properly be made, Her Majesty's Judiciary. At least that way we will get some guidelines. It will be very unfortunate if the first time that any guidelines as to the law's assessment of the meaning of substantial risk of serious handicap comes to be decided is in the context of a criminal prosecution. Under the law, until 1990 the reluctance of the police to intervene meant that no-one attempted to find out what 'capable of being born alive' meant between its passage into law in 1929 [9] and the advent of a negligence action in respect of an obstetrician's failure to advise a woman of the failure of an alpha-fetoprotein test to detect abnormality. The Court ducked the question then and was forced to determine it in 1989 when a radiologist was sued in respect of his failure to recognize spina bifida [10]. Only then was it established that 'capable of being born alive' meant capable of maintaining life by means of ones' own breathing, even though 60 years had elapsed since the Act was passed.

In the meantime, obstetricians should be advised to cover themselves by seeking to buttress their decisions by obtaining the sort of written evidence that a court would demand. That evidence should explicitly answer the statutory questions: Is the risk substantial and would the handicap be serious? The RCOG has recently reiterated its advice of 1996, and until we have guidance from a court on the meaning of the word 'substantial' in this Act, it would be wise to err on the side of caution [8]. How a court would interpret the meaning of 'substantial' could well determine on the context in which the question was posed. We could get almost any answer, from 20% – on the basis that a substantial risk is one that sensible people would take into account in ordering their affairs – to beyond all reasonable doubt, on the basis that a mature fetus should not be killed unless you are sure it will be handicapped. The latter is perhaps an extreme and unlikely view, but the court could easily demand the balance of probabilities.

Summary box 69.4

The current emphasis on patient rights is inconsistent with the role of the doctor as a co-decision maker assumed by the abortion law under the 1990 Act.

Professional discipline

Another feature of the landscape of which clinicians need to be aware is the changing role of the GMC. After the profession suffered body blows in public esteem through a series of scandals in the 1990s, the GMC was reformed so as to make it much tougher on the under-performing doctor. The standard of proof was reduced from the criminal to the civil standard: it was emphasized that the civil standard does not simply mean the balance of probabilities but the panels tend to take a confident approach to issues of fact. The innovations were surrounded with honeyed words about reform and rehabilitation, but in practice those doctors who have been identified as under-performing through the GMC processes have rarely found their way back into mainstream practice again. The National Clinical Assessment Service also grapples with the problem of the under-performing doctor, but its success rate for getting doctors back into practice once they have been identified as under-performing has not been good. These processes usually lead to the end of the clinician's career. The Medical Practitioners Tribunal Service, which adjucates on prosecutions by the GMC, now has a minority of doctors on its panels and the people who are there sometimes have a critical view of the profession.

It was also agreed by the profession that it should embark on some formal system of revalidation. Continuing professional education was instigated in the 1990s in response to the minimal-access surgery furore, and as a result the RCOG was the first College to instigate a system of formal recorded continuing professional education in the UK. It was agreed that revalidation needed to be something more, involving not only evidence of learning and reflection but also evidence of continuing ability, but the more ambitious programmes of revalidation fell on the stony ground of the unaffordable.

Postgraduate training

Another issue that is concerning for the future of the profession arises from the developments in professional training over the last 15 years. The introduction of the Working Time Directive in the UK halved the number of hours per week that the junior hospital doctor works. The introduction of the Calman Reforms and the Specialist Registrar Grade reduced the number of years of experience in training grades that a newly appointed consultant can be expected to have achieved by a similar proportion. The result is that the newly minted consultant acquires a fraction of the clinical hours of experience of their predecessor 30 years ago.

In dealing with junior hospital doctors over the last 30 years, one feels that the profession has squandered a monastic tradition of devotion and apprenticeship. The *BMJ* reports, for example, that junior surgical trainees are unable to tie knots, a basic skill that used to be acquired by medical students [11]. As a result, trainees cannot be entrusted, even under supervision, with the simplest procedures that recent predecessors could manage alone. Seniors report occasions when assistants have walked out at 17.00 sharp, although the operation had reached a critical point. The sense is that doctors are there to do a job within the hours for which they are paid, rather than to undertake a commitment to patients throughout the clinical pathway.

The result is a decline in continuity of care and an attitude to handover that depends on written records rather than real communication to another doctor who will accept the same responsibility. Far more time is devoted to handover so that the proportion of junior time available for the management of the sick has fallen still further.

Worst of all, the exposure of the junior doctor in each hour of experience that is gained is markedly reduced. One understands the need to protect patients and to ensure that the service they receive is safe and consistent, but the effects have been extreme. A newly appointed senior registrar of the 1970s would be likely to have performed more surgical procedures alone and to have experienced significant complications more frequently than the newly appointed consultant of today. These events were good for neither patient nor doctor. The emphasis on using the hours of training for that very purpose is all to the good, in the sense that the juniors are well taught in a procedure-specific sense. But it is no way to acquire an understanding of the natural history of disease in humans, or the flexibility to recognize when things are going wrong.

At the moment, the position is still being mitigated by the presence of senior consultants who benefited from the old-fashioned model of training. We are pedalling backwards to protect this year's patients at the expense of the experience of next year's consultants; thus, the last three National Confidential Enquiry into Perioperative Outcome and Death case studies have advised that all acute admissions should be seen by a consultant within 12 hours.

Every year these consultants retire and are replaced by colleagues who simply do not have the same sort of training. To some extent the problems can be mitigated in elective surgery by increasing subspecialty and higher training in courses post appointment as consultant, but we are encountering a brave new world in more and more hospitals where there is no consultant who benefited from the old-fashioned sort of training. The idea that junior consultants are going to acquire the experience and training that they need in the course of their early consultant years overlooks the fact that they are not in a training grade and that increasingly there is no-one there to train them if they do have the modesty to ask for help and guidance.

