An intriguing characteristic of aMSCs is what seems to be unique immunogenic and immunomodulatory properties [71,72]. These cells appear to be immunologically privileged when compared to mesenchymal cells derived from fetal or adult tissue. Their depressed immunogenicity is stable or even further down regulated after multiple passages in culture [71,73]. It has been shown that MSCs enhance the engraftment of umbilical cord blood-derived CD34+ hematopoietic cells [68]. The amniotic fluid has been proposed as a useful source of MSCs to be cotransplanted with hematopoietic stem cells from the same donor [58]. This could be particularly useful in the setting of umbilical cord blood transplantation between siblings.

In utero, transamniotic gene transfer has shown some promise in animal models [74,75]. Young, highly proliferative, less differentiated fetal cells are natural targets for the optimization of gene therapy. Thus, amniotic and placental stem cells could certainly make useful targets for genetic manipulation. This is a potentially exciting development for the foreseeable future.

More recently, an actual biological role for aMSCs has been uncovered. It has been demonstrated that these cells actually enhance normal fetal wound healing [76]. This germane finding was apparently the first demonstration of a biological role for any amniotic cell. It also provided biological validation for the use of aMSCs in regenerative strategies. Within the

FIGURE 26.5
Representative gross view of a longitudinally opened aMSC-engineered tracheal implant at necropsy showing the intraluminal glistening typical of epithelialization, confirmed histologically.

spectrum of reparative and regenerative processes, fetal wound healing is closer to the latter than to the former. When compared with healing at any stage of postnatal life, wound healing in the fetus involves significantly less inflammation and can be almost scarless, particularly early in gestation. That study has added a new facet to fetal and general wound healing, and has also lent biological support to the use of these cells in a spectrum of conceivable regenerative strategies.

Finally, the translational relevance of aMSCs in fetal tissue engineering has been underlined by the viability of scaled up manufacturing of human aMSCs in compliance with regulatory guidelines and by the establishment of amniotic cell banks [77,78].

Embryonic-like stem cells

From the very little that is currently known about what could be more primitive, embryonic-like stem cells (ESCs) present in the human amniotic fluid, these cells are very scarce, representing zero (i.e., they cannot always be isolated) to less than 1% of the cells present in amniocentesis samples [59,61,62,64]. In addition, these cells have been identified mostly through markers commonly present in ESCs, such as (putatively – see next paragraph) Oct-4, stem cell factor, vimentin, alkaline phosphatase, CD34, CD105, and cKit, but these were not necessarily concomitantly expressed, nor are they exclusive of ESCs proper. Specifically, these markers can also be expressed, alone or in various combinations, in embryonic germ cells; embryonic fibroblasts; embryonal carcinoma cells; MSCs; hematopoietic stem cells; ectodermal, neural, and pancreatic progenitor cells; and fetal and adult nerve tissue; among others [50,67,79–81]. Telomerase activity, another marker for stem cell pluripotency, has also been detected in amniotic fluid cell samples.

As to Oct-4 expression, a central component of the characterization of pluripotency and supposedly expressed in these cells; it must be noted that a recent review study has revealed that the previous reports documenting its expression in these cells, and also in aMSCs, warrant careful re-examination with regard to vital technical pitfalls such as gene and protein isoforms, pseudogenes, and antibody choice, as well as primer design [82]. Although specific detection

of Oct-4A mRNA is achievable, an antibody that can reliably distinguish between Oct-4A (the correct isoform of Oct-4 associated with pluripotency and thus tumorigenesis) and the pseudogene Oct-4B actually remains to be described. Indeed, one could say that true pluripotency based on Oct-4A expression in these cells actually remains to be definitely established [82]. This is further underscored by the fact that these cells do not seem to be tumorigenic *in vivo*.

Still, it is well established that markers alone are not considered enough to characterize human ESCs. A uniform and universal differentiation potential needs to be demonstrated, which remains to be verified in these so-called amniotic ESCs. So far, some of the amniotic cells that express the markers mentioned above have been shown to differentiate into muscle, adipogenic, osteogenic, nephrogenic, neural and endothelial cells, but not necessarily from a uniform population of undifferentiated cells. On the other hand, in accordance with an ESC profile, these pluripotent cells seem to be clonogenic, as at least some of them express cyclin A, a cell cycle regulator. Therefore, although the data currently available can indeed be considered promising, final proof that true ESCs can be consistently isolated from the amniotic fluid, and at which gestational ages, remains to be established. Furthermore, multiple evidences of correspondence between what are considered amniotically-derived ESC-like cells and aMSCs point to the likelihood of basic nomenclature overlaps of what could be just one cell type receiving different names. Regardless, in light of the known presence of other, non-mesenchymal and non-ESC-like stem cells in the amniotic fluid, the simple term 'amniotic stem cell' is thus too vague.

PLACENTA

Different cell types are found in the placenta at different gestational ages, as a result of the mechanisms behind placental development. In humans, placental villous development starts between 12 and 18 days post-conception (p.c.), when the trophoblastic trabeculae of the placental anlage proliferate and form trophoblastic protrusions, the primary villi, into the maternal blood surrounding the trabeculae. Two days later, embryonic connective tissue from the extra-embryonic mesenchyme invades these villi, which then become secondary villi. Between days 18 and 20 p.c., the first fetal capillaries begin to appear in the now abundant mesenchyme of the villous stroma, marking the development of the tertiary villi, the first generation of which are the mesenchymal villi. Mesenchymal villi are the first structures providing the morphological requisites for materno-fetal exchange of gases, nutrients, and waste. They are also the precursors of all other villous types, namely immature intermediate villi, stem villi, mature intermediate villi, and terminal villi. At approximately the fifth week p.c., all placental villi are of the mesenchymal type. From about the 23rd week p.c. until term, the pattern of villous growth changes, with the mesenchymal villi transforming into mature intermediate villi, rather than into immature ones. During that phase, few mesenchymal and immature intermediate villi remain, in the centers of the villous trees, where they comprise a poorly differentiated growth reserve.

As shown above, placental villous sprouting entail active growth of both trophoblastic and mesenchymal tissue components in a coordinated fashion. Further differentiation of the mesenchymal villi into immature or mature intermediate villi is a determining factor in the balance between growth and maturation of the placenta, which, in turn, has a direct impact on the cell types that can be isolated from the placenta at different gestational ages.

The genetic and molecular mechanisms behind placental development have hardly begun to be clarified and should also have a bearing on the pluripotency of placental cells. Interestingly, against the conventional wisdom of searching for placental-specific genes that would control this process, most of the genes that have been shown to be essential for placental development are also involved in the development of other organs [83]. No more than a very limited set of genes is expressed exclusively in the placenta [83].

Since much of the placenta comes from the inner cell mass of the morula, the presence of embryonic progenitor cells in the placenta has long been proposed. More specific types of stem cells, such as trophoblastic, hematopoietic, and MSCs have also been identified in the placenta. Trophoblast stem cells, also known as trophoendoderm stem cells, are defined as cells with the potential to give rise to all differentiated trophoblast cell subtypes, as well as to yolk sac phenotypes. Interestingly, one trophoblast subpopulation, the cytotrophoblasts of the basal decidua, may undergo a full transition to mesenchymal phenotype when they infiltrate maternal mesenchymally-derived uterine stroma and arterial walls. At present, trophoblast stem cells have limited, if any, foreseeable potential for clinical application and will not be reviewed here. Placental/umbilical hematopoietic stem cells have already shown high clinical relevance, but can also be isolated from umbilical cord blood and will be reviewed in another chapter. Placental mesenchymal stem cells (pMSCs) and more primitive, ESCs will be further discussed below.

pMSCs

As described above, the placenta has a large mesenchymal component. While the role of this component in placental development has yet to be better understood, we already know that it relates, in part, to the pluripotent potential of pMSCs. For example, recruitment of these cells supports the so-called vasculogenesis that occur during vascularization of the villous sprouts, in addition to the angiogenesis based on the proliferation of endothelial precursors. These mesenchymal cells also play other roles in placental development, such as the paracrine signals that they send to control the stability of the cytotrophoblast column, which in turn determines the degree of trophoblast invasiveness. Yet, much about the mesenchymal core of the placenta remains to be elucidated.

pMSCs can be isolated by a number of different protocols. We have described an easily reproducible method, analogous to the one described above for the separation of aMSCs (i.e., based on mechanical separation and natural selection by the culture medium), which can be employed in both 'full thickness' and chorionic villus sampling placental specimens [29,65]. These cells have unique characteristics when compared with other mesenchymal cells. They proliferate more quickly in culture than comparable cells harvested from fetal or adult tissue, at a similar rate to that of aMSCs [29,65]. Also like aMSCs, they are often stained by monoclonal cytokeratin antibodies, which is a rare finding in mature mesenchymal cells, but common in fetal and umbilical stroma, smooth muscle tumors, and stromal cells associated with reactive processes. It is as yet unclear whether this immunoreactivity is a result of cross-reactivity between a common epitope found in smooth muscle cells, myofibroblasts, and intermediate-sized filaments of cytokeratin, or whether it actually indicates cytokeratin expression in non-epithelial cells.

In addition to their natural differentiation into smooth muscle cells during placental development, pMSCs have been shown to be able to differentiate into all mesodermal, as well as some neural cells lineages, *in vitro* [84,85]. Given the many similarities between pMSCs and aMSCs, as shown above, it is reasonable to speculate that these two cell subsets are actually the same. This, however, remains to be unequivocally demonstrated.

Embryonic-like stem cells

The embryonary origin of the placenta renders it a natural candidate for a reservoir of ESCs. From the few reported attempts to isolate ESCs from the placenta, like their amniotic counterparts, what could be ESCs are present in zero to less than 1% of the cells present in placental samples. These cells have also been identified mostly through certain markers, including CD34, CD105, and cKit, that, again, were not necessarily concomitantly expressed and are not exclusive of ESCs.

These pluripotent cells have shown potential for self-renewal, but a uniform and universal differentiation potential of these cells also remains to be verified. Like their amniotic counterparts, thus far some of these cells have been shown to differentiate into a variety of cell types, but not necessarily from a uniform population of undifferentiated cells. Another limitation of the existing data is the fact that the placenta is rich in hematopoietic stem cells, known not to be committed solely to the hematopoietic lineage. In addition to blood cells, they can also give rise, at least, to neurons, hepatocytes, and muscle cells, and might have contributed to the differentiation findings reported to date. Again, although the existing data is promising and in accordance with the origins of the placenta, final proof that true ESCs can be consistently isolated from that organ, and at which gestational ages, remains to be verified.

Another interesting potential development of the study of placental cells is the establishment of 3D models of the placenta and of maternal-fetal circulation through the maintenance of live engineered placental models in bioreactors. This could lead to a better understanding of normal and pathological placental physiology, possibly with indirect therapeutic benefits.

MATERNAL BLOOD

Fetal cells can be documented in the maternal circulation in the majority of human pregnancies. Fetal progenitor cells have been found to persist in the circulation of women for up to decades after childbirth [10]. Of particular interest, a novel population of fetal cells, often termed pregnancy-associated progenitor cells (PAPCs), appears to differentiate in diseased/injured maternal tissue, apparently providing some degree of local repair. The precise phenotypical identity of these cells, however, remains controversial. They have been considered to be a hematopoietic stem cell, a MSC, or possibly a novel cell type. At this time, peripheral maternal blood has yet to be proven as a viable source of fetal cells in consistently high enough numbers for tissue-engineering applications. This appealing perspective, however, surely deserves continued scrutiny.

ETHICAL CONSIDERATIONS

The use of fetal tissue has always been object of intense ethical debate. The main reason for the ethical controversies comes from the fact that the primary source of fetal tissue is induced abortion. Spontaneous abortion usually does not raise many moral issues. The National Institutes of Health, the American Obstetrical and Gynecological Society and the American Fertility Society, in accordance with the provisions that control the use of adult human tissue, have been regulating the use of fetal specimens from this latter source for decades. However, spontaneous abortion generally yields unsuitable fetal tissue, as it is frequently compromised by pathology such as chromosomal abnormalities, infections and/or anoxia. Arguments over the use of fetal tissue from induced abortion are largely based on somewhat limited scientific evidence, along with clashing religious and customary beliefs about the beginning of life. Not surprisingly, despite the efforts of numerous national and international ethical committees and governmental bodies, a consensus has not yet been reached. In the US, in spite (or perhaps because) of an ongoing moratorium on federal funding for fetal tissue transplantation research, an agreement on this issue may be slowly forming, albeit a stable solution should still be years away.

This polemic notwithstanding, tissue engineering, as a relatively novel development in fetal tissue processing, adds a new dimension to the discussion concerning the use of fetal tissue for therapeutic or research purposes. If specimens from a live, diseased fetus, or cells from a routine prenatal diagnostic procedure such as an amniocentesis or chorionic villus sampling, are to be used for the engineering of tissue, which in turn is to be implanted in autologous fashion, no ethical objections should be anticipated, as long as the procedure is a valid therapeutic choice for a given perinatal condition. In that scenario, ethical considerations are the very same that apply to any fetal intervention. On the other hand, if fetal-engineered tissue

is to be implanted in heterologous fashion, ethical issues are analog to the ones involving fetal tissue/organ transplantation, regardless of whether the original specimen comes from a live or deceased fetus, or from banked fetal cells obtained from the amniotic, placenta, or umbilical cord blood.

The distinction between autologous and heterologous implantation of engineered fetal tissue is a critical one in that, again, no condemnation of autologous use could be ethically justified. At the same time, regardless of whether an autologous or heterologous application is being considered, should the amniotic fluid or fetal annexes be definitely confirmed as dependable sources of ESCs, the ethical objections to embryo disposal now plaguing the progress of ESC research could possibly be avoided.

THE FETUS AS A TRANSPLANTATION HOST

One could envision a number of advantages of a fetus receiving an engineered construct *in utero*, not only from a theoretical perspective, but also from clinical and experimental evidence derived from intra-uterine cellular transplantation studies already reported. Those potential advantages encompass: induction of graft tolerance in the fetus, due to its immunologic immaturity; induction of donor-specific tolerance in the fetus by concurrent or previous intra-uterine transplantation of hematopoietic progenitor cells; a completely sterile environment; the presence of hormones, cytokines and other intercellular signaling factors that may enhance graft survival and development; the unique wound healing properties of the fetus; and early prevention of clinical manifestations of disease, before they can cause irreversible damage. Most of those advantages should be more or less evident, depending on the gestational timing of transplantation.

Fetal immune development

Among the potential benefits of *in utero* transplantation, the singularity of the fetal immune system deserves special attention. In that respect, basic research on fetal development, as well as studies involving pre and postnatal transplantation of lymphohematopoietic fetal cells have contributed to a better understanding of the fetal immune response.

Fetal tolerance resulting in permanent chimerism has long been shown to occur in nature in non-identical twins with shared placental circulation [86,87]. Little is known, however, about precisely when and by what mechanism this tolerance is lost. During fetal development, the precursors of the hematopoietic stem cells arise in the yolk sac, migrate to the fetal liver and then to the thymus, spleen and bone marrow. The fetal liver has its highest concentration of hematopoietic stem cells between the 4th and the 20th week of gestation. Because of their cellular immunologic 'immaturity', the fetal liver and, to a lesser extent, the fetal thymus have been studied as potential sources of hematopoietic stem cells for major histocompatibility complex/incompatible bone marrow transplantation for more than half a century now. Umbilical cord blood has been increasingly employed as a source of hematopoietic stem cells, in both autologous and heterologous applications [88,89].

Lymphocytes capable of eliciting graft versus host disease (GVHD) are found in the thymus by the 14th week of gestation, but not detectable in the liver until the 18th week. Despite considerable numbers of granulocyte-macrophage colony-forming cells, there is an almost complete absence of mature T cells up to the 14th week in human fetal livers. During gestation, while B cell development takes place mostly in the liver, T cell development occurs predominantly in the thymus. This fact is probably the reason why fetal liver cells are immunoincompetent for cell-mediated and T cell-supported humoral reactions, such as graft rejections and GVHD. Thus, in principle, tissue matching is not necessary in fetal liver transplantation, if this is harvested up to a certain point in gestation. In a number of animal models and small clinical series, fetal liver cells have induced no or merely moderate GVHD in

histoincompatible donor/recipient pairs. More recently, unique sub-populations of innate lymphoid cells (ILCs), a family of effectors and regulators of innate immunity and tissue remodeling, have been isolated from fetal lung and intestine [90]. The significance of this finding and its potential translational implications has only started to be explored.

Although fetal liver stem cells should not cause GVHD, they could still be subject to rejection. Because of this, fetal liver stem cell transplantation has been attempted in the clinical setting preferably in patients with depressed immune function, such as in immunodeficiencies, replacement therapy during bone marrow compromise and during fetal life (*in utero* transplantation). The same principle applies to the use of fetal thymus. Fatal cases of GVHD are considered much less likely in patients who receive fetal liver stem cells harvested before the 14th week of gestation. This complication, however, has been reported in a patient who received liver cells from a 16-week-old fetus [91]. With umbilical cord blood stem cell transplantation, the incidence of GVHD has been minimal [88,89]. Umbilical cord blood-derived MSCs have also been shown to help prevent (but not treat) GVHD in a rodent model [92].

On the other hand, umbilical cord and placental blood, while rich in hematopoietic progenitor cells, contain alloreactive lymphocytes. Although those lymphocytes are also immature, it is unclear, however, whether they are more or less reactive than adult ones. Compared with those from adult blood, the proportions of activated T cells and helper-inducer subsets (CD4/29) are significantly reduced, while the helper-suppressor (CD4/45A) subset is significantly increased [93]. Cord blood natural killer cell activity is low or similar to that in adult blood, but lymphokine-activated killer cell activity may be higher.

Another germane aspect of intra-uterine transplantation is the fact that maternal cells trafficking into the fetus may pose as the chief barrier to effective engraftment of allogenenic cells or tissues delivered prenatally. It has been recently demonstrated experimentally that there may be macrochimerism of maternal leukocytes in the fetal blood of, with substantial increases in T cell trafficking after intra-uterine transplantation [94,95]. This suggests that the clinical success of intra-uterine transplantation, at least of hematopoietic stem cells, may be improved by transplanting cells also matched to the mother.

APPLICATIONS OF *IN UTERO* TRANSPLANTATION

Cellular intra-uterine transplantation has been employed clinically for decades now, to treat a variety of diseases, including lymphohematopoietic diseases, beta-thalassemia, inborn errors of metabolism and genetic disorders, with some success. Knowledge of the optimal gestational age for transplantation, along with cell selection, route of cell administration and post-interventional tocolysis is still evolving. *In utero* hematopoietic stem cell transplantation is a non-myeloablative approach to achieving mixed hematopoietic chimerism and associated donor-specific tolerance, improving survival of other grafts later in life. Through prenatal transplantation of hematopoietic progenitor cells, both allogeneic and xenogeneic chimerisms have been induced in animal models and allogeneic chimerism has been achieved in humans [15,96–98]. A recent development in prenatal cell transplantation is neural stem cell delivery to the fetal spinal cord as a means of reversing at least some of the local damage associated with neural tube defects, i.e., different variations of spina bifida [13].

Tolerance of allogeneic intra-uterine implantation of an engineered construct has recently been first demonstrated in an ovine model of fetal tracheal reconstruction with heterologous cartilage engineered from aMSCs [33]. In like manner, tolerance to an airway construct made with autologous aMSCs and a xenologous decellularized matrix has also been shown in a fetal ovine model [43]. Clinically, structural airway anomalies could be justifiably repaired prenatally in select patients with defects so severe that breathing would otherwise be simply impossible at birth. Further potential benefits of prenatal implantation of engineered tissue,

such as for example advantages stemming from the unique wound healing capabilities of the fetus, among other potentially unsuspected ones, are yet to be fully explored.

CONCLUSIONS

Fetal tissue engineering may become a preferred perinatal alternative for the treatment of a number of birth defects. Given the recently proven viability of minimally invasive fetal cell sources, such as amniotic fluid, placenta, and umbilical cord blood, the promise of fetal tissue engineering applies to both life-threatening and non-life-threatening anomalies. Fetal progenitor cells from various sources are progressively becoming relevant, if not indispensable tools in research related to stem cells, tissue engineering, gene therapy, and maternal-fetal medicine.

Still, much remains to be learned and a variety of evolutionary paths, including unsuspected ones, have yet to be pursued in this relatively new branch of tissue engineering. The whole subfield of *in utero* implantation of engineered tissue also waits to be fully explored. Fetal tissue engineering shall also benefit from the progress expected for the different aspects of tissue engineering in general. Fertile experimental work from an increasing number of groups has introduced promising novel therapeutic concepts utilizing fetal cells. As long as progress is made in the ethical debate over the use of these cells and their banking, the reach of fetal tissue engineering, nonetheless, will likely go beyond the perinatal period, offering unique therapeutic perspectives for different age groups.

CHAPTER 27

Immunomodulation

Denise L. Faustman
Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts

INTRODUCTION

A long-standing goal of the transplant community has been to overcome the immunological rejection of transplanted tissues and organs. Although much of the research has been devoted to identifying new immunosuppressive agents and new combinations of existing agents for allotransplantation, immunosuppression still carries significant long-term side effects, especially enhanced susceptibility to infection. For xenografts, even stronger immunosuppression is necessary. One solution to allograft or xenograft acceptance may reside in novel therapeutic strategies that strive to prevent the need for long-term and high-dose immunosuppression.

Our laboratory has attempted to avert transplant rejection by immunologically modifying the foreign proteins on cells and tissues from the donor, instead of treating the host. Tissues and cells treated before transplantation allow the concealment or elimination of the antigens that summon immune rejection. This technology is sometimes referred to as 'donor antigen modification' or, more stylistically, 'designer tissue and organs' [23]. The goal is to avoid or reduce the need for immunosuppression by directly modifying the graft at the molecular or protein level. Modification at the *cellular* level, by eliminating donor lymphoid cell populations, had been previously successful in murine allografts. These cellular modifications were effective for whole organs and cell transplants in lower species, even for the avoidance of xenograft rejection. Designer tissues and organs modified at the *molecular* or *protein* level offer an alternative approach with greater selectivity and latitude in tailoring the graft to escape immune detection by the host.

Without the risks of massive doses of systemic immunosuppression, designer tissues and organs could be therapeutic for a broad range of chronic conditions that are not life threatening. They also could be offered to conventional organ transplant patients at earlier stages of their disease, when patients are healthier and better able to withstand surgical intervention. The main risk with designer tissues and organs is that the modified donor tissue could be rejected, a risk commonly encountered with any transplant. Because designer tissue can be potentially rendered safer and may ultimately avoid host intervention with toxic drugs, a broader spectrum of diseases could be treated and at earlier time points.

The purpose of this chapter is to describe the evolution of research into designer tissues, and to trace its contribution to a growing body of transplant research. The first success was with murine hosts given transplants of xenogeneic cells and tissues that had been modified at the *protein* level. This success allowed extension of the concept to the molecular level in the form of DNA modifications. This ability to modify proteins at the DNA, RNA, or protein level offers tremendous versatility in developing new cells or organs as biological therapies. Variations on the designer tissue concept are being probed in animal models of diabetes, solid organ failure, and neurological diseases. A concept launched in the laboratory in the early 1990s has already

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00027-6

culminated in landmark human clinical trials for Parkinson's and Huntington's disease using donor-modified pig neurons in humans.

The wide range of applications of designer tissues and organs for allo- and xenotransplantation is readily apparent; modified donor cells, tissues, and organs can be considered potential therapies for an almost limitless number of conditions as long as the dominant antigens are identified and then effectively shielded or eliminated prior to implantation.

ORIGIN OF THE DESIGNER TISSUE CONCEPT

The idea of targeting donor antigens instead of modifying the host immune system was stimulated by research on the molecular events surrounding the killing of cancer cells by cytotoxic T lymphocytes (CTLs; hereinafter referred to as T cells). In an elegant study, Spits and co-workers [1] identified the sequential stages of T cell destruction of the cancer cell. In contrast to earlier research, which focused primarily on the T cell, they examined the roles of cell surface markers on both the T cell and the target cell. By using antibodies against different cell surface markers on the cancer cells they were able to block distinct obligatory stages of T cell activation and destruction. They were able to tease apart *in vitro* the interactions between molecules on the T cell and the target cell. Spits and colleagues were among the first to identify three stages in T cell cytotoxicity:

1) Adhesion between T cell and target cell through two adhesion proteins,
2) T cell receptor activation through class I, and
3) T cell lysis of the tumor target cell through persistent class I and T cell receptor binding.

A critical finding was that one of the major classes of histocompatibility antigens on the surface of the cancer cell — the major histocompatibility complex (MHC) class I molecules — was involved in both adhesion to, and activation of, the T cell. Class I antigens and other classes of antigens encoded by the MHC complex serve to distinguish 'self' from 'non-self' because they differ across species and between members of the same species. Class I antigens had long been suspected of eliciting T cell cytotoxicity, but this study offered more detailed insight into their pivotal role. What this study also demonstrated was that antibodies to class I antigens on the cancer cell could block T cell adhesion and activation, thereby preventing lysis of the target cell. Indeed, further studies in the cancer field over the years have endeavored to dissect how this escape mechanism of down regulation of MHC class I is used by tumor cells naturally as a selection process to avoid immune detection [2].

Spits and co-workers crystallized the importance of class I antigens in immune rejection of cancer cells. While this study's goal was to dissect and promote CTL killing of the target, our goal was the opposite: to prevent tissue rejection at the same T cell target interface. We chose to 'mask' class I antigens on donor cells by using antibody fragments to class I, a system that prevented death of the target, and then transplant the modified donor cells into non-immunosuppressed hosts.

FIRST DEMONSTRATION OF THE CONCEPT

The first successful demonstration of the designer tissue concept used a xenogeneic model [23]. The cellular graft in the form of insulin secreting islets was coated with antibody fragments to conceal class I antigens, the grafted cells (of human origin) indefinitely eluded the immune system of the murine host. The grafted cells also functioned normally. The host even developed tolerance to the treated graft, as secondary transplants of untreated tissue were later accepted. The mechanism of donor-specific tolerance is still not fully defined, but may involve induction of T cell anergy through altered donor class I density. Altered class I density may be pivotal in T cell shaping in both the periphery as well as the thymus, as defined by Pestano et al. [3].

The graft consisted of purified human cadaveric islets that had been incubated with antibody fragments before being implanted into non-immunosuppressed mice. Pure antibody fragments that lack the portion of the antibody molecule that binds complement, the Fc fragment, were obligatory to prevent lysis of the target. When the Fc fragment is enzymatically cleaved from the $F(ab')_2$ fragment, the purified $F(ab')_2$ fragment binds to the graft for several days without fixing complement; this prevents the graft from being destroyed. Grafts survived for 200 days and functioned appropriately, as determined by assays for human C′-peptide, a proinsulin processing product. Finally, human liver cells similarly treated with antibody fragments also survived for an extended period.

Treatment with whole antibodies to class I antigens failed to prolong graft survival. Whole antibody class I proteins coated the donor cell, but also, upon transplantation, killed the cell due to host derived complement. Treatment with antibodies and antibody fragments to CD29 was effective in an allogeneic transplant barrier using cells, but not in a xenogeneic barrier. CD29 is an antigen with restricted expression on the passenger lymphocytes that accompany the graft. Passenger lymphocyte elimination can be important for allografts but less important for cross-species transplants. Treatment of cellular grafts with polyclonal antibody fragments to all antigenic determinants prior to transplantation did prolong allograft, and xenograft survival. Polyclonal antibody fragments with class I antibody fragment removal had minimal effects at facilitating cellular transplants.

For the sake of rigor, it is generally accepted that xenografts represent a more challenging transplant barrier than allografts. Furthermore, if experimental test concepts are applied to xenografts with success, similarly enhanced allograft survival is likely to ensue. If designer tissues could succeed in a difficult xenogeneic case, then these same procedures could be considered for simpler allogeneic transplant models. Additionally, cellular transplant models represent the intermediate model of simplicity. In the setting of cells, the graft tissue contains one dominant antigen that needs to be masked. For instance, human islet tissue stongly expresses class I antigens, while displaying only minimal expression of two adhesion molecules, intercellular adhesion molecule-I (ICAM-I), and lymphocyte function-associated antigen-3 (LFA-3) (which, in other tissues, are thought to stabilize binding and to contribute to T cell activation). Second, xenogeneic cellular transplants lack the vasculature that can be separated from the tissue to avoid hyperacute rejection, the earliest and most formidable barrier to discordant xenograft acceptance. Third, targeted antigens at the surface protein level, rather than at the genetic level, allow greater flexibility and less expense than the creation of genetically engineered pigs. Our goal was to conceal protein antigens that already appeared on the surface of graft cells. Other approaches, discussed later in this chapter, target antigens not at the protein level, but at the DNA and RNA level. The use of more sophisticated transgenic and anti-sense technology, respectively, can similarly prevent antigen expression. They also can validate the donor antigens as a target for the immune response.

In summary, this tough xenogeneic model establishes the paramount role of class I antigens on cellular transplants. By providing a challenging test of the designer tissue concept, it also helped to launch a novel therapeutic strategy.

EXPANSION OF RESEARCH ON DESIGNER TISSUES

The creation of designer tissues to produce tissues and organs with reduced surface proteins can be achieved using a variety of donor antigen modification techniques in various transplantation settings. This body of early research is, in part, summarized in Table 27.1 and can be classified by the method that interferes with the expression of the surface protein of interest. The methods to remove or disguise surface proteins in the donor cells can include antibody 'masking', gene ablation, anti-sense, and enzymatic treatments, and are the topic of this review.

TABLE 27.1 Designer donor tissues

Technique/Tissues	Allo/xeno	Donor/recipient	Target	Reference
Masking antibody				
Islets	Xeno	Human/mouse	Class I	[23]
Islets	Xeno	Human/mouse	All surface antigens	[23]
Islets	Allo/xeno	Human or monkey/monkey	Class I	[8]
Islets	Allo	Mouse/mouse	Class I	[4–6]
Neurons	Xeno	Pig/rat	Class I	[4–6], [9]
Neurons	Xeno	Pig/monkey	Class I	[10]
Liver cells	Xeno	Human/mouse	Class I	[23]
Gene Ablation				
Islets	Allo	Mouse/mouse	Class I	[12]
Islets	Allo	Mouse/mouse	Class I	[13]
Islets	Allo	Mouse/mouse	Class I	[4–6]
Liver cells	Allo/xeno	Mouse/mouse/ guinea pig/frog	Class I	[14]
Kidneys	Allo	Mouse/mouse	Class I	[11]

ANTIBODY MASKING

Antibody masking of xenogeneic tissue is the first of the donor antigen modification techniques to progress to primate and human trials. Pancreatic islet cells and neurons are the most common types of donor cells to be camouflaged with antibody masking, although any type of tissue can theoretically be treated once the dominant antigens have been identified. All of the studies cited below targeted class I antigens using antibody fragments and relate to cellular transplants.

Islet cell masking for the treatment of diabetes was early on pursued with mixed results. Osorio and colleagues [4–7] targeted class I antigens in a mouse allograft model. To approximate a diabetic state, the mice first were treated with a drug that chemically induced hyperglycemia. Then they received islet allografts that had been pretreated with antibody fragments. Graft survival was prolonged relative to controls, but within one month the grafts were eventually rejected. Investigators attributed the eventual allograft rejection to a variety of possibilities, including the absence of sufficient quantities of $F(ab')_2$ fragments, antiidiotypic antibodies against the $F(ab')_2$ fragment, and an immune pathway independent of class I activation of T cells. Steele and colleagues [8] investigated islet cell transplants in a primate model. Cynomolgus monkeys received either allogeneic or xenogeneic (human) islets. The grafts were pretreated with antibody fragments to class I antigens. Histologic evidence revealed that donor islets were present months after transplantation into non-immunosuppressed monkeys.

Neuronal xenografts with antibody masking have been investigated for Huntington's disease [9] and Parkinson's disease [10]. In the first study, fetal pig striatal cells were implanted into rats whose striatum had been lesioned one week earlier with injections of quinolinic acid. These injections destroy striatal neurons in an attempt to simulate the dysfunction present in Huntington's disease. Rats received either untreated tissue or tissue pretreated with $F(ab')_2$ fragments against porcine class I antigens. Control rats receiving untreated tissue were either immunosuppressed with the immunosuppressant cyclosporin A (CsA) or left untreated. Three to four months later, graft survival was found to be prolonged in animals given $F(ab')_2$-treated grafts and in the CsA-treated control animals given unaltered grafts. Grafts did not survive in non-immunosuppressed controls. Graft volume, determined histologically with the aid of computer image analysis, was significantly larger in the CsA group compared with the $F(ab')_2$ group. Yet, in both of these groups, immunohistochemistry revealed the graft cytoarchitecture to be well organized, and graft axons to have grown correctly in the direction of their target

nuclei. It was encouraging that pig neurons appeared to be capable of locating their murine target.

In a similar study design, Burns and co-workers [10] applied antibody masking to a primate model of Parkinson's disease. Porcine mesencephalic neuroblasts were implanted into monkeys with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced Parkinsonism. Measures of locomotor activity and dopamine fiber density in the host striatum confirmed that pre-treatment of donor tissue with $F(ab')_2$ fragments succeeded in restoring motor function and replenishing dopamine fibers at the site of implantation. A control animal, maintained on CsA after receiving untreated cells, showed similar improvement. A non-immunosuppressed control showed no improvement after transplantation, suggesting graft rejection.

The studies described in this section highlight the range of potential applications of antibody masking in both allo- and xenotransplants. Neuronal cell masking has been sufficiently effective to usher in human clinical trials.

GENE ABLATION

Gene ablation, or gene 'knockout' technology, offers another vehicle to modify donor tissue and organs. With gene ablation, the gene or genes encoding protein antigens can be permanently deleted, thereby eliminating antigen expression in all cells. In one common method of gene ablation, the target gene is inactivated in cultured embryonic stem cells via homologous recombination; a target vector containing an inactive version of the gene recombines with, and thereby replaces, the wild-type gene. Through reintroduction of the embryonic cells into a foster mother and through selective breeding, progeny can be produced that are homozygous for the mutation. Rejection by the host immune system is expected to be avoided when the targeted gene encodes a protein antigen slated for expression on the surface of donor cells.

The major advantage of gene ablation over protein modification of donor tissue is that the antigen is permanently eliminated in all cells, tissues, and organs in which it is expressed. The major limitation of this technology is that it is restricted to potential xenografts from pigs and requires pig 'farming', an expensive, albeit potentially abundant, source of donor tissue. The permanent nature of the modification also can sometimes be a limitation, especially when the protein encoded by the gene has additional functions. Inactivation of the gene might lead to physiological changes that compromise the utility of the donor tissue. Gene ablation can also target genes that encode proteins essential for the target protein expression.

Several transplantation laboratories have exploited the availability of knockout mice deficient in $ß_2$-microglobulin. $ß_2$-microglobulin is a peptide that performs a chaperone function as part of the class I molecule and is necessary for its assembly and expression. Mice homozygous for the $ß_2$-microglobulin mutation fail to display class I antigens on the cell surface, a feature that makes them highly desirable for transplantation studies. Class I ablation through the mutation is not necessarily a permanent depletion of class I due to host $ß_2$-microglobulin reconstituting the graft. Although much of the research described below has focused on islet cell and liver cell xenotransplants, one project examined whole organ allografts. Coffman and co-workers [11] found that kidneys from $ß_2$-microglobulin-deficient mice functioned significantly better in allogeneic recipients than did kidneys from normal mice.

The fate of pancreatic islet transplants from $ß_2$-microglobulin-deficient mice has been explored in several studies. The islets showed prolonged survival when implanted into a normal mouse strain [12,13]. Most grafts survived indefinitely (>80% beyond 100 days) and were capable of reversing hyperglycemia that had been chemically induced prior to transplantation. Investigators attributed the few instances of graft rejection to three possibilities. First, some surface expression of class I antigens can occur in the absence of $ß_2$-microglobulin. The presence of even a fraction of the total number of class I antigens may be sufficient for T cell recognition and lysis. Second,

ß$_2$-microglobulin circulating in the serum of the recipient can be used to reconstitute class I antigens on the donor tissue (because ß$_2$-microglobulin is a highly conserved protein not encoded by genes at the MHC locus). Third, rejection of the tissue from ß$_2$-microglobulin-deficient donors may be mediated by other immune pathways, such as by natural killer cells. Support for the second and third possibilities was presented by Li and Faustman [14] in their study of liver cell allo- and xenografts. Other studies also confirmed that masking of human leukocyte antigen (HLA) also enhanced susceptibility of cells to natural killer cells [15].

For whole organ xenografts, it has long been recognized that certain sugars on donor tissues especially the vascular endothelium, such as gal α(1,3) galactosyltransferase have a central role in hyperacute rejection. This hyperacute rejection is mediated by preformed antibodies in disparate species, often referred to as natural antibodies [16,17]. If hyperacute rejection of whole organ xenografts can be prevented, the other cellular barriers, such as disparate class I expression, can be addressed.

Given the important role of donor sugar epitopes in eliciting rapid organ rejection, knockout pigs were produced with the first strategy applied to donor antigen modification for this epitope. The pigs had complete elimination of the gene that encoded α1,3galactosyl-transferase. To the surprise of the scientific community, the knockout pigs continued to express considerable levels of the carbohydrate sugars.

Therefore, in the pig, more than one genetically encoded enzyme is able to successfully synthesize Gal α(1,3) gal surface sugars [18]. These studies demonstrate that although three prior methods can change donor antigen expression in cells, i.e., gene ablation, anti-sense for RNA, or 'masking' antibodies, some methods may have unexpected shortcomings specific to the interruption method.

RNA ABLATION

RNA ablation is another strategy that strives to prevent antigen expression by blocking gene transcription or translation. RNA ablation can be achieved through the creation of oligo-deoxynucleotides that are complementary to, and hybridize with, DNA or RNA sequences to inhibit transcription or translation, respectively.

To date, RNA ablation in the transplant field has been less frequently pursued. Ramanathan and co-workers identified an oligodeoxynucleotide that inhibited induction of class I and ICAM expression by interferon-γ [19]. The studies were performed *in vitro* in a cell line, K562, that normally has low-level expression of class I antigens. They first postulated that the oligodeoxynucleotide acted in the early stages of interferon-γ induction rather than post-translationally. In their follow-up study, they showed that the oligodeoxynucleotide acted even earlier via a novel mechanism: it inhibited binding of interferon-γ to the cell surface [19,20]. This may be an unusual mechanism for an oligodeoxynucleotide,, but it only enhances the possibilities for xenotransplant research. RNA ablation, unlike protein modifications with masking or DNA modifications in transgenic donors, offers an additional challenge. For RNA ablation to work, all cells must be equally treated with the interfering RNA. Anti-sense technology or even newer methods such as siRNA often result in uneven distributions of interruptions in the cells or organs. What these studies provide is yet another means of blocking expression of class I antigens or other transplantation antigens.

ENZYME ABLATION

Although MHC class I surface structures are extremely polymorphic, the polymorphisms are predominately confined to the exterior region of the protein and the regions of the protein that are exterior facing. This feature allows the host's immune system, i.e. T cells, the early opportunity to reject tissues transplanted from unrelated individuals.

As the genome effort has advanced and hundreds of MHC class I alleles of the gene have been sequenced, it has also become apparent that certain regions of the MHC structure are highly polymorphic in contrast to other regions of the protein that are highly conserved. Even across species, the conserved regions of the MHC allele compose the protein portions that are near and within the cell surface membrane. This conservation of structure is maintained across species as diverse as mice and humans.

The conserved regions of MHC class I within and across species have afforded, in solubilized cells, the opportunity to specifically purify these proteins by enzymatic cleavage. Most typically, cell lysates have been treated with papain to solubilize all MHC structures from the cell surface, usually at very acid pHs [21]. Papain has the remarkable ability to cleave the conserved hydrophilic regions of the class I protein without cleaving other cellular proteins [22]. Papain's conserved cleavage feature is preserved for mouse, human, and primate class I alleles.

We have gradually worked with this system in mouse transplant model to allow papain to cleave class I from all cells and have the cells remain fully viable at the end of the brief treatment. This MHC class I modification method, comprising pre-treatment with papain with modified buffers at physiological pH, now allows complete class I depletion and subsequent transplantation of cell transplants with prolonged survival. Survival of the transplanted cells in the form of insulin secreting islets or liver cells is comparable to either methods of genetically ablated class I deficient tissues or 'masked' class I deficient tissues.

Each method of modifying donor cell surface proteins, such as MHC class I, prior to transplantation has features that are unique to the translation of these methods to clinical trials (Table 27.2). The production of genetically-engineered donor pigs permits the generation of abundant tissue, but the donors' tissue will be xenografts, and will thus encounter tough

TABLE 27.2 Positive and negative features of different methods of donor antigen modification compared to systemic immunosuppressants

**Anti-sense or siRNA technology has had limited success in settings of cell or tissue transplantation and thus is not represented in the table as a method for donor antigen modification*

transplant barriers and high xenosis risk. Also, the cost of developing the herds of animals is very high. The generation of masking antibodies allows the donor tissue modifications to be applied to allografts or xenografts. The masking antibodies are protein fragments and can be designed to different donor HLA types. The production of masking antibodies is easier than the production of genetically engineered pigs, but requires manufacturing of a novel protein fragment and standardization for Food and Drug Administration (FDA) approval. Also the pre-clinical efficacy studies using masking antibodies would be specific for the species chosen, thus the translation to human studies would not use an identical antibody fragment. Finally, the use of specific enzymes to cleave off donor antigens such as MHC class I is inexpensive to develop and the same enzyme product could be applied to pre-clinical murine studies, baboon studies, and human indications. All three donor-tissue modifications could be combined with reduced or eliminated immunosupression, thus increasing the safety margins for cellular transplants for non-lethal diseases.

MECHANISMS OF GRAFT SURVIVAL AFTER CLASS I DONOR ABLATION OR ANTIBODY MASKING

The ability of class I modified tissues or cells to survive long term without host immuosuppression has been closely studied. Indeed, it was appreciated that although the method for altering donor class I expression prior to transplantation could be diverse, i.e., 'masking' antibodies, gene ablation of chaperone proteins or enzymes, a common theme in these models was the long-term stable survival of the functioning tissue. The transplants were viable and certainly re-expressed donor class I with the passage of time. Insight into the role of systemic tolerance in these transplants is important for future refinements of cellular transplant methods to optimize success.

Systemic tolerance of the graft was initially addressed for donor tissues with modified class I due to ablation of the class I chaperone protein, i.e., ß$_2$-microglobulin. First, as the donor and recipient diverge phylogenetically, so does the homology of the ß$_2$-microglobulin proteins. Donor grafts from highly divergent species have slower reconstitution of surface class I with ß$_2$-microglobulin from the host serum, and also shorter survival times [24]. The shortened survival times compared to less divergent cross-species transplants suggests some degree of donor class I antigen expression is beneficial after the transplant is established. Indeed, many have proposed the intact natural killer cells of the host, a natural defense against class I deficient tumors, as the reason for more brisk rejection, with more permanent class I depletion.

The reconstitution of donor surface class I with host ß$_2$-microglobulin in the gene ablation model also explains why transient ways of interruption class I allow systemic tolerance. The primary cellular grafts with transient class I interruption permit secondary, non-genetically manipulated or non-antibody-masked grafts to survive — if from the same donor [23]. The data using the 'masking' method to conceal class I, taken together, suggest donor-specific tolerance occurs in these transplant models.

Insights into the mechanisms of T cell tolerance in hosts receiving transient class I-ablated grafts may have been clarified. In a publication by the Cantor laboratory, peripheral CD8 T cell tolerance was mechanistically characterized in terms of maintenance of peripheral tolerance [3]. It has been recognized in some experimental settings that the persistence of peripheral class I-expressing cells is necessary for peripheral CD8+ T cell tolerance [25]. Using ß$_2$-microglobulin-deficient mice, potentially cytotoxic and mature CD8 T cells from a normal donor were transferred into the mutant host. The transferred T cells then failed to engage their T cell receptors. The CD8 cells downregulated their CD8 gene expression and underwent apoptosis. Thus, inhibition of, or interference with, the T cell receptor and CD8 binding to host class I triggered these CD8 cells into a pathway of cell death. This is an important observation, and lack of class I expression immediately after transplantation eliminated

potential direct and immediate T cell killing. As the genetically modified graft gradually re-expresses class I, it is protected from the next layer of the immune response, natural killer cell lysis of totally class I-negative transplants, and active host tolerance is additionally achieved.

Elimination of class I antigens also may be insufficient for select tissues and select combinations of donor and host species. Liver cells from ß$_2$-microglobulin-deficient donors were implanted into allogeneic recipients and two different xenogeneic recipients [14]. The allotransplants and the xenotransplants into guinea pigs were not effective. In contrast, xenotransplants of mouse cells into frog recipients survived, and when liver cells were transplanted from humans to mice in antibody-masking experiments, they were accepted [23]. These studies show that results of class I antigen removal vary according to the species combination of donor and host.

Gene ablation experiments have demonstrated the advantages and limitations of eliminating class I antigens. There are clearly dominant antigens on islet cells and neurons in some allogeneic and xenogeneic combinations. However, class I antigens may play a secondary role depending on the type of donor tissue, the species combination, and/or the disease state of the recipient. In most cases, re-expression of class I antigens on the donor cells was beneficial for long-term survival. Indeed with antibody 'masking' of class I, secondary transplants from the same donor were possible if the primary transplant was still in the host [23].

Rare cases of stable allograft acceptance in humans who discontinue their immunosuppressive regiments have been documented in the setting of whole organs such as kidney transplants. A study of a mouse model found that pre-engraftment of donor cells bearing a single foreign MHC class I allele resulted in lifelong donor cell acceptance and an immune system that both *in vivo* and *in vtiro* was unresponsive. Similar to the data presented above for temporary class I ablation, removal of the primary transplant reversed the systemic tolerance in a time dependent fashion. This suggests that the transplants can actively maintain host unresponsiveness towards a single MHC class I allele by continuously inactivating a reactive T cell [26].

ROLE OF CLASS I MODIFICATIONS IN RESISTANCE TO RECURRENT AUTOIMMUNITY

The fate of pancreatic islet transplants from ß$_2$-microglobulin-deficient mice has been explored in several studies using chemically induced mice as well as spontaneously diabetic mice. Non-obese diabetic (NOD) mice are a well recognized model of spontaneous type 1 diabetes and have a long prodrome of pre-diabetes from 6–8 weeks of age prior, progressing to spontaneous diabetes at approximately 18–24 weeks of age, the stage where islet destruction sufficient for hyperglycemia occurs. Although clinically asymptomatic, this stage of pre-diabetes is the most active phase of disease.

Class I depleted islets, either with masking antibodies or from donors with ablation of the ß$_2$-microglobulin gene, show prolonged survival when implanted into allogeneic mouse strains without autoimmunity [12,13]. Additional experiments also tested the transplantation of cells from ß$_2$-microglobulin hosts into the autoimmune prone NOD mouse strain, both in pre-diabetic mice and fully diabetic mice. When genetically modified islets were transplanted into young NOD (but not yet diabetic) mice, graft rejection due to ongoing autoimmunity almost invariably occurred [12]. Although at this stage NOD mice are clinically asymptomatic due to survival of some islets, this is the most active phase of disease. Soon after implantation into pre-diabetic NOD mice, but at a slightly delayed rate, islet allografts from ß$_2$-microglobulin-deficient mice or class I-masked xenogeneic islets are rejected after a two-fold increased survival beyond control islets. This modest prolongation is in contrast to almost complete success with recipients whose diabetes is chemically induced, or in NOD mice that are already hyperglycemic. Fully diabetic NOD mice receiving MHC class I deficient islets demonstrate indefinite survival [27]. In conclusion, class I deficient islets, rendered deficient

by a number of methods, can show modest to dramatic prolongations in survival in murine hosts with different stages of diabetic autoimmunity.

THE LAUNCHING OF XENOGENEIC HUMAN CLINICAL TRIALS IN THE UNITED STATES USING IMMUNOMODULATION

Few cross-species transplantation technologies have progressed to human clinical trials. In part, this has been due to primate models showing minimal efficacy. Also, early whole organ human clinical trials in the 1970s demonstrated minimal success, even with massive levels of immunosuppression. Additionally, some segments of the medical community have been concerned about cross-species infections, therefore necessitating new technologies to avoid the use of donor species closely related to humans, i.e., baboons. The testing of novel transplantation approaches needs to avoid the limitation of a severely compromised host immune system with decreased ability to fight infections.

Clinically close primate and rat models are available for neurological diseases such as Parkinson's disease. The approach of masking class I antibody fragments shows promise using porcine neurons for treating spinal cord injuries in rat models, and porcine liver cells for treating transient liver failure from hypotension or infection. Fetal neuronal xenografts with antibody masking have been investigated for Huntington's disease and Parkinson's disease [28]. In the first study, fetal pig striatal cells were implanted into rats whose striatum had been lesioned one week earlier with injections of quinolinic acid. These injections destroy striatal neurons, and attempt to simulate the dysfunction present in Huntington's disease. Rats received either untreated tissue or tissue pretreated with $F(ab')_2$ fragments against porcine class I antigens. Control rats received untreated tissue and were immunosuppressed with CsA; the others were not immunosuppressed. In treated animals, graft volume, determined histologically with the aid of computer image analysis, was significantly larger and better organized, and graft axons had correctly grown in the direction of their target nuclei. It was encouraging that the pig neurons appeared to be capable of locating their target. Also, because of the use of fetal tissue, the transplanted mass had become significantly enlarged at the time of autopsy, demonstrating post-transplantation survival as well as growth of the transplant. Six Parkinson's patients have now been treated with fetal pig neurons masked with class I antibody fragments and their long-term survival (>2 years) has been reported, with the patients demonstrating mild to marked functional improvements. Six more patients similarly treated with fetal pig neurons and CsA showed less clinical improvement, but still had function exceeding base line. At eight months, one of these patients died of a thromboembolic event and an autopsy was performed. As reported by Deacon et al. [28], similar to the primate studies performed before clinical trials, the fetal pig neurons survived and correctly sent out axons over long distances in the brain toward their target nuclei. This confirmed the suitability of using pig tissue in this transplant setting, and of using the masking approach to decrease tissue immunogenicity.

Additional clinical trials of masked neuron transplants have continued in the United States, including a blinded phase II/III trial using pig cells for treating Parkinson's disease has been conducted to evaluate safety and efficacy. The advantages of the donor antigen modifications methods include a lack of host interventions, thus allowing a broader audience for applications of cellular transplants for disease treatments.

COMMENT

Designer tissues and organs, created through donor antigen modification, hold tremendous promise for xenotransplantation and allotransplantation. Research in animal models has already demonstrated that long-term xenograft survival can be achieved without immunosuppression. This achievement has galvanized the transplantation community, since it shows

that an overwhelming obstacle to graft acceptance can be alleviated in select settings. Immune rejection need not occur if graft antigens can be immunologically masked, enzymatically cleaved or genetically eliminated. Researchers now have at their disposal a battery of techniques that operate at the DNA, RNA, or protein level to remove or conceal antigens. Improved xeno or allogeneic transplantation is within reach, not just for patients with life-threatening conditions, but also for patients with chronic conditions.

The successes with cellular and tissue grafts still are not the final solution for the far more difficult task of whole organ xenotransplantation or recurrent autoimmune disease. Solid organs have a multiplicity of antigens, particularly those which elicit hyperacute rejection due to differences in the expression of sugars between species. Once all dominant antigens are identified, the therapeutic strategy for whole organs and tissues is conceptually identical: modify the donor, not the host. The barriers for recurrent autoimmune disease still stand, but it is hoped that donor antigen modification may also be beneficial in this setting during select times in the disease process.

CHAPTER 28

Challenges in the Development of Immunoisolation Devices

Clark K. Colton
Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

INTRODUCTION

Immunoisolation devices can be used to transplant cells to treat a variety of human diseases without the need for immunosuppressive drugs. Transplanted cells are enclosed within a material that provides protection from the immune system while allowing adequate transport of nutrients, oxygen, waste products, and therapeutic products. There are three types of immunobarrier devices: (1) intravascular, (2) extravascular macrocapsules, and (3) microcapsules. Challenges exist which prevent the widespread applications of cell encapsulation therapies: tissue supply, effective immune protection of encapsulated cells, and maintenance of cell viability post-transplantation. This chapter discusses approaches that can be used to overcome these problems and focuses specifically on the maintenance of cell viability and function in the treatment of type 1 diabetes, including use of vascularizing membranes, *in situ* oxygen supply, exogenous oxygen supply, reduction of islet cell aggregate size, and manipulation of encapsulant properties. One method to enhance cell viability by increasing oxygen permeability of the encapsulating material with perfluorocarbons (PFCs) is discussed in detail, and a mathematical model is used to predict the extent of enhancement of islet viability and function.

Cell therapies have the potential to treat a large range of diseases by providing *in vivo* delivery of a required protein. A problem that complicates and restricts the use of such therapies is the need for transplanted cells to be protected from the immune system by immunosuppressive drugs. One engineering approach that addresses this problem is the use of immunobarrier devices which provide a physical barrier to protect transplanted cells from the recipient's immune system through use of a semipermeable membrane. Some diseases that have been investigated for treatment with immunobarrier devices are diabetes [1], hemophilia [2], anemia [3], parathyroid disease [4], chronic pain [5], Parkinson's disease [6], Huntington's disease [7], and amyotrophic lateral sclerosis [8]. An immunobarrier device can contain cells that constantly produce a therapeutic protein, as is required for the treatment of most of the diseases listed above, or, for the case of diabetes treatment, the cells secrete insulin in response to changes in the blood glucose level in a feedback-controlled manner.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00028-8

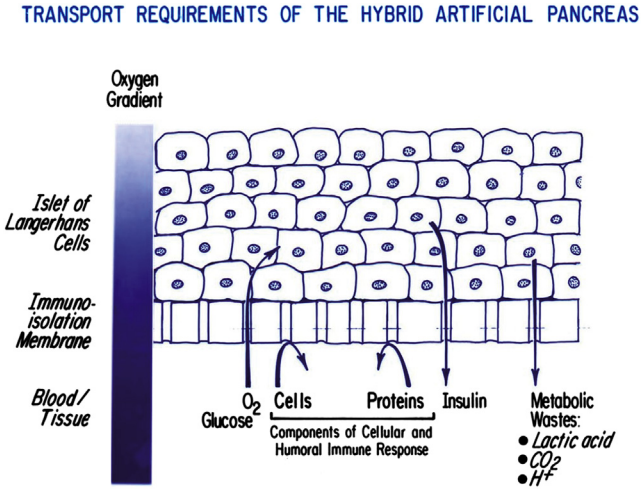

FIGURE 28.1
Essential elements of an implanted device that incorporates encapsulated cells illustrating the case of a biohybrid artificial pancreas. *Reproduced, with permission from Colton (1995) [10].*

The essential elements of an implanted device incorporating encapsulated cells are shown in Fig. 28.1, which is a conceptual illustration of a biohybrid artificial pancreas. The implanted tissues are separated from the host by an immunoisolation membrane (sometimes referred to as an immunobarrier membrane). Cells can be encapsulated at a high, tissue-like density, as illustrated in Fig. 28.1, or dispersed in an extracellular gel matrix, such as agar, alginate, or chitosan. The membrane prevents access of immune cells and prevents or minimizes access of humoral immune components, but permits passage of the secreted product (insulin). At the same time there must be sufficient access to nutrients, such as glucose and oxygen, and removal of secreted metabolic waste products, such as lactic acid, carbon dioxide, and hydrogen ions as well as nitrogenous products of metabolism. Transplanted cells must be supplied with nutrients by diffusion from the nearest blood supply, through surrounding tissue, the immunobarrier membrane, and the graft tissue itself.

This chapter focuses on the engineering challenges associated with developing immunobarrier devices and the methods that are under study to circumvent the problems of supply of tissue, protection from immune rejection, and maintenance of cell viability and function. The emphasis of the chapter is on immunobarrier devices used in transplanting islets for type 1 diabetes treatment with a focus on the challenge of maintaining cell viability and function. After describing the challenges, approaches are discussed to improve immunobarrier device designs to overcome some of these difficulties, including use of vascularizing membranes, *in situ* oxygen generation, exogenous oxygen supply, reduction of islet cell aggregate size, and manipulation of encapsulated properties. One particular approach is described in detail: this is the use of encapsulating materials that contain perfluorocarbons to enhance oxygen delivery and increase islet survival and function. A mathematical analysis is presented to demonstrate the benefits of this approach.

The material presented here builds on previous reviews of the field published since the early 1990s [9–13]. Consequently, in this chapter we focus on recently reported work.

ENGINEERING CHALLENGES

Device designs

Immunobarrier device designs typically fall into three categories: intravascular devices, extravascular macrocapsule devices, and microcapsules [9,10]. Intravascular devices create a vascular shunt between an artery and a vein. The device is typically made of a hollow fiber, where blood flows through the lumen and the transplanted cells are separated from the blood by an immunoisolating membrane. This device design is appealing because it

brings blood into very close proximity with the transplanted tissue, which will aid in nutrient, waste, and therapeutic protein transport. However, the implantation of this device is associated with greater risks because it disrupts the patient's vascular system, thereby leading to a greater risk of complications. Human clinical trials of this type of device for islet transplantation were being planned when they were stopped by the FDA because of a mechanical failure of the cannula in dogs and they have never been resumed. At this point in time this type of device is not under study.

The second device design type is the extravascular macrocapsule, which is typically a planar diffusion chamber or a hollow fiber. This type of device is typically implanted within a cavity of the body and contains tissue within the device lumen surrounded by an immunoisolating membrane. Delivery of oxygen and other nutrients requires diffusion from the surrounding tissue to the device, across the device membrane, and then through the interior of the device itself to the tissue. This type of device can be limited in the amount of tissue that can be included within the device due to oxygen supply limitations. Oxygen supply limitations can be even further aggravated by overgrowth of fibrotic tissue, which is another transport barrier, and which also consumes some of the oxygen (if there are cells present) that would normally be delivered to transplanted tissue [14]. Benefits of using macroencapsulation devices are that many tend to be made of materials that are very stable on implantation in the body, and if needed these types of devices can easily be retrieved because of their larger size. This type of device is under study for several applications, including diabetes [15] and diseases of the central nervous system [16]. Examples of materials used for macroencapsulation are polytetrafluoroethylene [17], which can be used to form an immunoisolating membrane or an exterior vascularizing membrane, poly-ether-sulfone [8], which is used for devices that have entered into clinical trials, alumina [18], and nanoporous micromachined silicon-based membranes [15], which can result in a more stringent control over the exact pore size of the material.

The final type of immunobarrier device is the microcapsule. These are small spherical gels ranging in size from 200 μm for islet conformal coatings to 2 mm for macrobeads. Microcapsules are currently being studied the most extensively for islet transplantation to treat diabetes. Each microcapsule typically contains 1 to 2 islets, and the microcapsules are most commonly transplanted into the peritoneal cavity. The peritoneal cavity is the implantation site of choice, because there is ample space for the implant, and immune responses are not as high as at other implantation sites, such as the subcutaneous space. Capsules in this location may be located far away from the blood supply and therefore have very limited oxygen, which can have detrimental effects on tissue survival. The feasibility of microcapsule implantation in the liver via intraportal injection (the location and method for naked human islet transplantations) is being studied in order to enhance microcapsule proximity to the blood supply [19]. A drawback of the liver as a transplantation site is that there is an increased immune response, which is found to be reduced by short-term immunosuppression with gadolinium chloride, rapamycin, or tacrolimus [19].

The most common choice of materials for microcapsules is alginate, a polysaccharide derived from seaweed. Alginate can be dissolved in water to form a viscous solution that, upon exposure to a divalent (e.g., calcium or barium) or a trivalent (e.g., gadolinium) ion, is transformed into a hydrogel. This very gentle gelation process is the reason for widespread use of alginate, because tissue can be encapsulated without causing damage to the cells. However, because it is a naturally derived product, its properties are batch and source dependent, and the impurities in the alginate itself can have detrimental effects on the success of immunobarrier devices. Alginate microcapsules usually come in one of two forms: alginate alone cross-linked with barium ions [1,20] or alginate cross linked with calcium and then coated with poly-L-lysine [21] or poly-L-ornithine [22] to form a perm-selective barrier and enhance capsule stability. Alternative materials to alginate are

being developed. One promising example is synthetic Tetronic polymers that thermally gel and chemically cross-link to form more stable gels while still needing gentle processing steps [23]. The capsule formation process for the Tetronic polymers is adaptable to the machinery developed for making alginate capsules [23]. A recent review of the field of micro-encapsulation [24] provides additional information.

Supply of tissue

Tissue for cell therapy applications can be derived from three main types of sources:

1) Human primary tissue,
2) Primary xenogeneic tissue, and
3) Cell lines.

Each type of tissue has reasons why it is an attractive and an unattractive source. Allotransplantation, or use of primary human tissue, is desirable because this tissue, were it to be transplanted alone, would illicit less of an immune response than tissue derived from another animal (xenotransplantation). Therefore it should be easier to provide immunoprotection to allotransplanted tissue compared to xenotransplanted tissue. However, the main drawback of primary human tissue is that it requires a cadavaric donor, and therefore the supply is extremely limited. Additionally, a procedure is required to isolate the tissue prior to transplantation, which can be costly and time consuming.

Some researchers are looking to use tissue derived from animal sources in immunobarrier devices. The main advantage of xenogeneic tissue is that its supply is not as limited. However, there is a risk of retroviral disease transmission, immunobarrier requirements are more stringent, and tissue isolation procedures still need to be developed.

The final type of tissue that is under study for transplantation is cell lines, of which the supply of a particular cell type is infinite and there are no isolation requirements. Cell lines can be allogeneic or xenogeneic in nature. When immunobarrier devices are used to deliver a desired product at a continuous rate, as is typically desired for gene therapy strategies, the use of cell lines has proven to be an adequate cell source for this application, as is discussed in a review of encapsulation of genetically modified cells and their clinical applications [16]. The main drawback of using cell lines for diabetes treatment is that the cell line must secrete insulin under the same feedback-control mechanisms as the islet and at the same rate. Also, in order to prevent hypoglycemia in diabetes treatments, the growth of the cell line should be arrested prior to transplantation. To date, this type of cell line has yet to be developed, although work is being done to address these issues in the hope that a fully functional beta cell line will solve the tissue-shortage problem associated with islet transplantation, and make the therapy available to all type 1 diabetic patients [25,26]. Stem cells also offer great promise as an unlimited source of cells for immunobarrier devices, but a greater understanding and control of the differentiation process is required in order to generate cells with the desired phenotype for a particular application.

Preventing immune rejection

Possible rejection pathways elicited by tissue in immunobarrier devices are shown in Fig. 28.2. The process may begin with diffusion across the immunobarrier of immunogenic tissue antigens that have been shed from the cell surface, secreted by live cells, or liberated from dead cells. Recognition and display of these antigens by host antigen-presenting cells initiate the cellular and humoral immune responses. The former response leads to the activation of cytotoxic T cells, macrophages, and other immune cells. Preventing cells from entering the tissue compartment is easily achieved using microporous membranes. This may be the only requirement for immunoisolation of allogeneic tissue, at least for periods up to several months [27]. With xenografts it is also necessary to keep out components of the humoral

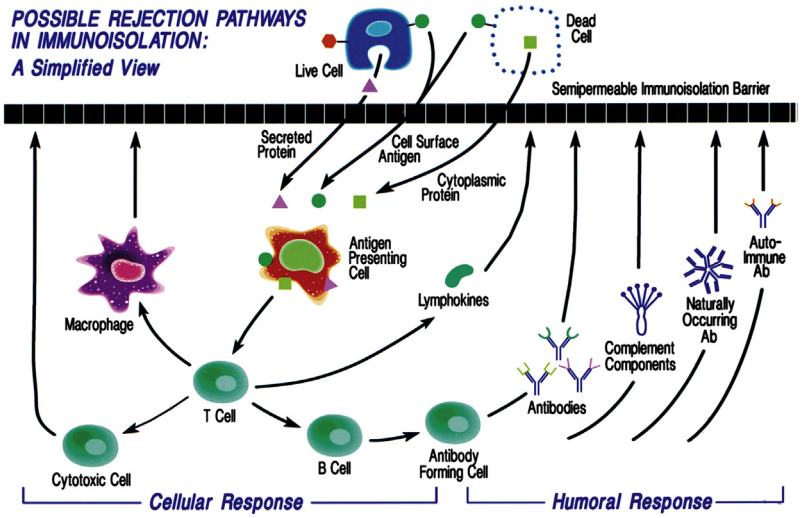

FIGURE 28.2
Possible pathways for immune rejection mechanisms with encapsulated cells. *Reproduced, with permission, from Colton (1995) [10].*

immune response, which is more difficult to accomplish. Such components include cytokines and lymphokines (e.g., interleukin-1), which can have deleterious effects on β-cells, as well as newly formed antibodies to immunogenic antigens that have leaked across the barrier. In addition, there may be naturally occurring antibodies, most likely IgM, to cell surface antigens on xenografts. Antibodies produced during pre-existing autoimmune disease, such as type 1 diabetes, might also bind to cell surface antigens. Lastly, macrophages and certain other immune cells can secrete low molecular weight reactive metabolites of oxygen and nitrogen, including free radicals, hydrogen peroxide, superoxide, and nitric oxide, which are toxic to cells in a non-specific fashion. The extent to which these agents may play a role in causing rejection of immunoisolated tissue depends on how far they can diffuse before they are inactivated by chemical reactions. Based on diffusion and reaction parameters for nitric oxide and superoxide, the reaction-length scales for nitric oxide and superoxide in water are estimated to be on the order of 1 mm and 1 μm, respectively [10]. Therefore a macrophage that is at the surface of an immunoisolating device secreting these molecules will be capable of delivering nitric oxide to the encapsulated tissue but not superoxide, for it will react away before it can diffuse far enough into the capsule to damage the tissue.

Cytotoxic events occur if antibodies and complement components pass through the membrane. Binding of the first component (C1q) to IgM or two or more IgG molecules initiates a cascade that culminates in the formation of the membrane attack complex, which can lyse a single cell. IgM (910 kDa) and C1q (410 kDa) are both larger than IgG (see Fig. 28.3), so if host IgM and C1q can be prevented from crossing the barrier, then a specific,

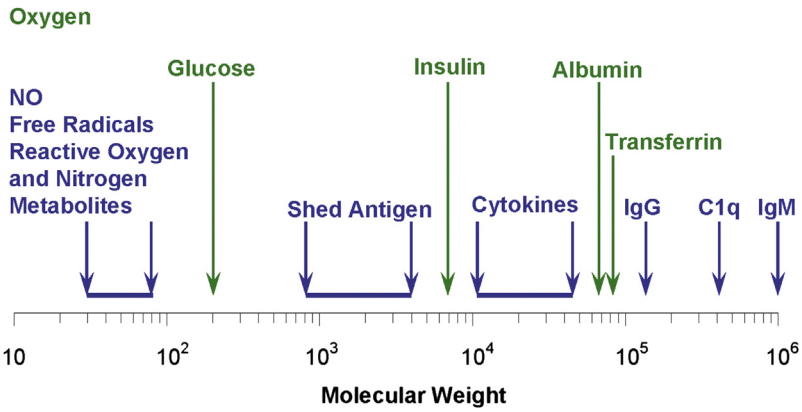

FIGURE 28.3
Comparison of molecular weights of immune system molecules and molecules required by cells for survival. *Modified from Colton (1995, Fig. 19) [10].*

antibody-mediated attack on the islet cell should be averted. If the alternative complement pathway is activated and not inhibited by the implanted tissue, then passage of C3 (200 kDa) across the membrane must be prevented.

The precise mechanism(s) that may play a role in rejection of encapsulated tissue are, in general, incompletely understood, and they probably depend on the specific types of cells present, the species and its phlyogenetic distance from humans, and the concentration of humoral immune molecules to which the implanted tissue is exposed. The latter depends on the transport properties of the immunobarrier membrane as well as on the total mass of cells implanted (which affects the magnitude of the immune response), the tissue density, and the diffusion distances between tissue and immunobarrier membrane (which affect access of the generated humoral components to the graft tissue). If complete retention of IgG (or even C1q and IgM) coupled with passage of albumin and iron-carrying transferrin (81 kDa) is required, there is a problem because of the size discrimination properties of membranes, in which there is invariably a wide distribution of pore sizes. If cytokine transport must also be prevented, the problem is even more difficult. A comparison of molecule sizes required for cell survival, the insulin that is required to be secreted so that the device is functional, and the immune system components are shown in Fig. 28.3. This figure demonstrates that if the cells require albumin and transferrin, then the transport of cytokines to the tissue cannot be blocked by an immunobarrier alone. The membrane would have to allow for cytokine transportation but could potentially contain components that could deactivate the cytokines before they reach the encapsulated tissue. If free radicals and other reactive oxygen and nitrogen species pose a significant problem, no passive membrane barrier will be able to provide immunoprotection, and some other approach (e.g., scavenging of free radicals, immunomodulation of transplanted tissue, local suppression of host immune response) will be necessary. The portion of overgrown allotransplanted alginate-PLL microcapsules containing rat islets explanted four weeks post-transplantation were shown to have mostly macrophages, with some fibroblasts on the capsule surface, without any NK cells, granulocytes, T cells, or B cells [21]. These results indicate that in an allotransplantation model it may be most important to block macrophage activation and neutralize the effects of nitric oxide and superoxide to prevent immune rejection.

Maintenance of cell viability

Maintenance of cell viability and function is essential and is limited by the supply of nutrients and oxygen. Diffusion limitations of oxygen in tissue *in vivo* are far more severe than those of glucose because the concentration of glucose in tissue is many times higher [28]. The requirements of specific tissues for other small molecules and for large macromolecules are poorly understood or have not yet been quantified; the possible existence of transport limitations for large molecules is highly dependent on immunobarrier membrane properties, whereas oxygen limitations are always serious. Oxygen partial pressure (PO_2) at levels high enough to keep cells alive can nonetheless have deleterious effects on cell functions that require high cellular ATP concentrations — for example, ATP-dependent insulin secretion [29]. Supply of oxygen to immunoisolated tissue is therefore the critical component that determines tissue survival and function.

Oxygen supply to encapsulated cells depends in a complicated way on a variety of factors, including:

1) The site of implantation and the local PO_2 in the blood,
2) The spatial distribution of host blood vessels in the vicinity of the implant surface,
3) The oxygen permeability of the membrane or encapsulant,
4) The oxygen consumption rate of the encapsulated tissue,
5) The geometric characteristics of the implant device, and
6) The tissue density and spatial arrangement of the encapsulated cells or tissues.

Despite encouraging results with various tissues and applications [16], the problem of oxygen transport limitations is one of the major hurdles that remain. The maximum PO_2 (about 40 mmHg for the microvasculature) available for extravascular devices limits the steady-state thickness of viable tissue that can be supported.

Islets are particularly prone to oxygen supply limitations because they have a relatively high oxygen consumption rate [29]. In the normal physiologic state they are highly vascularized and are supplied with blood at arterial PO_2. When cultured *in vitro* under ambient normoxic conditions, islets develop a necrotic core, the size of which increases with increasing islet size, as is to be expected as a result of oxygen diffusion and consumption within the islet [29]. Central necrosis of the encapsulated islets occurs after islet microcapsule transplantation, resulting in reduction in transplant volume when only a small fraction (~10%) of the capsules has fibrotic overgrowth [30]. The fact that necrotic tissue is at the center instead of the periphery of the islet indicates that it is likely a nutrient or oxygen supply limitation causing the necrosis and not a mechanism of the immune system. Hypoxia causes encapsulated islets in culture to become necrotic and to upregulate inducible nitric oxide synthase (iNOS), which indicates that islets are producing NO that can cause damage to themselves. Hypoxia also causes islets to upregulate monocyte chemoattractant protein 1 (MCP-1), which can attract macrophages and hence also induce islet damage post-implantation [31]. The results of all of these studies indicate that oxygen transport limitations exist within transplanted islet microcapsules and can have serious effects on islet survival.

Previous modeling studies have investigated how device designs affect oxygen transport limitations. Amongst devices that incorporate tissue in the form of slabs, cylinders, or spheres, the spherical geometry is the most beneficial when comparing the volume fraction of non-anoxic tissue in each geometry [11]. When small amounts of tissue are required for transplantation, the size of the device that is required is feasible in all geometries, but as the amount of tissue increases, especially for the large amount required for islet transplantation, the surface area of the slab, the length of the cylinder, or the number of microcapsules increases significantly [11].

The size of a planar diffusion device and the volume of microcapsules needed were estimated by assuming that 500,000 islets may be required to treat type 1 diabetes [32]. In a planar diffusion device with 120 μm islets sandwiched between 100 μm thick membranes and device surface oxygen partial pressure of 40 mmHg, the maximum islet density is 1100 islets/cm [2] for fully functional tissue, which corresponds to a total device surface area of 450 cm^2 [33]. If it is assumed that there is 1 islet/500 μm diameter microcapsule, then 500,000 capsules would need to be transplanted, equaling a total volume of 33 mL.

STRATEGIES FOR IMPROVING IMMUNOBARRIER DEVICES

Enhancement of immunoprotection capacity of devices

It will never be possible to create a device that provides complete immunoprotection. Therefore it is most likely necessary to augment the immunoprotection by short-term administration of immunosuppressive drugs, trapping or neutralizing small toxic molecules released during an immune response, or enhancing the resistance of the islet to the stresses experienced during an immune response. Administration of immunosuppressive drugs defeats the purpose of an immunobarrier device, but tissue survival can be enhanced if immunosuppressive drugs are administered to inhibit the immune response, when it is most severe, for a short time period post-transplantation. Administration of antibody molecules that block T cell costimulation pathways (CTLA4-Ig, anti-CD154, and anti-LFA-1) enhances the length of graft function for neonatal porcine cell clusters or adult porcine islets in alginate microcapsules [34,35]. Alternatively, in order to decrease the immune response post-transplantation, macrophage activation can be prevented by systemic administration of

gadolinium chloride [19] or local administration of clodronate liposomes to reduce cell overgrowth of alginate microcapsules [36]. These studies demonstrate that short-term immunosuppression, which is far less risky than lifetime immunosuppression, can be beneficial in promoting graft survival and enhancing the efficacy of immunobarrier devices.

An alternative approach to suppressing the immune system to enhance graft survival is to neutralize or trap the toxic molecules of the immune system that are released to destroy the transplanted tissue. Macrophages play a role in immune responses to immunoisolated tissues, and it has been demonstrated that the release of nitric oxide from activated macrophages, and not cytokines, is responsible for islet destruction, in a dose-dependent manner [37]. Therefore, including a nitric oxide scavenger such as hemoglobin within the microcapsules can inhibit islet cell death through nitric oxide-mediated mechanisms. Results have shown that the inclusion of live erythrocytes, fixed erythrocytes, or cross-linked hemoglobin in alginate microcapsules enhances islet survival with exposure to activated macrophages or nitric oxide [37,38].

Enhancement of oxygen transport to encapsulated tissue

In order for immunobarrier devices to be successful, the transplanted cells must remain viable and functional post-transplantation. Methods have been developed to enhance mass transfer to immunoisolated tissue, most specifically transport of oxygen, by using vascularizing membranes, *in situ* oxygen generation, exogeneous oxygen supply, thinner microcapsules, smaller islet cell aggregation, and enhancement of the oxygen-carrying capacity of encapsulating materials in order to ensure its permeability. Mass transfer of oxygen to an immunoisolated device can be enhanced if the vasculature is brought in very close contact with the device. The vasculature cannot come into direct contact with the tissue itself, which would be a breach of the immunobarrier, but vessels in close proximity to the device are beneficial. The Theracyte™ planar diffusion chamber (originally developed at Baxter Healthcare, later marketed by Theracyte, Inc) has two membranes:

1) An exterior vascularizing membrane that has an optimal pore size (5 μm) so that cells can penetrate the layer and vascularization is induced, and
2) An immunoisolating membrane, pore size 0.45 μm.

Both of these are made from PTFE [17]. The timecourse of membrane microarchitecture-driven neovascularization involves migration of vessels towards the membrane surface over a 10 day period [39], after which the microvascular structure stabilizes for a long period of time [40]. The Theracyte™ device has been effective in maintaining cell viability and protecting from allograft rejection in rodent models [41,42]. The device can be preimplanted in order to induce vascularization of the device prior to transplantation, which aids in islet survival post-transplantation [43]. In addition, infusion of the device with vascular endothelial growth factor (VEGF) improves the density of blood vessels that form around the device [44]. Other materials have been examined for use in promoting neovascularization, including a dual porosity electrospun nylon membrane [45] and a stainless steel mesh [46].

An alternative approach to overcoming oxygen limitations is to supply implanted tissue with oxygen generated *in situ* adjacent to one side of the immunobarrier device [47]. On the other side, the exterior of the device is exposed to either culture medium for *in vitro* studies or the host tissue for *in vivo* conditions. *In situ* oxygen generation can occur by the electrolytic decomposition of water in an electrolyzer [47]. The electrolyzer takes the form of a thin, multilayer sheet, within which electrolysis reactions take place on the anode and the cathode to form oxygen and hydrogen, respectively [47]. *In vitro* studies with βTC3 cells in the *in situ* oxygen generation device show that the thickness of viable tissue increases with oxygen generation [47]. Furthermore, insulin secretion rate from islets contained in such devices is higher with than without oxygen generation. However, control of the

maximum PO_2 to which islet cells are exposed is relatively complicated with this approach [12]. Another method described for *in situ* oxygenation is light illumination of encapsulated algae to produce oxygen by photosynthesis [48]. However, this method is far less efficient, and therefore more costly, than direct electricity for water hydrolysis.

An alternative to *in situ* generation is periodic supply of oxygen in gaseous form to an implanted device. One novel approach, termed the βAir® device, contains islets immobilized within a flat alginate slab, supplied with oxygen by diffusion through a gas permeable membrane from an adjacent inner gas chamber that is replenished daily through an external port and protected from the host immune cells by a microporous membrane, the pores of which are filled with alginate. Initial studies with the βAir® device achieved normoglycemia in diabetic rats with isogenic and allogenic islet implants [49,50] and demonstrated the benefit of supplying oxygen at increased PO_2 levels from one side of the alginate slab.

Oxygen transport to encapsulated islets can be enhanced by reducing the diffusion distance through the use of smaller capsules or thinner membranes. There are drawbacks to reducing the diffusion distance, because free radicals released from immune system effector cells may not become inactivated prior to reaching the encapsulated tissue, and the amount of shed antigens from the encapsulated tissue can be increased, thereby enhancing the recipient's immune response to the transplant. Alginate capsules made using an electronic droplet generator, as opposed to an air-driven droplet generator, can be made to be <500 μm instead of ~ 800 μm. There are also techniques in which only a thin coherent membrane is used to coat the islets. Examples are the use of an emulsion procedure to form calcium alginate PLO microcapsules [51] or by centrifuging an islet alginate cell suspension in a discontinuous gradient that contains a barium chloride layer [52]. Polyethylene glycol derivatives have also been employed to prepare extremely thin coatings with a layer-by-layer encapsulation technique [52a].

Two other approaches can be employed to enhance oxygen delivery to encapsulated tissue:

1) Enhance the dissolved oxygen-carrying capacity of the material and thus increase the oxygen permeability and the rate at which oxygen can be delivered to the tissue, for example, by combination of a highly concentrated perfluorocarbon (PFC) emulsion with alginate (PFC alginate);
2) Reduce islet tissue size so as to decrease the diffusion distance, for example, by dispersing the islets into single cells followed by reaggregation into cell clusters smaller than the original islet.

In a recent study [53] a theoretical reaction-diffusion model was used to predict the three-dimensional distribution of oxygen partial pressure in a spherical microcapsule and a planar slab containing islet tissue, from which the loss of cell viability and the reduction in insulin secretion rate was eliminated. Numerical simulations were carried out for normal alginate and PFC alginate to examine the effect of surface oxygen partial pressure, capsule diameter, slab thickness, and the size and density of dispersed islet tissue on viability and function. Results showed that hypoxic conditions can be reduced, thereby enhancing islet viability and substantially maintaining insulin secretion rate when PFC emulsion is incorporated in the encapsulation material or when smaller islet cell aggregates are used in both types of geometries. Components that can be used for enhancing oxygen permeability are organic compounds with high oxygen solubility, such as perfluorocarbons, silicone oils, or soybean oils. Perfluorocarbon emulsions have been developed as blood substitutes and could be incorporated into the encapsulation material to increase its oxygen permeability. Perfluorocarbons and silicone oils have been used to enhance oxygen transfer in bioreactors [53,54]. There are reports in the literature that including a perfluorocarbon emulsion in islet culture medium enhances islet function [55]. Perfluorocarbons have also been used in the storage of the pancreas prior to islet isolation to increase islet yield and storage time [56]. Inclusion

of hemoglobin in alginate microcapsules increases the length of islet survival after transplantation [57], but this enhancement likely results from a mechanism that does not involve enhanced oxygen permeability such as trapping of nitric oxide.

The effect of enhancing encapsulant oxygen permeability was examined experimentally [58] using two model systems: barium alginate and barium alginate containing a 70% (w/v) perfluorocarbon (PFC) emulsion. Mitochondrial function was assessed by oxygen consumption rate measurements. After low-oxygen culture for 2 days, islets in normal alginate lost substantial viable tissue and displayed necrotic cores, whereas most of the original oxygen consumption rate was recovered with PFC alginate, and little necrosis was observed. These findings suggested that enhancement of oxygen permeability of the encapsulating material with a concentrated PFC emulsion improved survival of encapsulated islets under hypoxic conditions.

In another recent report, small islet cell aggregates were studied to determine whether their survival and function were superior to intact islets within microcapsules because of reduced oxygen transport limitation and inflammatory mediators. Islet cell aggregates were generated by dispersing rat islets into single cells and allowing them to re-aggregate in culture. Rat islets and islet cell aggregates were encapsulated in barium alginate capsules and studied when cultured in low or normal oxygen or transplanted into mice. Encapsulated islet cell aggregates were able to survive and function better than intact islets in terms of oxygen consumption rate, nuclei counts, insulin-to-DNA ratio and glucose-stimulated insulin secretion. They also showed reduced expression of pro-inflammatory genes. Islet cell aggregates showed reduced tissue necrosis in an immunodeficient transplant model, and a much greater proportion of diabetic xenogeneic transplant recipients receiving islet cell aggregates had reversal of hyperglycemia than recipients receiving intact islets. These aggregates were superior to intact islets in terms of survival and function in low-oxygen culture and during transplantation and are likely to provide more efficient utilization of islet tissue.

We envision that the type of microcapsule that results in successful islet transplantation will provide some immunoprotection by preventing contact between islets and activated immune cells, complement components, and antibodies. However, this is likely not enough to provide complete immune protection, and inclusion of a costimulatory blocker such as

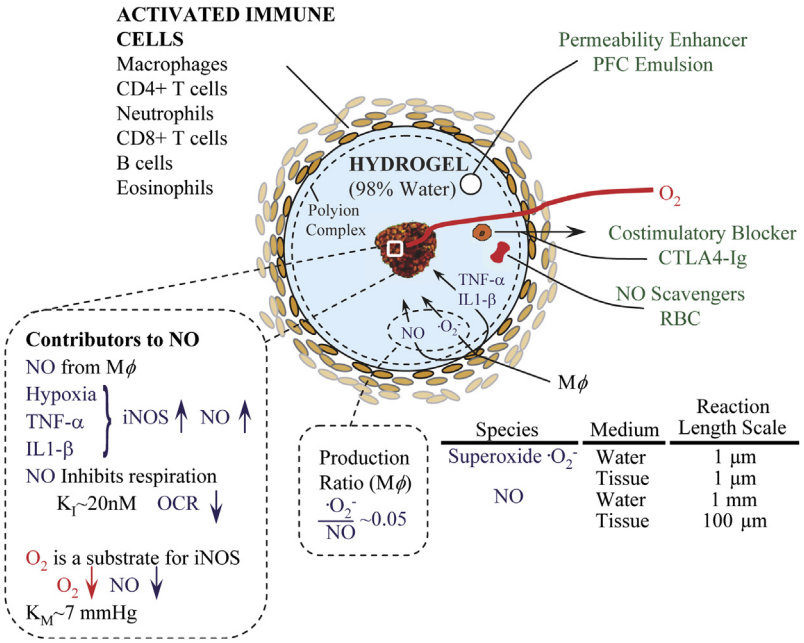

FIGURE 28.4

Activated immune cells surround the microcapsule, causing islet damage. Immune cell types are listed roughly in decreasing order of involvement in inflammatory and immune reactions to implanted immunobarrier devices. Macrophages damage islets through the release of nitric oxide, super oxide, and cytokines (labeled in blue). Oxygen supply (labeled in red) to encapsulated islets is limited, causing hypoxic conditions that are detrimental to islet survival. Potential methods to protect tissue from immune reactions or enhance oxygen delivery to improve encapsulated islet survival are labeled in green.

CTLA4-Ig and an NO scavenger such as red blood cells will greatly enhance the immunoprotective properties of the microcapsules. These modifications should help in preventing immune destruction of the islets, but increased delivery of oxygen is still required to maintain islet survival and function. Increased oxygen delivery can be accomplished by including a permeability enhancer, such as a PFC emulsion, in the alginate matrix. A picture of this ideal microcapsule that is likely to overcome many of the challenges that hamper immunobarrier devices is depicted in Fig. 28.4. The following section examines the oxygen levels within microcapsules that contain islets and a PFC emulsion for the purpose of improving islet survival and function.

THEORETICAL ANALYSIS OF PFC-CONTAINING MICROCAPSULES

One way to enhance oxygen delivery to immunoisolated tissue is to increase the permeability of the immunobarrier material. One method to enhance the permeability of alginate microcapsules for islet transplantation is to make the capsules from an alginate solution that contains a perfluorocarbon (PFC) emulsion. Perfluorocarbons are highly desirable materials for enhancing oxygen delivery, due to their very high oxygen solubility, approximately 25 times that of water on a volumetric basis. Enhanced solubility will lead to enhanced permeability because the permeability is the product of the gas solubility and diffusivity in the material of interest. We have currently been studying a perfluorocarbon emulsion made from perfluorodecalin and 20 wt% (w/v) Intralipid® (Baxter), a soybean oil emulsion [59]. To assess the benefits of PFC-containing microcapsules, a theoretical model has been developed to predict the local partial pressure of oxygen, which, in turn, is used to assess tissue viability and the fraction of normal insulin secretion for encapsulated islets and single cells. Predictions of the model will be presented for a 500 μm capsule that contains a 150 μm diameter islet or single cells that have a total tissue volume equal to that of the 150 μm diameter islet. A diagram of the two geometries is presented in Fig. 28.5. The islets are assumed to have the properties of rodent islets, in which the beta cells (Layer 1), comprising about 75% of the islet volume, are at the center of the islet and the non-beta cells form an outer shell (Layer 2) that is then surrounded by the alginate microcapsule (Layer 3). It should be noted that human islet beta cells are distributed throughout the entire islet; consequently, predicted beta cell viability and insulin secretion predictions will be slightly higher than for rodent islets.

Problem formulation

We used the one-dimensional species conservation equation for reaction and diffusion in spherical coordinates to predict the oxygen profile within the microcapsule:

$$D_i \frac{1}{r^2}\frac{d}{dr}\left(r^2 \frac{dC_i}{dr}\right) = V_i \tag{28.1}$$

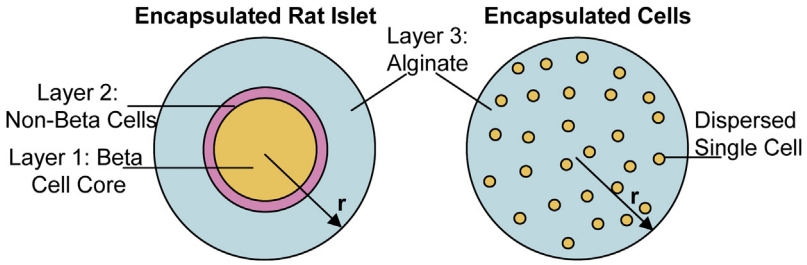

FIGURE 28.5
Capsule geometry (drawing not to scale).

where D_i (cm^2/s) is the effective diffusivity of oxygen in layer, C_i (mol/cm^3) is the concentration of oxygen in layer *i*, and V_i ($mol/cm^3/s$) is the local oxygen consumption rate per unit volume in layer i. For convenience, since partial pressures are equal across interfaces of different materials, we make use of oxygen partial pressure instead of concentration, which are related by:

$$C = \alpha P \tag{28.2}$$

where α ($mol/cm^3/mmHg$) is the effective Bunsen solubility coefficient in layer *i*, and *P* is the partial pressure of oxygen. Combining Eqs. (28.1) and (28.2) gives:

$$(\alpha D)_i \frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{dP_i}{dr}\right) = V_i \tag{28.3}$$

The oxygen consumption rate is assumed to follow Michaelis-Menten kinetics for all tissue,

$$V_i = \frac{V_{\max}(1-\varepsilon_i)P_i}{K_m + P_i} \tag{28.4}$$

where V_{max} is the maximum oxygen consumption rate for the tissue, ε_i is the tissue volume fraction in layer *i*, and K_m is the Michaelis-Menten constant. For the capsule that contains an islet, no oxygen is consumed in the alginate layer; therefore V_3 is equal to zero, and the tissue volume fraction in the islet Layers 1 and 2 is equal to 1.

Equation 28.3 is solved simultaneously for the three layers of the islet microcapsule, subject to the following boundary conditions. The islet is assumed to be centrally located. At the capsule center a symmetry boundary condition is used:

$$\left.\frac{dP_1}{dr}\right|_{r=0} = 0 \tag{28.5}$$

Transport and reaction parameters in Layers 1 and 2 are identical. There is no need for a separate solution in regions 1 and 2 or for the associated boundary conditions. At the interface between Layers 2 and 3 (the interface between the non-beta-cell portion of the islet and alginate), where $r = R_2$:

$$r = R_2 \quad P_2 = P_3 \tag{28.6}$$

$$r = R_2 \quad (\alpha D)_2\frac{dP_2}{dr} = (\alpha D)_3\frac{dP_3}{dr} \tag{28.7}$$

The final boundary condition required to solve the equations is the assumption that the external partial pressure of oxygen is specified at the capsule surface (P_s):

$$r = R_3 \quad P_3 = P_s \tag{28.8}$$

For the case of a capsule containing dispersed single cells that have a total volume equal to a 150 μm islet, the model consists only of one layer, $\varepsilon = 0.027$, the boundary conditions are represented by Eqs. (28.5) and (28.8), and all subscripts referring to layers can be dropped.

Material and tissue properties

Several material properties for each layer were determined from theoretical relationships. The ratio of the effective permeability $(\alpha D)_{eff,i}$ for layer i, consisting of a dispersed (*d*) phase and a continuous (*c*) phase (as occurs in the alginate layers of the model system), to the permeability of the continuous phase $(\alpha D)_c$ was calculated from Maxwell's relationship:

$$\frac{(\alpha D)_{eff,i}}{(\alpha D)_c} = \frac{2 - 2\phi + \rho(1+2\phi)}{2 + \phi + \rho(1-\phi)} \tag{28.9}$$

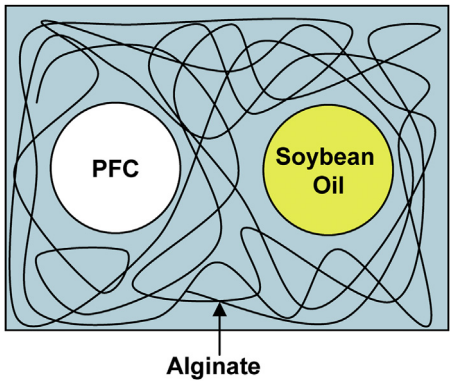

FIGURE 28.6
PFC alginate consists of PFC and soybean oil droplets surrounded by an alginate matrix with a continuous water phase.

where αD is the effective permeability of the material (mol/cm/mmHg/s), $\rho = (\alpha D)_d/(\alpha D)_c$ is the ratio of the permeability of the dispersed phase to the permeability of the continuous phase, and ϕ is the volume fraction of the dispersed phase. For the multiple dispersed phases employed in our model system, Maxwell's relationship was used sequentially, starting with the phase with the smallest particle size and ending with the phase with the largest particle size. For particle types of the same size, Maxwell's relationship was used for one particle and then the other (and in the reverse order), and the two results were averaged.

In the final PFC alginate composite phase, there were perfluorodecalin and soybean oil droplets of approximately the same size; the alginate polymer itself was treated as an impermeable phase dispersed in water (Fig. 28.6). The effective permeability of PFC emulsion was estimated by first using Maxwell's relationship for PFC droplets in water and then for soybean oil droplets in the PFC and water emulsion. Secondly, Maxwell's relationship was used for soybean oil droplets in water and then for PFC droplets in the soybean oil and water emulsion. The two effective permeabilities as calculated were averaged (Fig. 28.7). Finally, the effective permeability of PFC alginate was estimated with alginate as the dispersed phase and PFC emulsion as the continuous phase. The pure component material transport

TABLE 28.1 Transport properties of materials in system

	D (cm^2/s)	α (mol/mmHg/mL)	αD (mol/cm/mmHg/s)	Source
H_2O	2.78×10^{-5}	1.27×10^{-9}	3.53×10^{-14}	Avgoustiniatos and Colton (1997b)
PFC	5.61×10^{-5}	2.54×10^{-8}	1.42×10^{-12}	Tham *et al.* (1973)
Soybean Oil	2.13×10^{-5}	6.84×10^{-9}	1.46×10^{-13}	Bailey (1979) Fillion and Morsi (2000)
Tissue	1.24×10^{-5}	1.00×10^{-9}	1.24×10^{-14}	Avgoustiniatos and Colton (1997b)
Alginate	0	0	0	Avgoustiniatos and Colton (1997b)

TABLE 28.2 Effective permeability calculated using Maxwell's relationship

	αD (mol/cm/mmHg/s)
70 wt% PFC emulsion	9.92×10^{-14}
70 wt% PFC alginate	9.63×10^{-14}
Dispersed cells, 70 wt% PFC alginate	9.31×10^{-14}
Pure alginate	3.43×10^{-14}
Dispersed cells, pure alginate	3.35×10^{-14}

All capsules are composed of 2 vol% alginate.

properties are given in Table 28.1, and the effective properties for different alginate types are given in Table 28.2.

The enhancement of PFC emulsion permeability relative to that of water or to the Intralipid® emulsion used as the starting material is shown in Fig. 28.8. A 70 wt% PFC emulsion has approximately 2.8 times the permeability of water and 2.1 times the permeability of Intralipid®. There is a smaller relative enhancement in the permeability of the emulsion when compared to Intralipid® because Intralipid® contains soybean oil, which has enhanced permeability to oxygen compared to water. In comparison, a 90 wt% PFC

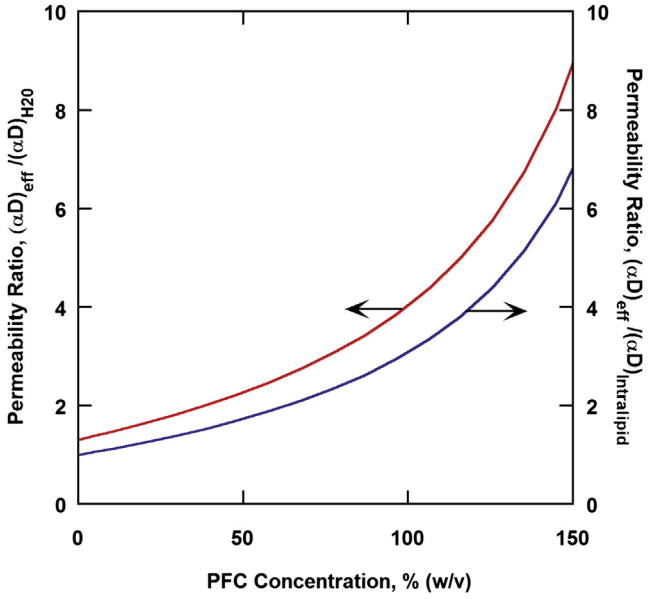

FIGURE 28.8
Permeability enhancement of PFC emulsion relative to water (left axis) or Intralipid® (right axis). PFC wt% = ρPFC × PFC vol%.

emulsion (maximum PFC loading in our experimental system) has 3.6 times the permeability of water, and a 110 wt% PFC emulsion (maximum reported loading for a PFC emulsion in the literature) has 4.6 times the permeability of water.