For a time it looked as if the newly appointed young consultants would take on the attitudes of their seniors when appointed and accept the notion of 24-hour responsibility necessary to provide continuity of care for those they regarded as their patients. The NHS decided in 2003, apparently in ignorance of the fact that most consultants still maintained the same standards of dedication they had acquired as juniors and worked way beyond the hours for which they were paid, that it would pay consultants for the hours they worked. The result was a massive bill that that threatened to cripple many Trusts and there had to be some firm negotiation. This change represented a turning point: the older doctors continue to provide the service their patients need despite the nominal fact that they are not being paid for it, but their attitudes already appear old-fashioned and are being replaced by a new respect for an appropriate work–life balance. A new generation has emerged, shaped in a fashion devised by the managers of the service rather than their clinical seniors.

Summary box 69.5

The modern intolerance of risk makes demands that are challenging the training of the next generation of consultants.

The conflict between the lack of training and the hostile environment

The combination of this crisis in professional training and the less-forgiving professional environment in which doctors work means that the prospects for the individual doctor are ever gloomier. The basic premise of the reforms proposed by the Shipman Inquiry was that there is a plentiful supply of newly minted doctors available to replace those who are found not to have kept their professional skills up to date. This premise is profoundly mistaken and an unprincipled attempt to entice doctors to quit poorer countries – it cannot provide a sustainable solution. In defending doctors before the GMC, we already find an unforgiving atmosphere and an assumption that someone must have done something wrong whenever a patient has died. The notion of being just to the doctor who is the respondent to a complaint is low down on a set of priorities which are headed by making sure that the service is 'safe' and giving satisfaction to somebody simply because they have complained.

Outside the portals of the GMC the complaints system within hospitals has been reformed and made similarly more hostile to the profession. The advice that one gives to professionals in these circumstances is much the same as it has always been – spend time with patients, talk to them and listen to them; explain in detail what is proposed, recognizing that the purpose of the consultation is to put your knowledge at the patient's disposal so that she can make her decision about what she wants to do. This explicitly involves an acceptance of the proposition that sometimes patients will make decisions which the doctor thinks are surprising, if not profoundly misconceived. The patient has an unfettered right to refuse surgery for good reason, bad reason or no reason. The doctor must ensure that the risks of inaction are spelled out as clearly as the risks of the intervention in question. The doctor's role is to advise and to recognize that while their skills are for their patient, their notes are for themselves and their own protection. It is as important to make detailed records of what is said to and by the patient as it is to make records of the clinical history that is elicited and the signs that are found.

It must also be recognized that the patient's right to choose in effect must sometimes mean a right to demand therapy that the doctor thinks is contraindicated. This is an issue with which the profession and the NHS is only beginning to grapple. It found its first utterance in the National Institute for Health and Care Excellence (NICE) guidelines concerning caesarean section [12]. The patient who demands an unfair share of resources in the form of a caesarean section that the doctor thinks is not medically indicated is not in the same position as the woman who insists on home delivery against medical advice. Both are demanding a share of medical resources that seems to exceed the clinical indication in the eyes of the medical attendant, but the woman who demands an operation is demanding that her doctor does something that appears to be inappropriate. She should be offered referral to a colleague where practical, but doctors should never find themselves doing an operation that they believe is contrary to their patient's best interests.

In other areas, the service operates on the premise that patients will not demand surgery which is not in their interests. How far that premise is well founded is unclear. We do have some experience of professionals being sued

for unnecessary procedures in the context of dentistry. There is a long-established line of cases in which patients have demanded extravagant, conservative restoration of teeth whose roots are unsuitable. The smile may be attractive at first but the life expectancy of the bridge is short. The same thing happens even more often in cosmetic surgery. The courts almost invariably criticize the dentist or the cosmetic surgeon for having performed a procedure contrary to the patient's best interests as the professional saw them. The conventional advice to a professional is that when a patient demands a procedure which appears to be contrary to their best interests, the professional should decline to perform it and offer to refer to someone else. That conventional advice must still be good in 2018, but as professional autonomy advances the question must arise as to whether the patient's right to choose will sooner or later entitle them to demand surgery which the doctor thinks is contraindicated, with the same freedom as the waiter should accept an order for an unsuitable combination of dishes. If the autonomy of the patient is paramount and the playing field of knowledge of the implications of medical procedures becomes ever more level, it is difficult to understand how the status quo can be preserved indefinitely.

Cerebral palsy

All this is a long way from the core of the issues which were at the forefront of professional concern when this chapter's first predecessor was written in 1999. Then, the concern of the obstetrician with the law was as it had been since 1980 when the House of Lords gave judgement in *Jordan* v *Whitehouse* [13] that the doctors involved would be sued by children suffering from cerebral palsy who sought to blame their disability on the doctor. Although Mr Jordan's case resulted in a victory for the defence, the experience of the defence organizations was that the public remembered only that a claim had been brought in respect of a brain-damaged child, not that it was lost. Although the defence witness who gave evidence that the damage could not have been caused by the actions of which complaint was made, Professor Ronald Illingworth found his evidence rejected at trial. He subsequently wrote an influential article in the *BMJ* 'Why blame the obstetrician?' [14], which drew on work already being done by neonatologists in America, and over the succeeding 30 years we have become used to a much more measured assessment of causation in these cases.

About half of the money paid by the NHS Litigation Authority, which deals with claims against the NHS, is devoted to cases of birth injury. However the provisions for future payments are dominated by these cases and these are growing at double the amount paid by commissioners for obstetric services. It is also true that the number of children in the population suffering from cerebral palsy has remained roughly constant despite improvements in obstetrics and paediatrics that have transformed the rates of infant mortality and the prospects of survival of the child once delivered. This is probably due to the increased age of the parturient woman since the introduction of *in vitro* fertilization, and has been associated with increased rates of maternal obesity, diabetes and associated complications. The EPICure II study [15] has found that advances in neonatology have brought more survivors from the extremes of prematurity, but still many suffer from the associated disability. It is also true that social expectations for a perfect result have made it difficult for us to defend such cases, even where the extremity of prematurity makes it clear that survival at all is astonishing. The introduction of a programme of Early Notification, requiring the NHS Litigation Authority to investigate potential cases before the parents complain, is likely to result in substantial increase in the number of such claims.

The advent of NHS indemnity in 1990 has taken the financial burden of these sorts of cases off the shoulders of the medical profession. Claims handling was centralized in 2002, so that there is an additional level of insulation between the individual doctor and the damage. Risk management and clinical governance demand ever higher and more intolerant standards, but the massive financial impact of these claims is insulated from the services delivered in the individual Trust in that year. There was a period when a multimillion pound claim against the Trust would or could cause cashflow problems that sent the Chief Executive cap in hand to the regional office of the Department of Health. That at least has gone, but as NHS liabilities now increase by £8 billion a year it has been replaced by the NHS going cap in hand to HM Treasury.

Outside the NHS, private obstetrics is being driven to the wall in England by the problems inherent in asking indemnifiers to cover claims that are regularly pleaded at over £40 million in an individual case.

Evidence-based Medicine in Obstetrics and Gynaecology

Siladitya Bhattacharya[1] *and Arri Coomarasamy*[2]

[1] *School of Medicine and Dentistry, University of Aberdeen, Aberdeen, UK*
[2] *Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, UK*

Clinical care constantly challenges health professionals to ensure that techniques for diagnosis, prognosis and treatment are up to date and consistent with best practice. Given the exponential rise in the numbers of scientific publications, doctors increasingly face the double challenge of keeping up with the latest information and choosing the best tests or treatments based on sound evidence from appropriately conducted research.

One way of doing this successfully is to practice evidence-based medicine (EBM). EBM is the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients [1]. It involves integrating clinical experience and skill with the best available external clinical evidence and awareness of an individual patient's situation and preferences in making clinical decisions about their care.

In this chapter we explore all three components and show that EBM is not the preserve of non-clinical researchers but that it is feasible to incorporate EBM within everyday practice by busy clinicians who devote their scarce reading time to selective, efficient, patient-driven searching, appraisal and incorporation of the best available evidence. Clinical decisions should be integrated with individual clinical expertise in deciding whether and how it matches the patient's clinical state, predicament and preferences, and thus whether it should be applied. Evidence-based guidelines, however, cannot compensate for poor clinical skills in eliciting a diagnosis or interpreting a test result or performing a procedure.

Practical evidence-based medicine

Any clinic consultation throws up a number of questions. For example, in a woman presenting with pelvic pain, what investigations are useful? If endometriosis is diagnosed, what is the best treatment which is consistent with the woman's circumstances and preferences? Similarly, if no cause can be found what is the most effective way of dealing with the symptom of pain? The key principles underpinning the practice of EBM in this and other similar situations are captured in the five As: Ask, Acquire, Appraise, Apply and Audit.

Ask: framing a structured question

The first step in the practice of EBM is to transform an overarching clinical question, for example what is the best way to manage a particular case, into a series of focused answerable questions in a manner which facilitates a systematic enquiry. A standard approach is to use five components – *p*opulation, *i*ntervention, *c*omparison, *o*utcome and *d*esign (PICOD) – to refine the question and enable a literature search to be carried out. Table 70.1 shows examples of how to frame similar questions. Although this approach may appear to be stilted, it merely disarticulates the steps of decision-making which most clinicians accomplish intuitively and rapidly in everyday practice.

Dewhurst's Textbook of Obstetrics & Gynaecology, Ninth Edition. Edited by D. Keith Edmonds, Christoph Lees and Tom Bourne.

Table 70.1 Framing a structured question

Component	Question in Obstetrics	Question in Gynaecology
Population	Overweight or obese pregnant women	Women with heavy menstrual bleeding
Intervention	Antenatal intervention comprising exercise and/or diet	Endometrial ablation
Comparator	Usual antenatal care	Levonorgestrel Intrauterine System
Outcome	Large for gestational age baby (wt > 90th centile)	Improved quality of life
Design	Randomised trial	Randomised trial

Summary box 70.1

Steps of evidence-based clinical practice

- Ask: a PICOD (*p*opulation, *i*ntervention, *c*omparison, *o*utcome and *d*esign) based approach to refine a question.
- Acquire: a hierarchical approach to literature searches, starting with known repositories of clinical practice guidelines and evidence-based reviews before moving onto primary research data.
- Appraise: all search contents should be subjected to a rigorous process of evaluation in the local context.
- Apply: applying the results of critical appraisal involves interpreting the evidence in the local context and integrating it with clinical expertise and awareness of patients' values and expectations.
- Audit: true adherence to the principle of EBM requires regular evaluation of clinical performance.

Acquire: searching the literature

A structured detailed literature search can be cumbersome and time-consuming, something that systematic reviewers and information scientists are well aware of. For busy clinicians there are significant advantages to a hierarchical approach to literature searches, starting with known repositories of clinical practice guidelines and evidence-based reviews rather than primary research data (Fig. 70.1). However, it is important that the methods used by guidelines, systematic reviews and individual studies are robust and reflect the nature of the clinical questions. Guidelines and evidence summaries in obstetrics and gynaecology are regularly produced and updated by a number of organizations including professional bodies such as the Royal Colleges and professional societies as well as national organizations such as the National Institute of Health and Care Excellence (NICE) in the UK, and in some conditions by international bodies such as the World Health Organization (WHO).