The relationship used to predict the local fraction (FS) of normal insulin secretion rate as a function of local oxygen partial pressure within the islet was developed from data on the effect of hypoxia on islet insulin secretion, estimating the oxygen partial pressure profile within the islet in the experimental system, and then determining the simplest model type and parameters(s) that best predict the insulin secretion level [29,33]. The result for a value of $V_{max} = 4 \times 10^{-8}$ mol/cm^3/s is:

$$\begin{aligned} P < 5.1 \text{ mmHg} \quad F_s &= \frac{P}{5.1} \\ P \geq \text{mmHg} \quad F_s &= 1.0 \end{aligned} \tag{28.10}$$

The fraction of normal insulin secretion averaged over the whole islet was determined by evaluating the volume integral of F_s in Layer 1. The fractional viability of the beta cell core (Layer 1) was estimated by determining the volume of tissue where $P_1 > P_c - P_c$ is the critical oxygen partial pressure below which tissue dies, and the value of P_c is assumed to be 0.1 mmHg.

Comparison of O_2 profiles in microcapsules containing single cells or an islet

The model equations were solved using the parameters given in Tables 28.1, 28.2, and 28.3. The resulting oxygen profiles for a surface oxygen partial pressure (PS) of 36 mmHg are given in Fig. 28.9. The results demonstrate that for the same amount of total tissue, its distribution within the capsule can greatly affect tissue survival and the minimum oxygen level that the tissue experiences. In a pure alginate capsule, the oxygen partial pressure drop from the capsule surface to its center is only 3 mmHg for dispersed cells, whereas P decreases to values equal to PC for a capsule containing one islet in the center, thereby indicating that there will be some loss of islet tissue in the pure alginate capsule. When the alginate microcapsule is made from a perfluorocarbon emulsion, the drop in the partial pressure of oxygen is smaller in both examples. The enhanced permeability of the PFC-alginate composite prevents oxygen partial pressure from decreasing to PC in the case of an encapsulated islet.

Predicted fractional viability and insulin secretion rate

By using the oxygen profiles shown in Fig. 28.9, the overall tissue fractional viability and insulin secretion rate were calculated for the capsules containing an islet. Comparison of beta cell fractional viability and relative insulin secretion for an islet centrally located in microcapsules containing 0, 30, 70, and 110 wt% PFC-alginate microcapsules are shown in Figs. 28.10 and 28.11, respectively. The range in capsule surface oxygen partial pressure (PS)

TABLE 28.3 Other model parameters

	Parameter value	Units
R_1	68	μm
R_2	75	μm

studied corresponds to the ranges that could occur in the peritoneal cavity, the most common implantation site of microcapsules. Experimental measurements of PO_2 in empty perfluorocarbon-loaded capsules have resulted in measurements ranging from 38 to 0 mmHg [60]. Over a range of PS there is an enhancement of beta cell survival for islets encapsulated in PFC-containing microcapsules, and the degree of enhancement is a function of PFC loading. Maintenance of normal insulin secretion of islet beta cells is substantially enhanced by including PFC in the microcapsules in a dose-dependent fashion (Fig. 28.11). The results in Figs. 28.10 and 28.11 demonstrate that including PFCs in alginate microcapsules can increase islet survival and even further enhance islet function after capsule transplantation.

Predicted fraction of normal insulin secretion for a centrally located islet in pure- and PFC-containing alginate microcapsules with variable PFC loading.
PFC wt% = ρPFC × PFC vol%.

FUTURE DIRECTIONS

Immunobarrier devices have the potential to provide treatments for many human diseases. Immunobarrier devices have entered into clinical trials in which transplantation of smaller numbers of cells or placement in less immune responsive sites is possible or even desirable, and recently a clinical trial with islet containing alginate microcapsules has begun [16,61]. No encapsulation method has yet come into widespread clinical use. Through studies of new immunobarrier materials, methods to enhance the immunoprotection properties of the materials used as immunobarriers, and methods to increase the oxygen supply to the encapsulated tissue, many human diseases, including type 1 diabetes, may one day be treated by cell therapies using immunobarrier devices.

CHAPTER 29

Embryonic Stem Cells

Irina Klimanskaya, Erin A. Kimbrel and Robert Lanza
Advanced Cell Technology Inc., Marlborough, Massachusetts

INTRODUCTION

Tissue engineering relies on the availability of cells capable of repairing or replacing damaged tissues and organs. Although multiple sources of cells from cadavers to animal tissues have been considered, stem cells are of intense interest because they can be expanded indefinitely in culture, and can also be directed to differentiate into a particular cell type of interest. Adult tissue-derived stem cells, such as those from bone marrow, fat, and skin are among the most studied and while some are currently being used in the clinic, these sources are donor-dependent, have limited expansion potential, and a highly restricted differentiation capacity. Ideally, having a single inexhaustible source of pluripotent cells that can generate large quantities of therapeutic cells would greatly facilitate regenerative medicine endeavors while simplifying quality control and safety testing. Human embryonic stem cells (hESCs) offer the unique possibility of meeting these criteria and thus may be able to circumvent many of the problems associated with variations in donor-dependent cell sources.

Derivatives of hESCs have been regarded by many as a panacea for the treatment of various ailments, ranging from osteoarthritis to blindness, heart disease and spinal cord injuries, among others. The list is long, and numerous promising studies in animal models indicate that the question now is not whether hESC-based therapies could be safe and effective but what indications are they best suited for and how soon can they become a standard of care. Before this happens however, several unique challenges will need to be overcome. For example, the generation of hESCs is wrought with controversy, since the standard derivation process involves destruction of a developing human embryo. Similar to adult tissue-derived cell sources, histo-incompatibility may also limit the widespread use of hESC-based therapies, since careful HLA matching will be needed to avoid immune rejection. Of note, the advent of induced pluripotent stem cells (iPSCs) could one day alleviate both the ethical and histo-incompatibility issues surrounding hESC use [1,2]. iPSCs can be generated from a person's own mature somatic cells and through the process of reprogramming, be turned back into a pluripotent state for use as a patient-specific renewable cell source with broad differentiation capabilities. Currently, iPSC technology is still being optimized for efficiency and safety, yet one day could rival hESC as the future of regenerative medicine. This chapter will focus on hESC and their derivatives, but much of the knowledge that has been gained through this research is applicable or even transferable to the iPSC field.

APPROACHES TO hESC Derivation

hESCs were first isolated in 1998 from the inner cell mass (ICM) of a pre-implantation human blastocyst in a landmark study by Thompson et al. [3]. As research with hESC gained interest,

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00029-X

great promise as well as great controversy was brewing in the press. hESCs theoretically have the capability to give rise to all tissues of the human body and may provide crucial therapeutic treatment for a wide variety of diseases. However, the only known hESC derivation process back in the late 1990s/early 2000s involved destruction of a human embryo, and this was seen by some as the equivalent of killing a human being. Acknowledging the enormous potential of hESC research while also trying to quell the ethical firestorm that hESC derivation had garnered, in 2001, the Bush administration made the decision to allow federal funding for hESC research on the condition that only hESC lines already in existence could be used. The NIH hESC registry list [http://stemcells.nih.gov/research/registry/ (Accessed May 21, 2013)] was established to keep track of the approved lines. The original hESC lines derived by Thompson et al. at the University of Wisconsin [3] were among the first hESC lines registered, and have become the most widely used and published hESC lines available. Since then however, many other hESC lines have been derived using private funds, and other stem cell banks and registries have been created. Examples include the University of Massachusetts (UMass) International Stem Cell Registry http://www.umassmed.edu/iscr/index.aspx (Accessed May 21, 2013), European Human Embryonic Stem Cell Registry http://www.hescreg.eu/ (Accessed May 21, 2013), and UK Stem Cell Bank http://www.ukstemcellbank.org.uk/ (Accessed May 21, 2013).

hESCs retain a fundamental property of ICM cells — the ability to give rise to all tissues of the human body. The same markers of pluripotency are found in both ICMs and hESCs — the transcription factors Oct-4, NANOG, Rex-1, cell surface antigens SSEA-3, SSEA-4, TRA-1—60, TRA-1—81 (Fig. 29.1) and high alkaline phosphatase activity [4,5]. Cells of the ICM only exist for a few days in the natural course of embryo development; they arise during blastocyst formation from a morula on day 4 and persist throughout the first days or hours post-implantation before

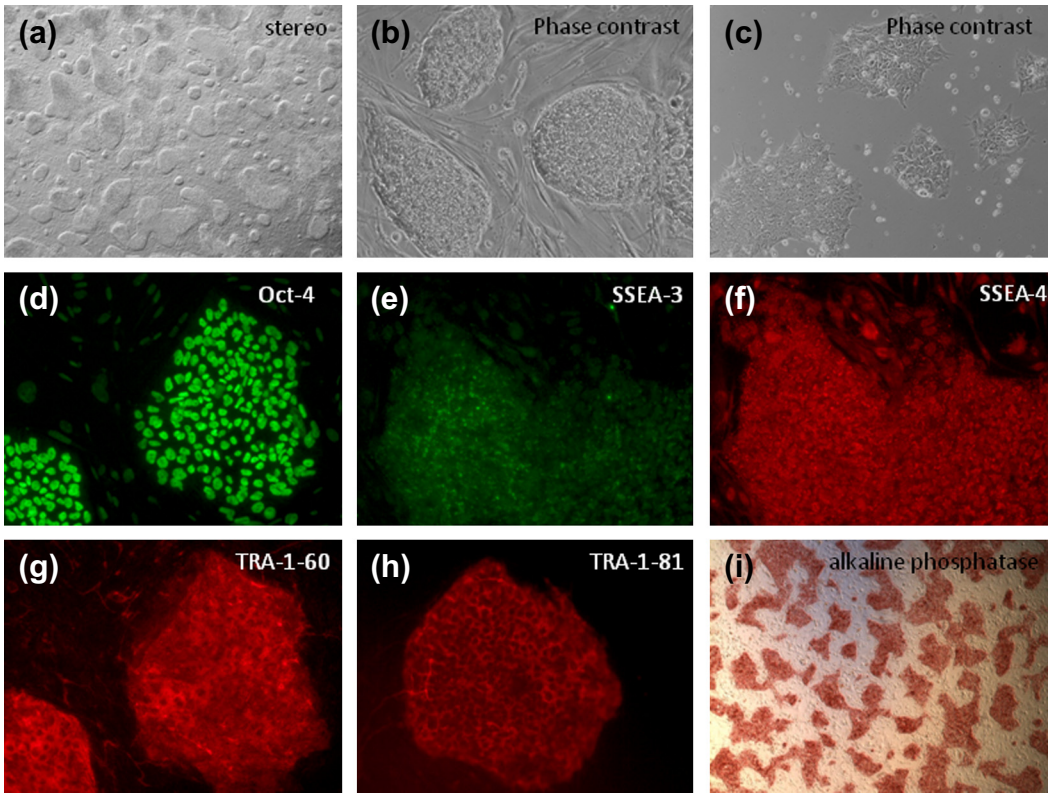

FIGURE 29.1

Morphology and markers of hESC. a, b — hESC grown on feeder cells, c — hESC grown on Matrigel, d—i — markers of pluripotency in hESC. a — stereo microscope image (as seen during mechanical dissesction), b, c — phase contrast, d — H immunofluorescence, i — bright field. d — Oct-4, e — SSEA-3, f — SSEA-4, g — TRA-1—60, h — TRA-1—81, i — alkaline phosphatase. beginning the highly orchestrated process of differentiation. Embryonic stem (ES) cells may be seen as an immortal extension of the ICM in culture; they retain high telomerase activity and can continue to self-renew indefinitely under appropriate culture conditions. When injected into immune-deficient mice, hESC form teratomas — tumors that contain derivatives of all three germ layers, the most typical ones being bone, cartilage, neural rosettes and epithelium of the airways and gut. Like the ICM of a developing blastocyst, pluripotent embryonic stem cells (ESCs) in culture are primed to differentiate, and as we will discuss later in the chapter, this makes working with them both easy and difficult at the same time.

Traditionally, ES cells have been derived from day 5–7 blastocysts with or without immunosurgery (removal of the trophoblast) by plating a blastocyst or an isolated ICM (Fig. 29.2) on a feeder layer of mitotically inactivated mouse embryonic fibroblasts [3,6]. However, new lines have now been derived using alternative approaches in an attempt to overcome the ethical issues surrounding embryo destruction during hESC derivation [7,8]. Moreover, the use of mouse feeder cells and animal products during hESC derivation and maintenance has been eliminated in newer methods because of safety concerns that they could harbor unknown xeno viruses. Producing cells that are compatible with a patient's own immune system is also an important consideration for preventing rejection. Thus at present, hESCs have been derived on human feeders [9–11] and even on feeder-free matrices [12]; they have been derived from growth-arrested IVF embryos that cannot be used for implantation [13], from unfertilized oocytes that are incapable of forming a developmentally competent embryo [14–17], and from a single blastomere of a morula stage embryo — a technology that allows the generation of hESCs while leaving the embryo unharmed [11,18–20].

Derivation of hESCs from chemically activated unfertilized oocytes (parthenote hESCs) was reported by several groups [14–17]. These studies showed that parthenote hESCs are very similar to ICM-derived hES cells: they have the same colony morphology and growth behavior, maintain a normal karyotype, express the same markers of pluripotency, and differentiate into derivatives of all three germ layers. These cells could become a solution to both the ethical and immune compatibility issues that plague traditional hESC lines, as a limited number of parthenogenetic hESC lines from carefully selected donors could match almost everyone on the planet because they have a reduced number of HLA. However, more recent studies showed

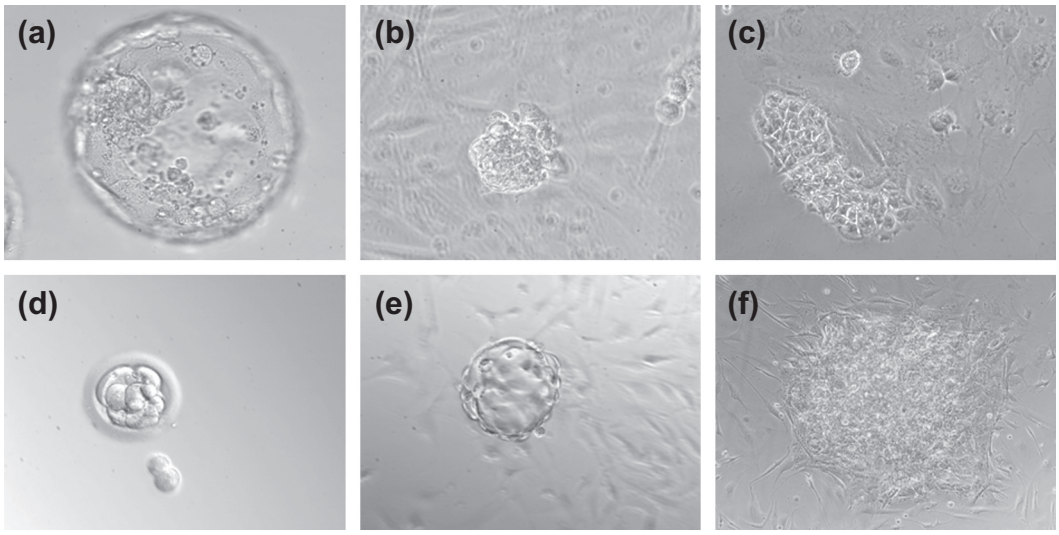

FIGURE 29.2
Early stages of hESC derivation from a blastocyst (a–c) and a single blastomere (d–f). a — expanded blastocyst, b — ICM after immunosurgery plated on feeder cells, c — ICM outgrowth, d — biopsied embryo and a developing blastomere, e — developing blastomere before plating on feeder cells, f — blastomere outgrowth.

that a large percentage of parthenogenetic blastomeres were affected by an excessive number of centrioles, a high aneuploidy rate [21], as well as genetic and epigenetic instability [22]. At this point in time, there are only limited data on the differentiation of parthenote hESCs [23–26] and properties of their derivatives, such as safety and functionality *in vivo*. While promising, it is probably too early to consider parthenogenetic hESC a safe alternative to 'conventional' hESC for generation of cells for regenerative medicine.

Another approach which has proven to be successful for generating hESCs without embryo destruction is the use of embryo biopsy. This procedure, commonly used in pre-implantation genetic diagnostics (PGD) in the course of IVF, involves removal of a single blastomere from a morula stage embryo and has resulted in hundreds of healthy babies being born. Using this procedure, we established several hESC lines from single blastomeres while the donor embryos were allowed to develop to the blastocyst stage and be cryopreserved [20]. Single blastomeres were first co-cultured with the biopsied embryos and then plated on feeder cells in microdrops [18–20]. Outgrowing colonies were treated the same way as ICM outgrowths (Fig. 29.2). In early experiments, blastomere outgrowths were co-cultured with GFP-expressing hESCs, which presumably helped to condition the microenvironment and help boost the outgrowth of hESC from blastomeres. After initial outgrowth was observed and the colony of blastomere-derived cells became large enough for passaging, GFP-negative colonies were marked under the fluorescence microscope and then mechanically dissected and re-plated; this procedure was repeated for several passages to ensure that the new cell lines were free of any contaminating GFP-expressing hESC. Additionally, after the blastomere-derived hESC lines were established, they were extensively tested for the absence of GFP-positive hESC used for co-culture and shown to be free of any GFP-expressing hESC [18,19]. Two hESC lines were generated that had similar properties to ICM-derived hESC: they stained positively for Oct-4, SSEA-3, SSEA-4, TRA-1–60, TRA-1–81, alkaline phosphatase, had a normal karyotype, and differentiated into derivatives of all three germ layers both in teratoma assays in NOD-SCID mice and *in vitro*. In the first proof of principle study, the derivation yield was low and the embryos were not preserved after the biopsy, but later this study was repeated using an optimized approach which allowed the derivation of new lines from single blastomeres with higher efficiency and still without embryo destruction. Biopsies that were performed to isolate a single blastomere did not significantly affect the embryos; they developed to the blastocyst stage and were then frozen as expanded and/or hatched blastocysts [20]. Five hESC lines were produced this way from biopsied embryos and all of the embryos developed into healthy-looking blastocysts prior to cryopreservation [20]. This technique was subsequently used by several other groups to derive hESC lines with high efficiency and/or without destroying the embryos [11,27,28]. Single blastomere-derived hESCs showed a similar transcriptional profile to 'conventional' hESCs [29], and several differentiation derivatives of single blastomere-hESCs appeared functional *in vitro* and *in vivo* [30,31]. By avoiding the destruction of human embryos, this technique has addressed the ethical concerns surrounding hESC derivation, thereby offering a way to overcome a major hurdle in developing hESC-based therapies.

MAINTENANCE OF hESCs

Currently there are several popular hESC culture systems in existence, and with a little optimization, all of them can be used to grow pluripotent cells with relative ease. Mouse embryonic fibroblasts or human fibroblasts derived from fetuses, or placenta, or foreskin have been used as feeders for many years, and the corresponding medium for this culture system is based on Knockout-DMEM (KO-DMEM) and Knockout Serum Replacement (KSR, both components from Invitrogen), supplemented with at least 8 ng/ml human bFGF [12,18–20]. Variations of this system include addition of Plasmanate (Talecris) [12,18–20] or using a 1:1 mix of Knockout-DMEM and F12 medium, or feeder-produced extracellular matrix instead of live feeder cells. On feeders, cultured hESCs have an entirely unique morphology and are best

described as well-defined colonies of small tightly packed epithelial-looking cells with a high ratio of nuclei to cytoplasm and visible nucleoli (Fig. 29.1). When grown in KO-DMEM:F12 media mix or in the absence of feeders (i.e., 'feeder-free'), hESCs can deviate from this phenotype and look more spread-out and even grow as a sheet of cells: however, such cells still retain their pluripotency and are able to both self-renew and differentiate (Fig. 29.1).

Recently, a robust and user-friendly feeder-free system that employs a very dilute Matrigel solution (extracellular matrix produced by Engelbreth-Holm-Swarm (EHS) mouse sarcoma cells) and matching defined medium was introduced by Stem Cell Technologies. Another feeder-free system, made by Invitrogen utilizes CellStart, a human placenta-derived extracellular matrix. Feeder-free protocols are usually provided by individual manufacturers together with a recommended medium and should be optimized by the researcher. In our own studies, we used extracellular matrix produced by mouse embryo fibroblasts, which was deposited and assembled by live cells and provided a three-dimensional growth surface similar to that provided by live feeder cells. This matrix was used in combination with KSR/Plasmanate-based culture medium and was successfully used for derivation of hESCs. Derivation of an hESC line when the initial outgrowth consists of only a few cells is more challenging than routine culture of millions of cells, and this culture system proved to be very supportive of such a demanding task [12].

SUBCULTURE OF hESC

To subculture hESC, several methods can be employed. Mechanical colony dispersion and hand picking has been the gold standard in the field as it allows one to select colonies of correct morphology with minimal stress to the cells, and is probably the only method to derive new lines when there are only a few pluripotent cells and the colony needs to be dissected to avoid differentiation. However, the operator should have appropriate experience because it is also possible to select for aneuploid cells that have a growth advantage as they are quicker to form good-sized and 'good-looking' colonies. On the other hand, a skilled operator may be able to rescue an aneuploid culture by carefully picking colonies of the correct morphology [34]. Of note, extra care must be taken to avoid damaging cells when using mechanical dispersion on hESC grown in a feeder-free system, as these colonies are more fragile than those grown in a feeder-based system. Mechanical passaging is very labor-intensive, and for large scale culture, as required for manufacturing of differentiated cells for therapeutic use, enzymatic dissociation of colonies into single cells and small clumps is much more efficient. Collagenase, accutase, trypsin, TrilpLE (Invitrogen) and EDTA are commonly used for dissociation of hESCs, but all of these can contribute to clonal aneuploidy at later passages, as single cells and small cell clumps (potentially containing aneuploid cells) are distributed throughout the cell population. The tendency of hESCs to undergo clonal aneuploidy reinforces the importance of routine karyotyping while subculturing them. G-banding with examination of a minimum of 20 cells or fluorescence *in situ* hybridization with probes to chromosomes 12 and 17 are appropriate karyotyping methods, as the gain of an extra copy of chromosomes 12 and 17 commonly gives aneuploid ES cells a growth advantage [32–34].

NUANCES OF hESC CULTURE

Almost every culture of hESCs will contain some differentiating cells, and if the colonies are allowed to overgrow, become multi-layered and/or touch each other, they will begin to show massive spontaneous differentiation within hours. Fig. 29.1 shows the morphology of hESCs grown on feeder cells and feeder-free on Matrigel in undifferentiated and slightly differentiated states. Once the cells begin to differentiate, it is more difficult to isolate self-renewing cells. Hand picking may be used in an attempt to isolate non-differentiated colonies, yet even normal looking colonies may harbor cells committed to differentiation; they may have already lost Oct-4 expression and may even express early differentiation markers like nestin (Fig. 29.3).

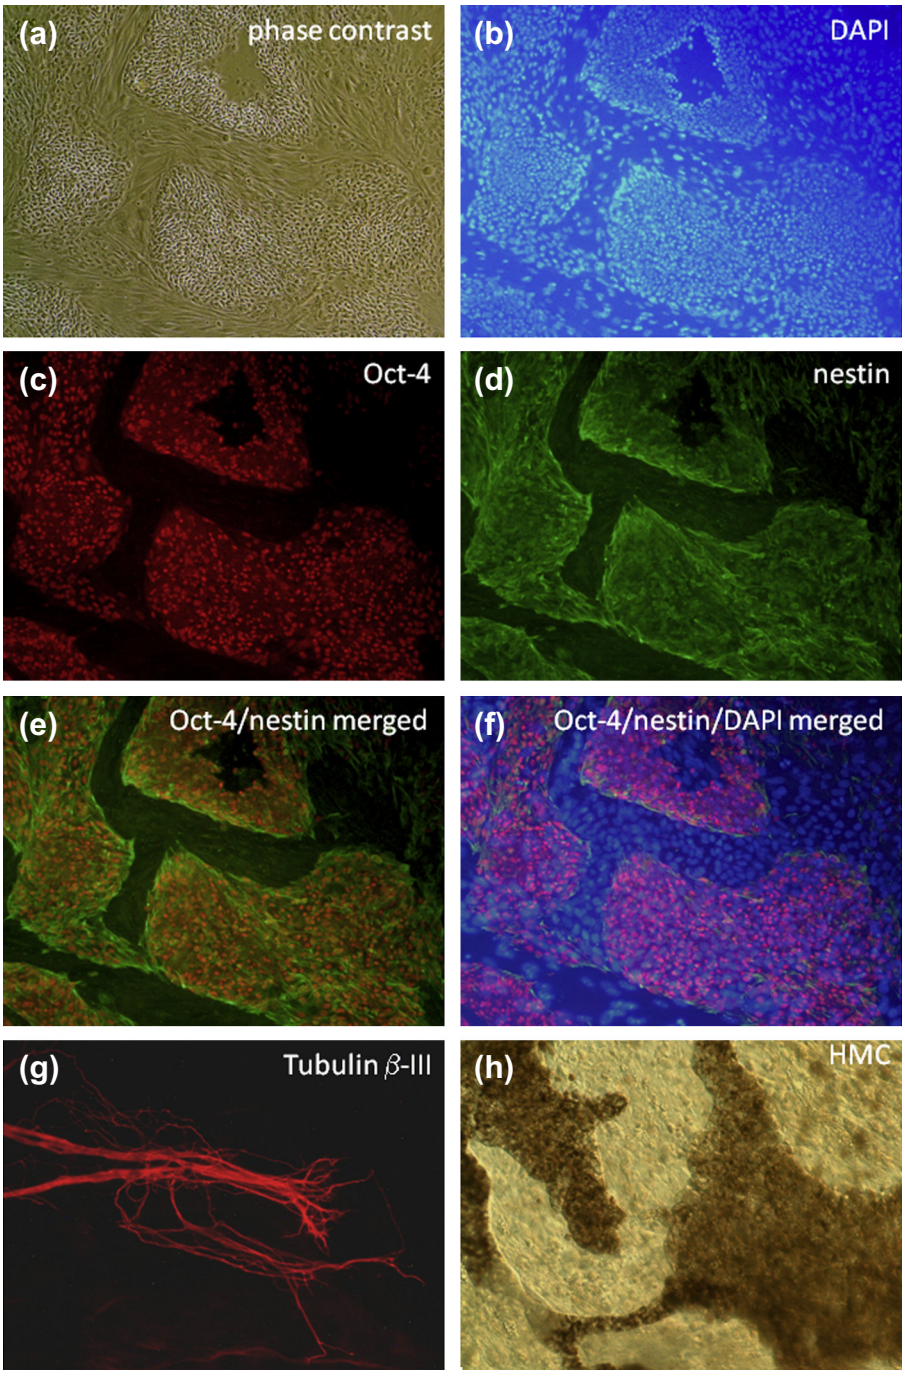

FIGURE 29.3
Spontaneous differentiation of hESC. a—f, nestin-expressing cells are seen within Oct-4 positive colonies. a — phase contrast, b — DAPI co-staining, c — Oct-4, d — nestin, e — Oct-4/nestin merged, f — Oct-4/nestin/DAPI merged. g — tubulin β-III staining showing a differentiated neuron, h — a cluster of RPE. Magnification: a—f, ×100, g, h, ×200. *Images of Oct4/nestin are courtesy of Jennifer Shepard.*

Other nuances of hESC culture come to light with experience and it has been observed many times that different culture conditions may predispose hESC to one or another differentiation route or make a routine differentiation method more difficult to perform. For example, embryoid body (EB) formation is a common first step in many differentiation protocols and it involves plating a suspension of freshly harvested hESC into plates with low adherence properties where they can aggregate into clumps and differentiate into cells of all three germ layers. EB formation occurs quite readily when hESCs have been growing on feeder layers: multitudes of large, round EBs form in suspension with little cell death. Yet, when hESC have been cultured in a feeder-free system, EB formation is problematic; the EBs that form are much smaller and sparser, with a lot of cell death observed in the culture. Additionally, our

experience with multiple hESC lines has shown that some slow growing lines are difficult to maintain due to spontaneous differentiation but they often show very good yields of derivatives when specifically directed to differentiate. On the other hand, other hESC lines are fast-growing and easy to maintain but do not differentiate as robustly. Given these types of peculiarities, differentiation protocols should be tested and modified when different ESC culture conditions or different hESC lines are used.

DIRECTED DIFFERENTIATION

While spontaneous differentiation of hESCs in an adherent state or via EB formation may produce certain types of derivatives (e.g., cardiomyocytes, adipocytes, retinal pigment epithelium, neurons), in many circumstances a higher yield or purity is desirable. Various bioactive factors and/or selective growth conditions can be employed to direct hESC differentiation towards a particular lineage and/or enrich for a desired cell type. While theoretically hESC can give rise to all cell types of the human body, in reality, some derivatives are easier to produce in culture than others, and some have a higher therapeutic potential than others. Some of the highly sought after derivatives with therapeutic value are cardiomyocytes, neural progenitors, hemangioblasts, mesenchymal stem cells, endothelial progenitors, smooth muscle cells, hepatocytes and insulin-producing beta cells. As we discuss below, many different hESC derivatives are being explored and developed for potential clinical use and to date, two derivatives have entered human clinical trials: oligodendrocyte precursors (trial #NCT01217008) and retinal pigment epithelium (trials ## NCT01345006, NCT01469832, NCT01344993; clinicaltrials.gov).

A very interesting hESC derivative with great potential for clinical application is the hemangioblast [35–37] – a multipotent cell which gives rise to both hematopoietic and vascular cells. These blasts can be expanded, cryopreserved (if necessary) and subsequently differentiated into multiple other cell types. Since hemangioblasts can give rise to all types of blood cells, they may one day serve as alternative cell source to primary hematopoietic stem cells for reconstituting the blood system after myeloablation. Or, alternatively, they may be used to generate large scale production of mature blood cells. Erythrocytes and platelets have both been efficiently generated from hemangioblasts [39,40]; the former carried oxygen in a manner similar to primary red blood cells, while the latter formed lamellipodia and filopodia in response to thrombin activation and contributed to thrombi formation at sites of induced vascular injury. Lu et al. have shown that hESC-derived hemangioblasts can also efficiently repair damaged vasculature in rodent models of ischemic reperfusion injury to the limb and eye [37]. In this study, human blast cells integrated into the endothelial network and differentiated into endothelial cells as was shown by double staining with antibodies to CD31 and human nuclear antigen. Another study demonstrated that hemangioblast-produced smooth muscle cells integrated into the vessel wall in nude mice [41]. Other cell types may also be generated from hESC through the use of a hemangioblast intermediate stage. The robust expansion capabilities of this multipotent precursor facilitate large scale production of more mature cell types further downstream.

Other potentially therapeutic cells that have been differentiated from hESCs are mesenchymal stem/stromal cells (MSCs). MSCs are plastic, adherent, fibroblast-like cells that, at a minimum, can differentiate into bone, fat and cartilage. The exact cell surface marker profile that defines true a MSC is still up for debate, yet most MSCs, including those derived from hESCs express CD73, CD90 and CD105 [42–47]. Given their differentiation capabilities, MSCs are being evaluated for treating joint disorders such as osteoarthritis and sports-related injuries. MSCs have also been shown to harbor powerful immunomodulatory properties and this has generated a lot of interest in using them to treat autoimmune disorders. Importantly, MSCs are able to evade immune rejection in non-HLA-matched patients, thereby facilitating allogeneic therapies without the need for immunosuppression. While the exact mechanism responsible

for their immuno-privileged status is unclear, the lack of HLA class II, CD40, and co-stimulatory receptors CD80 and 86, as well as the expression of HLA G, a class I heavy chain paralogue may all be involved [48]. MSCs can be isolated from various adult tissues such as bone marrow, adipose and dental pulp [49] and numerous publications have described the efficacy of these cells in treating animal models of human disease. Over 200 clinical trials are currently underway with adult-derived MSCs for treating anything from autoimmune disorders like lupus, to lung diseases like asthma, to healing wounds and diabetic ulcers. An emerging theory is that younger tissue sources such as cord blood, Wharton's jelly, and hESC may be a better source material for MSC than adult tissues, as their youthful nature facilitates greater *in vitro* expansion and preservation of therapeutic function [43,50–52]. Although hESC-derived MSCs have yet to be tested in clinical trials, they have shown promise in animal studies; they have exerted protective effects in mouse inflammatory bowel disease [43], rat tendon injury [42] and rat limb ischemic injury [46] models. As with tissue-derived MSCs, the possibilities for hESC-MSC clinical use are far-reaching and diverse. Because of their superior *in vitro* expansion capabilities and longer lasting immunomodulatory properties, MSCs derived from hESCs could one day compete with or even replace adult tissue-derived MSCs as an allogeneic off-the-shelf product that can be used with minimal immune suppression.

Cardiomyocytes were one of the first identified differentiated cell types produced from embryonic stem cells [53–60]. Observed in tissue culture dishes as 'beating hearts', patches of cardiomyocytes can easily differentiate from mouse embryoid bodies. Despite the ease of generating patches of cardiomyocytes, they are not easily purified from other cell types that spontaneously arise in differentiating ESC cultures. Multiple growth factors such as activin A and BMP4 and small molecules have been employed to enhance the differentiation of cardiomyocytes with varying success [59]. They can be purified using a Percoll gradient or, because they have a high mitochondria content, a fluorescent dye, tetramethylrhodamine methyl ester perchlorate (TMRM) that labels mitochondria and allows cell sorting can be used [60]. Cell surface markers such as VCAM1 and signal-regulatory protein alpha (SIRPA) have also appeared useful for purification of cardiomyocytes using antibody-based cell sorting [57,58]. Unfortunately, differentiated cardiomyocytes have a limited lifespan and engraftment potential, and the production scale obtainable from hESC is still far too low to repair an ischemic heart. Cardiac progenitor cells may be a better candidate, as they can proliferate and engraft better, and the search for efficient generation of such cells from hESCs is ongoing.

The treatment of diabetes has perhaps been one of the most highly sought after applications for hESC-based therapies, yet the need to effectively differentiate hESC into functional insulin-producing beta cells remains unmet. Multiple studies have been published which report insulin-producing cells differentiated from stem cells, but the majority of insulin-producing cells in culture also make glucagon, which indicates that they are not fully mature [61]. Promising protocols to differentiate hESCs into beta-like cells attempt to simulate different stages of endoderm development *in vitro* by using small molecules and growth factors, manipulating the substrate composition, and using a 3D microenvironment. Several groups have been able to identify stage-specific cell surface markers and isolate enriched populations of cells using PDX1, a pancreatic progenitor marker [62,63]. A staged suspension-based method allowed the scalable production of pancreatic progenitors which, upon engraftment, produced glucose-responsive, insulin-secreting, islet-like tissue that protected mice from streptozotocin-induced hyperglycemia [64]. Poly-hormonal beta-like cells are not fully functional and resemble poly-hormonal cells of early developmental stages, but they can mature into functional cells upon transplantation [65], and the main challenge now is to accomplish the second stage of differentiation of pancreatic progenitors *in vitro*.

Some of the very first and best-studied derivatives of hESC were cells of the neuronal lineage – perhaps, because they are the easiest to obtain in culture [Fig. 29.3] due to a widely recognized ability of hESC to assume a neuronal fate in the absence of other differentiating

signals [66–68]. Many mature and progenitor-like neuronal cell types have been isolated from hESCs [69–73] and shown to be functional in animal models. Such are dopamine-secreting neurons, which improve the behavior of Parkinsonian mice after their transplantation into the brain [71,72]; motor neurons, oliogodendrocytes and motor neuron progenitors [73–78] capable of improving function in a spinal cord injury model; and neural progenitors showing functional engraftment in the brain in experimental ischemia and stroke [79–84]. Oligodendrocyte precursor cells were the first hESC-derived product to be tested in a clinical trial, for the treatment of subacute thoracic spinal cord injury [www.geron.com/grnopc1 (Accessed May 21, 2013)]. While preliminary results from the trial did not show any deleterious effects due to injection of the hESC-derived product [http://ir.geron.com/phoenix.zhtml?c=67323&p=irol-newsArticle&ID=1635760&highlight=spinal cord (Accessed May 21, 2013)], its manufacturer Geron surprisingly shut down its entire ESC research division a year after the trial began, citing the need for financial restructuring and the desire to focus on oncology drug-based therapies [www.businesswire.com/news/home/20111114006308/en/Geron-Focus-Cancer-Programs (Accessed May 21, 2013)].

Besides Geron's oligodendrocyte precursors, the only other derivative of hESCs that has entered human clinical trials to date is Advanced Cell technology's (ACT) retinal pigment epithelium, or RPE. hESC-derived RPE [31,85–87] is being tested in Phase I/II clinical trials in both the US and Europe for two diseases that involve retinal degeneration, namely dry age-related macular degeneration and the heritable juvenile Stargardt's disease [www.advancedcell.com (Accessed May 21, 2013)]. RPE provides 'life-support' to the photoreceptor cells by supplying nutrients and removing shed photoreceptor fragments by phagocytosis, and its malfunction leads to photoreceptor degeneration and eventual blindness. RPE has several unique features that allow this cell type to be an attractive hESC derivative for regenerative medicine purposes:

1. It is easy to detect in culture and isolate with a high degree of purity. Differentiated RPE cell appear as pigmented clusters visible by the naked eye among spontaneously differentiating hESC after several weeks. Their morphology is very similar to that of cultured human RPE from *in vivo* sources – polygonal cells with different degrees of pigmentation. When RPE originating from hESC was first discovered in long term differentiating cultures of hESC, it was due to its unique morphology. Clusters of pigmented epithelial cells were observed and mechanically isolated, expanded and then confirmed to be of this cell type by the molecular marker analysis [85,86]. This 'mechanistic' approach is still being successfully used for isolation of RPE from differentiating cultures of hESC containing multiple layers of multiple cell types, RPE being a minor fraction among other derivatives. When such differentiated cultures are dissociated, it is possible to establish pure cultures of hESC-RPE using cell morphology as the only guidance throughout the mechanical hand picking of pigmented clusters because, although these cells are mature and differentiated, they are nevertheless fully capable of multiple divisions. One six-well plate of differentiating hESC can provide enough RPE at passage 2 to treat 10–20 patients (including many more millions of cells for quality testing).
2. The fully differentiated cells retain their proliferative potential for several passages, allowing one to scale up production without any loss of functional properties. This is owed to a distinctive feature of RPE called transdifferentiation. During this process, cells of a differentiated phenotype are capable of partial de-differentiation and re-differentiation for multiple passages. Under proliferation-promoting conditions, mature RPE cells lose their pigmented epithelial morphology and turn into neural progenitor-like cells (as if going back to their neuroectoderm developmental roots). This is accompanied by the down-regulation of mature RPE markers such as bestrophin, CRALBP, RPE65; loss of cell polarity and cuboidal morphology; and upregulation of neural and retinal progenitor markers – for instance, nestin, Pax6, Sox2, tubulin beta III. When the cells reach confluence and their proliferation slows down, they re-differentiate into pigmented epithelial polarized cuboidal cells and up regulate RPE markers, and if passed again, the cycle would continue for several

passages before they senesce and stop dividing or re-differentiating [85,86]. The ability of these fully differentiated cells to proliferate for several passages while maintaining their phenotype and capabilities after they re-differentiate each time is critical for the large scale production that is needed for both animal safety studies and human clinical trials.

3. hESC-RPE cells can be frozen and thawed without any loss of functionality and can be maintained in culture in a fashion that ensures optimal conditions for post-transplantation survival and functional engraftment. Thus, once mature RPE cells are isolated and plated at passage 0, it becomes possible to monitor and control the degree of their differentiation at each passage. Cells with optimal pigmentation and at the optimal differentiation stage can be identified with differentiation markers and produced for the final harvest. Our studies showed that there was a correlation between the adhesion/survival of RPE *in vitro* and the degree of maturity/melanin content [31] as well as between their effectiveness in animal models and their degree of pigmentation [31].

SAFETY CONCERNS

Safety is the number one requirement for the clinical use of cellular products. For hESC derivatives, this means that they have to be non-tumorigenic. They must be free of pluripotent cells, which can form teratomas *in vivo* and show no adverse effects in animal models. They should also be able to survive long enough to be effective after transplantation but not proliferate uncontrollably, although some proliferation followed by a steady quiescent state would be permissible and in certain cases even desirable. This may not be attainable for every derivative of hESCs, because for clinical use, large numbers of cells need to be generated in culture first. This means that cells of a given type should be able to proliferate in culture but nevertheless maintain a differentiated phenotype after transplantation. This requirement would only allow one to use either fully differentiated cells which are still capable of multiple population doublings (like RPE or MSC), or progenitor/stem cells which are already committed to a known lineage and do not 'misbehave' upon transplantation.

All cell products for clinical use need to be manufactured under Good Manufacturing Practices (GMP), pass sterility and micoplasma tests, and be free of known animal and human pathogens. The presence of animal products during derivation and maintenance of hESC and their progeny is currently unavoidable in most cases, but even co-culture with live animal cells is not forbidden by FDA (Food and Drug Administration) regulations. However, the use of animal cells or products adds more stringent testing of the source cells and their differentiated products. Extensive testing for animal viruses typical for the species whose products were used during manufacturing is required. Special guidelines exist for a xeno product — human cells that have been co-cultured with live animal cells — while cells manufactured in the absence of live animal cells and only exposed to animal products are not considered a xeno product. All bovine sera need to come from spongiform-free sources, typically from the US, New Zealand and Australia.

As previously mentioned, known spontaneous aneuploidy of hESCs in culture can occur quite readily and this presents an additional hurdle during manufacturing. Cells need to be frequently monitored for chromosomal aberrations. Additionally, any and all hESC derivatives need to undergo extensive testing in animal models to exclude any probability of tumor formation or other serious adverse effects. Such studies should be performed in immune compromised or immune suppressed animals to allow long-term survival of the donor cells. Ideally, the cells should be present in the host long term, in some cases throughout the lifetime of the animal; if they proliferate soon after transplantation, they should later become quiescent and stay negative for proliferation antigens, such as Ki67. They should maintain a normal phenotype which could be assessed by double staining animal tissues with anti-human antigen (nuclei, mitochondria) antibodies and antibodies to specific cell markers, and cause no adverse effects including neoplasia. The cells should be able to perform their function in

order to justify their transplantation in people. ACT's hESC-derived RPE met all these safety requirements in long-term studies (nine months) in mouse and rat animal models [31,85]: the cells integrated into the host's own RPE layer, provided photoreceptor support in the models of retinal degeneration (Royal College of Surgeons (RCS) rat) and Stargardt's disease (Elov4 mouse), showed no proliferation beyond the initial three months, had normal RPE morphology (cuboidal pigmented polygonal cells) and showed the late RPE marker bestrophin organized in a baso-lateral, and typical for RPE *in vivo* fashion.

CONCLUSIONS

hESCs offer the unique possibility of generating a wide variety of differentiated cells for tissue engineering 'from scratch'. Their immortal nature allows the production of hESCs in virtually unlimited numbers, enabling the creation of a Master Cell Bank, and together with the ability to produce differentiated derivatives, makes it possible to generate the desired cells on a scale large enough for both treating patients and performing all *in vitro* and *in vivo* tests necessary to ensure the safety and functionality of these cells. Such derivatives may include progenitor/tissue specific stem cells capable of differentiating further *in vivo* (which may offer advantages in tissue repair) and also mature differentiated cells which are still capable of proliferation. The derivatives, when cultured *in vitro* from a hESC origin, should be maintained in a manner that ensures their optimal *in vivo* performance. In the coming years, we will hopefully see more hESC-based therapies move from bench to bedside, not only for a range of diseases caused by tissue loss or dysfunction, but as an unlimited source of cells to replace more complex tissues such as skin, bone, and blood vessels, and eventually whole organs such as kidneys and hearts.

INTRODUCTION

Induced pluripotent stem cells (iPSCs) exhibiting high similarity to embryonic stem cells (ESCs) have been derived from diverse somatic cell types and many animal species. Given their easily accessible somatic cell origin, human iPSCs not only eliminate the ethical issues presented by human ESCs due to their embryonic origin, but also enable the easy production of patient-specific pluripotent stem cells. Similar to human ESCs, human iPSCs are capable of robust proliferation *in vitro* while retaining the developmental potential to differentiate into many cell types of the body. Thus, these cells can deliver an essentially unlimited number of patient-specific somatic cells for disease modeling, toxicity testing, drug screening and transplantation therapies. Towards these ends, many improvements have been made in the methods for iPSC derivation with the ultimate goal of generating high quality clinical-grade human iPSCs. This chapter gives a detailed overview of iPSC technology, the similarities and differences between iPSCs and ESCs, the current applications of human iPSCs, and current challenges for these applications. It will give readers a clear understanding of the current status of iPSC research and the impact of iPSCs on the future of regenerative medicine.

METHODOLOGICAL OVERVIEW OF iPSC Derivation

After the initial excitement over the successful derivation of iPSCs [1–3], three obstacles to realizing the full potential of human iPSCs immediately became apparent. First, the reprogramming efficiency was very low (~0.01–0.02%) for the original sets of reprogramming factors, the Yamanaka factors (*OCT4*, *SOX2*, *c-MYC*, *KLF4*) and the Thomson factors (*OCT4*, *SOX2*, *NANOG* and *LIN28*). There also appeared to be iPSC clone-to-clone variations with significant functional consequences [1,3]. Both would undoubtedly impede the industrial application of human iPSCs, which would require a robust and efficient process for the derivation and expansion of high quality cells in order to ensure a high success rate for samples having diverse genetic background and age groups. Second, the initial methods for iPSC derivation employed genome-integrating retroviral/lentiviral vectors, which could produce tumorigenic insertional mutations. Furthermore, residual and/or reactivation of transgene

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00030-6

expression during iPSC differentiation could affect lineage choice and the functionality of iPSC derivatives [2–3]. To overcome these problems, methods were needed in order to enable the derivation of iPSCs free of exogenous DNA (footprint-free). Third, most of the derivation and culture of human iPSCs employed undefined human ESC culture media and feeder cells. The inherent variations associated with both undefined culture medium and feeder cells greatly affect both the derivation efficiency and the quality of human iPSCs. The preparation of feeder cells (both autologous and non-autologous) can be labor intensive. More importantly, the use of feeder cells can introduce immunogenic antigens into human iPSCs, making them unsuitable for transplantation therapies [4]. Human iPSCs are thus ideally derived and cultured in chemically defined medium and matrix free of feeder cells.

IMPROVING REPROGRAMMING EFFICIENCY AND THE QUALITY OF iPSCs

Improving reprogramming efficiency and the quality of iPSCs has been a significant focus of the research following the initial derivation of iPSCs. Studies show that both reprogramming efficiency and the quality of iPSCs can be greatly affected by donor cell types, reprogramming factor stoichiometry, additional reprogramming factors and chemical compounds. To date, iPSCs have been successfully generated from many different somatic cell types, such as skin cells, neural cells, adipose tissue-derived cells and blood cells. It now appears that iPSCs can be derived from most, if not all, somatic cell types of the body. However, the specific donor cell type has significant impact on both the kinetic and efficiency of reprogramming. For example, compared to skin fibroblasts, a commonly used donor cell type, keratinocytes give over 100-fold higher reprogramming efficiency and 2-fold faster reprogramming kinetics [5]. Among the same somatic cell lineage, cells of early developmental stages and stem/progenitor cells were generally more amenable to reprogramming compared to terminally differentiated cells. An elegant demonstration of this notion is shown in a study carried out by Eminli et al. [6]. The authors generated high-degree chimera mice using iPSCs produced with inducible lentiviral vectors expressing the Yamanaka factors. Upon transgene induction, hematopoietic stem and progenitor cells isolated from the chimera mice gave rise to iPSCs at efficiencies nearly 300-fold higher than the terminally differentiated B and T cells (0.02–0.04%). In addition to reprogramming kinetics and efficiency, different donor cell types showed different minimal requirement for reprogramming factors. For example, although at least three transgenes, including *OCT4*, *SOX2*, *KLF4*, were used to reprogram most donor cell types, iPSCs can be successfully derived from human neural stem cells via the expression of a single *OCT4* gene [7], likely compensated by their endogenous gene expression. Nevertheless, efficient reprogramming is generally accomplished with more than one reprogramming factor. The inherent difference in the epigenetic stability between various donor cell types will be an important factor in the eventual selection of appropriate donor cell types for the derivation of clinical-grade human iPSCs.

A somewhat less studied factor significantly impacting both the reprogramming efficiency and the quality of iPSCs is the balance or stoichiometry between the expression of different reprogramming factors, mostly due to the difficulty in exerting precise control over transgene expression in donor cells. The first set of reprogramming experiments employed transgenes individually packaged into viral vectors. Transduction of differentiated cells was carried out with saturating multiplicity of infection for each transgene [1–3]. It was later found that the expression levels and ratios between different transgenes had great impact on both reprogramming efficiency and the quality of iPSCs. For example, the balanced expression of *OCT4*, *SOX2*, *NANOG* and *LIN28* led to a nearly 10-fold increase in the reprogramming efficiency of human neonatal foreskin fibroblasts [8]. Using fluorescent proteins that track the expression of each reprogramming transgene, it was found that an optimal level of *Oct4* expression relative to *Sox2*, *Klf4* and *c-Myc* was necessary to achieve efficient reprogramming [9]. Another illustration

of the importance of the reprogramming factor stoichiometry was shown by Carey et al. [10]. High expression of *Oct4* and *Klf4* along with lower expression of *Sox2* and *c-Myc* was able to produce iPSCs that efficiently generated 'all-iPSC mice' by tetraploid complementation, an unequivocal demonstration of iPSC pluripotency. Thus, care must be taken when drawing conclusions from current studies on iPSCs generated with different reprogramming factor stoichiometry.

The reprogramming efficiency and quality of iPSCs were also greatly affected by the combination of reprogramming factors used. The successful derivation of iPSC generally requires multiple rounds of cell division and the expression of transgenes for over 10 days [11]. Reprogramming by somatic cell nuclear transfer or cell-cell fusion, however, happens rapidly and efficiently. In nuclear transfer or cloning experiments, the nuclei of differentiated cells are transferred into enucleated eggs, which are then allowed to develop into whole new animals [12]. In cell-cell fusion experiments, the somatic cell nuclei can be reset to a state of pluripotency when fused with pluripotent stem cells such as embryonic carcinoma cells, ESCs, and embryonic germ cells [13]. This pointed to the existence of additional factors that can facilitate reprogramming. Indeed, although both the Yamanaka factors and the Thomson factors were sufficient to restore pluripotency in differentiated human somatic cells, the combination of both sets of reprogramming factors (*OCT4*, *SOX2*, *c-MYC*, *KLF4*, *NANOG* and *LIN28*) led to significantly improved reprogramming pace and efficiency ($\sim$100 fold) [14]. Replacement of the wild-type *c-MYC* with transformation-deficient *N-MYC* or *L-MYC*, which are enriched in human ESCs, resulted in even higher reprogramming efficiency and less tumorigenic iPSCs [15]. Additional reprogramming factors were identified, e.g., *AICDA* [16], *TBX3* [17], *Nr5a2* [18], *SV40LT* [19], and the list is still growing. Among these factors, *Nr5a2* was able to replace *Oct4* in iPSC derivation from mouse somatic cells [18]. The p53 pathway was shown to limit iPSC establishment [20–22]. And its suppression by either short hairpin RNA or protein expression (e.g., SV40LT) significantly increased both the kinetic and efficiency of reprogramming. More interestingly, microRNAs enriched in ESCs were also found to enhance the production of iPSCs. The miRNAs, miR-291-3p, miR-294 and miR-295, appeared to be the downstream effectors of *c-Myc* [23]. Successful production of both mouse and human iPSCs using mature microRNAs only (e.g., mir-200c, mir-302 and mir-369) were also reported [24–25]. Aside from native genes, synthetic transcription factors were shown to dramatically improve reprogramming. For example, fusion between the powerful transactivation domain of VP16 or *MYOD1* and *OCT4* resulted in significantly improved reprogramming efficiency [26–27].

One area of iPSC research that has been rapidly expanding in recent years is the application of small molecules in the derivation, culture and differentiation of iPSCs. Combined genetic and chemical engineering has not only improved our current understanding of the establishment and maintenance of pluripotency, but also greatly facilitated the practical applications of iPSC technology. The list of small molecules implicated in reprogramming are continuously growing, and include chromatin modifiers such as DNA methyltransferase inhibitor 5-aza-cytidine and histone deacetylase inhibitor valproic acid; cell signaling modifiers such as mitogen activated protein kinase/ERK kinase (MEK) inhibitors, glycogen synthase kinase-3 (GSK3) inhibitor CHIR99021, TGF-β/Activin/Nodal receptor inhibitors; and others such as vitamin C [28]. These compounds were not only able to improve both the pace and the efficiency of iPSC derivation, but also could affect the outcome of the pluripotent state of iPSCs obtained. The use of epigenetic modifiers including both DNA methyltransferase inhibitors and histone deacetylase inhibitors, however, requires caution. Their broad and nonspecific effects will cause an overall dysregulation of gene expression, increasing safety concerns for the practical applications of human iPSCs. For example, 5-aza-cytidine is highly mutagenic [29], and mice with global alterations in DNA methylation levels develop tumors at a high frequency [30]. Some of these molecules can replace specific reprogramming transgenes. For example, the inhibition of TGF-β signaling can bypass the requirement for exogenous *c-Myc* or *Sox2* [31–32], and the use of kenpaulane can substitute for *Klf4* [33]. The replacement of

reprogramming genes with small molecules, however, was often accompanied with significant decreases in both the kinetic and efficiency of reprogramming.

Progress made over the last several years has put iPSC technology within reach of many laboratories around the world. However, with the identification of more and more reprogramming factors and chemical compounds, identifying an optimal iPSC reprogramming approach has become increasingly complicated. It remains to be addressed how different combinations of reprogramming factors and their stoichiometry, along with chemical compounds, affect the reprogramming process and the epigenetic status of iPSCs. This is further complicated by the fact that different donor cell types might require a different set of reprogramming factors and stoichoimetry for optimal reprogramming. These are the issues that need to be taken into consideration when interpreting results from current studies on iPSCs produced by different methods.

Generating footprint-free iPSCs

Currently, genome-integrating retroviral/lentiviral vectors are the most used transgene delivery system for iPSC derivation. Compared to most available transgene delivery systems, these vectors enable prolonged expression of reprogramming factors, thus providing an efficient means for iPSC derivation. However, the retention of these viral vectors and transgenes in the genome of iPSCs creates many problems for the applications of iPSCs. Removal of transgenes via Cre/loxP recombination can alleviate problems associated with reprogramming factors [34]. Residual viral vector sequences, however, are still retained in the iPSC genome, causing potentially tumorigenic insertional mutations. For practical applications, ideally iPSCs would be free of vector and transgene sequences. For this purpose, many methods have been developed, including repeated treatments of reprogramming factors (plasmids, minicircle DNA, non-integrating adenoviral vector and proteins) [35–38]. These methods, however, are generally associated with low reprogramming efficiency. *piggyBack* transposon-based vectors were also used to derive footprint-free iPSCs because of their seamless excision property [39–40]. Although good reprogramming efficiency was achieved with this approach, the removal of vector and transgenes from iPSCs can be labor-intensive.

One method allowing efficient production of footprint-free iPSCs employed a vector based on Sendai virus, a single-stranded RNA virus that does not integrate into the host genome [41]. The Sendai viral vectors replicate constitutively in the cytoplasm of infected cells, allowing the generation of iPSCs. The established iPSCs can gradually lose these vectors over extended culture, which occurs at a variable rate among different iPSC clones. This process could be sped up by the introduction of temperature-sensitive mutations in the polymerase-related genes [42]. Nevertheless, stringent screening of iPSC clones completely free of viral vectors will be required. Any residual presence of the Sendai viral vectors in iPSCs carries risks of amplification when iPSCs or their differentiated derivatives are introduced *in vivo*. Additionally, this method requires viral packaging. Although commercially available, packaged reprogramming Senviral vectors are far from cost-effective.

A second method used synthetic modified mRNAs for the derivation of footprint-free human iPSCs from fibroblasts [43]. Compared to viral and DNA-based reprogramming methods, the mRNA-mediated transgene delivery offers a safer approach for the derivation of clinical-grade human iPSCs. The requirement for repeated transfections, however, limits the application of this method to cells types that are easily transfectable. It remains to be seen whether this method is robust enough for processing multiple donor cell samples, and whether it can be readily adapted to cells that are relatively resistant to lipid-mediated transfections, such as cells of hematopoietic lineages. As the selection of appropriate donor cell types likely will be important for the derivation of clinical-grade human iPSCs, a reprogramming method that is readily applicable to different cell types and multiple donor cell samples will be highly desirable.

We have previously developed an oriP/EBNA-1(Epstein-Barr nuclear antien-1)-based episomal reprogramming approach for the derivation of footprint-free human iPSCs [8]. Compared to currently available methods, this approach has several advantages. First, the oriP/EBNA-1-based episomal vectors have wide host cell range, enabling the application of this method to most, if not all, human somatic cell types. Second, it does not require viral packaging. Third, no repeated treatments of reprogramming factors are needed. A single transfection of episomal reprogramming vectors is sufficient for the derivation of human iPSCs. Moreover, higher transfection efficiency of human somatic cells can be achieved with these vectors due to oriP/EBNA-1-mediated nuclear import and retention of vector DNA [44]. Fourth, the oriP/EBNA-1-based episomal vectors replicate once-per-cell cycle and are generally present at a low copy number per cell, thus minimizing DNA rearrangement and genome integration [45]. Last, the removal of episomal vectors from established human iPSCs can be easily accomplished by extended cell culture without any additional manipulation due to the silencing of the viral promoter that drives the expression of EBNA-1 in iPSCs, and the inherent instability of oriP/EBNA-1 episomal state (e.g., stably established episomes are lost from cells at a rate of approximately 5% due to defects in plasmid synthesis and partitioning) [46]. Although the initial report on the oriP/EBNA-1-based episomal reprogramming method yielded low efficiency from fibroblasts, this did not seem to be inherent to the oriP/EBNA-1-based transgene delivery system. Using this system, iPSCs were efficiently produced from cord blood, bone marrow, and to a lesser degree, adult peripheral mononuclear cells [47–48]. Additionally, by modifying reprogramming culture conditions, efficient iPSC derivation was achieved using this method from fibroblasts, adipose tissue-derived cells, and even hard-to-reprogram terminally differentiated B cells [49–51]. Thus the oriP/EBNA-1 based episomal reprogramming approach offers a robust alternative for the routine derivation of footprint-free iPSCs from cell types readily available from living humans.

Developing defined reprogramming conditions

Most methods currently developed for iPSC derivation and culture use undefined culture media, matrix or feeder cells with animal origins. This creates problems for both industrial and clinical applications of human iPSCs. The preparations of both undefined culture media and feeder cells consistently yield products with variable qualities, directly impacting both the derivation and quality of iPSCs. Direct contact of human iPSCs with animal products risks contamination of animal pathogens and immunogenic antigens such as non-human sialic acid [4]. Human skin fibroblasts and adipose tissue-derived cells were successfully used as both the feeder cells (isogenic) and the donor cells for iPSC derivation and culture [52–53]. The use of isogenic feeder cells, however, does not resolve problems associated with quality variations, and does not provide a universal solution for iPSC derivation from different donor cell types, such as cells of hematopoietic lineages. It is highly desirable to develop chemically defined conditions for all steps of iPSC production, including the isolation and culture of human donor cells, iPSC derivation and expansion. Various xeno-free or chemically defined conditions have already been established for the isolation and culture of many human somatic cell types, such as skin fibroblasts, adipose tissue-derived cells and hematopoietic precursors. Studies of human ESC culture in the last decade have also enabled the development of chemically defined culture media such as TeSR from STEMCELL technologies [54] and STEMPRO® hESC SFM from Invitrogen [55]. Defined surfaces have been identified that could support the robust proliferation of human pluripotent stem cells in chemically defined culture media, e.g., recombinant vitronectin [56] and E-cadherin [57]. These defined culture conditions can be readily adapted to the expansion and maintenance of human iPSCs. Conditions that support human ESC and iPSC proliferation were often directly used for the derivation of iPSCs. These conditions, however, are generally not optimal for the iPSC derivation. For example, although TGF-β signaling plays a critical role in the proliferation of human ESCs and iPSCs, and its ligands are often included as an important component in chemically defined

human ESC and iPSC culture media, the inhibitors of the TGF-β receptor were, nevertheless, able to greatly promote the derivation of iPSCs [58]. Thus modifications of the ESC and iPSC culture media are required to establish robust chemically defined conditions for the derivation of iPSCs [49–50].

To summarize, iPSC technology has undergone rapid progress in the last several years. Methods are already available for the efficient derivation of footprint-free human iPSCs under chemically defined conditions. With these technological advancements made, the question now is whether iPSC derivation or the transdifferentiation between different somatic cellular states can be accomplished with pure chemicals without the use of either genetic factors or their RNA and protein products. In this pure-chemical reprogramming, there would be no genetic modifications of the iPSC genome caused by insertion of exogenous DNA or the expression of mutagenic reprogramming factors. However, robust screening of iPSC genome will still be necessary since small molecules can be mutagenic, especially when chromatin modifiers are used.

COMPARISON OF iPSCs and ESCs

Pluripotent stem cells are characterized by their robust, unlimited self-renewal ability and the potential to differentiate into all cell types of the body. Although different pluripotent states have been identified, i.e., naïve pluripotent state (e.g., mouse ESCs originated from the inner cell mass (ICM) of pre-implantation blastocysts), and primed pluripotent state (e.g., mouse epiblast derived stem cells or EpiSCs originated from the epiblast of post-implantation mouse embryos [59–60]), for the purpose of this discussion, we will only focus on mouse ESC-like iPSCs, and human ESC-like iPSCs.

Mouse ESCs have domed colony morphology in culture, and their self-renewal is supported by either leukemia inhibitory factor and BMP4 signaling [61], or dual inhibition of differentiation-inducing signaling from FGF/ERK (e.g., SU5402, PD184352 and PD0325901) and GSK3β (CHIR99021) [62]. Mouse ESCs express cell surface antigen SSEA-1 and key pluripotent marker genes such as *Oct4*, *Sox2*, *Nanog*, *Klf2*, *Klf4*, *Rex1* and *Stella*. They can form embryoid bodies and differentiate into any somatic cell type *in vitro*. They can form teratomas consisting of differentiated cells of all three germ layers when injected into immunodeficient mice. They can contribute to all cell lineages including germ cells in chimera mice when injected into blastocysts, and give rise to all-ESC mice by tetraploid complementation. Mouse iPSCs that share all these key features have been obtained. They showed morphology, growth properties and gene expression pattern similar to mouse ESCs, formed teratomas, gave rise to live-birth chimeras, and more importantly, produced viable mice through tetraploid complementation [63–64], the unequivocal test for authentic pluripotency. Thus the reprogramming technology can produce iPSCs that are molecularly and functionally equivalent to ESCs. However, all iPSCs are not equal. Significant variations between different iPSC clones have been observed. Although they share similar morphology, growth properties, global gene expression pattern and the ability to form teratomas, many iPSC clones failed to efficiently contribute to chimeras, or to produce viable mice through tetraploid complementation [1]. Attempts to identify markers for authentic pluripotency came upon the imprinted Dlk1-Dio3 gene cluster on mouse chromosome 12F1 [65–66]. Loss of imprinting at this locus, however, did not strictly correlate with reduced pluripotency, although it did decrease the efficiency of generating all-iPSC mice [10]. Thus the ability to form all-iPSC mice remains the only reliable test for authentic pluripotency.

Human ESCs, despite their ICM origin, share many features with mouse EpiSCs. They have flat compact colony morphology. Their growth depends on FGF and TGFβ signaling. They express cell surface antigens SSEA-3, SSEA-4, Tra-1–60, Tra-1–81 and pluripotent marker genes *OCT4*, *SOX2*, *NANOG*. Similar to mouse ESCs, these cells can form embryoid bodies and differentiate

into many somatic cell types *in vitro*, and form teratomas consisting of differentiated cells of all three germ layers. Due to both ethical and practical reasons, it is not possible to test whether these cells can contribute efficiently to chimeras when injected into blastocysts, or produce all-ESC humans. Human iPSCs share all key features with human ESCs. Their equivalence, however, has been constantly challenged. For example, human iPSCs were suggested to have a gene expression signature unique from human ESCs, retain residual gene expression of donor cells, harbor residual DNA methylation signatures characteristic of their donor cells, and favor their differentiation along lineages related to the donor cells (epigenetic memory) [67–69]. Prolonged passaging of iPSCs or treatment with chromatin modifiers was shown to reduce these abnormalities, bringing human iPSCs closer to human ESCs. Although these results raised concerns, the question is still open regarding whether human iPSCs are molecularly and functionally equivalent to human ESCs. One factor contributing to this controversy lies in the selection of control human ESC lines used for comparison. Since human ESC lines are known to exhibit significant variations between them, and their derivation and culture history affect both the genetic and epigenetic status of these cells, it is problematic to draw conclusions based on comparisons between a limited number of human iPSC and ESC lines. Considering studies on mouse iPSCs, the epigenetic memory seen with various human iPSC clones most likely reflects incompleteness in reprogramming. With optimized reprogramming conditions, including the combination and stoichiometry of reprogramming factors, chemically defined reprogramming culture (e.g., inclusion of appropriate small molecules), and iPSC expansion conditions for each donor cell type, we will likely be able to obtain high quality human iPSCs molecularly and functionally equivalent to human ESCs and with much reduced heterogeneity between different iPSC clones on a routine basis.

CURRENT APPLICATIONS OF HUMAN iPSCs

Despite the ongoing debate regarding the equivalence of ESC and iPSCs, human iPSCs have nonetheless found their way into many applications previously envisioned for human ESCs. One such application, which received immediate attention, was disease modeling. The ease of generating patient-specific human iPSCs provides a valuable experimental platform for modeling human diseases, and may greatly facilitate the development of novel therapeutic treatments. From diseases characterized by single gene defects and rapid disease progression in early childhood, to disorders with complex genetic and epigenetic etiology [70–71], human iPSCs could provide an unlimited number of previously inaccessible and clinically relevant cell types for mechanistic studies on diseases, examples of which are shown in Table 30.1. Given the heterogeneity in the quality of human iPSCs produced with most currently available methods, and the lack of better markers or functional assays to confirm the authentic pluripotency in these iPSCs, some technical caveats must be considered when interpreting results from these promising studies. For example, the residual expression or reactivation of reprogramming factors using a genome-integrating transgene delivery system could affect the molecular characteristics of human iPSCs, their differentiation into specific lineages of interest and the functionality of differentiated derivatives, complicating the interpretation of phenotypes arising from diseases and imperfect reprogramming.

A second area where human iPSCs can be of immediate use is in toxicity testing and drug discovery. From lead drug candidates to numerous chemical compounds to which we are increasingly exposed during our daily life, the need for toxicity testing has never been greater. Traditional toxicity testing relies on animal models, transformed cell lines or primary human cells. Animal models are limited by ethical constraints, cost, time and failure to predict species-specific toxicity. Transformed cell lines are generally karyotypically abnormal, and often do not accurately recapitulate the functions of their primary counterparts. Primary human cells are extremely limited in their tissue source, exhibit high variations in the quality between different donors, and often undergo dedifferentiation during *in vitro* culture such as primary

TABLE 30.1 Application of human iPSCs in disease modeling

Disease	Cell phenotype
Neuronal	
Spinal Muscular Atrophy[a]	Motor neuron with selective deficits.
Friedreich's ataxia (FRDA)[b]	GAATTC triplet hyperexpansion in FXN gene Repeat instability in FRDA iPS cells
Schizophrenia (SCZD)[c]	Diminished neuronal connectivity in conjunction with decreased neurite number, PSD95-protein levels and glutamate receptor expression
Parkinson's disease[d]	Elevated amount of alpha-synuclein in midbrain dopaminergic neurons
Familial Alzheimer's disease (FAD)[e]	Increased amyloid beta42 secretion, which responds sharply to gamma-secretase inhibitors and modulators
Cardiac	
LEOPARD Syndrome[f]	PTPN11 mutation; enlarged cardiomyocyte cell size with higher degree of sarcomeric organization and preferential localization of NFATC 4 in the nucleus
Long QT Syndrome[g,h]	Prolonged action potential in ventricular and atrial cells, reduced I(Ks) current
Hepatic	
α1-Antitrypsin Deficiency[i]	Aggregation of misfolded α1-antitrypsin in endoplasmic reticulum
Familial Hypercholesterolemia[i]	Deficient LDL receptor-mediated cholesterol uptake
Glycogen Storage Disease Type 1a[i]	Elevated lipid and glycogen accumulation
Aging	
Hutchinson-Gilford progeria syndrome (HGPS)[j]	LMNA mutation, premature senescence phenotype, absence of nuclear DNAPK holoenzyme

hepatocytes and cardiomyocytes. Compared to these test materials, human iPSCs can provide a better alternative with unlimited availability and consistent quality. For example, about one third of withdrawals of pharmaceuticals for safety reasons were because of their cardiotoxicity. Thus an effective early screen for cardiotoxicity can significantly decrease late-stage drug attrition. As a proof of concept, in a study by Guo et al. [72], human iPSC-derived cardiomyocytes were shown to predict the performance of 28 different compounds with known cardiac effects with much higher accuracy than the traditional cell line and animal models. These cells were able to identify compounds with severe cardiac toxicity where the traditional models failed, as well as those compounds without clinical manifestation that tested positive with traditional models. In addition to toxicity testing, human disease-specific iPSC-derived differentiated derivatives can provide an effective substrate for drug screening. For example,

human iPSCs derived from patients with Rett syndrome (RTT) were able to generate functional neurons with fewer synapses when compared to controls. These RTT neurons were used to test the effects of drugs in rescuing synaptic defects, thus providing a previously unexplored developmental time window before the disease onset for potential therapeutic intervention [73]. Also human Alzheimer's disease iPSC-derived neuronal cells were capable of amyloid beta peptide (Abeta) production, which was sensitive to the inhibition of beta- and gamma-secretase inhibitors. Thus these cells potentially could be used for anti-Abeta drug screening upon sufficient neuronal differentiation [74].

Perhaps the most captivating application of human iPSCs is their therapeutic potential. With their unlimited proliferation potential and the ability to differentiate into clinically relevant cell types, human iPSCs can provide an essentially unlimited cell source for autologous cell replacement therapies. Patient-specific human iPSCs can be derived from easily accessible donor cells such as those from skin, blood or adipose tissue. These cells can be either used directly for differentiation, or be genetically modified to repair specific genetic defects or to deliver therapeutically important proteins prior to differentiation. Methods for efficient gene targeting of human iPSCs and ESCs include helper-dependent adenoviral vectors [75] and engineered nucleases such as zinc-finger nucleases [76] and TALENs [77]. Differentiated cells such as cardiomyocyte, hepatocytes, neural cells or blood cells can be enriched to high purity to avoid contamination with iPSCs and transplanted back into patients for therapeutic intervention. Many proof of principle experiments have been successfully carried out in animal models. For example, mice were rescued after transplantation with hematopoietic progenitors obtained *in vitro* from autologous iPSCs in a mouse model of sickle cell anemia [78]. Mouse iPSC-derived dopamine neurons of midbrain character were able to improve behavior in a rat model of Parkinson's disease upon transplantation into the adult brain [79]. Mouse iPSC-derived pancreatic beta-like cells corrected a hyperglycemic phenotype in two mouse models of type 1 and 2 diabetes [80]. Human iPSC-derived retinal pigment epithelium cell transplantation was shown to facilitate the short-term maintenance of photoreceptors and the long-term maintenance of visual function in the retinal dystrophic rat [81]. Clinical trials of several human pluripotent stem cell-derived cell types (e.g., retinal pigment epithelium cells) are currently underway. Although promising, no final conclusion can yet be drawn about the therapeutic benefits of these trials.

CHALLENGES

Since the initial report of iPSC derivation in 2006, much progress has been made in both their derivation and applications. Human footprint-free iPSCs can now be routinely obtained from different donor cell types, and can be efficiently directed to differentiate into many clinically relevant cell types, under chemically defined conditions. However, as we gain more insight into these cells, more questions arise about their applications both *in vitro* and *in vivo*.

One question currently under debate is whether iPSCs are molecularly and functionally equivalent to ESCs. Since viable mice can be produced from iPSCs by tetraploid complementation, it is safe to conclude that the iPSC technology is able to produce pluripotent stem cells that are molecularly and functionally equivalent to ESCs. This, however, does not exclude the existence of significant clone-to-clone variations and the retention of epigenetic memory in many clones analyzed in published literature as a result of incomplete reprogramming. Due to the lack of better markers and efficient functional assays for authentic pluripotency, especially for human iPS cells, it will take some time to put this question to rest. However, it is technically possible to identify a reprogramming method that produces high quality iPSCs with minimal clone-to-clone variations by selecting appropriate donor cell types, the combination and stoichiometry of reprogramming factors, and reprogramming culture conditions including the use of small molecules. In addition, for practical purposes, it

might not be essential to produce human iPSCs molecularly and functionally equivalent to human ESCs.

A second question relates to the differentiation of iPSCs and ESCs. The application of human iPSCs relies on their ability to differentiate into clinically relevant cell types. Although efficient differentiation has been achieved from human iPSCs for many cells types such as cardiomyocytes, hepatocytes and neuronal cells, these differentiated derivatives appeared to be in fetal stages [82]. This presents problems for cells that show significant functional difference between adult and fetal stages. For example, adult hepatocytes have highly active drug metabolism activity that their fetal counterparts lack. Human iPSC and ESC-derived hepatocytes, although they have basic hepatic metabolism and the ability to support hepatic virus amplification [83], generally have significantly reduced functions in drug metabolism compared to the adult hepatocytes. This limits their usefulness in drug toxicity testing. Prolonged culture of human iPSC-derived cells appeared to improve their functions. However, normal tissue maturation takes place over an extended period of time, which is not entirely practical for industrial applications. It would be interesting to know whether such maturation can be greatly sped up by either small molecule treatment or genetic engineering via introduction of appropriate genes. Besides issues with cellular maturation, differentiation of human iPSCs and ESCs into certain clinically important cell types has yet to be achieved. For example, transplantation of hematopoietic stem cells (HSCs) from bone marrow, peripheral blood and umbilical cord blood is a well-established medical procedure to treat patients with certain life-threatening diseases. However, the application of this therapy is limited by the availability of donor cells and immune rejections. Patient-specific human iPSCs could potentially provide an unlimited number of donor cells without the complication of immune rejections. Additionally, genetically engineered HSCs can be used to treat certain illnesses that are currently without cure. For example, with the introduction of anti-HIV transgene(s), human iPSC-derived HSCs could provide a one-time-cure for HIV. Human iPSCs, however, have yet to produce HSCs that are capable of robust long-term engraftment *in vivo*.

The main concern for the *in vivo* application of human iPSCs stems from their genetic and epigenetic stability. Multiple mutations, copy number variations (CNVs) and aberrant epigenetic modifications have been found in iPSCs [84–86]. Although some of these changes can be attributed to pre-existing mutations in donor cells, mutations accumulated during iPSC expansion and incomplete reprogramming, there appears to be increased mutation rate during reprogramming. More recent data, however, suggest that the genetic and epigenetic instability of iPSCs observed could be partially technical. For example, in a study using iPSC lines derived with episomal vectors, no CNVs were found, and the single-nucleotide variants found were not selectively enriched for known genes associated with cancers [87]. Additionally, extended culture of iPSCs could be accomplished without a substantial increase in mutational burden [88]. Thus with the selection of donor cell types with low somatic mutation rate and appropriate methods for the reprogramming and culture of human iPSCs, it is possible to significantly reduce their genetic and epigenetic instability. Nevertheless, it will be essential to carefully examine the genetic and epigenetic status of human iPSCs before these cells can be used for transplantation therapies. Due to the genetic and epigenetic modifications, transplantation of human iPSC derivatives carries risks of tumor formation. Although human iPSCs can form benign teratomas *in vivo* when present in sufficient number, this risk can be greatly minimized by prior removal of human iPSCs from differentiated cells. Residual human iPSCs could efficiently activate and be lysed by natural killer cells [89]. Mutations and aberrant epigenetic modifications of human iPSCs, however, can result in malignant tumors. Moreover, they can also lead to the expression of developmentally inappropriate genes and other immunogenic antigens in human iPSC-derived cells that can elicit immunoreactions even in autologous transplantations [90].

CONCLUSION

iPSC technology has opened up many venues for research and applications previously unfeasible. In the past several years, we have seen increased applications both *in vitro*, such as disease modeling, toxicity testing and drug screening, and *in vivo* transplantations in various animal models, all with promising results. However, both technical and scientific hurdles exist, including finding an optimal reprogramming approach for producing high quality iPSCs with minimal clone-to-clone variations, minimal genetic and epigenetic mutations, and differentiation into functionally mature cell types. The genetic and epigenetic instability observed in human iPSCs raises cautions for their *in vivo* applications in clinical transplantation therapies. Nevertheless, the field is making rapid progress. Realizing the full potential of human iPSCs is not out of reach.

CHAPTER 31

Stem Cells in Tissue Engineering

Haruko Obokata and Charles A. Vacanti
Brigham and Women's Hospital/Harvard Medical School, Department of Anesthesiology, Laboratory for Tissue Engineering and Regenerative Medicine, Boston, Massachusetts.

POTENTIAL STEM CELL SOURCES FOR USE IN TISSUE ENGINEERING

Introduction

A stem cell is defined as a cell that has the capacity for self-renewal and the potential to differentiate into any cell type in the body. In contrast, a progenitor cell 'has the ability' to generate cells specific to the tissue or organ from which it was procured, but does not have the ability to cross germ lines.

Many types of adult stem cells have been reported over several decades. However, stem cells that would be useful in tissue engineering need to be:

1) Easily obtained in large numbers,
2) Safe to implant,
3) Able to differentiate into the cells needed.

Therefore, the types of stem cells which may be useful for tissue engineering are limited. Potential adult stem cells for use in tissue engineering, such as mesenchymal stem cells, hematopoietic stem cells, adipose stem cells, and skin stem cells are easy to access and relatively easy to obtain in large numbers. They are basically safe because they are harvested from adult tissues. Pluripotent stem cells, such as ES cells and iPS cells, are able to provide sufficient numbers of cells because they have an infinite proliferative potential, however, their tumorigenic potential often prevents their clinical application.

Hematopoietic stem cells

While diversification of cell types is largely completed at, or soon after birth, many tissues undergo self-renewal in response to acute injury or normal usage throughout life [1,2]. Therefore, some somatic stem cells are also maintained throughout the whole life span for the regeneration of specific tissues, such as the epidermis, hair, small intestine, and hematopoietic system.

Stem and progenitor cells, origins, phenotypes, lineage commitments, and transdifferentiation [3]

The existence of hematopoietic stem cells (HSCs) in bone marrow was first demonstrated by James Till and the late Ernest McCulloch in 1963 [4]. One of their important findings was the

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00031-8

demonstration of the radiation sensitivity of mouse bone marrow (BM) cells by showing that limiting numbers of BM cells could give rise to clonal colonies of elytroid and myeloid cells in the spleens of the irradiated hosts. Although it was postulated that each spleen colony was genetically unique and had thus arisen from a single cell, the phenotype of those cells was still unknown. Through an investigation using cell sorters, Irving Weissman [5] showed that a population of mouse BM cells expressing the surface antigens Thy1 (low) and Sca1 from which lineage differentiation markers were absent (Lin negative) was able to rescue irradiated BM far more effectively than unsorted BM cells. The potency of the cells in that population was demonstrated by injecting as few as 30 cells into a lethally irradiated mouse, which rescued half of the recipients from BM failure, whereas 13,000–33,000 unsorted BM cells were needed to achieve the same effect. This result surely indicated that the proposed stem cells were greatly enriched by this protocol. This study led to many further studies, and human hematopoietic stem cells were isolated based on murine hematopoietic stem cell isolation protocols. Using long-term repopulation combined with a limiting dilution design, stem cell frequency in the bone marrow was determined to be 1 in 10,000 nucleated cells [6,7]. This type of assay is now a standard in hematopoiesis, for the evaluation of stem cell markers [3,5] and for evaluation of stem cell differentiation and regulation [8–10], and it has also been key in studying other populations of hematopoietic stem cells quantitatively [11–13]. According to the character of hematopoietic stem cells, the definition of stem cell is the potential of self-renewal and multi-lineage differentiation.

HSCs offer the advantage of being relatively easily to harvest from bone marrow, and to isolate and purify *ex vivo*. Recent studies indicate that the traditional wall separating the hemato-poietic and mesodermal tissue systems and lineages is being demolished. Interestingly, HSCs possess the unexpected potential for myogenesis and cardiomyogenesis [14–20]. Further-more, purified mouse HSCs can regenerate liver cells [31], and cells able to regenerate bone are also found in blood [21]. These studies suggest that HSC tendency to result in hematopoiesis is a result of environmental stimuli.

Skin stem cells

Since skin is a rapidly renewing tissue, similar to the gastrointestinal and hematopoietic systems, the epidermis is an attractive tissue in which to study stem cell biology. Although People empirically knew of the existence of epidermal stem cells, the culture of keratinocytes was quite difficult because of the contamination of fibroblasts which have high proliferative potential. Green and his colleagues discovered that co-culture with irradiated-3T3 cells results in differentiation to epidermal cells. This protocol resulted in many studies, and trans-plantation of epithelial cell sheets fabricated by this protocol is the first tissue engineering and regenerative medicine technique to be used in clinical application. The studies of epidermal stem cells *in vitro* were finally started in the late 1970s. In an effort to identify cells with a high proliferative capacity in the human epidermis, Barrandon and Green [22] studied the self-renewal ability of human epidermal cells in replating assays.

In their study, 50–100 keratinocyte cells (KCs) were individually plated. More than 50% of cultured human KCs formed colonies. Six days later, colonies were re-suspended and each plated into a 100 mm Petri dish. Different cell types resulted in different types of colonies in secondary cultures [22]. Cells that form mostly large smooth colonies with less than 5% of small abortive colonies are termed holoclones. Paraclones are terminally differentiating cells that form small and abortive colonies. Cells intermediate between stem and differentiated cells formed meroclones, intermediate in appearance and reproductive capacity. In the studies of Barrandon and Green [22], cultured KCs produced 28% holoclones, 49% meroclones, and 23% paraclones. It is believed that the holoclones are stem cells and the paraclones are transit-amplifying cells [22], thereby suggesting a hierarchy of epidermal stem cells beginning with an epidermal stem cell, which gives rise to a continuum of cell populations, with progressively

diminishing capacity to proliferate and self-renewal. These studies provided an important examination method for KCs capable of self-renewal *in vitro*.

In 1990s, the niche of epithelial stem cells was spotlighted. The bulge is a less morphologically distinct structure in the adult human compared with the adult mouse. However, studies of label-retaining cells indicated that human hair follicle stem cells were located in the bulge of the human hair follicle [23,24]. Human bulge cells were found to express Keratin 15, and Keratin15-expressing human KCs were slow cycling, proliferated at the onset of follicle growth, and were expressed a high level of β1 integrin [23,25]. Moreover, bulge cells isolated by laser capture micro dissection were highly clonogenic *in vitro* [24]. A recent study demonstrated that CD34 positive cells were predominantly in G0/G1 highly expressing α6-integrin. Therefore, CD34 was a specific marker of murine bulge KCs [26]. Although CD34 was not expressed in human bulge cells [24,27], the bulge has been accepted as a site of hair follicle stem cells in humans. A recent study utilized human bulge cell markers to determine that human hair follicle stem cells were maintained in men with androgenetic alopecia, but that CD200-rich and CD34-positive progenitors were decreased [28].

It is evident that methods to evaluate epidermal stem cells are inadequate, and long-term repopulation assays that measure sustained epithelial tissue regeneration, analogous to most acceptable assays in hematopoiesis, are essential for progress in epidermal stem cell biology.

Kaur and his colleagues developed a transplantation assay based on repopulation of the epidermis inside a rat trachea which had been implanted subcutaneously in a severely combined immuno-deficient mouse [29,30]. This assay allows long-term maintenance of transplanted epidermal cells *in vivo*. Similarly, Schneider and his colleagues developed an *in vivo* transplantation assay for epidermal stem cells [31] based on well-established functional assays for hematopoietic stem cells [32–35]. This assay was combined with limiting dilution analysis to enable the quantization of the frequency of long-term repopulating cells in a population of KCs.

The *in vivo* transplantation assay for epidermal stem cells allows quantization of epidermal stem cells. This assay has been used to demonstrate that the frequency of murine epidermal stem cells in this model is less *in vivo* than previously predicted, and more in line with hematopoietic stem cell frequency (i.e., of the order of 1 in 10,000[31]). It has also shown that rapidly adherent colony-forming cells are not enriched in long-term repopulating cells [36] and that although no significant difference in aged vs. young epidermal stem cell (long-term repopulating cell, nine weeks of repopulation) frequency could be detected, transient-amplifying cell (short-term repopulating cell, three weeks of repopulation) frequency was greater in the aged [37].

Engineering the correct shape and physical structure of a graft is relatively simple in epidermis and other surface epithelial tissues, and indeed can be achieved *ex vivo*. This reflects the essentially two dimensional organization of skin and other epidermal surfaces, and is in sharp contrast with other systems such as the skeleton, where effective engineering involves the reconstruction of complex shapes and architectures. These directly affect proper function, are normally generated over a long period of time, and cannot be achieved *ex vivo*.

As mentioned above, transplantation of cultured skin grafts was performed as the first example of tissue engineering and regenerative medicine. According to the study in 1987, only holoclones are the product of a true stem cells, as defined by their exceptional self-replication ability (>140 doublings), which is not ascribed to either meroclones (a population of transient-amplifying cells) or paraclones (a population of senescent or differentiating progenitors) [22]. In principle, a small but pure population of holoclone-generating cells would be all that is required for generating epidermal grafts. The recent identification of a keratinocyte stem cell marker (p63) may provide a new tool for this approach with respect to epidermis [38].

Skin autografts are produced by culturing keratinocytes to generate an epidermal sheet, and then transplanting this sheet along with a suitable dermis-like substrate [39]. But the success of these procedures has been variable, with graft failure resulting in many cases after a promising initial engraftment. The specific technological challenge in restoration of epithelial surfaces in turn consists of the definition of culture conditions, and of carriers that are specifically designed to maintain an adequate stem cell compartment in the engineered graft. Dependence of epithelial surfaces on relevant stem cell compartments is further highlighted by the successful reconstruction of damaged corneas using stem cells derived from the limbus in conjunction with an amniotic membrane [40,41]. One of the feature technologies is the discovery of temperature-responsive dishes. Using these dishes, fragile cultured epithelial cell sheets were easily harvested as an intact cell sheets without using any enzymes. Okano and his colleagues succeeded in applying these cell sheets for the surface deficiency of skin, cornea and trachea in a clinical study [42–44].

Mesenchymal stem cells

Mesenchymal stem cells (MSCs) are currently the most prolific cell source that could potentially be used therapeutically for the treatment of human disease, and numerous clinical trials are underway. MSCs may be isolated from human BM. The first experimental evidence for the existence of a stem cell population in this tissue compartment other than the HSCs was uncovered in the 1960s.

Transplantation of decellularized bone to ectopic sites demonstrated that cells present in other tissues could be induced to generate bone. Pursuing the source of this potential, Friedenstein identified adherent 'fibroblast-like' cells in those tissues arising from BM that were capable of osteogenesis *in vivo* [45].

Such cells were believed to be a component of the BM stroma. They existed to support and nurture the hematopoietic functions of the BM, but also possessed the ability to differentiate into other cells types, such as chondrocytes and adipocytes demonstrated additional lineage potentials. At this point, the multi-potency of such adherent fibroblastic cells was recognized and they became known as MSCs rather than simply marrow stromal cells [46]. The name change proved to be quite fortuitous because it soon became apparent that MSCs could be derived from sources other than BM. By the late 1990s, it seemed that umbilical cord blood, in addition to being a valuable source of HSCs, also contained multipotential cells similar to those found in the BM [47]. While it should have been no surprise that the umbilicus would require the presence of stromal cells to generate a niche capable of supporting its HSCs, some sources of MSC were less obvious. Recently, MSCs with similar characteristics to bone marrow-derived MSCs have been isolated from other tissue sources, including trabecular bone [48], periosteum [49], synovial membrane [50], skeletal muscle [51], skin [52], pericytes [53], peripheral blood [54], deciduous teeth [55] and periodontal ligament [56]. Although the stem cell populations derived from these sources are valuable, common problems include the small number of harvested cells and limited amount of harvested tissues. Therefore, almost all adult-derived stem/progenitor cells require at least some degree of *ex vivo* expansion or further manipulation before they can be used pre-clinically or clinically to satisfy efficacy and safety requirements.

The degree of similarity between MSCs from such seemingly diverse sources is still a matter of some debate, despite early suggestions that they are present in the connective tissues of many organs, surround blood vessels as pericytes, and may contribute to the maintenance of organ integrity.

We may find that other adult or tissue-specific stem cells are capable of similar feats, but to date the evidence for this is not strong, and the ubiquitous nature of MSCs suggests that they may have a degree of plasticity not enjoyed by other stem cell types. The ease of obtaining MSCs has

resulted in them being the subject of more intensive investigation which has brought them closer to the point of medical or commercial application than many other types of stem cell.

Adipose-derived stem cells

An entire field of medicine now centers on the use of adipose-derived stem cells (ASCs) [57] for tissue repair, since human adipose tissue is ubiquitous and easily obtained in large quantities with little donor site morbidity or patient discomfort. Therefore, the use of autologous ASCs in therapeutics seems to be feasible and has been shown to be both safe and efficacious in preclinical and clinical studies of injury and disease [58,59].

Although ASCs are an attractive cell source for tissue engineering, their characterization is not yet complete. To date, all attempts to discriminate clearly between ASCs and fibroblasts have been unsuccessful. Compared with ASCs from later passages, freshly isolated fat cells and early passage ASCs express higher levels of CD117 (c-kit), human leukocyte antigen-DR (HLA-DR), and stem cell-associated markers such as CD34, along with lower levels of stromal cell markers such as CD13, CD29 (b1 integrin), CD44, CD63, CD73, CD90,CD105, and CD166 [60–62]. Several studies have shown that CD34-positive ASCs have a greater proliferative capacity, while CD34-negative ASCs are more plastic [62,63]. ASCs share many cell surface markers with pericytes and bone marrow MSCs. Therefore, several studies suggest that ASCs may exist in the perivascular tissue *in vivo*, although their exact location remains undetermined.

ASCs exhibit telomerase activity to some extent, although it is lower than that in cancer cell lines, which indicates that ASCs have the capacity for self-renewal and proliferation [64]. In addition, Puissant and his colleagues [65] reported on the lack of HLA-DR expression and the immunosuppressive properties of human ASCs.

Routinely, 1×10^7 adipose stromal/stem cells have been isolated from 300 mL of lipoaspirate, with greater than 95% purity [66]. In other words, the average frequency of ASCs in processed lipoaspirate is 2% of nucleated cells, and the yield of ASCs is approximately 5,000 fibroblast colony-forming units (CFU-F) per gram of adipose tissue, compared with estimates of approximately 100–1,000 CFU-F per milliliter of bone marrow [67].

To date, there have been numerous scientific publications demonstrating that ASCs possess the potential to differentiate toward a variety of cell lineages both *in vitro* and *in vivo* [68], and some of the research has been passed on to patients in the form of clinical trials. Although ASCs are of mesodermal origin, it is now clear that they can differentiate into ectoderm and endoderm lineage cells as well as mesoderm [69].

ASCs can differentiate into adipogenic [70–72], osteogenic [73], chondrogenic [73–75], myogenic [75], cardiomyogenic [76,77], angiogenic [78,79], tenogenic [80], and periodontogenic lineages [81], and tissue regeneration studies with suitable scaffolds and growth factors in appropriate external environment have been applied [82,83]. Some studies have reported the differentiation potential of ASCs toward cells of the ectodermal lineage. One study has also reported that ASCs cultured in monolayers with retinoic acid or on a fibrin matrix in the presence of EGF express the epithelial markers, cytokeratin 18 or E-cadherin and cytokeratin 8, respectively [84]. In another study, ASCs exposed to vasoactive intestinal peptide were induced to form retinal pigmented cells, which are of ectodermal origin, as indicated by the expression of retinal pigment epithelium (RPE) markers, namely best rophin, cytokeratins 8 and 18, and RPE 65 [85].

It has also been demonstrated that ASCs can differentiate into neuronal or neuronal precursor cells, both morphologically and functionally, under appropriate culture conditions [86]. In addition, recent studies have revealed that when ASCs are administered intravenously in a spinal cord injury model, they migrate to the injured cord, partially differentiate into neurons and oligodendrocytes and eventually may help to locomotor some functions [87].

Finally, it has been shown that ASCs can differentiate into endoderm lineage cells. Several reports have shown that ASCs have the potential to differentiate into hepatocytes as indicated by the presence of HGF, FGF-1 and FGF-4 [88,89].

DISCOVERY OF EMBRYONIC STEM CELLS

ES cells have attracted attention as a promising source of cells for tissue engineering, as they can self-renew almost indefinitely in culture and have the capacity to differentiate into all cell types of the body. ES cells are isolated from the inner cell mass of the developing blastocyst. *In vitro*, they can be maintained as undifferentiated cells via culture on murine embryonic fibroblasts (MEFs) or via culture in feeder-free conditions using a defined medium composition to supply essential cytokines and nutrients to promote the undifferentiated phenotype [90].

The concept of pluripotency, the ability of a single cell type to differentiate into multiple other types of cells arose from detailed histological studies of teratocarcinomas, which are neoplasms composed of seemingly undifferentiated cells randomly interspersed with somatic tissues. The fact that a single cell suspension produced from teratocarcinomas could give rise to completely new neoplasms in immuno-deficient mice suggested the presence of stem cells in their tissue mass. The nature of these somatic tissues in teratocarcinomas provided abundant information about various stages of differentiation. Lewis Klein Smith and Barry Pierce [91] were the first to develop conditions for isolating and culturing these cells, and these cells were published as 'embryonal carcinoma cells' (EC cells) in 1964. Not only the concept of pluripotency, but also the basal culture methods of pluripotent stem cells, which are come down to iPS cells, were established by the discovery of EC cells. Mouse embryonic stem cells (mESCs) were derived by the work of Martin Evans, Matthew Kaufmann, and Gail Martin [90]. Evans and Kaufmann demonstrated for the first time that they had succeeded in isolating the inner cell mass (ICM) of a mouse embryo at the blastocyst stage, and had allowed these cells to survive and develop [92]. Michael Sherman reported that an enriched culture medium containing 10% heat-inactivated fetal calf serum promoted 90% of mouse blastocysts to hatch from their zona pellucida and attach to the culture dish, although he was unable to prevent differentiation of the ICM into epithelial cells. Evans and Kaufmann solved this problem by isolating the ICMs from the blastocysts using the immune surgery method and disaggregating them into single cell suspensions. These cells were passaged onto irradiated MEFs, whereupon colonies of cells that were morphologically similar to EC cells finally appeared [93]. Unlike EC cells, the mESCs had normal karyotypes and were able to form embryoid bodies when cultured without their feeder fibroblasts. EC cells were widely used to study early embryonic cell differentiation, but within a few years after the discovery of mESCs, these were supplanted by mESCs principally because mESCs are thought to be more representative of those cells present in the ICM. A major contributing factor to the success of establishing the mES cell line was the introduction of leukemia inhibitory factor (LIF) into the mESC culture media to prevent differentiation [94]. LIF-supplemented culture medium allows mESCs to grow without feeder cells. This mechanism is based on the biology of the rodent, in that several rodent species possess the diapause phenomenon; which permits the generation of a new batch of fertilized embryos while the mother is still pregnant with a previous set. The new embryos arrest at the blastocyst stage of development until the uterus is vacated. This phenomenon is not observed in humans.