If high-quality evidence-based guidelines are unavailable, the next step is to search for good-quality systematic reviews relevant to the questions at hand. If none is found, the next step is to seek primary research papers whose methodologies need to reflect the clinical question. For example, for effectiveness of interventions such as medical or surgical treatments or more complex interventions, the appropriate studies are randomized trials. Either cohort or case–control studies might be appropriate for investigating the aetiology of clinical conditions, while cohort studies are suitable for assessing prognosis. Test accuracy is often evaluated by cross-sectional studies in which new tests are compared against a gold standard.

Summary box 70.2

Sources of evidence relevant to clinical questions

- Guidelines: include evidence as well as its interpretation in a specific context.
- Systematic reviews: synthesis of available evidence.
- Randomized trials: best way of evaluating treatments.
- Observational studies: demonstrate association between causes and consequences.
- Diagnostic test accuracy studies: assess the ability of a test to correctly identify a condition.

A list of some relevant sources of guidelines and evidence-based summaries is shown in Table 70.2. The Cochrane Library and the Centre for Reviews and Dissemination (CRD) databases, including Database of Abstracts of Reviews of Effects (DARE), NHS Economic Evaluation Database (NHS EED) and Health Technology Assessment (HTA) Database), undertake high-quality evidence synthesis exercises in a number of topics including obstetrics and gynaecology. In addition, publications databases such as Medline and PubMed are also sources of many systematic reviews. PubMed contains a systematic review filter called PubMed clinical queries, while Medline has the indexing time 'reviews, systematic' as a 'publication type'. If no systematic reviews can be found, it is necessary to search for primary studies of relevance.

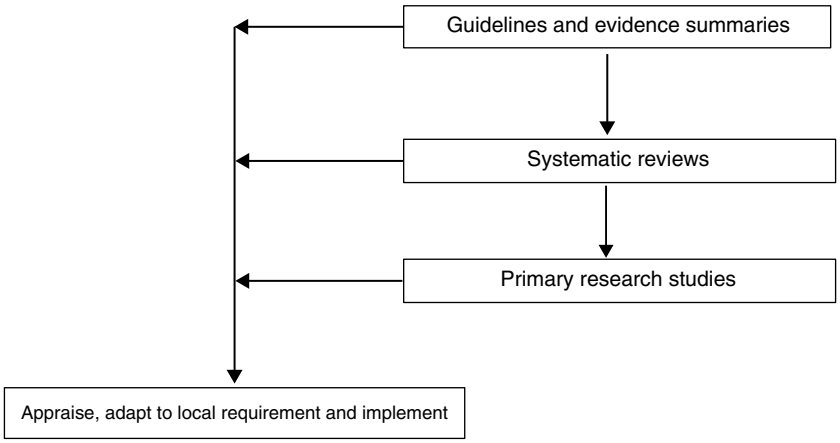

Figure 70.1 Searching the literature for evidence.

Table 70.2 Sources of some guidelines and evidence based summaries in obstetrics and gynaecology

Royal College of Obstetricians & Gynaecologists	https://www.rcog.org.uk/guidelines
National Institute for Health and Care Excellence (NICE)	https://www.nice.org.uk/guidance/published?
American College of Obstetricians and Gynaecologists	http://www.acog.org/Resources-And-Publications
International Federation of Gynaecology and Obstetrics	http://www.figo.org/publications-resources
NHS National Library for Health	https://www.nice.org.uk/about/what-we-do/evidence-services/journals-and-databases

Finding articles of relevance in order to answer a clinical question amongst over 1 million biomedical articles published each year is hugely challenging. It is necessary to choose appropriate keywords to search databases for publications. Strategies that increase the accuracy and efficiency of searches are available at the site established by the Centre for Evidence-Based Medicine (http://www.cebm.net/category/ebm-resources/). A systematic search needs training and practice and input from a librarian or information scientist. It requires careful choice of keywords, which need to be matched to medical subject heading terms and combined using Boolean operators such as 'and' or 'or'. Within PubMed, three tools which are particularly useful include PubMed Clinical Queries, PubMed Slider Interface for Medline and PubMed, and PubMed Related Article.

Appraise: critical evaluation of the literature

Because of methodological variations, recommendations from guidelines and the conclusions of systematic reviews and primary research papers cannot all be accepted with confidence. Many may be methodologically sound but not be directly relevant to the particular clinical question under consideration. Some may not be affordable, feasible or culturally acceptable. Thus it is important that all search contents are subjected to a rigorous process of evaluation in the local context.

Guidelines

Guidelines can vary in quality. Good clinical guidelines must be multidisciplinary, evidence-based and evidence-linked. The Grade Working Group [2] offers useful advice on how to link guidance to the strength of the evidence base and its relevance to the clinical question and its context. A good guideline needs to be scientifically valid, usable and reliable. Most importantly, it must lead to better patient outcomes [3]. The AGREE collaboration has developed an appraisal instrument for clinical guidelines, tested it across a number of countries and found it to be user-friendly and consistent and able to discriminate between guidelines of varying quality. Criteria for high-quality clinical guidelines include clear articulation of scope and purpose, stakeholder involvement, rigour of development, clarity of presentation, applicability and editorial independence. It is available at www.agreecollaborartion.org.

Systematic reviews

A systematic review generates an overview of relevant studies using an explicit, methodical and reproducible way to locate, appraise and synthesize data. It may or

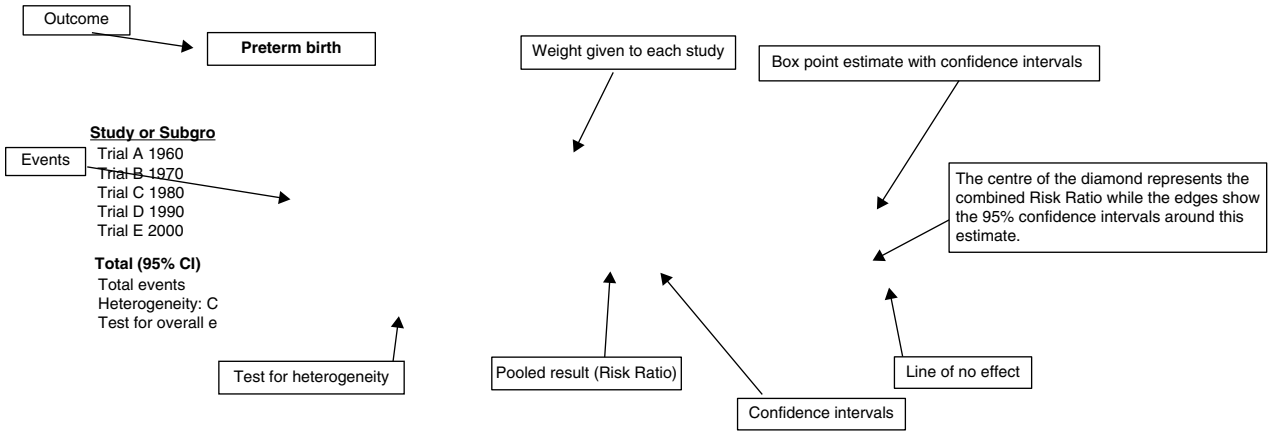

Figure 70.2 Forest plot of aggregated data from randomised trials.

may not include formal aggregation of quantitative data from individual studies or meta-analysis. Results of meta-analysis are often presented as Forest plots (Fig. 70.2). Good systematic reviews have a clear question, comprehensive and methodical search of the literature, explicit criteria for inclusion and exclusion of studies, assessment of study quality and meta-analysis where appropriate. As sources of high-quality evidence, well-conducted systematic reviews of randomized trials are preferable to individual randomized trials, as single studies may be unrepresentative of the total literature on a subject. Inconsistent results across studies can be explored and the ability to pool data allows greater precision around estimation of effects in interventions.

An initial appraisal of the quality of a systematic review should include an assessment of the credibility of the methods used and confidence in the effect estimates [4], i.e. the validity of the methods and effect size and precision of the results. The results of any research need to be relevant to the local context, be applicable to the patient group under consideration and address outcomes which are important for patients. The treatment must be affordable and provide benefits which outweigh any harms. Formal ways of evaluating the quality of systematic reviews are discussed below.

Randomized trials

A randomized trial should be able to transcend many of the risks of bias associated with observational studies. In large trials, random allocation to the treatment or comparison group should result in women in both arms being similar as regards known and unknown confounders. Differences in treatment outcomes between them can then be assumed to be genuinely due to the treatment itself rather than any other factor [5]. Non-randomized studies with control arms may offer some information about the effect of the treatment in question but they could exaggerate the potential benefits of treatment due to deliberate selection of women most likely to benefit from it. Because flaws in the design, conduct, analysis and reporting of randomized trials can distort the impact of treatment, a formal assessment of risk of bias is important in assessing trial quality. There are a number of sources of bias associated with the conduct and reporting of clinical trials.

Selection bias can occur if there are major differences between the randomized groups that could influence the outcome of the intervention being evaluated, and can be minimized by using robust methods for random sequence generation. Concealment of allocation up until the point of randomization is critical in order to avoid any chance of prior knowledge about which option (intervention or comparison) a participant would receive. Performance bias can be mitigated by masking participants and clinicians so that knowledge of the allocated intervention does not influence care or interpretation of outcomes. Masking of personnel can also minimize the risk of detection bias, where knowledge of the intervention received could affect interpretation and reporting of outcomes. Attrition bias reflects loss of patients to follow-up in a non-random fashion and could bias the final results; this can be avoided by ensuring that outcomes are reported in all patients, with clear reasons for any exclusions. Finally, reporting bias can occur if only certain outcomes were included in the final publication. The Cochrane risk of bias tool [6] addresses potential chances of selection, performance, detection, attrition and reporting bias as well as any other sources of bias in a systematic manner with clear criteria for reporting high, low or unknown risk of bias.

Diagnostic test accuracy studies

Tests used in clinical practice are usually evaluated by diagnostic accuracy studies in terms of sensitivity, specificity, predictive values and likelihood ratios. Conventionally, patients are classified into those who test either positive or

negative for a particular condition. A common way of evaluating tests is to determine the proportions of patients with normal and abnormal test results who are identified correctly. Sensitivity is the proportion of true positives and specificity refers to the proportion of true negatives that are correctly identified by the test. However, none of these parameters gives us an estimate of the probability that the test will give the correct diagnosis. This information is presented in terms of positive and negative predictive values. Positive predictive value represents the proportion of patients with positive test results who are correctly diagnosed while negative predictive value is the proportion of patients with negative test results who are accurately identified. The predictive value is strongly influenced by the prevalence of the condition under investigation. If the prevalence of the disease is very low, the positive predictive value will be poor even if both sensitivity and specificity are high. In population-based screening, as in cervical smear tests, it is inevitable that many women with positive test results will be false positives. We can compare the probability of getting a test-positive result if the patient truly had the condition of interest with the corresponding probability if he or she were healthy. The ratio of these probabilities is called the likelihood ratio, calculated as sensitivity/(1 – specificity). The likelihood ratio indicates the value of the test for increasing certainty about a positive diagnosis. In general, the higher the likelihood ratio of an abnormal test, the greater its usefulness. For example, likelihood ratio values of 10 or more suggest that the test could be extremely useful, while a value of 1 suggest that it is useless. For a negative test, a likelihood ratio of 0.1 or less suggests that it is useful, while a value of 1 indicates that it is not. In practice, the applicability of a test depends on a given context, prevalence of the condition being tested for, clinical and cost consequences of being test positive, and personal preferences of the patient.