Seventeen years after the discovery of mESCs, the derivation of human ESCs was reported by James Thomson using cleavage stage human embryos produced by *in vitro* fertilization for clinical purposes. hESCs were more difficult to grow in culture than mESCs, but behaved in a broadly similar fashion in terms of their apparent immortality, expression of key surface antigens, and their ability to generate teratomas in immuno-deficient mice. It was not possible to examine germ line transmission following injection into blastocysts, since manipulation of

human embryos in this manner is illegal. The method used by Thomson and his colleague was similar to that of Evans in his mESC derivation work; however, the delay in obtaining hESCs may be attributed to ethical issues and the unavailability of human embryos for study. The original article describing the first five hESC lines was published in Science in November 1998 [95], and although it is a fairly brief report, the significance of this development cannot be underestimated since it is the forerunner of hundreds of new hESC lines derived in the following 13 years. Subsequent research has shown that hESCs, while similar to mESCs, have many unique characteristics for modeling human development.

Control over mES/hES cell differentiation has been extensively studied via manipulation of the parameters of the stem cell microenvironment; which is referred to as the stem cell niche. Thus, both soluble and insoluble factors of the niche which modulate differentiation have been thoroughly investigated, to determine the parameters amenable to inducing a particular cell fate.

ES cells require the EB formation to produce progenitor cell populations. One typical strategy for clinical applications using ES cells is that partially differentiated or tissue-restricted progenitor cells are isolated from the ES cells, and expanded *in vitro* to generate adequate progenitor cell populations before clinical application. ES cells differentiate into various mature somatic cell types, presumably via precursor cells, when the appropriate stimuli are applied. For instance, mesodermal progenitor cells were obtained after EB formation stimulated with BMP [96]. Moreover, multipotent hematopoietic progenitor cells [97,98], cardiac progenitor cells [99,100], endothelial progenitor cells [101] and neuronal progenitor cells [102–104]have been isolated from ES cells after appropriate stimuli. Recently, Lu and his colleague have reported an efficient and reproducible method for generating large numbers of such bipotential progenitors (hemangioblasts) from hESCs using an *in vitro* differentiation system [105]. In addition to obtaining a relatively high purity of progenitor cells by separation methods such as FACS and magnetic affinity cell sorting, stage-specific growth factor treatment or genetically altering the ES cells may greatly enhance their differentiation into desired progenitor lineages.

MSCs are generated from a number of different developmental origins [106]. Recent advances in stem cell biology have identified mesenchymal progenitor cell populations that can undergo multi-lineage differentiation into different mesenchymal tissues, such as cartilage, fat, and bone. These cells efficiently engrafted when injected into SCID mouse, and did not show any tumorigenic potential. A similar strategy has been applied to isolate clinically applicable mesenchymal precursor cells from hESCs without feeder support and EB formation [107].

There are potential limitations when using MSCs for tissue engineering and repair. These limitations include the relatively low frequency with which these cells occur in the marrow stroma, and also donor site morbidity. Additionally, the self-renewal and proliferative capacity of MSCs is limited and decreases with age [108]. The greater proliferative capacities of hESC-derived mesenchymal cells compared to human MSCs, and lack of teratoma formation *in vivo* highlight the former's significant potential for tissue engineering and regenerative medicine applications [109]. hESC-derived progenitor cells such as mesenchymal cells may have potential application in tissue regeneration and provide a tool for elucidating the mechanism of lineage commitment specification from ES cells, which may provide a platform for efficiently generating specialized transplantable cells for clinical applications.

INDUCED PLURIPOTENT STEM CELLS

In 2006, the generation of induced pluripotent stem cells (iPSCs) was reported by the laboratory of Shinya Yamanaka. The study demonstrated the reprogramming of mouse somatic cells to pluripotency. Retroviral transduction of just four genes (Oct4, Sox2, Klf4, and c-Myc) reprogrammed mouse embryonic fibroblasts and adult tail fibroblasts to show characteristics reminiscent of mESCs. The resulting cells were named iPSCs. They are capable of contributing

to chimeric animals with germ line transmission, and their contribution to all tissues of the resulting offspring indicative of their pluripotency [110–112]. Yamanaka's group extended their earlier work and showed that human adult dermal fibroblasts could be reprogrammed by retroviral transduction of Oct4, Sox2, Klf4, and c-MycOCT4, SOX2, KLF4, and C-MYC with good efficiency [113]. James Thomson's laboratory found that a slightly different set of factors, OCT4, SOX2, NANOG, and LIN28, were sufficient to allow iPSC generation from fetal and adult fibroblasts [114] via lentiviral rather than retroviral transduction. Lentiviral transduction allows the transduction of non-dividing cells, which was not previously possible using retroviruses. Initial iPSC studies used retroviruses for gene transfer into target cells, since it was believed these genes would be silenced [115,116], but alongside their inability to infect non-dividing cells [117], it was noted that gene silencing was not maintained in iPSC, giving the risk of tumorigenesis.

Constitutive lentiviral use, in which transgene silencing is poor [116,118] was superseded by inducible lentiviral methods which hoped to attain full silencing of transgene expression upon attainment of the pluripotent state. However, a common problem with these vector types is the possibility of mutations upon integration or reactivation of the transgenes, which has been shown to lead to tumorigenesis. New vectors have since been developed that can be removed from the programmed genome, and further developments of RNA-based reprogramming systems, such as those using micro-RNAs, isolated proteins, and small molecules, show some promise for deriving integration-free iPSC lines but there are still concerns that the somatic genome may not have been fully reprogrammed to pluripotency [119,120]. Some of the concerns are manifested as an epigenetic trace left over from the cell of origin. Even though this trace may be erased by overextended passage, the observation raises the concern over the impact and importance of cell of origin and its subsequent translational value.

Another issue in the iPSC field is the representative nature of a single iPSC line – this again points to the fact that 'not all iPSCs are equal', and again should act as a caution when considering patient-specific iPSCs (see below). These problems could restrict the clinical utility of iPSCs and are under intense investigation by many groups. However, generation of *in vitro* models of human disease using patient-specific iPSCs is allowing investigation and the generation of a wealth of data that promises to make a major impact on science and medicine. As an illustration of the use of iPSCs for modeling disease in a dish, we can turn to the work of Rusty Gage. At a time when Pharma is retreating from neurodegeneration/neuropsychiatric research because of cost and paucity and inadequacy of animal models, the use of iPSCs as

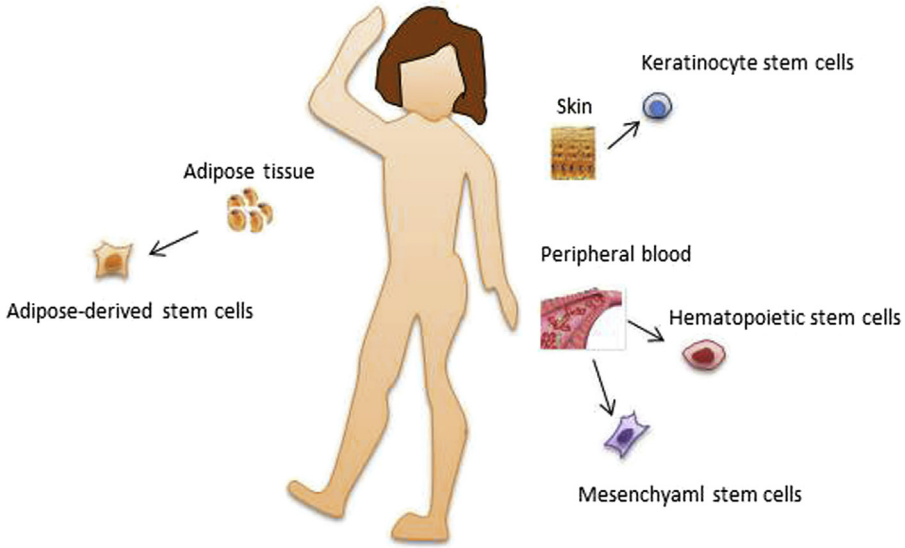

FIGURE 31.1
Adult stem cells for tissue-engineering applications. Blood, skin and adipose tissue are considered to be appropriate cell source for tissue engineering.

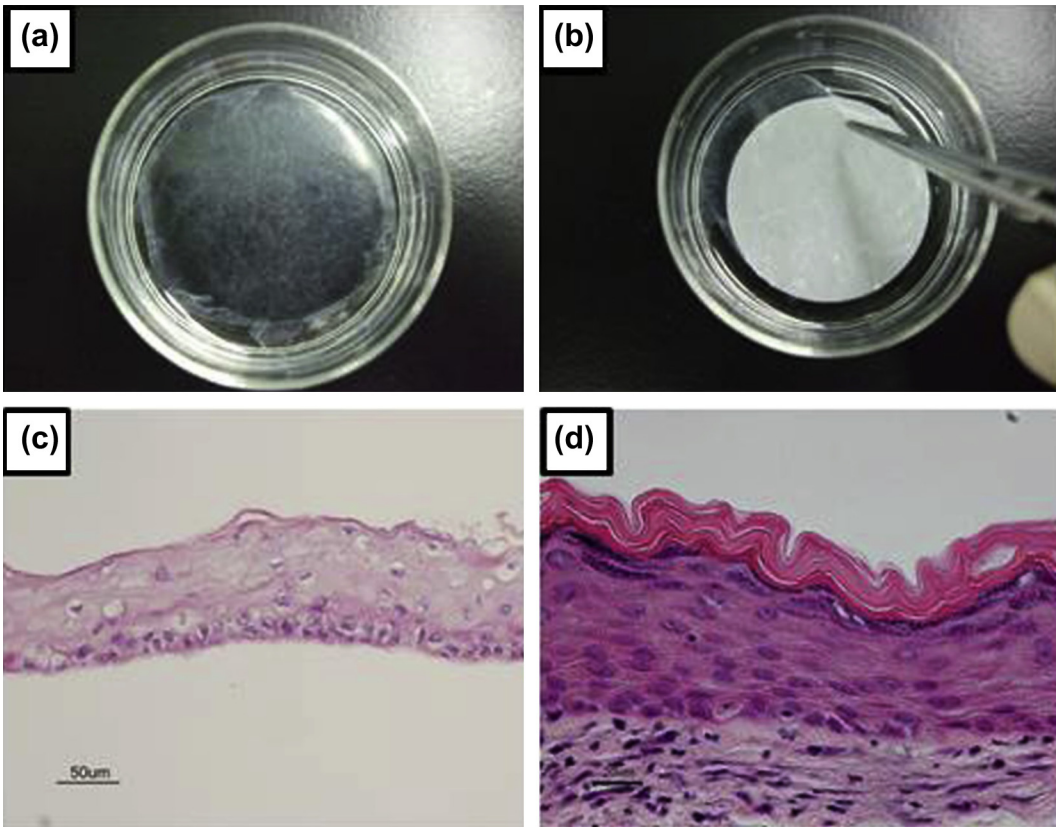

FIGURE 31.2

(c) Harvested human keratinocyte cell sheet. (d) Transplanted human keratinocyte cell sheet on murine connective tissue.

a 'disease in a dish' assumes massive potential. Gage derived iPSCs from the fibroblasts of schizophrenic patients, and subsequently differentiated them into neurons. These cells showed reduced connectivity and synapse formation. Most dramatic was the rescue of this 'disease phenotype' by application of the antipsychotic, loxapine [121]. There is a long road between disease in a dish and cures for psychiatric disorders, but at least iPSCs offer a tractable system to interrogate cellular and molecular mechanisms.

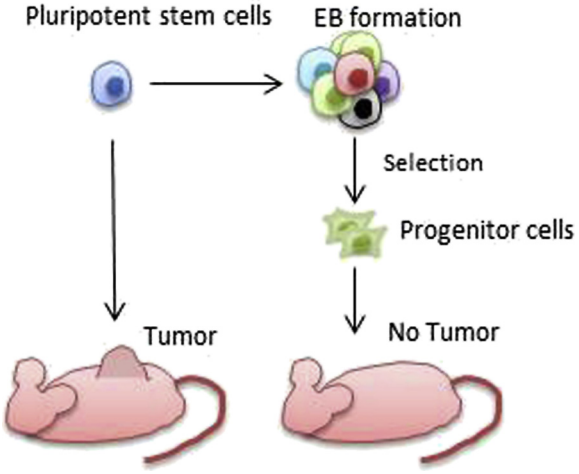

FIGURE 31.3
Strategy for harvesting progenitor cells from ES cells.

iPS cell generation.

CONCLUSION

As introduced in this chapter, each cell source for tissue engineering poses different challenges. Blood, skin and adipose tissue have been considered to be good stem cell sources because they are easy to access and allow relatively non-invasive harvesting. However, stem cell harvested from adult tissues always raises concerns about the limited number of cells procured. In recent years, it was hoped that ES cells and iPS cells would be appropriate cell sources for tissue engineering because of their pluripotency and proliferative potential. It has not been determined which cell source is most appropriate for which tissue-engineering application. To elucidate the true nature of stem cells, further data will be needed to open the door to potential applications.

CHAPTER 32

Embryonic Stem Cells as a Cell Source for Tissue Engineering

INTRODUCTION

It has been estimated that approximately 3,000 people die every day in the US from diseases that could have been treated with stem cell-derived tissues [1]. Given the therapeutic potential and growing public awareness of stem cells to treat disease, it is not surprising that embryonic stem cell (ESC) research has been rapidly expanding since mouse ESCs (mESCs) were first isolated in 1981 [2,3] followed by the isolation of human embryonic stem cells (hESCs) in 1998 [4,5] from the inner cell mass (ICM) of human blastocysts (Fig. 32.1).

Adult stem cells have been used clinically since the 1960s for therapies such as bone marrow transplantation, and these cells hold great therapeutic promise. ESCs also offer major benefits, including their ease of isolation, ability to propagate rapidly without differentiation, and — most significantly — their potential to form all cell types in the body. Additionally, ESCs are an attractive cell source for the study of developmental biology, drug/toxin screening studies, and the development of therapeutic agents to aid in tissue or organ replacement therapies. Regarding the latter application, which is the focus of this chapter, ESCs have the potential to exhibit a considerable impact on the field of tissue engineering, where current treatments for large tissue defects involve graft procedures which have severe limitations. Specifically, many patients with end-stage organ disease are unable to yield sufficient cells for expansion and transplantation. In addition, there exists an inadequate supply of harvestable tissues for grafting, and that which is available has associated risks, such as donor site morbidity, infection, disease transmission and immune rejection.

Tissue-engineering-based therapies may provide a possible solution to alleviate the current shortage of organs. Expectations for the potential of stem cells have increased even more after

the revolutionary finding of the generation of induced pluripotent stem cells (iPSCs) that profoundly modified the principles of cell fate and plasticity, and at the same time may represent a novel remarkably important cell therapy tool. iPSCs were originally generated by the introduction of four transcription factors (Oct3/4, Sox2, Klf4 and cMyc) in a somatic committed cell, the fibroblast, converting it to a pluripotent ESC-like state [6]. This work gave rise to a completely new field that is not covered in this chapter, and the reader is directed to a number of excellent papers and reviews on this topic.

Tissue engineering has been defined as an interdisciplinary field that applies the principles of engineering, materials science and life sciences toward the development of biologic substitutes that restore, maintain, or improve tissue function [7]. Thus, tissue engineering may provide therapeutic alternatives for organ or tissue defects that are acquired congenitally or produced by cancer, trauma, infection, or inflammation. Tissue-engineered products would provide a life-long therapy and may greatly reduce the hospitalization and health care costs associated with drug therapy, while simultaneously enhancing the patients' quality of life.

A central part of such strategy is the cell source to be used and the methods whereby sufficient numbers of viable differentiated cells can be obtained. ESCs represent a powerful source of cells capable of multi-lineage differentiation because they can potentially provide a renewable source of cells for transplantation. ESC-derived cells can be used directly as cellular replacement parts, or in combination with other materials (typically in the form of scaffolds, Fig. 32.2). Despite this promise, the application of ESC to tissue engineering faces numerous challenges, including appropriately differentiating the cells to the desired lineage in a controlled and homogenous fashion, and avoiding implantation of undifferentiated ESCs which can potentially form teratomas. Currently, ESC-based tissue-engineering research is focused on elucidating soluble and immobilized cues and respective signaling mechanisms that direct cell fate, on characterization and isolation of differentiated progeny, and on establishing protocols to improve the expansion and homogeneity of differentiated cells.

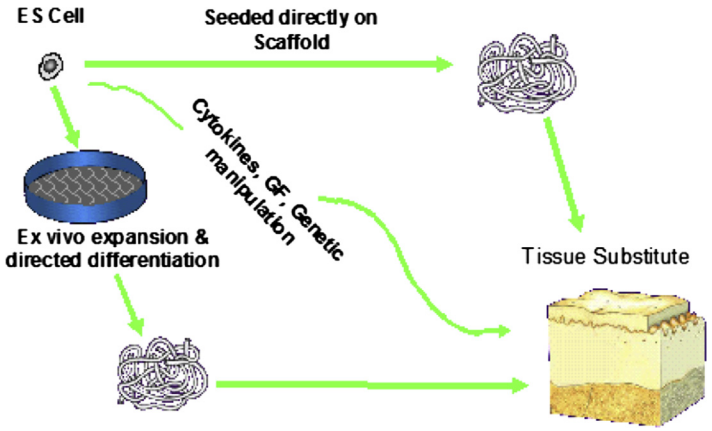

FIGURE 32.2
Approaches for using ES cells for scaffold-based tissue engineering. ES cells can be used in tissue-engineering constructs in a variety of methods. ES cells can be expanded in culture and then seeded directly onto scaffold where they are allowed to differentiate. Alternatively, stem cells can be directed to differentiate into various tissues and enriched for desired cells prior to seeding the cells onto scaffolds.

This chapter discusses key concepts and approaches for:

1) The propagation of undifferentiated ESC,
2) The directed differentiation into tissue specific cells,
3) The isolation of progenitor and differentiated phenotypes,
4) The transplantation of progenitor and differentiated cells, and
5) The remaining challenges for translating ESC-based tissue-engineering research into the clinical therapies.

Whenever possible, approaches using hESCs are reported.

MAINTENANCE OF ESCs

The self-renewal of ESCs is a prerequisite for generating a therapeutically viable amount of cells. Over the past few years much insight has been gained into the self-renewal of ESCs. Both murine and human ESCs (mESC and hESCs) were first derived and maintained in culture using mouse embryonic fibroblast feeder (MEF) layers and media containing serum. Considerable behavioral, morphological, and biochemical differences have been observed between mESCs and hESCs, and the research of animal ESCs is not easily translated to human ESCs [5,8,9]. For example, mESCs form tight, rounded clumps whereas hESCs form flatter, looser colonies, grow more slowly and demand strict culture conditions to maintain their normal morphology and genetic integrity. Unlike mESCs, which can be maintained in an undifferentiated state in the presence of leukemia inhibitory factor (LIF), hESC cultures require, in addition to LIF, supplementation of the basic fibroblast growth factor (bFGF) or the use of a feeder layer. Although both mESCs and hESCs express common transcription factors of 'stemness', such as Nanog, Oct4, and alkaline phosphatase, in the human system undifferentiated ESCs express Stage Specific Embryonic Antigen-3 (SSEA-3) and SSEA-4 and SSEA-1 is only expressed upon differentiation, whereas the opposite expression is observed in the mouse system. Due to these differences, efforts in hESC research focus on understanding the mechanisms of hESC self-renewal.

Mouse and human iPSCs have marker expression profile and biological properties very similar to the mouse and human ESCs, respectively, and this is a general proof of principle of their real pluripotent state. However, after initial studies, data are emerging that iPSCs are actually not identical to ESCs [10], and a growing body of evidence indicates that the epigenetic memory of the original cell type reprogrammed is at least partially maintained (reviewed in reference [11]). This may result in a more limited level of pluripotency in terms of spectrum of differentiation if compared to ESCs, but not necessarily a more limited spectrum of possibility of tissue differentiation for transplantation purposes if the original cell type is chosen accordingly [12].

Therapeutic applications of stem cells require moderate to large numbers of cells, hence requiring methods amenable to scale-up. Therefore, xenograft cell sources have also been considered. Using cultures of hESCs on human feeders it was found that human fetal muscle fibroblasts, human fetal skin fibroblasts and adult fallopian tubal epithelial cells supported the pluripotency of hESC culture *in vitro* [13]. The same group derived and established a hESC line on human fetal muscle fibroblasts in entirely animal-free conditions [13]. Since then, different fetal and adult cells have been examined and shown to support the continuous growth of hESCs [14–17]. However, the use of hESCs for therapeutic application requires defined culture medium and controlled cell derivation, maintenance and scale-up. To overcome these obstacles, combinations of self-renewal signals for hESCs have been investigated including soluble factor, extracellular matrix (ECM), cell-cell interactions and mechanical forces.

Significant attempts have been made to identify culture conditions and media components which can regulate hESCs self-renewal. Growth factors in culture media can bind the cell surface receptors to promote self-renewal. These soluble factors include bFGF [18,19], tumor growth factor β1 (TGFβ1)/ActivinA/Nodal ligands [20,21], insulin-like growth factor (IGFs) [18,22], Wnt ligands [23,24] and glycogen synthase kinase-3 GSK-3 inhibitors [25]. In one study, it was shown that hESCs can be expanded on human fibronectin using a medium supplemented with bFGF and TGFβ1 [26]. Noggin, an antagonist of bone morphogenetic protein (BMP), was found to be critical in preventing the differentiation of hESCs in culture. The combination of Noggin and bFGF was sufficient to maintain the proliferation of undifferentiated hESCs [27].

It has been also demonstrated that Wnt ligands affect ESCs self-renewal and differentiation. For example, spontaneous differentiation of mouse embryonic fibroblast inhibits by addition of Wnt1 to culture media [23]. In addition, hESC differentiation induces by using Wnt3 [28]; however, hESC self-renewal perturbs by the activation of canonical Wnt/β-catenin pathway through the expression of stabilized β-catenin [29]. Furthermore, hESCs maintained in media containing high concentrations of bFGF (24–36 ng/ml), alone or in combination with other factors, show characteristics similar to cultures maintained with feeder cell-conditioned medium [30,31].

The derivation of hESCs has also been achieved with minimal exposure to animal-derived material, using serum replacement (SR) and human foreskin fibroblasts as feeder cells [32], instead of the feeder layer [33], providing well-defined culture conditions [34]. Research is currently under way to determine how these conditions maintain cell integrity over long-term culture. For example, mTeSR, which contains TGFβ1, LiCl, bFGF, pipecolic acid, and GABA, supports long-term self-renewal of feeder-independent hESC cell culture [34]. In addition to growth factors, lipid molecules such as sphingosine-1-phosphate (S1P) [35–37], albumin [38], and synthetic lipid carriers [39] have been shown to regulate the self-renewal and differentiation of hESCs. Although growth factor and media compositions can control hESC self-renewal, challenges including maintenance of pluripotency, and production of biologically and functionally identical cells still remain.

In addition to soluble factors, a defined ECM or biomaterial may be required for maintaining the hESC self-renewal ability. Various biomaterials, such as Matrigel [40], human fibronectin [41], human vitronectin [42], collagen I [43], complex humanized matrices [44], hyaluronic acid hydrogels [45] or calcium alginate hydrogel [46], have been used as a structural support for hESC self-renewal. As an example, Xu et al. showed that hESCs can be maintained on Matrigel or laminin and MEF-conditioned media [47]. Cells grown in these conditions meet all the criteria for pluripotent cells: they maintain normal karyotypes, exhibit stable proliferation rate and high telomerase activity and they differentiate into derivatives of all three germ layers, both *in vitro* and *in vivo*. In an attempt to find ideal ECM components or biomaterials for *in vitro* feeder-cell-free culture of hESCs, Hakala et al. compared various biomaterials including ECM proteins (i.e., collagen IV, vitronectin, fibronectin, and laminin), human and

animal sera matrices, and Matrigel in combination with a variety of unmodified or modified culture media. Matrigel in combination with defined mTeSR1 culture medium was found to be superior matrix for hESC culture compared to other biomaterials used in this study [40]. Similarly, in a combinatorial study, Brafman et al. developed a high throughput technology, an arrayed cellular microenvironment, to assess the self-renewal of hESC cultured on different ECMs in media composed of different growth factors. Long-term self-renewal of hESCs was obtained on a biomaterial consisting of collagen IV, fibronectin, collagen I, and laminin in defined StemPro media and MEF-conditioned media [48].

Self-renewal and differentiation of ESCs can be also regulated through intercellular interactions [49–52] and mechanical forces [53–55]. Cell-cell interactions and formation of ESC colonies affect the self-renewal and spontaneous differentiation of ESCs. It has been shown that the size and shape of colonies play an important role in controlling ESC expansion [49,52]. Various microfabrication technologies have been employed to control ESC shape and size, such as micropatterning of substrate with ECMs [49] to confine colony formation to patterns, or formation of hESCs colonies in 3D microwells [50,51]. Another important factor in hESC self-renewal is the application of mechanical forces (e.g., cyclic biaxial strain [53,54] or shear stress [55]) to the cells. Although the physiological effects of mechanical forces on self-renewal and proliferation of ESCs remain unknown, it has been shown that these forces can regulate cellular differentiation. For example, fluid flow-induced shear stress has been demonstrated to enhance the elongation and spreading of undifferentiated hESCs and induce vascular differentiation of hESC at higher shear stress [55].

Large-scale production of hESCs is critical for tissue-engineering applications, which require large numbers of cells. It is generally accepted that 'classical' laboratory culturing methods are not suitable for the large-scale production of ESCs for therapeutic applications, and new culture systems are needed. Although two-dimensional (2D) methods such as the high density cultures of ESCs have been developed by combining automated feeding and culture methods [56], three-dimensional (3D) culture may be a more suitable technology for large-scale expansion of ESC production.

At the present time, the aggregation of multiple ESCs is necessary to initiate EB formation. The formation of large cellular aggregation may prevent nutrient and growth factor diffusion as well as metabolic waste removal from the aggregates in suspension cultures in large-scale systems. A small number of methods have been developed for the differentiation of mESCs in controlled cultures. Hanging drops and methylcellulose cultures have been shown to be somewhat efficient in preventing the agglomeration of EBs, but their complex nature makes their upscaling a rather difficult task.

A much simpler process in spinner flasks resulted in the formation of large cell clumps within a few days, indicative of significant cell aggregation in the cultures [57]. Compared to static culture system, spinner flasks enhance homogenous expansion of hEBs and can be easily scaled up to 10,000L bioreactor tanks [58]. In one study, it was demonstrated that the growth rate of hEB is higher when cultured in stirred vessels than in other culture systems (e.g., static culture and rotary cell culture system) [59]. However, an increase of the culture medium stirring rate to avoid agglomeration within the stirred vessels resulted in massive hydrodynamic damage to the cells due to the extensive mixing in the vessels. Therefore, in order to establish a scaleable process for the development of EBs, there is a need for dynamic cultivation under controlled mixing conditions. One approach used a static system for an initial aggregation period of four days, followed by a period in dynamic culture in spinner flasks, to successfully achieve the bulk production of cardiomyocytes from differentiating mES cells [60].

In addition to suspension cultures using hEBs, stirred vessels can be also used for the scale-up expansion of undifferentiated hESCs through the combination of a microcarrier with the stirred culture systems. Various microcarriers such as polystyrene [61], collagen-coated dextran

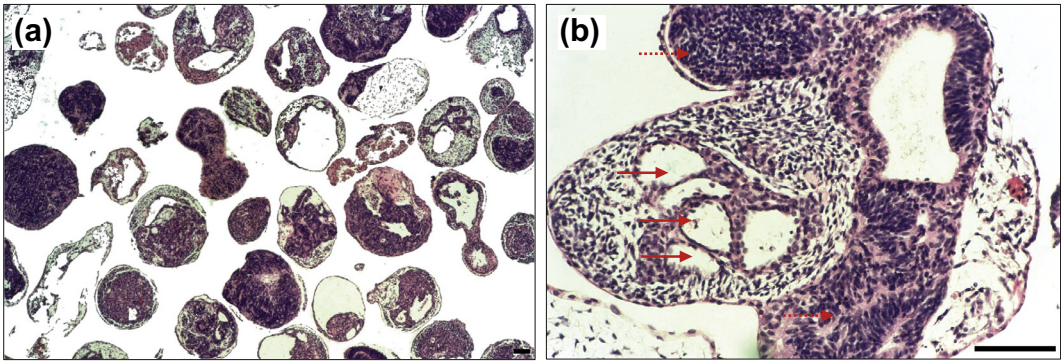

FIGURE 32.3

Formation of human EBs in a rotating cell culture system. (a—b) Haematoxilin- and eosin-stained sections of EBs after one month in culture, showing the formation of (a) a small and relatively homogenous population of human EBs, and (b) a variety of cell types such as: epithelial neuronal tubes (dashed arrows), and blood vessels (solid arrows) (Scale bars: 100 μm). *(Adapted from reference [66].)*

[62] and Matrigel-coated cellulose [63] have been used to promote hESC expansion in spinner flasks. In addition to hESC expansion, this combination of microcarriers and stirred culture systems has been used for directing hESC differentiation to definitive endoderm [64] and cryopreservation and recovery of undifferentiated hESCs adhered to microcarriers [65].

Another dynamic approach which was highly effective for hESCs is to generate and culture EBs within rotating cell culture systems [66]. These bioreactors provide exceptionally supportive flow environments for the cultivation of hESCs, with minimal hydrodynamic damage to incipient EBs, reduced EB fusion and agglomeration, and they allow the uniform growth and differentiation of EBs in three dimensions, as they oscillate and rotate evenly (Fig. 32.3a). hESCs cultured within these systems formed aggregates after 12 hrs that were smaller and more uniform in size and evenly rounded due to minimal agglomeration; the yield of EBs was three times higher than that measured for static cultures. Also, dynamically formed EBs exhibited steady and progressive differentiation, with cyst formation and elaboration of complex structures such as neuro-epithelial tubes, blood vessels and glands (Fig. 32.3b) [66].

Different rotary cell culture systems, including slow turning lateral vessel (STLV) and high aspect rotating vessel (HARV), have been used to promote the efficiency of EB formation and differentiation of stem cells [66—69]. Generally, STLV systems are preferable to HARV for the EB aggregate formation and differentiation. It has been shown that the HARV system can lead to significant aggregation with large necrotic areas at the center and differentiations at the peripheries of aggregates. The aggregation rate of hESCs can be controlled by using the STLV system, which results in the formation of small-size hEBs [58,66].

To further enhance the large-scale differentiation of hEBs, a perfused STLV system was combined with a dialysis chamber to allow the diffusion of media as well as removal of waste products from the bioreactor [70]. Compared to static cultures, uniform growth and differentiation of hEBs to neural lineage was promoted when the combined rotary cell culture system/dialysis chamber was used [70]. Although rotary cell culture systems provide low-shear environments for hESCs cultivation and differentiation, they can only be scaled-up to volumes of 5—500 mL, which is much lower than the scalability of stirred culture systems. Although still an area of active research, these technologies have demonstrated the potential of engineering for the development of scalable technologies to expand ESC provision for research and therapies.

DIRECTED DIFFERENTIATION

Perhaps the biggest challenge in the clinical use of ESCs is the lack of knowledge of how to predictably direct their differentiation. For example, although ESCs can generate cells of

hematopoietic, endothelial, cardiac, neural, osteogenic, hepatic and pancreatic tissues, it has been very difficult to achieve directed differentiation into these tissues. The lack of homogeneous differentiation may be attributed to the intrinsic property of ESCs of differentiating stochastically in the absence of proper temporal and spatial signals from the surrounding microenvironment. Various techniques have been employed to control the differentiation of hESCs and to isolate a specific germ layer for tissue regeneration applications. The limitation of current techniques used for controlled differentiation is the low transformation efficiency, which results in a cell population containing ectoderm and mesoderm germ layers. The segregation of these germ layers can be achieved by using appropriate differentiation protocols. In this section we describe some of the current approaches used to direct the differentiation of ESCs and give examples of their use.

Genetic reprogramming

This approach includes the introduction of specific gene(s) into hESCs, which enable the production (by enhancement or selection) and propagation of specific cell type populations. Different techniques for knocking-in and knocking-out genes into hESCs have already been established. Transfection of undifferentiated hESCs with specific plasmid was established using either chemical reagents or electroporation. The latter was further shown to be useful for the generation of homologous recombination events [71]. Another technique is the introduction of transgenes into hESCs by self-inactivated lentiviruses. This transduction technique was shown to be efficient, with sustained expression in undifferentiated hESCs as well as in hESCs, which undergo differentiation [72,73]. However, both undifferentiated and differentiated hESCs were successfully infected by using adenoviral and adeno-associated viral vectors [74]. Another approach, which uses genetic manipulation, is the introduction of suicidal genes, which permit the ablation of the cells if necessary [75]. Using this approach, hESCs were transfected to express the herpes simplex virus thymidine kinase gene [76].

Genetic techniques involve both positive and negative regulators. The positive regulators include the constitutive or controlled expression of transcription factors that have been shown to derive the differentiation into particular tissues. For example, the over-expression of the Nurr transcription factor has been shown to increase the frequency of ESCs that differentiate into functional neural cells [77]. Alternatively, the negative regulators can be incorporated to induce the apoptosis of cells that differentiate to varying pathways. For example, neomycin selection and suicide genes that are activated by certain transcription factors can be used [78]. In a recent study, Zoldan et al. developed a 3D siRNA delivery system using lipid-like materials, lipidoids, for the efficient transfection of hESCs. This system was used to direct differentiation of hESCs to a specific lineage by knocking down Kinase Insert Domain Receptor (KDR) to prevent the differentiation of endoderm layer, leading the separation of this germ layer from mesoderm and ectoderm [79]. The developed 3D RNA delivery technique have shown to be preferable over a 2D environment for directing hESC differentiation, in which the transfection reagents are added to the media used for *in vitro* culture of hESCs-seeded 2D substrates. Clearly, all these techniques would benefit from a deeper understanding of inner workings of transient cells and knowledge of the differentiation pathways and lineages. Further analysis of the stem cell and progenitor hierarchy through high-throughput analysis of gene and protein profiles should accelerate this process. Despite the power of these approaches, one potential concern is that the genetic modifications may make the cells unsuitable for transplantation.

Microenvironmental cues

Another approach to directing ESC differentiation is through the use of microenvironmental cues that are important in regulating adult and ESC fate decisions. During development, cells of the inner cell mass are exposed to a series of tightly regulated microenvironmental signals. However, in tissue culture the complex expression patterns and spatial orientation of these signals can be lost. Currently, ESCs are grown in their primitive state as aggregated colonies of

cells. To stimulate differentiation, two main methods have been examined. In one method, differentiated cells are derived from EBs. EBs can be formed from either single cell suspensions of ESC or from aggregates of cells. EBs mimic the structure of the developing embryo and recapitulate many of the stages involved during its differentiation, and clonally derived EBs can be used to locate and isolate tissue specific progenitors. EBs initiate many developmental processes and create suitable conditions for differentiation of cells into all three germ layers and are generally formed through suspension or hanging drop methods.

In general, the differentiation of ESCs in EBs produces a wider spectrum of cell types, due to the EBs' ability to better mimic the temporal pattern of cell differentiation seen in the embryo. In some applications, the combined use of EBs and adherent cultures has resulted in better cell yields. For example, to induce ESC differentiation to cardiomyocytes, EB formation in suspension cultures followed by differentiation in adhesion cultures has been shown to optimize the percentage of cells that give rise to cardiomyocytes [80,81]. Similarly the production of hepatocytes has been shown to be induced by first culturing the cell in EBs and then in 2D cultures [82].

Neural progenitor cells were isolated from hESCs that showed positive immunoreactivity to neuron-specific antigens, responded to neurotransmitter application, and presented voltage dependent channels in the cell membrane [83–86]. Various differentiation approaches, including adherent culture or EB suspension culture, have been used to direct the hESC differentiation to the neural lineage [87] (Fig. 32.4a).

To promote neural differentiation, different soluble factors such as BMP-inhibitors, retinoic acid (RA), and other supplements (e.g., N2, B27, ITS) are added to the media in adherent culture methods. In EB suspension culture systems, neural induction factors should be added during differentiation to induce neural differentiation of hESCs. The differentiated cells are then cultivated on adherent culture to allow for the neural cell growth. In both approaches, the morphological characteristics of the neural progenitors can be maintained and expression of NP-markers in the medium supplemented with FGF2 and B27 [87] (Fig. 32.4b). Highly enriched cultures of neural progenitor cells were isolated from hESCs and grafted into the stratum of rats with the Parkinson's disease [88]. The grafted cells differentiated *in vivo* into dopaminergic neurons and corrected partially behavioral deficits in the transplanted animals. A subsequent study showed that hESCs implanted in the brain ventricles of embryonic mice can differentiate into functional neural lineages and generate mature, active human neurons that successfully integrate into the adult mouse forebrain [89].

Oligodendrocytes and their progenitors were also isolated in high yield from hESCs [90]. Transplantation of these cells into animal models of dysmyelination resulted in integration, differentiation into oligodendrocytes and compact myelin formation, demonstrating that these cells displayed a functional phenotype. In addition to *in vivo* differentiation of hESCs to neural lineages, ESCs can be combined with a biomaterial to induce the *in vitro* differentiation of ESCs to specific neural lineages in the presence of differentiation-inducing agents. For examples, electrospun fibrous scaffolds not only enhanced the differentiation of mouse ESCs into specific neural lineages such as neurons, oligodendrocytes and astrocytes, but also supported the neurite outgrowth [91]. In recent years, the use of carbon nanotubes (CNTs) for the neuron differentiation from hESCs and neural growth has been also explored [92,93]. It has been shown that 2D scaffolds composed of poly(acrylic acid) grafted CNT thin films promoted hESCs' neuron differentiation efficiency as well as protein adsorption and cell attachment compared to poly(acrylic acid) scaffolds without CNTs [92].

The differentiation of hESCs to neural lineages is induced by supplementation of the culture medium with biochemical agents. Recently, it has been demonstrated that nanopatterning of the substrate can effectively control hESC differentiation to neural lineages in the absence of

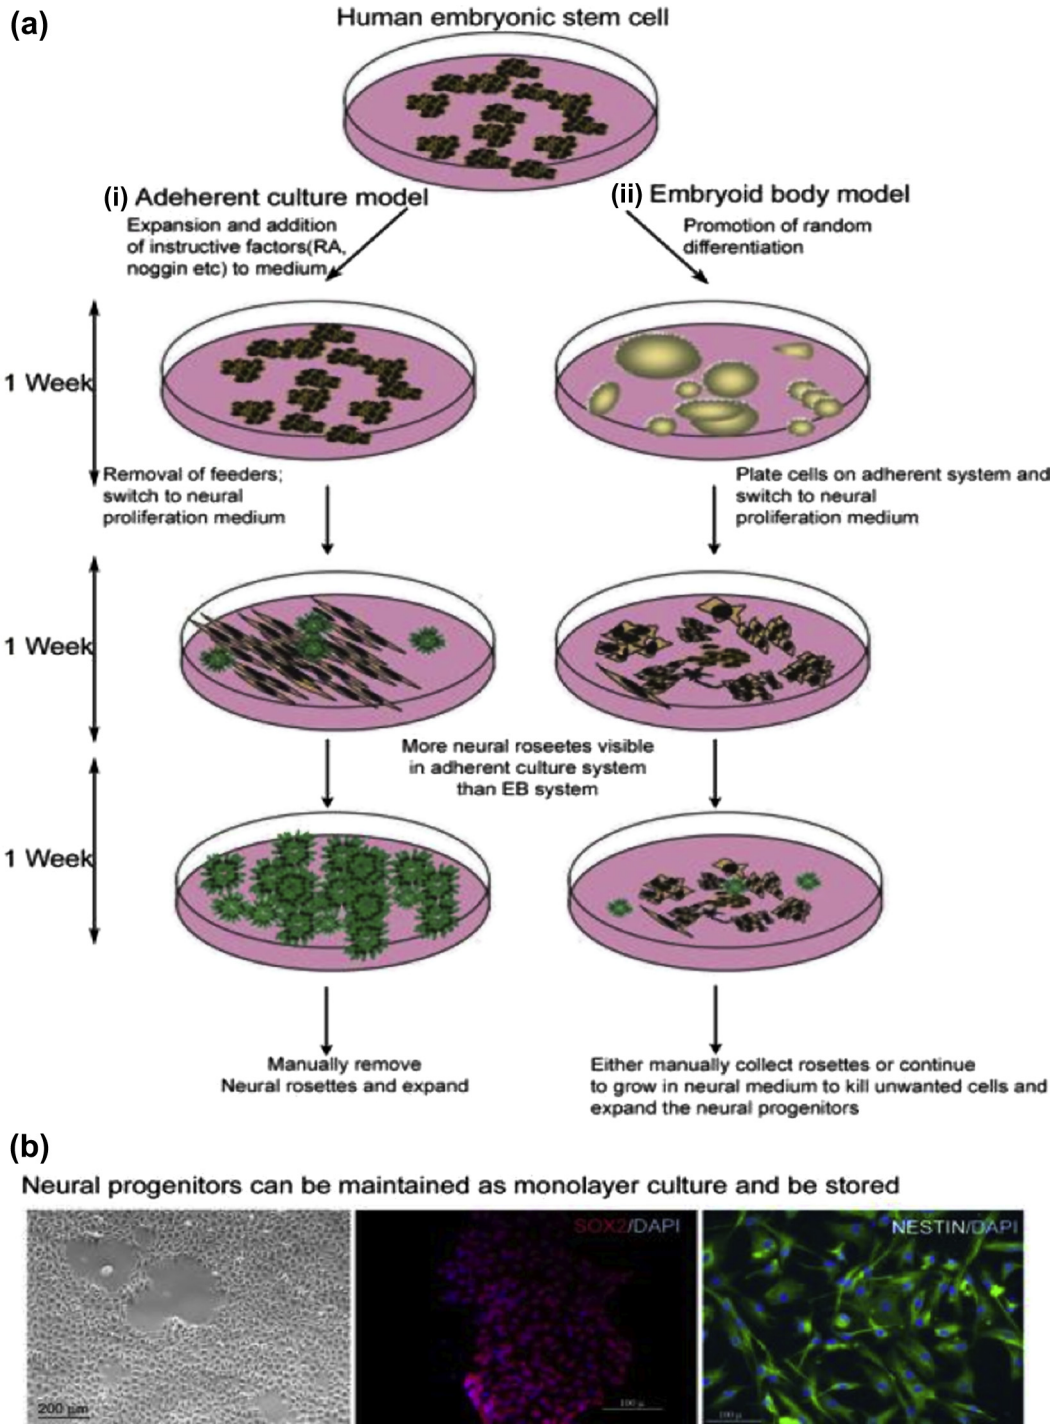

FIGURE 32.4

Differentiation of hESCs into neural progenitor cells. (a) Directed differentiation of hESC to neural lineages by adherent or EB suspension culture, (b) bright field image (left panel), and expression of neural progenitor markers including SOX2 (red, middle panel) and Nestin (green, right panel), indicating that the neural progenitor generated by these methods preserved their characteristic morphology and exhibited the expression of neural progenitor by culturing in medium containing FGF2 and B27. *(Adapted from reference [87]).*

any biological and biochemical agents. In one study, a UV-assisted capillary force lithography technique was developed to generate 350 nm pattern arrays using polyurethane acrylate [94]. The hESCs seeded on these patterns differentiated to neuronal lineage after five days of culture without the addition of differentiation-inducing agents [94].

ESCs have been shown to give rise to functional vascular tissue. Three different strategies have been employed to induce vascular differentiation of ESCs:

1) EB formation;
2) Uco-culture with fibroblast feeder layers or target cells; and
3) 2D monolayer culture of ESCs in defined chemical conditions combined with differentiation stimuli [95] (Fig. 32.5).

Spontaneous differentiation of ESCs to EB aggregates in a medium supplemented with cytokines has been shown to promote their differentiation to smooth muscle cell, pericytes, and endothelial cells [96,97]. One limitation of this strategy is that the ESCs differentiate to a heterogeneous cell population composed of vascular cells and other cell types from different germ layers. Various approaches have been employed to improve the efficiency of EB protocols to promote vascular cell differentiation, such as addition of VEGF-A [98] or BMP4 [99] to culture media and using magnetic-activated cell sorting (MACS) or fluorescence-activated cell sorting (FACS) [100].

Another approach to directing the vascular differentiation of hESCs is the use of co-culture systems, where undifferentiated ESCs are seeded onto mouse fibroblast feeder layers such as stromal cells [101], MEF [102], or mouse ECs [103] to enhance vascular differentiation. Alternatively, 2D monolayer culture on Matrigel [104], collagen IV [105], and fibronectin [106] combined with differentiation stimuli (e.g., addition of GFs/Cytokines [104] or RA [107], mechanical stimulation [108], and hypoxia [109]) have been used for vascular hESC differentiation. Although these strategies increase the differentiation efficiency, isolation of progenitor cells expressing markers (e.g., CD34, Stem Cell Antigen [Sca]-] or Flk1) during ESC differentiation is a crucial requirement for deriving homogenous vascular cell populations [104].

Early vascular progenitor cells isolated from differentiating mESCs were shown to give rise to all three blood vessel cell types: hematopoietic, endothelial and smooth muscle cells [110]. Once injected into chick embryos, these vascular progenitors differentiated into endothelial

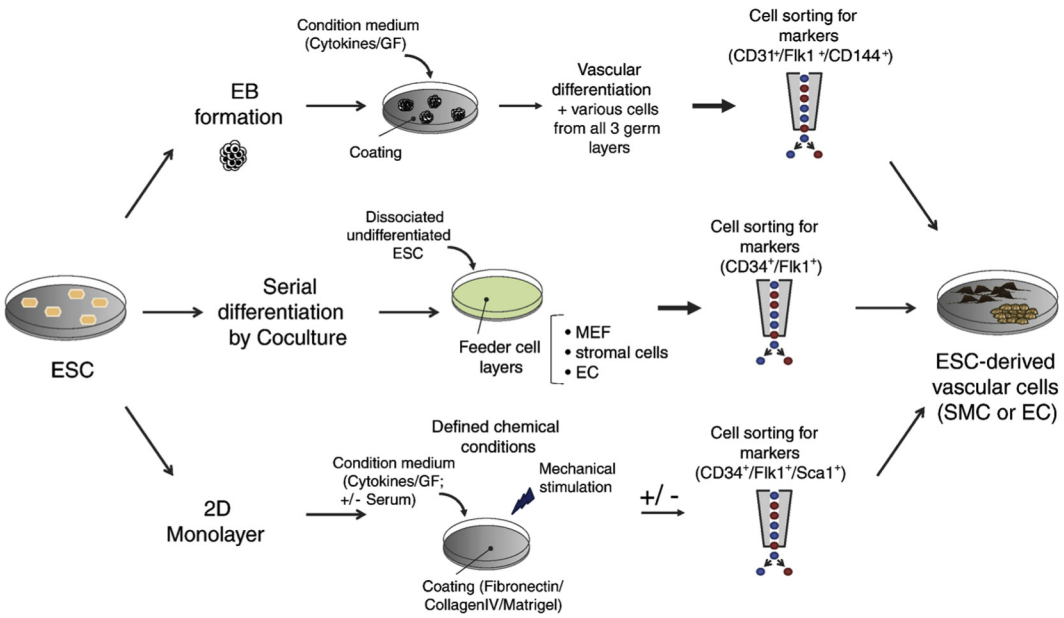

FIGURE 32.5

Approaches used for vascular differentiation of ESCs. Vascular cell differentiation is mainly induced by three culture methodologies: differentiation through EBs, co-culture with fibroblast feeder layers or target cells, and monolayer culture of ESCs in defined chemical conditions. *(Adapted from reference [95].)*

and mural cells and contributed to the vascular development. hESCs can also be differentiated into endothelial cells by using platelet endothelial cell adhesion molecule-1 antibodies [111]. *In vivo*, when transplanted into immunodeficient mice, these cells appeared to form microvessels.

Furthermore, it has been shown that monkey ESCs can give rise to endothelial cells when the embryonic cells were exposed to a medium containing combinations of growth factors. The isolated cells were able to form vascular-like networks when implanted *in vivo* [112]. Endothelial progenitor cells have been isolated from hES cells which presented hematopoietic [113] or smooth muscle cells competency. hESCs have been reported to differentiate into hematopoietic precursor cells when co-cultured with bone marrow and endothelial cell lines [114]. When these precursor cells are cultured on semisolid media with hematopoietic growth factors, they form characteristic myeloid, erythroid and megakaryocyte colonies.

Cardiomyocytes have been isolated from hES cells for the treatment of cardiac diseases. The most common approach to induce *in vitro* differentiation of hESC to cardiomyocytes is the formation of EB aggregates followed by few days post-plating on a 2D substrate to obtain cells with cardiomyocyte characteristics [115]. Cardiomyocyte differentiation of hESCs can be also induced by co-culturing undifferentiated hESCs with a mouse visceral endoderm-like cell line (END-2) [116]. Cardiomyocytes isolated from hES cells expressed sarcomeric marker proteins, chronotropic responses, and ion channel expression [116]. Upon differentiation, beating cells were observed after one week of culture under differentiation conditions. These increased in number over time, and could retain contractility for over 70 days [117]. The beating cells expressed markers characteristic of cardiomyocytes, such as cardiac α-myosin heavy chain, cardiac troponin I and T, atrial natriuretic factor, and cardiac transcription factors GATA-4, Nkx2.5, and MEF-2. Electrophysiology demonstrated that most cells resembled human fetal ventricular cells. Despite the progress made over the last decade, knowledge about the mechanism of the formation of functional cardiomyocytes from hESCs remains limited.

Insulin-producing β cells were also generated from hESCs [118], by spontaneous differentiation of hESCs in adherent or suspension culture conditions [119] and using media which contained growth factors [120,121]. Reverse transcription-polymerase chain reaction detected an enhanced expression of pancreatic genes in the different cells [120]. Immunofluorescence and *in situ* hybridization revealed high percentages of insulin-expressing cells [120].

Recently there has been great interest in examining the osteogenic potential of ESCs derived from both mice and humans. hESCs can differentiate into osteogenic cells with the same media supplements that are used to differentiate adult mesenchymal stem cells (MSCs). Due to their high self-renewal capability, ESCs are preferable to MSCs for bone regeneration, as the latter have limited abilities for self-renewal, proliferation, and differentiation into the osteogenic lineage [122]. Current issues associated with the osteogenic differentiation of hESCs include the formation of non-homogeneous cell populations and limited numbers of differentiated cells. To overcome these limitations, various growth factors and reagents such as β-glycerophosphate, ascorbic acid, dexamethasone, and osteogenic factors have been used to create osteoprogenitor cells from hESCs [123–126]. In addition, the differentiation efficiency of hESCs into a homogeneous osteogenic cell population was improved through co-culturing of hESCs with human primary bone-derived cells (hPBDs) in the absence of exogenous factors [127].

The osteogenic cells derived from hESCs (OC-hESCs) were seeded on a apatite-coated poly(D,L-lactic-co-glycolic acid)/nano-hydroxyapatite (PLGA/HA) composite scaffold and subcutaneously implanted in immunodeficient mice to examine *in vivo* bone formation [128]. The results of *in vivo* studies demonstrated that the implanted OC-hESCs and apatite-coated PLGA/HA scaffold induced the formation of large amounts of new bone tissue within the defect site, demonstrating the suitability of hESCs for bone regeneration [128]. Our group

showed that culturing hESCs without EBs leads to an over seven-fold increase in the number of osteogenic cells and to spontaneous bone nodule formation after 10–12 days [129]. In contrast, when hESCs were differentiated as EBs for five days followed by plating of single cells, bone nodules formed after four weeks only in the presence of dexamethasone.

We show that the cultivation of hESC-derived mesenchymal progenitors on three-dimensional osteoconductive scaffolds (derived from fully decellularized trabecular bone) in bioreactors with medium perfusion was shown to lead to the formation of large and compact bone constructs. Notably, the implantation of engineered bone in immunodeficient mice for eight weeks resulted in the maintenance and maturation of bone matrix, without a single incidence of the formation of the teratomas that were consistently observed when undifferentiated hESCs are implanted, alone or in bone scaffolds. This showed that tissue-engineering protocols can be successfully applied to hESC-progenitors to grow bone grafts for use in basic and translational studies [209].

In another study, native heart extracellular matrix (ECM) was successfully used to direct the cardiac differentiation of human embryonic stem cells (hESCs) *in vitro* [210]. A series of hydrogels was prepared from decellularized heart ECM blended with collagen type I at varying ratios. Maturation of cardiac function in EBs formed from hESCs was documented in terms of spontaneous contractile behavior and the mRNA and protein expression of cardiac markers. Hydrogel with high ECM content (75% ECM, 25% collagen, no supplemental soluble factors), increased the fraction of cells expressing cardiac marker troponin T (*c*TnT), when compared to either hydrogel with low ECM content (25% ECM, 75% collagen, no supplemental soluble factors), or collagen hydrogel (100% collagen, with supplemental soluble factors). The ability of native ECM to induce cardiac differentiation of hESCs without the addition of soluble factors makes it an attractive biomaterial system for basic studies of cardiac development and potentially for the delivery of therapeutic cells into the heart.

3D versus 2D cell culture systems

In an appropriate environment, ESCs can differentiate into complex 3D tissue structures. These environments are designed to resemble the key features of the hESC's niche and are favored over the 2D systems, which limit the cellular interactions and signaling, and hamper the subsequent differentiation of hESC into functional tissues [130,131]. The scaffold may act as a temporary ECM; providing physical cues for cell orientation, spreading, differentiation and the remodeling of tissue structures.

It has been demonstrated that the biochemistry, topography, and physical properties of the scaffold can regulate stem cell differentiation and function [131,132]. Culture of hESCs in PLGA scaffolds in specific media containing transforming growth factor β, activin A, or insulin-like growth factor induced the differentiation of the cells into 3D structures with characteristics of developing neural tissues, cartilage, or liver, respectively [133].

It was also demonstrated that the 3D environment created by cell encapsulation in Matrigel failed to support hESC growth and 3D organization, and this was likely due to the fact that this gel was unable to resist the force of cell contraction. Furthermore, when these cells were cultured in PLGA and poly(lactic acid) (PLA) scaffolds in the presence of media containing nerve growth factor and neurotrophin 3, enhanced numbers of neural structures were observed [134]. In one study, hESC-derived EBs cultured with a 3D collagen scaffold exhibited liver-specific genes expression and albumin production in the presence of exogenous growth factors and hormones [135]. The addition of signaling factors such as activin A and Wnt3a to this system may improve the efficiency of hESCs differentiation and production of functional hepatic endoderm [136].

Similarly, the culture of ESCs in a 3D collagen scaffold, stimulated with exogenous growth factors and hormones, led to the differentiation of the cells into hepatocyte-like cells. These

cells were characterized by the expression of liver-specific genes and synthesis of albumin, and the differentiation pattern observed compared favorably to cells differentiated in a 2D system. It was also reported that the differentiation of rhesus monkey ESCs in 3D collagen matrices was different from that which took place in monolayers [137]. Alginate scaffolds were also used for the differentiation of hESCs [138]. These scaffolds induced vasculogenesis in encapsulated cells to a larger extent than cells grown in bioreactors. Tantalum scaffolds also increased the differentiation of mESCs into hematopoietic cells as compared to traditional 2D cultures [139]. Therefore, the 3D culture systems can promote hESC differentiation and assembly into functional tissues, through better mimicking of the 3D structural organization of native tissue compared to 2D systems.

High-throughput assays for directing stem cell differentiation

Today, chemists and engineers are equipped with tools which give them the ability to synthesize molecules and test their effects on cells in a high-throughput manner. For example, libraries of small molecules, polymers and genes have been generated and used to screen candidate molecules to induce osteogenesis [140] and cardiomyogenesis [141] in ESCs as well as the dedifferentiation of committed cells [142]. The use of chemical compound libraries may provide a method of addressing the complexities associated with native microenvironments by directing cell behavior through interacting with transcription factors and cell fate regulators.

Microscale technologies can facilitate high-throughput experimentation and provide a powerful tool for screening whole libraries of molecules and biomaterials. Robotic spotters capable of dispensing and immobilizing nanoliters of material have been used to fabricate microarrays, where cell-matrix interactions can be tested and optimized in a high-throughput manner. For example, synthetic biomaterial arrays have been fabricated to test the interaction of stem cells with various extracellular signals [143]. Using this approach, thousands of polymeric materials were synthesized and their effects on differentiation of hESCs [144] and human mesenchymal stem cells (hMSC) [145] have been evaluated. These interactions have led to unexpected and novel cell-material interactions. Although the molecular mechanisms associated with the biological responses have yet to be clarified, such technology may be widely applicable in cell-microenvironment studies and in the identification of cues that induce desired cell responses.

Also, these materials could be used as templates for tissue-engineering scaffolds. Such an approach is a radical departure from traditional methods of developing new biomaterials, where polymers have been individually developed and tested for their effect on cells. In addition to analyzing synthetic material libraries, the effect of natural ECM molecules on cell fate can be evaluated in a high-throughput manner [143]. In one example, combinatorial matrices of various natural extracellular matrix proteins were tested for their ability to maintain the function of differentiated hepatocytes and to induce hepatic differentiation from murine ESCs [146]. Recently, Huang et al. used a micro-scale direct writing (MDW) technique to print ECM components (e.g., collagen IV, gelatin, and fibronectin) into diverse geometries and compositions on 2D surfaces for assessing the effect of ECM geometry and composition on ectodermal differentiation of murine ESCs [147]. It was shown that ECM compositions, soluble factors, and surface topography could regulate ESC attachment and differentiation [147].

Microfabrication techniques have been also used to control cell-cell interaction and to form hESC-derived EB aggregates with defined sizes and geometries. For example, in one study, soft lithography was used to fabricate cell-repellant poly(ethylene glycol) (PEG) microwells for the formation of EB aggregates with controlled sizes and shapes, determined by the geometry of the microwells (Fig. 32.6a). The EB cell aggregates formed within the microwells remained viable and maintained their geometries over at least 10 days of culture. Using this system, the EB aggregates could pattern into various shapes and sizes (Fig. 32.6b–d) [148]. To control the

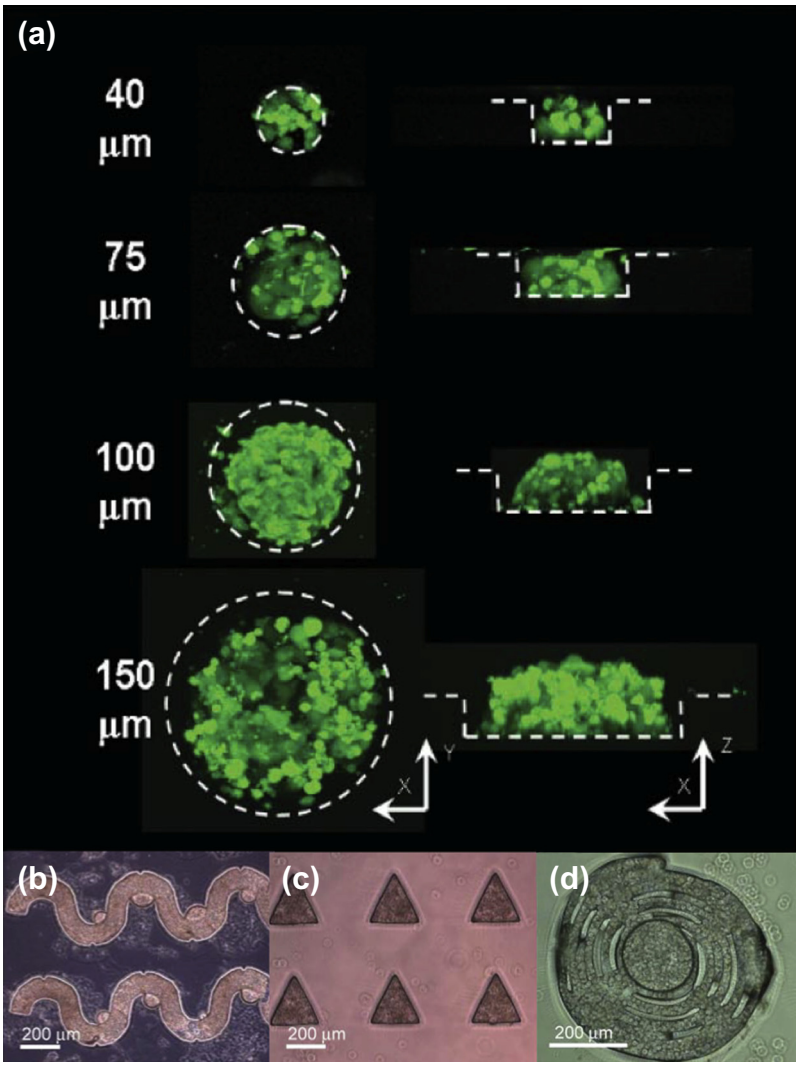

FIGURE 32.6
Microwells for the formation of EBs with controlled size and shape. (a) Confocal images of fluorescently labeled EB cell aggregates within microwells with different diameter raging from 40 μm to 150 μm on day 5 of culture; formation of EBs with different shapes including (b) curves, (c) triangles, and (d) swirls. *(Adapted from reference [148].)*

shape and direct the differentiation of EBs, RA-loaded PLGA microspheres were used to deliver morphogenic factors within EB microenvironments in a spatiotemporally controlled manner [149]. Homogenous differentiation of cystic spheroids with a bi-epithelial morphology was obtained when EBs were cultured on the fabricated microspheres [149].

In another study, the effect of EB aggregate size on its differentiation was investigated by seeding ESC on PEG microwells of various diameters [150]. It was found that larger microwells (450 μm diameter) induced differentiation of ESC to cardiogenesis through the expression of Wnt11. However, EBs formed in small (150 μm) microwells differentiated to endothelial cell by increased expression of Wnt5a [150].

Cell arrays have been also used to pattern stem cells on substrates. Arrays of cells can be used to localize and track individual cells, enabling the clonal analysis of stem cell fates. For example, clonal populations of neural stem cells were immobilized within microfabricated structures and their progeny were tracked using real-time microscopy, yielding information about cellular kinetics and cell fate decisions in a high-throughput manner [151]. Using this approach, it is possible to study the response of individual stem cells to various micro-environmental signals.

Cell patterning on geometrically defined shapes has been used to study the effects of cell shape on cell fate decisions. As cells adhere onto a micropatterned substrate, they align themselves to

the shape of the underlying adhesive region. A change in shape induces changes in the cell cytoskeletal features, which in turn influence cell apoptosis, proliferation [152] and differentiation [153]. Co-culturing ESCs with secondary cells can promote their differentiation into specific cell lines [154]. For this purpose, Fukuda et al. developed a technique to fabricate micropatterned co-cultures of ES with secondary cell lines on surfaces containing three different layers of hyaluronic acid, fibronectin, and collagen [155]. First, the hyaluronic acid was micropatterned on a glass substrate. Then, fibronectin was then deposited on the areas of exposed glass to create cell adhesive regions. After the cell attachment on fibronectin-coated areas, a layer of collagen was added to hyaluronic acid patterns to switch surface properties and facilitate the adhesion of the second cell type. Using this system, the patterned co-cultures of ECs with NIH-3T3 and AML12 cells could be obtained [155]. Further elucidation of the molecular mechanisms indicated that cell shape regulated the activation of the RhoA pathway demonstrating that mechanical stresses can be crucial for directing stem cells differentiation. Therefore, controlling cellular microenvironment using micropatterning may be used for directing cell fate for tissue-engineering applications.

Physical signals

Mechanical forces affect the differentiation and functional properties of many cell types, and are being increasingly used in tissue engineering. For example, functional autologous arteries have been cultured using pulsatile perfusion bioreactors [156]. Although it is known that mechanical stimuli (such as cyclic stretching and fluid shear stress) may be required to direct the differentiation of ESCs, understanding their effects is still in its infancy [157].

In one study, fluid shear stress was applied to induce Flk-1-positive ES differentiation into vascular endothelial cells through the activation of Flk-1. The expression of vascular endothelial cell-specific markers such as Flk-1, Flt-1, VE cadherin, and PECAM-1 enhanced in the presence of shear stress; however, shear stress had no effect on markers of epithelial or smooth muscle (keratin, or α-SMA) [157]. In another study, Shimizu et al. demonstrated that cyclic uniaxial stretching on Flk-1-positive ES cells for 24 hrs significantly increased the expression of VSMC markers α-SMA and smooth muscle-myosin heavy chain (SM-MHC), decreased the expression of EC marker Flk-1, and had no effect on the other EC markers (Flt-1, VE cadherin, and PECAM-1) [158]. Platelet-derived growth factor (PDGF) receptor beta kinase inhibitor blocked cell proliferation and VSMC marker expression that were induced by applying mechanical stimulation [158]. Mechanical stretching and fluid shear stress have been also used to direct ES cell differentiation into cardiovascular lineages [159,160]. Taken together, these studies demonstrate that mechanical stimulation can enhance the ability of ESCs to respond to exogenous signals, and promote their differentiation into a specific lineage. In one study, the hESC differentiation on deformable elastic substrates was inhibited by applying a 10% cyclic stretch [54]. The expression of Oct4 and SSEA-4 was promoted in the presence of mechanical stimulation, demonstrating an increase in hESC self-renewal. It was also found that mechanical stretch inhibited hESC differentiation when the cells were cultured in a mouse MEF-conditioned medium. However, differentiation of hESCs was not affected by mechanical stimulation when an unconditioned medium was used [54].

Other environmental factors that may be required include electrical signals. For example, it was found that electrical field stimulation could affect cardiac differentiation and reactive oxygen species (ROS) generation in hESC-derived EBs [161]. Hopefully, with time, such techniques will allow for the development of ESC-based tissue-engineering applications. The design of bioreactors that control the spatial and temporal signaling that induce ESC differentiation requires further collaborative efforts between engineers and biologists.

Microfluidic systems can be also used to investigate the effect of growth factor and chemical environments on stem cell differentiation in a high-throughput manner. For example, a microfluidic device was developed to generate a concentration gradient of growth factors for

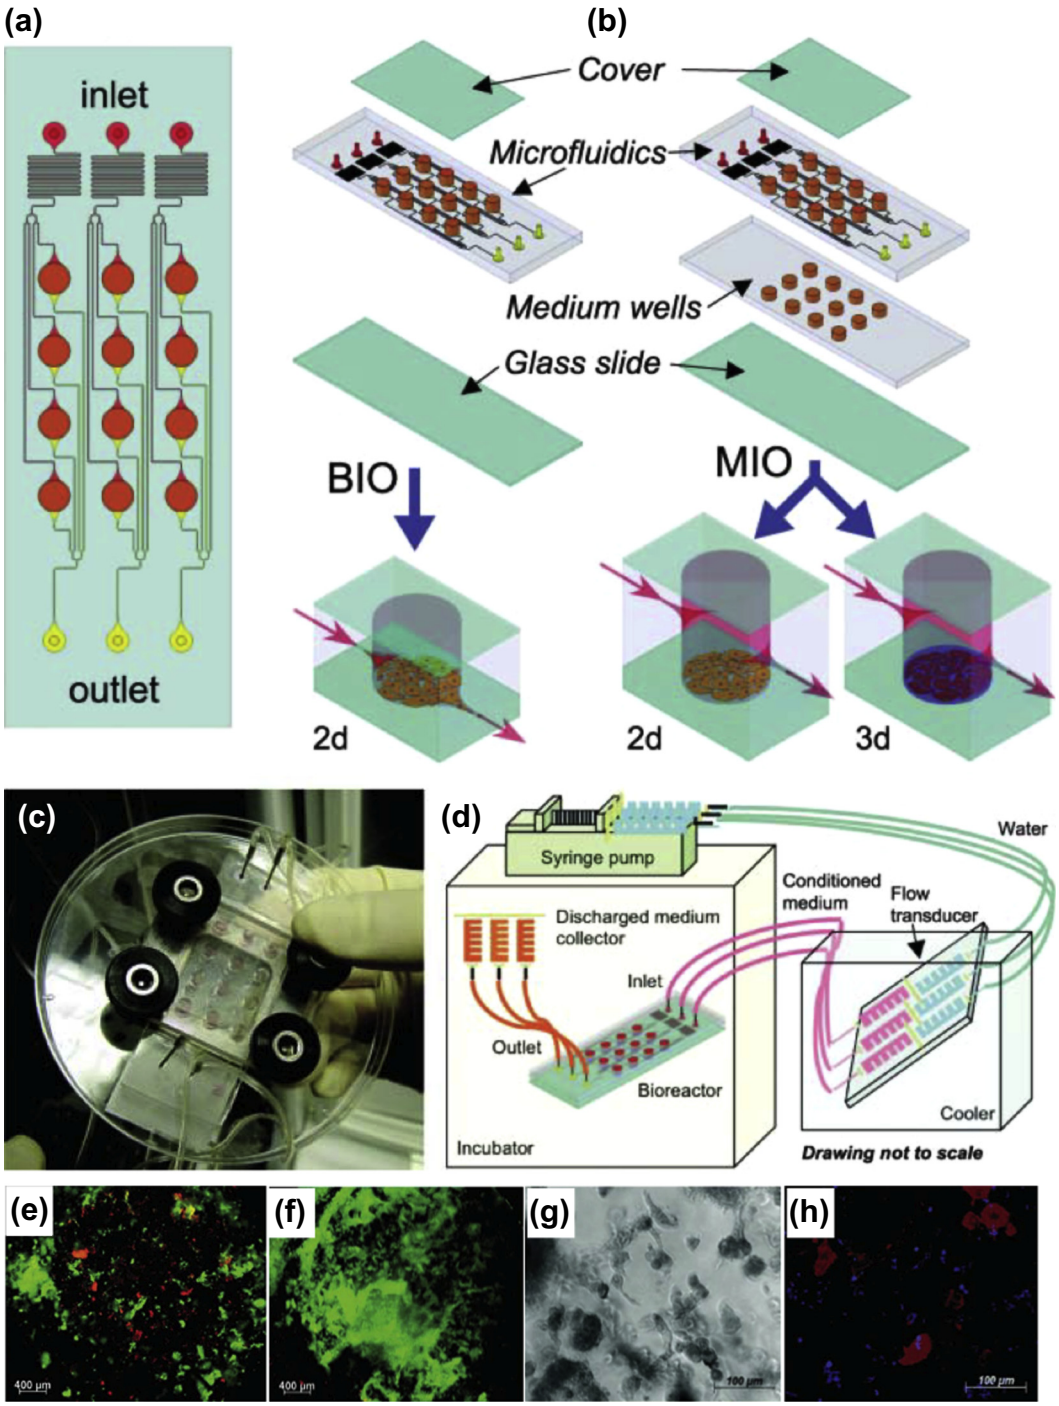

FIGURE 32.7

Microarray bioreactors. (a) The micro-bioreactor wells with 3.5 mm in diameter are arranged in an array. The medium (red) is delivered using three inlets through the flow transducers to four wells (orange) via microfluidic channels (100 mm wide) and waste medium removes from each bioreactor through a separate set of channels (yellow). (b) Two configurations were used: a bottom inlet/outlet (BIO) configuration, and a middle inlet/outlet (MIO) configuration (right) that allows for 3D cultivation. (c) Image of a single MBA with compression frame and fluidic connections. (d) Experimental setup. MBAs and medium collectors are placed in an incubator, and the medium reservoirs are maintained external to the incubator in an ice bath; (e—f) Representative images of hESCs on day 4 of culture (e) without and (f) with perfusion of culture medium (live cells are red and deal cells are green); (g) bright field image of differentiated hESCs, demonstrating that hVEGF addition to culture media resulted in hESC sprouting and elongation outside the colonies. (h) Confocal image of vascular differentiated hESC indicating the expression of a-SMA (shown in red). *(Adapted from reference [55].)*

optimizing the proliferation and differentiation of stem cells. The developed platform enabled rapid optimization of media compositions by exposing the cells to a continuous gradient of various growth factors within the microfluidic environment to induce proliferation and differentiation in a graded and proportional manner, depending on growth factor concentration [162]. In another study, micro-bioreactor arrays (MBAs) system composed of a microfluidic platform and an array of micro-bioreactors was designed to investigate the effect of culture microenvironments on hESCs differentiation both in 2D and 3D culture conditions [55,163] (Fig. 32.7a–d). Medium perfusion promoted the viability of encapsulated hESCs within hydrogels (67% viability in perfused culture compared to 55% in static culture) (Fig. 32.7e,f). In addition, using this system, it was possible to induce the vascular differentiation of hESCs through the addition of vascular growth factor (hVEGF) to the culture media [163] (Fig. 32.7g,h).

ISOLATION OF SPECIFIC PROGENITOR CELLS FROM ESCs

Although hESCs can generate specific functional cell types from all three germ layers, it is typically not possible to directly differentiate the cells in culture and obtain pure cell populations. Isolation of a specific differentiated population of cells for transplantation will eliminate the presence of undifferentiated hESCs which have tumorigenic potential, and allow for efficient use of the various cell populations for therapeutic purposes. With the exception of few cases where the enrichment of cells of interest was almost fully achieved [83,88,90], the protocols adopted for the differentiation of hESCs do not yield pure cell populations. Therefore, there is a need for suitable techniques to isolate desired cells from heterogeneous cell populations (Table 32.1). One approach for achieving this is to isolate specific cells by using cell surface markers and FACS. In this case, the initial population of cells is immunostained by a single or a combination of different markers, and the desired cell type is isolated by FACS. Part of the initial population of cells is also labeled with isotype controls to gate the populations. The use of FACS yields a pure population of cells, and allows one to select cells using different markers [113], but the limitations of this technique may hamper the final cell survival.

Magnetic immunoselection has been used very often to isolate specific differentiated cells [84,114,164]. Initially, the cells are labeled with relevant cell surface antibodies conjugated with magnetic beads. The magnetically labeled cells are then separated from the other ones by a magnetic column, to purities that are generally higher than 80% [164]. Although these purities are slightly lower than the ones obtained by FACS, the magnetic selection is less harmful to the cells than FACS. Recently, different surface markers specific for cardiomyocytes have been identified: Emilin2 [165] and later SIRPA [166,167] and VCAM [167,168]. These findings allow the prospective isolation of live cardiomyocytes, from ESCs or iPSCs-differentiated mixed cardiac population, with purities above 95%.

Another potential method for cell isolation is through reporter gene knock-in modifications [169]. For example, to trace hepatic-like cells during differentiation of hESCs in culture, a reporter gene expressed under the control of a liver-specific promoter was used [169]. For that purpose, hESCs underwent stable transfection with eGFP fused to the albumin minimal promoter sequence. This methodology allowed one to follow the differentiation pattern of hESCs into hepatic-like cells and to isolate those cells by FACS using the fluorescence of eGFP. Similarly, hESCs genetically manipulated to carry the Nkx2.5-eGFP reporter construct allow the isolation of cardiac cells [167]. Since Nkx2.5 is an early cardiac transcription factor, it allows the identification and isolation of early cardiac progenitors.

Isolation of a specific differentiated population of cells may also be accomplished by mechanical/enzymatic separation of cells exhibiting specific morphology, functional activity or adhesion to a substrate. For example, cardiomyocytes have been isolated by dissecting contracting areas in embryoid bodies and dissociating those areas using collagenase [170].

TABLE 32.1 Summary of methodologies to enrich specific lineages from hES cells

Cell type	Methodology followed to enrich specific lineages	Cell lines	Reference
Cardiomyocytes	Flow activated cell sorting	hES2	[165]
Cardiomyocytes	Flow activated cell sorting, Magnetic immunoselection	hES2, 3	[166]
Cardiomyocytes	Introduction of a reporter gene and cell selection by flow activated cell sorting	hES3Nkx2.5^{eGFP}	[167]
Cardiomyocytes	Flow activated cell sorting	KhES1	[168]
Cardiomyocytes	Flow activated cell sorting	cmESC, KhESC1, 2, 3	[171]
Cardiomyocytes	Flow activated cell sorting	hES2	[165]
Cardiomyocytes	Discontinuous percoll gradient	H1,H7,H9	[117]
Cardiomyocytes	Enzymatic and mechanical dissociation	N/A	[170]
Cardiomyocytes	Enzymatic dissociation	HES2	[116]
Hematopoietic progenitor cells	Magnetic immunoselection	H1, H1.1, H9.2	[114]
Hematopoietic progenitor cells	Flow activated cell sorting	H1, H9	[206]
Hematopoietic progenitor cells	Magnetic immunoselection	H1, H9	[164]
Leucocytes	Selective adhesion of cells	H1	[207]
Endothelial cells	Flow activated cell sorting	H9	[111]
Endothelial-like cells	Flow activated cell sorting	H1, H9	[113]
9 Ectoderm			
Neurons and glia	Magnetic immunoselection	H1, H7, H9	[84]
Neurons and glia	Enzymatic dissociation and selective adhesion of cells	H1, H9, H9.2	[85]
Oligodendrocytes	Selective adhesion of cells	H7	[208]
10 Endoderm			
Hepatocyte-like cells	Introduction of a reporter gene and cell selection by flow activated cell sorting	N/A	[169]

Oligodendroglial cells were isolated from stem cell aggregates that adhered to a specific substrate [90]. In addition, neuroepithelial cells were isolated from embryoid bodies attached to a tissue culture-treated flask by using dispase [85], an enzyme that selectively detached neuroepithelial islands from the embryoid bodies, leaving the surrounding cells adhering. It is also possible to take advantage of the cell body content of specific cell types. For example, cardiomyocytes have a higher mitochondrial density than their progenitors and other cardiovascular cells, such as smooth muscle and endothelial cells. It is thus possible to isolate cardiomyocytes by flow cytometric sorting using the mitochondrial dye tetramethylrhodamine methyl ester percholate without genetic modification or surface antigen staining [171].

TRANSPLANTATION

The first application of stem cells as a cellular replacement therapy is associated with bone marrow transplantation and blood transfusion in which donor hematopoietic stem cells repopulate the host's blood cells [172]. Today, modalities are being developed for cell-based therapies of numerous diseases, including diabetes, Parkinson's disease, spinal cord injury, liver failure, muscular dystrophy, bone and cardiovascular disease, among others. Despite the advances in the development of disease models [173], only a few studies have reported the *in vivo* functionality of hESC-derived cells. In most cases, the cells are injected into a disease area and their functionality is evaluated by immunohistochemistry and functional tests. Using such methods, partial functional recovery of a mouse model of Parkinson's disease after hESC-derived neural progenitor cells has been reported [88]. Also, transplantation of hESC-derived oligodendroglial progenitor cells into the *shiverer* model of dysmyelination resulted in myelin formation [174].

Studies of neural regeneration in animal models have given very promising results [175–177]. In particular, hESC-derived oligodendrocytes have been shown to repair injured spinal cord in animal models with rebuilding myelin sheets [178]. Based on this system, in 2010 Geron started the first clinical trial for the treatment of patients with spinal cord injury. In the same year, a clinical trial also started for the treatment of the Stargardt's macular dystrophy [179], a pathology characterized by the death of photoreceptor cells in the central part of the retina (called the macula). This trial was based on the promising observation that hESCs are able to differentiate into RPEs (retinal pigmented cells) [180].

A new important step towards the clinical application of hESCs for infarct therapy is the very recent finding that hESC-derived cardiomyocytes electrically couple and are protective against arrhythmias in the recipient heart when transplanted into guinea-pigs [181], an animal model with a much closer heart physiology to humans than that of rodents.

Despite the ability of stem cells to differentiate into cells with desired phenotypic and morphological properties, there has been very few scaffold-based tissue-engineering studies that use ESCs, by differentiating these cells in culture, selecting desired cell types and seeding these into scaffolds. Ideally, scaffolds provide cells with a suitable growth environment, facilitated transport of oxygen and nutrients, mechanical integrity and suitable degradation. The scaffold brings the cells into close proximity and thereby enhances the formation of tissue structures.

Tissue-engineering scaffolds are comprised of either synthetic or natural materials, or a composite of the two. Scaffolds are commonly made of synthetic materials such as hydroxyapatite, calcium carbonate, PLA, poly(glycolic acid) (PGA), PLGA, poly(propylene fumarate), and natural materials such as collagen, Matrigel or alginate. Natural materials typically have better biocompatibility, while synthetic materials provide better control of various properties such as degradation rate, biomechanics, and structure [7]. hESC-derived endothelial progenitors were seeded onto highly porous PLGA biodegradable polymer scaffolds to form blood vessels that appeared to merge with the host vasculature when implanted into immunodeficient mice. These endothelial progenitor cells were also able to support the formation of vascularized skeletal muscle [182]. Osteoblast-like cells derived from hESCs were also transplanted into an animal model by using a poly(D,L-lactide) scaffold. After 35 days, regions of mineralized tissue could be identified within the scaffold by Von Kossa staining and expression of human osteocalcin [123]. For cardiac tissue engineering, synthetic materials were used in the form of injectable hydrogels and surfaces that can be treated to get detached cardiomyocyte layers [183,184].

Transplantation and immune response

One of the major obstacles for successful transplantation of hESC-derived differentiated cells is their potential immunogeneity. As long-term immunosuppressive therapy would limit clinical applications, the creation of immunologic tolerance would enable stem cell-derived therapy. Methods currently under development include:

1) The establishment of hESC line banks large enough to represent the majority of tissue types;
2) Nuclear reprogramming of the cells to carry patient-specific nuclear genome (therapeutic cloning);
3) Creation of 'universal cells' by manipulating the major histocompatibility complex (MHC) [185];
4) Deletion of genes for immune response proteins using homologous recombination (as mentioned above); and
5) The generation of hematopoietic chimerism, to create the required tolerance for tissues or cells derived from it [186].

The latter method was demonstrated using rat embryonic-like stem cells that permanently engrafted when injected into full MHC mismatched rats [187].

Although the rejection of ESC-derived tissues is triggered by minor histocompatibility antigens, simple host conditioning with monoclonal antibodies against CD4 and CD8 could be sufficient to induce transplantation tolerance of ESC-derived donor tissue, but not of primary animal tissue [188]. It was recently observed that hESCs-derived mesenchymal progenitors have strong immunosuppressive properties resulting, similar to bone marrow mesenchymal stem cells, in inhibiting CD4+ or CD8+ lymphocyte proliferation and being more resistant to natural killer cells [189].

As an alternative to the novel approach of iPSC generation for autologous transplantation or disease-specific drug screening, therapeutic cloning or somatic cell nuclear transfer (SCNT), the process through which Dolly the sheep was cloned in 1997, might be an important tool to create hESCs from patient-specific genome, and thus preventing immunorejection [190] (Fig. 32.8).

This is important for the application of hESCs in tissue engineering, where transplantable populations of cells can be generated with genes that are derived only from the patient. Studies to date have demonstrated that cells derived by SCNT can be expanded in culture and will organize into tissue structures if transplantated with biodegradable scaffolds. However, before SCNT research can be translated into human therapies, the reliability of the overall process needs to be improved, including prevention of the alterations in gene expression.

Immunoisolation systems may help overcome the problems with the immunological incompatibility of the tissue. Thus, immunoisolation of cells may prove to be particularly useful in conjunction with ESCs to overcome the immunological barrier associated with the ESC-based therapies. Cells may be immobilized within semi-permeable polymeric matrices that provide a barrier to the immunological components of the host. Membranes can be designed to be permeable to nutrients and oxygen while providing a barrier to immune cells, antibodies and other components of the immune system, by adjusting the cutoff size of membrane pores [191,192]. Within these systems, the engineered tissues can either be implanted or used as extra-corporeal devices. Such closed tissue-engineering systems have been used for the treatment of diabetes [193–195], liver failure [196–198], and Parkinson's disease [199–202]. For example, ESC-derived β-cells that can respond to insulin or dopamine-producing neurons can be used in clinics without rejection. In addition, closed systems can protect the host against potentially tumorigenic cells.

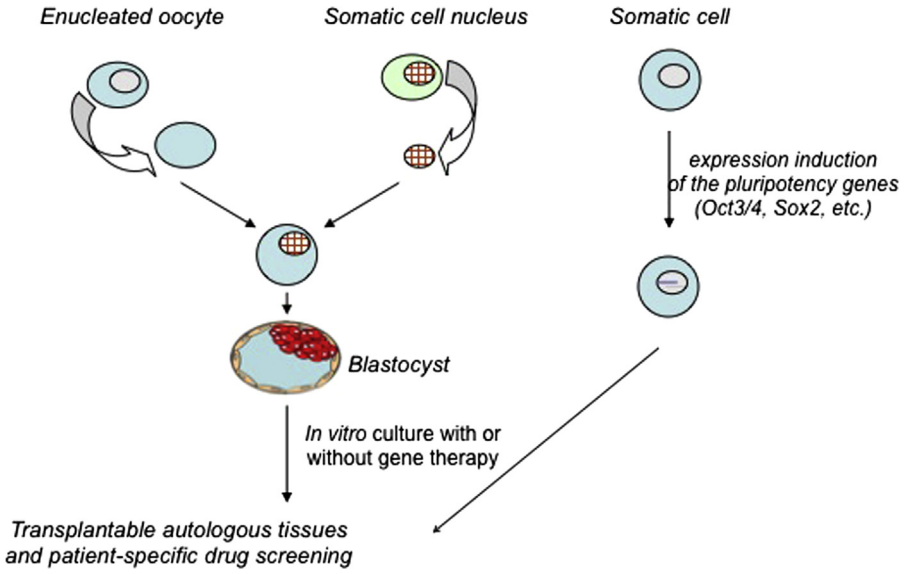

FIGURE 32.8
Schematic diagram of therapeutic cloning.
A somatic cell nucleus is transferred into enucleated oocyte to form a cell capable of giving rise to a blastocyst, which can be used to derive therapeutic cells. Alternatively, somatic cells are reprogrammed into iPS cells that can also be differentiated into therapeutic cells. In both cases, the resulting cells are used to engineer tissues for regenerative medicine and drug screening applications.

Currently, engineering and biological limitations such as material biocompatibility, molecular weight cutoff and immune system reaction to shed antigens by the transplanted cells are some of the challenges that prevent these systems from widespread clinical applications.

FUTURE PROSPECTS

Despite significant progress in the field of tissue engineering and ESC biology, there are a number of challenges that provide a barrier to the use of ESCs for tissue engineering. These challenges range from understanding cues that direct stem cell fate to engineering challenges on scale-up, to business questions of feasibility and pricing.

Although the derivation of hESCs from the ICM of preimplantation blastocysts has become a standard procedure and has been performed in a variety of laboratories, live human embryos must be destroyed in the process, which is ethically unacceptable. However, recent reports show that embryonic stem cells can be isolated without destroying blastocysts [203]. The generation and use of iPSCs require no embryo at all, overcoming the ethical issues associated with ESCs.

Since 2001, federal funding can be used for research using the existing 60 lines of embryonic stem cells, but not for the creation of new cell lines, even from surplus embryos normally discarded in fertility clinics. The existing federally approved lines are not adequate for human therapies, as they have been prepared using mouse cells and thus pose a risk of contamination. Major advancements since 2001 have established methods to culture hESCs without mouse feeder layers. It has recently been proposed that a common ground for pursuing hESC research may exist through assessing the death of a human embryo in the ethical context surrounding organ donation. Specifically, Landry and Zucker argue that a significant fraction of embryos generated for *in vitro* fertilization undergo irreversible arrest of cell division and thus can be considered as organismically dead, yet can still be used to harvest cells [204]. Donation of these embryos could ethically be considered analogous to the donation of essential organs from cadavers. Although criteria for determining the irreversible arrest of cell division have yet to be defined, it will certainly be interesting to see if these theories can be experimentally established and how these arguments will fare with those who currently oppose hESC research. In support of the therapeutic promises held by hESCs, in 2009 the limitations of the use of federal funding for research on hESCs have been reduced, encouraging research in this field.

Stem cells and their progeny reside in a dynamic environment during development, thus a scaffold should be designed to mimic the signaling and structural elements in the developing embryo. The use of 'smart' scaffolds that release particular factors and/or control the temporal expression of various molecules released from the polymer can help induce differentiation of ESC [205]. For example, by dual delivery of vascular endothelial growth factor (VEGF)-165 and PDGF, each with distinct kinetics, and from a single polymer scaffold, resulted in the formation of stable vascular networks [205]. An alternative approach to modifying the surface exposed to the cells is to immobilize desired ligands onto the scaffold. For example, RGD peptides, the adherent domain of fibronectin, can be incorporated into polymers to provide anchorage for adherent cells.

Another difficulty with the currently used materials is limited control over the spatial organization of the scaffold. Spatial patterning is necessary to create tissues that resemble the natural structure of biological tissues. In the direct cell patterning system, cells can be seeded into the scaffold at particular regions within the cells. For example, the direct attachment of two different cell types in different regions of the scaffold has been used to generate cells of the bladder. Cell patterning was critical for the effective co-culture of hepatocytes and fibroblasts.

CONCLUSIONS

A number of challenges are still ahead of us before ESC-based therapy can become clinically viable. These include directing the differentiation of ESCs (i.e., using controlled microenvironments or genetic engineering), ensuring their safety (i.e., by eliminating tumorogenicity), functionally integrating differentiated cells into the body, achieving long-term immune compatibility, and improving the cost and feasibility of cell-based therapies. Each of these challenges is currently being addressed. In particular, since ESCs can give rise to many different cell types, solving these challenges for the various possible tissue types will be a major undertaking. Further research is required to control and direct the differentiation of ESCs, in parallel with developing methods to generate tissues of various organs, to realize the ultimate goals of tissue engineering. We might be getting close to a day when ESCs can be manipulated in culture to produce fully differentiated cells that can be used to repair specific organs. Clearly, our ability to overcome these difficulties is not confined within any single scientific discipline but rather involves an interdisciplinary approach. Solving these challenges could lead improved quality of life for a variety of patients that could benefit from tissue-engineering approaches.

CHAPTER 33

Postnatal Stem Cells in Tissue Engineering

Pamela Gehron Robey[1] and Paolo Bianco[2]
[1] Craniofacial and Skeletal Diseases Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health, Department of Health and Human Services, Bethesda, Maryland
[2] Department of Molecular Medicine, Sapienza University of Rome, Rome, Italy

INTRODUCTION

In its first inception, tissue engineering was based on the use of natural or synthetic scaffolds seeded with organ-specific cells *ex vivo*. This approach was somewhat distinct from guided tissue regeneration, which utilized scaffolds and/or bioactive factors to encourage local cells to repair a defect *in situ*. These two approaches are now merged in the current field of tissue engineering, which encompasses multiple and diverse disciplines to use cells, biomaterials and bioactive factors in various combinations to restore and even improve tissue structure and function. Stem cell-based tissue engineering represents a major turn in the conceptual approach to reconstructing tissues. By expanding the repertoire of available cells, identifying potential targets, developing the technological means of generating functional tissues *ex vivo*, and above all, by making it possible (or promising) to engineer tissues that otherwise would not be amenable to recreation, advances in stem cell biology have a profound impact on tissue engineering at large.

In many cases, tissue engineering seems to have more use for postnatal stem cells than nature itself. This is especially apparent in the case of postnatal stem cells derived from tissues with low turnover, or no apparent turnover at all. If neural stem cells were able to repair the loss of dopaminergic neurons in the intact brain *in vivo*, there would be no Parkinson's disease for which to envision stem cell-based therapies. Dental pulp stem cells do not regenerate primary dentin *in vivo*, but vast numbers of cells can be made from the pulp of a single extracted tooth to generate copious amounts of new dentin. Current definitions of stem cells, in fact, include a technological dimension in many cases (a cell that can be expanded *ex vivo* and bent to the generation of differentiating cells). Importantly, the two neighboring fields of cell therapy (reconstruction of functional tissues *in vivo* using cells) and tissue engineering proper (reconstruction of functional tissues using cells and something else) merge significantly once a stem cell angle is adopted for either, not only with respect to the ultimate goals, but also to several biotechnological aspects.

The need for postnatal stem cells in tissue engineering

Given the fact that differentiated cells and their immediate progenitors can be used to successfully recreate a tissue in many instances, one may wonder why postnatal stem cells are such

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00033-1

an important ingredient in tissue engineering. The answer lies in the need for tissue turnover. Although not a tissue-engineering approach *per se*, bone marrow transplantation provides the best example for the requirement of postnatal stem cells for the restoration of tissue homeostasis. While lethally irradiated recipients may survive for short periods of time when transplanted with different populations of hematopoietic cells, even those containing hematopoietic progenitor cells, the recipient will succumb if the true hematopoietic stem cell (HSC) is not provided, due to the rapid turnover of blood [1]. This is also the case, not only for tissues with rapid rates of turnover such as in the skin and the gastrointestinal tract, but also in tissues with slower rates such as bone and muscle, and for tissues with very low rates, such as in the pancreas and kidney. In reconstructing organs and tissues, if the postnatal stem cell is consumed, the construct will ultimately fail. That is not to say, however, that tissue-engineering approaches using more mature cells populations for tissues with very low rates of turnover are not useful, but rather to highlight the need for recognition of tissue dynamics when devising cell-based tissue-engineering approaches.

THE RESERVOIRS OF POSTNATAL STEM CELLS

During development, the inner cell mass of the blastocyst undergoes gastrulation, and becomes specified into the three distinct germ layers; ectoderm, mesoderm and endoderm (Fig. 33.1). Each of these embryonic germ layers contain fetal stem cells that become more and

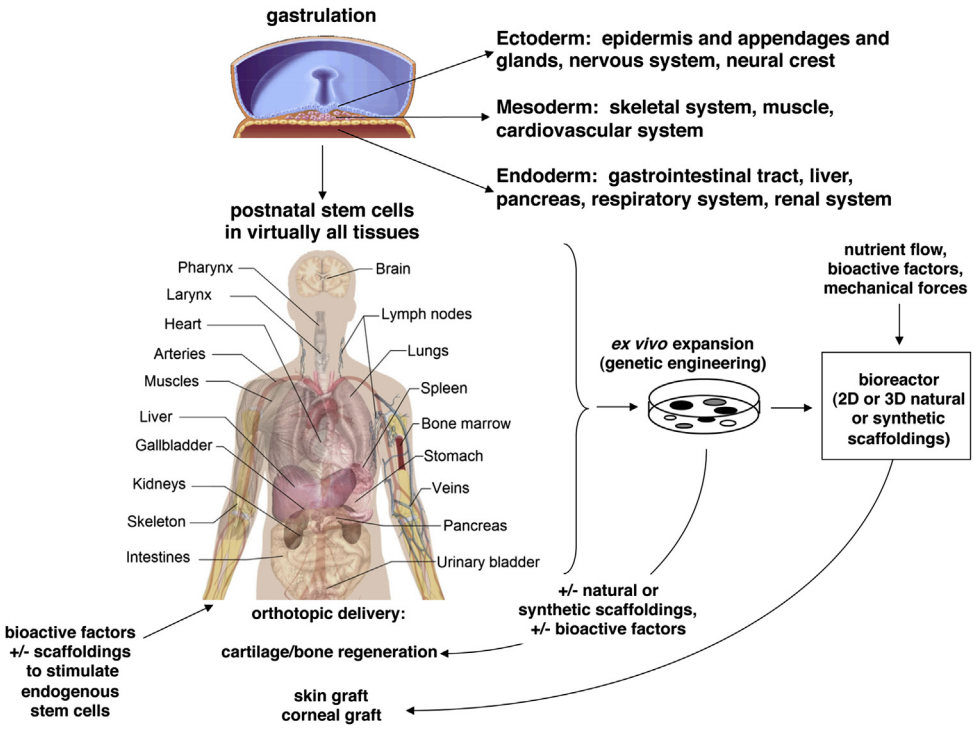

FIGURE 33.1

Current applications of postnatal stem cells in tissue engineering. During gastrulation, the three embryonic germ layers are formed that give rise to organ and tissue-specific stem cells. Virtually all tissues in the postnatal body have cells with some regenerative capabilities that can be potentially utilized in tissue engineering. For approaches other than hematopoietic cell transplantation, cell populations need to be expanded *in vitro* to obtain sufficient numbers of cells, and are delivered orthotopically in various combinations with bioactive factors and scaffolds. Generation of 3D structures *ex vivo* prior to transplantation requires the use of bioreactors in which cells are seeded onto scaffoldings and subjected to nutrient flow, bioactive factors and mechanical forces to induce formation of functional tissue for transplantation. In the future, it may be possible to stimulate endogenous local stem cells to repair damaged tissue, perhaps in combination of growth factors and scaffolds to guide regeneration.

more specified as embryonic development progresses. Even beyond embryonic development, it is now evident that virtually every tissue contains some kind of a postnatal stem/progenitor cell. How these tissue-specific stem/progenitors are maintained, or whether they are established *de novo*, in the postnatal organism, is not well understood at this time [2]. Clearly, however, an understanding of the developmental process of tissue specification is an essential point in devising tissue-engineering approaches.