Observational studies

While randomized clinical trials are the best way of assessing effectiveness of treatments, data from observational studies are useful sources of evidence in answering questions regarding cause, diagnosis and prognosis of clinical conditions. Most randomized trials are able to report on adverse effects which are relatively infrequent and/or take many years to present due to limitations of power and duration of follow-up. Large observational studies with long-term follow-up data can be helpful in terms of identifying long-term side effects as well as demonstrating whether the outcomes achieved in the context of a trial can be duplicated in an unselected population.

Where trials do not exist, are underway or are simply not feasible due to ethical or other considerations, the only source of data on the effectiveness of an intervention could be controlled non-randomized prospective studies (i.e. cohort studies). It must be remembered that these studies are prone to bias and their results could be overturned by the results of future randomized trials. For example, observational data on hormone replacement therapy suggested that it was protective against myocardial infarction, but randomized trials suggested an increase in risk [7].

Formal methods used for critical appraisal of systematic reviews and primary research studies

There are several sources of guidance for critical appraisal of research studies. The Centre for Evidence-Based Medicine offers training as well as practical tools for critical appraisal (http://www.cebm.net/critical-appraisal/). One of these is CATmaker (http://www.cebm.net/catmaker-ebm-calculators/), a computer-assisted critical appraisal tool that helps to create Critically Appraised Topics (CATs). The Critical Appraisal Skills Programme (CASP, http://www.casp-uk.net/#!casp-tools-checklists/c18f8) also offers a set of tools which assist clinicians in assessing the quality of research evidence. CASP favours a three-step approach, assessing first the validity of the results to decide whether the study was unbiased by evaluating its methodological quality. The second step is to consider whether the study's results are clinically important and the level of precision around the results. The final step is establishing how the data apply to a specific question and how likely it is that the intended population shares the same characteristics as those of the research subjects. Criteria for assessing the quality and relevance of systematic reviews, randomized trials and diagnostic studies are summarized in Table 70.3.

Applying the evidence

One of the major challenges is the global evaluation of the best available evidence not just in terms of precision but also validity and local relevance in order to estimate our level of confidence and inform the strength of any clinical recommendations arising from it. The Grading of Recommendations Assessment, Development and Evaluation (GRADE) system has addressed this issue by categorizing the quality of evidence into four groups [8]. High quality indicates that further research is very unlikely to change our confidence in the estimate of effect. Evidence is deemed to be of moderate quality if further research is likely to have an important impact on confidence in the estimate of effect and could change it. Low quality implies that further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate. Very low quality evidence suggests significant uncertainty around any estimate of effect [8]. Results of randomized controlled trials

Table 70.3 Criteria for critical appraisal Based on the Critical Appraisal Skills programme (CASP) checklists (http://www.casp-uk.net/#!casp-tools-checklists/c18f8)

	Systematic reviews	Randomised trials	Test accuracy studies
Validity	Clear research question	Clear research question	Clear research question
	Inclusion of papers with the appropriate design	Random allocation of patients to treatments	Appropriate reference standard (gold standard test)
	Relevant studies included	Masking of participants and clinicians	New diagnostic test and reference standard administered to all
	Quality assessment of the included studies	Similar baseline characteristics	Test results independent of results of reference standard
	Clear justification for aggregation of data	No difference in clinical care between intervention and comparison group apart from allocated treatment	Clear description of disease status of the tested population
		All participants accounted for	Detailed description of test
Precision	Effect size		
	Precision of effect size (confidence intervals)		
Relevance	Applicability of the results to the local population		
	Inclusion of all important outcomes		
	Balance of benefits versus potential harm and costs		

are initially regarded as high-quality evidence, but can be downgraded for several reasons: study limitations, inconsistency of results, indirectness of evidence, imprecision and reporting bias. Study design and precision of results have been discussed earlier. Consistency refers to similarity in the direction of effect across studies, an explanation for outliers and plausible outcomes in subgroups. Directness signifies the extent to which people and outcomes in the literature are relevant to those of interest. This can be due to a number of factors, including lack of direct comparison, differences in the nature of individual treatments within a single generic group, publication of surrogate rather than definitive outcomes, and cultural differences in perceptions of harm and benefit.

Conversely, observational studies reporting on treatment outcomes are rated as 'low quality' but may be upgraded if the effect of an intervention is substantial, if there is a convincing dose–response relationship or if all plausible biases are likely to decrease (rather than inflate) the magnitude of any treatment effect.

Applying the results of critical appraisal involves interpreting the evidence in the local context and integrating it with clinical expertise and awareness of patients' values and expectations. In the first instance, a key question is whether the findings are applicable to the specific patient group. It requires consideration as to whether the treatment or test would be effective in the patient or clinic population concerned and asks the question: Are there reasons to believe that the results from the literature would not apply to them? Many treatments which are otherwise effective are associated with adverse effects, such as drug side effects or operative and postoperative complications. While a detailed analysis may not always be possible, it is important that all clinically relevant outcomes are assessed over a reasonable period of time, thus allowing a balanced appraisal of the harms, benefits and costs.

Patients may have a different set of values which may inform their priorities and preferences around healthcare. Appreciation of the patient's perspective and facilitating a balanced discussion that allows joint decision-making are essential components of this step. If true EBM is to be practised, the current conflict between the objective collection of data and its subjective interpretation has to be addressed. Ways of overcoming bias at this very last stage of implementation include decision analysis, involving explicit decision-making algorithms [9] and computer-based decision support systems. In many situations, particularly in benign gynaecological settings, there could be several options which patients could consider. Involvement in the decision-making process and confidence in the decision made could improve their perceived effectiveness of the intervention itself.

Evaluating performance

True adherence to the principle of EBM requires clinicians to evaluate their own performance. This can involve assessing progress at each step of the process in terms of whether the questions asked were answerable, if evidence was identified and appraised and integrated with clinical expertise and the patient's circumstances to generate a rational treatment plan. It also allows the

clinician to reflect on whether the risks and benefits of treatment were considered along with the patient's own preferences [1].

Conclusion

EBM allows clinicians to offer treatments which are effective. This is accomplished through improved skills in asking relevant questions, finding and appraising the best evidence before application of the results in routine practice. Increased popularity of EBM has been accompanied by a growth in web-based access to clinical guidelines and systematic reviews as well as tools for critical appraisal. There is now universal agreement that successful decision-making in clinical situations needs to integrate the highest quality of evidence with clinical expertise and the values, preferences and personal circumstances of each patient.

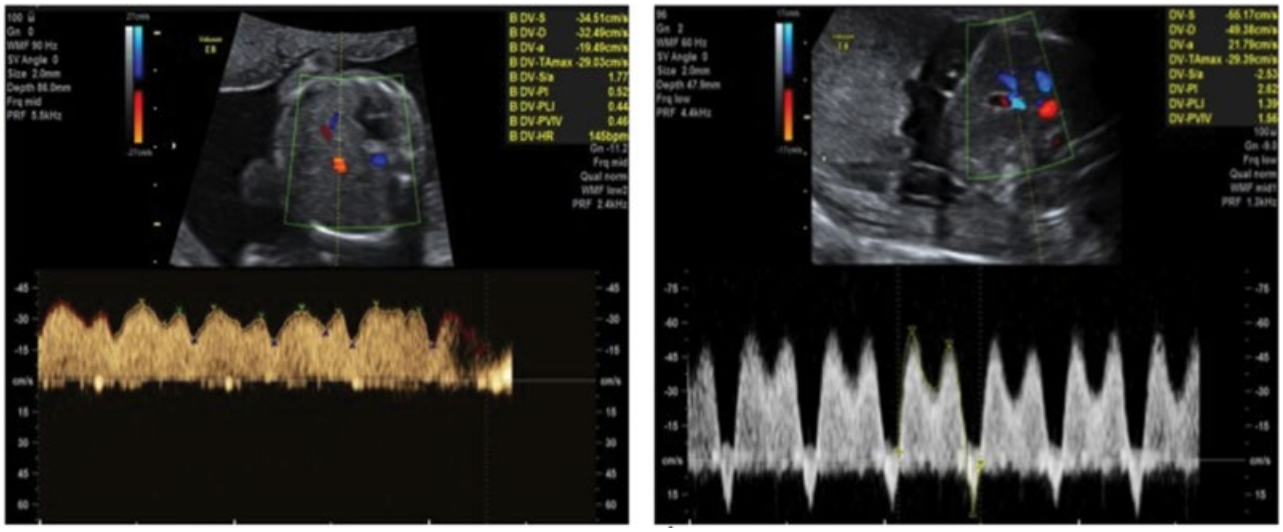

Plate 17.3 Ductus venosus waveforms: (a) normal; (b) reversed a-wave.

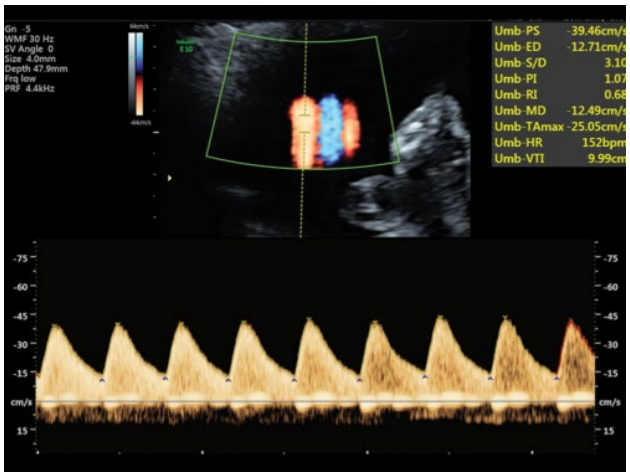

Plate 18.4 The umbilical artery is typically assessed in a free loop. The vein and arteries can be identified with colour Doppler and pulse wave is used to illustrate the waveform characteristics, which can be measured and compared with standardized charts. In this example there is forward flow in diastole, a normal finding in the third trimester of pregnancy.

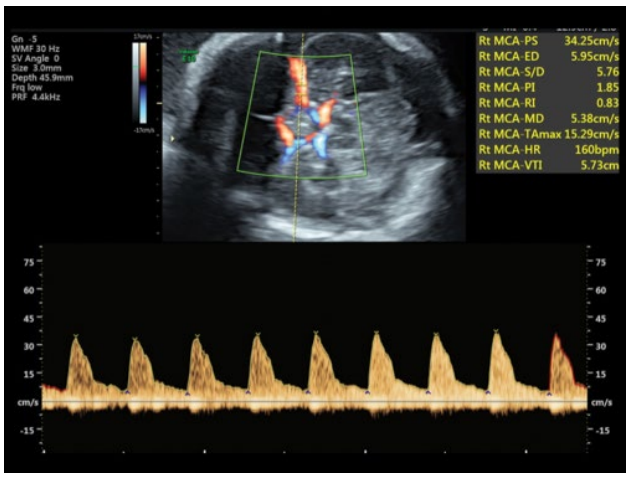

Plate 18.5 The middle cerebral artery waveform can also be assessed by first identifying the vessels running away from the circle of Willis, then using pulse wave to demonstrate the waveform (sampling approximately 5–10 mm away from midline structures). In this example there is low flow in diastole, a feature of normal perfusion.