Current approaches to stem cell-based tissue engineering rely primarily on the use of postnatal stem cells (Fig. 33.1), although new approaches utilizing pluripotent stem cells [human induced pluripotent stem cells (iPSCs)] may offer an alternative if hurdles such as genetic stability and strict differentiation can be overcome. First identified in constantly (and rapidly) self-renewing tissues such as blood (mesoderm origin), skin (ectoderm origin) and the gastrointestinal tract (endoderm origin), the repertoire of postnatal stem cells has expanded to include perhaps every single tissue in the body (Fig. 33.1), regardless of its rate of tissue turnover or ability to regenerate (reviewed in reference [3]). Not all of these tissue-specific postnatal stem cells, however, are equally accessible for safe harvest, or available in sufficient quantity (or amenable for *ex vivo* expansion) to generate the number of cells needed for tissue regeneration. However, lessons on the dynamics of tissue homeostasis (growth and turnover) that can be learned from these cells have an obvious impact on the design of future tissue-engineering strategies nonetheless. In addition, mechanisms whereby postnatal cells maintain differentiated functions in tissues and organs are relevant to future pluripotent stem cell-based approaches, and can only be learned from postnatal cells [4].

Mesodermally-derived postnatal stem cells

BONE MARROW — A SOURCE OF MULTIPLE POSTNATAL STEM CELLS

It has long been known that bone marrow is the home of at least two different types of stem cells, the HSC (reviewed in reference [5]), and the skeletal stem cell (SSC, also known as the bone marrow stromal stem cell, or 'mesenchymal' stem cell, ([reviewed in references [6] and [7])); each able to reconstitute the hematopoietic and skeletal system, respectively. AC133 (CD133) positive endothelial progenitors are also a marrow component [8], although they are somewhat different from endothelial precursors of non-marrow origins [9] (Fig. 33.2).

TRANSDIFFERENTIATION — A THING OF THE PAST

It was initially thought that bone marrow cells (either hematopoietic or non-hematopoietic) could differentiate into other cells types, based on studies that infused these cells systemically.

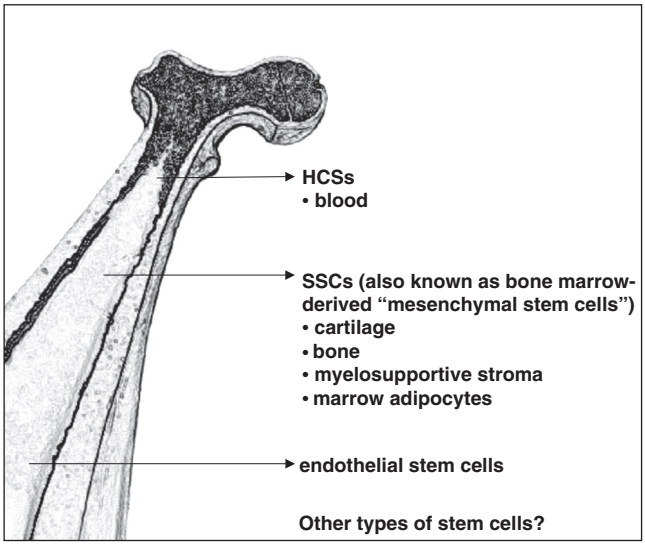

FIGURE 33.2
Bone marrow as a central source of postnatal stem cells. Bone marrow consists of at least two well defined populations of postnatal stem cells, the hematopoietic stem cell (HSC) and the skeletal stem cell (SSC), both of which form numerous phenotypes within their cellular system, but may also form cells outside of them. Endothelial precursors ($AC133^{+}$) have been identified, although they may differ from endothelial precursors from non-marrow sources. The presence of three different types of stem cells place bone marrow high on the list of tissues that are easily accessible and able to be harvested in sufficient quantity for use in tissue engineering.

Circulating, marrow-derived cells contributed to the regeneration of skeletal muscle in response to injury [10], and in mouse models of muscular dystrophy [11,12]. Donor-derived cells have also been detected in neuronal tissue, newly formed vasculature, in the kidney, and even in the oral cavity following bone marrow or mobilized peripheral blood transplantation (reviewed in reference [13]). The vast majority of these studies relied on the expression of a few markers, and did not convincing demonstrate functionality of the 'transdifferentiated' cells [4]. In some cases, formation of a differentiated cell of donor origin could be attributed to cell fusion with endogenous cells [14], which is a natural process that occurs in some tissues such as in the liver and in muscle. Nonetheless, bone marrow is a unique source for two of the most commonly used postnatal stem cells: the hematopoietic stem cell (discussed elsewhere in this volume) and the bone marrow stromal (skeletal) stem cell (described in more detail below).

STROMAL STEM/PROGENITOR CELLS (ALSO KNOWN AS 'MESENCHYMAL STEM CELLS')

The first concept of a stromal stem/progenitor cell emerged from the work of Friedenstein and Owen, based on the inherent skeletal properties of bone marrow stromal cells (BMSCs) and their subpopulation of stem cells, and was limited to the skeletal system. Upon *in vivo* transplantation with an appropriate scaffold in an open system, the progeny of a single cell, the Colony Forming Unit-Fibroblast (CFU-F), formed bone, hematopoiesis-supportive stroma and marrow adipocytes, and formed cartilage when transplanted in closed systems, or in cell pellet cultures *in vitro* (reviewed in reference [15]). Based on their mesodermal origin (except for in the facial bones, which derive from neural crest), it was later envisioned that BMSCs would not only regenerate skeletal cell types, but also other mesodermal derivatives such as muscle, tendon, ligament, etc., through the so-called 'mesengenic process'. This was originally modeled on BMSCs, which were then renamed 'mesenchymal stem cells' (MSCs) [16]. However, during development, there is no common mesodermal (or mesenchymal) cell even for bone formation [17], let alone for tendon, muscle, or other connective tissues. Nonetheless, reports emerged suggesting that BMSCs have the ability to differentiate into skeletal muscle, cardiomyoctes, tendons, etc. (reviewed in reference [18]), but usually needing extensive chemical modification of culture conditions, expression of a limited number of markers of the differentiated phenotype, and less than rigorous assays demonstrating their functionality [19].

In attempts to identify markers that could effectively isolate these multipotent bone marrow-derived 'MSCs', their cell surface was intensively investigated. Subsequently, BMSCs were described as being CD29, CD44, CD71, CD90, CD106, CD120a, CD124 positive (and Stro-1 positive in freshly isolated cells) (reviewed in reference [19]). However, none of these markers are specific for BMSCs, or for the SSC subset within the BMSC population. The majority of these markers are expressed by many connective tissue cell populations, whether or not they have been determined to contain a subset of stem cells by rigorous criteria (the ability of the progeny of a single cell to reform a tissue and to self-renew). Furthermore, it is well known that the pattern of expression of many of these markers change, depending on the culture conditions and length of time in culture [19].

Because of the lack of specificity of these markers, studies rapidly appeared describing the isolation of 'MSCs' from a long list of non-skeletal tissues. In addition, it became a mainstay to compare the differentiation potential of these non-skeletal 'MSCs' to that of BMSCs by using *in vitro* differentiation osteogenic, adipogenic and chondrogenic assays and expression of mRNAs representative of differentiated cell types [20], instead of by appropriate *in vivo* transplantation assays (e.g., as in reference [21]). However, current *in vitro* assays cannot be used to reliably predict the inherent osteogenic and adipogenic potential of a cell population, and chondrogenic differentiation is often not convincing [19]. In an attempt to clarify the nature of 'MSCs', a 'recommendation' was made that the name 'mesenchymal stromal cell' be used (due to the lack of convincing data of stemness in many cases) for cells that are: 1) adherent in

culture, 2) express CD105, CD73 and CD90, but lack expression of CD45, CD34, CD14, CD11b, CD79a and HLA-DR markers, and 3) able to differentiate into osteoblastic, adipogenic and chondrogenic cells *in vitro* [22]. Unfortunately, due to the widespread use (and abuse) of this definition, this recommendation has done little to clarify the nature of connective tissue stem/progenitor cells, to the extent that it is now commonly thought that 'MSCs' are ubiquitous [23], and are equivalent in their differentiation properties [24], in spite of the lack of rigorous analyses. In essence, the over-emphasis on these artificial assays has overshadowed efforts to reveal the inherent differentiation potential of non-skeletal connective tissue stem/progenitor cells.

In addition, based on the intense search for stem cell sources that would avoid the ethical and biological issues (use of allogeneic cells) associated with hESCs, the idea became prevalent that BMSCs (and other 'MSCs') are pluripotent [25,26]. This new twist emerged from early studies that aimed to treat generalized disorders of the skeleton and other mesodermal tissues by systemic infusion or direct orthotopic injection of BMSCs. What followed were suggestions that 'MSCs' were able to 'transdifferentiate' into cell types outside of the mesodermal lineage, such as neuronal cell types, hepatocytes, insulin-producing cells, etc. (reviewed in references [18,27]). However, it is now recognized that 'transdifferentiation' of BMSCs and other postnatal stromal cells is a rare event, if it occurs at all [19]. Furthermore, it is becoming increasing clear that 'MSCs' are tissue specific. Upon *in vivo* transplantation, BMSCs from bone support the formation of a hematopoietic marrow [21], whereas dental pulp 'MSCs' form dentin and a pulp-like complex, and do not support the formation of a hematopoietic marrow [28]. Yet while the notion of transdifferentiation outside of a specific lineage is no longer considered to be scientifically sound, numerous papers continue to be published suggesting the use of cells from one type of tissue to form another (e.g., adipose-derived stromal cells to form bone [29]). This is not to be confused with current efforts in directed reprogramming (e.g., skin fibroblasts into chondrocytes [30]), whereby cells are partially reprogrammed through the introduction of certain transcription factors, but without going back to a completely pluripotent state. Clearly, there is an urgent need for rigorous assessment of the differentiation capacities of different populations of postnatal connective tissue stem/progenitor cells, in order for tissue engineering efforts to progress into a clinical reality.

PERICYTES

The identity of local connective tissue stem/progenitors has long been sought, but the lack of specific markers of a stem/progenitor cell in any connective tissue has made this a challenging task. However, recent studies suggest that pericytes, cells located on the extravascular surface of blood vessels, may be the source of tissue-specific connective tissue stem/progenitors that emerge through what might be a common developmental process [19]. As an example, during development of bone marrow, blood vessels gain access to what will become the medullary cavity by invading through a layer of committed osteogenic cells [31]. Due to the association of the osteogenic cells with endothelial cells, they change not only their morphology, but also cease to synthesize and deposit bone matrix, and proliferate along with the developing blood vessel. These formerly osteogenic cells, now pericytic cells, further proliferate to establish the bone marrow stroma upon which hematopoiesis occurs [32]. It has been demonstrated that CD146 (Muc18/MCAM) is a useful marker for isolating pericytes from bone marrow [33]. Prospective sorting for $CD45^{-}/CD31^{-}/CD146^{+}$ cells isolated all of the CFU-Fs in bone marrow, a subset (1:5) of which were found to be multipotent by *in vivo* transplantation. Of note, these cells were positive for all of the other markers that have been associated with 'MSCs', making them connective tissue cells, but of a different flavor: $CD146^{+}$ pericytes [33]. Studies in other connective tissues have also alluded to the pericytic nature of the local/stem progenitor cell, such as in dental pulp and in adipose tissue based on Stro1 and CD146 expression [34,35], and in muscle based on alkaline phosphatase and CD146 expression [36]. Subsequently, it was speculated that 'MSCs' from all tissues are pericytes [24,37]. However, it is

yet to be determined in a systematic fashion if, indeed, all pericytes are the source of local stem/progenitor cells in all connective tissues. The developmental origin of pericytes varies from tissue to tissue, and their biology is complex and not well understood to date [38,39]. In support of the idea that pericytes are committed to a particular lineage, it can be noted that transcriptome analysis of 'MSCs' isolated from different tissues do in fact display their inherent differentiation preference; e.g., undifferentiated BMSCs express low levels of osteogenic transcription factors and bone matrix proteins [40], and undifferentiated adipose-derived stromal cells express low levels of adipogenic transcription factors [41].

Ectodermally-derived postnatal stem cells

Embryonic ectoderm gives rise to the dermis and its appendages (hair follicles, mammary glands and other types of subcutaneous glands), to the nervous system, and to neural crest cells that contribute to the development of multiple tissues (Fig. 34.2). There are numerous examples of the isolation and characterization of postnatal stem cells derived from all of these. In particular, the epidermis has long been known to contain a stem cell within the basal layer of the epidermis, and also within the bulge region of hair follicles (reviewed in reference [42]). As discussed below, these and other ectodermally-derived postnatal stem cells, in particular, limbal stem cells, are under intensive investigation for their potential use in tissue engineering. Other ectodermally-derived tissues, such as mammary gland and the nervous system, are well known to contain stem cells (reviewed in references [43,44], respectively), as discussed elsewhere in this volume.

Endodermally-derived postnatal stem cells

The gastrointestinal tract, and all derivatives thereof, including the liver and prancreas, the respiratory system, and the renal system are derived from embryonic endoderm (Fig. 33.1). More specific discussions of these types of stem cells and their use in tissue engineering are included elsewhere in this volume, but the reader is referred to recent review articles for more information on intestinal stem cells [45], liver stem cells [46,47], potential pancreatic stem cells an area that is hotly debated [48], lung stem cell [49] and renal stem cells [50].

CURRENT APPROACHES TO TISSUE ENGINEERING USING POSTNATAL STEM CELLS

Approaches for the regeneration of functional tissue using non-hematopoietic postnatal stem cells can be envisioned by three different scenarios:

A) Expansion of a population *ex vivo* prior to transplantation into the host (with or without an appropriate carrier);
B) Recreation of a tissue or organ *ex vivo* for transplantation;
C) Design of substances and/or devices for *in vivo* activation of stem cells, either local or distant, to induce appropriate tissue repair (Fig. 33.1).

In all of these cases, considerable knowledge of the stem cell population's dynamics is required in order to predict and control their activity under a variety of different circumstances.

Ex vivo culture of postnatal stem cells

Ex vivo expansion of tissue or organ-specific postnatal cells, used either alone or added to carriers and scaffoldings or with growth factors, at the time of transplantation has been the primary approach in tissue engineering to date. However, *ex vivo* expansion in a fashion that maintains an appropriate proportion of stem cells within the population is a significant hurdle that must be overcome. For example, in spite of enormous efforts, the culture conditions for maintaining HSCs (let alone expanding their number) are as yet undefined. It is perhaps for this very reason that currently there are only a handful of examples in which *ex vivo* expanded

postnatal stem cells are used successfully to restore structure and function (e.g., for skin and corneal regeneration). The key to successful expansion will lie in understanding cell proliferation kinetics (asymmetric versus symmetric division) [51,52]. The efficacy achieved by the use of *ex vivo* expanded populations, whether stem or more committed in character, may also depend, at least in part, on the nature of the tissue under reconstruction. As mentioned above, the rate of tissue turnover most likely defines the rate of success.

While optimizing culture conditions represents one hurdle, the issues of time and quantities represent others. In most cases, the amount of time required to generate the number of cells sufficient to repair defects induced by trauma or disease is in the order of weeks. In cases of trauma, this poses a large problem if the use of autologous stem cells is considered. There are numerous studies aimed at increasing the proliferation rate of various populations of postnatal stem cells; however, it is as yet unclear if this is in fact beneficial or desirable. The use of various cocktails and growth factors may indeed speed up the *ex vivo* expansion process, but may change the nature of the cell population by depleting the stem cells within it, or by altering the populations' biological activities. For example, basic FGF has been used to increase the proliferative capacity of BMSCs [53], but upon *in vivo* transplantation, cells grown with FGF-2 failed to support the formation of marrow (the home of the SSC [40]), which is where the SSC resides, indicating that the SSC had been lost. For these reasons, the use of allogeneic populations that could be used 'off the shelf' from unrelated donors would be preferable, but raises the same issue of rejection as in organ transplantation. Although it has been suggested that some postnatal stem cells appear to escape from immune surveillance in allogeneic settings and are immunomodulatory (BMSCs, as an example [54]), definitive proof is lacking. Furthermore, differentiation of stem cells imposes the expression of a mature tissue-specific phenotype, including a complete histocompatibility profile [55]. Use of allogeneic cells would most likely require concomitant immunosuppressive therapy, which has its own list of side effects. Co-transplantation of allogeneic bone marrow to reconstitute the hematopoietic system has been proposed as a way of inducing tolerance [56]. Studies in organ transplantation in conjunction with bone marrow or mobilized blood transplantation after immune ablation indicate a substantial improvement in long-term survival. In this type of approach, allogeneic cells could be better envisioned, provided that a single donor would be the source of cells for the tissue to be restored, along with the immune system.

Delivery of stem cells

As important as it is to control the *ex vivo* behavior of the cell population, consideration of how they will be delivered, and most importantly, how they will be integrated into the recipient in a functional fashion is of paramount importance. What the response of exogenous cells with or without scaffolds will be to the host environment, and vice versa, is not always predictable. In cases utilizing cells in association with scaffolds, integration relies on the rapid establishment of host-derived vascular and neuronal networks for viability, and cues must be provided. The host, in turn, must provide the signals that will dictate the differentiation if progenitor (not fully committed) populations are utilized. Furthermore, the recipient host tissue must also support the maintenance of the stem cell's niche, if not the creation of it *de novo*.

Systemic infusion and injection

Delivery of bone marrow or mobilized blood by systemic infusion for restoration of the hematopoietic system by HSCs is clearly an example of the efficacy of this method of delivery, but it is currently the only one. The success of systemic infusion is based on the fact that in terms of physical structure, blood is a simple, fluid entity. Furthermore, it is the physiological nature of blood cells to circulate through all parts of the body (and of HSCs as well under certain circumstances). Although systemic infusion of non-hematopoietic cells has been attempted for the delivery of cells to sites of injury, most adherent populations of cells lack the

cell surface characteristics needed for them to escape into extravascular spaces (reviewed in reference [57]), and the vast majority of the cells are trapped in the lungs and disappear very rapidly [58]. While it is thought that systemically infused non-hematopoietic cells 'home' or are 'recruited' to sites of injury, definitive proof of physiological signaling is lacking. The appearance of small numbers of cells at such sites is most likely due to vascular compromise, and it has been shown that these cells do not persist. Even upon direct injection into injured tissues, few cells of donor origin can be found after extended periods of time. Consequently, the reconstruction of two or three-dimensional structures requires different approaches, as discussed below.

CARRIERS AND SCAFFOLDS

Due to the solid state of tissues other than blood, transplantation of non-hematopoietic postnatal stem cells requires some form of support, whether it be for injection of cells (a semi-solid carrier to temporarily hold them in place and prevent their loss to the circulation), or for transplantation of constructs of cells with scaffolds (generally a solid structure of particular shape). Natural or synthetic, carriers and scaffolds must be biocompatable, bioresorbable and non-immunogenic. Furthermore, they must also be instructive, and dictate appropriate cell growth and differentiation, and support the recapitulation of a stem cell niche, which is essential for tissue renewal upon transplantation. The most commonly used natural scaffolds include either individual purified extracellular matrix (ECM) proteins such as collagen, fibronectin and laminin (or peptides derived from them), or devitalized ECM from skin, submucosa of the small intestine, urinary bladder and others, and these can be autologous, allogeneic or even xenogeneic. Such devitalized ECMs contain not only the structural proteins (which also have other important biological activities) that define the three-dimensional organization of the tissue, but also the local repertoire of growth factors that are stored within them (reviewed in reference [59]). Various chemical and non-chemical treatments have been applied to ECMs and their components in attempts to modify their biomechanical and immunological properties upon transplantation, but these have resulted in less than desirable effects due to inactivation of their conducive and inductive properties, and inhibition of their resorption and replacement. If left unmodified, ECMs generally promote infiltration and proliferation of cells and differentiation *in vitro* and *in vivo*, and are ultimately turned over upon transplantation (reviewed in reference [59]). New approaches include the use of recombinant human proteins that can be fabricated into scaffolds without the potential introduction of infectious agents, and with various combinations of proteins suited for a particular application [60].

Synthetic scaffolds are designed not only to mimic the biological properties of ECMs, but also to have enhanced material properties appropriate for a particular tissue. Polyglycolic acids, polyhyroxyalkonates and hydrogels are the most common examples, and all can be manipulated to form a broad range of structures with varying degrees of porosity and rigidity [61,62]. Synthetic scaffolds can also be functionalized [63], to include morphogenetic and growth factors, or even naked plasmid DNA to transduce in-growing cells to produce these important factors, such that they can become as instructive as ECMs [64,65].

RECONSTRUCTION OF SURFACE (2D) TISSUES

While more complicated than bone marrow transplantation, recreation of two-dimensional tissues is a relatively straightforward task in tissue engineering, although not routine to date. This is based not only on the relatively simple structures of surface tissues, but also on the fact that, generally speaking, surface tissues (e.g., skin) exhibit a high rate of turnover, thus making it easier to replace damaged tissue with applied exogenous cells. Reconstruction of surface tissues relies not only on appropriate *ex vivo* expansion conditions, but also on selection of appropriate scaffolds. As such, epithelial grafts (e.g., skin and cornea) are currently the only successful stem cell-based applications, other than bone marrow transplantation, and also provide an example of the impact of postnatal stem cell biology on the success of cell-based

tissue reconstruction. The use of *ex vivo* expanded keratinocytes for the generation of skin grafts was first brought to a clinical setting by the pioneering work of Green and coworkers [66], but persistent engraftment was not routine. It is now recognized that both the expansion culture conditions in which the cells are grown and also the scaffolding upon which they are placed, must support self-renewal of epidermal stem cells (cells that give rise to holoclones as opposed to transiently amplifying meroclones or more differentiated paraclones) [67]. Expansion of keratinocyte populations on fibrin substrates was found to maintain the stem cell population and to improve long-term maintenance of skin grafts [68]. Currently, there are a number of commercially available products, some of which incorporate dermal fibroblasts in a collagen gel, which is then layered with *ex vivo* expanded epidermal cells [69]. They provide coverage of severe wounds and are maintained while the recipient generates new skin. The standard starting material for establishing epidermal cultures is skin, however, there is evidence that in certain circumstances, a stem cell located in the bulge region of the root sheet of hair follicles has the ability to form not only new follicles and sebaceous glands, but also interfollicular epidermis (reviewed in reference [70]). These cells, which can be obtained non-invasively, are highly proliferative, and have been used to treat leg ulcers [71], and not surprisingly, to regenerate hair [72], albeit only in mice to date.

There have been a number of studies and a small clinical trials to molecularly engineer autologous epidermal stem cells to correct gene defects causing a form of severe blistering (junctional epidermolysis bullosa) prior to generation of skin grafts (reviewed in references [73,74]), and there is a current trial using a similar approach to treat dystrophic epidermolysis bullosa underway (clinicaltrials.gov # NCT01263379). But beyond generation of skin grafts and the treatment of genetic skin disease, perhaps the most significant success story in cell-based tissue engineering is seen in the use of stem cells from the limbus of the sclera for corneal epithelium regeneration. Limbal stem cells have been expanded in culture on fibrin substrates to generate sheets of epithelial cells that are able to reconstitute a damaged corneal surface with dramatic beneficial clinical results [75].

RECONSTRUCTION OF THREE-DIMENSIONAL TISSUES

Reconstruction of tissues with more complicated (and large) 3D structures than surface tissues presents a far more difficult challenge. In cases of large segmental defects treated with cell/scaffold constructs, there is a need for the rapid establishment of vasculature to meet nutrient demands, and also for neuronal networks in many cases. Furthermore, due to the generally slow turnover of complicated 3D tissues, replacement of existing damaged or diseased tissue by an exogenous cell/carrier application imposes an additional challenge. But again, selection of appropriate carriers and scaffolds for complex 3D structures is of utmost importance for ultimate success.

Using the skeletal system as an example, numerous pre-clinical studies in a variety of animal models have demonstrated that BMSCs, when used in conjunction with appropriate carriers, regenerate new bone in critical sized defects that would never heal without intervention (reviewed in references [76,77]). A wide variety of carriers were tested, ranging from collagen sponges, synthetic biodegradable polymers to synthetic hydroxyapatite derivatives (reviewed in reference [78]). To date, ceramic-based scaffolds appear to be superior to others, although there is no optimal scaffold to date [79]. A carrier that provides immediate stability, especially in the case of weight bearing bones, and yet be completely resorbed as new bone is formed and remodeled, has yet to be fabricated. Nonetheless, a small number of patients were treated with *ex vivo* expanded BMSCs in conjunction with hydroxyapatite/tricalcium phosphate ceramic particles with good outcome [80], and numerous clinical studies are in progress (see clinicaltrials.gov). In addition to healing segmental defects, BMSCs were also used to construct vascularized bone flaps. In cases where morbidity of the recipient site is an issue, it can be envisioned that a new bone rudiment could be grown elsewhere in the body and then transferred, with vasculature intact [81], as was attempted in the reconstruction of the mandible [82].

With respect to treatment of cartilage defects, appropriate scaffold selection presents different challenges. Suitable carriers must allow for chondrogenic differentiation of postnatal stem/progenitor cells capable of forming cartilage (BMSCs and periosteal-derived cells), and prevent vascular invasion while providing a conduit for nutrient flow. Furthermore, they must provide the appropriate microenvironment to maintain the cartilage phenotype and prevent hypertrophy. Natural polymeric gels such as hyaluronic acid, collagen, alginate and chitosan provide an adequate three-dimensional structure to maintain the chondrocyte phenotype, but are not well modeled into specific shapes and have very poor biomechanical properties. For these reasons, synthetic biodegradable polymers such as polylactic acid and polyglycolic acid, and mixtures of both, that can be crosslinked and molded to form porous three-dimensional structures are thought to provide more adequate scaffolding, and have been used to construct cartilage in with predefined shapes (reviewed in references [83–85]). In designing constructs of stem cells and scaffolds, the differences between the elastic cartilages of the ear and nose and articular cartilage must also be considered to ensure that tissues form with the appropriate biomechanical characteristics.

EX VIVO TISSUE/ORGAN RECONSTRUCTION

The creation of tissues and even organs prior to transplantation is a rapidly expanding area of research (as discussed elsewhere in this volume). This approach relies on expanding cell populations on, or in, either natural or synthetic scaffolds in some form of a bioreactor. The initial designs primarily provided nutrient flow through the developing tissue. However, many tissues grown under these circumstances fail to achieve the biomechanical properties required for tissue function *in vivo*. For example, the construction of blood vessels using a variety of biomaterials and cell populations using culture perfusion yields structures that histologically resemble native blood vessels. Yet when transplanted, these constructs failed due to their inability to withstand changes in pressure. A substantial improvement in such constructs was achieved by subjecting the developing tissues to pulsatile flow conditions (reviewed in reference [86]). Perfusion type bioreactors support the growth of tissue with only a nominal number of cell layers and are amenable for construction of relatively simple structures. Construction of larger, more complex, three-dimensional structures requires the development of even better bioreactors that will support cell survival to achieve a significant cell mass (reviewed in references [87,88]). Another critical aspect of using large constructs is the development of supporting vasculature. While constructs can be placed in vascular beds in some cases, it will be essential to design constructs that rapidly induce vascularization, perhaps by including the angiogenic factors, such as Vascular Endothelial Growth Factor (VEGF), or cells that produce it, or even by including endothelial cells and their precursors, which tend to assemble themselves into primitive tubular structures that may allow for more rapid establishment of organ perfusion (reviewed in references [89,90]).

Activation of local and distant endogenous stem cells

While the *ex vivo* reconstruction of entire organs that are functional is the goal the bioengineering world, what perhaps is even more challenging is the goal of inducing endogenous stem cells to become activated to reconstruct a tissue. Most tissues in the body display at least some sort of regenerative capability [91,92], but in many cases this remains insufficient to mount a spontaneous and successful repair response *in vivo*. The application of exogenous growth factors, cytokines and morphogens or their induction by genetic means, perhaps in combination with appropriate scaffolds, might be envisioned to 'encourage' local stem/progenitors to regenerate a functional tissue. In all cases, a regulated morphogenetic process is needed to establish normal structure and function. Definition of the intrinsic properties of regenerative cells and extrinsic signals that may trigger a recapitulation of developmental processes is critical.

LOCAL CELLS

Based on the reasoning that following an injury, signals that normally activate a local cell to initiate repair would be either obliterated or not of a high enough magnitude, numerous studies have attempted to provide appropriate morphogenetic and growth factors. However, this approach has been uniformly disappointing, most likely due to the short half-life of such soluble factors, and lack of an appropriate scaffolding. Scaffolding provides not only a template for the organized outgrowth of local cells, but also provides a substrate upon which to stabilize and/or orient factors (or parts thereof) for appropriate presentation to a cell (reviewed in references [93,94]). However, in using 'smart' constructs, tissue regeneration of large defects may not be complete due to exhaustion of the local stem cell population, hence the need to maintain a stem cell niche during the activation of local stem/progenitor cell populations. Furthermore, some clues about the negative impact of local constraints upon the native, albeit incomplete, repair capacity of cells and tissues may be found in studies of spinal cord regeneration. Following injury, there is phase characterized by neurite outgrowth from the severed end, however, this is short-lived due to the production of inhibitory factors by cells within the myelin sheath, and gliosis impedes neurite outgrowth (reviewed in references [95,96]). Thus, regeneration by endogenous cells must not only take into consideration bioactive factors and scaffolding that are necessary to maintain the in-growing population with the appropriate balance of stem cells, transiently amplifying cells and differentiating cells, but also the inactivation of local inhibitory factors that work against the process.

MOBILIZATION AND RECRUITMENT OF DISTANT STEM CELLS

Cytokine administration has become a well-established procedure for mobilization of HSCs into peripheral blood for the purposes of hematopoietic cell transplantation. Such mobilization is based on not only a complex series of events that liberates the HSC from its niche in bone marrow, but also on the inherent ability of HSCs to escape into and to survive in the circulation (reviewed in references [97,98]). However, it is not clear that other postnatal stem cell populations present in marrow or any other tissue are equally amenable to liberation by current procedures. It has been reported that bone marrow-derived endothelial precursors are liberated into the circulation following a number of different stimuli induced by trauma [99], however, it is unclear to date if they actually participate in neovascularization [9], and in fact, prevailing evidence suggests that they do not [100]. Likewise, there are numerous reports of stromal-like cells being present in the circulation, although their numbers are vanishingly small in humans [101,102]. Many reports also suggest that their numbers are increased in different pathologies, injury or after stimulation with various factors, and that these cells originate from bone marrow (i.e., that they are BMSCs) (reviewed in reference [103]). However, based on our current inability to do lineage tracing studies with a BMSC-specific promoter, the origin of these cells is not known. Furthermore, the question of whether these stromal-like cells play a significant role in repair of distant tissues is highly controversial. Lack of convincing evidence of mobilization of non-hematopoietic cells most likely rests in the facts that:

1) Without *ex vivo* manipulation, they lack the features that enable their escape into the circulation,
2) They appear to have limited ability to persist in the circulation due to their unanchored state and/or their entrapment in the lungs (and also the spleen and kidneys), and
3) They are unable to escape from the circulation except in the case of vascular defects, and even then, their numbers are limited.

Whether or not procedures can be developed that will overcome these hurdles is a major question.

CONCLUSIONS

The recent advances in pluripotent and postnatal stem cell biology have most certainly captured the public's attention, and have raised expectations for miraculous cures in the near future. While certain applications that utilize postnatal stem cells are in practice or will be shortly, the majority are in their infancy and will take much more effort. However, the current sense of urgency in translating recent findings into clinical applications should not lead this field to repeat the mistakes experienced in the field of gene therapy. The development of tissue engineering as a viable medical practice must proceed in an evidence-based fashion in all of the associated disciplines that are involved, and several hurdles are yet to be overcome. First, our current understanding of postnatal stem cell biology is rudimentary, at best. The manner in which we isolate stem cells and manipulate them and their progeny appropriately relies heavily on a clear understanding of cell population kinetics. This also requires a complete understanding of their response not only to bioactive factors, scaffoldings and delivery systems, but also to the host microenvironment in which they must survive and function. Secondly, more efficient bioreactors that adequately model the microenvironment and also allow for scale-up of the tissue-engineering process must be developed. Thirdly, in order to translate what we learn into clinical application, development of appropriate pre-clinical models to prove the principle that postnatal stem cells do indeed have a positive biological impact is absolutely essential. In analyzing these models, stringent criteria must be defined to determine efficacy, and we must remain principled in assessing them. Exciting times, yes, but also a time for due diligence to bring what started off as a scientific curiosity into medical reality.

Gene Therapy

This page intentionally left blank

CHAPTER 34

Gene Therapy

Stefan Worgall [1,2] and Ronald G. Crystal [2]
[1] Department of Pediatrics and Department of Genetic Medicine, Weill Medical College of Cornell University, New York, New York
[2] Department of Genetic Medicine, Weil Medical College of cornell University, New York, New York

Gene therapy uses the transfer of genetic information to modify a phenotype for therapeutic purposes [1]. The application of gene transfer to tissue engineering has a myriad of possibilities, including the transient or permanent genetic modification of the engineered tissue to produce proteins for internal, local or systemic use, helping to protect the engineered tissue and providing stimuli for the engineered tissue to grow and/or differentiate. To provide a background for the application of gene transfer to tissue engineering, this chapter will review the general strategies of gene therapy, detail the gene transfer vectors used to achieve these goals, and discuss the strategies being used to improve gene transfer by modifying the vectors to provide cell-specific targeting and by regulating the expression of the targeted gene. Applications which combine gene therapy and stem cell therapy will be reviewed. Our overall goal is to provide a state-of-the-art review of the technology of gene therapy, including the challenges to making gene therapy for tissue engineering a reality. For details regarding the applications of gene therapy to specific organs and clinical disorders, several reviews are available [1–10].

STRATEGIES OF GENE THERAPY

The basic concept of gene therapy is to transfer nucleic acid, usually in the form of DNA (or RNA in retrovirus and lentivirus vectors) to target cells. The vector with its gene cargo can be administered *ex vivo*, where the gene is transferred to the cells of interest in the laboratory and the genetically modified cells restored to the patient, or *in vivo*, when the nucleic acid is administered directly to the individual (Fig. 34.1). Independent of the overall strategy, an

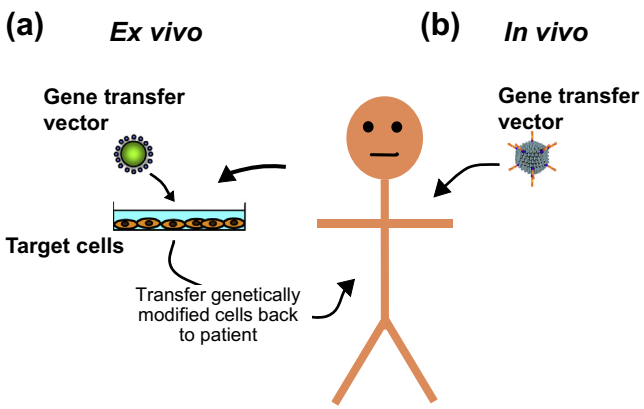

FIGURE 34.1
General strategies for gene therapy for tissue engineering. (a) *Ex vivo* strategies use a gene transfer vector to genetically modify autologous target cells (e.g., skin fibroblasts) *in vitro*, followed by transfer of the genetically modified cells back to the patient. (b) *In vivo* strategies transfer the therapeutic gene by direct administration of a gene transfer vector to the patient.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00034-3

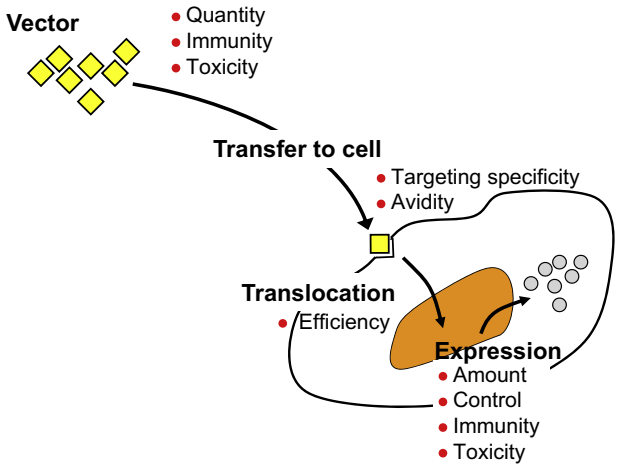

FIGURE 34.2
Issues relating to successful gene transfer. In addition to the choice of vector, successful gene transfer requires decisions regarding the quantity of vector to be used, and that the vector does not induce immunity and/or toxicity that will limit its use. The vector has to be transferred to the cell, a relatively easy task for *ex vivo* strategies, but *in vivo* may require enhancing targeting specificity and vector avidity to its receptor. Once reaching the target cells, the vector must insure its gene cargo is efficiently translocated to the nucleus. In the nucleus, the gene must be expressed in appropriate amounts, with control if necessary, and without appreciable immunity and/or toxicity induced by the gene product.

expression cassette containing the genetic sequences to be delivered, typically a cDNA along with regulatory sequences to control expression, is inserted into a 'vector', a non-viral or viral package used to improve efficiency and specificity of the gene transfer. Together, the choice of vector, the design of the expression cassette and the coding sequences of the gene determine the pharmacokinetics of the resulting gene expression.

Simple in concept, gene transfer is complex in execution. In addition to choosing an *ex vivo* or *in vivo* strategy, the major issues relating to successful gene therapy are the design of vector, how the vector is delivered to the cell population of interest, translocating the vector/expression cassette from outside the cell to the nucleus, and the expression of the gene to obtain the desired therapeutic effect (Fig. 34.2). Independent of the choice and design of the gene transfer vector, successful gene therapy requires decisions regarding the quantity of vector required to modify the numbers of target cells necessary to obtain the desired therapeutic effect, and consideration of whether or not the vector will evoke a host immune response and/or cause unacceptable toxicity. The gene therapist must also decide how to get the vector to the target cells, including targeting specificity and avidity of the vector for its relevant receptor. Once the vector reaches the cells of interest, the gene cargo within the vector must be translocated from outside of the cell to within the nucleus. In designing the gene transfer strategy, it is critical to decide whether or not the gene is to be inserted into the chromosomal DNA of the target cells. Finally, the transferred gene must be expressed, with the concomitant issues of amount and control of expression, and host immunity and toxicity that may be evoked by the expression of the gene. In the sections that follow, we will discuss all of these issues.

EX VIVO VS. *IN VIVO* GENE THERAPY

There are generally two strategies by which gene therapy technology can be used for genetic engineering; *ex vivo* transfer of genetic material with subsequent transfer of the modified cells or tissue to the host, and *in vivo* transfer, with direct administration of the gene therapy vectors to the patient (Fig. 34.1).

Ex vivo

The *ex vivo* strategy has the advantage that the cell population can be purified and carefully defined, and the transfer of the gene is limited to that cell population and not to other cells or tissues. The challenge for this approach is that, for most applications, once returned to the patient, the genetically modified cells need to have a selective advantage to modulate the therapeutic goal. For applications where long-term expression of the gene is required and

the transferred cells subsequently replicate within the patient, the vectors used to transfer the gene must mediate the integration of the gene, so that it persists when the cell divides [1,9].

The *ex vivo* strategy typically is used to genetically modify hematopoietic cells, such as CD34+ cells derived from bone marrow, or skin fibroblasts [4,9]. Examples of *ex vivo* gene transfer strategies include the correction of hereditary immunodeficiencies with retroviral vectors, transfer of the factor VIII gene to autologous fibroblasts to treat hemophilia A, and transfer of suicide genes to T cells to control graft vs. host disease and some leukodystrophies [11,12,14–16,27]. The *ex vivo* strategy is also the most suitable strategy to use gene transfer to genetically modify stem cells. The recent advances in induced pluripotent stem cell (iPSC) technology, where reprogramming genes are transferred to somatic cells *ex vivo* to generate embryonic or adult stem cells, broadens the *ex vivo* gene therapy approach to the promising but yet unchartered territory of iPSC therapy for human disease [17,18]. For tissue engineering applications, the *ex vivo* strategy is applicable to providing genes to enhance and/or modulate the growth of the engineered tissue, as well as to protect the engineered tissue from host responses or disease processes.

Although *ex vivo* gene therapy can be carried out using cells derived from a non-autologous source, potential immune rejection of non-matched cells generally requires that autologous or closely matched donor cells be used for the tissue-engineering strategy. However, the immune system can potentially recognize components of the vector and/or transferred gene product. For *ex vivo* strategies in general, immune recognition of the gene therapy vector is minimal, as the immune system will not be in contact with the total dose of gene therapy vector used to transfer the gene *in vitro*, but only the residue of the vector within the cells to be transferred. There is the possibility of immune recognition via MHC presentation of viral antigens inducing anti-vector immunity, and this may be responsible for shutdown of gene expression over time.

In vivo

In vivo gene transfer strategies administer the gene therapy vector either directly to the target organ or deliver it via the vascular system into vessels feeding that organ. *In vivo* gene transfer has an advantage over *ex vivo* strategies in that it avoids the cumbersome (and costly) process of removing cells from the patient, manipulating the cells *in vitro*, and returning the genetically modified cells to the patient. Challenges that need to be overcome for *in vivo* gene transfer strategies include the induction of immunity by the gene transfer vector, transport of the gene therapy vector to the targeted cells/organ, efficient binding of the vector to the cell, translocation of the genetic material to the nucleus, and toxicity and immunity induced by expression of virus and/or transgene peptides.

The retina has so far been an ideal target for the *in vivo* gene therapy approach because:

1) It is in a confined, relatively small space;
2) The gene therapy vector can be administered directly;
3) Vectors with natural tropism for retinal cells are available; and
4) It is immunoprivileged.

The *in vivo* gene therapy approach has recently achieved a significant success by achieving correction of the genetic disease Leber's congenital amaurosis [19,20].

CHROMOSOMAL VS. EXTRA-CHROMOSOMAL PLACEMENT OF THE TRANSFERRED GENE

One critical decision in strategizing gene therapy is whether the transferred gene is to be inserted into the chromosomal DNA of the targeted cells or is designed to function in an extra-chromosomal location within the nucleus. There are advantages and disadvantages to both strategies, and the choice is determined by the specific aim of the gene transfer.

As described below, some gene transfer vectors (e.g., retroviruses, lentiviruses) insert their genome, and hence the transferred gene, directly into the chromosomal DNA of the target cells. This has the advantage that it is permanent, and when the genetically modified cells divide, both daughter cells have the newly transferred sequences, as they are now part of the genome of the genetically modified cell population. This is a desirable feature for applications where persistent gene expression is required, such as for the correction of a hereditary disorder. The disadvantage is that, once inserted, the gene cannot be removed, and thus unless controls are designed into the transferred sequences, it cannot be shut down. Equally important is the issue of the randomness of where the gene is inserted. If the gene is inserted into a relatively 'silent' region of the genome, the resulting gene expression will be low, while gene expression from other regions will be high [21]. This genome regional modulation of the level of gene expression will be different for each targeted cell. While there are some more favored regions of gene insertion for given vector characteristics, the genetically modified cells essentially become a mixed population in terms of where the gene has been inserted. Thus, expression may be low for some cells, while other cells may be average or high expressors. More troubling, if the gene is inserted into a region influencing cell proliferation, the result may be uncontrolled cell growth, i.e., malignancy. This phenomenon, referred to as 'insertional mutagenesis', has been observed in experimental animal and human applications of gene transfer [21]. Several strategies have evolved out of these observations to improve the safety of integrating gene therapy vectors [22–26].

Some vectors (e.g., non-viral, adenoviruses, adeno-associated viruses) transfer the gene into the nucleus, but mostly into an extra-chromosomal location, where the gene is transcribed using the same transcriptional machinery as for genomic DNA [1,10]. The consequence of this strategy is that as long as the cells do not proliferate, and as long as host defenses do not recognize the genetically modified cell as foreign, expression of the transferred gene will persist. However, if the cell divides, the transferred gene will not be replicated, and gene expression in the daughter cells will eventually wane as proliferation continues. The consequences are transient expression of the gene, a 'pharmacokinetic' result that is ideal for some applications (e.g., angiogenesis, most cancer therapies), but not desirable for applications requiring persistent expression (e.g., correction of a genetic disease). Independent of the issue of persistence of gene expression, extra-chromosomal placement of the gene has the advantage that insertional mutagenesis and variability of gene expression secondary to variability of chromosomal insertion are not of concern.

GENE TRANSFER VECTORS

There are two general classes of commonly used vectors for gene therapy: non-viral and viral (Fig. 34.3, Table 34.1). Although a variety of vectors have been developed in both classes, the most commonly used non-viral vectors are naked plasmids and plasmids combined with liposomes, and the commonly used viral vectors are adenoviruses, adeno-associated viruses, retroviruses and lentiviruses [1,5,6,8,10,27].

Independent of the vector used, all carry an expression cassette which includes the gene to be transferred together with the relevant regulatory sequences to control the expression of the gene once it has been transferred to the target cells (Fig. 34.3a). The typical expression cassette includes (5′ to 3′) a promoter, an intron (this is not critical, but it usually enhances gene expression and enables identification of the cytoplasmic mature mRNA from the pre-mRNA and transferred expression cassette), the transgene itself (usually in the form of a cDNA, but it can contain one or more introns, or can be the generic form of the gene), and finally the polyA/stop and other 3′ regulatory sequences, if desired. In special cases, such as *trans*-splicing (discussed in the section on regulation of expression), the expression cassette may contain only a fragment of the gene together with sequences to direct splicing into an endogenous nuclear pre-mRNA.

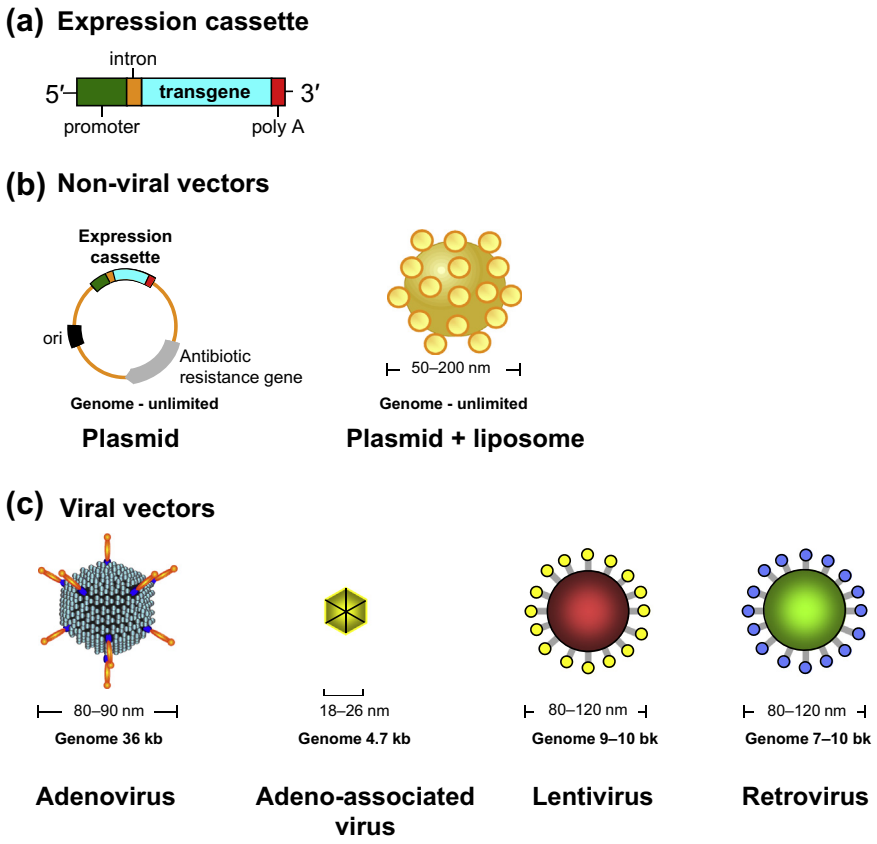

FIGURE 34.3
Commonly used gene therapy vectors. (a) All gene transfer vectors contain an expression cassette with (5′ to 3′) a promoter, usually an intron, the transgene and a polyA site/stop signal. (b) Commonly used non-viral vectors, including naked plasmids (typically comprised of an origin of replication, the expression cassette and antibiotic resistance gene), or plasmid combined with a liposome. The plasmid genome can be unlimited in size, but usually the expression cassette is <10 kb; the liposome/plasmid combination ranges from 50 to 200 nm in diameter. (c) Commonly used viral vectors, including adenovirus, adeno-associate virus, lentivirus, and retrovirus. Shown is the size of the genome of each viral vector, as well as the relative size of each vector. The size of the expression cassette depends on how much of the viral genome is included.

Non-viral vectors

The most simple gene transfer vectors are plasmids. To achieve relevant transduction of cells *in vivo*, the plasmids are usually combined with liposomes to facilitate attachment and entry into target cells [28–30]. A variety of physical methods have also been developed to promote entry of plasmids into target cells, including microinjection, hydrodynamic administration, electroporation, ultrasound and ballistic delivery (the so-called 'gene gun') [28]. Most of these physical methods of gene delivery are not applicable for *in vivo* gene transfer due to the inaccessibility of the target cells for direct manipulation.

Plasmids contain a relatively simple expression cassette, with the transgene driven by a promoter and flanked by an intron and the polyadenylation/stop site (Fig. 34.3a). Plasmid DNA has an unlimited size capacity; however, because plasmids >10 kb are potentially unstable during production, most gene transfer strategies being considered for human applications use plasmids <10 kb. Although plasmids can efficiently transduce cells *in vitro*, their efficiency *in vivo* is limited. There have been may attempts to correct hereditary disorders with plasmid gene transfer alone, but with little evidence of expression of the plasmid-directed mRNA in those trials [31,32]. Part of the reason of the inefficiency of plasmid-mediated gene transfer is that plasmids have no means of directing their traffic to the nucleus [29,30]. For gene transfer applications for tissue engineering, the most that can be envisioned for the use of plasmid-based systems is to use them in an *ex vivo* approach with possible need for selection of the transduced cells.

Adenovirus

Adenoviruses are non-enveloped viruses containing a linear, double stranded DNA genome of 36 kb. Among the 49 different Ad strains that infect humans, the subgroup C, serotype 5 and

TABLE 34.1 Characteristics of most commonly used gene transfer vectors

Vector type	Maximum expression cassette capacity (kb)	Transfers genes to non-dividing cells	Anti-vector immunogenicity	Chromosomal integration	Expression	Other characteristics
Plasmids / liposomes	< 10[1]	Yes	None	No	Transient	Poor transduction efficiency
Adenovirus	7–8[2]	Yes	High	No	Transient	Typically, mediates expression for 1 to 3 wk
Adeno-associated virus	4.5	Yes	Low	No[3]	Persistent in non-dividing cell populations	Expression usually takes 1 to 3 wk to be initiated
Retrovirus	8	No	None	Yes	Persistent	Risk for insertional mutagenesis, difficult to produce in high titer
Lentivirus	8	Yes	None	Yes	Persistent	Theoretical safety concerns regarding HIV components; risk for insertional mutagenesis, difficult to produce in high titer

[1]*Plasmid size are generally not limited, but plasmids with >10 kb expression cassette capacity are more difficult to produce with consistent fidelity and thus are generally not suitable for gene human transfer.*
[2]*Typically, Ad vectors have a 7–8 kb capacity for the expression cassette; the capacity can be increased by removing additional viral genes.*
[3]*Wild type adeno-associated virus (AAV) integrates in a site-specific fashion into chromosome 19, a process mediated by the rev gene; rev is deleted in the AAV gene transfer vectors; whether or not there is minimal integration of the genome AAV gene transfer vectors is debated (Summerford and Samulski, 1998; Qing et al., 1999; Summerford et al., 1999; McCarty et al., 2004).*

serotype 2 are widely used in gene transfer studies, and the only serotypes used in humans to date. The Ad5 genome is composed of early and late genes [33]. The E1 region controls the replication of the virus. Conventionally, the Ad gene transfer vectors have a deletion in E1 and E3 (a non-essential region). The expression cassette containing the promoter, and the gene to be transferred is usually inserted into the E1 region. The vectors are produced in the 293 embryonic kidney cell line that provides the E1 information in *trans*, enabling replication of the recombinant vector.

Ad vectors can hold 7 to 7.5 kb of exogenous sequences [33]. If more space is needed, the E2 or E4 region can also be deleted and the vector made in cell lines providing these deleted sequences. The Ad capsid is an icosahedral structure composed of 252 subunits, of which 240 are hexons and 12 are pentons. Hexon is the major structural component of the Ad capsid, forming 20 facets of the icosahedron, and is composed of three tightly associated molecules of polypeptide II forming a trimer. Polypeptide IX is associated with the hexon protein and serves to stabilize the structure. Each penton contains a base and a non-covalently projecting fiber. Sequences within the fiber are the primary means by which Ad interacts with cells, with the penton base providing secondary attachment sequences.

Several cellular receptors have been identified for Ad vectors and they differ for various serotypes (Table 34.2), see also reference [76]. The primary Ad receptor for the subgroup C Ad is the coxsackie adenovirus receptor (CAR) [34]. CAR is expressed on most cell types, and thus Ad group C vectors, but also some group A, D, E and F serotypes are capable of transferring genes to most organs [35,76]. Besides the primary CAR receptor, epitopes in the penton base of the group C Ad vectors use $\alpha_v\beta_3$ (or $\alpha_v\beta_5$) surface integrins as co-receptors for virus

TABLE 34.2 Cell receptors of commonly used viral-based gene therapy vectors

Vector	Virus group/serotype[1]	Receptor	Reference
Adenovirus	Group C, serotypes 2, 5	CAR[2]; co-receptors – $\alpha_V\beta_3$, $\alpha_V\beta_5$ integrins	[36,34]
	Group C, serotypes 2, 5 Group B, serotypes 3, 35	Heparan sulfate	[196,37,38]
	Group C, serotype 5	Vascular cell adhesion molecule I	[40]
	Group C, serotype 5	MHC class I α2	[39]
	Group D, serotype 37	Sialic acid	[197]
	Group B, serotypes 3, 11, 14, 16, 21, 35, 50	CD46	[41,42]
	Group B, serotype 3	CD 80, CD 86	[43]
Adeno-associated virus	AAV1	Sialic acid (N-linked)	[70,71]
	AAV 2	Heparan sulfate proteoglycan; co-receptors – fibroblast growth factor receptor 1, $\alpha_v\beta_5$ integrin	[66,198,75,67]
	AAV 3	Heparan sulfate proteoglycan	[67,37]
	AAV4	Sialic acid (O-linked)	[68]
	AAV5	Sialic acid (N-linked); coreceptor – platelet-derived growth factor receptor	[68,69,77]
	AAV6	Sialic acid (N-linked), heparan sulfate proteoglycan; coreceptor – epithelial growth factor receptor	[70,78,71]
	AAV8	Unknown primary receptor; coreceptor – laminin receptor	[79]
	AAV9	Galactose (N-linked); coreceptor: laminin receptor	[79,72]
Retrovirus	MoMLV[3]	Ecotropic	[83,199]
	470A MLV, VSV[4]	Amphotropic (phosphatidylserine?)	[83,200,199,85]
Lentivirus	HIV-1 (envelope protein)	CD4 – co-receptors – CCR5, CXCR4	[201]
	Pseudotyped with VSV-G	Amphotropic (phosphatidylserine?)	[202,85]

[1] *Adenoviruses are categorized in groups and serotypes; AAV is categorized in clades and serotypes, only the serotypes are listed.*

internalization [36]. Heparan sulfate has also been identified as a receptor for Ad2, Ad3, Ad5 and Ad35 [37,38]. Ad5 has been shown to bind to vascular cell adhesion molecule 1 (VCAM 1) on endothelial cells and possibly also to MHC class I a2 on the cell surface [39,40].

The group B serotypes Ad 11, 14, 16, 21, 35 and 50 utilize CD46 instead of CAR, enabling more efficient gene transfer into hematopoietic cells, cells of the urinary tract epithelium and salivary glands [41,42]. For Ad3 of the subgroup B Ad vectors, CD80 and CD86, which are usually expressed on antigen-presenting cells, have been identified as a receptor for viral entry [43].

In addition to Ad vectors being effective in delivering genes to a wide variety of cell types for therapeutic purposes, Ad vectors interact rapidly with antigen-presenting cells such as dendritic cells, leading to the induction of immunity against the vector and potentially also against the transgene if it is foreign to the host [44,6]. When Ad are directly administered in large doses to animals and humans, there is an innate and acquired immune response against the vector, resulting in local inflammation and infiltration of CD4, CD8 and dendritic cells

[44,45]. The immune response is multifaceted, consisting of humoral and cellular immunity against both the capsid proteins and against the transgene expressed by the vector if it is foreign to the host. Intravenously administered Ad also interacts with a variety of host proteins, in particular coagulation factor X 46,47.

Several strategies have been investigated to circumvent the problem of host responses evoked against Ad gene transfer vectors, including the use of immunosuppressants administered together with the vector, or including transgenes expressing immunomodulatory factors to suppress the immune responses against the vector [44]. Considerable effort has also been expended on circumventing the host response by designing vectors with larger genomic deletions (e.g., of E1 plus E2 and/or E4 with complementing cell lines) which evoke milder immune reaction [5,44,48].

One challenge to the use of Ad vectors is pre-existing immunity against the vector, resulting from previous infection with a wild type Ad virus from the same serotype [44]. The acquired host responses to Ad vector administration generally results in the inability to re-administer a vector of the same serotype. To circumvent this issue, alternative serotypes can be administered, thus circumventing immunity against the first vector [49]. Also, serotypes to which humans are usually not exposed have been developed as gene transfer vectors. One example is Ad serotype 48, to which humans rarely have pre-existing immunity. A chimeric Ad vector, in which the hexon loops of Ad5 are replaced by those of Ad48, has been shown to be a possible strategy for an Ad-based genetic vaccine approach [50], and could also be envisioned as being useful for tissue-engineering applications.

Another strategy for circumventing pre-existing anti-Ad immunity is the use of non-human Ad serotypes [51–53]. Non-human, primate-derived Ad vectors were developed to overcome pre-existing immunity to common human Ad serotypes and to broaden the repertoire of Ad when used as vaccines [54–56]. For example, Ad vectors based on non-human primate serotypes C68, C6, C7 do not circulate in the human population and are therefore not affected by pre-existing immunity [51–53].

Adeno-associated virus

Over the past few years, AAV (adeno-associated virus) vectors have emerged as one of the most promising viral vectors for *in vivo* gene therapy in humans [8]. AAV is a single stranded DNA virus that belongs to the *Dependovirus* genus of the *Parvoviridae* family. AAVs were originally isolated as contaminants in laboratory stocks of adenoviruses [57]. Nine subtypes of AAV have been described for which humans are the primary host [57,12]. These isolates were found to be different based on the antibody response generated against them and were thus categorized as AAV serotypes 1–9. A substantial portion of humans have detectable antibodies against these serotypes. The capsid structures have so far been solved for all serotypes, except AAV3 [12]. The exact nature and sequelae of the natural infection with AAV in humans are not known and there is possibly no human disease associated with AAV.

An AAV consists of a single stranded 4.7 kb genome with characteristic termini of palindromic repeats that fold into a hairpin shape known as inverted terminal repeats (ITR) [57,12]. During replication into a double stranded form, it expresses genes involved in replication (*rep*) and genes that code for the capsid proteins (*cap*). In the absence of a helper virus such as adenovirus or herpes simplex, wild type AAV is capable of infecting non-dividing cells and integrating its genome into chromosomal DNA at a specific region on chromosome 19, persisting in a latent form. In the gene vectors, *rep* and *cap* are deleted, and most of the vector genome resides and functions in an extra-chromosomal locations [57].

In the AAV vectors, the *rep* and *cap* genes are replaced with an expression cassette. During vector production, the *rep* and *cap* gene products as well as the necessary helper virus elements

(usually Ad-derived) are supplied *in trans*. AAV vectors are commonly produced by transfecting two plasmids into the 293 human embryonic kidney packaging cell line. DNA coding for the therapeutic gene is provided by one plasmid, and the AAV *rep* and *cap* functions plus the Ad helper functions are provided by the second plasmid. Titers are generally significantly lower compared to those obtained for Ad vectors, but are sufficient to produce enough vector for clinical trials.

Numerous studies in animals have been performed to assess the safety and efficacy of AAV-based vectors, and AAV1, 2, 6, and 8 serotype-based human and chimpanzee-derived AAVrh10 vectors have been assessed in humans [58,8]. AAV vectors are capable of transducing non-dividing cells *in vitro* and *in vivo*. The exact molecular intracellular state of the vector genome has not been completely elucidated, but there is little evidence that the vectors integrate when used in gene therapy *in vivo*. Most transgene expression is thought to be derived from extra-chromosomal viral genomes which persist as double stranded circular or linear episomes [59,10]. This limits the usefulness of AAV for applications involving dividing cells such as stem cells, since only one daughter cell will receive the vector genome [240].

One disadvantage of AAV vectors is their packaging capacity, which is limited to expression cassettes of about 4.5 kb. This size limitation is a challenge for the use of AAV vectors for clinically relevant large transgenes, such as dystrophin (11 kb) for muscular dystrophy, or factor VIII (7–9 kb) for hemophilia A. Various efforts have been made to deliver larger transgenes using AAV vectors, including co-administration of two vectors each carrying one half of the transgene, leading to intermolecular recombination during concatamerization, an intermediate state of the vector genome. *Trans*-splicing may also be employed as a strategy to circumvent the need to package the full-length cDNA into the AAV vector; instead of delivering the full coding sequences, the gene is split into two pieces that then combine at the pre-mRNA level [60].

The host immune response against AAV vectors is not as strong as that observed with Ad vectors [8,44,61–63]. AAV vectors generate humoral immunity against the capsid proteins, which impairs readministration of vector of the identical serotype. Cellular immunity against AAV has been detected following administration to experimental animals and humans, but, unless high doses are used, there usually are no destructive cytotoxic T cell responses generated against the vector or the transgene [61]. However, recent experiences with liver-directed AAV delivery for hemophilia have challenged this notion [8,62,63].

There is usually persistent expression of the transgene directed by AAV vectors, particularly in organs with non-dividing (or slowly dividing) cells, such as liver, muscle, heart, retina and brain. The overall expression levels of the transgene appear to be lower with AAV compared to Ad and are dependent on the target organ. Recently novel AAVs have been identified from tissues of non-human primates and humans [10,64,65]. These AAVs have substantial heterogeneity in the capsid genes, and are useful as chimeric capsids combined with the AAV2 genome, leading to improved infection of organs or tissues previously not considered to be valuable targets for AAV gene transfer.

AAV interacts with its target cells by binding to cell surface receptors (Table 34.2). For AAV2, the primary attachment receptor is heparan sulfate proteoglycan [66]. AAV3 may share heparan sulfate proteoglycan as the primary attachment receptor. However, AAV3 may use other receptors, as AAV3 has been shown to infect hematopoietic cells, which were not effectively infected by AAV2 [67]. AAV4 and AAV5 use sialic acid as the primary attachment receptor. AAV4 uses O-linked sialic acid, whereas AAV5 uses N-linked sialic acid [68,69]. AAV1 and AAV6 use N-linked sialic acid as receptor [70,71]. Recently, N-linked galactose was identified as the receptor for AAV9 72. The primary receptors for AAV7 and 8 remain unknown. AAV 12, originally isolated from a stock of simian adenovirus 18, does not require cell surface heparan sulfate proteoglycans nor sialic acid for transduction and shows strong

tropism for nasal epithelia [73,74]. It is being developed as vaccine vector against respiratory pathogens [74].

AAV2 also uses co-receptors for efficient infection, including $\alpha_V\beta_5$ integrin [75] and fibroblast growth factor-1 [76]. Efficient infection with AAV5 appears to require a coreceptor; platelet-derived growth factor has been identified as a possible coreceptor for AAV5, but may also be able to act as the primary receptor [77]. Epithelial growth factor receptor has been identified as a coreceptor for AAV6 [78]. AAV 8 and 9 use the laminin receptor as a coreceptor [79].

Retroviruses

Retrovirus and lentivirus vectors are both RNA-based vectors belonging to the family of retroviridae. Because lentiviruses are capable of infecting non-dividing cells, they are discussed separately below. The original retroviral vectors used for gene therapy were based on endogenous murine viruses. Of these, the Moloney murine leukemia retrovirus (MMLV) was the first widely used gene transfer vector and was the first to be used to treat an hereditary disorder using an *ex vivo* strategy [80].

The genome of the retrovirus vector is a 7 to 10 kb single stranded RNA containing long terminal repeats (LTR) on both ends that flank *rev, gag, pol* and other regulatory genes which are required for viral function. The RNA genome of the replication-deficient retroviral vectors contains an expression cassette of to up to 8 kb that replaces all viral protein-coding sequences. The LTRs flank the expression cassette and allow transcription initiation by host cell factors. The vectors are rendered self-inactivating by deletion of the promoter and enhancer in the 3′ LTR to prevent LTR-driven transcription. The packaging of the genomic RNA is controlled in *cis* by the packaging signal Ψ. The production of the retrovirus vectors requires a packaging or producer cell line in which the viral *gag, pol* and *env* proteins are expressed in *trans* from separate helper products. Recombination between the helper constructs and the vector can be minimized by using non-retroviral regulatory sequences to control expression [81]. Enhancer and promoter sequences can be deleted from the 3′ LTR to create a transcriptionally silent 5′ LTR during infection of the target cells. This strategy provides the basis for self-inactivating vectors and can also be used for the substitution with tissue-specific promoters [82]. The main reason why MMLV viruses can only infect non-dividing cells is that they are unable to cross the nuclear membrane and can only achieve completion of the infection with provirus integration during cell division.

Retroviruses enter the cells via cell fusion of the envelope protein with the cell membrane. The murine viruses are able to infect only murine cells (ecotropic), whereas derivatives of MMLV or human retroviruses like vesicular stomatiitis virus (VSV) can infect both human and murine cells (amphotropic; Table 34.2). Providing the virus with a different coat, a process referred to as 'pseudotyping', can change the specificity of binding and entry into target cells. Over the past decade, there has been considerable effort in the development of pseudotyping strategies of retroviral vectors [81,83–85].

Most of the gene transfer strategies for retroviral vectors have been *ex vivo* approaches due to the difficulty of producing high titer concentrated preparations and the rapid inactivation of the retroviral vectors *in vivo* by complement. Due to their ability to infect rapidly dividing cells, retroviral vectors have been used extensively to develop gene transfer strategies to hematopoietic cells. The first clinical trial to treat a hereditary disorder was to use a retrovirus to transduce T cells of patients with adenosine deaminase – severe combined immunodeficiency (SCID) [80], and since then the technology has evolved to permit successful treatment of children with SCID [86–88].

One advantage of using retroviral vectors is the permanent integration of the vector genome into the host genome, providing long-term and stable expression of the transgene. This, however, also carries the greatest risk of retroviral vectors, in that they may induce insertional

mutagenesis with the subsequent development of malignancies. This has been observed in clinical trials using MMLV-based retroviral vectors, in which five out of 20 patients developed leukemia due to insertional mutagenesis [89–91]. To increase the safety of gene therapy, self-inactivating retrovirus and lentiviral vectors with internal promoters have been developed [23–26,92]. These theoretically reduce the risk of undesirable activation of genes adjacent to the integration site and favor integration near transcription start sites [89,93,94]. Retroviruses are more vulnerable to silencing than lentiviral vectors [93]. However, important advances have been made in understanding the integration mechanisms to retain retroviral vectors as a viable option for human gene therapy for genetic hematopoietic cell disorders [22,25,26,95,96].

Lentivirus

Based on the knowledge that the human retrovirus HIV-1 is able to infect non-dividing cells such as macrophages and neurons, replication-defective versions of HIV were developed, capable of infecting non-dividing cells and achieving stable long-term expression through integration of the provirus into chromosomal DNA [97,98]. The genome of a lentivirus vector is a 9 to 10 kb single stranded RNA genome, containing components of HIV-1, but otherwise similar to that of retroviral vectors. All viral protein-coding sequences are deleted and are replaced with an expression cassette that can be up to 8 kb in length.

Unique to lentiviruses are the central polypurine tract (cPPT) and central termination sequences (CTS), *cis*-acting sequences that coordinate the formation of a central DNA flap which improves nuclear import [99]. This may explain the increased transduction efficiency of lentiviral compared to retroviral vectors. A *rev*-responsive element can be incorporated into the vector to facilitate the nuclear export of unspliced RNA. The packaging of the genomic RNA is controlled in *cis* by the packaging signal Ψ.

Despite the greater complexity of the lentivirus genome, the basic principles of generating vectors free of replication-competent virus are similar to those for retroviral vectors. Packaging systems use the HIV *gag* and *pol* genes, with or without the *rev* gene [100,101]. The HIV virulence genes *tat*, *vif*, *vpr*, *vpu* and *nef* are completely absent from lentiviral vectors, thus making it theoretically impossible that a virus similar to HIV can be inadvertently produced [102]. The production of lentiviral vectors in high concentrated titers is still a challenge, but the production issues are slowly being solved [98].

The cellular receptors for the lentivirus vectors are the same as for HIV1-1, including CD4, together with the chemokine co-receptors CCR5 and CXCR4 (Table 34.2). However, the lentiviral gene transfer vectors are usually pseudotyped with envelopes from other viruses, such as VSV-G, mediating the binding and entry into target cells similar to retroviral vectors. Efficient gene transfer of lentiviral vectors has been reported for a variety of dividing and non-dividing cell types, including muscle, neurons, glia and hematopoietic cells. Lentivirus vectors have been successfully used to correct disease phenotypes in experimental animals for central nervous system (CNS) disorders such as metachromatic leukodystrophy using *in vivo* administration of the lentiviral vector to the brain [103] or, using an *ex vivo* strategy, by infecting hematopoietic stem cells with the β-globin gene to correct β-thalassemia [104]. There have only been a few clinical studies using lentiviral vectors, but the results for an *ex vivo* approach correcting hematopoietic stem cells with lentiviral-mediated gene transfer in patients with adrenoleukodystrophy, a severe demyelinating disease, or thalassemia have been very promising [14,16,96].

Like retroviral vectors, insertional mutagenesis is a concern for the clinical use of lentiviral vectors, and liver cancers have been observed in mice infected *in utero* or neonatally with lentiviral vectors [105]. One hypothesis for this phenomenon is based on potentially oncogenic sequences present in the woodchuck hepatitis virus-derived post-transcriptional

regulatory element (WPRE) that was included into the vector to increase mRNA stability [105]. Approaches that have been taken to decrease the risk of genotoxicity in lentiviral vectors include:

1) Self-inactivating (SIN) long terminal repeats that delete transcriptional control elements [25,106];
2) Integration systems that do not bias towards insertion near active genes or promoters [107]; and
3) Weaker internal promoters [108].

Besides being the most promising vector system for *ex vivo* gene correction strategies, lentiviral vectors have evolved as a powerful tool to silence gene expression by RNA interference [109]. Extensive human and murine siRNA-expressing lentiviral libraries are now available (RNAi consortium: http://www.broadinstitute.org/rnai/trc, accessed July 11, 2013) and lentiviral vectors are also efficient to knockdown cellular miRNA [110].

CELL-SPECIFIC TARGETING STRATEGIES

Viral gene transfer vectors use the receptors of their wild type versions to enter into cells (Table 34.2). Modification of gene transfer vectors to target specific cell types or tissues is an attractive means of increasing the specificity of the vectors to the target cell, and may also enable the vectors to infect cells which are usually not infected by unmodified vectors. In general, targeting modifications can be accomplished by either genetic modification of the vector genome to change the properties of the outer surface of the vector or by chemical modification of the vectors via the addition of ligands (Table 34.3). Based on the targeting strategy used, the range of tropism can be widened or narrowed (Fig. 34.4).

Targeting of Ad vectors

Strategies have been developed to re-direct Ad tropism and to enhance Ad tropism for cells difficult to transfer genes to because of lack of Ad receptors. In general, Ad vectors exhibit a broad tropism due to the widespread expression of the primary Ad receptor CAR and the secondary integrin receptors $\alpha_V\beta_3$ and $\alpha_V\beta_5$. While the widespread expression of the Ad receptors enables the efficient infection of a wide range of target cells, it poses the problem of unwanted uptake and gene expression in non-target tissue when the vectors are administered *in vivo*. There are some tissues that have low expression of CAR (e.g., endothelial cells, antigen-presenting cells and some tumor cells), which limits the use of Ad vectors for these targets.

Most genetic targeting strategies for Ad vectors have been focused on ablating CAR binding and have introduced new peptides or other ligands to the fiber knob domain, the primary site for the interaction of group C Ad vectors with CAR [111]. Fiber modifications to modify the target cell binding of Ad vectors include the introduction of poly(L) lysine to allow binding to heparan-containing receptors and the integrin-binding motif RGD, which is essential for penton-mediated internalization to allow integrin-mediated binding and uptake [112]. Peptides can also be incorporated into other sites of the Ad capsid to achieve retargeting, such as incorporation of RGD into the hexon [113] and poly(L) lysine into polypeptide IX [114].

Another approach to the genetic retargeting of virus vectors is to create chimeras of different serotypes, which are known to use different cellular receptors. Replacing the fiber or fiber knob domain of the Ad5-based vector with that of Ad3 or Ad7 has been shown to achieve CAR-independent infectivity [115–117]. Replacement of the fiber of Ad2 with that of Ad17 has led to improved infectivity of airway epithelial cells [118]. Replacement with the fiber of Ad35 achieved improved infectivity of hematopoietic cells [119,120] and Ad16 enhanced infectivity of cardiovascular tissue [121]. Ad5 vectors pseudotyped with fibers of the subgroup D Ad 19 and 37 increased the infectivity of endothelial and smooth muscle cells [122]. Recognition peptides for fiber modification have been identified by phage display, [123–125] and other

TABLE 34.3 Alteration of viral gene transfer vector cell targeting by modifying capsid/envelope structure

Modification	Viral vector	Examples	Purpose/target	Reference
Genetic alteration of capsid/envelope proteins	Adenovirus	Delete CAR[1]	CAR-independent infection	[203]
		Add RGD[2] to fiber	$\alpha_V\beta_3$, $\alpha_V\beta_5$ integrins	[112]
		Add polylysine to fiber or protein IX	Broadening infectivity by targeting heparan-containing molecules	[112,114]
		Replace Ad5 fiber with Ad19 or Ad37 fiber	Improved infection of smooth muscle and endothelial cells	[122]
		Replace Ad5 fiber with Ad37 fiber	Infection of hematopoietic cells	[119]
		Replace Ad5 fiber knob with Ad3 fiber knob	CAR-independent infection	[117,204]
		Replace Ad5 fiber with Ad7 fiber	CAR-independent infection	[116]
		Replace Ad2 fiber with Ad17 fiber	Improved infection of airway epithelial cells	[118]
		Replace Ad5 fiber with Ad16 fiber	Improved infection of smooth muscle and endothelial cells	[121]
		Replace Ad5 fiber with trimerization motif of phage T4 fibritin	Chimeric fiber phage fibritin molecules targeted to artificial receptors	[126]
		Replace Ad5 fiber knob with CAV2[3] fiber knob	Target to CAR-deficient cells	[205]
		Replace Ad5 fiber with fiber of ovine AdV7	Targeting to kidney and 'detargeting' of CAR	[206]
		Add VSV[4]-G epitope to Ad5 fiber knob	Targeting tropism to CAR-deficient cell expressing phosphatidylserine	[207]
		Replace 7 hypervariable regions (HVR) of Ad5 hexon with HVR of Ad48	Circumvention of anti-Ad5 hexon immunity for Ad-based HIV vaccine	[50]
	Adeno-associated virus	Pseudotyping entire capsid with different serotype	Targeting tropism based on capsid serotype	[132]
		Pseudotyping with capsid of multiple serotypes	Generate mosaic AAV to target different serotype tropisms	[133,134]
		Addition of L14[5] to AAV2 capsid	Targeting to L14-binding integrins	[208]
		Incorporation of tumor-targeting peptide to AAV2 capsid	Targeting to CD13	[209]
		Insertion of serpin receptor ligand to AAV2 capsid	Targeting to serpin receptor	[210]
		Ad5 capsid with Ad37 fiber and partial AAV genome	Vector with increased capacity and tropism for hematopoietic cells	[119]

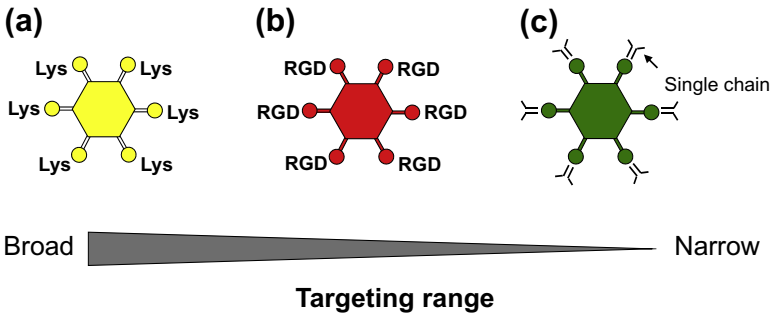

FIGURE 34.4
Examples of modifications of tropism of gene transfer vectors. Shown are three examples of modification of adenovirus vector tropism. (a) The addition of polylysine to the Ad fiber protein provides broad tropism; (b) the addition of the integrin-binding motif RGD enhances targeting of cells expressing $\alpha_v,\beta_{3,5}$ integrins; and (c) the addition of single chain antibodies to the Ad fiber targets cells expressing the antibody ligand. Strategies AC provide broad to narrow cell-specific targeting.

complex genetic modifications of the fiber to retarget the Ad vector have been reported [126,127]. These cell-targeting modifications can also be combined with the use of tissue-specific promoters to achieve selective infection and transcription in the targeted cell type. For example, inserting the RGD motif into the fiber has been combined with the use of the endothelial cell-specific Flt-1 promoter, which resulted in more specific infection and gene expression in endothelial cells [128]. Finally, a capsid-modified Ad/AAV hybrid vector was able to achieve long-term expression in human hematopoietic cells [119].

Besides genetic modification of gene therapy vectors to modify tropism and target vector uptake to a particular cell type, chemical modifications of Ad vectors have been utilized for targeting. Ad vectors have been complexed to cationic lipids, polycationic polymers or cholesterol to increase the efficiency of gene transfer *in vitro* and *in vivo* [129–131]. Bispecific monoclonal antibodies have been added to the fiber to target specific cell types expressing the ligand for that antibody.

Targeting of AAV vectors

The strategy of creating AAV chimeras by pseudotyping with capsids of different AAV serotypes has been used to broaden the tropism of AAV vectors [10,132–134]. Most of these vectors used the vector genome derived from AAV2 along with the capsid from another serotype. As an example, this strategy has enabled enhanced transduction in lung-directed gene transfer using an AAV5 pseudotype [135]. This *in vitro* process also been used *in vivo* with systemic administration of a chimeric viral library, resection of the target tissue and PCR amplification of the sequestered vector genomes [136]. This approach has led to the identification of a heart-tropic [137] and neuron-tropic [138] AAV chimeric vectors.

Targeting of retroviral and lentiviral vectors

The classic method to broaden the tropism of retroviral and lentiviral vectors is by pseudotyping, creating chimeras using envelope glycoproteins from other viruses. Most retrovirus vectors are based on MuMoLV, an ecotropic virus, which infects only murine cells. To achieve infection of human cells, the vectors are propagated in packaging cells that express the envelope of the amphotropic or non-murine viruses such as 4070A murine leukemia virus, gibbon ape leukemia virus, VSV or the feline endogenous virus RD114 [83,84]. Various envelopes have also been used for lentiviral vectors to increase infectivity of specific cell types, including VSV-G for muscle [139], Ebola for airway epithelial cells [140,141], rabies-G for motor neurons [142] and hantavirus for endothelium [143]. Hybrid proteins of the murine amphotropic envelope have been combined with the extracellular domains of GALV or RD114 envelope to enhance infection of CD34+ cells [144,143]. As with Ad vectors, strategies have been developed to target retro- and lentiviral vectors by adding ligands to the envelope

glycoprotein. Examples include peptide sequences from erythropoietin [145], heregulin [146], epithelial growth factor and ligands for the Ram-1 phosphate transporter [81] as well as the addition of single chain antibodies [147,148]. The efficiency of these modifications, however, has not been very high and the vector production yield is significantly impaired.

Another strategy has been to utilize the membrane proteins that are incorporated during the budding process for targeting. For example, incorporation of the membrane-bound stem cell factor provided not only a growth signal for the CD34+ cells expressing c-kit, the receptor for stem cell factor, but also lead to increased infection efficiency of the CD34 cells [149]. Monomethoxy poly(ethylene) glycol conjugated to VSV-G protects the vector from inactivation in the serum, leading to a prolonged half-life and increased transduction of bone marrow following intravenous administration in mice [150]. Another strategy for targeting of retro- and lentiviruses *in vivo* has been to target retrovirus producer cells [151].

REGULATED EXPRESSION OF THE TRANSFERRED GENE

A variety of strategies have been developed to regulate expression of the genes transferred by gene therapy vectors (Table 34.4). The ability to regulate gene expression is particularly important for applications where too much expression of the gene transfer product could lead to unwanted effects, e.g., sustained expression of a growth factor that could potentially be tumorigenic. For *in vivo* strategies of gene transfer, tissue-specific regulation of gene expression may be warranted to avoid expression of genes in undesired cells or tissues. In the context of the use of gene transfer vectors to genetically modify stem cells, regulation of gene expression may be critical to avoid differentiation into an unwanted tissue or cell type. The regulation of the gene expression of the transgene could also be combined with inducible systems of suicide genes or factors that could destroy the genetically modified cells, should unwanted differentiation occur.

To turn gene expression on and off at will, a number of inducible promoters and inducible regulated systems have been developed that are applicable to be used in gene transfer vectors (Table 34.4). For example, inducible gene expression in gene transfer vectors can be achieved using inducible promoters such as those responsive to glucocorticoids, cGMP, heat shock protein, radiation, and insulin. Inducible regulated systems also include systems based on response to tetracycline, antibiotic resistance, chemical-induced dimerization, steroid receptors and insect ecdysone receptors. The basic mechanism for these systems is a combination of ligand-binding synthetic inducer or repressor proteins and a promoter control system that regulates transgene expression.

The tetracycline-responsive system has been widely used to study gene function and to generate conditional mutants in cell lines and transgenic animals [239]. The transgene is placed behind a promoter that also contains binding sites for the tetracycline response element (TRE), which can act as a repressor or inducer of transgene expression. A fusion protein that binds to the inducer doxycycline needs to be present on a separate gene construct. The tetracycline transactivator binds to the TRE and activates the transcription in the absence of doxycycline. Upon addition of doxycycline, the expression is turned off (Tet-off). Another fusion protein that can be used is the reverse tetracycline transactivator, which only binds to TRE in the presence of doxycycline, causing induction of expression upon addition of doxycycline (Tet-on). Expression can be controlled in a graded manner: the more doxycycline is added, the greater the level of suppression or induction. The disadvantages of this system are the potential side effects of doxycycline. The tetracycline system has been used for regulated gene transfer with gene therapy vectors, including Ad [103,152], AAV [153–155], retroviral [156,157], and lentiviral vectors [158,159].

The steroid receptor systems use a mifepristone-binding progesterone receptor fused to the DNA-binding domain of the yeast GAL4 protein and the transactivation domain from the

TABLE 34.4 Regulation of Expression of the Transferred Gene

Category	Strategy	Note	Reference
Inducible promoter	Glucocorticoid-responsive	Multiple response elements	[216]
	cGMP[1]-responsive	Multiple response elements	[217,218]
	Heat shock protein-inducible	Hyperthermia and cellular stress induce gene expression	[219,220]
	Radiation-inducible		[221]
	Insulin-responsive		[221,222]
	Tetracycline-responsive	Repressible-TET_{off} or inducible TET_{on} systems	[103,156,153,158, 159,154,155]
	Antibiotic resistance	Streptogramin class antibiotic (e.g., pristinamycin) induces pristinamycin-induced protein preventing expression	[223]
		Erythromycin binds to prokaryotic DNA-binding protein MphR(A)[2]	[224]
	Chemical-induced dimerization (FKBP/FRAP[3])	Rapamycin induces heterodimerization of FKBP and FRAP	[225–227]
	Steroid receptor	Transactivator (GLVP[4] or Glp65) targeting genes with GAL-4-binding site in the presence of mifepristone (RU486)	[222,162]
	Insect ecdysone receptor	Ectodysone receptor ligand induces transactivation of transgene	[161,160]
Tissue-specific promoter	Liver	Albumin, α1-antitrypsin, liver- activated protein (LAP), transthyretin promoters	[228–231]
	Smooth muscle	Smooth muscle actin, SM-22, smooth muscle myosin heavy chain promoter	[232,166]
	Prostate	Prostate-specific antigen promoter	[233,234]
	Neuron	Synapsin I, neuron-specific enolase	[163]
	Dendritic cells	Dectin 2, vFLIP	[164,165]
	Vasculature	VE-cadherin, smoothelin B	[235]
	Tumor vasculature	Tie2	[236]
Trans-splicing	Therapeutic *trans*-splicing	Target pre-mRNA is trans-spliced into independent pre-mRNA	[170,237]
State of differentiation	Differentiation-specific endogenous transcriptional regulatory elements	Beta-globin gene expression by endogenous transcriptional regulatory elements or from other genes with a similar expression pattern	[171,172]
Gene disruption	Non-homologous end-joining gene disruption by zinc finger nucleases	Disruption of CCR5 gene to create resistance to HIV in T cells and hematopoietic stem cells	[173,174]
MicroRNA	Target cell-specific microRNAs	No transgene expression by incorporating a target sequence for microRNA in the 3′UTR	[238,176]

[1]*cGMP – cyclic guanosine monophosphate.*

[3]*FKBP (McCarty et al., 2004) – FK506-binding protein; FRAP – FK506-binding protein rapamycin-binding).*
[4]*GLVP – a mifepristone-activated chimeric nuclear receptor.*

NfkB p65 subunit [160,161]. The fusion protein binds to a GAL4 activating sequence to regulate gene expression. Upon addition of mifepristone, gene expression is induced, and upon removal of the drug, gene expression returns to baseline within five days.

The insect ecdysone receptor system consists of a fusion protein of the transactivation domain of the glucocorticoid receptor fused to the ecdysone-binding nuclear receptor and an ecdysone-response element placed upstream of the promoter driving the transgene expression

[161,162]. Upon addition of ecdysone, an insect hormone with no mammalian homologs, the fusion protein dimerizes and induces expression. Because there are no known mammalian factors binding to the insect protein, there is very low background expression in the absence of the drug and expression can be very tightly controlled.

Another strategy to control gene expression at the desired location is the use of tissue-specific promoters (Table 34.4). The majority of tissue-specific promoters have been used to target expression to the liver and the cardiovascular system by targeting muscle cells. Recently, lentiviral vectors with tissue-specific gene expression in dendritic cells and neurons have been reported [164–166]. The challenge in the use of tissue-specific promoters is that the level of expression is usually lower than the commonly used strong viral promoters. However, viral promoters such as CMV have been shown to be subject to silencing after several weeks *in vivo*. This has been seen in airways, cardiomyocytes and smooth muscle cells, in particular with non-viral gene transfer [167].

Another modality for regulating gene expression is by *trans*-splicing at the pre-mRNA level. In therapeutic trans-splicing, the sequence of the target pre-mRNA is modified by being trans-spliced to an independent pre-mRNA, the sequences for which are delivered exogenously by a gene transfer vector [168,60]. Therapeutic *trans*-splicing can be used to alter coding domains, to create novel fusion proteins, to direct gene products to various cellular compartments and to enable gene therapy with large genes or genes coding for toxic products. *Trans*-splicing gene transfer strategies also offer the advantage that the expression of the *trans*-spliced sequence is controlled by endogenous regulation of the target pre-mRNA. Trans-splicing strategies have been used to correct animal models of hemophilia, X-linked immunodeficiency with hyper IgM and cystic fibrosis [169,170,177].

To achieve transgene expression limited to the therapeutic target cells, endogenous transcriptional regulatory elements from the endogenous locus or from other genes with a similar expression pattern can be incorporated into the vectors [171,172]. This approach will be useful, for example, in gene therapy for thalassemia or sickle cell disease.

Another approach to selective expression is T cells that are resistant to HIV infection, generated through disruption of the expression of CCR5, an essential HIV coreceptor, by a gene transfer strategy of non-homologous end-joining gene disruption by zinc finger nucleases [173,174].

Another strategy to regulate transgene expression is to take advantage of the differential expression of microRNAs between mature cell lineages and stem cells [175,176]. Transgene expression can be suppressed in cells expressing a specific microRNA by incorporating a target sequence for that microRNA in the 3′ untranslated region [110,176].

COMBINING GENE TRANSFER WITH STEM CELL STRATEGIES

In general, stem cells are categorized into embryonal stem cells, the bone marrow-derived stem/progenitor cells, including mesenchymal stem cells (MSCs), endothelial progenitor cells (EPCs) and the tissue-derived stem cell populations [178]. Stem cells offer the potential for tissue regeneration, and the combination of gene therapy and stem cell approaches is a promising strategy for directing the differentiation of stem cells into the desired cell type, and for regulating and controlling the growth and differentiation of the stem cells. Stem cells have the potential for both self-renewal and differentiation, and are dependent on signals from their microenvironment to direct stem cell maintenance or differentiation. The precise spatial and temporal presentation of these signals is critically important in development and will most likely be the decisive factor in the success of stem cell therapies [179]. As the potential of stem cells to be used clinically becomes more realistic, gene transfer strategies may play a pivotal role in controlling stem cell growth, by either preventing uncontrolled growth and/or directing differentiation into specific cell types, and regulating gene expression. In addition,

as more of the microenvironmental cues that control stem cell differentiation into the desired phenotypes become known, the potential to use gene transfer strategies to express or inhibit these signals becomes a viable strategy to support stem cell therapy. The use of gene transfer for reprogramming somatic cells to pluripotency has been a rapidly growing field over the past years [180]. Genetic modification of these cells using gene therapy holds immense promise for cell-based therapies and tissue engineering, once safe and robust methods to generate these cells and their differentiation have been established. Three general areas can be currently envisioned for gene transfer to be helpful in stem cell therapies:

1) To control unwanted stem cell growth or differentiation;
2) To provide environmental cues for stem cell differentiation; and
3) To regulate gene expression.

In addition, gene transfer may also be useful for marking stem cells as a modality to track the cells and their progeny *in vivo* [181].

Gene transfer to stem cells

The challenges in developing gene transfer strategies for stem cells are:

1) How to most efficiently infect the cells;
2) Gene silencing during differentiation;
3) If gene expression should be transient or persistent; and
4) If gene expression is persistent, should it terminate once the cell has differentiated into the desired phenotype?

Gene transfer has been accomplished into a variety of stem cell types. Human and murine embryonal stem cells have been successfully infected with subsequent gene expression with adenovirus, AAV and lentiviral vectors [182]. The reported efficiency of each of these vector systems is limited, however, requiring selection to obtain pure populations of genetically modified cells. Gene expression can be affected by subsequent differentiation of the cells, and it is not clear how the stem cell properties are affected by the various gene therapy modalities themselves without transgene expression. Bone marrow-derived endothelial progenitor and MSCs have been successfully transduced with the most commonly used gene therapy vectors [4].

Gene transfer to control uncontrolled stem cell growth

Gene transfer strategies developed to control the growth of cells for cancer gene therapy applications can be applied to controlling the unwanted growth of stem cells, in particular, the risk of the development of teratomas with embryonic stem [183]. Some of the suicide gene transfer strategies, including the prodrug strategies using herpes simplex thymidine kinase (HSV-TK) (ganciclovir) and cytosine-deaminase (5-fluorocytosine) that lead to activation of cell death following administration of the prodrug may prove useful. Other suicide genes used with regulatable gene expression systems (as outlined above, Table 34.4) may be useful for controlling potential malignant stem cell growth, as long as there is no 'leak' of baseline gene expression of the suicide gene.

Gene transfer to instruct stem cell differentiation

Gene transfer strategies may prove useful in providing the necessary environmental factors necessary to develop specific phenotypes from stem cells. For example, expression of growth factors or other known differentiation signals secreted by the stem cell should aid in mediating differentiation, i.e., the genetically modified stem cell would create its own microenvironment, favorable for differentiation. Expression of these factors could be regulated by inducible gene expression systems. For example, the cytokines required for the differentiation in the respective lineage have been identified for muscle-derived MSCs, with their potential for the treatment of skeletal, cardiac and smooth muscle injuries and disease [184]. The technology of

induced pluripotent stem cells has been possible by this approach. Differentiated pluripotent cells can be either generated from embryonic stem cells (donor oocytes) or from reprogrammed somatic cells, induced pluripotent stem cells (iPSCs) [18]. Induced pluripotent stem cell technology has emerged as one of the most promising strategies to generate patient-specific embryonic and adult stem cells [17,18]. IPSCs were initially developed from murine somatic cells by expressing reprogramming transcription factors implicated in pluripotency [185]. The human version was developed shortly thereafter [186–189]. The factors required for reprogramming somatic cells have been introduced by retroviruses and lentiviruses. Because of the risks with integration and that low-level residual expression of reprogramming factors may alter the differentiation potential of the human iPSCs, non-integrating vectors, plasmids and Ad vectors have also been used for transient expression of reprogramming factors in mice to generate iPSCs [190,191], although with much lower efficiency. Episomal vectors, based on the Epstein-Bar virus, have been used successfully [193]. Non-viral methods also used include expression plasmids, piggyback transposone, Cre/loxP excisable polycistronic constructs, CPP-tagged reprogramming proteins and synthetic modified RNA [189,17,18].

Gene transfer to regulate gene expression

Regulation of gene expression is critically important in the maintenance and differentiation of stem cells, and the transfer of genes coding for factors that regulate endogenous gene expression in response to specific stimuli could prove very helpful for stem cell therapies. This concept has been used in gene transfer strategy to regulate angiogenesis in the ischemic myocardium. AAV vector-mediated transfer of a hypoxia, a responsive element to ischemic myocardium, resulted in endogenous expression of the vascular endothelial growth factor (VEGF) [193]. Similarly engineered transcription factors capable of activating endogenous VEGF expression have been successfully transferred with adenoviral vectors [194]. As more of the gene expression and regulation patterns critical for stem cell differentiation and maintenance are known, the possibilities to direct or aid in gene expression using gene transfer are significant.

One potential barrier to using embryonic stem cells in humans is rejection of the transplanted cell by the immune system [196]. This could theoretically be circumvented by using gene transfer with the relevant gene to autologous stem cells. For example, transfer of genetically modified iPSCs (Fig. 34.5a) or transfer of a genetically corrected nucleus to an enucleated egg from an unrelated donor would result in the generation of genetically modified embryonic stem cells that could be then differentiated, and the corrected, differentiated cells transplanted to the same patient (Fig. 34.5b).

CHALLENGES TO GENE THERAPY FOR TISSUE ENGINEERING

Although proven to be very effective in a variety of model systems, the major challenges for gene therapy to cure human diseases include circumvention of immune responses against viral vectors, transferring the genes to a sufficient number of cells to change the phenotype and controlling the expression of the gene. The main hurdle for successful gene therapy to compensate for a missing or defective protein has been the host response to the gene therapy vector, the lack of long-term gene expression and problems related to integration into the host genome. However, short-term expression of transgenes has been feasible in humans and has been shown to be efficient in a variety of cell types and tissues. Immunogenicity against a non-self transgene, as well as vector-derived proteins, may be an issue if gene transfer is being used for permanent expression of a transgene. Controlling the gene expression is a challenge that needs to be addressed, especially if gene transfer strategies are combined with stem cell strategies. Most regulatable gene expression systems show some baseline expression, which may be problematic if gene transfer is used to regulate gene expression for stem cell differentiation.

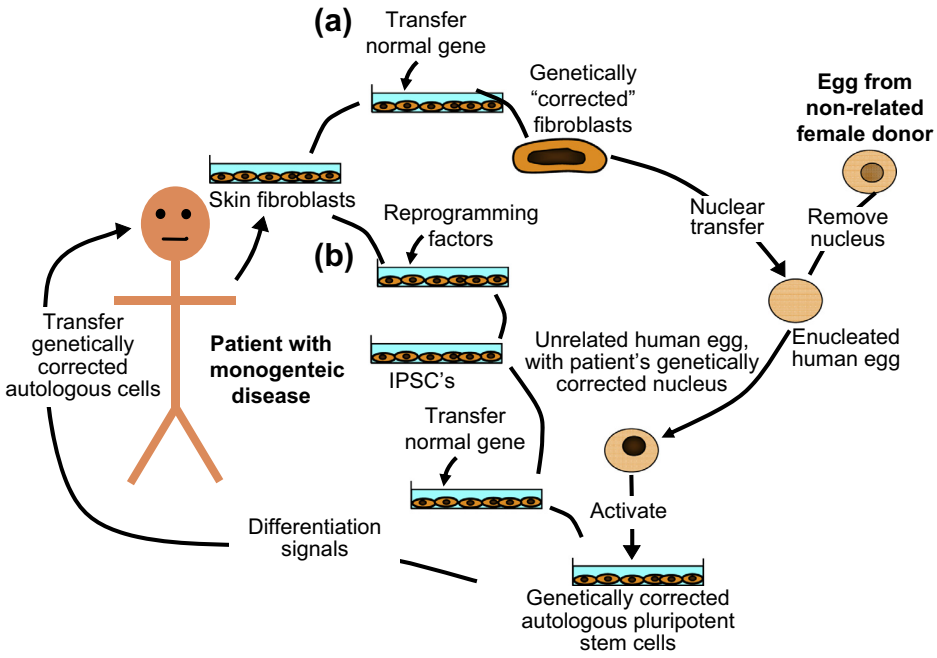

FIGURE 34.5

Strategies to combine gene therapy with nuclear transfer and stem cell therapy. Shown are two examples to genetically modify skin fibroblast or skin-fibroblast-derived induced pluripotent stem cells of an individual with a monogenetic disease to correct the abnormality. (a) The nucleus of the genetically corrected fibroblast is transferred to an enucleated egg of an unrelated donor to generate corrected autologous pluripotent stem cells. (b) Induced pluripotent stem cells are genetically corrected. Both genetically corrected pluripotent stem cells can then be differentiated and transferred back to patient.

Over the past decade, progress has been made in addressing many of these challenges. Gene therapy in humans has led to promising results for *ex vivo* hematopoietic stem cell gene transfer with retroviral and lentiviral vectors and for *in vivo* gene therapy with AAV vectors. As the focus continues on solving the remaining issues, together with gene therapy, the knowledge gained from successes and setbacks will prove beneficial in its use for tissue engineering and stem cell applications.

INTRODUCTION

This chapter provides an overview of intracellular gene and nucleic acid delivery by engineered nanoparticles (NPs) and viral vectors, including particle and vector design, strategies for overcoming cellular barriers, and methods for delivery to cells that are particularly relevant to tissue engineering and regenerative medicine. NPs include a variety of engineered, chemically defined, colloidal objects capable of entering cells and tissues and delivering cargo intracellularly. Viral vectors broadly include a variety of infectious particles with diverse properties that can be adapted to tissue engineering and other applications. This chapter focuses on nonviral and viral design approaches for safe and efficacious intracellular delivery of nucleic acids, including design of gene-functionalized tissue-engineering scaffolds for local delivery to pathological sites.

FUNDAMENTALS OF GENE DELIVERY

The engineering of nonviral and viral nucleic acid delivery systems is a valuable approach for enhancing tissue engineering and regenerative medicine. Nucleic acid-based drugs are broadly sought for the replacement of missing, mutated, or deficient genes, for augmentation of cell function by gene addition or overexpression, and for gene suppression by RNA interference (RNAi) to silence aberrant or pathologic genes. Gene replacement or addition is a more mature but still challenging field that involves transfer and chromosomal integration of DNA that encodes the desired gene through nonviral or viral delivery.

Because of the potency, specificity, and transient activity of RNAi, engineering vectors for delivery of this class of gene therapy has become a major focus of the tissue engineering and medical communities, and significant progress has been made toward technologies that enable therapeutic gene silencing *in vivo*. Gene expression knockdown can be achieved through several different strategies, the earliest of which was utilization of antisense oligodeoxynucleotides (ODNs), which are single-stranded DNAs that bind to complementary mRNAs and yield a relatively modest reduction in gene expression [1]. The mechanism for endogenous post-transcriptional regulation through microRNA (miRNA) was subsequently elucidated, and it was discovered that delivery of double-stranded RNA (dsRNA) achieved more potent gene

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00035-5

silencing than ODNs [2,3]. Short hairpin RNA (shRNA), which more closely mimics the structure of endogenous miRNA, has also been delivered directly or via encoding plasmids [4]. In both cases, the enzyme Dicer cleaves the larger precursor/transcript to form small interfering RNA (siRNA), which is a 19−21 base pair, double-stranded RNA [5]. siRNA can also be delivered directly to cells, a strategy that circumvents the need for Dicer processing and allows direct loading into the RNA-induced silencing complex (RISC). The activated RISC mediates recognition and enzymatic degradation of mRNA that is complementary to the siRNA antisense/guide strand [3]. Due to the greater instability of RNA, the therapeutic application of RNAi is more susceptible to degradation and poses unique hurdles, compared to DNA delivery.

Gene augmentation/replacement and RNAi therapies face both common and unique delivery barriers. Both approaches require intracellular delivery across the plasma membrane. Therapies for stable gene expression, including shRNA, must localize to the cell nucleus, while RNAi activity of siRNA depends upon delivery to the cytoplasm where the RISC machinery is located. In both cases, a variety of viral and nonviral delivery approaches can accomplish these tasks. Nonviral approaches, which offer a potential safety margin, typically involve formulation with synthetic reagents such as polymers or lipids; however, these synthetic formulations are typically less efficient at triggering cell uptake and navigating subsequent intracellular delivery barriers. Recent advances in viral technologies have made them safer, and there are numerous ongoing trials for clinical applications of viral technologies. At the same time, high throughput screening and other advanced synthetic approaches are yielding more efficient nonviral carriers than ever before, and recently, the results have been released from the first successful RNAi clinical trials involving delivery with synthetic nanovectors. The sections 'Viral Nucleic Acid Delivery' and 'Nonviral Nucleic Acid Delivery' below survey the latest technologies for both nonviral and viral approaches to nucleic acid-based drug delivery, and subsequent sections address tissue engineering applications and recent clinical trial results.

BIODISTRIBUTION, TARGETING, UPTAKE, AND TRAFFICKING

For successful gene therapy *in vivo*, viruses or nonviral plasmid/siRNA carriers have three main delivery barriers that must be overcome:

1) Efficient biodistribution to the desired site of action (i.e., tumor or site of tissue damage/dysfunction),
2) Internalization of the cargo by the targeted cell type, and
3) Trafficking to the subcellular compartment where the cargo will be active (i.e., cytoplasm for siRNA or nucleus for plasmid).

Viruses have evolved to efficiently overcome the latter two barriers, but achieving efficient access to the desired target cells is still a challenge. The successful design of synthetic delivery systems requires consideration of all three of these barriers and a thorough understanding of the mechanisms that dictate the interactions of nonviral delivery systems with target cells.

Tissue biodistribution/targeting

The most straightforward approach to site-specific delivery is local application, such as inhalation of dispersed solutions into the lungs to treat cystic fibrosis, or direct injection into the affected tissue, such as muscle for muscular dystrophy. Local, sustained delivery from biomaterial scaffolds is another approach that is especially popular for tissue-engineering, and because this is the unifying topic of this book, we have dedicated the section 'Engineering Tissue Scaffolds for Viral and Nonviral Nucleic Acid Delivery' to tissue-engineering-specific gene therapy technologies. The current section discusses methods for enhancing target site-specific bioactivity of nucleic acid-based drugs delivered intravenously. Systemic delivery systems should be designed with functionalities that enhance the deposition or accumulation (biodistribution) of the therapeutic in a particular tissue, prolong the association of the

therapeutic within the target site, mediate specific binding to and uptake by a target cell population, and increase trafficking of the cargo to the desired intracellular compartment. Typically these functions are achieved through optimization of physicochemical properties to preferentially enhance non-specific accumulation at defined sites and/or inclusion of ligands that target cell receptors uniquely expressed or overexpressed by the target cell type.

Key characteristics for intravenously delivered drug carriers are avoidance of rapid blood clearance by the reticuloendothelial system and preferential accumulation and retention at the site of disease. Long blood half-lives are vital for optimal performance of delivery systems designed to passively accumulate in target tissues. For example, drug carriers with long circulation times can extravasate through abnormally large fenestrations of the cancer vasculature and non-specifically accumulate into tumor tissues through the enhanced permeation and retention (EPR) effect [6]. The EPR effect is believed to occur more in tumors than healthy tissues because tumor blood vessels are characterized by poorly adherent endothelial cells with wide fenestrations and the lack of a smooth muscle cell layer. Therefore, there is easier passage of larger biomacromolecules or NPs from the vasculature. Furthermore, poorly formed lymphatic drainage in tumors is believed to increase retention at these sites. Utilization of EPR-like vascular leakiness to achieve non-specific local accumulation is also potentially a generalized approach for targeting sites of tissue inflammation. For example, in osteoarthritis, synovial inflammation increases local vascular permeability, and long-circulating delivery systems can more readily accumulate at these sites relative to healthy tissues [7].

Optimization of physicochemical properties such as surface charge, size, shape, and mechanical properties are major design considerations for achieving the desired biodistribution of nonviral delivery systems (see recent reviews [8,9]). Traditionally, nanocarriers have been synthesized using bottom-up synthetic approaches to form NPs such as micelles, dendrimers, and liposomes (examples discussed in more detail below in the section 'Nonviral Nucleic Acid Delivery') that have been predominantly limited to formation of structures spherical in shape. For these spherical structures, it has been hypothesized that NPs in the size range from approximately 10—200 nm may be ideal. Structures smaller than 10 nm suffer from rapid renal filtration and systemic clearance. It has been reported that the upper limit for escape from tumor leaky vasculature may be as high as 1.2 μm, though it varies based on tumor location and type [10,11]. In a study of 80, 170, and 240 nm spherical NPs, the smallest NPs had longer circulation times, decreased hepatic clearance, and increased tumor accumulation relative to larger particles [12]. Furthermore, smaller particles would be more desirable in terms of more rapid diffusion through the tissue matrix and potentially achieving more homogenous tissue distribution following vascular extravasation [13]. Thus, it may be desirable to design gene delivery vectors to be as small as possible, as long as they are above the size cutoff for renal filtration.

In addition to size, the shape of nonviral vectors has a significant effect on behavior for *in vivo* systemic delivery applications; for example, rod-shaped filomicelles have ten times longer circulation times relative to spherical micelles [14]. Recently, innovative techniques have been developed in labs such as those of Mitrogotri [15], DeSimone [16], and Roy [17] that enable nanofabrication of particles with arbitrarily-defined size and shape. Decuzzi and Ferrari have contributed computational modeling and *in vivo* experimental data on this topic, and they have uncovered a significant effect of particle shape on biodistribution and ability to achieve vascular targeting [18]. In recent studies, these authors showed that shape-defined, discoidal porous silicon nanovectors accumulate up to five times more in tumor tissues than spherical particles with similar diameters, and these shape-defined particles have also been effectively utilized for two-stage delivery of siRNA [19]. In the case of micron sized particles, stiffness of particles has been shown to have a significant impact, with stiffer particles rapidly distributed to the lungs, and those with a lower elastic modulus preferentially sequestered in the spleen [20].

Surface chemistry, in particular surface charge, can be tuned to act synergistically with physical properties such as size and shape in order to engineer optimal delivery systems. For example,

neutrally-charged NPs generally have lower rates of opsonization [21], and cationic NPs with superficial amines produce the highest levels of complement activation [22]. Xiao et al. recently utilized a micellar NP (~20 nM in size) to systematically study the effect of surface charge on biodistribution of a series of seven NPs with zeta potential ranging from −27 to +37 mV in tumor-bearing mice [23]. Using a ratio to represent the preferential accumulation in the tumor relative to the liver, NPs with a zeta potential of −27, −18, −9, +4, +19, +30, and +37 mV produced tumor:liver ratios of 0.82, 1.28, 1.75, 1.18, 0.84, 0.60 and 0.40, respectively. The authors determined that a 'slight' negative charge (in their case, −8.5 mV zeta potential) was ideal for tumor accumulation and that 'highly' positively or negatively charged NPs were preferentially cleared by macrophages (Kupffer cells) in the liver. Arvizo et al. [24] produced similar results using gold NPs, and they found that neutral or zwitterionic surfaces (−1.1 or −2 mV, respectively) produced longer circulation times and better tumor biodistribution than highly negative (−38 mV) or positive (+24 mV) NPs.

As discussed in more detail in the section 'Nonviral Nucleic Acid Delivery', most nonviral nucleic acid delivery systems involve formulation with an excess of cationic biomaterials in order to tightly package the polyanionic nucleic acid cargo into nano-sized particles. Unfortunately, the presence of surface-exposed cationic materials is not amenable to achieving the optimal, 'slightly' negative surface charge desirable for systemically delivered nonviral vectors. Attachment of poly(ethylene glycol) (PEG), or PEGylation, is a popular approach for giving cationic carriers more stealth by shielding non-specific cell interactions, reducing reticuloendothelial system clearance, and extending the blood circulation half-lives [25]. There are several fundamental properties of PEG that make it desirable for systemic delivery applications. It is a flexible, hydrophilic, and non-toxic polymer that reduces opsonization and non-specific interaction with blood cells. It can diminish the access of degradative enzymes to drug cargo and provide increased steric bulk, which minimizes rapid renal clearance. The desirable performance of PEG is well documented in these regards, and PEG polymers are incorporated into therapeutic proteins and liposomal drug nanocarriers currently in the clinic.

For gene therapy, one risk is that the inertness achieved by PEGylation can mask underlying functionalities necessary to trigger cell uptake and/or endosomolytic activity of nonviral delivery systems. The most common strategy for increasing internalization of PEGylated nanocarriers is incorporation of ligands, antibodies, or peptides that bind to specific cell receptors that internalize drug carriers and ferry them into the cell, and this approach will be discussed in more detail below. Several promising approaches are also under development for attaching PEG by linkages that are reversible when exposed to signals uniquely present in the target tissue. For example, one can use attachment chemistries that are labile when exposed to tumor microenvironmental hallmarks such as mild acidity and high matrix metalloproteinase (MMP) activity in order to trigger shedding of PEG from the nanocarrier surface [26–28].

Conjugation of cell receptor ligands to the surface of (PEGylated) nonviral carriers is one of the most studied preclinical approaches for enhancing localization, retention, and bioactivity in specific target tissues. Targeted delivery can potentially increase bioavailability of the therapeutic agent at its site of action and concurrently reduce off-site effects. Significant progress has been recently made in actively targeting unique markers on the vascular endothelium in specific tissues. For example, phage display technology has been instrumental in identifying targeting peptides that bind to specific 'vascular zip codes', and peptides identified using this technique present a potentially promising strategy for enhancing tissue-specific accumulation of nonviral delivery systems [29]. In order to achieve delivery into the tissue, transcytosis must occur across the vascular endothelium or, for the brain, the blood-brain barrier (BBB). Recently, systemic strategies to increase drug penetration into the brain have been developed, including temporary disruption of the blood brain barrier, chemical modification of available therapeutic substances, utilization of endogenous transport systems, and employment of lipid-based delivery systems [30].

Many other targeting approaches increase binding to cells at the target site once extravasation from the vasculature has occurred, i.e., following tissue accumulation through the EPR effect. For these approaches, biodistribution is primarily dictated by the physicochemical properties of the vector, and the targeting moiety affects retention and/or bioactivity at the site. Active binding to extravascular cells in the target site can enhance local retention through decreased diffusion or clearance from the tissue, and this prolonged residence time and/or targeting to actively internalized receptors can improve bioactivity. For example receptors for ligands such as transferrin [31] and folate [32] are commonly targeted because they have increased expression on a variety of cancer types and because targeting these internalizing receptors can be used to deliver cargo intracellularly through receptor-mediated endocytosis. The ligands themselves (i.e., folate and transferrin) can be used to functionalize nonviral vectors or antibodies against these receptors can be utilized. While there has been limited clinical success of targeted nonviral vectors to this point, a variety of techniques are being actively pursued to develop targeting moieties based on natural ligands, antibodies or their fragments, peptides, aptamers, sugars, and small molecules, and screening techniques such as peptide phage display are aiding in the discovery of new tissue-specific drug targets. Though they will not be reviewed in detail here, it should also be mentioned that several methods have also been studied for externally-stimulated tissue targeting and drug release in response to an externally applied stimulus, such as light, ultrasound, ionizing radiation, or magnetic force [33].

Cellular uptake and intracellular trafficking

Once gene delivery systems have reached the target tissue, their route of internalization and trafficking to the desired subcellular compartment is paramount to achieving optimal bioactivity. To a large degree the mode of internalization dictates the subsequent route of trafficking within the cell. Thus, an understanding of intracellular uptake and trafficking facilitates the design of better and more efficient gene delivery systems. For additional information, the reader is referred to recent reviews on nanovehicular uptake and trafficking [34,35].

Endocytosis is a generalized terminology used to describe cellular internalization. Endocytosis of nonviral vectors is the result of co-localization with the external side of the cell membrane (via receptors or non-specifically) followed by formation of invaginations in the cell's plasma membrane that bud off inside the cell, forming lipid bilayer-enclosed vesicles that sequester the internalized cargo. Three kinetic modes of endocytosis can be defined: fluid-phase, adsorptive, and receptor-mediated endocytosis [36]. Fluid-phase endocytosis refers to the bulk uptake of solutes in exact proportion to their concentration in the extracellular fluid. This is a low-efficiency, non-specific process. In contrast, receptor-mediated endocytosis involves internalization of macromolecules that are bound and concentrated at the cell surface before internalization. In adsorptive endocytosis, molecules preferentially interact with non-specific binding sites (e.g., electrostatic interaction of cationic vectors with anionic heparin sulfate proteoglycans). Internalized endocytotic vesicles subsequently undergo a complex series of fusion events that direct the internalized cargo to other intracellular compartments.

Endocytosis occurs by multiple mechanisms that fall into two broad categories: phagocytosis, or cell eating (of large particles), and pinocytosis, or cell drinking (of fluid and solutes) [37]. Phagocytosis is typically restricted to specialized mammalian cells (dendritic, macrophages, monocytes, and neutrophils). Distinct subcategories of pinocytosis will be discussed further below, including macropinocytosis (MPC), clathrin-mediated endocytosis (CME), caveolae-mediated endocytosis (CavME), and lipid raft-mediated endocytosis (LRME). Transcytosis and exocytosis, though they will not be discussed at length here, are 'competing' cellular pathways that involve passage directly through the cell and expulsion of intracellular material into the external environment, respectively. A summary of different mechanisms is presented in Table 35.1, and schematic illustrations of different uptake/exocytosis mechanisms and their possible intracellular fates are depicted in Fig. 35.1.

TABLE 35.1 Efficiency of nanoparticle entry via multiple portals as differentiated by cargo chemistry/size[a] and cell type

Phagocytosis	Pinocytosis					
		Macropinocytosis (fluid phase)	Clathrin-mesiated (CME)	Caveolae-mediated rafts	Lipid rafts	Clathrin- and Caveolin-independent
Vehicle size	1–10 μm[b]	1–5 μm[b]	<150 nm	<60 nm	40–60 nm	200–300 nm
Cell types	Dendritic, macrophages, monocytes	Many cells	Many cells	Differentiated endothelial cells, apipocytes, epithelial, and muscle cells	Lymphocytes, cancer cells, rodent macrophages	Specialized cells, endothelial cells, and others
Efficiency of uptake[c]	+++++ for specialized cells	+++	+++++	+	+	++++

[a]*Typically, cargo chemistry determines a size range due to technological limitations (e.g., dendrimer-based and micellar-based nano-vehicles are limited to rather small sizes).*
[b]*Phagocytosis and macropinocytosis most likely do not contribute to the nanovehicular uptake.*
[c]*The efficiency of uptake may depend on nanoparticle type and chemistry. The proportion between different uptake mechanisms may vary. Estimated on scale of 1–5, 5 being the highest.*

Macropinocytosis is generally considered to be a non-specific process where cells take up large volumes of extracellular fluids and solutes. Macropinocytosis is characterized by membrane ruffling and formation of protrusions that ultimately produce large endocytic vesicles called macropinosomes (>1 μm in size, up to 5 μm), which sample large volumes of the extracellular milieu. The macropinocytosis process is constitutive in specialized cells (macrophages and dendritic cells) and in some tumors, and greater internalization may be achieved by non-specific binding of solutes to the cell membrane (adsorptive pinocytosis). Although the pH of macropinosomes decreases, they do not fuse into lysosomes. This pathway provides some advantageous aspects, such as the increased uptake of particles and macromolecules, the avoidance of lysosomal degradation, and the ease of escape from macropinosomes because of their relatively leaky nature.

CME constitutively internalizes cell membrane sites with concentrated receptor–ligand complexes to form clathrin-coated vesicles (size ~100–150 nm), and it functions for efficient cell uptake of essential nutrients, antigens, growth factors, and pathogens. Since receptors are differentially expressed in various cells types and tissues, receptor-mediated endocytosis via clathrin-coated pits provides a potential strategy for cell- and tissue-specific delivery of nonviral gene vectors. Molecules entering via this pathway experience a drop to approximately pH 6 in the early endosomes, with a further reduction to approximately pH 5 during progression to late endosomes and lysosomes [38]. While the initial events in the endocytosis of the receptor–ligand complex are similar for most systems, the processing of the ligand can differ, depending on both receptor and cell type. Following CME, ligands and receptors are sorted to their appropriate cellular destinations, such as lysosomes, the Golgi apparatus, the nucleus, or back to the cell surface membrane. In the conventional model, the internalized ligands are degraded in the acidic endo-lysosomal compartments while the receptor is recycled back to the plasma membrane.

CavME is mediated by flask-shaped invaginations in the cell membrane called caveolae (50–60 nm in size) that are particularly abundant on endothelial cells. Caveolae are cholesterol and sphingolipid-rich microdomains of the plasma membrane, and they are concentrated 'hot spots' for a diversity of signaling molecules and membrane transporters. A unique aspect of CavME is that it is a non-acidic and non-digestive route of internalization that bypasses lysosomes and thus may be an advantageous route for drug delivery. However, caveolae are internalized slowly and their fluid-phase volume is small; this results in low capacity for uptake of external cargo. Thus, it is unlikely that they contribute significantly to constitutive endocytosis, although in endothelial cells, caveolae constitute 10–20% of the cell surface [37].

Lipid raft-mediated, endocytosis-independent uptake is an alternative pathway that can be operative for anionic and neutral-lipid liposomes, solid-lipid NPs, and hydrophobic (i.e., polystyrene) NPs. Lipid rafts are cholesterol and sphingolipid-rich 40–60 nm microdomains and are characteristic of cells that lack caveolin and caveolae. This uptake mechanism is likely mediated through scavenger receptors that are involved in the uptake of both lipophilic and anionic cargo [39]. For example, scavenger receptor class B (SRB1; CD36 superfamily of proteins), which is expressed on mature macrophages, binds to a diversity of protein, polyribonucleotide, polysaccharide, and lipid ligands that are 'polyanionic'. The involvement of SRB1 in liposome uptake was further supported by the competitive inhibition of hepatic cell uptake of neutral phospholipid/cholesterol liposomes by the strong polyanion polyinosinic acid [40]. Lipid raft-mediated endocytosis bypasses lysosomes and is facilitated by a transmembrane potential that exists across cell membranes. This is a unique feature relative to caveolae-mediated endocytosis, which requires an energy input.

Physicochemical properties of NPs play a significant role on the level of uptake and the mode of transport into cells. Numerous studies have shown that surface charge has a significant impact on cellular internalization of nanocarriers [41]. Size has also long been known to affect uptake, with several studies concluding that NPs in the 100–200 nm range possess the best

properties for cellular uptake [42]. Great strides have been made in the last decade in terms of understanding the interplay between size and shape on cell internalization. Using polystyrene particles of various sizes and shapes, Champion and Mitragotri studied phagocytosis by alveolar macrophages, and they were some of the first to report on the importance of shape rather than just size [43]. In particular, the local particle shape at the cell-particle interface was found to dictate macrophage phagocytosis versus spreading on particles (Fig. 35.2a). Recently, DeSimone et al. tested uptake in non-phagocytic HeLa cells for a series of particles with varying sizes and shapes that were fabricated using a lithographic method called PRINT (Particle Replication In Non-wetting Templates; Fig 35.2b) [44]. They found that the internalization kinetics of the NPs by HeLa cells depended on aspect ratio and particle size and/or volume. The most striking finding was that rod-like particles were internalized more rapidly, with cylindrical particles of 150 nm diameter and a 3:1 aspect ratio showing the most rapid uptake in their study. Their data also indicated that the PRINT particles utilized a combination of the different internalization pathways described above to enter the cells, suggesting that size and shape alone cannot be utilized to fully define the mechanism of uptake and subsequent intracellular trafficking.

In addition to optimizing their physical properties, nanovectors can be endowed with a variety of other specialized constituents that dictate their mode of cellular internalization, either by binding to specific internalizing receptors or by directing traffic to specific intracellular compartments such as the cytoplasm and nucleus. Several examples of amine-containing polymers exist that buffer endosome acidification and lead to endosome disruption through the osmotic proton sponge mechanism, which is discussed in more detail in the section 'Nonviral Nucleic

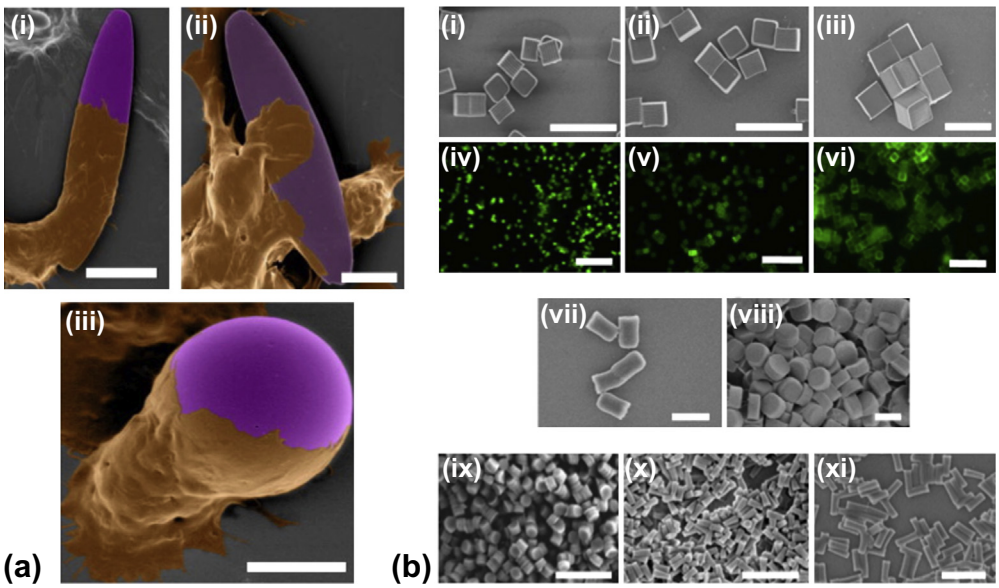

FIGURE 35.2

Nanoparticulate shape variation. (a) Scanning electron microscopy images provided evidence that particle internalization is dependent on local particle shape from the perspective of the phagocyte (cells and particles were colored brown and purple, respectively). Phagocytosis progressed further when the cell approached the end of the opsonized elliptical particle relative to when contact was initiated on the flatter, more elongated side of the particle. Phagocytosis progressed further when a smaller particle dimension was approached by the cells, i.e., as shown for the smaller spherical particle in panel (iii). Scale bar = 10 μm is sub-panel (i) and 5 μm in sub-panels (ii)—(iii) (43). (b) Panel of micrographs demonstrating PRINT particles varying in both size and shape. Sub-panels (i)—(iii) show scanning electron micrographs of cubic particles of size 2, 3, and 5 μm, respectively, and sub-panels (iv)—(vi) show fluorescence micrographs of the same cubic particles. Sub-panels (vii) and (viii) show scanning electron micrographs of cylindrical microparticles of 1 μm in height with diameters of 0.5 and 1 μm, respectively. Sub-panels (ix)—(xi) show scanning electron micrographs of (ix) 200 nm diameter and 200 nm height (x) 100 nm diameter and 300 nm height and (xi) 150 nm diameter and 450 nm height. Scale bars = 20 μm for (i)—(vi) and 1 μm for (vii)—(xi) (44).

Acid Delivery' below. Poly(alkylacrylic acids) are another class of polymers that can mediate endosomolysis, but they act through an active membrane disruption mechanism. In this case, protonation of carboxylates within acidic environments transitions the polymers from an anionic, hydrophilic state into an uncharged, hydrophobic, and more compact state that is membrane interactive/disruptive [45]. NPs that show a transition in their surface charge from anionic (at pH 7) to cationic in the acidic endosomal pH (pH 4–5) have also been shown to enable escape from endosomal compartments [46].

For plasmid gene delivery, trafficking to the nucleus is of particular significance. As discussed below in the section 'Nonviral Nucleic Acid Delivery', polymers and lipids are the two main classes of biomaterials used to formulate nonviral vectors, and choice of vector can affect, among other things, the mode of cell internalization. For example, the uptake of cationic lipids proceeds mainly by the clathrin-dependent pathway, but internalization of polymer-based systems is more dependent on the polymer and the cell type. Polymer-based delivery systems can proceed by both clathrin-dependent and clathrin-independent pathways simultaneously in the same cells [47]. Independently blocking either the clathrin- or caveolae-dependent pathway does not dramatically affect quantity of uptake, but blockage of caveolae-mediated uptake significantly abrogates gene expression, suggesting this route of uptake plays a significant role in intracellular trafficking to the nucleus [47,48]. In agreement with this result, Sullivan and authors have shown that use of histone H3 tail peptides that predisposes trafficking of polyplexes to caveolar pathways can be used to enhance plasmid transfection [49]. Their follow-up work has provided mechanistic evidence that caveolar polyplexes are trafficked to cell nuclei through a retrograde Golgi-to-ER (endoplasmic reticulum) pathway [49]. Other mediators of intracellular trafficking have also been successfully co-delivered to modulate NP intracellular trafficking. For example, fusogenic endosomolytic peptides or nuclear localization signals (NLS) can be attached to NPs to enhance targeting to the nucleus. Recently, it has also been shown that treatment with histone deacetylase (HDAC) inhibitors can be used to liberate polyplexes from sequestration at the perinuclear recycling compartment/microtubule organizing center (PNRC/MTOC) and to increase transgene expression by up to forty-fold [50].

VIRAL NUCLEIC ACID DELIVERY

Introduction to viral gene therapy

A virus is a NP consisting exclusively of biological components, including proteins, lipids, carbohydrates, and nucleic acids. Each virus carries a viral genome that encodes the structural and functional elements of the infectious particle, but does not encode the necessary machinery for transcription, translation, and genome replication. Therefore viruses infect living cells and can only replicate inside these hosts by hijacking native cellular transcription and translation processes.

Viruses have evolved over billions of years to be extremely effective at infecting and replicating within host cells. Therefore, many of the challenges of nonviral gene delivery, such as cellular uptake, trafficking, and nuclear import, are readily addressed by the innate biological properties of viral vectors. To take advantage of these properties, researchers have re-engineered natural viral vectors by removing all pathogenic components and signals necessary for virus replication within infected cells, and replacing them with therapeutic genetic sequences. This approach has been widely successful in engineering vectors for efficient gene delivery in research but has encountered severe hurdles en route to clinical efficacy.

The first gene therapy clinical trial occurred in 1990 and used a retroviral vector for gene delivery to T cells of patients with severe combined immunodeficiency [51]. Over the past decade, there have been roughly 100 new clinical gene therapy clinical trials each year worldwide [52]. Over 66% of these trials have used viral vectors for gene delivery. The first gene therapy approved for clinical use was an adenoviral p53 vector for cancer treatment in China in

2003 [53]. More recently, a second gene therapy was approved in Europe consisting of an adeno-associated virus (AAV) encoding a gene to treat a rare genetic disorder known as lipoprotein lipase deficiency [54]. These are the only two approved gene therapies, which is a reflection of both the potential for viral gene therapy, but also of the challenges in engineering either viral or nonviral vectors with the ideal combination of efficacy and safety necessary for broader clinical adoption.

The recent approval of an AAV-based gene therapy in Europe, as well as many other clinical successes of viral gene therapy in recent years, are anticipated to pave the way for other new gene and cell therapies [55]. However, the viral gene therapy field encountered severe complications before reaching this more recent sequence of positive results. In 1999, a patient named Jesse Gelsinger was treated in a clinical trial with an adenoviral vector as a therapy for a genetic metabolic disease. He died four days after vector administration due to a severe inflammatory episode and multi-organ failure, which was later linked to an immune response against protein components of the virus [56]. One year later, another landmark event occurred when the first reports of successful gene therapy for curing a genetic disease, in this case a fatal immunodeficiency disorder, were reported [57]. In all, 20 children were treated with autologous hematopoietic stem cells transduced with retroviral vectors carrying a therapeutic transgene, and ultimately 17 of these patients were cured of the disease [58]. However, five of these cured patients later developed leukemia as a result of integration of the viral vector into the genome near to an oncogene, leading to oncogene activation [59]. One of these five patients died as a result of the leukemia. Due to these adverse events, viral gene therapy was the subject of social and scientific stigma in the first part of the twenty first century. However, scientists have been able to identify and address the mechanistic causes of these adverse events, leading to improved viral vectors and numerous ongoing and successful clinical trials as described above. Nonetheless, the fundamental source of these challenges is the complexity of viral vectors, each of which contains hundreds to thousands of copies of dozens of distinct biological macromolecules that perform complex functions. This is a primary motivating factor for engineering nonviral delivery vehicles comprised of defined chemical components to achieve precise control over all elements of gene transfer and expression.

Although the clinical trial results discussed above are largely focused on rare hereditary disorders, the history and critical concerns of viral vector development are essential to understanding the potential of viral nucleic acid delivery for tissue engineering and regenerative medicine. Furthermore, new medical technologies such as gene delivery are often first developed for fatal diseases for which there is no other option, such as genetic disorders and cancer. The technology development and demonstration of safety and efficacy of gene transfer in these areas is directly translatable to applications in other fields, including tissue engineering.

Types of viral vectors

A variety of viral vectors have been employed to deliver genes to cells. Each approach has its own advantages and disadvantages, including packaging capacity, persistence of expression, immunogenicity, and non-specific effects on the cellular genome [60,61].

Adenoviruses are the most commonly used therapeutic viral vector, largely due to applications in cancer therapy. An adenovirus consists of a double-stranded DNA genome and a protein shell, known as a capsid (Fig. 35.3). The adenoviral particle binds to cells through fiber proteins in the capsid that recognize specific receptors on the cell surface, followed by endocytosis of the virus. The adenoviral vectors exist extrachromosomally in the nucleus and therefore they are not copied with the cellular genome during cell division. As a result, gene expression is transient as the vector is degraded or diluted out during cell replication. The adenovirus has an outstanding ability to escape endosomes, enter the cytoplasm, and pass through the nuclear membrane pore. Despite extensive investigation of dozens of viral vectors for cancer treatment and promising results in clinical trials, the FDA (Food and Drug

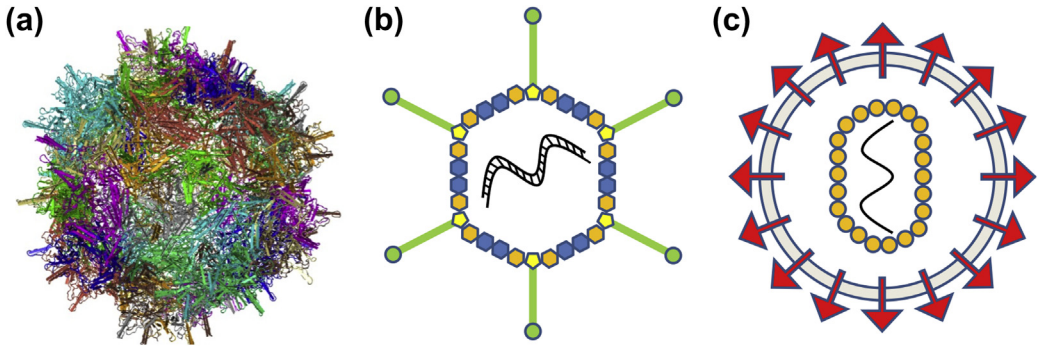

FIGURE 35.3

Representative schematics of viral structures. (a) Adeno-associated virus. The crystal structure of the AAV capsid proteins that encompass the vector and interact with cellular receptors is shown (MMDB ID 20256). Capsid monomers are represented by different colors. (b) Adenovirus. Adenoviral vectors consist of a capsid shell made up of proteins known as hexon (blue), penton (orange), and the penton base (yellow), to which the fiber protein (green) is attached. The double-stranded DNA viral genome is packaged inside the capsid. Other accessory proteins are not shown. (c) Retrovirus/Lentivirus. Retroviral and lentiviral vectors are encompassed with a lipid bilayer envelope (gray), which contains proteins that interact with cell surface receptors (red). Within the envelope, a capsid shell (orange) surrounds the single-stranded RNA genome.

Administration) has not approved any virus-based therapeutics because of widely reported toxicities and immunogenicity of the capsid proteins [62]. Because of this significant immunogenicity, any adenoviral vector can only be delivered once to a patient. Therefore, adenoviruses are not an optimal choice for chronic conditions but can be very useful for modifying cells *ex vivo*. The primary advantage of the adenovirus is its ability to achieve very high concentrations of viral preps ($>10^{12}$/ml). Unlike unstable RNA viruses with lipid bilayers, including retroviruses and lentiviruses, adenoviruses can easily be concentrated to high viral titers and can infect dividing as well as non-dividing cells with high efficiency. This is a major advantage for some applications, including *in vivo* gene transfer to tissues such as the lung, where cell division is infrequent.

Adeno-associated viruses (AAV) are small viruses with single-stranded DNA genomes and a protein capsid (Fig. 35.3). Unlike other viral vectors developed for gene therapy, wild-type AAV is not known to cause any human disease. The main disadvantages of AAV are that the vector can efficiently package only small transgene cassettes (up to 4.7 kb), the capsid proteins can be immunogenic, and the preparation of the recombinant vector is complex. Nonetheless, AAV is quickly becoming the preferred vector in the gene therapy field [63,64]. This is because like adenovirus, AAV can be prepared to high concentrations and is relatively stable in storage. Additionally, recombinant AAV does not efficiently integrate into the genome and, therefore, there is little risk of disruption of native genes. In contrast to adenoviruses, the AAV vector is particularly stable within the nucleus and can exist with high levels of gene expression for months or years [65,66]. As discussed in more detail below, many serotypes of AAV exist and the capsid proteins are exceptionally flexible for being re-engineered to target new cell types. AAV can also be engineered for tissue-specific targeting following systemic delivery [67].

Retroviral and lentiviral vectors contain a single-stranded RNA genome, a protein capsid, and a lipid bilayer, known as the envelope, that also contains transmembrane proteins (Fig. 35.3). The vectors are able to efficiently carry about 8–10 kb of transgenic material. A disadvantage of these vectors relative to adenoviruses and AAVs is that the RNA genome and lipid bilayer make them comparably unstable, with a half-life of less than 12 hours at 37°C. This also creates challenges for storage, and the titers of these viruses are relatively low (10^6–10^7 particles per ml), although they can be concentrated to $>10^9$/ml. The major advantages of retroviral- and lentiviral-mediated gene transfer are that recombinant viruses are capable of transferring genes to a wide range of different primary cell types, in contrast to nonviral systems, and the genes

are stably integrated into the chromosomal DNA. Therefore these vectors are ideal for applications requiring long-term gene expression. However, the integration of these viral vectors into the genome also has the potential to disrupt endogenous genes, such as critical oncogenes and tumor suppressors, as discussed above [68]. There are two ways in which this has been addressed. First, self-inactivating (SIN) vectors have been developed in which the strong viral promoters and viral splice sites have been disabled, and therefore, the virus is less likely to alter the expression of nearby genes [69]. Second, integrase-deficient lentiviral vectors have been engineered that have the advantages of high-efficiency lentiviral transduction. However, these virions do not integrate into the genome, and they result in only transient gene expression [70]. It is becoming more common that lentivirus is preferred over retrovirus, as retroviral transduction is dependent on cell division whereas lentiviral transduction is not [71].

Herpes simplex virus type-1 (HSV-1) is a human neurotropic virus used primarily as a vector for gene transfer to the nervous system, although the wild-type HSV-1 can infect and lyse other non-neuronal epithelial cells [72]. Because of its large genome size, up to 30–50 kbp of transgenic material can be packaged into recombinant HSV-1 vectors. At present, two major classes of HSV-1 vectors have been developed: replication-defective viruses and replication-conditional mutants. However, the ability of HSV and these mutant recombinants to establish lifelong latent infections raises concerns about the use of these vectors in humans. Efforts have been made to create HSV-1 amplicon vectors essentially free of HSV-1 helper virus, which might be a promising genetic vehicle for *in vivo* gene delivery.

Most commonly, viral vectors are used to deliver cDNAs of transgenes encoding proteins that will confer some therapeutic effect. In the context of tissue engineering, these transgenes may facilitate progenitor cell expansion, cell differentiation, tissue formation, and/or wound healing. However, viruses can also be used to deliver small interfering RNAs to silence target gene expression [73]. In order to take advantage of the RNAi mechanisms of processing short double-stranded RNAs by the RISC complex, viral vectors are designed to express shRNAs that mimic the structure of the naturally occurring miRNAs. Both AAV and lentiviral vectors are routinely used for shRNA-mediated gene knockdown. Other possible cargo for viral vectors includes aptamers and ribozymes [74]. Viral particles have also been engineered for the transfer of proteins across the cell membrane [75].

Engineering viral vectors

The natural evolution of viruses has produced a wide variety of gene transfer vectors with innate capabilities for overcoming many of the challenges of gene delivery to living cells, including recognition of cell surface proteins, internalization, endosomal escape, trafficking to the nucleus and transfer across the nuclear membrane, and ultimately transcription of viral genes. However, these natural properties do not necessarily address all of the challenges for many applications of gene delivery for gene therapy, regenerative medicine, and tissue engineering. Additional challenges include virus purification, immunogenicity of viral proteins, proper virus localization following systemic delivery, targeting the virus to specific cell types, tissue-specific gene expression, and controlled release of viral vectors from biomaterials. To address these challenges, the biological properties of these vectors can often be re-engineered via rational design. Alternatively, the complex properties of these systems may be more easily altered by high throughput selection of large libraries of variants of viral particles [76].

Viral particles predominantly interact with cells via the proteins on the surface of the virus. In the case of retroviruses and lentiviruses, these interactions occur through the proteins in the lipid envelope that comprise the outer barrier of the particle, whereas for adenoviruses and AAVs, the capsid proteins encompass the particle [76]. Therefore, exchanging these proteins with those of other serotypes, in a process known as pseudotyping, provides a means of changing the tropism of the virus, which is defined by the types of cells the virus will transduce. Modifying the capsid and envelope proteins can also be used to alter the recognition of the

viral particles by the immune system. For example, pseudotyping adenoviral vectors with alternative capsid proteins led to increased transduction of human cell lines and primary cells, including transduction of intact human saphenous veins and human bone marrow stroma cells for seeding onto scaffolds for bone tissue engineering [77]. Adenoviral pseudotyping has also been used to evade antivector immunity [78]. The pseudotyping of retroviruses and lentiviruses is particularly straightforward since the envelope proteins exist in the lipid bilayer and do not serve important structural roles, as the capsid proteins do [79]. This approach has been used to broaden virus tropism to facilitate transduction of many cell types [80] or to narrow tropism to target transduction to a specific cell type, such as neural stem cells in the brain [81]. Pseudotyping these vectors can also enable the transduction of tissues that are otherwise resistant to gene transfer, such as the airway epithelium [82] and spinal cord [83]. AAV has been pseudotyped both by using capsid proteins from alternative serotypes, mixing capsids from two serotypes, and generating single chimeric capsid proteins with elements from multiple serotypes [76].

As an alternative to pseudotyping, which uses surface proteins from other virus serotypes, grafting targeting peptides into their genetic coding sequence can also functionalize the capsid and envelope proteins. For example, insertion of the Arg-Gly-Asp integrin-targeting peptide into adenoviral vectors has directed viral transduction to cells expressing high levels of integrin receptors [84,85]. This approach has also been used to preferentially direct viral transduction to endothelial cells [86]. Alternatively, biotin-binding peptides [87], single chain antibodies [88], and genetically-encoded imaging agents [89,90] have been incorporated into adenoviral capsid proteins as general approaches for redirecting cell targeting or tracking viral localization. Similar strategies are being explored for AAV [91], although they are in general more challenging due to the structural complexity of the capsid [76]. Single chain antibodies have also been grafted into retroviral and lentiviral vectors to control targeting [92], though typically with a decrease in overall transduction efficiency [93]. Alternatively, growth factors and cytokines have been inserted into the envelope to target transduction to cells bearing the complementary receptor [94,95].

In many cases, our understanding of the structure-function relationships of the viral proteins is insufficient to allow rational design of highly active engineered proteins with new functions. In these circumstances, a directed molecular evolution strategy may be useful. In this approach, large libraries of viral variants are created and library members with desirable properties are selected [96]. For example, display of random peptide libraries on AAV and adenovirus have led to vectors with increased selectivity and/or transduction efficiency of endothelial cells [97] and myoblasts [98]. Random mutagenesis or DNA shuffling and selection of novel AAV capsids has led to new variants with beneficial immune evasion and purification properties [99,100] and enhanced the transduction of human airway models [101,102], specific neural cell types [103,104], and induced pluripotent stem cells [105]. Collectively these technologies provide a means to design improved viral vectors for a variety of applications.

In contrast to genetic modification of the viral proteins, adaptors or chemical modifications can be used to redirect viral transduction. PEGylation can be used to mask viral vectors from the immune system, but in many cases this approach will decrease overall transduction efficiencies [106]. Conjugation of the PEG group to a functional targeting moiety, such as an antibody, can lead to simultaneous protection of the vector and delivery to specific cell types *in vivo*, such as endothelial cells [107]. Other work has used bispecific adaptors that bind both the viral surface proteins and a particular cell surface receptor [108,109]. The incorporation of antibody-binding domains or biotin molecules into viral capsids has led to a general approach in which the virus can be retargeted to any cell type via an antibody linker targeted to a cell surface epitope [110] or a fusion protein of streptavidin and a targeting ligand [111].

The methods described above are predominantly designed to control which cells a virus will transduce. Another approach to controlling gene expression is to use an engineered promoter

that can be regulated in magnitude, time, space, and/or tissue type [112]. These approaches are applicable to both viral and nonviral systems. The most commonly used inducible gene expression system is based on the small molecule antibiotic tetracycline [113]. Examples of this system that are relevant to tissue engineering include its use to control gene expression for bone tissue engineering [114,115], treatment of arthritis [116], and control of drug or hormone production by engineered tissues or implanted cells *in vivo* [117], among others. Systems have also been developed to control gene expression in response to a variety of other chemical inducers, including ecdysone [118], rapamycin [119], and other antibiotics. Other systems to control gene expression of implanted cells have been based on skin lotions [120] and inhaled gases [121]. In addition to chemical inducers, gene expression can also be controlled from promoters that are sensitive to hypoxia and temperature, which have been used to trigger gene-mediated cardioprotection and angiogenesis [122,123]. More recently, optogenetic approaches have emerged in which genes are placed under the control of light-inducible proteins from plants or the eye [124–126]. Consequently, the magnitude, dynamics, and spatial patterning of gene expression can be controlled with illumination *in vitro* and *in vivo*. In the future, this approach may be used to control tissue formation as part of a regenerative medicine strategy. Finally, gene expression can be restricted to certain cell types by regulating transgenes with promoters that correspond to genes only expressed in particular tissues. This approach has been widely successfully employed to create promoters that are specific to bone, cartilage, skeletal muscle, cardiac muscle, and liver.

NONVIRAL NUCLEIC ACID DELIVERY

Introduction to nonviral nucleic acid delivery

While viral delivery systems are equipped with inherent, evolved mechanisms for efficient intracellular delivery, engineered, nonviral nucleic acid delivery systems can offer a well-defined and potentially safer alternative that can be cheaply made on large scales. However, optimizing these systems to approach the efficiency of intracellular delivery achievable with viral vectors has remained problematic. A variety of synthetic systems have been sought for nonviral nucleic acid delivery, primarily based on polymers (synthetic and natural), lipids/liposomes, and inorganic NPs. Significant progress has been made in the development of nonviral carriers that can overcome the primary intracellular delivery barriers such as cellular internalization, escape from endo-lysosomal pathways, and trafficking to the desired intracellular space (i.e., cytoplasm for siRNA and nucleus for plasmid).

Although there are a host of delivery systems that have shown efficacious results *in vitro*, only a fraction have succeeded *in vivo* in preclinical models, and promising clinical data have only recently started to emerge. The remainder of this section will provide a more thorough overview of polymer, lipid, and inorganic NP technologies that have been recently developed for delivery of nucleic acids.

Synthetic polymers

A variety of natural and synthetic polymers have been developed for nucleic acid delivery systems. The literature on the design and utilization of standard synthetic polycations, such as polyethylenimene (PEI), poly(2-(dimethylamino)ethyl methacrylate) (PDMAEMA), and cationic dendrimers, biodegradable synthetic polycations such as poly(beta-amino esters) (PBAE), glycopolymers, and peptide/protein-based polymers is briefly surveyed herein.

The earliest polymeric approaches to nonviral gene therapy employed cationic, amine-rich polymers such as PEI, PDMAEMA, and the cationic poly(amido amine) (PAMAM) dendrimers (Fig. 35.4). PEI is commonly used in both in its linear and branched forms for DNA plasmid delivery, whereas PDMAEMA is typically utilized as a linear homopolymer or as a diblock polymer with PEG or other compositions (e.g., see discussion below on pH-responsive,

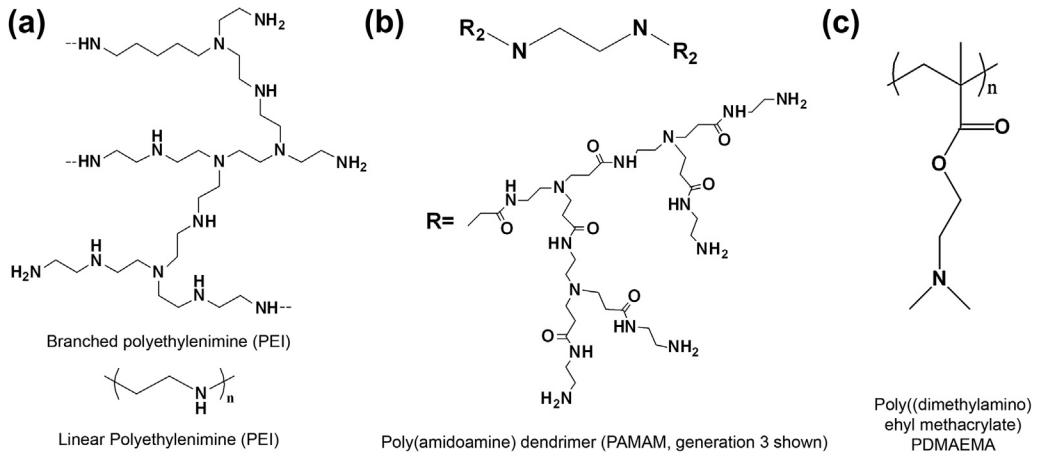

FIGURE 35.4

Polycationic polymers for nanoparticle production. (a) PEI (branched and linear), (b) PAMAM dendrimers and (c) PDMAEMA are representative polycationic polymers that have been thoroughly studied for polyplex formation and delivery of nucleic acids.

endosomolytic micelles with a PDMAEMA corona). Dendrimers such as PAMAM have more complex 'tree-like' architectures that form spherical, monodisperse macromolecules. These branched structures are synthesized either from the central core towards the periphery (divergent synthesis) or starting from the outermost residues (convergent synthesis). Commonly used, commercial PAMAM forms spherical polymers with good aqueous solubility because of its highly charged, exposed surface groups, which include abundant primary amines for convenient functionalization [127].

The amines can serve three primary functions in these systems: nucleic acid packaging, enhanced cell uptake, and endosome escape. By mixing with polycations in aqueous solutions, DNA and siRNA, with their negatively charged, phosphate-containing backbone, can be electrostatically condensed into particles, termed polyplexes. Typically, an excess of the polycation is used during polyplex formation, yielding particles with an overall net positive charge. The positive surface charge of the polyplexes increases interaction with negatively charged cell membranes, a process that is likely mediated through anionic, heparan sulfate proteoglycans anchored on the cell surface [128]. This binding enhances their endocytotic cell uptake. Following endocytosis, these polyplexes are capable of mediating endosomal escape through the osmotic disruption (e.g., the hypothesized 'proton sponge effect') [129].

Cationic polymers composed of secondary and tertiary amines, which enable endolysosomal escape through the proton sponge mechanism, have been shown to efficiently transfect nucleic acids into cells [130]. Although these net cationic polyplexes can effectively delivery nucleic acids *in vitro*, they can cause cytotoxicity, and they have a limited biodistribution profile if delivered intravenously. This is because the cationic surface charge of these polyplexes causes aggregation with serum proteins and red blood cells. These non-specific interactions can cause disproportionate biodistribution to the capillary beds of the lungs, very short circulation times, and acute toxicity [131]. Thus, many recent strategies have focused on decreasing the cytotoxicity and improving steric stabilization of cationic polyplexes. As discussed above, the incorporation of poly(ethylene glycol) (PEG) onto the polyplex surface is an important design aspect for reducing the positive surface charge, improving biodistribution, and decreasing acute toxicity [132,133]. More recently, a number of groups have also pursued bioreducible polycation variants that are degraded by the reducing environment in the cell, and consideration of this design parameter has yielded polyplexes with lower cytotoxicity and higher transfection efficiency [134,135].

Micelles formed from synthetic polymers represent another promising category of nucleic acid carriers [136]. In the area of nucleic acid delivery, the Kataoka group has focused on micelles

driven by electrostatic interactions, or polyion complex (PIC) micelles [137]. These nanovehicles typically self-assemble after mixing of nucleic acids with diblock polymers, consisting of PEG and a polycationic segment such as poly(Lys). This class of carriers has been shown to achieve gene silencing *in vitro*, and recently, a variant composed of a diblock polymer consisting of PEG, poly(Lys) and cyclic Arg-Gly-Asp (RGD) targeting peptides was found to efficiently achieve gene silencing and reduced tumor mass following delivery of anti-angiogenic siRNA [138].

More traditionally, micelles are defined as core-shell self-assemblies of amphiphilic diblock polymers into morphologies where a more hydrophobic block forms the micelle core, and a more hydrophilic block forms the corona. This class of micelles, which self-assemble into NPs in aqueous solutions even in the absence of added nucleic acid, has recently shown great promise [139–141]. One recent example of a micelle-forming polymer is composed of a block of poly(DMAEMA) and a second block that consists of a random terpolymer of 50% butyl methacrylate (BMA), 25% DMAEMA, and 25% propylacrylic acid (PAA) (Fig 35.4). When a concentrated stock solution of this polymer in ethanol is added dropwise into an excess of phosphate-buffered saline (PBS), the polymer self-assembles into micellar NPs of approximately 50 nm in diameter, with the poly(BMA-co-DMAEMA-co-PAA) terpolymer block in the particle core. The 50 mol% of the hydrophobic BMA drives self-assembly, and electrostatic interactions between PAA and DMAEMA also help to stabilize the micelles near physiologic pH. The homopolymer block of DMAEMA forms the micelle corona and provides a cationic surface that can be used to electrostatically condense siRNA into serum stable siRNA-NPs, sometimes referred to as micelleplexes (Fig. 35.5a). DMAEMA and PAA monomers both contain protonatable groups (tertiary amine and carboxylic acid, respectively) with pK values approximately equal to physiologic pH. The net charge of the anionic PAA and cationic DMAEMA is relatively balanced at physiologic pH, which stabilizes the micelle core. However, due to concurrent protonation of DMAEMA and PAA, the core-forming terpolymer block acquires a net positive charge when it enters the acidic endo-lysosomal pathway. This causes a shift to a net cationic state that electrostatically destabilizes the micelle core, exposing the terpolymer block, and activating its membrane disruptive activity (Fig. 35.5b). This terpolymer composition has been fine-tuned for intracellular delivery based on the BMA content [140] so that this pH-driven transition occurs in environments representative of the early and late endosomal compartments.

The micelles in Fig. 35.5a have a cationic surface charge that is not amenable to effective intravenous delivery because, as described for PEI and PDMAEMA homopolymers, particles with cationic surfaces have short circulation times. As discussed above, reversible PEGylation can be utilized to create more stealthy cationic carriers in the circulation while maintaining

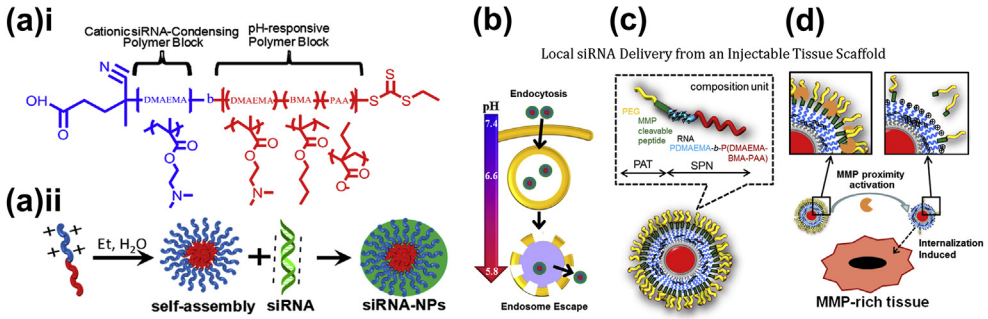

FIGURE 35.5

siRNA-NPs. (a) Diblock copolymer (i) composition and (ii) scheme for self-assembly/siRNA loading. (b) These siRNA-NPs are designed to respond to the more acidic pH in the endo-lysosomal pathways following endocytotic uptake. This triggers endosomal membrane disruptive activity and mediates siRNA delivery into the cytosol. (c) Environmentally activated siRNA-NP with MMP-removable PEG surface layer and (d) concept for MMP-dependent PEG removal and cell uptake.

key, underlying functionalities. For example, a variant of this micelle has been created with a PEG corona that can be removed by naturally occurring proteases for 'proximity activated targeting' (PAT) [27,142–145] (Fig. 35.5c). The intact PEG corona reduces non-specific binding and uptake in the circulation, while high MMP activity at the pathological site releases the corona and triggers activation of the underlying siRNA-NP (Fig. 35.5d).

Evidence suggesting that toxicity profiles are improved with biodegradable versions of traditional polycations has spurred the development of new and better optimized biodegradable polymer chemistries. PBAEs are one very promising class of biodegradable polycationic nucleic acid carriers that have been shown to be superior to *in vitro* transfection reagents such as Lipofectamine 2000 [146,147]. A key characteristic of PBAEs is that they are amenable to parallel, high throughput synthesis for simultaneous screening of large numbers of polymer variants. Using this approach, PBAE compositions have been identified with transfection activity superior to other nonviral agents and that rival the performance of viral vectors in some applications [148,149]. Conveniently, poly(β-amino ester)-based carriers rapidly hydrolyze and degrade into low molecular weight diols and bis(β-amino acids) in response to the pH drop that occurs during endosomal/lysosomal trafficking, which both facilitates nucleic acid release and makes them less cytotoxic than polymers like PEI [146]. Other promising, new biodegradable, polycationic materials in development have shown very promising preclinical data (i.e., poly(amine-co-esters) [150]), supporting the concept that polymeric nonviral vectors will continue to advance nearer to clinical reality.

Polymers derived from natural sources or monomers

Amino acids and saccharide-based materials have been extensively explored for nucleic acid delivery, as more thoroughly reviewed elsewhere [151,152]. These natural building blocks have the potential to have reduced cytotoxicity and if optimized, superior overall function relative to fully synthetic biomaterials. Here, peptide-based and carbohydrate-based nucleic acid delivery polymers will be surveyed.

The first amino acid-based polymer to be pursued was poly(L-lysine) (poly(Lys, Fig. 35.6a) [153], and many iterations of this cationic polymer have been extensively studied in a fashion similar to PEI and the other synthetic polycations described above. Poly(Lys) can efficiently complex nucleic acids, but its transfection efficiency is low, and it requires cell treatment with

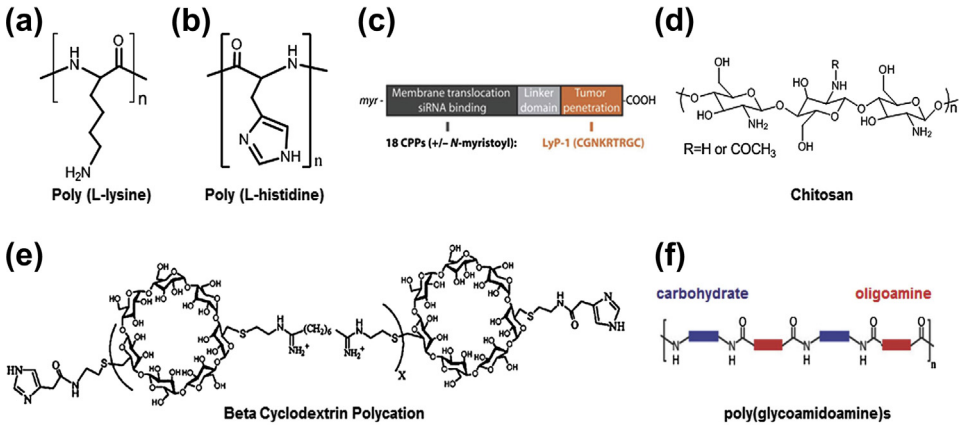

FIGURE 35.6

Examples of polymers derived from natural components that are used for nucleic acid delivery. Amino acid-based polymers such as (a) poly(Lys), (b) poly(His), and (c) CPP-containing peptides have been actively tested for delivery applications. Likewise, (d) chitosan and polymers containing (e) β-cylcodextrins and (f) other carbohydrate-containing polymers such as PGAAs have also shown tremendous potential. *Illustrations in panels c, e, and f are respectively based on references [173,185,255].*

endosomolytic agents such as chloroquine to enhance gene expression. Nonetheless, the early studies on poly(Lys) yielded important mechanistic insights related to polyplex formulation, intracellular trafficking, and endosome escape [153]. While the clinical promise of poly(Lys) is limited, these early studies have had a significant impact on the field.

Poly(histidine) (poly(His)) (Fig. 35.6b) is another amino acid-based polymer that has shown some usefulness for gene therapy. The amino acid His has an imidazole R-group containing a secondary amine that endows poly(His) with proton sponge activity for endosome escape [154]. Polymers containing both Lys and His have also been utilized successfully in combinations. In these hybrid polymers, the primary amines on Lys are fully protonated and cationic at physiologic pH, enabling efficient electrostatic complexation with DNA. The lower pKb of the secondary amines from His provide complementary proton sponge activity for endosome escape [155]. However, the transfection efficiency of polymers with poly(His) grafted to poly(Lys) is significantly improved by the addition of the endosomal disruption agent chloroquine, indicating that the polymers alone are still partially prone to endosomal entrapment [156]. Highly branched architectures of His/Lys polymers and His-containing reducible polycations have also been found to efficiently deliver siRNA [157,158]. There is also a precedent for incorporation of amino acid-based subunits into other gene therapy systems in order to produce 'hybrids' with enhanced delivery functionality. For example, His has also been used to modify chitosan (discussed more below) to enhance its endosomal escape and transfection efficiency [159].

Cell-penetrating peptides (CPPs) and pH-responsive fusogenic peptides are two other classes of peptides that have been rigorously explored to trigger cell uptake and endosomal escape, respectively. These peptide classes have been used both in unison and as components of multifunctional polymer and liposomal delivery systems. Most CPP and fusogenic peptides are derived from bacterial toxins and viral vectors, or they are synthetic analogs of the naturally occurring peptides. The trans-activating transcriptional factor (TAT) of HIV-1 [160] and the antennapedia peptide derived from *Drosophila* [161] are two examples of well-studied CPPs. These peptides are typically rich in cationic amino acids, and as a result, synthetic, arginine-rich CPPs of various types have also been found to mediate biomacromolecular cargo cell uptake. The ability of CPPs to trigger cell internalization has been leveraged for delivery of several classes of therapeutic cargo including plasmid DNA and siRNA (see additional information in recent CPP reviews [162,163]).

Another class of peptides useful for nucleic acid delivery is the fusogenic peptides, which are pH-responsive peptides that can fuse with or form pores through the endosomal membrane. An example is the diphtheria toxin, which has a subunit that forms transmembrane pores in endosomes that enable entry of a disulfide-linked toxin fragment into the cytosol [164]. Another example is hemagglutinin, an influenza protein that creates pH-dependent endosomal membrane fusion to deliver the viral genetic material into the cytoplasm [165]. The peptide GALA is a synthetic, pH-dependent, fusogenic peptide that has been extensively characterized [166]. GALA self-assembles and inserts into lipid bilayers at acidic pH, forming a pore that allows traversal of the membrane [167]. For example, GALA has been successfully applied to enhance efficiency of cytosolic delivery of nucleic acid cargo packaged in PAMAM and liposomes [168–170].

Bhatia and authors recently reported one of the most promising peptide-based nucleic acid delivery approaches to date [171,172]. In their work, they have designed and screened a library of peptides that were made from the fusion of two peptide sequences known to have tumor penetration and CPP activities. A small linker sequence consisting of a 4-glycine spacer was incorporated between the two functional aspects of the peptide, and the CPP N-terminus was modified with by myristylation in order to incorporate more hydrophobicity and to enhance particle stability and the potential for membrane interactions (Fig. 35.6c). In this study they screened a variety of candidate CPPs, including a total of 18 different peptide forms, in order to

optimize performance in terms of uptake, endosomal escape, and cytosolic release/bioactivity [171]. In their follow-up work, they showed that silencing of the oncogene inhibitor of DNA binding 4 (ID4) using this class of carriers suppressed growth of established tumors and significantly improved survival in ovarian tumor-bearing mice [172]. CPPs are generally thought to act through a non-specific cell uptake mechanism that is not desirable for achieving site-specific effects *in vivo*, and this study represents a breakthrough in harnessing the power of CPPs with preferential activity at a specific tissue site.

The polysaccharide chitosan, oligosaccharides like cyclodextrins, and a variety of other saccharide-containing glycopolymers represent another class of polymers for nucleic acid delivery. For example, natural anionic saccharide-based polymers can be fabricated into thermodynamically stable, polyelectrolyte complex (PEC) NPs through spontaneous association triggered via mixing of polyelectrolytes of opposite charge, as reported by Prokop et al. [173,174]. Typically, PEC NPs are made by mixing polyanionic core polymers, such as alginate or chondroitin sulfate with corona polycations such as spermine hydrochloride or poly(methylene-co-guanidine) hydrochloride (PMCG). This multipolymeric nanoparticulate approach has been shown to be effective for gene transfer *in vitro* [175], particularly in cell systems that are normally refractory to gene transfer, such as pancreatic islets and antigen-presenting cells (Fig. 35.7). In addition, PEC coronal surfaces can be decorated with PEG-ligand complexes to increase cell targeting and reduce non-specific uptake.

Chitosan, which is a polysaccharide composed of glucosamine and N-acetyl glucosamine units bonded via β(1→4) glycosidic bonds is one of the most thoroughly studied saccharide polymers (Fig. 35.6d). Chitosan benefits from being a 'green' approach because it is a renewable resource derived from chitin. This natural polymer is also biodegradable and not toxic.

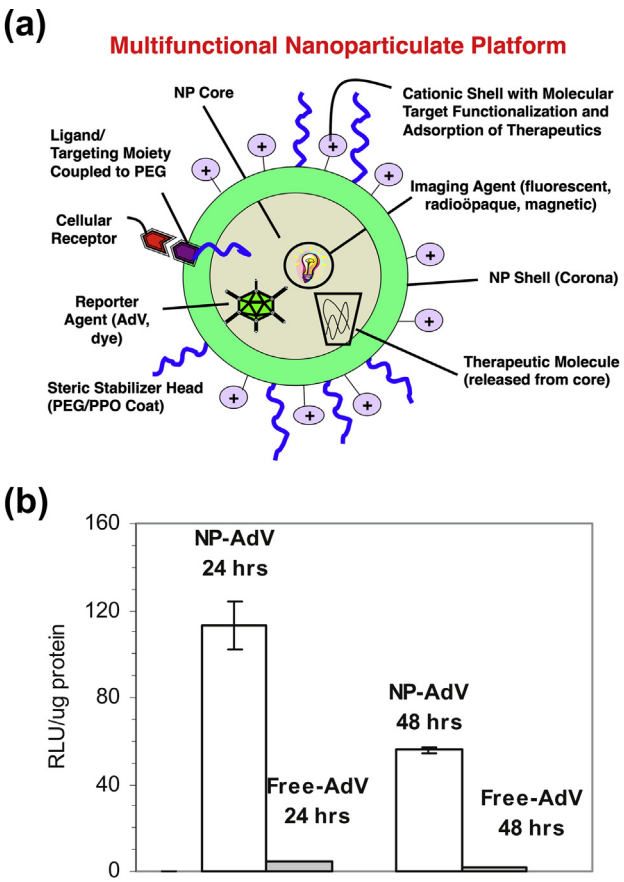

FIGURE 35.7
PEC NPs: Engineering for Enhanced Adenoviral Gene Delivery. (a) Schematic illustration of the construction of a multifunctional, nanoparticulate PEC. The PEC core can serve as a carrier for optical and chemical reporters, viral vectors, imaging agents, and pharmacological agents. The cationic nanoparticle (NP) shell can anchor both stabilizers and targeting ligands. (b) Delivery to pancreatic islets *in vitro*. NP were formed by ultrasonic dispergation of a polyanionic (core) solution of sodium alginate, cellulose sulfate, and a luciferase-expressing adenovirus (AdV) into a cationic (corona-forming) bath containing spermine HCl, PMCG, $CaCl_2$, and pluronic F-68. Particles were then purified by centrifugation. Freshly isolated murine islet cells were transduced with either adenovirus-containing NP or free AdV. Luciferase activity was markedly elevated by nanoparticulate encapsulation of AdV at both time points [175]. *Courtesy of ACS.*

The Alonso laboratory introduced chitosan-based NPs [176] made via ionotropic gelation, based on the interaction between the negative groups of pentasodium tripolyphosphate (TPP) and the positively charged amino groups on chitosan. The chemistry of chitosan is also adaptable to nonviral gene therapy, since it contains several primary and secondary amines capable of endosomolysis via the proton sponge effect. Therefore, chitosan has been examined as a pH-responsive polymer for nucleic acid delivery. Howard et al. employed chitosan NPs containing siRNA to knock down enhanced green fluorescent protein (eGFP) in both H1299 human lung carcinoma cells and murine peritoneal macrophages (77.9% and 89.3% reduction in eGFP fluorescence, respectively) [177]. The chitosan NP has a high potential for transmucosal delivery. Effective *in vivo* RNA interference was achieved in bronchiolar epithelial cells of transgenic eGFP mice after nasal administration of chitosan/siRNA formulations (37% and 43% reduction as compared to mismatch and untreated control, respectively). The principal drawbacks of chitosan are poor solubility in physiological buffers and lower endosomolytic activity compared to some stronger proton sponge polymers. As a result, several variants of chitosan have been made with modifications to increase endosomal escape and solubility. For example, PEI and imidazoles have both been conjugated to chitosan to enhance its performance in gene therapies [178].

Cationic polymers containing beta-cyclodextrins (β-CD) have arguably been one of the most promising polymeric carriers tested to date. Cationic β-cyclodextrin-based polymers (βCDPs, Fig. 35.6e) synthesized by the condensation of a diamino-cyclodextrin monomer with a diimidate comonomer are capable of forming polyplexes with nucleic acids, and their transfection performance depends on βCDP structure [179]. The β-CD-containing polycations are especially unique because cyclodextrins contain an interior cavity that can be used to form inclusion complexes with hydrophobic moieties. For example, β-CD binds tightly to the hydrophobic molecule adamantine, and this provides a convenient 'handle' from which to functionalize the surface polyplexes made from βCDPs with PEG or targeting ligands [180,181]. The Davis laboratory has translated this concept from benchtop to clinical trials [182]. This carrier was the basis for a recent report demonstrating RNA interference in man for the first time using targeted polymeric NPs. This carrier was composed of βCDPs functionalized with both PEG and the cancer-targeting ligand transferrin [183].

A variety of other novel, synthetic cationic glycopolymers are also in the developmental pipeline for clinical applications of nucleic acid delivery [152,184]. The Reineke lab has made key contributions in this area, and an example class of glycopolycations developed by this group are the poly(glycoamidoamine)s (PGAAs, Fig. 35.6f) [184]. A library of PGAAs was made through the condensation reaction between carbohydrate and oligoamine comonomers (Fig. 35.6f). These PGAAs were varied based on a variety of parameters including the carbohydrate size, the hydroxyl number and stereochemistry, the amine number, and whether or not heterocyclic groups were present. These polymers have been screened for gene delivery, and optimized formulations have been identified that facilitate efficient DNA packaging and intracellular delivery properties. The Reineke group has also sought a variety of trehalose-based polymers, and promising results continue to suggest the potential for clinical translatability of this safe and efficient class of polymers [185].

Lipid-based delivery systems

Lipids are one of the most commonly used approaches for nucleic acid transfection. Lipid agents can form small, artificial, spherical liposomal vesicles with a lipid bilayer membrane surrounding an aqueous interior. Liposomes can be produced from natural non-toxic phospholipids and cholesterol. Liposome properties vary substantially with lipid composition, size, surface charge, and the method of preparation. Because of their size, hydrophobic and hydrophilic compartments, as well as biocompatibility, liposomes are promising systems for drug delivery. Hydrophilic drugs can be encapsulated, or cationic lipids can be used to form

lipoplexes with anionic nucleic acids. Like other nucleic delivery systems discussed, PEGylation can be used to shield liposomal surfaces to reduce non-specific protein and cell interactions and to improve circulation time [186]. Targeting of liposomes has also been accomplished by anchoring a variety of targeting ligands, such as antibodies, to the liposomal surface [187]. The earliest approaches to lipid-based nucleic acid delivery focused on cationic lipids such as N-[1-(2,3-dioleyloxy)propyl]-N,N,N-trimethylammonium chloride (DOTMA, Fig. 35.8a) and were initiated over 20 years ago [188].

The majority of IV-delivered siRNA drugs that have advanced into clinical testing to date employ lipid-based delivery systems, with the lipid NP (LNP) delivery technology serving as the centerpiece for numerous trials on candidate drugs developed by Tekmira and Alnylam. Langer and Anderson have been significant contributors to the recent literature on optimization of lipid-like materials for delivery of siRNA through a series of high throughput combinatorial approaches seeking to identify optimized lipid-like materials, or lipidoids, for siRNA delivery. In some of the first published work using this approach, they synthesized nearly 700 lipidoids based on the conjugate addition of alkyl-acrylates or alkyl-acrylamides to primary or secondary amines [189]. This library featured compounds with varied alkyl chain length, linker degradability, amine R-groups, and post-synthesis quaternization of the amine to induce stable cationic charge (Fig. 35.8b). The resulting lipidoids were used to package siRNA and screened for optimal transfection efficiency *in vitro* and *in vivo*. In these studies, efficient gene silencing activity was shown in both rodents and non-human primates at doses of 2.5 mg/kg and greater. In a follow-up paper, they synthesized a library of 126 lipid-like compounds using a unique synthetic strategy based on epoxide chemistry [190]. Their screen

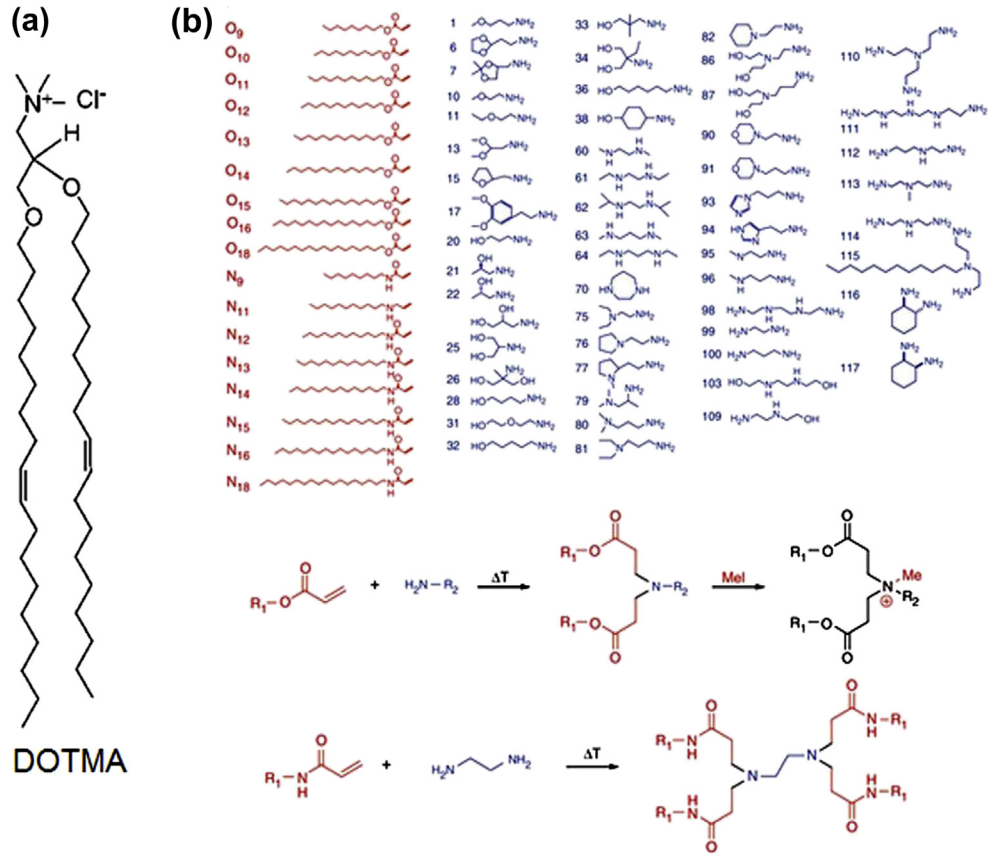

FIGURE 35.8
(a) Lipids traditionally studied for nucleic acid delivery include DOTMA and DOTAP. (b) Recent progress has been made using high throughput combinatorial approaches for identifying optimal siRNA delivery systems [189].

in this study identified some of the most potent RNAi delivery compounds produced to date, and their best lipidoids produced liver-specific silencing at 0.01 mg/kg in mice and at 0.03 mg/kg in non-human primates. Similar work has also been utilized recently to identify lipidoids for transfection of pDNA, and compounds were identified that were superior to Lipofectamine 2000™, which is a gold standard of commercially available *in vitro* transfection reagents [191], One of the limitations to much of the lipidoid work is that it has been primarily limited to liver targets. The promising current data suggest that clinical success will be established first in the liver and that subsequent work will optimize this class of carriers for additional clinical applications.

Inorganic NPs

In some applications, especially with inorganic NPs, 'theranostic' technological advances have been pursued that combine both image contrast and therapeutic functionalities. For example, quantum dot NPs, renowned for their optical properties, have been functionalized to successfully deliver siRNA [192,193]. NPs that provide MRI contrast have also been successfully utilized to simultaneously provide image contrast and siRNA delivery [194]. Recently, gold NPs have come to the forefront of inorganic NP approaches for siRNA delivery. Mirkin has been a leader in this field through development of polyvalent siRNA conjugates on the surface of gold NPs [195]. These particles are efficiently internalized by pattern-recognition scavenger receptors and can mediate gene silencing without addition of any additional transfection reagents [196]. Interestingly, these gold NPs surrounded by a dense shell of covalently bound siRNA have been recently found to efficiently penetrate the epidermal layer of the skin, indicating that they may be especially useful for clinical applications where topical delivery is a logical approach [197].

These skin-penetrating nanoparticles may obviate the need for the previously popular biolistic particle delivery systems. This older method uses a handheld gene gun with a pulse of helium to fire gold particles coated with DNA into target cells. This method of transfection is an effective physical means of rapid plasmid delivery into mammalian tissue. It is generally restricted to local expression in the dermis, muscle, or mucosal tissue since the gold particles are shot into confined tissue sites. Transfection depth is limited to about 1 mm, and about 10% of the cells in the tissue (skin) can be transfected. From a translational perspective, the DNA-loaded particles have a relatively long shelf life, and they have been successfully used for cutaneous administration of growth factor/receptor constructs [198–200].

ENGINEERING TISSUE SCAFFOLDS FOR VIRAL AND NONVIRAL NUCLEIC ACID DELIVERY

Nonviral delivery from scaffolds

Local, nonviral delivery of nucleic acids from biomaterial scaffolds presents a promising approach for tissue regeneration. Scaffold-based delivery can provide an efficient means to stimulate local, site-specific effects without the need for targeting and other challenges presented by systemic, intravenous delivery. These approaches can be designed for both delivery of gene-encoding plasmids and RNAi gene silencing through delivery of siRNA or plasmids that encode shRNA. These local, nonviral gene therapies have applicability for improving repair of a variety of tissues such as skin wounds, bone defects, and myocardial infarcts.

There is a relatively established precedent for scaffold-mediated plasmid delivery for increasing expression of growth factors such as platelet-derived growth factor (PDGF) to induce blood vessel and tissue formation within the scaffold [201]. It has been shown that embedding plasmid DNA within a biodegradable tissue scaffold or immobilizing it on a biomaterial surface can provide a 10–100 fold increase in transfection efficiency because of increased local concentration and extended retention of plasmid at the cell-biomaterial interface [201–203]

relative to a local injection of plasmid-containing solution. Mechanistically, 'substrate-mediated delivery' of nucleic acids is believed to operate through multiple modes of endocytosis, though caveolae-mediated uptake may play the largest role [204]. This bioinspired approach to tissue regeneration is also analogous to the pathways that viruses 'hijack' when they attach to extracellular matrix as a strategy to increase their cell internalization and infection [205]. The seminal work on scaffold-based plasmid delivery by Mooney and Shea has been subsequently applied in a diversity of applications, including delivery from both natural [206] and synthetic biomaterials [207,208]. Through more complex approaches to surface immobilization, plasmid delivery systems can also be engineered to control spatial patterning, concentration gradients, and temporal profiles in 2D and 3D [209]. Work is also underway to optimize the therapeutic benefits of substrate-mediated delivery by using enzymatically labile tethers [210], cell-specific targeting proteins [211], and other means of cell-specific targeting and intracellular release.

Scaffold-based local RNAi through delivery of siRNA is a more recent development and was initially approached primarily using natural biomaterials such as alginate, collagen, and agarose [212–214]. The first *in vivo* studies recently demonstrated gene silencing in skin wounds using Lipofectamine 2000 siRNA lipoplexes embedded in agarose gels. These commercially available cationic lipoplexes were released in a rapid burst and were effective for short-lived, topical siRNA application [214,215]. Pre-fabricated, electrospun scaffolds made from ε-caprolactone and ethyl ethylene phosphate copolymer (PCLEEP) nanofibers have also been pursued for the release of siRNA/transfection reagent (TransIT-TKO) complexes and have been shown to achieve more sustained delivery of bioactive siRNA [216].

A polyester urethane PE-UR scaffold-based platform has been recently developed for local delivery of siRNA-NPs [140,141] in regenerative applications [217]. These siRNA-NPs are composed of a diblock copolymer (see composition Fig. 35.5a). The PE-URs can be fabricated using a two-component foaming process that allows injection into a defect, followed by rapid curing *in situ* [218]. The siRNA-NPs can be embedded within the matrix as the porous, biocompatible, and biodegradable scaffold cures. The formed scaffolding can provide mechanical support, a template for tissue in-growth, and controlled drug release to regenerating tissues [218]. PE-URs adhere to tissue [212] and biodegrade both hydrolytically and oxidatively into biocompatible side products at rates that can be tuned based on the polyester triol and isocyanate precursor compositions [219].

In proof-of-concept studies [217], siRNA-NPs have been delivered from PE-UR scaffolds made from polyester triol and lysine triisocyanate (LTI) precursors that form a 3D polyurethane network when mixed (Fig. 35.9a). Water is added to this reaction as a blowing agent to create an interconnected porous network. Lyophilized siRNA-NPs can be simply added to the polyester triol prior to mixing with LTI, leading to siRNA-NP incorporation into the PE-UR matrix as it cures (Fig. 35.9b). siRNA-NP incorporation into the porous PE-UR scaffold is homogenous and results in sustained release of the siRNA-NPs from the scaffold (Fig. 35.9c). The released siRNA-NPs are stable during incorporation and subsequent release (Fig. 35.9d), and their gene silencing bioactivity is maintained post-release (Fig. 35.9e). Ongoing studies have confirmed the ability to achieve efficient local silencing (> 80% knockdown within the scaffold) of a target gene for over 1 month *in vivo*.

Viral delivery from scaffolds

The most common approach to viral gene delivery for tissue engineering is to genetically modify the cells in standard cell culture, and then subsequently seed them onto a three-dimensional scaffold [61,220]. However, this approach involves extra procedures and manipulation of the cells that adds significant complexity to an expensive and work-intensive process. Therefore, there has been considerable effort in functionalizing biomaterial scaffolds with viral vectors, such that cell seeding onto the scaffold and cell transduction by gene

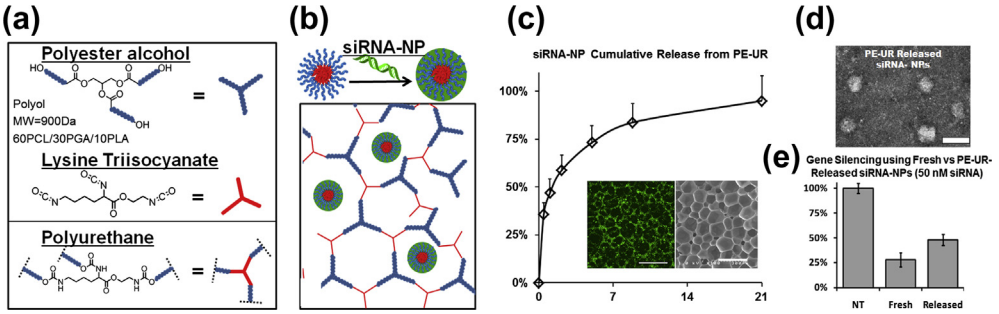

FIGURE 35.9

PE-UR scaffold delivery of siRNA-NPs. (a) Polyester triols and lysine triisocyanate are the primary precursors of the PE-UR network formed via hydroxyl-isocyanate reaction. (b) Lyophilized siRNA-NPs can be incorporated into the scaffold during curing. (d) TEM images confirmed release of intact siRNA-NPs from the scaffold (scale = 100 nm) and (e) qRT-PCR confirmed maintenance of gene silencing bioactivity of siRNA-NPs post-release.

delivery vehicles becomes a single procedure [221]. This approach may also enhance transduction efficiency by co-localizing the cells and virus and also protect them from the immune system. Patterns or gradients of viral vectors can be generated to spatially control gene transfer and tissue development. Material-mediated gene delivery also preserves and protects the vector from the immune system and controls the regional localization of the virus. These approaches typically involve either encapsulation of the virus within a hydrogel, immobilization of the virus to a surface, or a combination of both of these strategies. The unique biological properties of each virus require distinct techniques for each vector.

The incorporation of adenovirus into hydrogels or protein matrices has led to control over the spatial and temporal delivery to surrounding tissue while also protecting the virus from loss of activity [222,223]. Delivery of therapeutic genes from hydrogels can also enhance the wound healing properties of materials such as fibrin [224] and collagen [225]. This approach has been particularly successful in promoting the healing and integration of dental implants in animal models, suggesting a promising application in oral defects and disease [226]. Adenovirus may also be bound to exposed surfaces of polymer scaffolds via conjugation of anti-adenovirus antibodies to chemically reactive surfaces [227] or the use of biotinylated adenovirus [228]. This strategy can be used to spatially organize gene transfer by controlling chemical functionalization [229]. Adenovirus has also been widely used in gene-eluting stents and heart valves to prevent restenosis and valve disease [230–232].

Schwarz and colleagues have shown that the enhanced stability of AAV vectors can be exploited to create biomaterials, allografts, and other tissue substitutes with freeze-dried AAV coatings that are taken up by cells after implantation. The coating of bone allografts with osteogenic and angiogenic factors encoded by freeze-dried AAV vectors led to increased bone healing [233]. The same approach has also been used to engineer bone tissues *in vitro* by coating allografts [234] or polymer scaffolds [235].

The electrostatic properties of the retroviral and lentiviral lipid bilayer can modulate virus interactions with biomaterials, leading to enhanced and controlled transduction of cells [236]. This approach has been used to create gradients of retroviral particles on three-dimensional scaffolds that encode genes that direct tissue formation, providing a means for more complex tissue formation that better mimics natural development [237]. Ionic interactions can also be used to load lentivirus onto hydroxyapatite NPs that protect the virus to enable incorporation into hydrogels [238,239]. Lentivirus has also been immobilized onto a variety of other materials with various properties that can be tailored for controlled gene transfer *in vitro* and *in vivo* [240,241].

CLINICAL APPLICATIONS OF TISSUE ENGINEERING TO NUCLEIC ACID DELIVERY

There are now a wide variety of promising strategies and preclinical studies that have demonstrated effective delivery of plasmid, viral, and oligonucleotide agents, and there has been some translation to the clinic. Viral vectors (adenovirus and adeno-associated virus) require extensive safety testing prior to large-scale studies, and the adverse reactions to systemic administrations in early clinical studies discussed above cast a shadow over any new clinical trial. To avoid adverse, off-target effects, many current trials that involve transient gene transfer *in vivo* utilize direct injection of viral particles into the target tissue: myocardium, skeletal muscle, vitreous humor, and synovium [242]. This form of administration limits systemic exposure, immune response, and potential hepatotoxicity. Hence the development of safe and effective nucleic acid delivery systems remains an important medical objective.

A current compilation of gene therapy clinical trials gives some insight into strategies and targets [52]. There are a wide variety of classes of delivered transgenes among which antigens (20.5%), cytokines (18.4%), receptors (7.2%), tumor suppressors (8.3%), and growth factors (7.5%) predominate. Correction of deficiencies is another significant category (8%), while siRNA currently comprises a small fraction (0.6%) of current trials. Cancer therapy is the overwhelming therapeutic target (64.4%). The dominant viral vectors in current clinical trials are adenovirus (23.3%) and retrovirus (19.7%), and newer vectors like AAV (5%) and lentivirus (3%) have produced exciting preclinical data and are expanding. Naked (plasmid) DNA, which involves the carrier systems discussed in this chapter, is also a significant approach (18.3%). At this point, only 3.6% of current trials have advanced to Phase III, indicating the challenging, uphill path to drug development and nucleic acid delivery.

As discussed above, there have been many recent examples of clinical efficacy of viral gene therapies for rare genetic disorders and cancer, including approval of commercial products [53,54]. However, only a few clinical approaches have utilized biomaterials or tissue scaffolds to date. The only clinical approach that has combined a therapeutic adenoviral vector with a scaffold is the GAM501 formulation, which is a collagen matrix containing adenovirus that expresses rhPDGF-BB. Although early trials certified the safety of this formulation for both bone and skin applications [225], a Phase IIb trial comparing the vehicle with vehicle + vector showed that the collagen scaffold alone was as effective in healing diabetic foot ulcers as the combination product when compared to standard of care [243]. Another example of a vector combined with a biomaterial is the liposome-encapsulated AAV that has been administered intranasally for possible therapy in cystic fibrosis and AAT deficiency, but no conclusive efficacy has been demonstrated (www.clinicaltrials.gov). Similarly, (DOTAP):cholesterol NPs have been employed in recent clinical trials to transfer the TUSC2(FUS1) tumor suppressor gene to patients with recurrent and/or metastatic lung cancer [244].

In addition to viral DNA delivery, several recent clinical studies have focused on RNAi delivery strategies [74,245]. Recent clinical trials include the intravenous administration of I5NPQPI-1002 (siRNA targeted at p53) for acute renal failure in a proprietary, stable nucleic acid-lipid particle technology developed by Alnylam/Tekmira, the use of siG12D LODER (sustained polymeric release of siRNA targeted at the K-RasG12D mutation) for direct injection into advanced pancreatic adenocarcinoma, Atu027 (siRNA-lipoplex directed against protein kinase N3) for suppression of solid tumors, and CALAA-01 (siRNA in a cyclodextrin NP decorated with PEG and transferrin directed against the M2 subunit of ribonucloetide reductase) for head and neck tumor suppression [246,247]. At this point, lipid-based systems have advanced further than polymers in terms of clinical application, and of the nearly twenty total siRNA-based clinical candidates under active testing, seven are based on lipid NP technology [248]. Many of these trials are primarily the result of the combined work of Alnylam and Tekmira, and promising results are coming out from a variety of programs for treatment of

transthyretin-mediated amyloidosis (TTR), hemophilia, hypercholesterolemia, and liver cancer. More recently, inorganic NPs have also come into focus as a promising clinical prospect, especially for delivery of siRNA [197].

OUTLOOK

Two decades of laboratory-based gene and nucleic acid delivery have provided compelling arguments for continuing the refinement of vehicles and mechanisms for improving the safety and efficacy of gene manipulation. Recent advances have begun to yield the production of both viral and nonviral vectors that offer improved spatiotemporal control over expression kinetics and distribution. There are sharp contrasts among the design features for systemic vs. local delivery, acute vs. sustained activity, regulated vs. constitutive expression, and extrachromosomal vs. chromosomal localization. For systemic or local delivery applications, the proportion of viral or nonviral payload that reaches its intracellular target is governed by the biodistribution or local release to the target tissue site, the clearance rate of particles, the efficiency of intracellular uptake, and trafficking to the optimal intracellular compartment. For systemic applications, one should maximize the circulation time, minimize the non-specific cellular uptake, and maximize retention and/or uptake once the target cell has been reached. In contrast, local, scaffold-based delivery applications are more simply dependent on rapid cell recognition and intracellular delivery. Thus, the delivery criteria vary by applications, and there is a compelling need for safer and mode-specific therapies.