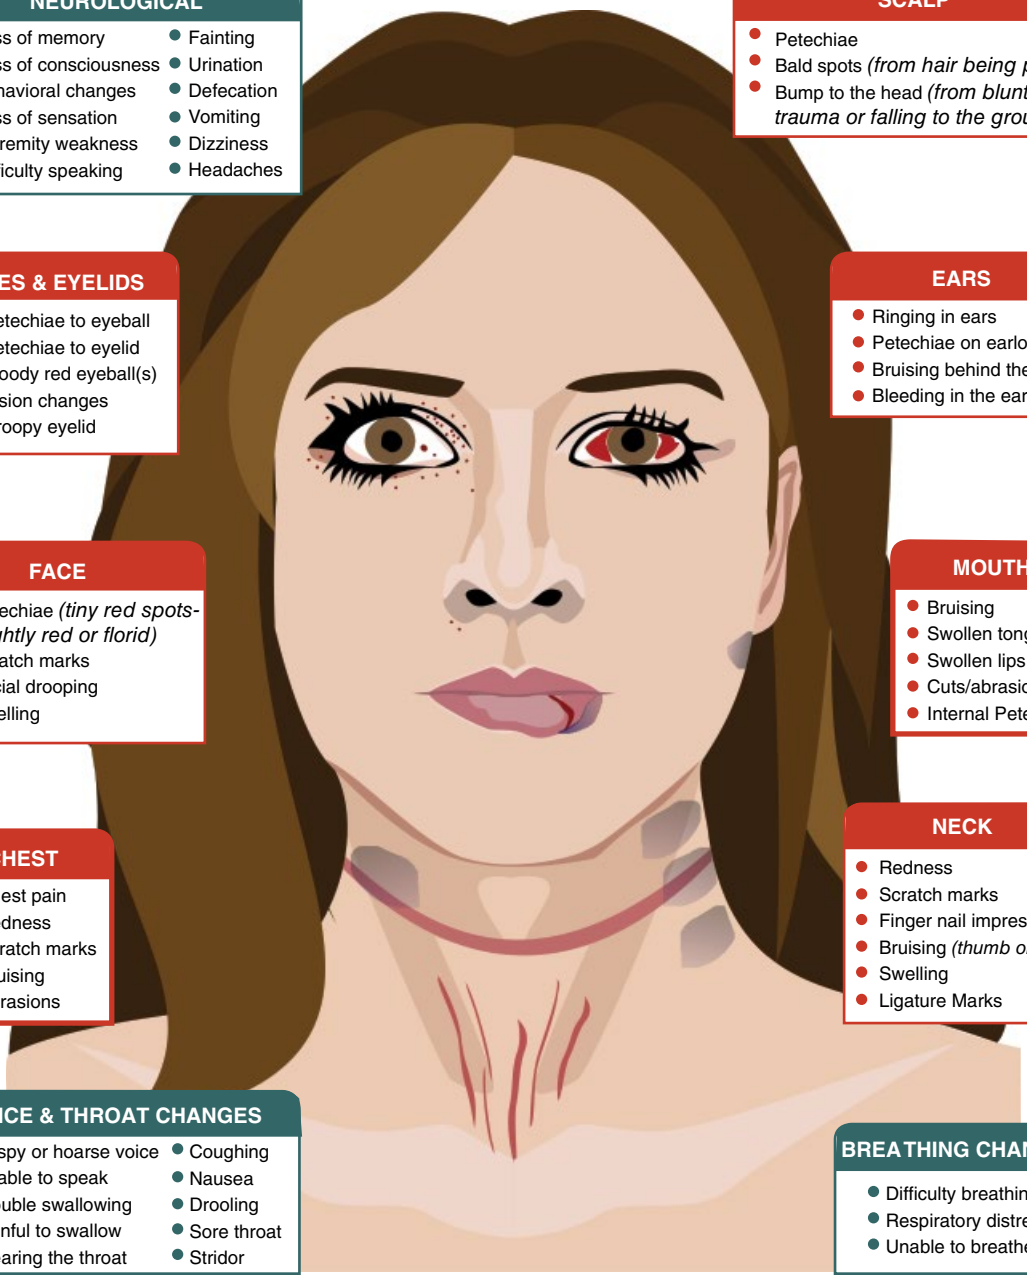
SIGNS AND SYMPTOMS OF STRANGULATION



NEUROLOGICAL

- Loss of memory
- Loss of consciousness
- Behavioral changes
- Loss of sensation
- Extremity weakness
- Difficulty speaking
- Fainting
- Urination
- Defecation
- Vomiting
- Dizziness
- Headaches

SCALP

- Petechiae
- Bald spots *(from hair being pulled)*
- Bump to the head *(from blunt force trauma or falling to the ground)*

EYES & EYELIDS

- Petechiae to eyeball
- Petechiae to eyelid
- Bloody red eyeball(s)
- Vision changes
- Droopy eyelid

EARS

- Ringing in ears
- Petechiae on earlobe(s)
- Bruising behind the ear
- Bleeding in the ear

FACE

- Petechiae *(tiny red spots-slightly red or florid)*
- Scratch marks
- Facial drooping
- Swelling

MOUTH

- Bruising
- Swollen tongue
- Swollen lips
- Cuts/abrasions
- Internal Petechiae

CHEST

- Chest pain
- Redness
- Scratch marks
- Bruising
- Abrasions

NECK

- Redness
- Scratch marks
- Finger nail impressions
- Bruising *(thumb or fingers)*
- Swelling
- Ligature Marks

VOICE & THROAT CHANGES

- Raspy or hoarse voice
- Unable to speak
- Trouble swallowing
- Painful to swallow
- Clearing the throat
- Coughing
- Nausea
- Drooling
- Sore throat
- Stridor

BREATHING CHANGES

- Difficulty breathing
- Respiratory distress
- Unable to breathe