Numerous challenges must be overcome to optimize the therapeutic potential of nanovehicular delivery of nucleic acids and genes. Even with local release, better targeting and uptake strategies are important to raising the therapeutic index of genetic agents. In the coming years, we expect vigorous progress from both the cell and molecular perspective that will further enhance our understanding of the basic phenomena involved in drug/gene/vehicle uptake. Internalization of the delivery systems leads to a poorly defined trafficking process that is difficult to manipulate. Elucidation of the non-endocytic pathway(s) mechanism may enable the creation of rationally designed vehicles. Currently, it is not fully understood how the nanovector particle size, steric stabilization, targeting ligands, and cargo chemistry can be collectively optimized to positively influence the mechanism of uptake. However, the diversity of nanovehicle uptake mechanisms are constantly becoming better defined for different cell types, offering the possibility that genetic engineers can successfully manipulate or leverage uptake pathways to influence uptake to predominantly occur by the desired cell type and via the desired internalization route [249].

Engineering viral vectors with new properties, including enhanced targeting abilities and resistance to immune responses, is a growing area of research, particularly in the area of generating viral vectors with novel gene delivery capabilities. Rational design of viral vectors has yielded successful advances *in vitro* and *in vivo*. However, there is often insufficient knowledge of viral structure-function relationships to re-engineer existing functions or create new capabilities, such as virus-cell interactions, whose molecular basis is distributed throughout the primary sequence of the viral proteins. High throughput library screening and directed evolution methods offer alternative approaches to engineer viral vectors with desired properties. Parallel and integrated efforts in rational and library-based design promise to aid the translation of engineered viral vectors toward the clinic [76].

Newly emerging fields are likely to have a significant impact on gene delivery and tissue engineering in the near future. For example, a primary goal of synthetic biology is to engineer novel gene regulation systems with enhanced control and precision [250,251]. This has led to the development of various complex systems such as genetic logic gates and autonomous oscillators for greater control of gene expression in mammalian cells. Similarly, the field of genome editing with engineered nucleases, recombinases, and transposases is revolutionizing

gene therapy by enabling the targeted addition of genes to specific sites in the genome and the controlled alteration of genome sequences, in contrast to the addition of transgenes [252,253]. Many of these approaches incorporate the advantages of both conventional viral and nonviral strategies and are beginning to enter clinical trials.

As with other areas of drug development, the expense of preclinical toxicology testing of novel delivery vehicles can slow the pace of implementation. Clinical development can only proceed after safety has been established, and the bar will inevitably be higher for systemic formulations.

Further investigation is necessary for rational selection of suitable nano delivery vehicles for a specific application. Investigators tend to focus preferentially on one class of vehicles, and few generalized design rules are available to guide the optimal selection for a specific application. The desirable delivery route, localization, target cell, and biocompatibility of nanovehicles will, in the end, dictate the utility of individual constructs for each application. For both viral and nonviral approaches, the continuous efforts to improve currently available systems and to develop new methods of gene delivery are bringing us closer to more widespread adoption of safer and more efficient gene delivery systems in the clinic.

INTRODUCTION

The chance of a woman developing breast cancer in her life time is approximately 12% [1]. It was estimated that in 2012 there would be approximately 230,000 new breast cancer cases and 40,000 breast cancer related deaths in the United States [1]. The chance of breast cancer related death in women is approximately 3%, second only to lung cancer. Fear of disfigurement due to mastectomy or lumpectomy and limitations of breast conserving options have precipitated interest in tissue-engineering breast reconstruction options. Similarly, the impact of the disease, both psychological and physical [2,3], and the limitations of current two-dimensional (2D) bioassays used to understand, combat, or prevent the disease have driven the interest in engineering 3D tissue test systems.

This chapter summarizes the various cell types that may be useful for breast reconstruction, the polymers that are being used or that are being explored for use in breast reconstruction, and the limitations/advantages of specific animal models that allow one to test new tissue-engineering approaches. Avenues to potentially promote the vascularization of engineered tissues are discussed, as the major limitation in engineering large tissue volumes is the inability to deliver nutrients and remove waste products once the tissue is implanted. Finally, the chapter overviews the concept of tissue engineering to create benchtop breast tissue test systems that may be able to aid in developing breast cancer therapies and, eventually, vaccines.

BREAST ANATOMY AND DEVELOPMENT

The breast is a dynamic organ that evolves constantly throughout a woman's lifetime. This tissue comprises multiple cell types that actively interact with each other [4]. Microenvironmental signals are key to the developmental processes of the breast throughout maturation [1].

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00036-7

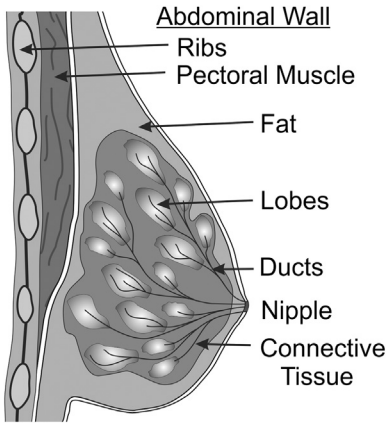

FIGURE 36.1
Breast physiology.

The complexity of the breast must be considered when investigating strategies for engineering breast tissue; however, understanding of the many interactions that occur between the stromal cells and epithelial cells in the breast tissue remains limited. Evidence indicates that paracrine molecules produced by stromal cells likely determine the success or failure of tissue-engineered solutions for breast tissue repair [5]. To better understand the development of breast cancer, it is important to first review the anatomy of the breast and the structures and functions of the tissues (Fig. 36.1). The breast structure is located on top of the pectoralis muscle, which is located on top of the rib cage [6]. Each breast contains 15 to 20 lobes which comprise 20 to 40 lobules. It is inside these lobules that the mammary glands responsible for milk production are found [7]. The lobules are connected together through ducts; the milk is collected in the ducts and then flows out through the nipple. The space between these structures is filled with fat and fibrous tissue, the ratio of which determines breast density. A high concentration of lymphatic vessels and lymph nodes is found throughout breast tissue; these structures facilitate the flow of lymph, which comprises white blood vessels called lymphocytes and a fluid from the intestines called chyle, which contains proteins and fats [8]. The lymph flows to the nearby lymph nodes located in the underarm, above the collar bone, and behind the breast bone [7]. Blood vessels are also present to carry blood around the tissues to provide nutrients to the cells. The size and shape of the breast is determined by the skin envelope and the adipose tissue surrounding the connective and glandular tissues. The firmness of the breast mound is dependent on the number of adipose clusters located within the breast, with higher adipose content resulting in a softer breast mound. The deep fascia and a thin layer of loose connective tissue are located between the breast and the pectoralis muscle; the connective tissue allows the breast to move freely over the deep fascia. The breast is attached to the skin through suspensory ligaments, also termed Cooper's Ligaments, which provide additional support and contribute to the shape of the breast mound [9].

Several changes occur in the breast as a women goes through puberty and menopause. During puberty, hormones released by the ovaries and pituitary gland cause the tissue to grow and the ducts to expand, forming mature ductal structures. While the structures are completely formed, they do not become fully active until pregnancy, when the lobules grow and begin producing milk. During menopause, when hormones are no longer produced by the ovaries, the lobule count in the breast decreases and those lobules that remain shrink in size. This change leads to a lower breast density, since the ratio of dense, fibrous tissue to adipose tissue decreases. For this reason, a woman's breast is typically denser before menopause than after [9].

BREAST CANCER DIAGNOSIS AND TREATMENTS

Historically, breast cancer was not detected at a very early stage and therefore was treated with radical mastectomy, or removal of the entire breast, underlying pectoral muscles, and axillary lymph nodes. As breast cancer detection methods improved, however, breast cancer was discovered at earlier stages, allowing modified radical mastectomies or removal of small tumors. Randomized prospective clinical trials, conducted over 18 years comparing less deformative techniques, demonstrated equivalent survival rates to modified radical mastectomy [10]. These studies demonstrated that, for most women with small breast tumors, simple excision (lumpectomy) of the breast cancer, sampling of the axillary lymph nodes, followed by radiation provides a similar outcome to a radical mastectomy.

Different treatment options can be used in combination to maximize the desired outcome. Breast cancer patients have therapeutic options, such as chemotherapy, radiation, and hormone therapy, and/or surgical options. Most often the treatment will be a combination of surgical and therapeutic options; treatment is determined on a patient by patient basis since individual cases of breast cancer have distinct characteristics. The treatment option is chosen based on stage of the cancer (e.g., *in situ* or invasive), size of the tumor, health condition of the patient, and several other factors.

There are two main surgical procedures, mastectomy and lumpectomy. The progression of the breast cancer is the main determinant of procedure. If the cancer has spread beyond the tumor mass formation, then a mastectomy, or removal of the entire breast, is recommended. If the cancer has not progressed outside the initial tumor mass, then a lumpectomy, or removal of the cancerous mass, can be performed followed by the use of an adjuvant therapy, most often radiation [11].

A mastectomy involves the removal of the interior of the breast mound, the nipple, the areola, as well as a wide margin of tissue around the incision. Prior to surgery, the extent of the axilla tissue that must be removed in order to remove the cancerous tissue is determined. Cancer cells most easily spread through the lymphatic system, so the progression of the cancer can be determined by examining the lymph nodes around the cancerous breast [11]. Because of the ease of travel through the lymphatic system, it has become common practice to remove some of the surrounding lymphatic vessels and nodes.

BREAST RECONSTRUCTION

There are no cosmetic surgical procedures available for lumpectomy patients. Following a mastectomy, patients are given the option of undergoing breast reconstruction surgery. The type and timing of reconstruction is determined first by the physical limitations of the patient and then by preference. An option that has grown in popularity is breast reconstruction immediately following mastectomy [12]. Previously, it was thought that reconstruction should be delayed to prevent any possible interference with an adjuvant therapy. However, benefits to immediate reconstruction include one surgery and hospital stay, better psychological outcomes, and improved aesthetic results. Risks involved with this combination surgery include extended surgical time and an increase in complexity of the procedure [12]. The risk and rewards of undergoing such a procedure are evaluated on a patient by patient basis. There are two primary types of tissue implants for breast reconstruction; synthetic and autologous.

Synthetic implants

Generally, synthetic implants are simpler and require less surgical time, but the results are not as aesthetically satisfactory. The simplest reconstruction is a silicone breast implant, which is a silicone gel- or saline-filled silicone bag that is implanted in the submuscular position beneath the removed breast mound. In some instances, the void volume may be increased by the progressive inflation of a tissue expander [12] prior to placement of a silicone breast

implant. Because an implant is a foreign body, it may trigger a substantial inflammatory response, resulting in fibrosis, thickening, capsular contraction and an unnatural shape and tactile quality. Also, implants may leak and require replacement. Silicone-filled implants are now rarely used due to fears of possible complications caused by the leakage of silicone.

Tissue flaps

Autologous breast reconstruction relies on the use of the patient's own tissue, is more complex, requiring more extensive surgery and a longer recovery time but the results are much more natural and aesthetically pleasing than those of prosthetic implants. There are several primary tissue retrieval sites, including the abdomen, the back, and the buttocks or thigh. The transverse rectus abdominis myocutaneous (TRAM) flap, located on the abdomen, is surgically excised, including fatty tissue, abdominal wall skin, often with the blood supply network intact, and is molded into the breast mound. A TRAM flap procedure requires that an additional surgery be performed to reconstruct the nipple-areola and to improve the shape of the reconstructed breast mound; a weakening of the abdomen as well as contour abnormalities of the abdomen can occur after this procedure [9]. The latissimus dorsi flap is removed from the back in a similar but less involved manner than removal of the TRAM flap. Disadvantages of this flap procedure include susceptibility to atrophy and lack of patient-to-patient tissue volume consistency. Muscle-free flaps from the buttock (gluteal) or thigh (tensor fascia lata) may also be used; in some instances a muscle sparing procedure may be used, wherein only fat/skin is transplanted. Adipose tissue matrices, devoid of lipids and cells, have been investigated for use in soft tissue defect repair [13].

Cell transplants

Some of the very first studies performed regarding adipose tissue replacement used a method called autologous fat transplantation. This methodology simply involved harvesting adipose tissue from a location on the patient and transplanting that tissue to the breast tissue void. This procedure was completed without a scaffold in place to guide the shape of the tissue replacement. The results of this type of procedure were very poor, with 50–70% reduction in volume due to the resorption of the grafted tissue. Resorption occurred because adipocytes are anchorage dependent and require a scaffold to survive. Additionally, the adipocytes found in the tissue graft were terminally differentiated and, therefore, could not proliferate [9]. After several failed attempts, it was determined that a scaffold was required for proper breast tissue replacement.

The cellular material used for transplantation is obtained from lipoaspiration, a process that can damage and lyse the cells. Researchers are developing means with which to treat lipoaspirate, for example, the lipoaspirate may be washed in a polyoxamer, which is thought to stabilize the cellular membranes of damaged adipocytes, and lend greater stability for implantation and graft survival. Preliminary studies suggest that the treatment can increase implant viability post implantation [14].

Cellular scaffolds

Breast tissue engineering is another reconstructive option, beyond that of synthetic or autologous implants. Breast tissue engineering may involve cellular or acellular scaffolds. Much of the current research is still focused on traditional approaches of *ex vivo* cell expansion; however, due to financial, regulatory and logistical obstacles, more focus must be placed on 'just-in-time' delivery options that do not incorporate cell expansion *ex vivo*. Currently, viable breast tissue-engineering technologies have not been translated from the laboratory to the clinic due to several existing challenges related to cell culture, scaffold type, and animal model selection that affect our ability to build a vascularized tissue that maintains volume in the long-term.

CELL TYPES AND RELATED CHALLENGES

Many issues must be considered when choosing which cell type(s) should be used in human breast tissue engineering. The first consideration is that there is substantial variability in the size, shape and consistency of the breast. The breast changes over time, with a tendency for breast parenchyma (glands and ducts) to involute or regress as a woman ages, particularly after menopause, and be replaced by fat [15]. Also, comparing breast tissue among women of any given age, there is considerable variability in the size, shape, tactile, elastic and tensile characteristics of the tissue. The tensile and elastic characteristics of the breast are influenced by three major factors:

1) The amount and quality of fat within the breast;
2) The amount and quality of glandular and ductal tissue in the breast;
3) The mechanical characteristics of the fibrous support structures of the breast (Cooper's ligaments).

The creation of a functional breast with lactational ability is not needed and, in fact, may add to a woman's breast cancer risk by introducing mammary epithelial cells that may be predisposed to cancer development. The major, immediate goal of breast reconstruction is to produce a breast mound with all of the aesthetic properties of a normal breast.

Normal breast tissue comprises adipocytes; however, these lipid-laden fat cells (adipocytes) are terminally differentiated and will not divide further *in vivo* or *in vitro*. Indeed, studies have shown that if not maintained in a 3D culture environment, these differentiated cells will likely de-differentiate and become fibroblastic [5]. Hence, use of adipocytes requires harvesting fat in the exact volume required for the construct [16–18]. Additionally, the majority of mature fat cells in a lipoaspirate sample rupture [8,9,18]; accordingly, measures must be taken to compensate for or prevent this loss.

Pre-adipocytes may be used for engineering soft tissue [19,20] as these cells are not as susceptible to retrieval damage and can potentially be expanded in culture. Pre-adipocytes are similar to fibroblasts in structure and possess the ability to expand in culture [21]. Several studies have shown ways of inducing differentiation into adipocytes. These cells can be successfully harvested and isolated from sites such as the subcutaneous tissues or the omentum. Investigations of autologous pre-adipocyte implantation with a sheep model have been promising [22]. Technologies are being developed to allow simple harvesting and fast isolation of pre-adipocyte cells for immediate re-implantation into the patient [23]. Studies in mice have shown that the incorporation of 'adipose-derived regenerative cells' in fat grafts decreases cell apoptosis and increases expression of growth factors [24].

Possible other cell types include smooth muscle cells, fibroblasts, skeletal muscle and elastic cartilage. Fibroblasts contribute greatly to the support structure of the breast by laying down bands of collagen that connect the breast tissue to the skin and to the pectoral muscle, as well as helping maintain the overall shape. The density and firmness of the breast is determined primarily by the glandular epithelium and ductal structures, where tissues that have similar tactile and elastic properties are almost exclusively muscle. Smooth muscle cells can be readily isolated from a number of organs and expanded in culture; implantation of smooth muscle-containing polymers can lead to the reformation of significant tissue masses, with reorganization of the smooth muscle tissue into appropriate 3D structures [25]. Muscle myocytes can also be greatly expanded *in vitro*, and have been demonstrated to reform functional tissue masses under appropriate conditions [26,27]. However, it remains to be demonstrated that smooth or skeletal muscle myocytes will maintain a tissue mass over long periods of time without neural stimulation. An alternate approach might even be to incorporate chondrocytes in an engineered breast tissue. Elastic cartilage has many of the mechanical properties of glandular breast tissue that are potentially important for tissue engineering of breast (e.g., elasticity). Chondrocytes can be expanded in culture, and are able to survive in low

oxygen tensions. Chondrocytes have been used extensively in tissue engineering to engineer a variety of tissue constructs both *in vitro* and *in vivo* [28–30].

However, the more commonly studied cell types for breast tissue engineering include human bone marrow-derived mesenchymal stem cells (hBMSCs) and human adipose-derived mesenchymal stem cells (hASCs) [31]. Both cell types have the ability to differentiate into adipocytes when introduced into an adipogenic differentiation medium. The hBMSCs are harvested from the bone marrow, through a relatively painful procedure, which lessens their clinical relevance, while hASCs can be harvested in large volume from adipose tissue obtained via biopsy or liposuction [31]. Recognizing that regeneration may most effectively occur *in situ* with cues from the native tissue, cell types such as mesenchymal stem cells and embryonic stem cells have rapidly become the most popular cells for breast tissue-engineering research. Human embryonic stem cells, hESCs, are readily able to differentiate into adipocytes [31]; however, a great deal of work will need to be done to ensure terminally differentiated cells, that once transplanted, do not have the potential to form a tumor mass. The implantation of embryonic stem cells has the potential to result in teratoma formation *in vivo* [32,33]. Studies in mice have shown that the formation may be site dependent and may be exacerbated in the presence of specific biomaterials [34].

Standard cell isolation and expansion protocols must also be developed; critical steps influencing successful outcomes will include aseptic technique in the harvest, routine quality control testing of all cultures, long-term cell storage, and on-site operating room handling. It may also be possible to isolate all the cell types required for breast tissue engineering from a single tissue source; furthermore, it may be advantageous to retrieve tissue isolates rather than cellular isolates [35]. For example, fat, in addition to adipocytes, contains a large vascular network, composed primarily of capillary endothelial cells and some vascular smooth muscle cells as well as a collagen stromal structure produced by fibroblasts [36]. Hence, multiple cell types or cellular aggregates (tissue isolates) can potentially be obtained from this tissue. In attempting to produce fat tissue *in vivo*, it may be beneficial to expand the cellular components of fat without isolating each component, as the complexity of the mechanisms may be crucial and impossible to rebuild from cellular blocks. Given the complexity of tissue, it is most likely that a mix of cells, with respect to maturity and type, will result in the most promising tissue-engineering solution.

SCAFFOLDS

An important consideration in engineering breast tissue is the scaffold selection. Selection of a material chemistry and form to use as a scaffold depends on the purpose and characteristics of the tissue that is being replaced as well as the physical characteristics and health of the patient. Scaffolds may be fabricated to induce tissue integration or they may be developed to house or attract cells which, in turn, assist in inducing tissue integration. Several key characteristics make a biomaterial suitable for tissue-engineering application. First, with *in vivo* endpoint, favorable biomaterials must be absorbable or degradable, and therefore facilitate new tissue integration with native tissue over time. The shape and texture of the material does not have to resemble that of natural tissue but it should induce growth of new breast tissue resembling native tissue, i.e., be soft and pliable. Cellular affinity is another important aspect of a biomaterial, whether considering *in vivo* or *in vitro* endpoint. The biomaterial must interact favorably with cellular components without negative impact (e.g., the material cannot be tumorigenic or toxic). Some element of porosity or surface texture is helpful and potentially allows cellular ingrowth into the material and/or transfer of nutrients and waste products, the establishment of a vascular network into the biomaterial scaffold [37], and/or differentiation of multipotent cells [38].

Synthetic materials

Aliphatic polyesters of polyglycolide (PG) and polylactide (PL) are well characterized synthetic biodegradable polymers which are clinically familiar to biomedicine and are familiar also to

tissue-engineering researchers [39]. PG is highly crystalline, has a high melting temperature, and has low solubility in organic solvents. PL is more hydrophobic than PG due to the presence of a methyl group. PL has a low water uptake and its ester bond is less susceptible to hydrolysis, due to steric hindrance by the methyl group. Therefore, PL degrades more slowly and has higher solubility in organic solvents than PG. Copolymers of PL and PG can be readily synthesized; their physical properties are modulated by the ratio of glycolic acid to lactic acid. Often incorrectly named in the literature, polylactide and polyglycolide are synthesized by ring opening polymerization, while the lower molecular weight polylactic acid and polyglycolic acid are synthesized by step growth. The latter are on the order of thousands of Daltons and are limited to use in structures with low mechanical demands, such as films and spheres [40]. Aliphatic polyesters can be readily processed into various physical forms appropriate for tissue-engineering applications. A number of techniques have been proposed to generate highly porous scaffolds, including solvent casting/particulate leaching [41], phase separation [42], emulsion freeze-drying [43], fiber extrusion and fabric formation [44], and gas foaming [45,46].

Polyethylene glycol (PEG) scaffolds [47] are readily modified by degradation and adhesion peptides and thus have been the subject of pre-adipocyte studies. The combination of adhesion and degradation features appears to allow the highest adhesion and proliferation of pre-adipocytes. Non-degradable polymers have also been examined for tissue reconstruction applications. For example, *in vitro* studies have been conducted with fibronectin-coated polytetrafluoroethylene scaffolds (PTFE). Human pre-adipocytes have been shown to successfully attach, proliferate, and differentiate into adipocytes on the PTFE scaffolds [48]; however, these non-degradable scaffolds are likely better suited for 3D *in vitro* tissue test systems.

A number of other synthetic polymers could be used to fabricate scaffolds for breast tissue reconstruction, including polycaprolactones, polyanhydrides, poly(amino acid)s, and poly (ortho ester)s [49]. Polycaprolactone (PCL) is an aliphatic polyester, a semi-crystalline polymer with high solubility in organic solvents, a low melting temperature, and a low glass transition temperature (T_g). The degradation rate of PCL is much slower than PG or PL; because of the low T_g, PCL has a flexible, sticky quality which can be advantageous in a scaffold. PCL has been tested in scaffold form in animals [50,51] and is used clinically in orthopedic applications. Polyanhydrides are usually copolymers of aromatic diacids and aliphatic diacids. These materials degrade by surface erosion, the rate of which can be controlled depending on the choice of diacids [52]. Poly(amino acid)s have been studied due to their similarity to proteins, and have been widely investigated for use in biomedical applications such as sutures and artificial skin [53]. Poly(amino acid)s are usually polymerized by ring opening of N-carboxyanhydrides; versatile copolymers can be prepared from various combinations of amino acids. However, due to the low solubility and limited processability of poly(amino acid)s, 'pseudo'-poly(amino acid)s were developed [54]. It has also been reported that poly(amino acid)s containing L-arginine, L-lysine or L-ornithine cause endothelium-dependent relaxation of bovine intrapulmonary artery and vein, and stimulate the formation and/or release of an endothelium-derived relaxing factor identified as nitric oxide [55]. Poly(ortho ester)s are biodegradable polymers, which degrade by gradual surface erosion and have been investigated for controlled drug delivery.

Naturally-derived materials

Naturally-derived polymers have been used for adipose tissue engineering; scaffolds produced from these materials typically are hydrogels or structural forms like mesh, sponges [9], or beads. Investigations have been conducted, for example, using Matrigel™ (reconstituted basement membrane of mouse tumor) and fibroblast growth factor 2 (FGF-2) to induce *in situ* adipogenesis. Matrigel™ consists largely of type IV collagen, laminin, and perclan and, although a highly variable material with many ill-defined components, is considered the gold standard in cancer cell biology benchtop studies. Preliminary small animal studies have

demonstrated the migration of native pre-adipocytes as well as endothelial cells into Matrigel™ when this material is injected into subcutaneous tissue [9,37,56].

Hyaluronic acid (HA) is a natural component of the extracellular matrix of many tissues. HA comprises repeated sequences of glucuronic acid and acetylglucosamine; this material is susceptible to enzymatic degradation via hyaluronidase. Simple modifications have been made, such as cross linking the chains to form insoluble hydrogels [57]. In its natural form, HA plays a role in enriching wound healing by promoting early inflammation and stimulating angiogenesis [58]. Hyaluronan benzyl ester (HYAFF® 11) scaffolds are derived from hyaluronic acid that is esterified with benzyl groups at the glucuronic acid monomer. Researchers experimented with these sponges, seeding them with human pre-adipocytes and surgically implanting them into subcutaneous tissue of athymic nude mice. The sponges allowed good cellular penetration as well as the development of new vascular networks within the sponges. However, adipose tissue development remained sparse [59]. The researchers also compared collagen scaffolds to HYAFF® 11 scaffolds *in vivo*, and concluded there was increased implant weight, adipose tissue formation and distribution of cells in the HYAFF® 11 scaffolds [60]. Hydrogels of hyaluronic acid have been prepared by covalent cross linking with various kinds of hydrazides [61] and have been used in drug delivery [62].

Collagen is the best-known tissue-derived natural polymer and is the main component of all mammalian tissues, including skin, bone, cartilage, tendon, and ligament. Collagen has been used as a tissue culture or artificial skin scaffold due to its high cell affinity. However, collagen offers a limited range of physical properties, can be expensive [63], is highly variable, and can elicit a strong immunologic response. Chemical modification and incorporation of fibronectin, chondroitin sulfate, or low levels of hyaluronic acid into the collagen matrix can change cell adhesion [64]. *In vivo* comparisons of freeze-dried collagen scaffolds with hyaluronic acid sponges and non-woven mesh, implanted in mice for 8 months, revealed a greater number of adipocytes in the hyaluronic sponges than in the non-woven mesh. This difference was mainly attributed to the porous nature of the sponge, which allowed greater surface area for adipocyte cell distribution and growth [60,65]. Recent studies also have assessed the idea of creating a fibrovascular tissue bed or natural scaffold, using a pre-expansion vacuum into which fat cells are transplanted [66].

Alginate is a naturally occurring hydrogel that can be easily formed into an injectable gel or beads, but must be modified with a peptide sequence to allow cell attachment [22,67,68]. Interestingly, the human body does not contain alginase, the enzyme that breaks down the alginate chain, hence molecular weight is a crucial consideration for implantation as large molecular weight alginate chains will not be eliminated from the body. That is, the molecular weight of many alginates is typically above the renal clearance threshold of the kidney [69]. Alginate chains are bound together with divalent ions that migrate in areas of divalent ion deficiency, causing uncontrolled dissolution. To address this point, hydrolytically degradable, covalently cross linked hydrogels derived from alginate were developed [70]. Specifically, polyguluronate blocks with molecular weight of 6,000 Da were isolated from alginate, oxidized, and covalently cross linked with adipic dihydrazide. The gelling of these polymers could be readily controlled, and their mechanical properties depended on the cross linking density. It was also demonstrated that alginate gel degradation can be readily regulated by controlling the molecular weight distribution of the polymer chains in the gels, and their susceptibility to hydrolytic scission by partial oxidation [71].

Other materials have found limited, preliminary use in breast tissue engineering. Chitosan is relatively biocompatible and biodegradable [72,73], making it useful for breast tissue engineering [74] and wound healing [75]. Chitosan is abundant and easily derivatized by coupling molecules to the amino groups [75,76] and has shown early success in murine studies focused on injectable breast tissue-engineering systems [35]. Fibrin glue has been used as an adipocyte scaffold and, in small animal studies, has facilitated maintenance of adipose tissue up to

one year after implantation [78]. Fibrin is a blood based product, a characteristic which has slowed its translational appeal in the United States.

Therapeutic scaffolds

Some scaffolds provide more than a simple matrix on which cells will grow. Some scaffolds have an incorporated therapeutic agent such as a drug or growth factor, and are termed therapeutic scaffolds. The concept behind these scaffolds is that the therapeutic agent incorporated in the scaffold is released as the cells remodel the scaffold during cell growth and proliferation. The therapeutic agent therefore has a direct effect on the surrounding tissue where the scaffold is placed; accordingly, the use of growth factors and the stimulation of cell growth must be carefully evaluated in breast cancer related reconstruction, to avoid facilitating the cancer process.

Indeed therapeutic agents can affect the tissue surrounding the implanted scaffold. An example can be seen in a study where the therapeutic agent, angiogenin, was incorporated into a scaffold [79]. Angiogenin is a drug that has been shown to promote neovascularization, so the intent of its incorporation was to help promote the growth of new vasculature throughout the scaffold, increase the chances for the success of an implanted tissue replacement, and improve the overall outcome of the procedure. The investigators subcutaneously implanted these scaffolds into rabbits and, after 28 days, the scaffolds were excised. The study showed that scaffolds with incorporated angiogenin had increased neovascularization. Other therapeutic scaffolds have been designed; for example, a collagen/chitosan/glycosaminoglycan scaffold was assessed [80]. The agent for this therapeutic scaffold, transforming growth factor-beta 1 (TGF-β1) targeted cells grown on the scaffolds rather than the surrounding tissue. Accordingly, TGF-β1 was incorporated into chitosan microspheres that were embedded into the scaffold.

A final example of a therapeutic scaffold is one in which the agent targets and neutralizes a specific type of cell found in the surrounding tissue, such as a cancer cell. Researchers developed, for example, scaffolds with nanoparticles containing emodin, an anti-cancer drug [81]. These scaffolds were intended to fill a site where a cancerous tumor was removed from the breast. The concept of this scaffold is that as cells proliferate on the scaffold and remodel it, the emodin contained within the nanoparticles is released and neutralizes cancerous cells in the surrounding tissue. These scaffolds were implanted next to the mammary fat pads of nude mice in which cancerous cells had been injected. The results of this study indicated that the size and number of the tumors next to emodin-loaded scaffolds were reduced compared to those next to scaffolds without emodin.

Injectable scaffolds

Early scaffolds took forms such as foams or mesh; they required implantation via an open surgical procedure. However, the reality of the transport and surgical limitations of large volume implants led to the development of alternate scaffolds [82]. Injectable scaffolds can be combined with cells and surgically implanted in a minimally invasive manner, including by syringe, catheter or endoscopic needles [83,84]. These injectable materials take forms such as gels, beads, or composite gels. Examples of injectable scaffold chemistries that have been assessed for breast tissue engineering include alginate, chitosan, hyaluronic acid, collagen, polyanhydride, degradable PEGs, decellularized adipose tissue, small intestinal submucosa, and blends thereof [13,35,82,85,86]. While gels support cell growth and readily conform to a defect, they typically do not support the necessary functions of anchorage dependent cells and are therefore useful as carriers but not as scaffolds in breast tissue engineering. Beads and composites (which contain beads or other filler) in contrast, are amenable to breast tissue engineering.

Combination scaffolds

It is likely that a combination of biomaterials, with respect to chemistry and form, will result in the most promising tissue-engineering solution. Scaffold combinations that use two or

more types of materials can be used to help combat and overcome the weaknesses and shortcomings of one material. For instance, a material that has excellent cell attachment characteristics but is not very durable can be combined with a more durable material, hopefully resulting in a scaffold that is both durable and able to support cell growth.

One of the first combination breast tissue-engineering scaffolds was an injectable composite comprising beads in a delivery gel [82]. Indeed, cellular constructs that are approximately 500 μm in thickness or less, once implanted, may optimize diffusional transport of nutrients to the cells while each small cell-polymer unit becomes vascularized. Accordingly, these injectable composites were developed specifically to allow trafficking and infiltration of blood vessels, nutrients, waste products, other factors and cell types, within the discrete portions of the scaffold (i.e., between beads) [35,82]. The beads, or a fraction of the beads, may be selectively loaded with appropriate factors to induce tissue growth or prevent abnormal tissue growth. The gel is degradable and facilitates delivery of the composite through a needle, and also allows the composite to conform to and fill an irregular defect site. The gel may be loaded with factors for release on degradation. A variety of studies have been conducted to demonstrate the modularity of an injectable composite approach [35,68,82,87,88].

It is unlikely that there is a one-size-fits-all biomaterial chemistry or form; accordingly, there is interest in a wide range of combination scaffolds. In one study, gelatin sponges, polyglycolide mesh, and monofilament polypropylene mesh were used to construct three-dimensional scaffolds of predefined shapes on which human adipose-derived mesenchymal stem cells (hAD-MSCs) were grown [89]. The scaffolds were made of an outer polypropylene mesh pocket that contained gelatin sponge cubes and polyglycolide mesh. Gelatin is an attractive scaffold for cell growth and attachment and can be molded into a desired shape but rapidly loses its dimensional stability over time. The polyglycolide mesh was used to increase the surface area available for cell attachment. Polypropylene mesh was used because of its ability to maintain dimensional stability after being implanted into the body. These scaffolds were seeded with a high density hAD-MSC suspension and cultured for 2 weeks. Subsequently, the scaffolds were implanted into the backs of nude mice for 2 months and then excised for analysis. Analysis showed that the scaffolds contained new adipose tissue as well as neovascular structures. The gelatin cubes, as well as the polyglycolide mesh, were completely absorbed by the body but the outer polypropylene mesh retained the predefined dimensions; the neovascular structures may simply be the transient part of the normal foreign body response.

STRATEGIES TO ENHANCE THE VASCULARIZATION OF ENGINEERED TISSUE

A critical challenge to engineer breast tissue, or any tissue of significant thickness, remains the development of a vascular network to support the metabolic needs of the engineered tissue and integrate it with the rest of the body. Adipose tissue is highly vascularized, with a resting blood flow two to three times higher than that of skeletal muscle. The presence of vascularized networks in natural metabolic organs results in short diffusion distances between the nutrient source and the cells [90], and these vascular networks must be created in engineered tissues as well. Nutrient diffusion *in vivo* is constrained to a distance of approximately 150 μm. Most metabolically active cells that are located further than this distance from a nearby capillary are subject to hypoxia. Thus the success of any large engineered tissue hinges on its blood supply. The important interrelationship between pre-adipocytes and endothelial cells was demonstrated in hypoxic culture experiments. Frye and coworkers [91] exposed cell cultures of pure pre-adipocytes, as well as mixed cultures of pre-adipocytes and microvascular endothelial cells, to hypoxic conditions (5 to 2% O_2) and found that pre-adipocytes co-cultured with microvascular endothelial cells had higher viability than cultures consisting of pre-adipocytes alone.

Several general approaches have been taken to date to promote angiogenesis in engineered tissues; however, none provide a robust, consistent solution to this complex problem. Bland and colleagues [92] provide a detailed review of approaches to combat hypoxia in

tissue-engineered systems. In short, this problem has been unsuccessfully addressed in the long-term by incorporating endothelial cells or angiogenic factors in tissue-engineered implants. Concerns about blood vessel promoting factors are high when targeting solutions for breast cancer patients. The composite injectable systems do provide the option of gradually building smaller volumes of tissue over time to collectively build a large volume [93]. Many studies highlight angiogenic response at short time points, suggesting that the foreign body response provides the necessary vascularity [94,95]. Indeed, while this is the case in the short term (and at later defined intervals as the material is further degraded or absorbed and elicits further response), the vascularity is temporary only. Blood vessel ingrowth occurs slowly with this approach, will likely not be sufficient to engineer large tissue volumes, and will likely subside with termination of the foreign body response. Other approaches attempt to actively modulate the vascularization process by either delivering angiogenic molecules or blood vessel forming cells (e.g., endothelial cells) to the site at which the tissue is being engineered. Prevascularization, either *in vitro* or *in vivo*, has also been proposed and investigated by numerous groups, but the problem of integrating newly developed vasculature with host tissue remains unsolved.

Microstamping using nano-fluid chambers is one research approach of interest in liver tissue engineering [96], where the long-term goal is to develop a 3D vascular bed *ex vivo* that could be anastamosed to the host vasculature to support cellular engraftment. This approach could also be developed for breast tissue engineering. Another approach involves the direct association of an implant with a pre-existing blood supply. Experiments with nude mice were performed in which silicone molds packed with polyglycolide fibers were sewn to the inferior epigastric blood vessels. These silicone molds were injected with a combination of Matrigel and FGF-2. *In situ* adipogenesis was demonstrated over a 4 to 20 week time course. Direct application of a vascular pedicle to a construct is another promising approach. Prefabricated flaps have been created with vascular pedicles since the 1960s; vascular pedicles can be supplied in many different configurations. In general, however, conduits comprising an intact artery and vein fare better than those comprising a single vein alone [97,98].

Special considerations

The need for nipple reconstruction occurs after mastectomy. Traditional implants include free composite grafts, local tissue transfer, and prosthetic devices. Free composite grafts were initially used and were created from autologous tissues such as the labia, inner thigh, cartilage (auricular or costal), the contralateral nipple, or the toe. Complications at the graft site made this technique less desirable. Local tissue flaps are the most popular option for nipple reconstruction. Commonly used techniques include the bell flap, the modified star flap, and skate flap [99–102]. Unfortunately these techniques can be hindered by flap necrosis and poor aesthetic results, including loss of nipple projection. Additionally, the presence of underlying subcutaneous fat is important for bulking; this layer is not always sufficient. Tissue-engineering approaches include the use of tissue flaps coupled with acellular, naturally-derived (collagen, extracellular matrix, etc.) matrices [103] and/or fat grafts.

BREAST CANCER MODELING

As Savage stated, 'Cancer is not a simple disease' [104]. A significant challenge to both the development of breast cancer treatments and fundamental understanding of breast cancer processes is the development of a tool, a model, which allows isolation and control of specific parameters of interest. The study of basic disease processes and treatments in a patient is generally very inefficient because of the number of confounding biological (and ethical) issues. In response to this challenge, researchers have proposed animal models, mathematical models, and benchtop test systems as the means to more effectively study breast cancer.

Animal models

It is important to first consider the application for which an animal study is planned before the selection of the animal model itself. Either the nude (nu/nu) or severe combined immunodeficiency (SCID) mouse model is used for the transplantation of human-derived cells [105]. These animals have compromised immune systems to the extent that they will often accept xenogeneic transplanted tissues, and these mice have been particularly useful for transplantation and immunologic studies of human tumors, bone marrow, skin and other tissues [93,106,107]. SCID and nude mice are used to evaluate various polymer constructs with and without human cells *in vivo*, without the adverse effects of a major immunologic reaction. Furthermore, basic questions about human cells and polymers *in vivo* may be answered without launching human trials prematurely. Development of these models may not be straightforward since there are subtle differences between strains with respect to the acceptance of various tissues and growth of the implanted tissues in different sites (e.g., a tissue may grow in one mouse strain but not in another, or may grow in a subcutaneous site but not in an internal location). Even though mice are genetically altered for immunodeficiency, the particular genetic modifications can vary. These varying genetic modifications can cause varying levels of different hormones throughout the host body. Hormonal differences will result in adipose tissue development differences that will likely result in different biological reactions to the same implant. Several different genetic varieties of laboratory rats exist, which poses complications when attempting to compare studies [105]. Biologically, males and females of the same species have different hormone levels due to differences in development and maturation. Additionally, gender-induced differences in hormones cause a difference in adipose tissue development which may result in different biological reactions to similar scaffold constructs [105].

Nude mice lack a T-lymphocyte response, while SCID mice lack both a T- and B-lymphocyte response. However, both types have natural killer cells that may interact with some transplanted materials. These mouse colonies must be monitored closely for changes in the immune status of the mice that, at times, occurs spontaneously. In addition, the human cells must be routinely screened for the human immunodeficiency virus, hepatitis and mycoplasma before being transplanted into immunosuppressed mice to assure the safety of the animals and workers, and the validity of the experiments.

One other complicating factor is the size of the actual animal in question. Small size animals include animals such as mice and rats, while larger sized animals include sheep, domestic pigs, and cows [105]. When considering mammary tissue, the larger sized animals are more physiologically relevant to humans. This issue raises the question of applicability of relating animal model results to an expected human clinical trial outcome. Large animals can accommodate the same size implant as one that would be used in a human. Also, the internal anatomy of larger animals, such as the domestic pig, is much more similar to the human anatomy in regard to organ size and heart rate. It has also been shown that the histoarchitecture and hormonal control of the mammary glands of larger animal models is much more applicable to humans than those of rodents [108]. Studies have shown that bovine cells as well as human cells do not grow in the mammary fat pads of immune suppressed mice. This observation suggests that the fat pads of rodents do not provide an environment suitable for the proper growth of human or bovine mammary epithelium. It has also been shown that progesterone has a very different effect on the mammary tissue of mice when compared to that in larger animals, including humans. In mice, progesterone stimulates epithelial proliferation and ductal side branching, whereas progesterone has a limited effect on the mammary epithelium of larger animals and humans.

There has been excellent success using inbred female Lewis rats as a small animal model for the development of transplantable tissues with absorbable polymers such as PG, PL, poly(lactide-co-glycolide), and hydrogels such as alginate [109]. This model allows transplantation of cells

between individuals without concern for immunologic rejection, which parallels the likely autologous nature of cell transplantation for breast engineering. In addition, the Lewis rat is larger than many other strains, allowing the testing of larger (1−2 cm) or multiple constructs in the same animal.

In evaluating larger animals as models for breast tissue engineering, animals with skin and subcutaneous tissues that are similar to humans are required in order to evaluate larger constructs subcutaneously. For this reason, the same animal must be used as a tissue donor and recipient. Porcine skin and subcutaneous tissues are very similar to that in humans, but most pigs continue to rapidly gain weight throughout their lives, which makes monitoring implants very difficult. Sheep have very little subcutaneous fat and, depending on the location, have well-defined subcutaneous space for cellular engraftment. Hence, if new adipose tissue is formed there is a high probability that this is developed from the implanted cells. One of the few locations in the sheep where there are significant fat deposits is the omentum. Researchers have shown that pre-adipocytes isolated from the omentum can be expanded in culture, seeded onto porous alginate-RGD fragments [22], where they attach, proliferate, and spread onto the biomaterial surface. Cellular alginate-RGD fragments were subsequently injected into the nape of the neck of sheep to determine if new adipose tissue would form. Although the cells were autologous and not labeled with a tracking marker, there appeared to be *de novo* adipose tissue formation in the cell implant sites compared to the acellular biomaterial control sites.

Indeed, further investigation of breast tissue-engineering options within a large animal that has biological characteristics comparable to that of humans is required. The bovine mammary gland consists of the same anatomical structures and tissue types as that of the normal human breast [110]. Histological evaluation reveals that bovine mammary tissue is more similar to that of humans than is mammary tissue of traditional animal models such as mice and rats. The ductal structures in the human and cow are surrounded by relatively dense stromal tissue [111,112] unlike the ducts in the mouse which are almost completely enclosed by adipocytes [113].

Table 36.1 summarizes the similarities and differences seen in mammary gland development in mice, humans, pigs, and ruminant animals like sheep, goats, and cows. However, larger sized animals present logistical and financial issues. Large animals are much more expensive than smaller animals and fewer researchers are trained in, or have the facilities for, the proper care of these larger animals [108].

Breast tissue test systems

To better mimic aspects of the *in vivo* setting, three-dimensional tissue test systems are used to model experimental clinical conditions. Events that are notable in a 2D setting may not be present in a 3D setting, or vice versa [5]. Breast tissue test systems can be used to inform tissue-engineering reconstructive techniques, or to better understand and prevent the disease process. Many studies have been conducted to assess breast cell co-cultures in 3D. The 3D material, i.e., the scaffold, has enormous influence on cellular behavior, and can be selected according to the biological aspect of interest. Obviously, 2D cultures are not amenable to the study of ductal structures or questions regarding spatial co-location [114].

In order to distinguish tissue test systems from *in vivo* human or animal models and refine the expectations of an *in vitro* model, a tissue test system can be defined as a modular unit of 'useful' biology. A tissue test system is depicted in Fig. 36.2 as a tissue model built using a Lego™-like approach with biological and non-biological components that can then be used to answer biological questions. The three primary questions that must be considered in designing a test system are:

1) What is the biological question of interest and how can this question be answered with an approximate biological model?

TABLE 36.1 Comparative aspects of mammary gland development [108]

Attribute	Mice	Humans	Pigs	Ruminaants
Morphology	Sparse ducts: alveolar	TDLU	TDLU	TDLU
Stromal histology	Adipose » connective	Intralobular, interlobular connective » adipose	Intralobular, interlobular connective » adipose	Intralobular, interlobular connective » adipose
No. of ductules/TDLU (Types 1, 2, and 3, respectively)	N/A	11, 47, 81	9, 24, 64	Not defined
No. of galactophores	1	~ 8–15	2	1
Epithelial proliferation	Concentrated in endbuds and alveoli	Concentrated in endbuds or TDLU	Concentrated in endbuds or TDLU	Peripheral zones of TDLU
Response to estrogen	Endbud	Epithelial	Endbuds, TDLU	Epithelial
Response to progesterone	Alveoli	Negative, or No Effect	No Effect	No Effect
Mammary tumors	Spontaneous, viral origin	Spontaneous	Rare, few cases	Rare, few cases
Tumor precursor	AH, ADH, DCIS	ADH, DCIS	Unknown	Unknown
Tumor hormone dependence	Rare	50–60%	Unknown	Unknown

Abbreviations: TDLU: terminal ductal lobular unit, AH: alveolar hyperplasia, ADH: atypical ductal hyperplasia, DCIS: ductal carcinoma *in situ*, TDLU: terminal ductal lobular unit.

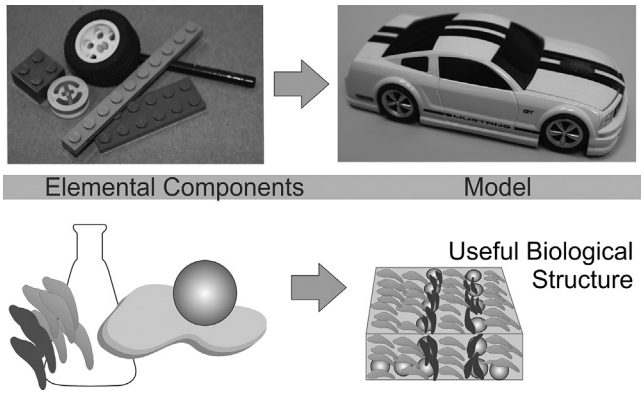

FIGURE 36.2
Top row shows the Lego™ approach where plastic blocks are used to build complex models. The analogy to biofabrication of a tissue test system is shown in the bottom row where the elemental components, cellular units, biomaterials such as beads, fibers, or gels, and biochemical agents are assembled to produce a tissue model.

2) What are the elemental components (i.e., the Lego blocks) and how are the elemental components arranged to make the biological model?
3) How will the elemental components be assembled and the final tissue cultured?

One cannot survive in the world without mentally forming cause and effect relationships — models — that provide useful advice about behaviors of the systems around us. Many natural systems are understood through models which provide useful information, such as predicting the future state of a system for a change in environmental conditions. As an example, the behavior of a resistance may be described by the simple Ohm's law mathematical model of the voltage across the resistance equals the resistance multiplied by the current, $v = Ri$. This model is 'useful' to make calculations such as how many light bulbs could be connected to an electric circuit. The Ohm's law model is easy to use, scales to more complex problems, is consistent and reliable since it works for anything that is a pure resistance, has been verified by experimentation, is cost effective to use, can be extended to account for additional physical phenomena, and increases understanding of the system. Thus, even though the Ohm's law model is not a copy of the resistance it provides useful information. A tissue test system holds the same promise to provide a model that facilitates the creation and sharing of new knowledge of breast tissue processes.

The Ohm's law resistance model has obvious limitations. When the model is tested under unmodeled conditions like very high temperatures, the information from the resistor model becomes less accurate and hence less 'useful'. In this case the resistance model can be updated by changing the constant resistance to a function of temperature, i.e., $R(T)$. Specifically, the resistor model must be designed to include the phenomena that affect the accuracy and resolution needed to provide useful information for a specific question of interest. Thus, a breast tissue test system must be defined to match the expectations of the user to provide useful information. Practically, a tissue test system must be defined to meet the user's needs and likely should not be an exact duplication of the *in vivo* biology; rather, it should capture only the salient physiological, mechanical, biochemical, morphological, and biological elements needed to study a specific phenomenon.

A general schematic of the process of designing, fabricating, and using a tissue test system is shown in Fig. 36.3. Tissue test system development begins with sampling the physical system

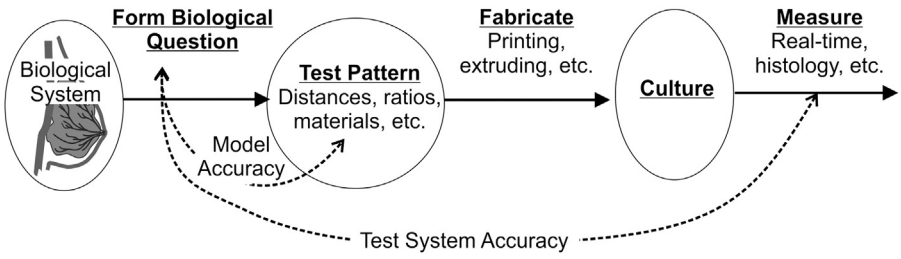

FIGURE 36.3
Process of developing biologically relevant tissue test systems.

to identify the scope and features needed in the test system model. The first challenge in using a tissue test system is defining what behaviors in the native system must be included to address a specific question of interest; that is, what does one intend to learn from the tissue test system and what are the first-order factors that affect the behavior under study. Model accuracy is used here to describe the translation of a biological question into a test pattern or structure for the tissue test system. Note that high model accuracy does not mean that the test pattern must be an exact reproduction of the biological structure, in this case the breast; rather, it must be a representation of the underlying chemical, physical, electrical, etc. phenomena that are useful for answering a specific biological question regarding breast tissue. In fact, a well-designed test system will exclude factors that confound answering the biological question of interest. Hence, different biological questions will require different test system models. As an example, there are currently test systems, such as those addressing adhesion assays, that comprise cells seeded onto a plate. These are relatively straightforward test systems to implement and hence are often the first assays performed. Such a flat, two-dimensional (2D) system can answer important questions; for example, adhesion assays were used to study the expression and function of Laminin-511 during metastatic breast cancer progression [115]. These results can inform decisions regarding incorporation of Laminin-511 in a breast tissue implant, or regarding selection of reconstructive biomaterials that may promote or inhibit production of this extracellular protein. Note, however, that 2D cultures are not amenable to the study of breast ductal structures or questions regarding spatial co-location [114]. Following Fig. 36.3, the test pattern must be fabricated, for example by cell printing, and then cultured. The fabrication system to produce a desired test system and then the culture system, e.g., a bioreactor, to produce the environmental conditions, such as temperature or pH, present significant instrumentation challenges. Test system accuracy describes the overall degree to which the biological question of interest can be studied in the *in vitro* culture.

An established tool in breast cancer studies that is also applicable to breast reconstruction research is the breast tissue organoid, which is formed by digesting harvested tissues into duct-like structures that resemble the original organ in appearance or function. While it is obvious that an organoid model formed by removing tissue and allowing the remaining tissue to grow in a new manner is not a physical copy of the breast tissue, it has been shown that this simplified model can produce useful results. For example, in the work by Cellurale and coworkers [116] the authors were able to isolate the role of cJun NH2-terminal kinase signaling in mammary gland development and tumorigenesis using mammary organoid cultures. In other studies [117], organoids were used as the basic building block of human mammary epithelial cell cultures. The organoid model uses an elemental component that already has significant structure and is directly derived from the biological source. There are more general approaches to building test systems that use biofabrication techniques to assemble smaller elemental pieces. Fig. 36.4 shows additional considerations in biofabricating a test system

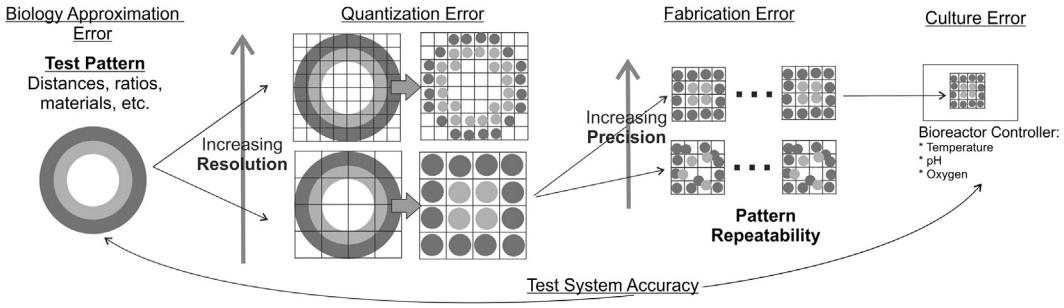

FIGURE 36.4
Sources of error in biofabrication of tissue test systems include the quantization error that arises from resolution of the fabrication instrumentation, the fabrication errors that arise from the precision and repeatability of the fabrication instrumentation, and the culture errors that arise from the ability of the culture controller to reproduce environmental conditions.

model. The first source of potential error is the discretization of a proposed test pattern based on the resolution of the fabrication system. The two-dimensional pixel error is illustrated in the second column of Fig. 36.4 where it can be seen that the biofabrication system with the coarser resolution produces a lower-fidelity replica of the test pattern. The 3D equivalent of pixel error is the voxel error which includes the pixel error as well as a depth component. For example, if a test pattern is defined at the cellular level using micron resolution, such as a scan of a histology slide, then a biofabrication technique that has a smallest fabrication component on the order of a millimeter can only produce an approximate copy of the desired pattern. Thus the approximation of continuous biology with discrete fabrication components leads to quantization error.

The second fabrication error type is in the ability of the biofabrication technique to result in placement of elemental components at a desired location. As illustrated in the third column of Fig. 36.4, high precision means that the system can closely replicate the discretized test pattern. The ability of a process to produce identical replicates of a test pattern is then defined as the pattern repeatability. This is defined as different from the machine precision because occurrences such as cell settling in storage reservoirs can cause evolution of the biofabrication instrumentation precision over time. Note that there is much debate about how much quantization error and fabrication error can be tolerated in building a useful tissue structure. One consideration is that tissue structures will self-assemble from an appropriate starting condition [118]. Specifically, placing cells 'close enough' will allow them to move and assemble based on their natural behaviors. Any approach to tissue fabrication will require that nature take over for the final stage of tissue assembly, the idea of 'close enough' is actively debated. There are two main technologies used to place the cellular components to fabricate a tissue system (see Fig. 36.5a). In the first approach, known as drop-on-demand deposition, a fixed quantity of cells and medium are deposited as a single drop. A representative method of forming these droplets is inkjet printing [119]. Inkjet printing uses either a thermal or mechanical process to eject a fixed droplet size (on the order of 100pL). This same process is used in many home color printers. A biofabrication system based on thermal inkjet printing is shown in Fig. 36.5b. A second technology is the deposition of a small block or pellet of cells through extrusion or separation from a feedstock. Speed, cost, damage to cells, and resolution are the differences that distinguish these technologies.

The ability of the tissue culture system to reproduce environmental conditions can greatly affect overall results, the culture error shown in the last stage of Fig. 36.4. An important part of specifying the tissue test system is to define the environmental conditions, e.g., dissolved oxygen level, that will be used to incubate the tissue. The capability of the culture system to produce these conditions must be considered; limitations occur in the ability of the instrumentation to measure a quantity of interest and the ability of the control system to modulate that quantity. As with all aspects of the tissue test system, the environment is a simplified model of the actual environment and as such must be designed at the start of a project to address a specific question of interest.

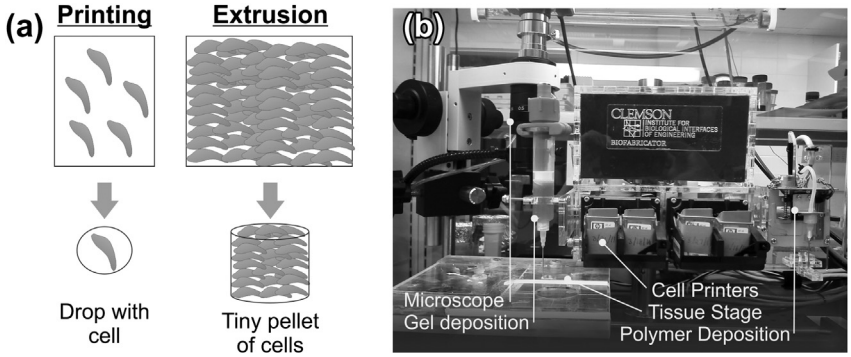

FIGURE 36.5
(a) Two general approaches to cell deposition, printing of cells in medium and extrusion of small cell pellets. (b) Photo of a biofabrication system with multiple deposition stations for cells and biomaterials.

As a final consideration, the state or feature of interest must be measured in the tissue or medium during and/or after culture. A tissue test system can present the same imaging and measurement challenges as *in vivo* experiments – real-time measurements like oxygen levels, discrete measurements like magnetic resonance imaging, and endpoint analysis like classical histology may all be used but have the same fundamental instrumentation limitations. However, there are several important advantages of a tissue test system over an *in vivo* model. First, there is the possibility that sensors can be embedded directly into the tissue design. For example, it is possible to embed a temperature sensor in the center of a tumor mass as it is fabricated. Second, the tissue is potentially more amenable to direct observation than *in vivo*, e.g., a tumor model could be grown on a microscope stage and images automatically taken at regular intervals to observe spreading or growth. There is generally improved access to both inputs and outputs of the culture in a test system, agents can be applied without metabolism or complex pharmokinetics distorting the input. As an example, it is possible to apply an anti-angiogenic agent to a cell culture and know the local concentration without measurement because the pharmokinetics can be easily modeled as a mixing problem in a fixed volume. Similar arguments suggest that observation of outputs, such as metabolic byproducts, are more accessible in a test system. Perhaps the most important advantage that the tissue test system can have over an *in vivo* test is that, given low fabrication errors and culture errors, each copy of the test tissue should be nearly identical. This means that replicates can increase the power of observations and increase the ability of outside groups to repeat experiments and results. In general, a tissue test system should make the biology of interest more accessible for observation and manipulation.

In summary, tissue test systems are an evolving approach to modeling complex biological systems *in vitro*. Ethical, economic and scientific drivers will ensure that this technology continues to evolve. However, the use and expectations of the test system must recognize that the tissue and culture environment is an approximate model that must be designed to address a specific question of interest. As researchers and clinicians begin to appreciate all of the subtleties of designing, fabricating, culturing, and assessing tissue test systems, these approximate models will help reveal the complexities of breast biology and disease processes and therefore will provide the insight to engineering breast tissue. As tissue test systems, the basic units of useful biology, become standardized they can be integrated to produce systems capable of answering ever more complex questions.

In silico breast cancer models

Mathematical modeling of breast cancer continues to advance rapidly, so much so that any summary is nearly obsolete at the time of writing. However, a brief overview of some approaches helps demonstrate the potential and challenges of mathematical and computer models. Generally speaking, there are two starting points for deriving a mathematical model, the first is the application of basic chemical and physical equations (first principles) to create a model, and the second is the observation of physical behavior and use of mathematical tools to capture this behavior. A model may be proposed to work at a specific scale, such as at the molecular level, the cellular level, the organ level, the organism-wide level, or the population level. Initially, models were developed to capture the behavior of an isolated system at a fixed scale. As modeling sophistication has increased, multi-scale models [120] of connected subsystems have evolved. Often the models are referred to as '*in silico*' to indicate that the simulation is performed on a computer and to highlight their similarity in role to *in vivo* or *in vitro* models. As with other modeling approaches, the best model is the one that allows the user to address the question at hand.

As an example of a simple model, tumor angiogenesis is modeled as a set of two interconnected differential equations, one subsystem models tumor growth and one subsystem models the carrying capacity of the vascular network [121]. This model appears to be a gross

summary (as an ordinary differential equation) of the physical diffusion processes and the effects of the biological signals that stimulate or inhibit angiogenesis. However, analysis of the model has provided new insight into the scheduling of anti-angiogenic treatments. The traditional dosing of such a therapy centers on applying a constant dose at regular time intervals; however, the model provides the structure to apply optimization and control techniques that suggest a more efficient use of the treatment agent [121,122]. There will always be questions about the resolution and accuracy of any mathematical model. For example, the angiogenesis model may not be sufficient to model clinical cancer treatment. By connecting a second subsystem model, the movement of bone-marrow-derived endothelial progenitor cells to the tumor site and their effect on tumor growth can be used as a starting point to model vasculogenesis [123]. Such a model can clarify further the possible treatment strategies, including chemotherapy and anti-angiogenic therapies aimed at suppressing vascularization, which may be incorporated in a tissue-engineered implant.

CONCLUDING REMARKS

Tissue engineering may provide a means of both assessing and building reconstructive breast implants for a woman undergoing lumpectomy or mastectomy. The development of vascularization and the long-term retention of tissue volume are keys to viable breast reconstruction options. Benchtop tissue test systems will be critically important in addressing these two major issues, by facilitating markedly improved understanding of the normal and diseased states and, accordingly, assessing and developing advanced reconstructive options.

CHAPTER 37

Progenitor Cells and Cardiac Homeostasis and Regeneration

Annarosa Leri, Jan Kajstura and Piero Anversa
Center for Regenerative Medicine, Departments of Anesthesia and Medicine, and Division of Cardiovascular Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts

INTRODUCTION

Complementary methodologies introduced in various laboratories have provided clear evidence of the dynamic state of the normal and pathologic heart. This novel view of cardiac biology has introduced the concept of the heart as an organ that is permissive for myocardial regeneration. However, the magnitude of myocyte turnover and the cell of origin of the newly formed parenchyma remain a matter of debate. These two relevant issues are discussed in our chapter. Understanding the biological process that leads to myocyte formation is a challenging task that requires the characterization, at the single cell level, of the phenotypical and functional properties of myocytes and non-myocytes within the heart. By this approach, it is possible to discriminate whether myocyte renewal is accomplished by:

a) The commitment of stem cells that generate all specialized lineages within the cardiac tissue;
b) The replication of pre-existing myocytes to produce more cells of identical lineage; or
c) The dedifferentiation of pre-existing cardiomyocytes that lose their specialized function, acquire progenitor properties, re-enter the cell cycle, and, eventually, regain the original specialized phenotype.

These multiple mechanisms of tissue restoration may act in concert to regenerate organs like the heart with a complex structural and functional identity. This information is of critical relevance for the development of novel cell-based therapies that may prevent the onset of heart failure or delay its evolution.

CARDIAC PROGENITORS IN THE ADULT HEART

Because of the controversy concerning the true existence of stem cells in the heart and their role, if any, in cardiac homeostasis and repair, an overview of the characteristics of the multiple progenitor cell classes identified in the adult heart is needed for a better understanding of the cell of origin of the newly formed cardiomyocytes. Several laboratories have demonstrated that the heart contains a compartment of primitive cells with the characteristics of stem cells; however, the identification of the actual cardiac stem cell (CSC), equivalent to the

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00037-9

hematopoietic stem cell (HSC) in the bone marrow, has been controversial. After the discovery of c-kit-positive CSCs (see the section 'C-Kit-Positive Cardiac Stem Cells'), different classes of progenitor cells have been characterized in the adult heart, but whether they represent distinct categories of undifferentiated cells with diverse functional properties is currently unknown. A variety of surface antigens, transcription factors and functional assays have been used to define these cells.

The first identification of myocardial progenitors was based on the ability of stem cells to expel toxic compounds and dyes through an ATP-binding cassette transporter [1]. This property, used initially to isolate side population (SP) hematopoietic cells, defines a pool of putative cardiac progenitors which form colonies in semisolid media and differentiate into cardiomyocytes. Although a comprehensive analysis of stem cell properties was not performed in this early study, the work by Rudnicki and collaborators introduced the concept of a myocardial stem cell that participates in the response of the heart to ischemic injury.

The presence of ABC-transporter activity has been tested repeatedly by exposing cardiac cells to the DNA-binding dye Hoechst 33342; functionally competent cells clear the fluorochrome, become Hoechst-low, and occupy a side position in the fluorescence-activated cell sorter (FACS) profile [2]. However, the protocol for the separation of bone marrow SP cells cannot be applied to solid organs such as the heart without caveats. This technical difficulty has led to the isolation of several classes of unrelated cardiac SP cells.

SP cells were found to comprise a surprisingly large pool of cardiac cells in the mouse ($\sim$2%) which were Sca1^{high}, c-kit^{low}, CD34^{low}, and CD45^{low}. The ability to extrude dyes was attributed to the expression of the multidrug resistance protein Abcg2. Despite their high percentage and the presence of the vascular marker Sca1, lineage tracing assays indicated that Abcg2-positive cells do not include endothelial cells (ECs) [3]. A distinct side cell population was reported to include 4%, 2%, and 1.2% of cells in the fetal, neonatal, and adult rat heart, respectively. Bcrp1 was considered the molecular determinant of the SP phenotype [4]; however, most Bcrp1-positive cells expressed CD31 and were located within the intima of the vessel wall. CD31-negative Bcrp1-positive SP cells were also detected in the peri-vascular region and myocardial interstitium; they expressed CD29 and N-cadherin at the interface with myocytes and smooth muscle cells (SMCs). After injury, SP cells generated predominantly vimentin-positive fibroblasts and calponin-positive SMCs; a small fraction of cells acquired the myocyte and EC lineage [4].

An atypical subset of SP cells was considered to represent embryonic fetal remnants of neural crest-derived cells. These cells formed clonal spheroids, expressed markers of neural precursors, including nestin and Musashi-1, and generated *in vitro* neuron-like dendrites and peripheral nerve cells [5]. Following, transplantation into chick embryos, these SP cells formed cardiomyocytes.

The unusual and dissimilar properties of the multiple SP pools identified in the adult heart emphasized the need to introduce substantial modifications to the original protocol employed in the bone marrow and establish a methodology better suited for cell isolation from the adult mouse myocardium [2]. The SP functional assay was combined with labeling of the surface markers Sca1 and CD31 to select for Sca1-positive/CD31-negative cardiac cells, a subset of cardiac SP cells with enriched cardiomyogenic potential [6]. By this approach, functionally homogenous SP cells were obtained and their molecular properties clearly defined. SP cells express in a developmentally regulated manner the P-glycoproteins Abcg2 and Mdr1: Abcg2 is responsible for dye efflux during postnatal development, whereas in adulthood this function is mediated exclusively by Mdr1. Sca1-positive, CD31-negative, cardiac SP cells can acquire the molecular and functional characteristics of adult myocytes [6]. Abcg2 promotes proliferation and survival of SP cells inhibiting differentiation. Deregulation of Abcg2 may alter the fate of

these progenitors, resulting in uncontrolled cell growth or death [7]. Additionally, the canonical Wnt signaling plays a crucial role in the maintenance of the self-renewal ability of this cell class [8]. Bone marrow SP cells do not contribute to the maintenance of the cardiac SP cells in physiological conditions, but can repopulate the resident pool after injury.

Different protocols have resulted in the isolation of distinct Sca1-positive cells, which do not possess the functional properties of stem cells. Sca1 progenitors were found to represent 2% of heart cells and 15% of the myocyte-depleted fraction [9]. In culture, only 3–4% of Sca1-positive cells displayed sarcomeric proteins, and the *in vivo* delivery of these cells led to modest cardiomyogenesis mediated by fusion with resident cells. A distinct immunoselection strategy resulted in the isolation of a pool of murine Sca1-positive cells that accounted for 0.3% of the myocyte compartment [10]. Approximately 10–40% of the cells expressed the pan-leukocyte marker CD45 and the hematopoietic/endothelial epitope CD34. After exposure to oxytocin, Sca1-positive CD45-negative cells showed cardiac transcription factors and contractile proteins organized in sarcomeric structures [10]. In permissive media, Sca1 cells differentiate into osteocytes and adipocytes, strongly suggesting that the Sca1 antigen identifies a heterogeneous cell population composed of hematopoietic, mesenchymal, endothelial, and cardiac progenitors. Monolayered sheets of Sca1-positive cells placed over the necrotic myocardium prevented negative remodeling and improved cardiac function after infarction [11]. This finding raised the possibility that cell transplantation acts through the release of humoral factors, activating endogenous CSCs or recruiting bone marrow cells to the infarcted myocardium. In addition, these cells generate SMCs, ECs, adipocytes, and osteoblasts.

State of the art imaging protocols have been developed to follow *in vivo* the destiny of Sca1-positive cells [12]. Sca1-positive cells were isolated from transgenic mice that constitutively express luciferase and EGFP, enabling *in vivo* tracking by non-invasive imaging and post-mortem identification by immunolabeling [12]. The robust bioluminescence signal at day two decayed with time and the non-viable infarcted portion of the wall was not reduced by cell treatment. Consistently, echocardiographic and MRI measurements did not show functional improvement; an extremely small number of EGFP-positive regenerated myocytes and vessels were found at sacrifice. Poor survival and rapid death of injected cells are common outcomes when neonatal cardiomyocytes, mesenchymal stromal cells, bone marrow mononuclear cells, and human embryonic stem cell-derived cardiomyocytes are adoptively transferred [13]. This phenomenon has prompted the development of novel strategies involving pre-activation with growth factors, application of bioengineering methods, and genetic modifications to achieve long-term homing to the injured myocardium. However, the role of Sca1-positive cells in cardiac homeostasis remains to be defined.

An alternative source of progenitor cells has been identified in the epicardium, which represents an epithelial sheet on the cardiac surface. The epicardium derives from an extracardiac transient structure, the proepicardium, which is located near the venous pole of the developing heart [14]. In avian species, the proepicardium is viewed as the site of origin of hemangioblasts, a pool of immature cells that are considered critical for the development of the coronary circulation. Hemangioblasts migrate from the proepicardium to the avascular heart tube, giving rise first to the epicardial sheet and subsequently to the endothelial and smooth muscle layers of coronary vessels [14].

Proepicardial cells may not contribute directly to cardiomyogenesis in birds but favor the expansion of myogenic precursors through a paracrine mechanism [15]. In mammals, the identification of an equivalent hemangioblast remains controversial [16], although the existence of a murine hemangioblast has been claimed by *in vitro* studies of embryonic stem cell differentiation. Cells expressing brachyury and flk1 generate in culture hematopoietic cells and, at later time-points, myocytes, ECs, and SMCs [17]. Whether brachyury-flk1-positive cells exist *in vivo*, however, is unknown.

The embryonic fetal epicardium hosts several classes of progenitor cells, uncovering previously unexpected functions of this outer cardiac layer. The epicardial markers WT1 and Tbx18 mark distinct pools of progenitors that travel from the proepicardium to the myocardium, where they form the epicardium and give rise to electrically coupled cardiomyocytes [18,19]. A population of c-kit-positive epicardial cells has been identified in the human heart. These cells accumulate in the subepicardial space of hearts affected by ischemic cardiomyopathy [20]. Experimentally, c-kit-positive epicardial cells migrate from the epicardium to the infarct, where they proliferate and differentiate into myocyte precursors and vascular cells [21]. This process is coupled with upregulation of fetal epicardial markers [22]. The recognition of growth factors modulating the behavior of epicardial progenitors may allow their activation *in situ*, possibly influencing the treatment of the human disease.

The expansion of progenitor cells in non-adhesive substrates leads to the formation of floating spheres. This peculiar form of anchorage-independent growth has been used for the expansion of cardiospheres from endomyocardial biopsies [23]. Cardiospheres contain a core of c-kit-positive primitive cells, several layers of differentiating cells expressing myocyte proteins and connexin 43, and an outer sheet composed of mesenchymal stromal cells. C-kit-positive cells within the aggregates do not correspond to a uniform class of progenitors because of the heterogeneity dictated by the uncommitted or early committed state of the cells, their quiescent or cycling condition, or their migratory properties. This may explain the observed differences in the regenerative potential of single-cell-derived clonal c-kit-positive CSCs [24] and c-kit-positive cells sorted from cardiospheres [25].

The expression of connexin 43 at the interface between immature and differentiated cells may play a dual role. Connexin 43 in undifferentiated progenitors favors their proliferation, whereas connexin 43 in cells committed to the myocyte fate promotes electric coupling with the surrounding cells and the acquisition of functional competence. The presence of intercellular gap junctions within the cardiospheres raises the possibility that the differentiated cells may function as supporting cells. If this were the case, then the cardiospheres would reconstitute *in vitro* the complex structure of the cardiac niches identified *in vivo* [26].

The ISL1 transcription factor is associated with the commitment to the myocyte lineage of cardiac cells that have lost their undifferentiated stem cell fate. ISL1 and GATA4 are transcriptional coactivators of the myocyte transcription factor MEF2C. The cardiomyocyte specification dictated by the expression of ISL1 is coupled with a modest ability of these cells to divide and form clones and, most importantly, to the lack of self-renewal ability. ISL1-positive cells are restricted to the embryonic fetal heart and are no longer present at birth [13], making the possibility of their clinical implementation extremely unlikely. By lineage tracing [27], a few myocytes and vascular ECs and SMCs were found to originate from ISL1-positive cardioblasts, but the frequency of this event was very low.

Collectively, these findings indicate that the heart contains populations of immature cells, which, to a different extent, give rise to cardiomyocytes participating in tissue repair. However, the role of these cell categories in cardiac homeostasis and pathology has to be determined, and the clinically relevant question of whether the human heart possesses a class of CSCs to be employed therapeutically remained to be defined.

C-KIT-POSITIVE CARDIAC STEM CELLS

Cardiomyocytes, as the majority of cells in adult organs, are long-lived cells. If cells persist for most of the lifespan of an animal or individual, their functional capacity is expected to decline with time, compromising organ performance. According to the dogma, ventricular myocytes are terminally differentiated cells and their lifespan corresponds to that of the individual. The number of myocytes attains an adult value a few months after birth, and the same myocytes are believed to contract 70 times per minute throughout life. However, several reports have

provided evidence supporting the view that myocytes die and new cells are constantly formed in the normal heart at all ages. Both processes are markedly enhanced in pathologic states and the imbalance between cell growth and cell death may be an important determinant of the onset of ventricular dysfunction and its evolution to terminal failure.

The c-kit receptor tyrosine kinase was detected originally in a class of murine HSCs with long-term reconstituting ability in irradiated recipients. More recently, c-kit has been found in several populations of stem cells in the adult lung, liver, brain, and pancreas [13]. Several lines of evidence have been accumulated in favor of the view that cardiac cells expressing the c-kit receptor are *bona fide* stem cells; they include the capacity to self-renew, form multicellular clones, and give rise to a committed progeny *in vitro* and *in vivo* [24,28–30] (Fig. 37.1). However, differentiation assays of stem cell clones *in vitro* have inherent limitations including the possibility that culture conditions result in the preferential acquisition of a selective lineage phenotype, masking the *in vivo* potential of the founder cell. Similarly, the identification of multiple phenotypes in the progeny of transplanted non-clonal stem cell populations does not provide a direct evidence of the multipotentiality of each administered cell. This problem has been overcome by the delivery of single-cell-derived clonal CSCs to the injured myocardium;

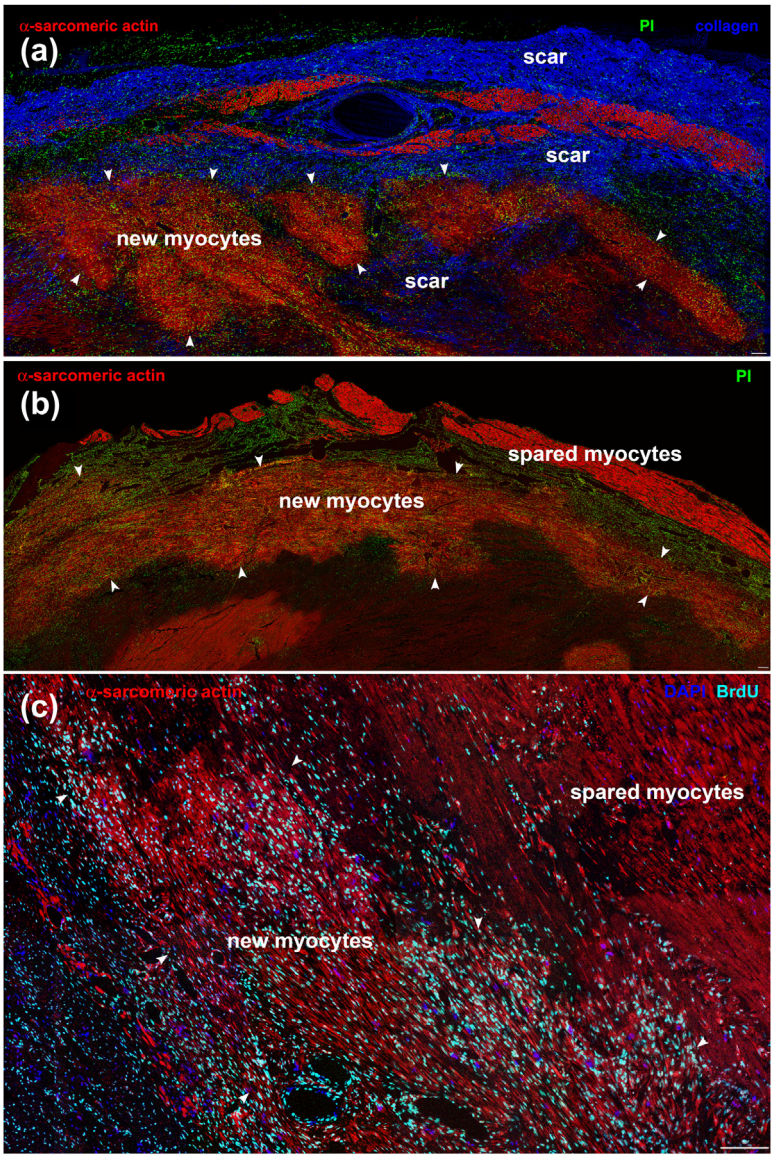

FIGURE 37.1
Myocardial regeneration after infarction. (a) Non-treated infarcted canine heart: the healing process is characterized by the formation of a scar (collagen I-III, blue). (b) Newly-formed myocytes are clustered (α-sarcomeric actin, red, arrowheads) within the area of damage. (c) Bright blue fluorescence in nuclei corresponds to BrdU labeling of accumulated newly formed myocytes.

by necessity, all regenerated structures derive from the individual founder cell that underwent amplification *ex vivo* [24].

Criticisms, however, have been raised concerning the possibility that serial passaging may modify the original properties of CSCs and that tissue injury may affect in an unpredictable manner the fate of CSCs *in vivo*. Novel protocols have been introduced to document unequivocally that cardiomyocytes and coronary vessels originate from CSCs in the non-damaged heart and during physiological aging. Specifically, viral tagging and clonal marking have been implemented to determine whether a resident stem cell pool is present in the myocardium and participate in organ homeosatsis physiologically [30]. Genetic tagging with retroviruses was introduced more than 20 years ago for the characterization of individual HSCs and their progeny [31]. The analysis of the clonality of CSCs and myocyte turnover cannot be performed in humans since it requires genetic tagging of the undifferentiated cells so that the clonal marker of individual mother cells is traced in the specialized progeny *in vivo*. C-kit-positive CSCs located in the niches of the atrio-ventricular groove and apex of the mouse heart were infected with a lentivirus carrying EGFP and the destiny of the labeled cells was determined 1−6 months later [30], providing the opportunity to assess the behavior of tissue-resident primitive cells in the non-injured heart. Although the rate of myocyte turnover in the intact heart is slower than the rapid pace at which cells renew themselves in the presence of damage, the intrinsic properties of CSCs are better characterized when tissue lesions are absent. A common integration site was identified in isolated c-kit-positive CSCs, cardiomyocytes, ECs and fibroblasts, documenting the multipotentiality of CSCs and the clonal origin of the differentiated cells [30]. During a six month period, each EGFP-positive CSC divided around eight times giving rise to 230 cardiomyocytes. These findings, together with data obtained with BrdU pulse-chase assays [26,30,32], indicate that activation and differentiation of CSCs is an ongoing process which results in a significant renewal of cardiomyocytes in the adult mouse heart.

Although viral clonal marking represents the only protocol that can establish the multipotentiality of CSCs *in situ*, limitations involve the low efficiency of CSC infection and the impossibility to collect serial samples of the transduced progeny in small animals. Moreover, whether the insertion site confers a selective advantage or disadvantage to the growth of single cells may be easily assessed in blood cells but cannot be established with certainty in the heart. An additional variable that may influence the assessment of myocyte formation from tagged CSCs involves the insertion of the proviral integrant in repressive regions of the mouse genome [33]. However, silencing of the reporter gene interferes with the recognition of labeled cells by immunohistochemistry but does not affect the analysis of integration sites by PCR.

EGFP is a widely used fluorescent tag for the analysis of the fate of progenitor cells *in vivo* following adoptive transfer, and in lineage tracing and viral clonal marking assays. The immunogenic potential of this foreign protein has raised questions on the appropriateness of its utilization in long-term studies. Processed peptides derived from EGFP may be presented by the major histocompatibility complex on the cell surface, potentially inducing a T cell immune response against the labeled cells. Cells transduced with genes perceived as foreign proteins by the recipient may actively engraft but may be subsequently cleared by the immune system [34]. The magnitude of immunological rejection of cells carrying EGFP remains controversial and most likely context-dependent. Different degrees of bone marrow ablation from sub-lethal irradiation to minimal conditioning have been employed to prevent rejection of EGFP-infected hematopoietic cells [35]. This phenomenon may result in an underestimation of the number of EGFP-positive CSCs and their tagged progeny.

An important aspect of the clonal analysis by viral marking of CSCs *in vivo* consists of the possibility to study the behavior of these primitive cells within their natural habitat, the CSC niches.

CARDIAC STEM CELL NICHES

Stem cells are sheltered in specialized structures called niches, which provide a microenvironment designed to preserve their rarely dividing and lineage negative phenotype [36]. Interstitial structures with the architectural organization of niches have been found in the heart of animals and humans [24,26,37,38–40]. CSCs, progenitors, precursors and early differentiating cells are clustered together in the niche and are coupled with the supporting cells, myocytes and fibroblasts, by gap and adherens junctions [26]. Gap junctions are intercellular channels formed by individual structural units called connexins while adherens junctions are composed of cadherins [41]. Some of the molecular mechanisms that regulate growth, migration, and differentiation of CSCs within the cardiac niches have been identified recently.

In the niches, stem cells divide symmetrically and asymmetrically. When stem cells divide symmetrically, two self-renewing daughter stem cells may be formed. The purpose of this modality of replication, which occurs in active phases of growth during prenatal organ development, is the expansion of the stem cell pool. Stem cells can also divide symmetrically into two committed daughter cells; this type of cytokinesis is triggered by an emergency situation requiring the restoration of the lost tissue upon a pathological insult. With asymmetric division, two differently fated sibling cells are generated: one daughter-stem cell and one daughter-committed cell. The non-stem cell sister is a short-lived committed progenitor cell that divides and simultaneously differentiates, i.e. the amplifying cell [36]. When the amplifying cell has acquired complete maturation, it cannot divide further; it has reached terminal differentiation and growth arrest. The objective of asymmetric division is the maintenance of a steady state in which organ homeostasis is conditioned by a tight balance between stem cell formation and the production of a committed progeny. The developmental choice made by CSCs at any given time has a direct impact on the number of stem cells, progenitors, precursors, amplifying cells and, ultimately, mature cells in a tissue. The size of the amplifying myocyte pool conditions the magnitude of the homeostatic and regenerative response in damaged heart.

The inhomogeneous intracellular segregation of selective proteins in daughter cells at the time of mitosis constitutes the intrinsic determinants of CSC fate in animals and humans. Genes, including numb, α-adaptin and members of the Notch pathway, interact to enable single primitive cells to produce differently destined sibling cells [42]. Numb can segregate to one of the two daughter cells or be equally distributed in the cytoplasm of both daughter cells [43]. Numb is expressed during mitosis, from late prophase to telophase, and in the early stages of life of the new daughter cell. Numb localizes to endocytic vesicles and binds to the endocytic protein α-adaptin, inducing the internalization and inactivation of the Notch receptor.

CSCs that receive Numb become unresponsive to Notch while Numb-negative CSCs retain their responsiveness to Notch and adopt the phenotype associated with Notch activation. Signaling through the Notch receptor can occur only between closely adjacent stem cells and supporting cells [44]. The Notch ligands are transmembrane proteins which upon binding cleave the Notch receptor so that its intracellular domain is translocated to the nucleus where it forms complexes with transcription factors of the recombinant DNA-binding protein (RBP). These effector pathways are operative in the heart and Notch1 activation by the Jagged1 ligand promotes upregulation of the cardiac-specific transcription factor Nkx2.5 and the commitment of CSCs to the myocyte lineage within the cardiac niches in the mouse heart [37,38]. Activation of Notch1 receptor is a critical determinant of the transition of adult CSCs to the compartment of amplifying myocytes, and inhibition of this pathway has dramatic negative consequences on the adaptation of the heart to ischemic myocardial injury (Fig. 37.2).

In addition to Notch1 activation, CSC commitment within the niches may be influenced by the transfer of ions and small molecules from terminally differentiated cardiomyocytes to adjacent stem cells through gap junctions within the niches. Local activation of resident CSCs by growth factors acutely after infarction results in a significant recovery of ventricular muscle

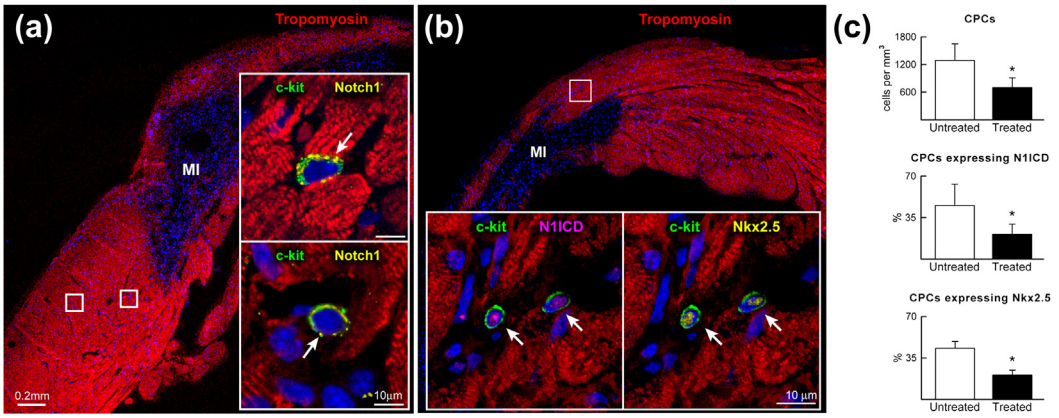

FIGURE 37.2

Notch1 function in the infarcted heart. (a) CSCs are detected in the viable myocardium of the border zone of an infarcted mouse heart. The areas included in rectangles are shown at higher magnification in the insets. CSCs express c-kit (green, arrows) and Notch1 (yellow). Myocytes, red (tropomyosin). MI: myocardial infarction. (b) Following Jagged1 stimulation, the Notch1 receptor is cleaved and its intracellular domain (N1ICD) transfers to the nucleus. N1ICD (magenta) in CSCs is consistently accompanied by the presence of Nkx2.5 (yellow). (c) Notch blockade with *in vivo* administration of γ-secretase inhibitor reduces the number of CSCs and the fraction of CSCs positive for N1ICD and Nkx2.5 in the border zone. $P < 0.05$ vs. untreated mice.

mass. However, only 20% of the regenerated myocytes acquire the adult phenotype over a period of four months while the vast majority of cells display fetal–neonatal characteristics [45]. Similarly, the intramyocardial injection of CSCs induces a substantial restoration of the infarct but the newly formed myocytes are small and resemble fetal–neonatal cells [24,28–30,32,37,40]. In contrast, the occasional migration of CSCs from the border zone to the remote myocardium results in the formation of myocytes which are indistinguishable from the pre-existing adjacent cells. The differences in the phenotype and organization of regenerated myocytes in the infarcted region and in the distant non-infarcted myocardium are apparent not only experimentally but also in the aging and diseased human heart [46–48]. With acute and chronic infarcts, a large number of myocytes is formed but the new cells consist predominantly of clusters of small, proliferating, mononucleated myocytes. The recognition that CSCs can differentiate into two cell populations, i.e., small poorly differentiated and large mature myocytes, is interesting and puzzling at the same time.

In areas of injury, the orderly organization of the niches is destroyed, raising the possibility that alterations in the control of CSC fate prevent the full maturation of cardiomyocytes. Although the mechanism regulating the growth of CSCs into small versus large myocytes is currently unknown, coupling of CSCs with post-mitotic myocytes within intact niches may be critical in determining their fate. MicroRNAs (miRs) are small RNA molecules that may have the ability to traverse gap junctions, and by this means may migrate from cardiomyocytes to CSCs dictating their destiny. MiR-499 was found to traverse gap junction channels and translocate from cardiomyocytes to structurally coupled hCSCs favoring the activation of the differentiation program [39]. These findings emphasize once more that the control of stem cell growth is not intrinsic to stem cells, but depends on communications with the microenvironment. The lack of an appropriate connection between CSCs and the surrounding myocytes may oppose CSC differentiation. The mircrine effect of cardiomyocytes on CSCs is coupled with downregulation of Sox6 and Rod1 in the primitive cells and upregulation of lineage-specific genes. Collectively, these observations are consistent with the view that the heart possesses an intrinsic capacity for regeneration, which may be exploited therapeutically.

ORIGIN OF NEWLY FORMED CARDIOMYOCYTES

Numerous reports indicate that cardiomyocytes in the adult heart derive from activation of resident stem/progenitor cells. Alternatively, it has been proposed that the origin of the

regenerated cells can be found in a non-stem cell source and consists of pre-existing myocytes, which retain the ability to proliferate or undergo dedifferentiation. The analysis of the newly formed progeny provides important information that may retrospectively lead to the recognition of the founder mother cell (Fig. 37.3). Cyclin and cdk activity, BrdU incorporation, and expression of the cell cycle proteins Ki67, MCM5, Cdc6, and phospho-histone H3 have been recognized in myocyte nuclei [13]. The identification of the mitotic spindle and contractile ring during karyokinesis and cytokinesis has further demonstrated the existence of a subpopulation of immature myocytes in the adult heart [49]. In all cases, replicating cardiomyocytes are typically mononucleated, have a 60–80% smaller volume than non-cycling myocytes, and show a disorganized contractile apparatus with modest accumulation of myofibrils [46–49].

This pattern of growth is incompatible with the notion that mature cardiomyocytes correspond to a functionally homogenous pool of cells that, upon need, re-enter the cell cycle and divide to generate new cells. According to basic principles of cell biology, this process would imply that differentiated cardiomyocytes have to double in size prior to cytokinesis and would form two daughter cells of average size. Adult myocytes in animals and humans measure ~20,000–25,000 μm^3; if these cells were to re-enter the cell cycle and divide, they would need to achieve a volume of ~40,000–50,000 μm^3 before daughter cells are formed. This sequence of events does not occur physiologically and the attempts made to reactivate the cell cycle in mature myocytes have generally been unsuccessful. In this regard, forced re-entry of myocytes into the cell cycle results in abortive mitosis with formation of anaphase bridges and apoptotic cell death [50].

As mentioned above, replicating myocytes are small and mononucleated, suggesting that these cells may derive from dedifferentiation of post-mitotic myocytes, proliferation of pre-existing immature myocytes, or activation and commitment of stem cells. To discriminate among these

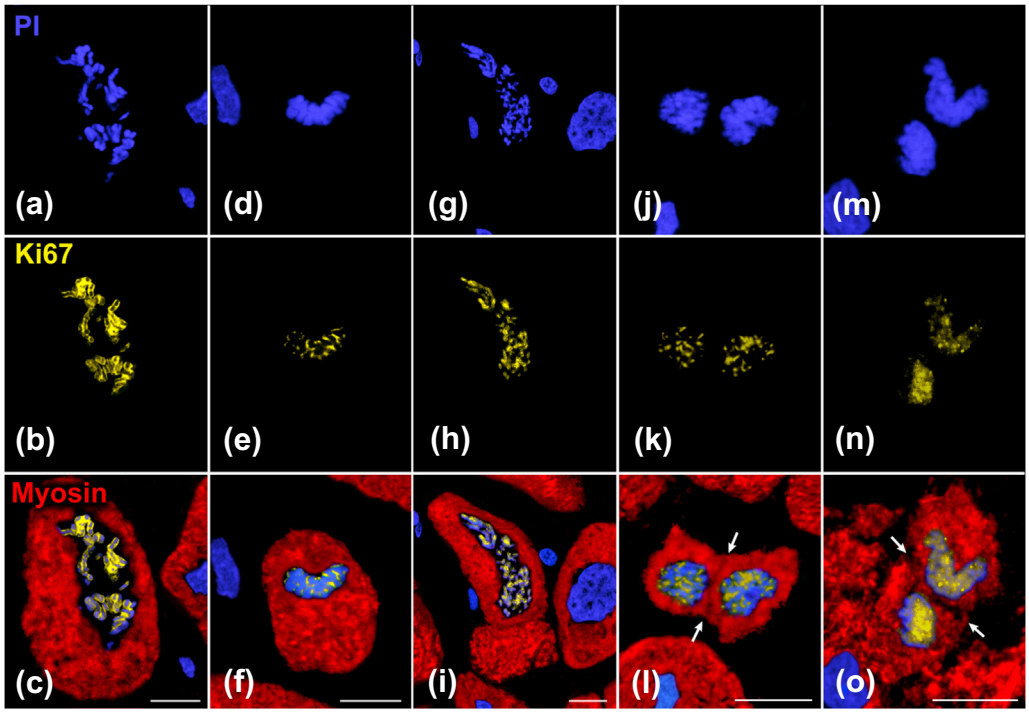

FIGURE 37.3

Mitosis, karyokinesis, and cytokinesis in myocytes. a, d, g, j, and m illustrate chromosomes by the blue staining of propidium iodide (PI). b, e, h, k, and n show Ki67 in chromosomes (yellow). c, f, i, l, and o depict the combination of cardiac myosin (red) in myocytes with PI and Ki67 staining of mitotic nuclei. Arrows point to cytokinesis.

possibilities and to prove or disprove that progenitor cells sustain cardiomyogenesis in the adult heart, studies at the single cell level must be performed. It is surprising that although stem cells are defined as single cellular entities able to self-renew and differentiate, CSCs are rarely studied clonally. Population-based analyses of stem cell behavior often fall short in defining mechanisms that may be unique to these specialized cells. The implementation of clonal assays for the study of individual stem cells is experimentally complex but is crucial for their identification and for the understanding of the mechanisms that govern stem cell growth and fate.

Clonal-based protocols include isolation and separation of single cells which are then tested retrospectively *in vitro* and *in vivo* and genetic tagging *in situ*. These methodologies have been applied infrequently to the heart and are restricted to the study of the properties of c-kit-positive CSCs. Based on clonal analysis of CSCs [24,30], the phenotypic characteristics of newly formed myocytes have been documented to reflect those of transit amplifying cells, a population that is typically present in stem cell-regulated organs [51]. Transit amplifying cells occupy an intermediate position in the hierarchy of cells within an organ and have a unique ability to divide and simultaneously differentiate. By this mechanism, amplifying cells increase the number of irreversibly committed cells generated by stem cell growth. *In vitro* and *in vivo* findings strongly suggest that replicating myocytes are transit amplifying cells derived from the lineage determination of primitive cells, supporting the view that cardiomyogenesis is controlled by a pool of resident CSCs [24,28,30,52].

With pathological cardiac hypertrophy, idiopathic dilated cardiomyopathy, acute myocardial infarction, or in the presence of hibernating myocardium, myocytes with decreased myofibrils and expansion of the undifferentiated cytoplasm have been found [13]. Partial loss in the normal distribution pattern of titin, desmin, and cardiotin has been reported, together with the re-expression of fetal genes, including α-smooth muscle actin, atrial natriuretic peptide, α-skeletal actin, and α-smooth muscle actinin. Cardiomyocytes with these structural characteristics have been interpreted as the product of cell dedifferentiation, resulting in the acquisition of an immature proliferative cell phenotype. Dedifferentiation of adult cardiomyocytes has also been claimed following inhibition of p38-MAPK [53], myocardial injection of the extracellular matrix component periostin [54], or the growth factor neuregulin [55], although the effect of periostin on myocyte replication *in vivo* has been challenged [56].

Myocytes essentially identical to those commonly involved in the prenatal and early postnatal development of the myocardium reappear in the diseased human heart, and this process may be mediated by the release from macrophages of a member of the IL-6 inflammatory cytokines, oncostatin M [57]. However, enhanced delivery of oncostatin M by macrophages in an *in vivo* model of dilated cardiomyopathy or myocardial infarction fails to promote myocyte regeneration, raising questions about the claimed beneficial effects of myocyte dedifferentiation on ventricular remodeling and cardiac hemodynamics. Similarly, the dedifferentiated cardiomyocytes identified in the human dilated and infracted heart never reached karyokinesis or cytokinesis. The expression of the fetal gene program with hemodynamic overload may simply reflect regenerated myocytes derived from commitment of resident CSCs, rather than dedifferentiation of terminally differentiated post-mitotic myocytes, which acquire an unwanted, mechanically inefficient cell phenotype [13].

Oncostatin M has also been argued to reverse *in vitro* the structural organization of post-mitotic myocytes resulting in the upregulation of several stemness genes, including c-kit [57]. Although the c-kit protein was never identified and the potential contamination of culture preparations from resident c-kit-positive progenitor cells was not excluded, a reinterpretation of the data on c-kit-positive CSCs was offered [58]. Despite the absence of *in vivo* findings, the validity of multiple demonstrations of resident c-kit positive CSCs was challenged, but the rationale for this scientific view is unclear.

Recently, the possibility of dedifferentiation was tested in fetal myocytes, obtained from mice at E16-E18 expressing EGFP under the control of the c-kit promoter; these cells should be more prone to reprogramming with respect to adult myocytes [59]. Mitotic and non-dividing myocytes expressed different levels of sarcomeric proteins but were all EGFP/c-kit-negative, excluding the occurrence of cell dedifferentiation and the reacquisition of a progenitor-like phenotype. Importantly, the generation of myocytes by dedifferentiation of mature cells, if it occurs, would have a minor role in physiological cell renewal, being restricted to cardiomyocytes. Similarly, dedifferentiated myocytes would be severely limited in their ability to sustain or improve ventricular performance following injury. Myocytes in the absence of adequate vascular supply and tissue oxygenation would be mechanically inefficient. Conversely, CSCs are multipotent and form cardiomyocytes and coronary vessels, fundamental components of myocardial repair, in a coordinated manner.

Following disassembly of the sarcomeric contractile apparatus, which physically impedes cytokinesis, differentiated cardiomyocytes have been claimed to replicate, reconstituting up to 20% of the zebra fish ventricle after resection. By cre/lox cell lineage analysis, the regenerating myocardium has been shown to derive primarily from a subpopulation of GATA4-positive cardiomyocytes rather than non-myocyte sources such as stem cells. The poorly organized sarcomeric structure of replicating GATA4-positive myocytes has led to the hypothesis that dedifferentiation constitutes the primary regenerative step [60]. However, the failure in the induction of the early myocyte commitment genes Nkx2.5 and Hand2 in the replicating myocytes indicate that the cells of origin underwent limited dedifferentiation or, most likely, that replicating GATA4-positive cardiomyocytes correspond to cells at the late stage of commitment of CSC differentiation. In the mouse heart, Nkx2.5 expression precedes GATA4 in transit amplifying cardiomyocytes originated by the lineage specification of CSCs [37].

A comparable regenerative response has been observed after surgical resection of the apex of the left ventricle in the neonatal mouse heart [61]. Again, cardiomyocyte proliferation was suggested to be the crucial cellular adaptation supporting the repair process. Despite the need of single cell analysis for the understanding of stem cell biology, population-based genetic fate mapping strategies have been employed to distinguish the contribution of pre-existing myocytes and progenitor cells to the regenerative process in the zebrafish and mouse heart. Unfortunately, this approach is inadequate to answer this question since CSCs engineered with fluorescent constructs placed under the control of promoters encoding myocyte-specific transcription factors and sarcomeric proteins show transgene protein expression [62]. Although the GATA4 and α-myosin heavy chain promoter promoters are generally considered to be active only in mature cardiomyocytes, the expression of the reporter gene in c-kit-positive cells reflects very early stage of cardiogenic lineage commitment of CSCs [37,62]. These observations support the view that myocyte regeneration in the zebrafish and neonatal mouse heart may be mediated by CSCs destined to a myocardial fate.

The intrinsic limitations of lineage tracing approach imply that the evidence of dedifferentiation is based exclusively on cellular morphology. Cells characterized by an intermediate phenotypical phase between a primitive and a fully mature phenotype have arbitrarily been considered the product of dedifferentiation. However, the lack of structural markers typical of a given cell type is not by itself indicative of the developmental stage of the cell; it is impossible to define *in vivo* whether the cell of interest is undergoing differentiation or whether it is in the process of reverting to an earlier differentiation state.

MYOCYTE TURNOVER AND CARDIAC AGING

The controversy on the growth reserve of the adult heart in animals and humans has not been resolved, and the extent of myocyte renewal claimed by different groups varies significantly. On the basis of retrospective carbon 14 (^{14}C) birth dating of cells, it has been reported that

~1% and ~0.45% replacement of myocytes occurs annually in the human heart at 25 and 75 years of age, respectively [63]. These findings indicate that only 50% of myocytes are renewed during the entire life of the human heart, from birth to death, whereas an equal number lives as long as the organ and organism, up to 100 years of age and longer. Although the possibility of myocyte regeneration was confirmed, the actual magnitude of the process is in contrast with the level of myocyte apoptosis found in the adult human heart [64] and the progressive increase in myocyte loss that occurs with aging in humans.

In a recent study, myocyte turnover was determined in normal female and male human hearts, collected from a large cohort of patients, 19 to 104 years of age, who died from causes other than cardiovascular diseases [48]. Myocyte regeneration was found to increase as a function of age, demonstrating that the age of cardiomyocytes does not coincide with the age of the organ. At all times in life, the heart contains myocytes which are younger than the organism. This discrepancy becomes more apparent in the senescent myocardium, in which a large proportion of myocytes is ~5 years old, or younger, in both women and men. The older the human heart, the younger is its myocyte compartment. From 19 to 104 years of age, essentially none of the myocytes present at birth are preserved in the young adult, middle-aged or senescent heart. In the female heart, myocyte replacement occurs at a rate of 10%, 14%, and 40% per year at 20, 60, and 100 years of age, respectively. Corresponding values in the male heart are 7%, 12%, and 32% per year, documenting that myocyte turnover involves a large and progressively increasing number of parenchymal cells with aging [48].

The striking differences between these results and the data derived from the integration of ^{14}C into the DNA of myocyte nuclei may be dictated by several variables that have been analyzed in original articles, reviews, and commentaries [13,65,66] and will not be discussed extensively here. Briefly, an inherent limitation of ^{14}C birth dating is related to the need to introduce mathematical models with assumptions that affect the computed cell turnover values [63]. Additionally, the use of troponin I expression as a marker for the isolation of a representative pool of myocyte nuclei restricts the selection to a population of $p16^{INK4a}$-positive senescent cells that exhibit marked alterations in the permeability of nuclear pore complexes [65].

It is important to emphasize that the study of cardiomyogenesis with age has to follow a stringent approach to minimize variables that confound the accurate measurement of cardiomyocyte turnover and later in life the etiology of the aging myopathy and its evolution. Therefore, specific selection criteria have to be introduced clinically, anatomically and histologically. The latter is particularly relevant, because multiple focal areas of myocardial damage and tissue fibrosis, indicative of extensive myocyte loss, are not detectable grossly and are frequently associated with an apparently normal cardiac weight, resulting from reactive hypertrophy of the remaining viable myocytes. Additionally, the concept of aging has to be carefully defined.

'Chronological age' corresponds to a time-dependent process. Old age is associated with increased morbidity and mortality and chronological age does not take into account the health of the individual. Conversely, 'biological age' is the objective assessment of a human being's health and therefore reflects the presence or absence of disease. The expression 'functional aging' has been introduced to emphasize the limitations inherent in the definition of health of an individual with respect to chronological age. This principle is based on what human beings can do in relation to others in society but it may be extended to characterize the level of functional competence retained by tissues and organs in the elderly. Finally, the concept of 'successful aging' suggests that this process is the product of a balance between gains and losses [67]. Compression of morbidity and enhanced quality of life is the foundation of successful aging.

The structural and functional alterations of the heart that accompany advancing age in otherwise healthy individuals have been interpreted as adaptive to the arterial changes that occur with aging [68]. Aging results in arterial stiffening and increased arterial systolic pressure that,

together with a mild increase in peripheral vascular resistance, leads to aortic dilatation and vessel wall thickening. In turn, these modifications promote an increase in thickness of the left ventricular wall, myocyte death and deposition of collagen [68]. Collectively, these adaptations are accountable for the decrease in reserve of the old heart. The changes in cardiovascular reserve are insufficient to produce clinical heart failure but they affect the threshold for its symptoms and signs, severity and prognosis [68]. Although cardiac aging may represent a successful adaptation of the organ to the burden of time, aging is the major independent risk factor for chronic heart failure (CHF) in the Western world. Morbidity and mortality for CHF continue to increase and parallel the extension in median lifespan of the population. At present, there are 5.7 million patients with CHF in the United States alone with an incidence of 670,000 new cases per year [69]. And the overwhelming majority of individuals with CHF are 65 years of age or older.

Studies in humans have been conducted by comparing individuals of different ages and only chronological age was considered in the interpretation of the results. However, as discussed above, chronological age and biological age do not necessarily coincide, and organism and organ aging do not necessarily proceed at the same pace. Moreover, the chronological age of individual cells in an organ is highly heterogeneous, being conditioned by the birth date of the cells; additionally, biological age differs according to the extent of damage that cells have suffered. If these variables are not considered, the possibility that an aging myopathy and the manifestations of clinical heart failure in the elderly occur independently of coronary artery disease and hypertension cannot be tested.

CARDIAC STEM CELL SENESCENCE

The demonstration that the heart harbors stem cells capable of creating functional myocardium accounts for the partial repair that occurs acutely after infarction or in the senescent heart in humans. However, it also raises the question why this regenerative response is incomplete and resident CSCs cannot reconstitute the muscle mass lost after an ischemic insult or as a result of the chronic process of aging. In the bone marrow, self-renewal of old HSCs is limited by telomere attrition [70]. Longitudinal studies in primates have documented that the expansion phase of the most primitive HSC pool coincides with the presence of long telomeres. The loss of 2–3 kbp of telomere sequences promotes a change to a functional mode characterized by a decrease in the rate of blood cell turnover. Under these circumstances, the preservation of cell number can be achieved only by increasing the lifespan of the progeny which inevitably results in the accumulation of old cells [71]. A similar condition is encountered in the aging heart.

During the course of life, CSCs undergo progressive telomere erosion which is dictated by the loss of DNA sequences that occurs at each cell cycle and as a consequence of oxidative damage [72,73]. Shortening of telomeres in CSCs may favor their symmetric division to daughter-committed cells limiting self-renewal and enhancing myocyte formation. However, this adaptive response of CSCs is inefficient because cell death exceeds cell production and newly generated cells may acquire rapidly the senescent phenotype. When differentiating CSCs traverse the transient amplifying compartment, the numerous and repeated rounds of division impose attrition on the telomeric DNA of forming myocytes [24,32,48]. A subset of CSCs with critically short telomeres may remain confined to the niche area where they cannot proliferate and differentiate. Epidermal stem cells with critically short telomeres do not translocate from the bulge of the hair follicle to the basal layer of the skin and the papilla of the hair follicle and this impairs hair growth and cutaneous cell turnover [74]. These possibilities are consistent with the characteristics of the senescent heart phenotype: impaired CSC function and accumulation of senescent myocytes.

Loss of DNA does not affect all telomeres homogeneously. Shortening preferentially occurs in a fraction of telomeres [75]. CSCs may have comparable mean telomeric lengths but exhibit

significant differences in the length of individual telomeres. Telomeric shortening in specific chromosomes can influence the destiny of a CSC and its decision to divide symmetrically or asymmetrically. CSCs with short telomeres in specific chromosomes may be programmed to generate only transit amplifying myocytes through symmetric division and permanent loss of stemness. The non-uniform shortening of telomeres has been documented in old CSCs in an animal model of cardiac aging. Thus, the shortest telomere may be critical for cell viability and chromosome integrity [76].

Telomeric shortening occurs in aging CSCs in spite of the presence of telomerase activity [72,73]. This finding is consistent with results obtained in HSCs. HSCs express low to moderate levels of telomerase, but telomeres shorten considerably with age [77]. Two possibilities have been proposed in an attempt to explain telomeric shortening in the presence of detectable telomerase activity: a suppressor of telomerase function may be upregulated during the cell cycle or a competition may occur between the reassembly of telomeric chromatin and extension of telomeres by telomerase [77]. In HSCs, telomere shortening occurs at a rate of 50–100 base pairs per population doubling; a similar rate of telomere attrition has been found in human CSCs *in vitro* [24] and may characterize the aging process of CSCs *in vivo*.

Throughout life, adult stem cells undergo numerous rounds of divisions but, at the same time, experience long periods of quiescence. Thus, primitive cells are subjected to replicative senescence, with telomeric shortening and accumulation of replication errors, as well as stress-induced senescence, with a considerable load of damaged macromolecules, DNA double strand breaks, and oxidative DNA injury. CSC aging mediated by telomeric shortening triggers the expression of several gene products, which interfere with the cell cycle but mostly with G1-S transition. Surprisingly, the number of CSCs increases with age in the myocardium [32]. However, during aging CSCs become unable to divide and the number of functionally competent cells decreases with time.

Five biomarkers of hCSC senescence which are strictly linked to chronological age have been identified: telomeric shortening, attenuated telomerase activity, increased number of telomere-induced dysfunction foci (TIFs), and enhanced expression of $p16^{INK4a}$ and $p21^{Cip1}$ [78]. Severe heart failure has similar effects on the hCSC compartment. Senescent hCSCs are characterized by the expression of phosphorylated histone H2AX and p53 binding protein. Both γ-H2AX and 53BP1 are markers of DNA double strand breakage and their presence in old hCSCs from donor and explanted hearts identifies DNA lesions at the sites of telomere hybridization spots. TIF-positive hCSCs reflect old cells in which the DNA damage response is activated. This process may precede irreversible growth arrest dictated by the expression of $p16^{INK4a}$ [79].

CONCLUDING REMARKS

The human heart is a highly dynamic organ regulated by a pool of resident hCSCs that modulate cardiac homeostasis and condition organ aging. Hopefully, recent findings will resolve the long debate that has divided the scientific community into strong opponents and passionate supporters of the regenerative potential of the human heart, offering a more biologically valid understanding of cardiac growth and repair. A common ground can now be found to translate this different perspective of cardiac biology into the development of novel strategies for the management of the human disease.

Importantly, hCSCs with preserved growth reserve have been detected in old and explanted hearts at the end of their physiological lifespan. This category of hCSCs is expected to generate a young myocyte progeny within the senescent heart. The compartment of hCSCs in the old heart is composed of a subset of quiescent cells with preserved telomere integrity and a pool of highly proliferating cells that regulate organ homeostasis but lose telomeric DNA during each round of division. From a clinical perspective, the recognition that a subset of telomerase-competent hCSCs with long telomeres persists at all ages and with chronic cardiac diseases has

raised the possibility that autologous cell-based therapy may be feasible in patients with severe heart failure. Two clinical trials in which autologous cardiac-derived cells are administered to patients with sub-acute and chronic ischemic cardiomyopathy are ongoing [80,81]. The initial results are very encouraging warranting the need for large multicenter studies. Recently, a methodology has been developed to isolate from endomyocardial biopsies this compartment of functionally competent hCSCs to be expanded *in vitro*, prior to their intracoronary or intramyocardial delivery in very sick patients [82]. Although this approach has not yet been employed clinically, it generates therapeutically relevant quantity of cells, in the absence of invasive surgical techniques. This strategy is in the process of being implemented in forthcoming clinical trials.

INTRODUCTION

In the developed world, cardiovascular disease is the leading cause of death. Due to the minimal intrinsic ability of adult heart to regenerate itself following injury [1], myocardial infarction (MI) results in the rapid death of hundreds of millions of cardiomyocytes (CMs), and a vigorous inflammatory response. Over subsequent weeks to months, fibroblasts (FBs) and endothelial cells (ECs) form granulation tissue and a dense collagenous scar, which reduces the contractile function of the heart and leads to a pathological remodeling and, in many cases, heart failure. Adult CMs are terminally differentiated, thus it is not possible to expand them to sufficient numbers starting from small cardiac biopsies. Current clinical trials focus on cell replacement through the application of bone marrow mesenchymal stem cells, peripheral blood mononuclear cells, or resident cardiac cells. Most of these cell types have no intrinsic ability to give rise to a large number of CMs; instead they improve function through paracrine effects. Additionally, cells can be applied alone or in combination with different types and forms of biomaterials (e.g., hydrogels, scaffolds). An appropriate combination of a biomaterial, cell type, delivery method and tissue culture parameters can develop unique tissue constructs for multiple types of heart disease. Here we provide design criteria for generation of functional cardiac patches and discuss different biomaterials and cell types used during the tissue-engineering process.

CLINICAL PROBLEM

Cardiovascular disease is the leading cause of death worldwide. In the United States cardiovascular diseases account for approximately 30% of all deaths, with the cardiovascular disease population constantly increasing [1,2]. In 2008 alone, 86.2 million Americans were living with some form of cardiac disease, and this number is projected to grow to 40.5% of the American population by the year 2030 [3]. Concomitantly, the financial burden of disease is also projected to rise, from present estimates of $300 billion to $800 billion [3]. On a global scale, cardiovascular disease is responsible for 60% of deaths, and will become increasingly important as global obesity continue to rise. Importantly, cardiovascular disease is responsible for 80% of non-communicable diseases in low and middle income countries [4], with grave social and economic consequences.

One of the key limitations for treating cardiovascular disease is the lack of regeneration after myocardial injury. The majority of existing therapies aim to mitigate the progression of heart failure, intervening in the cyclic progression of the neurohormonal cascade, but the options for

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00038-0

improvement or regeneration of diseased tissue are limited. The most common pathogenesis is ischemic heart disease, which occurs when a portion of the heart does not receive a supply of oxygen from the blood. Coronary artery disease, or a narrowing of the lumen in the coronary arteries, most often by atherosclerotic change, limits perfusion of certain sections of the heart. Limiting oxygen delivery below a certain threshold leads to angina, characterized by reversible discomfort or heaviness to the chest. Complete occlusion of an artery, or MI, is associated with a typical pathological progression. Depletion of adenosine triphosphate (ATP) occurs within seconds, leading to irreversible cell damage by 20–40 minutes [5]. Coagulative necrosis begins ~30 minutes after coronary occlusion, followed by a robust inflammatory response that begins with the release of reactive oxygen species and neutrophil invasion ~24 hours post-infarction, and continues for the next 2–3 days, in parallel to the continued necrosis. Macrophages ultimately dominate the infarcted zone by 5–7 days post-infarction, and are responsible for removing dead cells and creating granulation tissue. Weeks to months after infarction, collagen deposition dominates, and a fibrous scar is formed [5].

Heart failure, which is the inability of the heart to adequately pump blood, ensues most commonly after ischemic injury, but may also have other etiologies, including valvular disease, hypertension, or genetic cardiomyopathies [6]. An increase in cardiac work requirements leads to one of two patterns of dysfunction in the heart; one where pressure overload dominates, leading to concentric hypertrophy of cardiomyocytes and a thickening of the myocardial wall, or a second one where volume overload dominates, leading to eccentric hypertrophy of cardiomyocytes and a thinning of the myocardial wall [5]. In either case, increased fibrosis, abnormal gene expression, and insufficient vascular function lead to pump dysfunction and an activation of the neurohormonal system, in which the sympathetic nervous tone, renin secretion, and arginine vasopressin secretion all increase. Together, these cues lead to myocardial remodeling at the cellular level that contributes to the progression of heart failure, by mechanisms that are not well understood.

Presently, heart transplant and Ventricular Assist Devices (VAD) can improve cardiac function, but the numbers of available donor hearts are limited, and the VAD is only a temporary solution. Therefore, biological treatment strategies that can enhance cardiac function are especially attractive for countering the pathophysiological progression of heart failure. With the advent of induced pluripotent stem cells (iPS), there is newfound promise for cardiac regeneration using patient-specific cells, since cardiomyocytes were previously unattainable by any other means. Present approaches involve direct cell injection or the creation of a cardiac patch. Cell injections are attractive due to relative simplicity, though poor cell retention is a recurring obstacle [7,8]. A cardiac patch approach would be aimed at replacing or repairing the specific lesion created by a MI, using a lab-grown piece of contractile cardiac tissue. Continuing challenges are the vascularization and electromechanical integration of such a construct, and these are among the key areas of active research.

ENGINEERING CARDIAC TISSUE: DESIGN PRINCIPLES AND KEY COMPONENTS

The heart functions as a highly organized physiological pump. The cardiomyocytes, comprising 80–90% of the heart volume, are not only elongated and hypertrophied, but are also aligned and electrically coupled to surrounding cardiomyocytes. They are constantly active, stimulated to beat, and therefore have a high metabolic demand for oxygen. Supporting cell types – endothelial cells and smooth muscle cells – organize themselves into a dense vascular network supplying nutrients to the cardiomyocytes. Fibroblasts support the cardiomyocytes and generate a collagen-dense matrix. On an organ level, pacemaker cells spontaneously generate action potentials that propagate the volume of the heart, generating a synchronous contraction. The flow of blood through the heart necessitates mechanical stress on it, as a preload that stretches the myocardium and an afterload to push against.

Fabrication of a functional cardiac patch depends on a multitude of parameters that collectively recapitulate some aspects of the complexity and function of the heart. Since cardiomyocytes are terminally differentiated, current studies are focusing on deriving a renewable source of them from embryonic and induced pluripotent stem cells. Other studies have aimed at recapitulating one or more physiologic aspects of cardiac tissue (e.g., the incorporation of multiple cell types, aligning cardiomyocytes, or electrical stimulation of cardiac tissue). Table 38.1 contains a collection of studies that aim to mimic aspects of the native myocardium. The three classical tenets of the tissue-engineering paradigm have been used for cardiac constructs: cell source, scaffold materials, and biophysical stimulation (Fig. 38.1).

Cell source

The limited ability of human cardiomyocytes to divide and expand has restricted the scope and therapeutic potential of cardiac tissue engineering. The first evidence that the application of cells may be a viable therapeutic approach for MI came from animal studies which used injection of fetal or neonatal CMs, and found that CM injection improved left ventricular function and thickness, thus attenuating pathological remodeling upon MI [1a–4a]. Injected CMs integrated through gap junctions and intercalated disks with the host CMs [5a]. However, these findings have limited clinical relevance, and human fetal and neonatal CMs cannot be readily obtained for transplantation due to obvious ethical issues.

The search for a clinically relevant cell source has led to the transplantation of skeletal myoblasts [6a], embryonic stem cell derived cardiomyocytes (ESC-CMs) [7a–9a], bone marrow derived mesenchymal stem cells (MSCs) [10a–11a] and hematopoietic stem (HS) cells [12a–14a] into animal models of MI (reviewed in references [15a] and [16a]). Among these cell sources, skeletal myoblasts and MSCs were pursued into clinical trials. A meta-analysis of recent clinical trials with injection of bone marrow and peripheral blood mononuclear cells demonstrated a significant, albeit low (3%), increase in left ventricular ejection fraction (LVEF) as well as a significant reduction in infarct size (−5.6%) and end systolic volume (−7.4mL) in patients treated by intracoronary cell injection after acute MI [17a]. A dose-response effect of the injected cell volume on LVEF change was also reported [17a]. During the last year, resident cardiac stem cells, either c-kit+ (SCIPIO) or those derived from cardiospheres (CADUCEUS) demonstrated promising functional improvements in Phase I clinical studies and restoration of viable tissue per MRI imaging, presumably due to the new CMs in addition to vascular cells [18a,19a].

Although these studies are encouraging, modest long-term improvements in function upon cell injection have motivated the investigation of new cell sources and methods that increase survival and retention of injected cells. Pluripotent stem cells such as hESCs or iPSCs can both give rise to bona fide CMs and be expanded to sufficient numbers (millions/patient) using existing technologies. The discovery of human iPSCs [20a] and the ability to generate CMs from them [21a] could provide effectively unlimited numbers of autologous CMs for cell therapy without the ethical concerns raised by the use of hESCs has enormous implications. Studies from a number of groups have shown that it is possible to generate CMs from mouse [58] and human ESCs [53] and iPSCs [21a]. The most efficient protocols to date are those that replicate the signaling pathways regulating lineage commitment in the early embryo [53]. These protocols are now being adapted to defined culture conditions, with the use of small molecules such as glycogen synthase kinase 3 inhibitors and chemical inhibitors of wingless-int (WNT) signaling [22a].

While in many ways iPSC-derived cardiomyocytes are ideal, the exact approach for their utilization is not entirely clear. Though the differentiation process has become more specific than previous work relying on stochastic cell differentiation, further refinements are possible and necessary. In particular, there are multiple phenotypes of cardiomyocytes, each with a different set of functions [10]. Certain cardiomyocytes are pacemakers or chamber-specific myocytes, and fine control over the generation of these phenotypes remains elusive. Laflamme

TABLE 38.1 Design parameters for cardiac tissue engineering

Native cardiac attribute	Engineering method	Results	References
Cell Source	Sequence of Activin and BMP-4 cytokines induces cardiac cell differentiation in human embryonic and iPS cells.	Flow cytometry at multiple timepoints revealed high sensitivity of multiple ES and iPS cell lines to concentrations of induction factors. However, optimization of the times and concentrations lead to improved differentiation yields.	Kattman et al., Cell Stem Cell 2011 [51]
	Lentiviral iPSC technology using epigenetically specific cell sources, ventricular cells vs. fibroblasts.	Ventricular cells as material for iPSCs improved cardiac differentiation potential when compared to using fibroblast cells, suggesting epigenetic memory for iPSC cell lines.	Xu et al. Cell Research 2012 [52]
Patient cell source	Induced pluripotent stem cells were derived from fibroblasts of patients with Long QT syndrome type I using infection with retrovirus encoded with Oct3/4, Sox2, KLF4, and c-MYC. They were subsequently differentiated into cardiomyocytes.	Generation of induced pluripotent stem cells was confirmed with Nanog staining, and generated cardiomyocytes showed striations when stained with cardiac troponin T. LQT1 disease phenotype of lengthened ADP 50 and ADP 90 was confirmed by single cell patch clamp. Myocytes generated from LQT1 patients showed KCNQ1 channel localization to the endoplasmic reticulum, suggesting a possible mechanism for the disease.	Moretti et al. NEJM 2010 [11]
	Induced pluripotent stem cells derived from patients with familial dilated cardiomyopathy were generated using Oct4, Sox2, Klf4, and c-MYC. They were subsequently differentiated into cardiomyocytes using the protocol developed by Yang et al. [53]	Immunofluorescence images of Oct4, Nanog, TRA-1−81 and SSEA-4, as well as hypomethylation as seen by quantitative bisulfite sequencing confirmed the generation of iPS cells. Multielectrode array analysis of dilated cardiomyopathy derived cardiomyocytes displayed similar beat frequency, interspike intervals, and field potential durations as the control group. Immunohistochemistry and transmission electron microscopy (TEM) displayed similar cell size, but dilated cardiomyopathy (DCM) derived cells had a higher relative percent of disorganized cells based on α-actinin staining. Overexpression of Serca2a resulted in restoration of contraction force as measured by atomic force microscopy (AFM). Treatment of cells with β-blockers decreased the percentage of disorganized cells.	Sun et al. Science Translational Medicine 2012 [14]
Multiple Cell Types	Porous PGS scaffolds were pre-seeded with cardiac fibroblasts encapsulated in Matrigel for five days and were subsequently seeded with cardiomyocytes for another five days. This was compared to constructs of cardiac fibroblasts co-seeded with cardiomyocytes.	Immunofluorescent analysis of constructs pre-seeded with fibroblasts showed a greater percentage of actin positive cells compared with vimentin-positive cells, and compared with actin positive cells in the co-seeded group. The pre-seeded group further showed lower excitation threshold, higher fractional area change, and increased fluorometrically measured DNA and protein content.	Radisic et al. J Biomed Mater Res Pt A 2007 [21]
	Endothelial cells were co-cultured in cell sheets with cardiomyocytes at different ratios.	Higher seeding ratios of endothelial cells resulted in higher density of vascular networks as appreciated by fluorescent images. Enzyme-linked immunosorbent assay (ELISA) for	Sekine et al. Circulation 2008 [22]

		secreted factors showed higher levels of vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and hepatocyte growth factor (HGF) in endothelial co-culture groups compared to cardiomyocytes alone. Fluorescent views of implanted co-cultured cell sheets showed neovascularization into the myocardium.	
	External endothelial cell addition to cardiac tissue constructs.	Increased cardiomyocyte DNA content demonstrated a 35% increase in cardiomyocyte proliferation due to addition of endothelial cells, validating co-culture effects of endothelial cells. Additionally vascular engraftment was shown when implanted with patent blood vessels.	Tulloch et al. Circ Res 2011 [23]
High Cell Density	Cell sheet method, where confluent layers of cells are detached from a temperature-dependent poly(N-isopropylacrylamide) substrate and stacked on top of other cell sheets using a cell sheet manipulator. Cell sheets were compared to cell injection in an infarct model.	There was a greater *in vivo* bioluminescence of implanted GFP-expressing cell sheets compared to injected GFP-cells. Macroscopic fluorescent views of cell sheets versus injected cells showed dense localization 4 weeks post transplantation. Immunohistochemistry showed a greater density of cells. TUNEL staining showed a significantly lower level of TUNEL positive nuclei compared to cell injection.	Sekine et al. Tissue Eng Pt A. 2011 [8] Haraguchi et al. Nat Protoc. 2012 [42]
Ultrastructure	Microcontact printing of fibronectin into rectangles of various aspect ratios and seeded with cardiomyocyte pairs.	Connexin-43 immunosignal and conductance as measured with dual-voltage clamp was greater in the 5.2 length:width ratio as compared to 3.5.	McCain et al. Am J Physiol-Heart C 2012 [54]
Alignment/ Anisotropy	Soft lithography of poly(glycerol) sebacate into accordion-like honeycombs of overlapping diamonds.	Differential long and short axis elastic moduli and excitation threshold that mimic the anisotropy of the heart. Immunofluorescent actin images demonstrating elongation in the preferred direction	Engelmayr et al. Nature Mater 2008 [31]
	PDMS microcontact printing of fibronectin into shapes of various aspect ratios.	Image analysis of immunofluorescence actin images demonstrated greater anisotropy in shapes with $>$ 2:1 aspect ratio as compared to the 1:1 group	Bray et al Cell Motil Cytoskel 2008 [34]
Extracellular matrix	Neonatal hearts were decellularized with antegrade coronary perfusion of SDS and were recellularized with neonatal cardiomyocytes, fibrocytes, endothelial cells, and smooth muscle cells.	Decellularization and recellularization were confirmed by histological analysis and staining. The perfused recellularized heart showed synchronous contraction as measured by electrocardiogram (ECG) and left ventricular pressure (LVP) after electrically stimulated depolarization. Ejection fraction totaled 25% of an equivalently aged healthy fetal heart.	Ott et al. Nat Med 2008 [25]
	Decellularized sheets of human myocardium were used as a scaffold for human mesenchymal progenitor cells suspended in fibrin and implanted into infarcted rat hearts.	Histological staining of extracellular matrix (ECM) proteins and tensile testing showed that decellularized tissues were similar to native tissue. Echocardiographs performed on constructs transplanted on rat hearts preserved left ventricular systolic area and fractional area change.	Godier-Furnemont et al. Proc Natl Acad Sci 2011 [26]
	Poly(glycerol sebacate) scaffolds were prepared at different stiffnesses by altering the curing time and were subsequently seeded with neonatal rat cardiomyocytes.	Low stiffness groups were found to have the greatest functional change (contraction amplitude) and also the greatest compressive stiffness.	Marsano et al. Biotech Prog 2010 [55]

Continued

TABLE 38.1 Design parameters for cardiac tissue engineering—*Continued*

Native cardiac attribute	Engineering method	Results	References
Cardiomyocyte Hypertrophy	Molded rings of neonatal rat cardiomyocytes, Matrigel, and Collagen I, and cultured in different hypertrophic stimuli (angiotensin II and phenylephrine versus hypertrophic inducing serum) on a cyclic stretch device for 12 days.	Immunofluorescent analysis of single cells in the angiotensin II and phenylephrine group showed no change in length but displayed increased width and total volume suggesting concentric hypertrophy. Similar analysis on the 'hypertrophic inducing serum' group displayed significant elongation without a widened morphology suggesting eccentric hypertrophy. Further evidence for hypertrophy in both groups is supported by high levels of gene expression of ANP and low levels of gene expression of alpha/beta myosin heavy chain (α/β-MHC).	Tiburcy et al. Circ Res 2011 [29]
Electrical stimulation	Carbon electrodes field stimulation.	Ultrastructurally improved contractile apparatus and gap junctions. Histology and immunostaining showed increased linear organization. Contracting force increased and improved electrical maturity.	Radisic et al. Proc Natl Acad Sci 2004 [48]
	Gold nanowire impregnated alginate scaffolds.	Electrical conductance through gold impregnated scaffolds was increased. Connexin 43 expression was doubled compared to non-impregnated controls.	Dvir et al Nat Nanotech 2011 [56]
	hES cardiomyocytes transplanted in ablated large animal heart model.	ECG mapping co-localized injected cardiomyocytes to ectopic ventricular pacing, demonstrating pacing potential of injected hES pacemakers.	Kehat et al. Nat Biotech 2004 [57]
Vascular Perfusion	Perfusion bioreactor through channeled scaffolds.	Perfused channeled scffolds showed nearly 50% increase in viable cells compared to non-perfused controls. Finite element modeling provides a rational approach for vascular perfusion design through engineered cardiac tissue.	Radisic et al. Nat Protoc 2008 [39]
	Omental pre-vascularization of cardiac patch.	Prevascularization improved engraftment on the infarcted heart, and mitigated decline in cardiac function based on echocardiography.	Dvir et al. Proc Natl Acad Sci 2009 [41]
Force generation	Engineered heart tissues, ring-shaped cardiomyocyte aggregates in a mixture of Matrigel and collagen, were placed onto load-adjusted coils to apply a passive, auxotonic, load on the tissues.	Engineered heart tissues on auxotonic load displayed a greater twitch tension by isometric force contraction analysis. Four weeks after implantation onto an infarcted rat heart, echocardiographs, MRI, and catheterization together demonstrated decreased left ventricular volumes, lower left ventricular end diastolic pressures, and shorter relaxation times when compared to sham-operated rats.	Zimmerman et al. Nat Med 2006 [30]
	Cardiomyocytes in porous chitosan-collagen scaffolds were stretched by moving four pins on the scaffold. Nominal strain of approximately 20% were applied at a frequency of 1 Hz for 6 days.	Regions of high local stress were determined using a mathematical model. Immunohistochemical analysis showed high levels of connexin-43 staining at the regions of high stress. Histological analysis and scanning electron microscopy (SEM) also demonstrated elongated morphologies in areas of high stress in comparison to areas of lower stress	Zhang et al. J Tissue Eng Regen M 2011 [33]

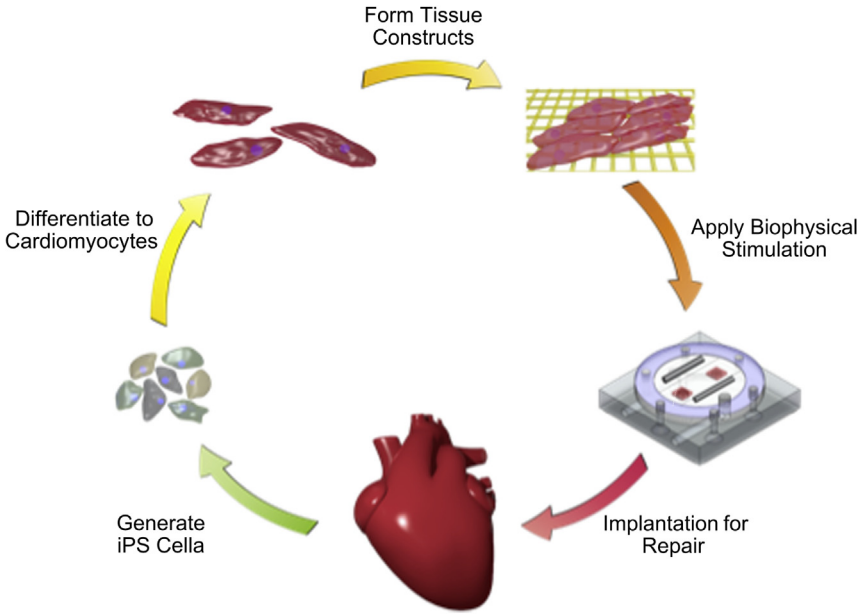

FIGURE 38.1
Cardiac tissue engineering approach.

and colleagues recently demonstrated conclusively that hESC-CMs can electrically couple and suppress arrhythmias in hearts upon MI induced by cryoinjury [63]. As cell death is a major problem for cell injection studies – with up to 90% of injected cells dying or being washed away from the injection site – the authors used a pro-survival cocktail consisting of Matrigel and various growth factors to enhance cell persistence upon injection [38].

Another issue is the cell maturity [18–20]. Being recently differentiated, iPSC-derived cardiomyocytes are relatively young, and further phenotypic maturation may be needed to grow them into adult-like myocytes with their inherent contractile properties. Furthermore, even after differentiation and maturation, it is unclear whether a pure population of cardiomyocytes would be most apt for building cardiac tissue, since co-culture effects improve function, mimicking the heterogeneity of cells found natively [21–24]. The cell-related parameters of interest for building a cardiac patch include cell identity that accounts for specific cardiomyocyte type, relative ratios of different cells, cell density, and cell maturity.

Scaffold

Scaffolds provide a three-dimensional environment in which the cells are cultured. The constituents and organization of the scaffold dictate the organization, maturation, and function of the forming tissue constructs. The scaffold material itself ranges from the native heart matrix itself [25–27] to natural hydrogels such as collagen and Matrigel [7,28–30] to synthetic polymers, such as poly(glycerol) sebacate (PGS) or polyacrylamide [31–33]. The scaffolds differ in the way they are processed (e.g., decellularization for native heart matrix versus temperature related gelation for Matrigel), their mechanical properties, their ultrastructure, and their biodegradability. With the wide library of materials to choose from, scaffolds can be made into virtually any size or shape, depending on the application. Micropatterning has been employed as a way to control cardiomyocyte alignment and cell-cell interactions on a single cell level [34–36], while macro-sized constructs offer amenability to force generation and animal implantation studies [24,37,38].

Due to the large metabolic demand of cardiomyocytes, scaffold design must take oxygen and nutrient delivery into account. The cardiac tissue engineering scaffolds are in general porous and perfusable to enable oxygen supply *in vitro* [19,39,40] and designed to promote angiogenesis to enable oxygen supply *in vivo* [37,41] Some methods of cardiac tissue engineering do not utilize scaffolding material; for example, the cell sheet method [8,42–44] relies on stacking confluent sheets of cardiomyocytes and the extracellular matrix these cells alone produce.

Biophysical stimulation

Further phenotypic maturation of cardiac constructs can be achieved using biophysical stimulation. Perfusion of engineered constructs helps alleviate the diffusional limitations [37,39,40], which is of particular importance for the highly metabolically active cardiac tissue. The flow of medium across or through the engineered construct mimics the vasculature found in native tissue in providing fresh media and nutrients while removing toxic metabolic products from the cells. These approaches are critically important for generating large, thick, clinically sized cardiac constructs with homogenous distributions of cells.

Other stimulation modalities rely on the excitation-contraction coupling property that is inherent to heart tissue [45]. Stimulation systems can excite cells using either electrical depolarization or mechanical strain. Mechanical stimulation systems use active or passive tension enhancing cellular organization, morphology and contractile force generation. Auxotonic systems maintain passive tension on engineered cardiac constructs, providing a tonic resisting force for the cells to pull against [30,46]. Phasic systems provide active, cyclic strain to improve cardiac function, though some studies have shown improved twitch forces created using the auxotonic method [23,30,33]. Electrical field stimulation uses electrodes to provide a depolarizing stimulus [20,40,47–50]. The electrical field which excites the cells of the construct creates a voltage difference across the two electrodes. This cyclic depolarization improves electrical synchronization of cardiac constructs, while also improving contractile function and cellular organization. Both of these modalities of biophysical stimulation lead to functional enhancements, such as improved cardiomyocyte ultrastructure, improved sarcomeric linearization and organization, and increased functional gap junctions.

DIRECTED CARDIAC DIFFERENTIATION OF HUMAN STEM CELLS

Cardiac tissue engineering requires a reliable source of cardiomyocytes. Human adult cardiomyocytes are unsuitable as they do not have the ability to proliferate. Recent advances in hESC and iPSC technologies have allowed for the generation of human cardiomyocytes from healthy progenitors as well as from diseased individuals. We describe here the differentiation of cardiomyocytes from an embryonic stem-cell-derived progenitor. We further discuss the purification and characterization of cardiomyocytes, as well as current efforts to generate patient-specific cardiomyocytes.

Derivation of cardiomyocytes from embryonic stem cells

One of the first accounts of generating human cardiomyocytes from an embryonic stem cell source comes from Yang et al. in 2008 [53]. This study focuses on the discovery of a common cardiovascular progenitor capable of generating the different cell types dominant in the adult heart, that is, cardiomyocytes, endothelial cells, and smooth muscle cells. This method uses a combination of several factors to recapitulate cardiac development (Fig. 38.2a,b), resulting in a large percentage of troponin positive cells (Fig. 38.2c). The embryonic stem cell cultures were first induced with activin A and BMP4, generating a *T*+ population, or one which overexpressed brachyury, a transcription factor important for defining the primitive streak and mesoderm. The cultures were next induced with Dickkopf-related protein 1 (DKK1), a canonical WNT inhibitor, and vascular endothelial growth factor (VEGF). DKK1 was necessary for generating cardiomyocytes, as demonstrated by a subsequent increase in ISL1, a marker for the secondary heart field, NKX2.5, a marker for cardiac differentiation, and increases in cardiac-specific proteins MLC2A and cardiac troponin T.

Interestingly, flow cytometric data of embryoid bodies at various stages of cultivation demonstrated three distinct populations at day 6 of induction (Fig. 38.2d). Stage I corresponds to a KDR^{low}/C-KIT^{neg} population, stage II corresponds to a KDR^{neg}/C-KIT^{pos} population, and stage III corresponds to a KDR^{high}/C-KIT^{pos} population. Kinase insert domain receptor (KDR)

Generation of cardiomyocytes from embryonic stem cells. (a) Cardiomyocyte derivation protocol and (b) corresponding schematic of development of cardiovascular lineages. (c) Percentage of troponin positive cells over time using the protocol in (a). (d) Flow cytometry reveals three populations on day 6 of differentiation KDR^{low}/C-KIT^{neg} (I), KDR^{neg}/C-KIT^{pos} (II), and KDR^{high}/C-KIT^{pos}, where differentiation of the KDR^{low}/C-KIT^{neg} population yielded the highest percentage of troponin positive cells. (e) Immunostaining for endothelial cell markers CD31 and vWF, cardiomyocyte marker cTNT, and smooth muscle marker smooth muscle actin (SMA) on cells differentiated from the KDR^{low}/C-KIT^{neg} lineage. (f) Flow cytometric analysis of human embryonic stem cell (hESC) derived cardiomyocytes sorted for signal regulatory protein alpha (SIRPA) on various days (8, 12, 20) of differentiation. (g) SIRPA positivity selects for a cardiomyocyte progenitor, resulting in up to 98% troponin positive cells.

and C-KIT were chosen for further investigation based on their significance in mouse stem cell studies. In particular, in mice KDR was shown to give rise to cardiac progenitors, and C-KIT was shown to derive hematopoietic and vascular lineages [58]. Low KDR expression and C-KIT positivity defined a cardiac progenitor, developing into cells with a greater number of cardiac troponin positive cells (>50%) compared with the other subpopulations (Fig. 38.2d). As lineages of cardiovascular cells are induced, significant populations of cardiomyocytes, endothelial cells, and smooth muscle cells form in culture (Fig. 38.2e). Transplantation of these progenitors into murine hearts has led to differentiation into the same three cell types — cardiomyocytes, endothelial cells, and smooth muscle cells, and resulted in an increase in

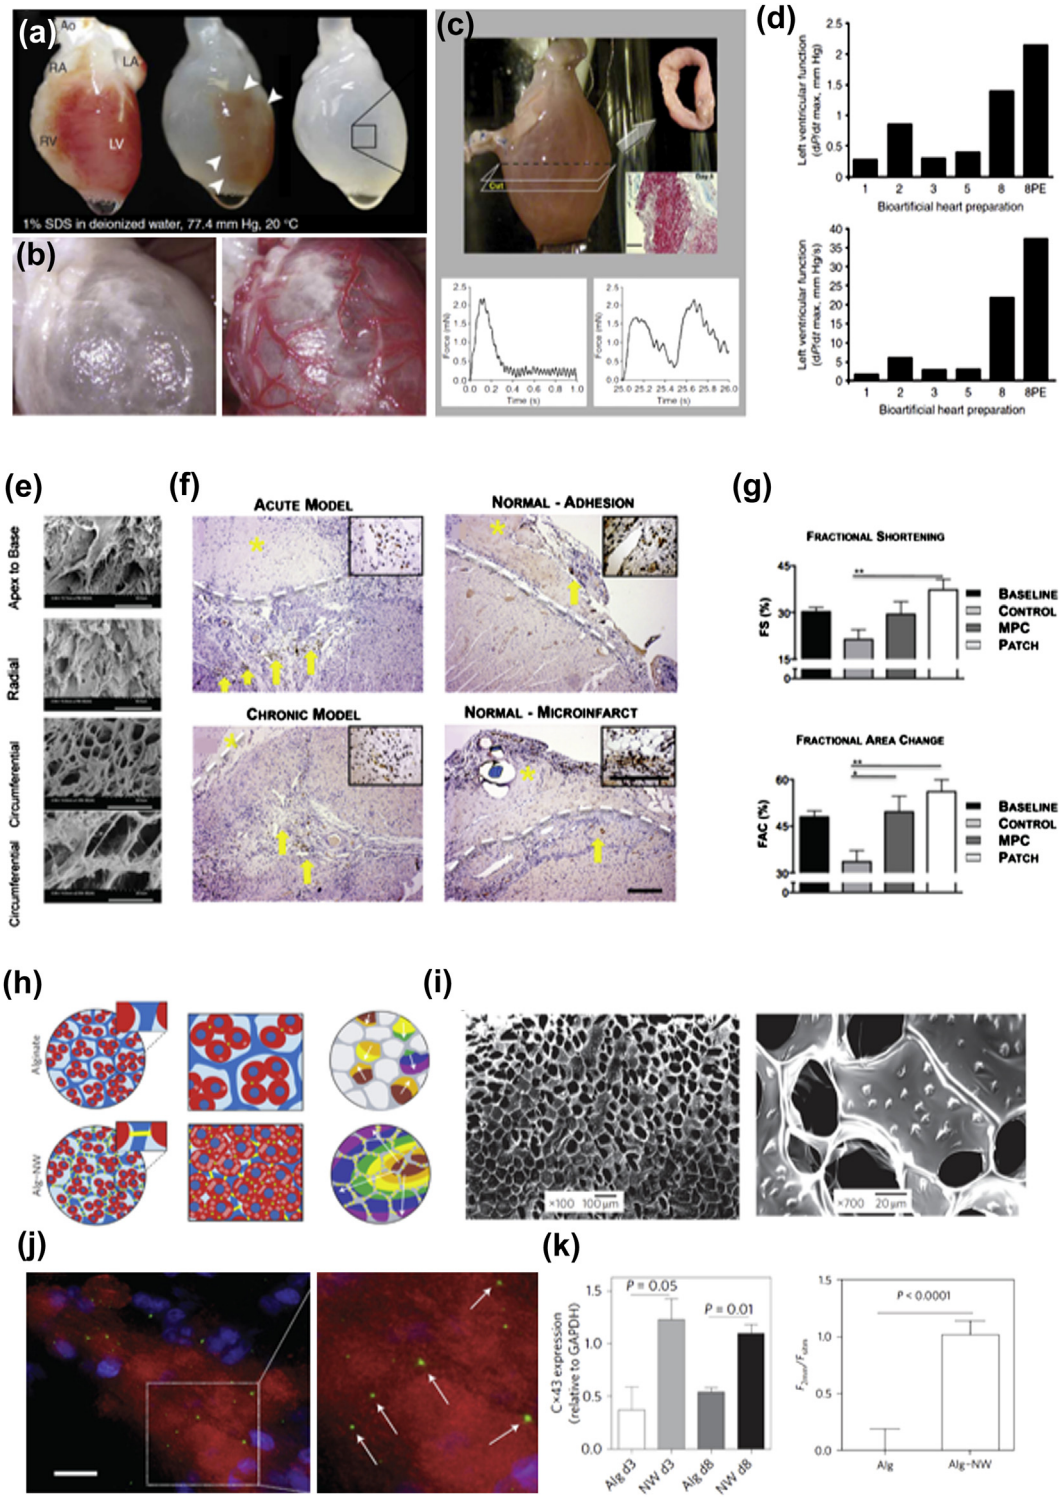

FIGURE 38.3

Scaffolds for cardiac tissue engineering. (a) Decellularization of whole neonatal heart with 1% SDS over the course of 12 hours. (b) Perfusion of the decellularized heart with the host vasculature through the aorta demonstrates maintenance of the decellularized blood vessels. (c) Hearts recellularized with cardiomyocytes beat spontaneously after four days in culture and can generate force when paced at 1 Hz or 2 Hz. (d) Maximum pressure and dP/dt after 8 days in culture and after stimulation with phenylephrine (PE). (e) Scanning electron microscope images of various slices of heart yield different pore sizes. (f) Migration of mesenchymal progenitor cells (MPCs) from MPC/Scaffold/transforming growth factor beta (TGFβ) constructs to acute infarcts, chronic infarcts, or normal myocardium four weeks after implantation. (g) Fractional shortening and fractional area change for 3d post-infarction rats (baseline) which were subsequently stratified into three groups: a control which received no additional intervention, an MPC group which received an injection of MPCs, and a patch group, which

ejection fraction (56% versus 39%). Whole cell patch clamp and microelectrode arrays of the cardiomyocytes demonstrated results consistent with cardiac phenotype. Together, these results suggest the identification of a cardiovascular progenitor which gives rise to cardiomyocytes, endothelial cells, and smooth muscle cells.

Purification and use of stem cell derived cardiomyocytes

While this original study and subsequent studies have identified ways of generating cardiovascular lineages [59], one major challenge was to separate the cardiomyocytes from the non-myocyte cell types. In a screen for a marker of human embryonic stem-cell-derived cardiomyocytes, signal regulatory protein alpha (SIRPA) appeared to specifically select for cardiomyocytes above the other cell types (including endothelial cells and smooth muscle cells) [60]. Indeed, cell sorting with this marker and depletion of endothelial cells and smooth muscle cells resulted in a 98% troponin positive population of cells (Fig. 38.2f,g). The generation of a pure cell source is of particular importance since implantation of undifferentiated cells may lead to teratoma formation. Further, a purified cell source allows for greater control over the cell densities and types present in tissue-engineered constructs.

Given the precision required to generate specific cell types from stem cells, protocols must be optimized. For example, the procedure originally proposed by Yang and coworkers has been further modified and applied to multiple cell lines, including iPSCs [51]. Use of microbioreactor arrays allows control over the three-dimensional cellular microenvironment in a multiplexed fashion, for experimental optimization of cell derivation procedures on a small scale [61]. Additionally, these devices allow to control more than simply the concentration or type of cytokines. Various electromechanical cues can be added in order to further recapitulate the cardiogenic niche, allowing true optimization of stem cell derivation procedures [62].

SCAFFOLDS

Cells alone do not compose functional tissues; other critical components include the substrate and extracellular matrix that surrounds and instructs the cardiac cells. Natively, the extracellular matrix provides microenvironmental cues, mechanical support and architectural guidance, acting as the scaffold upon which cardiac cells grow and function. Previous tissue-engineering scaffolds have used polymeric materials, lyophilized collagen sponges, and micropatterned anisotropic materials. These artificial materials have design advantages in that they can be microfabricated, functionalized and are highly reproducible, but other approaches have used decellularization of native matrix as a different starting point, providing a scaffold with improved biological activity at the cost of some of the versatility of the synthetic approaches.

Decellularization approach

Decellularization of native heart material is a powerful approach to easily recapitulate the *in vivo* architecture and extracellular composition of the heart. In 2008, Ott et al. decellularized whole rat hearts using a perfusion system of 1% sodium dodecyl sulfate (SDS) in deionized water, as shown in Fig. 38.3a [25]. The subsequent washes with detergent removed all of the cellular components from the native heart, leaving behind a 'ghost' heart, translucent in appearance, composed of thin walls of native heart matrix retaining the macroscopic and microscopic architecture.

received composite scaffolds containing MPCs in the decellularized scaffold. (h) Schematic of cardiomyocytes (red) in an alginate matrix or in the nanowired composite. (i) Transmission electron microscope images of alginate-nanowire composite scaffolds, where nanowires of approximately 5 μm in length were incorporated into the scaffold material. (j) Connexin-43 (green), troponin (red), and 4',6-diamidino-2-phenylindole (DAPI) (blue) immunostained cardiomyocytes organized in the nanowired scaffold. (k) Connexin-43 and actinin expression by western blot relative to glyceraldehyde 3-phosphate dehydrogenase (GAPDH) in nanowired group versus the alginate only group 3 or 8 days after seeding with cardiomyocytes.

When reperfused with a native blood supply, the decellularized hearts clearly showed maintenance of vascular channels, demonstrating the preservation of overall native morphology (Fig. 38.3b). When reseeded with neonatal rat cells, the heart regained a cellularized appearance, and sections cut from the reseeded heart were capable of beating and matched the pacing rate applied through an external electrical field, either at 1 or 2 Hz (Fig. 38.3c). Over the eight days of culture, there was an increasing trend of contractile function and pressure generation. The whole heart preparations were also exposed to phenylephrine, which increased contractile pressures, suggesting pharmacological responsiveness (Fig. 38.3d). Overall this study provided a basis for whole heart decellularization with subsequent repopulation, providing a cardiac pump function at 2% of the adult rat heart output.

Since cardiac MIs are localized within the whole heart, sometimes only a specific section, importantly the left ventricle may need to be the target of therapy [26]. Decellularized scaffold patches can be made from native human heart sections using sequential detergent washes. However, the direction of sectioning is important, as different planes of section result in different scaffold architectures and different pore sizes (Fig. 38.3e).

When vascular progenitor human MSCs are seeded onto these native scaffolds, they act as depots of vasculogenic factors, improving the recovery of left ventricular function damaged by infarction. As shown in Fig. 38.3f, the presence of infarct improved the migration of the vasculogenic MSCs into the damaged tissue, in both acute and chronic models, and suggested that the stimulus provided by injury improved the responsiveness of cardiac tissue to the therapeutic cells. Notably, cells did not stay at the surface epicardium of the heart; instead they penetrated into the myocardium even when only microinfarcts were created using sutures alone to damage the myocardium. These native cardiac patches acted as a vehicle for a vasculogenic cell-based therapy and showed improved heart function, using echocardiographic metrics such as fractional shortening and fractional area change of the regions infarcted (Fig. 38.3g). The use of the native matrix scaffold improved recovery above cell injection alone, proving additional benefit as a delivery vehicle for the vasculogenic cells.

Artificial scaffolds

Despite advances in using native matrices as scaffolding agents for the delivery of cells to the injured heart, the rational design of artificial scaffolds is still an active area of research. One primary limitation of fabricated scaffolds was their lack of electrical conductivity, a property that might enhance cell-cell communication and synchronization of the heart. Dvir et al. used gold nano-wires impregnated in a conventional scaffold material (alginate) to bestow conductive properties to the material [56]. Fig. 38.3g outlines how the conductive scaffold allows electrical signal propagation. Since alginate was chosen as the base scaffolding material, it maintained many of its familiar features. Even with the addition of gold nano-wires (Fig. 38.3h), the viscosity and material properties of alginate were not altered enough to change the porosity of the final scaffolds. The presence of the nano-wires improved the expression and organization of connexin 43, the primary gap protein associated with electrical-mechanical coupling and communication between cells, as assessed using immunofluorescent staining and western blot quantification (Fig. 39.3i). When calcium transients were investigated, the nano-wire-impregnated scaffolds showed fluorescent signals consistent with electrical propagation through the scaffold material, providing electrical stimulation to the cells. Engineered materials can thus add unique properties to cardiac scaffolds and tailor their functionality to that found in native heart muscle.

Freed and colleagues created an accordion-like scaffold using laser boring of 250 μm thick poly(glycerol sebacate) layers [31]. The accordion-like honeycomb was made by overlapping two 200 by 200 μm squares at an angle of 45°. The pore walls and struts were ~50 μm thick. The scaffolds were pretreated with cardiac fibroblasts followed by seeding of enriched cardiomyocytes. At the end of cultivation, the authors obtained contractile cardiac grafts with

mechanical properties closely resembling those of the native rat right ventricle. In addition, the cells in the pores were aligned along the preferred direction.

In another study, Feinberg et al. seeded a layer of neonatal rat ventricular cardiomyocytes on a polydimethylsiloxane membrane that could be detached from a thermo-sensitive layer of poly(isopropylacrylamide) at room temperature. Called Muscular Thin Films, these cell-covered sheets could be designed to perform tasks such as gripping, pumping, walking and swimming by careful tailoring of the tissue architecture, thin-film shape and electrical-pacing protocol [23a].

BIOPHYSICAL CUES

Biophysical stimulation has been used to improve the phenotypic maturity of cardiac tissue-engineered constructs. These stimuli are designed to be biomimetic, and simulate the native heart environment to facilitate proper cardiac growth and maturation.

Electrical stimulation

One of the primary features of the heart is its electrical connectivity and synchronization. Previous studies have shown improved conductive and functional characteristics of heart tissue grown in the presence of a stimulating electrical field. These results validate the use of electrical stimulation as a functional cue to improve phenotypic maturation of cardiac tissue, however, the precise techniques to apply electrical stimulation to engineered tissues is a topic of further exploration.

To establish baseline parameters, Tandon et al. compared multiple electrode materials and stimulation regimes to optimize electrical field conditioning of engineered heart tissue [50]. Petri dishes were outfitted with 1/8 inch rod shaped electrodes, spaced 1 cm apart, and 4 cm in length made from the following materials: carbon, steel, titanium nitride, and titanium. When comparing injected charge and recovery, the electrodes made of carbon recovered the most charge (95%), meaning had the least amount of lost charge due reaction products in the solution (Fig. 38.4a,b). The carbon electrodes were also best able to maintain a current through the bioreactor over the 2 ms time range for the depolarizing stimulus. With respect to effect on cell function, the results comparing various electrode materials was more modest, but carbon electrodes still had a favorable trend in their ability to properly capture the pacing of cardiac constructs as well as a lowered excitation threshold (Fig. 38.4c,d). This suggests that the carbon best communicates with the tissue-engineered constructs with minimal side reactions.

As seen with these and other studies, the effect of field stimulation improves cardiac tissue function, shown by increased Troponin and Connexin 43 markers, key proteins in both cell-cell connectivity and contractile apparatus (Fig. 38.4e).

Mechanical stimulation

Mechanical stimulation approaches the electrical-mechanical coupling of heart tissue from the stretching and mechanical contraction perspective. It has been shown that passive or active tension can increase the cardiac functionality and orientation of cardiac cells. In one study, chitosan, a polysaccharide-based scaffolding material, was processed to have defined channel pores for perfusion and high porosity for cell seeding (Fig. 38.4f–h). Due to its attractive mechanical properties (Fig. 38.4i), it was used with a radial stretch device to characterize contraction using active tension. Strain maps of the scaffolds could be generated modeling the surface mechanics of the chitosan, showing stereotyped stress fields around the large pore areas (Fig. 38.4j). Interestingly, increased cell density and organization followed the predicted stress map suggesting that the mechanical stress provides a biophysical cue for cellular organization and communication (Fig. 38.4k).

(g) Macroscopic image and (h) scanning electron microscope image of

Perfusion

Another critical biophysical stimulus — perfusion — is required for proper metabolic function. The transport of fresh oxygen and nutrients along with removal of metabolic products is particularly essential for cardiac tissue. Native tissue combines active perfusion and electrical-mechanical coupling, and in Maidhof et al, these two critical stimuli were combined in a novel bioreactor to enhance cell density and contractile protein expression of troponin [40]. A perfusion system, forcing fluid through a channeled scaffold was built around the standard paradigm of carbon electrodes. (Fig. 38.4l). This resulted in a more uniform cell distribution due to removal of diffusion limitations encountered when growing thicker pieces of cardiac tissue. When electrical stimulation was also applied, the cells were both more numerous while maintain an even density distribution throughout the tissue. (Fig. 38.4m) The two stimuli, perfusion and electrical stimulation, had an additive effect on troponin expression (Fig. 38.4n). The three biophysical stimuli — electrical stimulation, mechanical stretch and perfusion — all can contribute to the functional maturity of engineered cardiac tissues.

IN VIVO APPLICATIONS OF CARDIAC TISSUE ENGINEERING

The ultimate goal of cardiac tissue engineering is the implementation of cells or tissue constructs in an injured heart and subsequently improving cardiac function. An 'ideal' cardiac patch would not only beat spontaneously, but would also connect with the host vasculature, couple electrically with the surrounding myocardium, and generate force to improve the function of a failing heart. We describe in this section two methods of fabricating a cardiac patch, the first of which focuses on using mechanical load to create force-generating constructs, and the second of which focuses on introducing multiple cell types to enhance vascularization of the cardiac patch. Open questions for *in vivo* systems include the functional differences between cell injection and scaffold implantation, and the type of arrhythmogenic or immunogenic response the foreign cells will have when near the host tissue.

Engineered heart tissue

Zimmermann and colleagues (2006) outlined an approach to generate contracting rings of cardiac tissue which can be implanted into infarcted rat hearts, resulting in an improvement in cardiac function [30]. Engineered heart tissues were created by casting neonatal rat cardiomyocytes, collagen I, and Matrigel in a circular mold, followed by seven days of culture in 40% oxygen, under static, 'auxotonic' load, and in media containing insulin. Five of these loops were then stacked to create a large (15 mm diameter x 1—4 mm thick), fused, synchronously beating tissue assmbly amenable to implantation (Fig. 38.5a).

Structural and electrical integration with the host myocardium as well as whole heart function were examined in rats with infarcted hearts implanted with engineered heart tissues. Immunostaining of the engineered heart tissue four weeks after implantation showed an elongated, sarcomeric pattern suggestive of highly differentiated cardiomyocytes (Fig. 38.5b). Additionally, there was neovascularization within the tissues from the donor cells that connected to the host vasculature (Fig. 38.5c). Electrical coupling was improved in the engineered heart tissues, as demonstrated by lower total activation times and higher QRS amplitudes. *In vivo* studies allow for the functional examination of whole hearts. Rats with engineered heart tissues demonstrated shorter left ventricular end diastolic diameter and a lower maximum left ventricular volume when compared to sham-operated rats, suggesting no additional dilation

of the infarcted rat hearts as might be expected (Fig. 38.5d). Further, there was no decrease in fractional area shortening of the heart after the operation (Fig. 38.5e).

Vascularized cardiac patches

Vascular integration of the cardiac patch with the host myocardium is important for the prolonged survival of thick tissue patches, especially given the high oxygen demand of cardiac tissue. Stevens et al. demonstrated the utility of prevascularizing cardiac tissue prior to transplantation into the infarcted area [24]. Cardiac patches were created from human embryonic stem-cell-derived cardiomyocytes and human umbilical vein endothelial cells, on mouse embryonic feeders. Several experimental groups were investigated: a cardiomyocyte only group, a group consisting of cardiomyocytes and endothelial cells, and a group consisting of all three cell types. Histology showed that the group consisting of all three cell types resulted in the largest number of vessel-like structures (Fig. 38.5f), and the stiffest construct with higher collagen contents, that were most similar to native myocardium (Fig. 38.5g). Upon

implantation into a skeletal muscle environment, the tri-culture group demonstrated great area staining for β-myosin heavy chain, the greatest number of vessel lumens (Fig. 38.5h,i), and neovascularization and anastomosis with the host vasculature (Figs. 38.5j–m).

Electrical coupling of cardiomyocytes in the heart

One question remains whether or not cardiomyocytes, when applied to the heart, will form adequate connections with the host tissue, or if the engineered tissue constructs are proarrhythmic, thus potentially negating any therapeutic effect. In one recent study, Shiba et al. showed that these grafts may electrically couple with the host and suppress arrhythmias [63]. Human embryonic stem-cell-derived cardiomyocytes were transplanted onto a guinea pig cryoinjured heart and were subsequently analyzed for electrical coupling with the host tissue. They showed not only 1:1 coupling with the host myocardium, but also that the heart had reduced susceptibility to premature ventricular contractions, and sustained ventricular tachycardia. As a result, this study represents one of the first accounts that cardiomyocytes are non-arrhythmogenic when implanted. This supports the continued study of the interactions between the native host myocardium and the tissue-engineered construct.

MODELING OF DISEASE

In vitro models of disease represent an important avenue for studying disease and for identifying potential therapeutic options. Here we describe the use of patient specific cells to generate diseased cardiomyocytes. We further describe the utility of tissue engineering in providing a faithful representation of diseased myocardium, and how this may be used in high throughput screens and drug studies.

Generation of patient-specific cardiomyocytes

Induced pluripotent stem cells have allowed for the generation of patient-specific cardiomyocytes. One of the first accounts came from Moretti et al., who generated iPS cells from patients with a particular genetic mutation leading to Long QT syndrome and subsequently differentiated them into cardiomyocytes (Fig. 38.6a,b) [11]. Localization of the mutated channel (KCNQ1) in the endoplasmic reticulum confirmed this channel as the likely cause of disease (Fig. 38.6c,d). These cardiomyocytes displayed the electrophysiological phenotype of Long QT syndrome, including the classic lengthened action potential duration (Fig. 39.6e,f). The use of induced pluripotent cells to recapitulate the disease phenotype is particularly amenable to patients with genetic mutations. Since the study on Long QT syndrome, cardiomyocytes from patients with other diseases, including arrhythmogenic right ventricular cardiomyopathy and familial dilated cardiomyopathy, have been generated [13,14]. The iPS cells from patients harboring genetic cardiac mutations have been differentiated into CMs. These include cells from Timothy [12], Long QT [11], and LEOPARD [24a] syndromes and dilated cardiomyopathy patients [14].

Engineered heart tissue model for diabetes

While induced pluripotent cells are useful in generating cells from patients with specific genetic mutations, many cardiac diseases are multifactorial and require a biomimetic environment to faithfully reproduce the disease phenotype. Engineered heart tissue has been used by Song and colleagues to study the cardiac effect of diabetes and the effect of drug therapy on diabetic engineered heart tissues [64]. Briefly, the diabetic rat heart and high glucose cultivation conditions exhibited diminishing electrophysiological properties and increased ratio of myosin heavy chain isoform β to α, indicative of diseased states.

Tissue engineering as a platform for pharmacologic studies

Given the active nature of cardiac tissue, new methods have been developed to study the function of engineered cardiac tissues in multiplexed *in vitro* systems. [65] Particularly, Schaaf

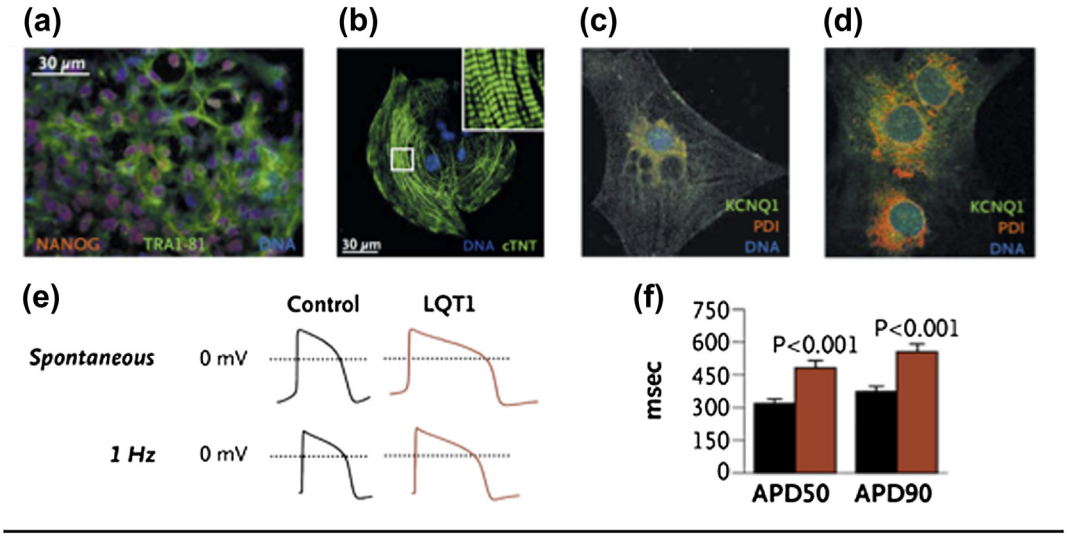

FIGURE 38.6

***In vitro* models of disease.** (a) Immunostain of induced pluripotent cells from LQT1 patients for Nanog and Tra1—81. (b) Troponin stain showing sarcomeric organization in induced pluripotent stem cell (iPS) derived cardiomyocytes. (e) Single cell action potentials of control and patient derived stem cells spontaneously beating or stimulated at 1 Hz. (f) APD50 and APD90 for control (black) or patient derived (red) cardiomyocytes.

et al. cast human embryonic stem cell derived cardiomyocytes in fibrin across a 24-well format which allowed the real-time measurement of force generation. [66] This system was then used to examine the effect of various proarrhythmic drugs (e.g., E-4031, quinidine, procainamide) on the beating dynamics of the heart tissue. As expected from the known electrophysiological effects of the drugs, the engineered tissues displayed irregular beating at low relaxation velocities.

In a separate study, sheets of engineered cardiac tissues were fabricated in a similarly multiplexed format which allowed the measurement of stress exerted by the cells [67]. Myocytes were seeded on a micropatterned surface to facilitate alignment of cardiomyocytes. The system was imaging compatible, allowing for the quantification of images or videos to determine contractility, action potential propagation, and cytoskeletal architecture.

SUMMARY AND CHALLENGES

The increasing population of patients with heart disease, and the limited availability of transplant organs, motivates the field of cardiac tissue-engineering, which aims to generate robust tissue for implantation and subsequent improvement in cardiac function. The stringent requirements of cardiac tissue, including: the ability to generate contractile force, substantial metabolic requirements, and the need to electrical integrate with host tissue have resulted in a multitude of techniques to develop *in vitro* cardiac tissue. Different scaffolds, including decellularized native heart and various artificial materials have been used to recapitulate the native architecture of the heart while providing conduits for vascularization. The addition of biophysical stimuli, including mechanical stretch and electrical stimulation, are aimed to phenotypically mature the cells. When considering these various strategies implemented to design and fabricate improved cardiac tissue, one overall obstacle as the field advances is standardization of experimental and measurement techniques.

This is even more critical with the recent advent of high yield differentiation strategies to generate iPS and ES derived cardiomyocytes, enabling for the first time, a human cell source with the potential to generate patient-specific cardiac tissues. The field of pluripotent stem cell mediated therapies is still in early development, and many fundamental obstacles still remain

before their full promise is realized. However, we are primed to leverage autologous, nonimmunogenic, patient-specific cardiomyocytes with advanced techniques for the cultivation of engineered heart tissue. The creative combination of these cells with three-dimensional vascularized matrices and biophysical stimulation will allow the generation of functional tissues and provide an opportunity to intervene on the global epidemic of heart disease [25a–29a].

INTRODUCTION

In the early 1900s, Alexis Carrel first described the utility and shortfalls of autogenous and synthetic grafts, including the unique challenges of small diameter synthetic grafts. Voorhees first utilized a synthetic vascular graft for larger artery replacement in the 1950s [1]. In 2012, small diameter arterial grafting continues to be associated with worsened long-term patency rates compared to autogenous vessels.

Since living with cardiovascular disease has become more prevalent in the last 100 years and people's lifespan across most of the world has been extended substantially in this time, there has been a growing need for vascular interventions. There are between 600,000 and 1.4 million bypass operations annually in the United States, and this number has remained stable in recent years. There has also been a significant growth in endovascular procedures for the lower extremity, and this has correlated with a decrease in major amputations [2]. Despite initial benefits of decreased early mortality and morbidity, these procedures are usually of inferior durability or outcome, and sometimes both. Thus there is a critical need to create small vessel vascular conduits and apply bioengineering approaches to endovascular therapies to improve the capacity and quality of patient care in the treatment of cardiovascular disease and injury.

This chapter discusses the experimental and clinically available bypass grafts, the modifications of these grafts to facilitate healing, current approaches to promoting arteriogenesis and therapeutic angiogenesis, to creating tissue-engineered vascular grafts, and concludes with tissue-engineering approaches in endovascular therapeutics.

CURRENT STATUS OF VASCULAR CONDUITS

Conduit patency and failure

Large diameter grafts, such as those used for aortic reconstruction, have a five year patency rate approaching 95%, but when synthetic grafts are used in the infrapopliteal region, the one year patency rates are less than 50% [3]. The best autogenous conduit is the left internal mammary artery for coronary artery bypass grafting; it has a greater than 90% 5-year patency. Vein, particularly good quality greater saphenous, is the conduit of choice for multi-vessel coronary artery bypass grafting and extremity vascular reconstruction. However its primary and secondary patency rates at one year in a patient population with critical limb ischemia were

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00039-2

recently reported to be 61% and 80%, respectively [4]; the results are not better in the coronary vasculature. Thus there are clinical needs that drive novel conduit creation and existing conduit remodeling.

A variety of mechanisms can lead to bypass failure, and they occur in a defined temporal sequence. Immediate graft failure is usually the result of technical error from the operation or the patient having a hypercoagulable condition; failure in the first month following graft placement is likely the result of thrombosis secondary to distal flow resistance. Small diameter grafts are prone to early thrombosis because of their lower flow rates and higher resistance. Thus graft thrombogenicity is of primary concern early after graft placement.

Anastomotic myointimal hyperplasia (IH) is the most common reason for graft failure from six months to three years after graft insertion. Small diameter grafts are particularly susceptible to IH.

Later graft failure is frequently due to the progression of distal atherosclerotic disease and beyond the direct influence of the conduit. However stiffness in the conduit or the target artery itself may contribute to the worsened prognosis after intervention in diseased compared to healthy arteries via flow disturbances, and the predilection towards inward remodeling. We have recently demonstrated that circumferential microstructural collagen alignment in the arterial media is associated with increased stiffness in distinct primate arteries (Fig. 39.1). One can envision endovascular approaches being individuated according to the stiffness of the target artery in order to promote favorable remodeling post-procedurally.

Pathophysiologically, denuded intima or exposed luminal area of a graft may lead to thrombosis via platelet deposition and activation of the coagulation cascade, and over time it promotes pathologic smooth muscle cell (SMC) migration, proliferation, and extracellular matrix (ECM) deposition, leading to IH. IH in turn narrows the vessel lumen (re-stenosis) disturbing blood flow to the point that it may occlude, thrombose, or cause symptomatic

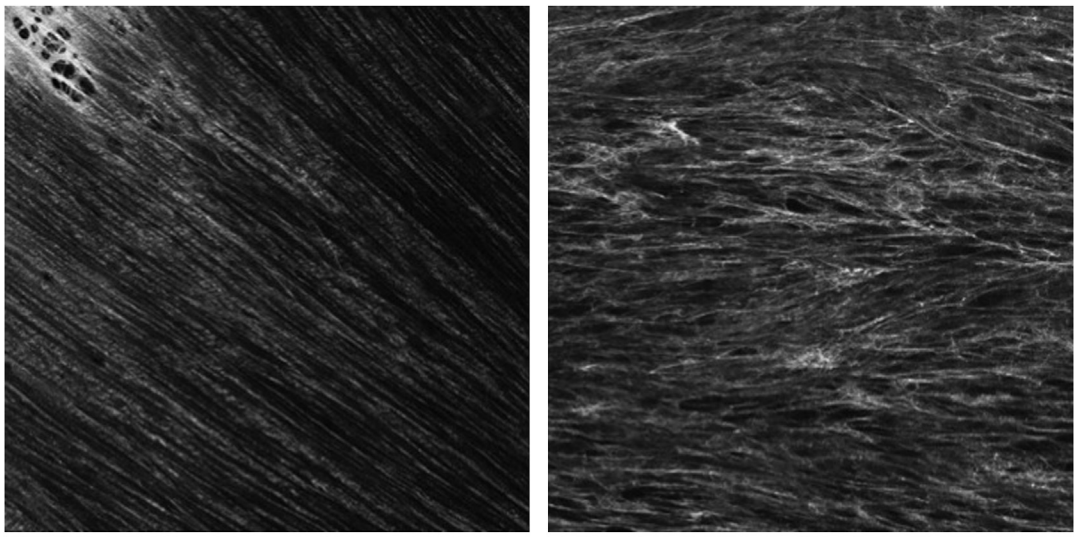

FIGURE 39.1
Differences in circumferential collagen alignment in the arterial media. Representative multiphoton image of differences in microstructural collagen alignment in the arterial media of the primate femoral (left) and carotid (right) artery.

ischemia in the relevant distal end organs like the brain (cardiovascular accidents), heart (myocardial infarctions), and extremities (critical limb ischemia). Since thrombogenicity and intimal hyperplasia represent the most common causes of graft failure and are both mediated at the luminal interface of the vessel or graft, the inner lining of grafts has been the subject of much investigation.

Cellular and molecular mediators of graft outcome

ENDOTHELIUM

In the absence of disease or injury, native blood vessels possess an endothelial lining that constantly secretes bioactive substances inhibiting thrombosis, promoting fibrinolysis, and inhibiting SMCs from switching from a contractile to a synthetic phenotype. The intima cues the vessel media to maintain blood flow and perfusion to meet distal tissue demands. Thus re-establishing this type of intimal lining quickly and completely in vascular grafts is vital to the patency of small diameter vascular grafts. Unfortunately, and unlike most animal models in use that spontaneously endothelialize synthetic grafts, humans manifest only limited endothelial cell ingrowth not extending beyond 1–2 cm of both anastomoses. However, endothelial islands have been described in the midportions of grafts at significant distances from the anastomosis, suggesting that other EC sources for graft endothelialization may exist. Interstitial tissue ingrowth accompanied by microvessels from the perigraft tissue is one potential source. There is also evidence that circulating endothelial cells, endothelial progenitor cells (EPCs), or stem cells can be directed to these areas. Such homing can be promoted through affixation of EC attractant antibodies to the grafts in a similar fashion to that utilized in coronary artery stents [5].

However, ECs growing on prosthetic graft surfaces are not necessarily the same as their normal quiescent counterparts in uninjured vessels. These ECs are often 'activated', secreting bioactive substances (e.g., PDGF) that actually promote thrombogenesis and changes in SMC phenotype. This has been seen in the perianastomotic region, which is the most frequent site of interventional failure after operation. SMCs found within the myointima of prosthetic grafts are also functionally altered. They produce significantly higher amounts of PDGF, as well as various ECM proteins, compared to those of the adjacent vessel, which along with the body's inflammatory reaction to prosthetic material, contribute to the development of intimal hyperplasia [6].

INFLAMMATION

The inflammatory response to vascular interventions is complex because these patients have systemic inflammation which may influence the degree and direction of local inflammation. Potent chemoattractants like complement 5a (C5a) and leukotriene B_4 recruit neutrophils to the graft surface where they localize in the fibrin coagulum of the graft's inner and outer capsule via β2 integrins. Also, IgG binds to the neutrophils' Fcγ receptors activating neutrophils' pro-inflammatory response while inhibiting normal clearance of bacteria. Neutrophils also interact with various other deposited proteins including C3bi and Factor X, and they adhere to the endothelial cells in the perianastomotic region through selectin- and integrin-mediated mechanisms. L-selectin is thought to modulate neutrophil/endothelial cell interactions by presenting neutrophil ligands to both E and P-selectin on the vascular endothelium. In addition, selectin-carbohydrate bonds are important for the initial cellular contact while the integrin-peptide bonds are responsible for strengthening this adhesion, as well as the transmigration of neutrophils. Both intercellular adhesion molecular-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on the EC surface bind these integrins as well, and ECs upregulate ICAM-1 and express VCAM-1 when stimulated by inflammatory agonists like IL-1, TNF, lipopolysaccharide, and thrombin. Further, activated neutrophils

release oxygen free radicals and various proteases, which result in matrix degradation and may inhibit both endothelialization and tissue incorporation of the vascular graft.

Circulating monocytes/macrophages are also attracted to areas of injured or regenerating endothelium, especially in response to IL-1 and TNF-α. There are many plasma monocyte recruitment and activating factors, including LTB_4, platelet factor 4, and PDGF. This process is propagated in the presence of these plasma activating factors, driving monocytes to differentiate into macrophages that direct the host's chronic inflammatory response via the release of proteases and oxygen free radicals.

A variety of cytokines are released from the inflammatory cells activated by vascular grafts. Lactide/glycolide grafts are composed of bioresorbable materials that are phagocytosed by macrophages; in culture these materials stimulate macrophages to release mitogens that stimulate vascular cells. This mitogenic activity appears to be related to the secretion of FGF-2 since pretreatment of the culture media with a neutralizing anti-FGF-2 antibody significantly diminishes the stimulatory effect on SMC growth in culture [7]. Cultured monocytes and macrophages incubated with Dacron and expanded polytetrafluoroethylene (ePTFE) have been demonstrated to produce different amounts of IL-1β, IL-6, and TNF-α that are biomaterial specific [8]. TNF-α is one of the factors that may contribute to the enhanced proliferation of SMCs caused by leukocyte-biomaterial interactions, while IL-1 may be partly responsible for the increased SMC proliferation caused by leukocyte-EC reaction. IL-1 also induces up-regulation of IGF-1 expression in ECs, and co-culture of neutrophils with IL-1β-treated ECs dramatically increases PDGF release.

Since the inflammatory reaction elicits a cascade of growth processes, it has been proposed that approaches attenuating the initial inflammatory reaction may improve long-term graft patency; alternatively, directing the inflammatory response to promote favorable cellular and protein responses may promote intimal generation and tissue incorporation.

PHYSICAL OR CHEMICAL MODIFICATION OF CURRENT GRAFTS TO IMPROVE DURABILITY

The long-term patency of vascular grafts depends upon the intrinsic properties of the graft itself and the hemodynamic environment in which the graft is placed, as well as patient variables (e.g., diabetes, renal failure, etc.), and may or may not be improved by prior or concomitant interventions such as proximal or distal angioplasty. Since it is now clear that tissue incorporation is important for long-term graft function, grafts that have this ability are now desirable for medium and small caliber vessel replacement. Polyethylene terephthalate (PET, Dacron) and ePTFE are the predominant materials currently used in prosthetic vascular grafts, but both of these react with blood components and perigraft tissues in concomitantly beneficial and detrimental fashions. All grafts, regardless of their composition and structure, evoke complex but predictable host responses that begin immediately upon restoration of perfusion, and this improved understanding of the cellular and molecular components of biomaterial/tissue interactions has led to more intelligent designs of grafts that maximize beneficial ingrowth while minimizing the chronic inflammatory changes that lead to graft dilation or occlusion. Thus, the chemical composition, construction parameters and biomechanical characteristics of a vascular graft are the predominant mediators of host interaction, and largely determine graft fate.

Surface characteristics

The thrombotic interaction at the grafts' luminal interface is dependent on both the chemical and physical properties of the graft (e.g., surface charge, surface energy, and roughness). A negative surface charge attenuates platelet adhesion and a positive charge promotes it, while a heterogeneous charge density distribution is also thought to be thrombogenic. A myriad of

approaches have been designed to limit the thrombotic reaction, including modification of surface properties, incorporation of antiplatelet or anticoagulant substances onto the graft surface, and endothelialization of the luminal surface. In addition to thrombogenic reactions to the luminal surfaces, the rate and extent of endothelialization will vary depending on the characteristics of the surface [9]. Therefore properties must be optimized for both reduced thrombogenic reaction and maximized endothelialization.

Surface modifications

The simplest modification of a graft surface is to coat it with a relatively inert polymer. Since the 1960s, it has been known that carbon coating decreases surface thrombogenicity through its negative charge and hydrophobic nature. Experimentally, the carbon-impregnated prosthetic graft was found experimentally to reduce platelet deposition, but the advantage of these grafts was not confirmed in a prospective multicenter clinical study of 81 carbon-impregnated ePTFE and 79 standard ePTFE grafts for below-knee popliteal and tibial/peroneal artery bypasses. Here the investigators failed to show a significant difference in patency rate between the two groups at up to 12 months after implantation [10].

Silicone polymer coating is another approach to alter the luminal surfaces of grafts; this process produces a smooth surface that is devoid of the usual ePTFE graft permeability and texture, and when followed by plasma glow discharge polymerization, it effectively abolishes pannus tissue ingrowth as well as graft surface neointimal hyperplasia in a baboon arterial interposition graft model. Further Nojiri et al. [11] have developed a three layered graft consisting of PET for the outer layer (to promote perigraft tissue incorporation), non-porous polyurethane in the middle layer (to obtain a smooth surface), and a 2-hydroxyethyl methacrylate and styrene (HEMA-st) copolymer coating for the inner layer (to establish a non-thrombogenic blood interface). These grafts with an ID of 3 mm were implanted in canine carotid arteries and remained patent for over one year. Only a monolayer of adsorbed proteins was described on the luminal surface of the grafts with no pannus ingrowth from the adjacent artery, no thrombus, and no endothelial lining or neointimal formation.

Protein adsorption

Another approach is to cover vascular grafts' lumens with proteins. Protein coating has been used as an alternative to preclotting with blood to decrease the initial porosity of Dacron grafts in order to limit transmural blood loss. Knitted Dacron prostheses coated with albumin, gelatin, and collagen have all been available for clinical use. As the impregnated proteins are degraded, the graft undergoes tissue ingrowth.

The most abundant serum proteins are albumin, fibrinogen, and IgG. They adsorb to grafts almost instantaneously following exposure to the systemic circulation. Subsequently there is a redistribution of proteins, known as the Vroman Effect, according to each protein's relative biochemical and electrical affinity for the graft surface and their relative abundance [12]. Since platelets and blood cells interact predominantly with the bound proteins and not with the prosthetic material itself, the constitution and concentration of bound protein has profound influence over the type and degree of cellular interaction with the graft. Fibrinogen, laminin, fibronectin, and vitronectin all have an arginine-glycine-aspartate (RGD) sequence that is recognized by platelets' glycoprotein (GPIIb/IIIa) receptor and initiate platelet activation. RGD sequences are also recognized by β_2 intergrin, which directs leukocyte adhesion to the graft. Additional plasma proteins, including complement components, can also be differentially activated directly by different synthetic surfaces. For example, the generation of the monocyte chemoattractant, C5a, is greater following implantation of Dacron compared to ePTFE grafts in an animal model [13]. In addition, the rapid accumulation of coagulant proteins such as thrombin and Factor Xa on the luminal surface after implantation contributes to the thrombogenicity of vascular grafts.

Porosity

The prevalence of open spaces or pores determines the porosity of a scaffold or synthetic graft, while the permeability of a graft is defined by its ability to permit passage of a substance through itself. Since ePTFE is composed of a number of solid nodes inter-connected by a matrix of thin fibrils with no uninterrupted transmural spaces, it is best categorized by the distance between these nodes, which is defined as the internodal distance (IND). This spacing, when above approximately 5–6 μm, as is commonly used in clinically available prostheses, allows for cellular ingrowth, but transinterstitial ingrowth is not strictly a function of porosity. We have shown that the extent of ingrowth varies greatly among different biomaterials (e.g., polyglycolic acid (PGA) and Dacron) despite these biomaterials having similar porosity [14].

Still, the rate of tissue ingrowth can be improved by optimizing graft porosity or permeability. Clowes et al. have demonstrated enhanced tissue ingrowth and complete re-endothelialization of 60 μm or 90 μm internodal distance ePTFE grafts in a baboon model [15]. However, transinterstitial capillary ingrowth was not seen with the more commonly used 30 μm internodal distance ePTFE. Human trials using ePTFE with these expanded internodal distances failed to show any advantage in platelet deposition compared to the standard 30 μm internodal distance ePTFE grafts [16].

Compliance

The compliance mismatch between arteries and grafts causes flow disruption *in vivo* which may contribute to anastomotic pseudointimal hyperplasia [17]. It is for this reason that various surgeons have suggested interposing a segment of vein between the synthetic graft and artery, creating a composite graft at the distal anastomosis. This has led some investigators to design more compliant grafts using more flexible materials and/or changing the parameters of graft construction to improve graft compliance. Although animal experiments have suggested concept validity, the clinical benefit of this approach remains controversial. Many factors may contribute to this confusion, including longitudinal variability in the diameter and compliance of the arterial tree and the effect of activated endothelium on intimal hyperplasia. Further there is a robust fibrotic response after implantation that leads compliant grafts to become incompliant after implantation; thus even if a compliance match were attained initially, it would not likely persist. In the para-anastomotic region there are dynamic changes in compliance that vary over time. First a para-anastomotic hypercompliant zone exhibits a 50% gain in compliance, then later its compliance is lessened 60% from baseline [18]. It is likely that this bimodal effect limits the practical value of this approach.

Thromboresistance

Early platelet deposition on vascular grafts is mediated by von Willebrand Factor (vWF) and platelet membrane glycoproteins. After adherence to a graft, platelets degranulate, releasing many bioactive substances, including serotonin, epinephrine, ADP, and thromboxane A2. These substances in turn activate additional platelets and promote a prothrombogenic reaction. Activated platelets also release growth factors, such as PDGF, EGF, TGF-β, which promote SMC migration and proliferation as well as ECM degradation and ECM protein synthesis. In addition, platelets release monocyte chemoattractants such as platelet factor 4 and β-thromboglobulin, which mediate the recruitment of macrophages to the graft. Platelet deposition and activation continues chronically after graft implantation as evidenced by increased thromboxane levels and decreased systemic platelet counts one year after Dacron graft implantation in a canine model [19], and human studies have confirmed platelet adhesion to grafts up to one year after implantation.

Since the deposition and activation of platelets elicits various pathologic cascades, the thrombogenic nature of the synthetic graft surface can lead to both early and late graft failure. A myriad of approaches have been studied to attenuate platelet deposition, aggregation, and

degranulation. Antiplatelet agents directly targeting platelet/graft-binding molecules such as platelet surface GPIIb/IIIa and different functional domains of thrombin have been shown to at least transiently decrease the accumulation of platelets on Dacron grafts [20]. Also the surface thrombogenicity of grafts can be altered experimentally as described earlier.

Similar approaches can be utilized to decrease thrombogenicity by disrupting the activation of the blood system's coagulation cascade on thrombogenic surfaces, such as cardiovascular stents and synthetic grafts. These are now commercially available in various formulations. Genetic approaches to increase thromboresistance have been employed by multiple groups through the over-expression of thrombotic inhibitors, but since ECs themselves are antithrombotic, there may be limited benefit of this approach when compared to a functioning endothelium.

Resistance to infection

Vascular graft infection is rare, but it is catastrophic when it occurs; as demonstrated by an amputation rate of approximately 50% and a reported mortality rate that ranges from 25–75%. In an attempt to limit this dreaded complication, penicillin and cephalosporins have been successfully bound to Dacron and ePTFE grafts and found to limit *Staphylococcus aureus* infection in animal models. Rifampin-bonded gelatin-sealed Dacron grafts have also been shown *in vitro* to lessen bacterial colonization [21]. Intuitively, tissue ingrowth itself may also provide resistance to infection.

Biological modification through exogenous sources

The delivery of potent angiogens or genes that promote EC-specific mitogenesis or chemotaxis upon prosthetic surfaces may be used to regenerate a rapid and complete endothelium after vascular intervention. Such prosthetics could store these genes or proteins and provide a controlled expression or release of these genes or proteins locally to circulating or surrounding ECs in a cell-demanded fashion. Ideally, this kind of prosthetic would be available as an off-the-shelf alternative to autogenous vein.

PROTEIN THERAPY

Although tissue incorporation is a desirable process for implanted prostheses, excessive vascular cell proliferation as well as ECM deposition can lead to intimal hyperplasia and ultimately graft failure. The ideal healing process in vascular grafts would be rapid endothelialization of blood contacting surfaces concomitant with a spatially and temporally limited subendothelial SMC growth, and followed by phenotypic and functional differentiation of cellular components and the subsequent remodeling of a mature ECM. The recent expansion of knowledge concerning the mechanisms responsible for the migration and proliferation of ECs and SMCs, angiogenesis, ECM deposition and remodeling, and physiologic parameters provides optimism for the possibility of manipulating the healing process through the directed manipulation of the microenvironment within the graft and perigraft tissue.

Since ECs have only limited capacity for regeneration, re-endothelialization of the relatively large surface areas encountered clinically exceeds the normal mitogenic and chemotactic capacity of surrounding ECs. Thus endothelialization of large surfaces requires the recruitment of ECs from sites beyond the anastomotic border via the circulation or through transinterstitial migration from the surrounding tissue and/or the vasa vasorum. This is possible under the direction of localized angiogenic stimuli, and to a limited degree this is what occurs *in vivo* as protease-driven ECM changes and local availability of growth factors, stimulate ECs, SMCs and fibroblasts to enter the cell cycle.

Platelet deposition and the perigraft inflammatory response lead to the release of many cytokines and proteolytic enzymes, which in turn incite secretion of a cascade of growth factors. Some of these growth factors are potent angiogens (e.g., vascular endothelial growth

factor (VEGF) and fibroblast growth factor (FGF)-family members) while others are angiogenic inhibitors (e.g., platelet factor 4, thrombospondin); still others (e.g., tumor necrosis factor alpha (TNF-α) and transforming growth factor beta (TGF-β)) exhibit both activities.

The local delivery of growth factors or selected ECM may be utilized to promote desirable cellular events, such as endothelial ingrowth of synthetic grafts. For example, local delivery of exogenous angiogenic factors through a biologic delivery system (e.g., fibrin) may induce transmural capillary ingrowth *in vivo*, which can be the source of cells for an endothelial lining within synthetic grafts. Bioresorbable grafts may also facilitate local angiogenic responses by stimulating macrophage release of angiogenic proteins. Fibroblast growth factors, notably FGF-1 (acidic FGF) and FGF-2 (basic FGF) have potent mitogenic, chemotactic, and angiogenic activity on vascular cells, but in order to deliver them locally to direct intimal regeneration, they require a delivery system that provides predictable local release with bioactivities preserved over a specific interval of time. Their ability to promote endothelial ingrowth has been tested experimentally after application to grafts. Our lab has evaluated the affixation of FGF-1 to synthetic surfaces. In early attempts, FGF-1 was applied to various synthetic grafts via a fibrin glue delivery system that, due to its structural orientation and state of polymerization, had been found not to be thrombogenic [22]. After delivering FGF-1 from fibrin glue to 60 μm IND ePTFE in both canine aorto-iliac and thoracoabdominal aortic models, there was a significant increase in luminal EC proliferation as assayed by *en face* autoradiography, and a more rapid development of a confluent Factor VIII positive endothelial blood contacting surface [23–24] (Fig. 39.2). There was also extensive transinterstitial capillary ingrowth observed throughout the graft wall. Cross-sectional autoradiography did find a significant increase in subendothelial myofibroblast proliferation in these treatment grafts at one month, but this returned to baseline at later time points. Still, treated grafts developed a significantly thicker pseudointima (139 μm ± 178 μm versus 93 μm ± 89 μm and 67 μm ± 151 μm) at 140 days. In order to limit this IH response, we have developed site-directed mutants based on the FGF-1 angiogen and bioactive

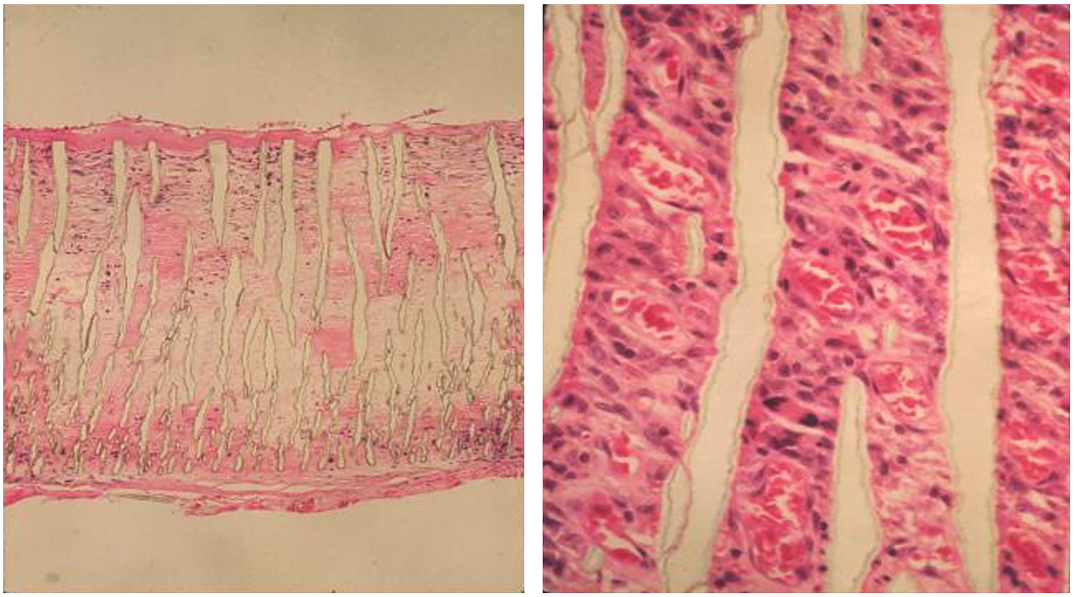

FIGURE 39.2

Transmural induction of endothelialization by FGF-1 on prosthetic graft. Fibrin glue delivery of exogenous FGF-1 promotes ePTFE endothelialization. The untreated control is pictured on the left side at 117x, and the FGF-1 treated graft is seen on the right at 486x. The treated graft demonstrates robust capillary ingrowth and cellular coverage not seen in the control graft. *Reprinted from the Journal of Surgical Research, Vol. 57; JL Gray, SS Kang, GC Zenni, DU Kim, PI Kim, WH Burgess, W Drohan, JA Winkles, CC Haudenschild, HP Greisler; FGF-1 affixation stimulates ePTFE endothelialization without intimal hyperplasia, pp. 600, 602; 1994, with permission from Elsevier.*

chimeric proteins that promote favorable characteristics including prolonged bioactivity, EC specificity, or increased potency, while removing unfavorable characteristics such as heparin-dependent activity and susceptibility to thrombin-induced proteolysis [25–26].

Co-immobilization of FGF-2 and heparin in a microporous polyurethane graft by crosslinked gelatin has also been demonstrated to accelerate tissue regeneration on synthetic grafts, associated with a greater extent of endothelialization via perianastomotic and transmural capillaries ingrowth, in a rat aortic grafting model [27]. A consistent 'neointima', approximately 40 m thick with intermittent endothelialization as well as SMCs and fibroblasts underneath the luminal surface were observed in the middle portion of treatment grafts, whereas the control grafts were only covered with a fibrin layer. However because of the cross-talk that exists in the vessel wall between endothelial cell (EC), smooth muscle cell (SMC), and fibroblasts, multimodal therapies that promote EC coverage while limiting activation of vascular smooth muscle cells (VSMCs) or the delayed delivery of cell cycle inhibitors may be required to optimize graft healing.

GENE THERAPY

Gene therapy shares the same promise as proteins, but it may also allow sustained or controlled protein expression in a desired location that is not possible with protein formulations. These qualities could obviate some of the current limitations encountered with the direct application of growth factor proteins to tissue beds for the regeneration of the endothelium.

This approach shows much promise as a delivery system, but single gene therapy trials have not yielded straightforward results. For example, although VEGF does improve endothelialization consistently, it does not reliably limit IH (and sometimes even promotes IH) in the literature. Gene therapy still requires cellular transduction or infection, and this has a variable effect on the cellular behavior. Also controversial results have been reported in the literature related to the proliferation, adhesion, and retention of genetically modified ECs on the surface of synthetic grafts. A major concern is that genetically modified ECs display poor retention on graft surfaces *in vivo*. This was demonstrated at six weeks in canine thoracoabdominal aortic ePTFE grafts seeded with lacZ-infected ECs compared to non-infected control ECs [28]. Further, Dunn [29] reported only 6% retention of ECs that had been retrovirally infected with thromboplastin on Dacron grafts after two hours of exposure to flow *in vivo*. For these reasons, little success has been documented to date concerning the long-term benefit of genetically modified EC seeded grafts *in vivo*.

CELLS

In addition to the emphasis on the endothelialization of the flow surface, the function of other cell types, particularly the SMCs, in the vascular wall have become better appreciated. It has been suggested that ECs by themselves cannot produce a stable intima without SMCs or fibroblasts underneath. In support of this contention, tissue fragments containing multiple cell types, including venous tissue, adipose tissue and bone marrow, have been seeded onto grafts and found to accelerate graft-healing processes. Interestingly, bone marrow cell seeding was also reported to induce an abundant capillary ingrowth in the graft wall and a rapid, complete endothelialization of the inner surface without intimal hyperplasia. Since the bone marrow stem cells have the ability to differentiate in response to their microenvironment and to proliferate as well as secrete cytokines critical to their survival, they may provide a useful cell source for blood vessel tissue engineering.

THERAPEUTIC ANGIOGENESIS AND ARTERIOGENESIS

Therapeutic angiogenesis

In addition to stimulating graft re-endothelialization via transmural angiogenesis, a number of cardiovascular pathologies and surgical interventions could also benefit from the ability to

therapeutically stimulate new blood vessel formation (neovascularization). Peripheral vascular disease, myocardial ischemia, wound healing, and tissue engineering are just a few of the many fields that may benefit from this approach.

GROWTH FACTOR THERAPY FOR ANGIOGENESIS

The process of neovascularization is controlled by a complex spatial and temporal expression of proteins, and to date most strategies have attempted to stimulate angiogenesis by injecting growth factors (as proteins) systemically or directly into target tissues. VEGF, FGF-1, and FGF-2 have been utilized frequently, reaching the point of clinical trials for the treatment of myocardial and/or peripheral limb ischemia. Many other growth factors also play a role in neovascularization and are under investigation in animal and *in vitro* models. The angiopoietins (Ang-1 and Ang-2), placental growth factor (PlGF), FGF-4, hepatocyte growth factor (HGF), ephrin-B2, and platelet derived growth factor BB (PDGF-BB) are a few of the many other proteins with the potential to be used for therapeutic neovascularization.

Due to short protein half-lives *in vivo* and their rapid diffusion out of target tissues, growth factor therapies require high initial concentrations, and repeat injections are required in order to achieve a noticeable response. Yet sustained protein levels are most likely needed in order to form a stable microvasculature. Since it is the local microenvironment concentration that determines the structure of the resultant microvasculature [30], these initially high concentrations can lead to demonstrable side effects, such as hyperpermeable or malformed vessels. Even sustained local concentrations may not elicit a sufficient angiogenic response because ischemic tissue may have an altered ability to respond to growth factors [31].

GENE THERAPY FOR ANGIOGENESIS

The genes of these same proteins have also been investigated as neovascularization therapies. As with gene delivery to vascular grafts, the goal of these approaches is typically local overexpression of the protein. Delivery of a single gene or protein has shown promise in animal models, but clinical results have fallen short of expectations. Overexpression of multiple proteins may have a synergistic effect on neovascularization. PlGF combined with VEGF has been shown to be significantly more potent than each factor alone in an animal model that was refractory to a single protein [32]. Combined delivery of adenovirus-mediated VEGF and Ang-1 has also been shown to promote greater perfusion and vessel stability in muscle flaps than VEGF alone [33]. Combined therapies may also be more effective in treatment of diseased or elderly patients who are known to have an impaired response to a single protein.

CELLULAR THERAPY FOR ANGIOGENESIS

Cellular therapies can also be used to enhance neovascularization. ECs injected into ischemic or engineered tissues are thought to be capable of mimicking vasculogenesis and to assemble into capillary structures, but may also act as sources of pro-angiogenic factors. Studies have shown that these cells can fuse with invading host vessels, recruit perivascular cells, and establish flow [34], and that support cells can prolong the existence of transplanted vessels [35]. Here ECs seeded alone into fibronectin-collagen type I gels and implanted into mice showed little perfusion and regressed from the gels after 60 days, while ECs combined with mesenchymal precursor cells resulted in the formation of vessels that established flow through connections with the mouse circulatory system. EPCs [36–37] may also be used to increase neovascularization. These cells may have increased proliferative capacity relative to mature ECs, and may be less sensitive to the short-term hypoxic conditions in tissues prior to establishing a blood flow. Injected EPCs selectively localize in ischemic tissues and may increase vascular density [36]. However, the mechanism for this increase is not clear. EPCs may develop

into new vascular structures or may increase neovascularization indirectly by recruiting monocytes/macrophages that then secrete angiogenic factors [37].

EPCs can also be genetically modified to enhance their therapeutic function. EPCs transfected to express VEGF stimulate a greater improvement in blood flow and angiogenesis in animal models of ischemia than EPCs alone [38]. While they have a longer life than fully differentiated cells, EPCs isolated from adults have reduced telomerase activity and regenerative capacity relative to embryonic stem cells. EPCs isolated from bone marrow and transfected to express telomerase reverse transcriptase (TERT) are more resistant to apoptosis and drastically increased neovascularization in an animal model of limb ischemia [39].

Modest but statistically significant improvements in the delivery of mesenchymal stromal cells to ischemic lower extremity and heart tissue have been demonstrated recently [40–41].

Arteriogenesis

Facilitating arterialization of capillary beds and expansion in size of smaller collateral arterial pathways (arteriogenesis) rather than formation of new capillary beds (angiogenesis) may be critical to facilitating adequate perfusion needed to overcome tissue ischemia. Recent work has shown that non-viral monocyte chemoattractant protein-1 (MCP-1) gene delivery increases arteriogenesis in a rabbit ischemic limb [42], and results from clinical trials suggest that VEGF gene therapy may also stimulate arteriogenesis. Less specifically, cell delivery can also enhance arteriogenesis.

Monocytes injected intravenously into rabbits following femoral artery ligation have been shown to home to sites of ischemia and stimulate arteriogenesis. By genetically modifying these monocytes with granulocyte-monocyte colony stimulating factor, collateralization was increased significantly [43]. Although promising, monocytes are also active participants in atherosclerosis, and it may be difficult to direct arteriogenesis without atherogenesis in these patients.

TISSUE-ENGINEERED VASCULAR GRAFTS

Driven by the desire to develop an ideal vascular substitute, the construction of tissue-engineered arterial grafts has been attempted with variable success. The potential benefits of tissue-engineered vascular grafts (TEVG) include the creation of a responsive and self-renewing tissue graft with functional intimal, medial, and adventitial layers (including both cellular and ECM components) that can be remodeled by the body according to its needs. Such grafts may improve graft durability and reduce the potential for graft infection by lessening the foreign body reaction and facilitating a more complete integration of the graft into the surrounding tissue.

In vitro TEVG

Weinberg and Bell were the first to develop a TEVG *in vitro* [44]. Using collagen and cultured bovine vascular cells, they demonstrated the feasibility of creating a TEVG, but their graft had prohibitively low burst pressures, hence requiring external Dacron for support. In the following decade L'Heureux et al. constructed a human blood vessel with an acceptable burst strength and a thromboresistant endothelium *in vitro* using cultured umbilical cord-derived human cells [45], but because of the immunogenic effects of the heterogeneic ECs *in vivo*, this graft devoid of ECs had only a 50% patency rate at eight weeks in a canine model. Since neonatal cells have a greater regenerative capacity, the above TEVG was not considered applicable to the aged population; that which would benefit most from a TEVG. Since these early efforts, considerable progress has been made.

ENDOTHELIAL CELL SEEDING

The prototype TEVG was created by seeding ECs onto ePTFE grafts *in vitro*, and then implanting them clinically. A confluent EC monolayer can prevent the development of myointimal hyperplasia by:

1) Preventing the deposition of platelets which release bioactive factors responsible for SMC migration, proliferation and production of ECM,
2) Maintaining a mechanical barrier to VSMC invasion via intimal basement membrane and the internal elastic lamina, and
3) Assuming a quiescent EC phenotype that does not stimulate SMC activity.

In 1978, Herring [46] first reported that endothelial cell seeding onto a graft surface enhanced graft survival in animal models. One of the early difficulties encountered was due to the relatively low cell density initially applied to the graft. Even though the cell density of the endothelial cell monolayer on a normal vein is approximately 10^3 ECs/mm^2, an initial density of at least 5 x 10^3 ECs/mm^2 is required for immediate confluent EC coverage of a small caliber vascular graft after exposure to the circulation. Studies on the kinetics of EC loss following seeding showed that between 20–70% of initially adherent cells are lost during the first hour and as few as 5% were retained after 24 hours [47]. Retained cells at least partially compensate for the cell loss by migration and proliferation. Preconditioning the seeded EC monolayer with graded shear stress promotes reorganization of the EC cytoskeleton and production of ECM, which in turn enhances the EC retention at flow exposure [48]. Additionally, Dacron and polyurethane have better cell attachment rates than ePTFE.

To maximize immediate cell inoculation density, a two stage seeding procedure is often performed in which endothelial cells are harvested, allowed to proliferate *in vitro*, and then seeded and grown to confluence on the vascular graft prior to implantation. The disadvantages of this technique include the increased potential for infection, the alterations of EC phenotype and function, the requirement of a 3–4 weeks waiting period for expansion of the cell population, and the necessity for two operative procedures. Zilla et al. demonstrated increased patency and decreased platelet deposition in clinically implanted endothelial cell-seeded (two stage approach) ePTFE femoropopliteal bypass grafts over three years as compared to unseeded grafts, and this group more recently reported an overall 7-year primary patency rate of 62.8% for 153 endothelialized femoro-popliteal ePTFE grafts [49]; this is comparable to the patency rate of saphenous vein grafts in this region. However, the seeded grafts have not been reproducibly shown to significantly reduce anastomotic pseudointimal hyperplasia.

There are also concerns about the ultimate function of those endothelial cells on the graft surface, the cells having been injured by the process of manipulation and/or exposure to a non-physiologic environment. Unlike their uninjured counterparts, injured endothelial cells produce a variety of procoagulants like von Willebrand Factor, plasminogen activator inhibitor, thrombospondin and collagen. Higher levels of PDGF and bFGF have also been measured in EC-seeded grafts; this is particularly concerning given their potential role in stimulating the migration and proliferation of SMCs, which can lead to IH.

ARTERIES ENGINEERED *IN VITRO*

The two main components of arterial generation *de novo* are the cells and their scaffolds. These components are not separable in practice, but they are separated in this chapter to emphasize their respective contributions.

There is much discussion about the proper cells to use for cell seeding *ex vivo* or cell homing *in vivo*. The EC is the most fastidious vascular cell to grow, and heterogenous ECs are highly immunogenic. Therefore in the absence of immunosuppression or genetic modification, autogenous ECs are a requirement for TEVG. TEVG media and adventitia can be created by using vascular SMCs or fibroblasts with or without exogenous matrix scaffolding. These cells

can be harvested from the patient in need, but since these patients are typically older with significant co-morbidities, their cells (particularly VSMC and ECs) may not retain sufficient doubling capacity to generate these TEVGs.

This may be due to the loss of telomere length that occurs with aging. Niklason and colleagues have demonstrated an increase in the population doublings of adult VSMCs through retroviral infection with the telomerase reverse transcriptase subunit (hTERT) without evidence of inducing cellular transformation [50]. However these arteries have a low bursting strength, which may be due to intrinsic and hTERT independent limitations of ECM protein production. More recently the Niklason laboratory has utilized multipotent cells to strengthen the matrix in these vessels and then decellularized them. As elastin formation in these vessels is incomplete, the decellularization process is much easier than that of healthy human arteries [51]. However elastin and elastic function of the artery is desired. Thus they are now evaluating ways of increasing elastin levels in TEVG [52].

Using a clinically relevant aged fibroblast-derived media, L'Heureux demonstrated a TEVG that has suitable bursting strengths at insertion, has a functional endothelium, and demonstrates mechanical stability in a variety of animal models out to eight months [53]. More recently this group has shown reasonable effective of this graft as a dialysis conduit [54–55].

Clinical success has been seen when using TEVG for vessel replacement in the venous system, which is potentially less challenging biomechanically. These TEVGs have been implanted in 42 pediatric patients with congenital heart defects. To date these grafts have been resistant to aneurysmal dilatation and had superb patency [56].

Various cellular and acellular approaches to TEVG scaffolds have also been pursued, and the challenge of the scaffold begins with providing satisfactory retention of cells *in vivo* or *ex vivo* in clinically relevant bioreactors and promoting optimal phenotypic characteristics of those cells. In addition, the scaffold or resulting vessel must have sufficient bursting strength to withstand the physiologic stresses of the circulation. After implantation this scaffold will undergo remodeling, and this can lead to aneurysmal dilatation and subsequent graft rupture. Niklason [57] reported encouraging results with a graft produced by seeding SMCs onto PGA scaffolds which were sodium hydroxide modified to promote cell attachment. This graft was cultured in an *in vitro* pulsatile radial stress environment for eight weeks prior to implantation. These grafts showed contractile responses to serotonin, endothelin-1, and prostaglandin $F_{2\alpha}$, and they expressed the SMC differentiation marker myosin heavy chain. Further, the grafts cultured under pulsatile conditions produced more collagen than those grown without pulsatile stress and exhibited a mechanical strength comparable to native human saphenous veins; this graft ruptured at 2150 ± 909 mmHg versus 1680 ± 307 mmHg for saphenous vein. Autologous ECs were seeded onto the luminal surface and were cultured for three more days before implantation. Four of the grafts were then implanted into swine saphenous arteries, of which two were generated under pulsatile stress and two under static conditions. Two pulsed grafts remained patent up to the fourth week without dilation or rupture while two non-pulsed grafts thrombosed after three weeks; the polymer remnants were no longer visible at four weeks.

Decellularized tissue scaffolds are appealing because they are already composed of native vascular ECM proteins that exhibit reasonable structural characteristics as well as providing instructive cues for cellular ingrowth. Using bone marrow derived cells incubated on decellularized canine carotid arteries, Byung-Soo Kim and coworkers demonstrated cellular incorporation into the scaffold and subsequent differentiation of these cells into endothelial and vascular SMCs and subsequently into three distinct vessel layers [58]. Others have used a more focused approach and induced or applied EPCs into similar scaffolds with promising results. The benefit of EPCs include a robust replication potential ideal for TEVG, and these cells acquire mature endothelial cell markers and function upon seeding into TEVGs [59]; these attributes may be further

augmented by gene therapy. Similarly adipose-derived stem cells have been used successfully as a cell source for TEVG by a number of investigators [60–61].

Using biologic gels, such as those composed of type I collagen or fibrin, one can promote tissue ingrowth and direct remodeling in a bioreactor, thereby promoting favorable characteristics such as improved mechanical strength or vessel reactivity over time [62]; such approaches are easily modified by the addition of growth factors with refined delivery systems in order to enhance and sustain cellular ingrowth [63]. Further refinement of these scaffolds can mimic the differential mechanical properties of the intimal and medial arterial layers. Syedian has recently reported development of TEVG from neonatal fibroblasts in a fibrin gel [64].

In vivo TEVG

Current clinically available synthetic vascular grafts, composed of ePTFE, Dacron, or polyurethane are permanent prostheses within the host after implantation. Theoretically, it is possible with bioresorbable materials to stimulate a rapid and controlled ingrowth of tissue to assume the load bearing sufficient for resistance to dilation, and to incorporate cellular and extracellular components with desirable physiologic characteristics to form a new artery *in vivo*, whereby the synthetic material itself would cease to be necessary following tissue ingrowth. Still, the limited regenerative capacity of aged or diseased cells discussed above may also compromise cellular ingrowth *in vivo*.

BIORESORBABLE GRAFTS

Aneurysmal dilatation of bioresorbable grafts can be expected to occur after sufficient degradation of the graft material and prior to adequate cell growth. The first published report of a fully bioresorbable graft was by Bowald in 1979 [65] and described the use of a rolled sheet of Vicryl (a copolymer of polyglycolide and polylactide). However, these early grafts were prone to aneurysmal dilation and rupture. We have reported that 10 % of woven PGA grafts have aneurysmal dilation within the first three months after implantation, and that this does not increase over the next nine months, suggesting that the critical time for the development of aneurysms is during prosthetic resorption prior to the ingrowth of tissue with a sufficient strength to resist hemodynamic pressures. These studies also demonstrated the ability of bioresorbable grafts to support sufficient cellular ingrowth. Here, four weeks after implantation, these 24 mm by 4 mm grafts contained an inner capsule with a confluent layer of endothelial cells and myofibroblasts amidst dense collagen fibers [66]. Similarly constructed and implanted Dacron grafts demonstrated an inner capsule composed solely of fibrin coagulum with minimal cellularity. Macrophage infiltration and phagocytosis paralleled the resorption of PGA, which was totally resorbed at three months.

In order to limit this catastrophic outcome, several approaches have been developed. One is to combine the bioresorbable material with a non-resorbable material in order to retain a mechanical strut. Another solution involves the combination of two or more bioresorbable materials with different resorption rates so that the more rapidly degraded material evokes a rapid tissue ingrowth while the second material provides temporary structural integrity to the graft. Thirdly, growth factors, chemoattractants, and/or cells can be applied to the graft to enhance tissue ingrowth, structure, and organization.

Using a more slowly resorbed compound, polydioxanone (PDS), we demonstrated 1/28 PDS grafts exhibited aneurysmal dilation with explant times as late as one year. The explanted specimens of these PDS grafts also demonstrated biomechanical characteristics similar to native arteries, being able to withstand static bursting pressures of 6000 mmHg and 2000 mmHg mean pulsatile pressure without fatigue [67].

Using the differentially resorbed approach with composite grafts woven from yarns of 74% PG910 and 26% PDS, we reported a one year patency rate of 100% with no aneurysms in the

rabbit aorta model. The PG910 was totally resorbed by two months and the PDS by six months. The regenerated arteries withstood 800 mmHg of pulsatile systolic pressure *ex vivo* without bursting, and a confluent, functional, von Willebrand Factor-positive endothelial cell layer over circumferentially oriented smooth muscle-like myofibroblasts formed in the inner capsule of both these grafts. Tissue ingrowth into all tested lactide/glycolide copolymeric grafts was observed to parallel the kinetics of macrophage phagocytosis and prosthetic resorption. *In vivo*, the rate of cell proliferation and collagen deposition in inner capsule also paralleled the kinetics of macrophage-mediated prosthetic resorption [68].

Partially resorbable grafts have also been investigated. Since Dacron was found to inhibit the macrophage-mediated arterial regeneration stimulated by the resorbable component PG910, polypropylene was evaluated as a non-resorbable component because of its high tensile strength, low fatigability, low degradation *in vivo*, and minimal inhibitory effect on cellular regeneration of grafts [69]. Composite grafts constructed from yarns containing 69% PG 910 and 31% polypropylene implanted into rabbit and dog arteries again demonstrated superb results without aneurysmal dilation. Galletti [70] used Vicryl (polyglactin 910) prostheses coated with retardant polyesters to temporarily protect the Vicryl from hydrolytic and cellular degradation. When implanted into the canine aorta, prosthetic resorption was noticed at four weeks and was complete by 24 weeks. In separate experiments, another group evaluated grafts prepared from a mixture of 95% polyurethane and 5% poly-lactide [71]. They found that only relatively compliant grafts that induced circumferential smooth muscle development contained elastin and remained mechanically stable without dilating. They concluded that modifications of the graft preparation including SMC seeding help to enhance the optimal orientation of the SMCs and prevent aneurysm formation.

THE LIVING BIOREACTOR

Campbell et al. have developed a modification of the Sparks' mandrel to create a TEVG. Here they utilize the abdominal peritoneum's reaction to foreign bodies as a living bioreactor [72]. After the graft has matured, it is removed from the mandrel and inverted; this creates a TEVG with a mesothelial inner lining. This graft's resistance to aneurysmal dilatation and rupture has not yet been proven.

CELLULAR RECRUITMENT

Since autogenous cells cannot populate a scaffold by migration or proliferation alone, they must be recruited internally via circulating ECs or EPCs or externally from the surrounding tissue or

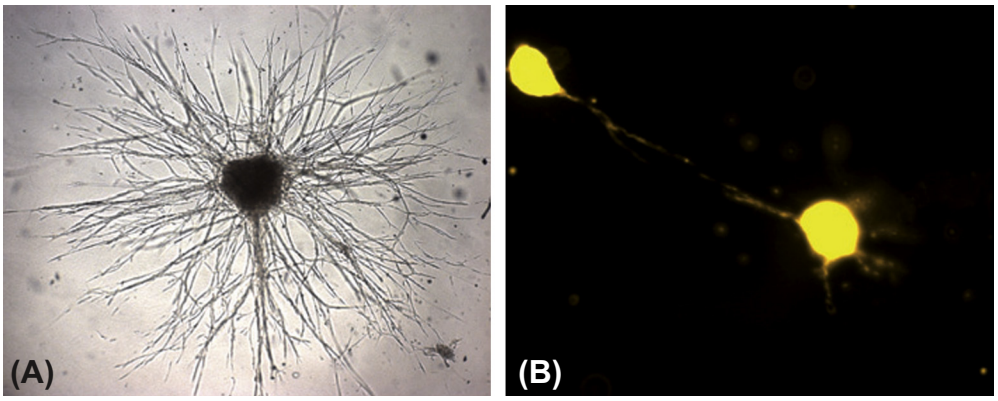

FIGURE 39.3
Three-dimensional *in vitro* induction of a capillary network. Robust capillary formation can be induced in ECs stimulated with angiogenic growth factors in a three-dimensional fibrin matrix. (A) Spherical induction of a radially oriented capillary network from an EC aggregate induced by sustained low-dose FGF-1 (1ng/mL). (B) When two EC aggregates are in proximity to each other, the EC sprouts are preferentially directed towards each other.

exogenous source through angiogenic ingrowth during tissue incorporation of the graft. In addition to the benefit provided by the localization of cells, transmural ingrowth also provides for cellular perfusion that extends beyond the distance supplied by simple diffusion (100 μm). We are currently designing three-dimensional capillary constructs (Fig. 39.3) that could provide grafts with the cellular and metabolic infrastructure requisite for the creation of a living TEVG through the induction of a *vaso vasorum* which can be incorporated into pre-existing capillary networks (inosculation). Proof of concept of this approach has been demonstrated in cardiac sheet grafts [73]. This induction can obviously be supplemented by the delivery of angiogenic proteins or genes to these constructs. With further research, a small diameter, totally resorbable vascular graft may be able to improve the current dismal long-term patency rates of small caliber grafts.

ENDOVASCULAR STENTS AND STENT GRAFTS

Endovascular stents were conceptualized prior to the introduction of angioplasty in 1969, and they have enjoyed increasing popularity in recent years. They have improved the durability of endovascular treatments and led a paradigm shift away from traditional operative approach to vascular disease. Angioplasty, stents and stent grafts are all endovascular interventions; they minimize the size of incisions, decrease lengths of hospital stays, and may confer some short-term survival benefit acutely after intervention. With over 1.5 million percutaneous coronary interventions occurring each year and a prevalence of in-stent stenosis ranging from 15—60% of patients, there is little wonder that much interest has been paid to the drug eluting stent (DES). But DES release broadly suppressive drugs to the surrounding tissue in order to limit neointimal stenosis, and they likely retard myointimal thickening rather than facilitate healing. This may be sufficient for short-term benefit, but may compromise the long-term durability of these vascular interventions. Long-term durability is likely to become more critical in the coming years because of the improved mortality rates in patients with cardiovascular disease. Thus it is critical to avoid complacency in clinical thinking, as what comprises a good result today is dependent on mortality rates that may not be applicable to today's patients. We firmly believe that promoting healing and not limiting the adverse effects of healing will provide for durable results.

Tissue-engineered cardiovascular stents

There are three basic types of stents: balloon expandable stents, which need balloon inflation to expand the stent into the arterial wall; self-expanding stents, allowing delivery in a collapsed form with the stent expanding to its predetermined size after release from the delivery device; and thermally expanding stents, made by shape memory metal alloys which exist in an easily manipulated form and which regain their memorized shape at a certain transition temperature. All these stents have been successfully used in iliac arteries with a two-year patency of approximately 84%. Improved endothelialization has also been reported using VEGF gene application to a modified metal stent [74], and although stenting itself has quickly become an important member of the endovascular armamentarium, the development of biodegradable stents has progressed slowly, mostly due to difficulties in replicating the properties of stainless steel stents [75]. Still the promise of cell-demanded sustained drug delivery in biodegradable stents has led to a renewed interest in this approach. Currently preliminary evidence supports the short-term stability of these stents and the ability of these stents to deliver bioactive agents to the vessel lumen, providing proof of concept for this approach.

Tissue-engineered stent grafts

Stent grafts are a collapsible hybrid product composed of either PET or ePTFE with stents providing for radial support; they are delivered intravascularly to patients' large vessels, in the same way as are cardiovascular stents. These stent grafts maintain flow through their lumen and are commonly used to exclude flow into aneurysmal portions of arteries. Theoretically, the

graft creates a barrier to exclude diseased arterial wall and provides a smooth flow conduit, while the stent support affixes the graft and may enhance luminal patency by resisting external compression. Stent grafts are delivered endovascularly, and since endovascular intervention reduces early operative morbidity and mortality, they have considerable consumer interest. However, the benefits of this approach over traditional operations is not clear, and it appears that outcomes are similar to that of the more traditional operative approach two years after intervention or operation.

The rapid improvements in stent grafts will likely lead to improved durability and decreased frequency of re-intervention. Therefore they will likely have a defined role in the treatment of patients with cardiovascular disease. For this reason it is important to define the known differences in healing between stent grafts and traditional bypass grafts.

Compliance changes between stent/unsupported graft/artery interfaces yield a remarkable hemodynamic disturbance. In addition, delivery procedures such as balloon dilatation may alter both graft intrinsic characteristics such as porosity, wall thickness, etc., as well as creating mechanical injury to the surrounding artery. In addition, unlike a conventional bypass, the endovascular graft is placed within the lumen of arteries with perigraft exposure to diseased arterial intima or to thrombus. All these factors change the healing characteristics of stent grafts compared to synthetic grafts. An inflammatory reaction and progressive thickening of neointima have been observed in both ePTFE and Dacron based stent grafts. When comparing endovascular grafts to conventional bypass grafting using a canine iliac artery model, endovascular stent grafts composed of ePTFE grafts and balloon expandable stents resulted in both a greater rate of endothelialization as well as an approximately five times thicker neointima in the mid-portion of the graft and a higher percentage of stenosis at the distal anastomosis when compared to conventional ePTFE grafts [76]. Pathological remodeling has also been reported after anchoring to the arterial wall, and it has been reported that stent placement may cause a variety of flow disturbances. The stent components themselves also stimulate a non-specific inflammatory reaction and induce neointimal formation, and tissue-engineered approaches including cell seeding with genetically modified cells may limit these complications [77–78]. The accumulation of experience, optimization of devices, and a better understanding of resultant pathological processes will likely allow the easy transfer of the recent advances in tissue-engineered grafts and vessels to stent grafts. This transfer is probably critical to enhancing their durability over time.

CONCLUSION

Much progress has been seen in recent years, and yet old things also become new again. Tissue engineering approaches to promoting graft healing continues to provide scientific successes and clinical limitations. As more patients live with cardiovascular disease than die from it, there is little doubt that promotion of graft healing will be more effective than inhibition of pathologic processes like IH. This creates a need for research investment, clinical trialists' audacity to apply promising ideas, and novel investigations to be tested to refine and improve these ideas.

INTRODUCTION

Heart valve function and structure

The physiological function of a heart valve is to maintain unidirectional non-obstructed blood flow without damaging blood elements, causing thromboembolism, or placing excessive mechanical stress on the leaflets and cusps. The native heart valve is remarkably well adapted to performing these functions. This capability arises from a near perfect correlation of structure to function, enabling the valve to avoid excess stress on the cusps while simultaneously withstanding the wear and tear of 40 million repetitive deformations per year, equivalent to some 3 billion over a 75 year lifetime [1]. There are four valves in the human heart: two semilunar and two atrioventricular. The semilunar heart valves include the structurally similar aortic and pulmonary valves while the atrioventricular heart valves include the tricuspid and mitral valves. The following text describes the relation of structure to function in the semilunar valves from a macroscopic (tissue) to microscopic (cellular) level.

Grossly, the semilunar heart valves are composed of three thin cusps that open easily when exposed to the forward blood flow of ventricular systole, and then rapidly close under the minimal reverse flow of diastole [1]. The three cusps of the aortic valve are the left, right and non-coronary cusps. Each cusp is attached to the aortic wall by a thick base known as a commissure. Despite the force applied to the leaflets during diastole, prolapse is prevented by substantial coaptation of the cusps in a crescent shaped region of the cusp termed the lunula. In addition, the structural elements within the aortic valve cusps are anisotropically oriented in the tissue plane, resulting in disproportionate mechanical properties of the valve cusps with greater compliance in the radial rather than the circumferential direction. This compliance allows the cusp thickness of the aortic valve to vary from 300 to 700 μm throughout the course of the cardiac cycle [2]. Further structural specializations that occur are lengthwise folding of collagen fibers, and orientation of collagen bundles in the fibrous layer toward the commissures. This orientation conserves maximal coaptation, and thereby prevents regurgitation. Thus, both the macroscopic valve geometry and the fibrous network within the cusps work to transfer stresses caused by the diastolic force to the aortic wall and annulus.

Microscopically, the semilunar heart valve is composed of three layers: the ventricularis, spongiosa, and fibrosa (Fig. 40.1). It is the unique extracellular structural characteristics within these layers that create a specialized biomechanical profile necessary for proper function. The fibrosa, which is exposed to the aortic lumen, is composed of primarily collagen fibers, which

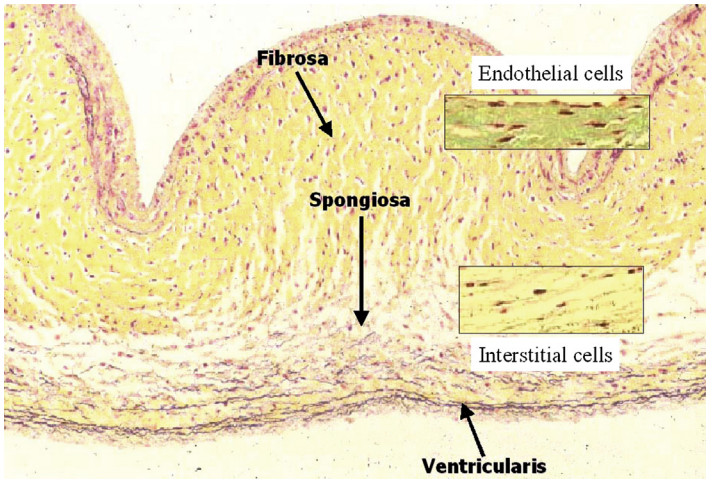

FIGURE 40.1
Histological cross section of a heart valve demonstrating the ventricularis, spongiosa and fibrosa. Also shown are interstitial cells and endothelial cells.

are densely packed and arranged parallel to the cuspal free edge. It is these collagen fibers, mostly type I and III, which provide most of the mechanical strength of the valve [3]. The ventricularis layer faces the ventricle and is composed of collagen and radially aligned elastin fibers. Elastin forms an encompassing matrix that binds the collagen fibrous bundles throughout the heart valve, thereby creating an elastin-collagen hybrid network of interconnected collagen fibers that provides greater mechanical strength [4]. The centrally located spongiosa is composed of glycosaminoglycans (GAG) and loose collagen fibers. The GAG side-chains of proteoglycans make a gelatinous substance in which other matrix molecules are able to form covalent crosslinks that support other components of the ECM [5]. Human heart valve GAGs are composed predominantly of hyaluronic acid, with smaller amounts of dermatan sulfate, chondroitin-4-sulfate and chondroitin-6-sulfate [6].

Cellular biology of the heart valve

VALVULAR ENDOTHELIAL CELLS

The two most prevalent cell types in heart valves are valvular endothelial cells (VECs) and valvular interstitial cells (VICs). VECs line the surface of valve cusps on both the aortic and ventricular surfaces. They provide a non-thrombogenic blood-tissue interface and maintain a semipermeable membrane that regulates the transfer of large and small molecules through the vascular wall [2]. Endothelial cells are also critical in the control of inflammatory and immune reactions, in controlling the proliferation of other cell types, and play a role in metabolism and protein synthesis [7].

The role of VECs in the heart valve is not passive. VECs can respond to external stimuli by phenotypically changing and acquiring new, inducible properties through a process known as endothelial activation. Both cytokines and hemodynamic forces have been shown to induce this process [2]. Once activated, VECs produce cytokines, chemokines, adhesion molecules, growth factors, and vasoactive molecules, all of which contribute to valve adaptation in response to the initial stimuli. Most often, this process is beneficial and allows for maintenance of valve homeostasis. However, a form of endothelial activation can occur that is known as endothelial dysfunction, which results in a surface that is adhesive to inflammatory cells or thrombogenic and can be a source of valve pathology [2].

Although VECs are often grouped together, there is in fact heterogeneity among these cells, as there is among endothelial cells in general. Their source, be it arterial or venous tissue, can affect cell phenotype, as can their location (aortic or pulmonary) [8]. Moreover, there is an increasing appreciation for the substantial data suggesting that VECs differ in many ways from

other types of endothelial cells. For example, in response to mechanical stress, VECs align perpendicularly to blood flow, whereas vascular endothelial cells in the aorta align in parallel with flow [9]. In a separate study, investigators demonstrated significantly different transcriptional gene profiles of VECs on aortic and ventricular sides of porcine aortic valves [10].

VALVULAR INTERSTITIAL CELLS

VICs are the most abundant cell type in heart valves and are primarily responsible for heart valve stability by the synthesis and remodeling of valve extracellular matrix (ECM). This process maintains the appropriate structural and functional relationship that allow for long-term heart valve competence. VICs contain varying characteristics of myofibroblasts, fibroblasts, and smooth muscle cells. There are five subtypes of VICs: embryonic, progenitor, quiescent, activated, and osteoblastic. Each subtype is unique and VICs can change phenotypically from one to another depending on the mechanical environment, chemical cellular or hormonal signals, or in response to injury.

While five subtypes do exist, the two most important distinct populations of VICs are those that are quiescent and those that are activated [5]. In the quiescent state, VICs most closely resemble fibroblasts in that they have low levels of α-smooth muscle actin [11]. Conversely, VICs are activated by a variety of different stimuli and conditions, including during embryonic valve development and with exposure to TGF-β or cyclic stretch. Additionally, various valvular pathologies can induce VIC activation. Importantly, studies have shown a distinct transition from quiescent to active VICs after implantation of a tissue-engineered heart valve. Similar results were seen after implantation of a pulmonary autograft as an aortic valve replacement [12].

VICs are of central importance to heart valve repair and maintenance operations. The constant and rigorous mechanical movement of valves results in persistent low level valvular damage and an ongoing extracellular matrix synthesis, remodeling, and degradation process. VICs regulate and perform this process by expressing ECM components and the proteins involved in matrix remodeling like matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs). Importantly, over-expression of MMPs has been observed in several heart valve pathologies, indicating a possible target for therapeutic intervention [13]. More investigation is needed to better understand the mechanism of action of MMPs and TIMPs and their importance in valve tissue morphogenesis, repair and remodeling.

Even though ample data exists regarding the reparative properties of VICs, their function is still not fully understood [5]. Important to understanding and potentially manipulating VIC phenotype and cellular activity is knowing how these cells send and receive signals, how mechanical information is transmitted from the ECM, and what specific factors can induce a variety of cellular responses like cell migration, adhesion, growth and differentiation [14].

Heart valve dysfunction and valvular repair and remodeling

HEART VALVE DYSFUNCTION

The American Heart Association has estimated that over 300,000 heart valve replacement procedures were performed in the United States between 1998 and 2005 [15]. Population growth, population aging, and improvements in longevity will fuel demand for heart valve replacements in the future, with a projected need of 850,000 in year 2050 [16]. The pathology of heart valve disease manifests itself in two ways, the first being a reduction in forward flow caused by failure of a valve to completely open, known as stenosis. The second is back flow during diastole caused by failure of a valve to completely close, known as insufficiency or regurgitation.

Aortic stenosis is a common valvular pathology. When severe, this disease can cause dyspnea on exertion, chest pain, and syncope. The most frequent cause of aortic stenosis is dystrophic calcification of the aortic valve cusps and ring (annulus). Overall prevalence of aortic stenosis

is 2% and is increasing with time as the American population ages. Bicuspid aortic valves are another cause of aortic stenosis, and represent one of the most frequent congenital cardiovascular malformations in humans. Bicuspid aortic valves are also sometimes associated with aortic insufficiency and increase the risk of infective endocarditis. The main source of chronic aortic insufficiency is aortic root dilation. This results in distended and outwardly bowed commissures as well as impaired cuspal coaptation.

Mitral valve prolapse is defined as the displacement of valve leaflets into the left atrium during systole and is the most common indication for surgical repair or replacement of this valve. Mitral valve prolapse is most commonly caused by myxomatous degeneration, and is also seen in patients with Marfan syndrome. Patients with mitral valve prolapse are exposed to increased risk of a variety of different complications including heart failure, bacterial endocarditis, mitral regurgitation, atrial fibrillation, and thromboembolic events [7]. The most common cause of mitral stenosis worldwide is history of rheumatic fever [2].

The leading cause of dysfunction of the tricuspid and pulmonary valves is congenital heart disease. Approximately 20,000 infants are born in the United States each year with a congenital heart defect, of which many involve absence or malformation of the pulmonary valve and pulmonary artery [17]. Major congenital heart disease diagnoses of the right ventricular outflow tract (which includes the pulmonary valve and pulmonary artery) include truncus arteriosus, pulmonary atresia with ventricular septal defect, severe tetralogy of Fallot, transposition with ventricular septal defect and pulmonary atresia, and double-outlet right ventricle. It is these children who would benefit most from tissue-engineered heart valves, which offer the potential to grow with the child thereby preventing need for re-operation.

VALVULAR REPAIR AND REMODELING

When valvular injury occurs, it stimulates VIC proliferation, migration, and apoptosis. The initial events in valve repair of a linear superficial denuding wound have been modeled *in vitro* and are characterized by prominent migration and proliferation of VICs [18]. The migration of VICs is governed by a sequence of processes including activation of integrins, which are cell surface heterodimeric receptors that control cell-ECM and cell-cell adhesion [19]. Changes in macroscopic mechanical stimuli like shear and solid stresses are also propagated via signal transduction through a complex cell-ECM network, which allows small external changes in valvular mechanics to ultimately affect cellular activity and function [7].

Activation of VICs results in a change of phenotypic subtype to activated myofibroblasts, as demonstrated in leaflets from patients with myxomatous mitral valve degeneration [13]. These phenotypic changes resemble the evolution of physiological wound healing in mitral valves associated with the phenotypic modulation of interstitial valvular cells from fibroblasts to myofibroblasts [2]. That said, when equilibrium is reached after injury, cells revert back to a quiescent phenotype like that of a fibroblast. However, in cases in which there is persistent injury or where a steady state equilibrium cannot be achieved, VICs will remain persistently activated, contributing to ECM remodeling and initiation of valvular pathologies [20].

Important to understanding VIC function and activation in response to injury is the interaction between VICs and the ECM. VICs takes cues from and act upon ECM by secreting ECM components and their proteolytic enzymes, and by promoting avenues of cellular migration. Interstitial collagenases, gelatinases and other MMPs are involved in the degradation and remodeling of connective tissue and are primarily secreted by activated VICs [21]. As in tissue throughout the body, MMPs in heart valves are critical in tissue morphogenesis, wound healing, and other tissue remodeling processes. The interaction between MMPs, their inhibitors (TIMPs), and their regulators are particularly important in cardiac and vascular remodeling [2]. In the degradation of ECM, interstitial collagenases MMP-1 and MMP-13 mediate the preliminary phase of collagen breakdown by disassembling the native helix of the

fibrillar collagen. The resulting collagen fragments are then accessible to further proteases, like gelatinases [22]. These interstitial collagenases are secreted by activated VICs in a similar manner as they are secreted by inflammatory cells in a multitude of systemic diseases [2]. That is, VICs are being stimulated by signal transduction, be it mechanical, chemical, hormonal, or otherwise, to produce and secrete soluble ECM proteases that allows for remodeling of ECM in response to changes in external environment. One means of signal transduction is cardiac catabolic factor, which is derived from porcine heart valves and found to stimulate collagen and proteoglycan breakdown *in vitro* [23]. While MMPs are a necessary component to normal remodeling of heart valves, excessive levels of MMP activity can lead to excess collagen and elastin breakdown, thereby weakening heart valve leaflets and predisposing to disease [13].

Heart valve replacement

Standard treatment for end-stage valvular dysfunction is heart valve replacement. The first successful implantation of a human valve was performed in 1952 [24]. Since then, more than 80 different designs of prosthetic heart valves have been developed [25]. Heart valve substitutes have undergone a progressive evolution, as newer models are developed to remedy the deficiencies of older devices. Prosthetic heart valves are either mechanical and composed entirely of synthetic material, or bioprosthetic and therefore fashioned from biological components. Slightly more than half of the world's implanted valves are mechanical, while the remainder are bioprosthetic [26]. While each type of heart valve is used successfully to improve the quality and length of life, each valve type also has its own unique set of problems [27].

The overall rate of complications is similar for mechanical prostheses and bioprostheses [28]. Four categories of valve-related complications predominate:

1) Thromboembolism, thrombosis, and secondary anticoagulation-related hemorrhage;
2) Prosthetic valve endocarditis;
3) Structural dysfunction including failure or degeneration of the prosthetic biomaterials; and
4) Non-structural dysfunction including complications arising from technical problems during surgical implantation such as perivalvular leak and biological integration (tissue overgrowth) [1].

Each valve type is associated with its own unique set of advantages and disadvantages.

The mechanical heart valve is characterized as having excellent durability due to the mechanical properties of the synthetic materials from which it is constructed. Unfortunately, these synthetic materials also give rise to poor biocompatibility. Specifically, mechanical prosthetic valves are associated with a substantial risk of thromboembolism and thrombotic occlusion caused by the lack of an endothelial lining and the flow abnormalities that result from a rigid outflow structure [29]. To minimize this risk, chronic anticoagulation therapy is required for all mechanical valve recipients. However, systemic anticoagulation renders patients vulnerable to potentially serious hemorrhagic complications. Thus, the combined risk of thromboembolic complications and hemorrhage secondary to anticoagulation constitute the principal disadvantage of mechanical prosthetic valves. A meta-analysis found an incidence of major embolism in the absence of antithrombotic therapy of 4 per 100 patient years, which was decreased to 2.2 per 100 patient years with anti-platelet therapy and to 1 per 100 patient years with anticoagulant therapy (e.g., warfarin) [30]. Disadvantages of long-term warfarin use include increased risk of bleeding complications, lifetime need for blood tests and therapy to maintain a therapeutic international normalized ratio (INR), and high rates of non-compliance [31]. In a review of randomized trials of anticoagulation therapy in patients 65 years and older, incidence of major bleeding ranged from 0% to 4.6% per year, with incidence of minor bleeding as high as 10.5% per year [32]. Indeed, patients over the age of 75 on anticoagulation for mechanical heart valves compared to patients who received a bioprosthetic valve assessed for bleeding rates had an odds ratio of 18.9 [33]. Other disadvantages of

mechanical heart valves include their ability to cause hemolysis and an increased susceptibility to endocarditis [34].

Bioprosthetic valve replacements such as glutaraldehyde-fixed xenografts and allografts are associated with a lower risk of thrombosis and hemolysis than mechanical heart valves [27]. Patients with glutaraldehyde-fixed xenograft valves do not require anticoagulation and therefore do not incur the risks of anticoagulation-associated bleeding. However, because of their mechanical properties and their composition of biologic material, the durability of a glutaraldehyde-fixed valve is more limited than that of the mechanical valve. The major disadvantage of tissue valves is progressive structural deterioration that eventually results in stenosis and/or regurgitation. The degradation mechanisms of bioprosthetic valves are progressive and the rate of failure is highly time dependent.

Alterations of their molecular composition and/or tissue structure of bioprosthetic valves during manufacturing can lead to valve failure [1]. One such example is the permanent fixture of one or more valve cusps in a specific configuration during manufacture which is associated with only one specific phase of the cardiac cycle [2]. In this case, normal cyclic rearrangements in the valve sub-architecture cannot appropriately occur and irregular tissue stress is created. Other examples include process-induced destruction to the endothelial coating which then allows penetration of inflammatory cells and plasma into the cusp after implantation, leading to valve inflammation-induced thickening and possible valve deterioration [2].

The principal problems for bioprosthetic valve durability after implantation are cuspal mineralization and non-calcific mechanical fatigue. Calcification occurs when calcium from plasma binds with residual organic phosphates of the crosslinked, non-viable cells of the preserved valve [7]. Further weakening can occur from proteolytic degradation of the collagenous ECM [35]. MMP activity has been demonstrated in explanted valve tissue that has undergone structural degradation, which signifies a degree of inflammation and ECM remodeling within damaged valves [36]. Similar findings have been found in *in vitro* models of valve function, suggesting that the mechanical stress that bioprosthetic valves are subject to may alone contribute to ECM degradation and prolonged remodeling [37].

Despite improvements over the last several years in bioprosthetic valve durability, structural valve deterioration is a significant problem particularly in patients less than 65 years old. In one study looking at patients having had a bioprosthetic aortic valve replacement, 60% of patients younger than 65 years required re-operation at 18 years post-implantation [38]. Indeed, the risk of structural failure is strongly age dependent, with individuals less than 35 years of age, and especially children and adolescents, having the highest rate. Nearly uniform failure occurs by 5 years in those less than 35 years old but 8–27% fail in 20 years in those older than 65 [39]. The major cause of bioprosthetic valve dysfunction is structural deterioration of the cuspal tissue [40]. Two distinct yet potentially synergistic processes are causal: [1] calcific degradation and [2] non-calcific degradation. Both eventually lead to failure of the connective tissue matrix of the tissue valve [1].

Another type of bioprosthetic valve is the cryopreserved homograft, which is particularly advantageous in those patients requiring aortic valve replacement or those needing congenital heart reconstruction with right-sided conduits [41]. However, the use of the cryopreserved homograft is a form of transplantation and thus subject to many transplant-associated problems, including the implanted tissue invoking a host immune response, thereby potentially increasing the risk and rapidity of structural valve deterioration. Cryopreserved homografts are currently the most biocompatible replacement heart valve and the treatment of choice in most pediatric cardiothoracic applications [42]. However, used in this application, they are severely limited by their inability to grow and by a significant incidence of structural deterioration resulting in limited durability and frequent need for re-operation. Overall, the poor long-term durability of currently available heart valves in young patients (children and

adults <35 years) makes clear the clinical need for an improved replacement heart valve, one which tissue engineering can help fulfill.

THE APPLICATION OF TISSUE ENGINEERING TOWARDS THE CONSTRUCTION OF A REPLACEMENT HEART VALVE

Tissue-engineering theory

The ideal heart valve replacement would be perfectly biocompatible, readily available, durable, and have the potential for growth. The construction of an autologous, tissue-engineered heart valve could potentially fulfill all of these requirements by utilizing natural mechanisms for repair, remodeling, and regeneration. The central paradigm underlying tissue engineering involves combining cells with a platform matrix to create neotissue [43]. The matrix acts as a three dimensional scaffold until proliferating cells produce sufficient ECM *in vitro* to permit *in vivo* implantation [2]. This process is followed by scaffold degradation, neotissue formation, and growth.

Tissue engineering is currently limited by the inability to construct microvasculature *de novo*, the inability to control innervation of neotissue, and the difficulties surrounding culturing certain cell types [44]. Although the semilunar heart valve is not totally avascular, oxygen and nutrients needed to sustain its function are supplied via two complementary pathways: diffusion from the blood stream and via a capillary network. Additionally, semilunar heart valves are composed of cells that are readily grown in culture. This allows for the isolation and expansion of autologous cells for construction of tissue-engineered heart valves. The blueprint for constructing an ideal tissue-engineered heart valve (TEHV) has evolved from a large body of research in bioprosthetic valves, diseased heart valves, and other tissue valve substitutes. Although these investigations have largely been clinical in nature, they have identified useful markers of cell function, matrix physiology, and matrix structure. This was summarized by five key concepts of functionally adaptive valvular remodeling/regeneration:

1) The highly specialized arrangement of collagen and other ECM;
2) Structural deterioration of native and substitute valves;
3) The quality of valvular ECM depends on valvular interstitial cell viability, function, and ability to adapt to different environments;
4) Cell viability in nearly all current bioprosthetic tissue valve substitutes is compromised or completely eliminated during processing;
5) The long-term success of a tissue-engineered valve replacement will, therefore, depend on the ability of its living cellular components to assume normal function with the capacity to repair structural injury, remodel the ECM, and potentially grow [2].

Tissue engineering offers the potential to create a non-thrombogenic, biomimetic, immunologically compatible tissue valve substitute that is capable of providing ongoing remodeling and repair which would allow growth in maturing recipients (Fig. 40.2) [2]. Such a technology would have dramatic implications in a clinical setting and greatly contribute to improving patient outcomes.

Biomaterials and scaffolds

Over the last several decades, an exhaustive variety of biomaterials have been explored to serve as scaffolds for tissue-engineered heart valves. These biologic scaffolds have the primary responsibility of promoting tissue regeneration and must be biocompatible, biodegradable into safe byproducts, easily manufactured and handled, highly porous to facilitate cell attachment, and yet mechanically stable enough to appropriate function [2].

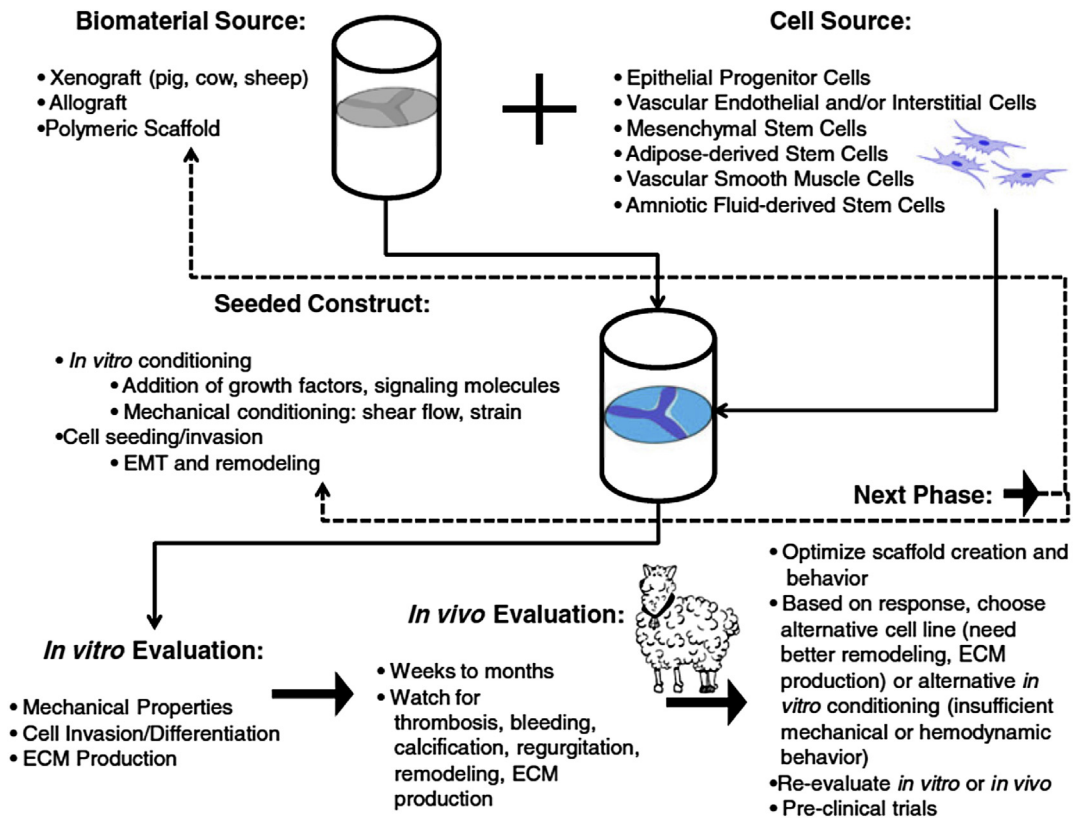

FIGURE 40.2
Overview of tissue engineering heart valves [46].

Scaffolds can be manufactured from either synthetic or natural materials. Natural biomaterials include ECM components such as collagen, fibrin, elastin, glycosamino-glycans, or decellularized tissues, such as heart valve, pericardium, arterial wall or small intestinal submucosa [45]. Synthetic polymers have the advantage in that they have predictable chemistry and their properties can be well-controlled [2]. Additionally, these materials are FDA (Food and Drug Administration) regulated and many have been approved in clinical applications [46]. The most commonly utilized synthetic polymers in tissue engineering include poly(glycolic acid) (PGA), poly(L-lactic acid) (PLLA), copolymer poly(lactic-co-glycolic acid) (PLGA), poly(ethylene glycol) (PEG), and polyhydroxyalkanoate (PHA).

A number of natural biodegradable polymers have been explored for use as scaffolds. They have the advantage of offering a more biocompatible template on which cells grow [5]. Decellularized small intestinal submucosal (SIS) matrix has been isolated to use in tissue engineering [47]. Other investigators have used porcine SIS scaffold as a resorbable matrix to make pulmonary valve leaflet replacement in porcine models [48]. When the explanted constructs were evaluated they revealed resorption of the submucosal matrix, fibrous connective tissue growth and formation of neo-vasculature.

Much of a heart valve's mechanical and tensile strength originates from its collagen composition and alignment [49]. Due to their highly conserved genetic code across species, collagens are weakly immunogenic and have been used widely for tissue-engineered heart valve constructs seeded with both human and porcine-derived cells [50,51]. Another natural scaffold that has been explored is fibrin gel. It has been used as an autogeneic scaffold in heart valve tissue engineering [52]. Some advantages of using fibrin gel as a material for scaffold construction include that it is made from the patient's own blood, and also that it is readily

biodegradable. However, early attempts at utilizing fibrin gel were limited by its tendency to shrink and its inability to withstand surgical implantation [5].

The process of removing cells from a biological matrix can reduce the immune response to the bioprosthetic while maintaining the potential for endothelialization by host VECs and VICs, either through cell ingrowth or via cell seeding [53]. Methods of tissue decellularization range from enzymatic digestion, detergent treatment, sonication and hypo-/hypertonic immersion [54]. These treatments effectively remove antigenic components such as nucleic acids, cell membranes, cytoplasmic structures, lipids, and soluble matrix molecules but retain elastin, collagen and GAG components of the scaffold ECM [55]. Decellularization has been utilized in porcine matrices that were subsequently seeded with human endothelial cells. The resulting construct had a confluent and viable monolayer cell surface, an important feature in reducing thrombogenic risk [56]. Further experimentation *in vivo* seeded a decellularized pulmonary valve with endothelial cells and carotid artery myofibroblasts followed by implantation in an ovine model [57]. After one month, the valve leaflets were completely endothelialized with dense infiltration by myofibroblasts by three months. However, enthusiasm was tempered by the finding of subvalvular calcification and inflammation resulting in increased thickening of the valve leaflets [5].

The commercially available SynerGraft valve (CryoLife Inc., USA) is based on the decellularized model of tissue engineering [58]. The SynerGraft decellularization process involves cell lysis in sterile water, enzymatic digestion of nucleic acids and a multi-day isotonic washout period. The method was developed as an alternative to glutaraldehyde crosslinking to decrease xenograft antigenicity. Histological evaluation 150 days post-implantation in porcine models showed intact leaflets with local myofibroblasts ingrowth and no calcification [5]. Early failure of the valve, however, was reported in human trials [59]. The SynerGraft matrix initiated an early strong inflammatory response followed by a lymphocyte response. Rapid structural degeneration of the valves occurred within 12 months. Furthermore, the valve scaffold was not repopulated with host cells, and calcific deposits were detected.

Proponents of synthetic matrices argue that customized polymers can be designed to exact specifications in a reproducible fashion. Also, by utilizing biodegradable polymers, complications associated with biocompatibility can be minimized. Initial work focused on polymers composed of polyglycolic (PGA) and polylactic acid (PLA) [60]. These 'off the shelf' polymers were selected because they are biocompatible, biodegradable, well characterized, and already FDA approved for human implantation. Cells readily attach to and grow on these synthetic polymers. The resulting neotissue construct possesses adequate biomechanical properties to be used for surgical application. However, the biomechanical profile of the construct is substantially different from that of a native heart valve. Tissue-engineered heart valves using polyglycolic acid and polylactic acid copolymer-based matrices are thicker, stiffer, and less pliable than native valves.

Early experiments used matrices made of a PLGA woven mesh sandwiched between non-woven PGA mesh sheets. The scaffolds were seeded with arterial myofibroblasts, followed by arterial endothelial cells and were then transplanted into the pulmonary position as a single leaflet in sheep. The seeded cells were seen in the structure after six weeks, and a post-mortem evaluation revealed a native tissue-like architecture [61]. Furthermore, there was confirmation of elastin and collagen production in the leaflets, which had mechanical properties similar to native leaflets [61]. This approach, however, resulted in only limited success, as the PGA and PLA polymers were too stiff for use as flexible trileaflet valves.

Polyhydroxyoctanoate (PHO), a more flexible synthetic polymer has been used to create a composite heart valve scaffold in a low-pressure pulmonary system [62]. The valve consisted of a layer of PHO film sandwiched between two layers of non-woven PGA felt. The leaflets were composed of a monolayer of porous PHO that was sutured to the conduit wall with

polydioxanone. Post-implantation examination revealed a uniformly organized tissue with large amounts of collagen and proteoglycans, but with no elastin. The PHO scaffold, however, had not completely degraded after 24 weeks, suggesting a longer degradation profile than glycolic or lactic acid polymers. Additional studies revealed smooth flow surfaces but could not demonstrate a confluent endothelium which could affect the long-term durability of the structures [63]. Additionally, although collagen and GAG deposition was seen, the constructs were devoid of elastin and demonstrated mild stenosis and regurgitation.

Hoerstrup and colleagues developed a novel composite scaffold material consisting of PGA coated with a thin layer of poly-4-hydroxybutyrate (P4HB) — a flexible, thermoplastic polymer with a more rapid degradation time than PHO [64]. Trileaflet heart valve scaffolds were fabricated from the composite material using a heat-application welding technique. Autologous myofibroblasts and endothelial cells from ovine carotid artery were seeded onto the scaffolds, cultured in a bioreactor for 14 days and then implanted in an ovine model [65]. When explanted, they showed increased ECM synthesis, more organized internal structure and improved mechanical properties over static controls.

It is not clear whether natural or synthetic scaffolds will ultimately prove to be more appropriate for tissue-engineered heart valve development, as there are still certain limitations associated with both. The design of a replacement aortic valved-conduit, for example, will require the inclusion of three dilated pouches alongside the 'cusp-like' leaflets to approximate the sinuses of Valsalva; atrioventricular (AV) valve designs may require the addition of other components of the AV valve apparatus, including chordae tendineae and papillary muscles [66]. Using stereolithography, Sodian and colleagues fabricated plastic models with an exact spatial representation of human aortic and pulmonary valves [67]. These models were then used to fabricate heart valve cell scaffolds using poly-3-hydroxyoctanoate-co-3-hydroxyhexanoate (PHOH) and P4HB, which were shown to function well in a pulsatile flow bioreactor under both normal and supranormal flow and pressure conditions. The choice and design of scaffolds will be integral to the successful clinical outcome of tissue-engineered heart valves. As well as conforming to a suitable anatomical shape, heart valve scaffolds will be required to possess both tensile and elastic properties. The scaffolds must be biocompatible, bioabsorbable or remodelable, and should provide a suitable template for facilitating development of new tissue. Scaffold permeability is also vital for the control of cell nutrition and removal of waste products [5].

The search for appropriate cell sources

An ideal cell source for tissue-engineered heart valves would demonstrate phenotypic plasticity and be able to change biomechanical properties in response to dynamic alterations in flow. It is an area of continued investigation. The use of autologous cells as opposed to xenograft or allograft tissue has the advantage of avoiding an immunological response that could result in rejection [68]. In an early attempt at tissue engineering a heart valve in 1995, valve leaflets were constructed by seeding cells from both autogeneic and allogeneic sources onto biodegradable polymeric scaffolds which were then implanted in an ovine model [61]. As anticipated, the autologous scaffold provoked less of an inflammatory response in the host, resulting in better performance and a higher success rate compared to allogeneic comparators.

A logical cell source for a tissue-engineered heart valve would be autologous VICs and VECs harvested from a patient's own heart valve leaflet. The use of these cells would eliminate the risk of rejection while imparting the requisite phenotypic profile [5]. Preliminary studies using an ovine model utilized valve biopsy samples as a VIC source [69]. In this study, the biopsy procedure generally did not appear to compromise leaflet function, with 9 of 13 animals showing intact valves and normal leaflet anatomy post-mortem. However, for human patients, it would be challenging to isolate and culture enough cells from a small biopsy to be of clinical use. It is also known that the ability to culture cells decreases with age, making this technique

less feasible in older patients. Additionally, patients requiring valve replacement have diseased VECs and VICs which may not be ideal for tissue engineering a replacement heart valve. Thus, the risks involved in valve biopsy are seemingly too high to make this a feasible technique in human trials. Recent studies have shown that decellularized human pulmonary valves seeded with autologous VICs and cultured *in vitro* demonstrated significant cell proliferation by four days, which suggests that such a construct can be manufactured in a shorter timeframe than initially thought [70].

Subsequent studies have utilized ovine femoral artery-derived cells as an autologous source [60]. This has failed to gain much favor given its potential for limb ischemia from disruption of the lower limb arterial blood supply. Myofibroblasts harvested from the carotid artery have also been investigated, but it was concluded by the investigators that the sacrifice of an intact tissue structure and the potential for injury introduced prohibitive risks [62]. In search of a more practical source, Shinoka et al. performed a study comparing dermal fibroblasts to arterial myofibroblasts as cells of origin for a tissue-engineered heart valve [71]. Unfortunately, leaflets derived from dermal fibroblasts were much thicker, more contracted and less organized than those derived from arterial myofibroblasts. It was therefore surmised that cells of mesodermal origin, such as arterial myofibroblasts, provide more specialized phenotypic properties than ectodermally derived skin fibroblasts.

Myofibroblasts derived from human saphenous vein have similar phenotypic properties to VICs but represent a more realistic source for clinical applications of tissue-engineered heart valves (TEHV) [72]. Unlike arterial cells, these cells can be harvested without the risk of limb ischemia [5]. These myofibroblasts were cultured on polyurethane scaffolds and were shown to be viable and confluent at six weeks. Moreover, compared to neotissue derived from aortic myofibroblasts, collagen production and mechanical stability were found to be higher in saphenous vein-derived structures. Follow-up studies have compared myofibroblasts isolated from ovine tricuspid heart valve leaflets to cells from jugular vein and carotid artery [73]. Interestingly, cells from jugular veins also demonstrated higher initial collagen production, but the study showed that all cell lines had a marked drop-off in collagen, elastin and GAG synthesis with time. This finding suggests that there is a critical timeframe for seeded cells to be placed on scaffolds while they are still able to perform necessary protein synthesis and organization [46]. In the first long-term follow-up of a clinical application of a TEHV, Dohmen et al. seeded a decellularized pulmonary allograft with cells isolated from saphenous vein and cultured in a bioreactor for two weeks. They cite 100% survival with adequate pressure gradients and no incidence of calcification at 10 year follow-up [74].

In the search for an alternative cell source, different stem cell sources have been investigated. In particular, umbilical cord-derived cells, amniotic fluid-derived cells, and chorionic villi-derived cells appear to carry great promise [14]. One group demonstrated the possibility of using autologous umbilical cord cells [75]. The isolated cells represented a mixed population of cells derived from umbilical cord artery, vein, and the surrounding Wharton's jelly. It was found that the cells demonstrated features of myofibroblast-like differentiation, such as expression of α-smooth muscle actin, vimentin, and deposition of collagen types I and III. More importantly, the cells successfully attached to scaffolds and formed a layered tissue-like structure comparable to scaffolds seeded with vascular cells [65]. Initial enthusiasm was tempered when it was observed that elastin was not being produced and GAGs were present only in low levels. Much more work is needed in characterization of the mixed cell population before the suitability of this source can be properly evaluated. Likewise, mesenchymal stem cells show promise, though many of the details remain to be elucidated. Their ability to develop into a variety of connective tissues, including bone, cartilage, muscle and fat, as well as easy collection via bone marrow puncture make these cells an attractive possibility [76]. In one experiment, human bone marrow stromal cells were collected and partially characterized using a number of myofibroblast markers [77]. Like umbilical cord cells, they were shown to express

α-smooth muscle actin and vimentin, and produce collagen types I and III. Biodegradable polymeric scaffolds cultured with mesenchymal stem cells *in vitro* demonstrated an organized internal structure and mature tissue development. Despite the encouraging results, it is not clear whether bone marrow stromal cells reliably differentiate into appropriate cell types in the scaffold or if they continue to remain differentiated *in vitro*, ensuring long-term function and durability of the replacement heart valve [78]. Investigations utilizing circulating endothelial and smooth muscle progenitor cells are at a similar stage [79]. However, given their remarkable differentiation potential, embryonic and adult stem cells may become valuable resources for heart valve tissue engineering.

The search for an ideal replacement for both VICs and VECs is ongoing, but the underlying goal across all these techniques is the same: transplanted cell populations in a scaffold can achieve the same distribution and differentiation pattern of cells in the native valve [80]. It is hard to prove this assertion, however, as there is limited data regarding the phenotypic profile of these cells once they are implanted into the scaffolds, especially when it comes to long-term follow-up data [5].

Cell seeding techniques

Growing valvular neotissue under *in vitro* and *in vivo* conditions remains a challenge in the development of reliable and reproducible tissue-engineered heart valves, and much of the difficulty is rooted in challenges of cell seeding and attachment to scaffolds. Indeed, cell attachment is a critical step in initiating cell growth and neotissue development [81].

Whereas relying on adjacent autologous myocardial cell growth into unseeded valve scaffolds has proven to be an unreliable and inconsistent technique, directed cell seeding either *in vitro* or *in vivo* has been successful. In seeding scaffolds under *in vitro* conditions, early strategies for improving cellular attachment included increasing seeded cell number or density, increasing scaffold porosity, or increasing scaffold surface area. More sophisticated techniques sought to enhance cell attachment by coating the matrix prior to seeding with various cell adhesion molecules like laminin [82]. Similarly, prior to seeding a pulmonary allograft for a Ross operation, Dohmen and colleagues covered the decellularized valve with a commercially available synthetic extracellular matrix protein to enhance cell attachment [74]. Cell seeding was then performed using a sedimentation technique, with excellent cellular attachment and eventual neotissue ingrowth [83].

Indeed, covering valvular scaffold with molecules that can target or attract specific circulating cells offers an avenue for *in vivo* autologous cell seeding which precludes the need for *in vitro* cell culture and all the microbial risks therein. Jordan and colleagues utilized this principle in conjugating a decellularized porcine pulmonary valve with CD133 antibodies as a means of promoting scaffold seeding by circulating endothelial progenitor cells [84]. This strategy led to increased endothelial cell attachment, increased interstitial cell number, increased structural proteins, and improved biomechanical properties when compared with unconjugated or traditional cell-seeded valves [84].

The method of cell seeding also influences efficiency of cellular attachment to scaffold. Traditional methods of seeding polymer scaffolds employed static cell culture techniques, in which a concentrated cell suspension is pipetted onto polymer scaffolds and left to incubate for a variable period of time, during which cells adhere to the scaffold. Dynamic cell seeding methods employ a seeding method in which either the medium or both the medium and scaffold are in constant motion during the incubation period. Dynamic cell seeding is often used in combination with a bioreactor and offers improved cellular attachment than static cell seeding [85]. Nasseri concluded that dynamic cell seeding onto tissue-engineering scaffolds increased cell adhesion, alignment in the direction of flow, cell infiltration, and seeding density [86]. There are various factors that can be further modulated in cell seeding, including

use of mixed versus pure cell populations, interval cell seeding, and single-step versus sequential seeding of different cells.

Adequate, uniform and reproducible cell seeding of both natural and synthetic polymeric scaffolds remains a challenge in the field. Optimization of rapid seeding techniques will be important in the development of a tissue-engineered heart valve, as it maximizes the use of donor cells, hastens the proliferation and subsequent differentiation of cells, decreases the time in culture, and provides a uniform distribution of cells [87]. Advances in the modification of scaffold surfaces to enhance cell adhesion and subsequent function offers a strategy to augment *ex vivo* valve seeding in a timely fashion [5]. This strategy also offers the potential to direct autologous circulating cell seeding of heart valves, which if successful precludes the need for *ex vivo* cell culturing and allows for an 'off the shelf' tissue-engineered heart valve.

Bioreactors

The use of bioreactors for tissue-engineering heart valves has increased over the last several years due to both improvement and complexity of available systems and the encouraging results that have been published with their use. Simplistically, a bioreactor is a biomimetic system used to optimize *in vitro* neotissue development. Ideally, the bioreactor system is designed to mimic the physiologic or pathophysiologic condition that is to be corrected with the engineered tissue. Factors such as shear stress, flow rate, flow profile, pressure, and media should be easily manipulated to change experimental conditions as researchers see fit [16]. Additionally, bioreactors should be easy to access, easy to exchange media, remain sterile under long culture times, accommodate multiple samples to facilitate adequate sample sizes for statistically significant comparisons, and should be arranged to allow for direct visualization of the samples [35]. In mirroring physiologic conditions in the heart, an ideal bioreactor for tissue-engineered cardiac valves consists of pulsatile flow and cyclic flex in order to generate the complex biomechanical environment that implanted valves must withstand [88]. Exposure to pulsatile flow modulates and the biomechanical properties of the neotissue, which is especially important in the development of a tissue-engineered heart valve in order to prevent premature valve deterioration [89].

One specific type of bioreactor used in the construction of a tissue-engineered heart valve is the pulse duplicator. This pulsatile bioreactor provides physiological pressure and flow to the developing tissue-engineered heart valve and promotes both the development of mechanical strength and the modulation of cellular function [90]. In using human umbilical cord blood-derived progenitor cells to seed heart valves made from biodegradable polymer, Sodian and colleagues used a pulse duplicator bioreactor wherein pulsatile flow (300–500 mL/min) and pressure (5 to 15 mmHg) were gradually increased over the course of seven days [91]. This technique led to tissue-engineered heart valves with similar connective tissue and extracellular matrix composition as that seen in native heart valves.

Other approaches to bioreactors for tissue-engineered heart valves include bioreactors that can provide cyclic strain or dynamic flexural strain. Exposure of seeded valve tissue *in vitro* to mechanical strain results in more pronounced and organized tissue formation with superior mechanical properties over unstrained controls and results in tissue-engineered heart valve cusps that are significantly less stiff than static controls [92]. This technique also yields substantial increases in DNA and net collagen content [93]. Cyclic flexure, which is a significant source of heart valve deformation, was used as the mechanical stimuli in a bioreactor into which cell-seeded and unseeded valves were incubated for three weeks. Cell-seeded valves undergoing cyclic flexure had >400% increase in effective stiffness compared to the unseeded controls and also had increased amounts of extracellular matrix [94].

Importantly, there is no uniform standard bioreactor that is used in tissue-engineering heart valves, in part because of the complexities of the mechanical environment *in vivo*. Further

understanding of the relationship between embryonic valve development and biomechanical signals may offer insight into designing an ideal bioreactor for *in vitro* development of heart valves.

Neotissue development in tissue-engineered heart valves

The process of neotissue development is poorly understood and appears to be controlled by a multitude of factors. In some ways it mimics embryonic development whereas in other ways it appears to be governed by the rules underlying tissue repair. In fact, it is probably a unique process governed by its own set of laws. The type of cells that are implanted and their interaction with the surrounding environment determine the type of tissue that ultimately develops from the cell-scaffold complex [43].

The environment in which the construct grows will influence the histological structure and extracellular matrix formed. Researchers have approached this phenomenon from several perspectives. In one approach, the formation of tissue begins *in vitro* by seeding cells onto a biodegradable scaffold and then maturing the tissue in a bioreactor prior to implantation *in vivo*. Using this approach, the scaffold is used as a cell delivery system and implanted *in vivo* shortly after cell attachment has taken place [44]. This approach uses a cell-scaffold construct to provide the initial structural integrity necessary to provide temporary physiological function until neotissue grows and remodels. The technique proposes that appropriate environmental signals for tissue repair and remodeling are inherently present in the *in vivo* milieu. In addition, *in vivo* biomechanical environmental forces provide important stimuli that affect the formation of extracellular matrix and direct the biomechanical properties of the developing neotissue. The key steps in this process include:

a) Cell proliferation and migration,
b) ECM production and organization,
c) Scaffold degradation, and
d) Tissue remodeling [1].

The mechanical and biological signals underlying neotissue formation remains an area of focused research. Recent studies of tissue-engineered vascular grafts in murine and ovine models have demonstrated that seeded mononuclear cells stimulate a robust infiltration of host macrophages during early timepoints [95]. Additional evidence suggests that circulating host bone marrow-derived cells are active in the acute inflammatory phase but do not represent a source of mature neotissue. Rather, macrophages appear to initiate an inflammatory cascade to drive vascular remodeling and neotissue ingrowth from the surrounding native vessel [96]. Other pathways specific to heart valve physiology may also be vital to understanding neotissue formation. One key process in the development of the heart valve is epithelial-to-mesenchymal transformation (EMT). It has been demonstrated that EMT pathways involving TGF-β3, BMP2 and VEGFA are activated and localized in TEHV remodeling [97]. Many groups believe that the identification of biomaterials that can induce EMT and direct cellularization of tissue-engineered heart valves will be invaluable to the field [46].

Tissue-engineered heart valves have been evaluated biochemically, molecularly, histologically, physiologically, biomechanically, and morphologically (Fig. 40.3). In each type of analysis, the tissue-engineered valve has been compared with the native valve [78]. These data can then be used to identify shortcomings in the tissue-engineered heart valve and aid in the rational design of an improved version. One challenge that remains is the identification of good biomarkers or methodologies for the non-invasive study of the structural remodeling and functionality of *in vivo* constructs so that a tissue-engineered valve can be followed over time [98].

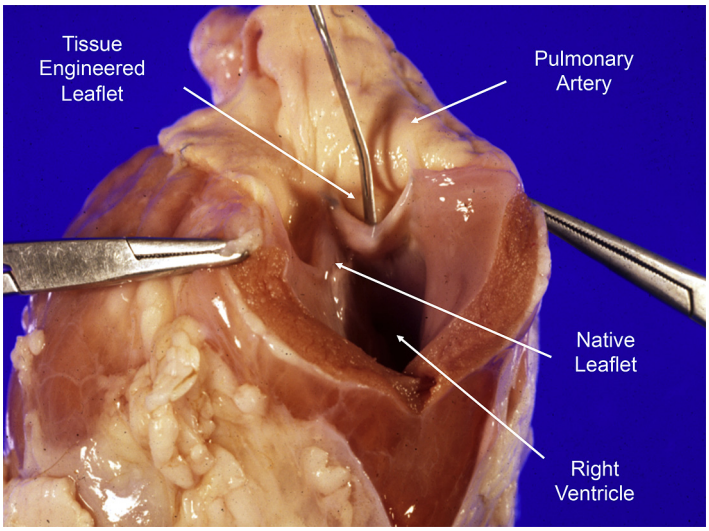

FIGURE 40.3
Photograph of a tissue-engineered valve in a sheep heart.

Clinical applications of the tissue-engineered heart valve

Dohmen et al. reported the first successful use of a tissue-engineered heart valve using a decellularized cryopreserved pulmonary allograft [74]. Since then, Dohmen and colleagues have published long-term data on a series of 11 patients who underwent the Ross operation with a tissue-engineered heart valve to surgically reconstruct the right ventricular outflow tract. In each case, the allograft was seeded in a bioreactor with autologous vascular endothelial cells that had been isolated from a segment of forearm vein two to four weeks prior to the operation. At ten years follow-up, the tissue-engineered heart valves showed excellent hemodynamic function. All patients remained in New York Heart Association class I heart failure and computed tomography showed no evidence of calcification or valve degeneration (Fig. 40.4) [99]. Despite the lack of a control group, the small sample size, and the lack of long-term biochemical or tissue samples, this study is a significant advance in the clinical application of tissue-engineered heart valves. Re-analysis of the group of patients at 15 and 20 years post-implantation will offer insight into the effect that autologous cell seeding has on allografts in preventing long-term complications that are seen in unseeded allografts and homografts like calcification and valve degeneration.

FIGURE 40.4
Multi-slice computed tomography shows a normal tissue-engineered pulmonary valve, without evidence of calcification or degeneration after 10 years in a male patient who was operated on at age 46 [99].

Other investigators have used decellularized scaffold implantations with autologous cell seeding to tissue-engineer cardiac valves. While not technically tissue-engineered valves, as that would require some degree of *ex vivo* cell seeding, this method holds the promise of valve implantation of allogenic or xenogenic tissue with a decreased host response to donor antigens. In lieu of data that host antigen recognition and antibody development may be linked to early tissue calcification and degeneration, the advantage of decellularizing a scaffold prior to implantation is that the cellular antigen burden decreases while the extracellular architecture and material properties are maintained [100].

Use of xenografts in this fashion was halted in 2003 after Simon et al. reported failure of SynerGraft decellularized porcine valves implanted in four children as pulmonary valves for right ventricular outflow tract reconstruction. In this study, two valves were severely degenerated at six weeks and one year after implantation, and one valve ruptured seven days after implantation, ultimately resulting in three deaths and the fourth child's valve explanted prophylactically [59]. Since then, focus has turned to allogenic decellularized pulmonary valves using the SynerGraft process with results so far showing promise for this technique over standard cryopreserved allogenic valves. Studies published to date comparing SynerGraft decellularized allogenic valves with standard cryopreserved valves show in the SynerGraft valves decreased short-term stenosis or regurgitation, decreased clinically significant insufficiency, lower peak valve gradients, and fewer interventions [101]. Brown and colleagues performed a multicenter retrospective cohort study of 342 patients undergoing right ventricular outflow tract reconstruction with SynerGraft or standard cryopreserved valves and showed decreased regurgitation in the SynerGraft group and overall safety and efficacy at four years post-implantation [41].

To date, synthetic scaffolds have not been used to fabricate a replacement heart valve for clinical use. However, the principles of tissue engineering outlined thus far and the approach of identifying and isolating a cell source, choosing a scaffold, and seeding the cells on to the scaffold were applied by Shinoka et al. in the first human clinical trial investigating tissue-engineered vascular grafts (TEVG) in children with complex congenital heart disease. The study began in 2001 and included 25 patients with an average age of five years undergoing extracardiac total cavopulmonary connection using the TEVG as a conduit. The synthetic scaffold used was a copolymer of polyglycolic acid and ε-caprolactone reinforced with poly-L-lactide. The scaffolds were seeded with autologous bone marrow-derived mononuclear cells. At one month post-implantation, all patients were alive and symptom free, and radiographic studies demonstrated no cases of TEVG aneurismal dilatation, thrombosis, or stenosis. Patients were followed serially with angiography, computerized tomography, or magnetic resonance imaging examinations. At one year there was one patient diagnosed with partial mural thrombus who was treated successfully with anticoagulation [102]. At late-term follow-up (average 5.8 years post-implantation), four patients had died of causes unrelated to the TEVG and four patients had developed TEVG stenosis requiring balloon angioplasty or stenting [103]. Overall, the tissue-engineered vascular conduits had reduced incidence of calcification, no risk of rejection because of autologous cell seeding, minimal risk of infection, and potential for growth [104]. Following the excellent results of Shinoka and colleagues, we are currently performing the first FDA-approved human clinical trial investigating use of TEVGs in children with congenital heart disease. Shinoka's results prove that the application of tissue engineering principles to vexing clinical problems has the potential to dramatically improve outcomes and lessen the morbidity and mortality of disease. All of these potential benefits would hold true for a tissue-engineered heart valve.

As the field of cardiovascular tissue engineering continues to expand, so too will the desire to apply methods and models in human clinical trials. It is essential for investigators to have thoroughly established the efficacy of techniques in large animal and pre-clinical models prior to translation into humans. Issues of bacterial contamination, insufficient cell seeding, and rapid degeneration of scaffold are common complications of tissue-engineered devices and

therefore strict protocols must be in place and adhered to in order for this promising field to expand clinically in an effective and responsible manner.

That randomized clinical trials are the gold standard for evaluating efficacy of new drugs and devices should not prevent the rationale translation of tissue-engineering technology to man. In most clinical circumstances in which tissue-engineered vessels or valves are to be applied, patients have poor prognoses, and therefore the benefit of tissue-engineered devices will outweigh the risks inherent in a new technology. For this reason, it behooves the FDA and other regulatory agencies to utilize the humanitarian exception for these devices in instances where pre-clinical data is promising and patient disease is severe. Most importantly, though, for physicians, scientists, regulators, and engineers, is to apply this promising technology in a responsible manner, placing the safety and well being of the patients as the top priority in all instances.

CONCLUSION

Successful development of a tissue-engineered replacement heart valve holds the key to better treatment and improved clinical outcomes for end-stage valvular disease. Although significant progress has been achieved since its inception in the early 1990s, the field is young and many key issues have yet to be resolved. We are still exploring the cellular and ECM biology that govern the maintenance of a normal valve. Better characterization of valve cells like VECs and VICs may offer clues to optimize cell seeding. Moreover, advances in other fields of tissue engineering and stem cell biology may provide new techniques and cell types that could transform either the cell source or cell seeding technique used in engineered heart valves. Similarly, growth in other fields like 3D printing or quantification of flow using magnetic resonance imaging may eventually find clinical applications of their respective technologic advancements in engineering heart valves. To that point, it is clear that tissue engineering is a multi-disciplinary, multi-faceted field that requires cooperation, coordination, and collaboration between experts in a variety of different specialties. Fostering these types of relationships using unique funding mechanisms and programs will help move this field forward and will ultimately benefit tissue engineering as a field and the patients that benefit from its growth.

CHAPTER 41

Generation of Pancreatic Islets from Stem Cells

Bernat Soria, Daniela Pezzolla, Javier López, Anabel Rojas and Abdelkrim Hmadcha
Andalusian Center for Molecular Biology and Regenerative Medicine (CABIMER), Department of Stem Cells and CIBERDEM, Sevilla, Spain

INTRODUCTION

Diabetes mellitus is one of the most prevalent chronic diseases. Glucose homeostasis disruption occurs when β-cells fail to secrete the insulin necessary to maintain the homeostasis of glucose in the blood flow. Over time, diabetes can lead to the rise of different long-term complications, such as diabetic foot, retinopathy, neuropathy, nephropathy and arteriosclerosis. Nowadays, the only treatments for diabetes consist of exogenous insulin supply or pancreas/islet transplantation, but the inability to achieve a tight control over glucose regulation by exogenous insulin administration and the shortage of pancreatic islets donors have motivated recent efforts to develop renewable sources and protocols for effective β-cell replacement.

Embryonic stem cells are non-specialized cells that share two important characteristics: *self-renewal*, which allows them to expand indefinitely while maintaining the undifferentiated state; and *pluripotency*, which is the capacity to differentiate into almost all specialized cell types. Proof-of-concept experiments demonstrate that embryonic stem cells have the ability to differentiate into insulin-producing cells, even if at a very low frequency.

In this chapter, we review the attempts that have been made thus far to convert embryonic stem cells into pancreatic endocrine cell types of potential use in the treatment of type I diabetes.

FIRST ATTEMPTS TO OBTAIN B-CELL LIKE CELLS BY DIFFERENTIATION

The first attempt to promote the differentiation of insulin-producing cells was carried out using a combination of directed differentiation and cell selection methods. Mouse embryonic stem cells (ESCs) expressing antibiotic resistance under control of either the insulin or the Nkx6.1 promoter [1,2] were driven to differentiate into nutrient-induced insulin-secreting cells which rescue streptotozotocin-diabetic mice from hyperglycemia when transplanted either into the spleen or under the kidney capsule. Furthermore, the cell type selection protocol allowed no tumor formation by the presence of non-differentiated ESCs. In contrast, most of the initial differentiation techniques that relied upon embryoid body (EB) formation appeared to be successful using either mouse ESCs [3–5] or human ESCs [6–7], but the absence of C-peptide, tumor formation and lack of demonstration of any rescue of diabetic animals revealed

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00041-0

that the observed intracellular insulin in these cells did not originate from *de novo* synthesis, but rather from uptake from the culture media [7–11].

Although pioneering results [1–2] showed that pancreatic β-cell-like cells may be obtained from ESCs, new differentiation strategies that can be used with human stem cells needed to be developed. Differentiation strategies were based on knowledge of early mouse development, the sequential expression of the transcription factors [12–14] and the signaling pathways [15] involved in β-cell formation. The application of such developmental principles to stem cell biology seem to be the key to obtaining a successful differentiation process, thus recent approaches chosen by the majority of investigators working on human ESC differentiation to produce insulin-secreting cells are based in a multi-stage protocol attempting to mimic all phases of *in vivo* pancreas development. Thus, the aim is to induce human ESCs to transition sequentially through mesendoderm, definitive endoderm, gut-tube endoderm, pancreatic endoderm and endocrine precursor stages, resulting in a final, functional, insulin-expressing cell.

STEPS TOWARDS β-CELLS: PROTOCOL COMPARISON

Obtaining mesendoderm and definitive endoderm

In order to make human ESCs differentiate into insulin-producing cells, the first goal is the efficient generation of definitive endoderm, which has been readily achieved by D'Amour et al. [16] using a combination of a TGFβ family member, Activin A, to activate Nodal signaling, and low serum concentration of media to avoid the activation of PI3K. Furthermore, to improve the yield of definitive endoderm cells, the activity of PI3K could be inhibited using two different inhibitors; LY 294002 [4,17] or wortmannin [18]. Wnt3a-mediated Brachyury expression is also important for the migration of precursor cells through the anterior region of the primitive streak (PS) and the formation of a mesendoderm population from which both endoderm and mesoderm will be generated depending on the magnitude and duration of Nodal signaling [19–20]. Hence, the efficiency of definitive endoderm generation can be further improved by exposure of human ESCs to a combination of Activin A and Wint3a in the absence of serum on the first day, followed by one day of culture in a medium supplemented with Activin A and 0.2% serum, and then three days in a medium supplemented with Activin A and 2% serum [21]. In contrast to Wnts, bone morphogenic proteins (BMPs) inhibit endoderm induction. Therefore, inhibition of BMP signaling using the BMP antagonist, Noggin, resulted in increased expression of PS/endoderm markers and in a rapidly reduced expression of PS/mesoderm markers, thus demonstrating the cooperative intertalk of canonical Wnt/β-catenin, Activin/Nodal and BMP signaling pathways during ESCs specification of PS, mesoderm and endoderm [22]. A different approach to inducing definitive endoderm has been recently published [23], and uses two small molecules identified as endoderm inducers (IDE1 and IDE2) with an efficiency similar to that obtained with the Activin A treatment described above.

Obtaining foregut patterning

Once definitive endoderm has been obtained, the next step is to trigger DE to foregut patterning, which results from the complex crosstalk between mesoderm and endoderm, involving gradients of fibroblast growth factors (FGFs), BMPs, retinoic acid (RA) and sonic hedgehog (SHH) [24]. During foregut patterning, high concentrations of FGF4 promote a posterior/intestinal endoderm cell fate, whereas lower FGF4 levels induce a more anterior/pancreas-duodenal cell fate [24]. In the same way, it has been shown that FGF2 specifies human ESCs-derived definitive endoderm into different foregut lineages in a dose-dependent manner. Specifically low doses of FGF2 promote a hepatic cell fate, intermediate FGF2 levels induce a pancreatic cell fate and high concentrations of FGF2 induce midgut endoderm small intestinal progenitors [25]. Retinoids are known as morphogens and differentiation inducers

during embryonic development and ESC differentiation, as reported by many investigators. These studies often used retinoic acid to induce pancreatic endoderm commitment in the definitive endoderm obtained by Activin A treatment [18,21,26–29]. In early development, SHH is highly expressed in the stomach and duodenal endoderm, but not in the pancreatic endoderm; hence specific inhibition of sonic hedgohog signaling has been shown to promote pancreatic differentiation by expanding the endoderm population of Pdx1-expressing cells [30]. In the same way, inhibition of SHH prevents stomach and duodenal endoderm specification, and the inhibition of BMP signaling pathway by Noggin has been shown to block hepatic commitment. Hence, to promote pancreatic endoderm specification at the expense of other foregut endoderm lineages, Cyclopamine, firstly introduced by León-Quinto et al. [2] for *in vitro* differentiation, and Noggin are often used in conjunction with RA treatment in human ESC differentiation protocols [18–29]. Curiously, anti-sonic hedgehog, which displayed better results than the non-specific small molecule cyclopamine, is not used.

Obtaining endocrine precursors

Notch signaling regulates the consecutive cell fate decisions required for the formation of specialized tissues, including β-cell generation. Once pancreatic endoderm is obtained, Notch inhibition seems to be critical for further differentiation towards an endocrine fate. This is consistent with the fact that Notch signaling represses transcription of Ngn3, a critical transcription factor for the formation of pancreatic endocrine cells. Notch activity serves to expand the pool of pancreatic progenitors preventing premature endocrine differentiation. During *in vitro* differentiation, it has been recently proved that EGF treatment can be used to expand the Pdx1-positive population of progenitor cells, which is necessary to obtain a large number of endocrine cells [18]. After EGF or FGF10 treatment, inhibition of Notch signaling using N-[N-(3,5-difluorophenacetyl)-L-alanyl-S-phenylglycine t-butyl ester (DAPT) a γ-secretase inhibitor had only a slight impact on promoting endocrine differentiation [21,31,32] probably due to a non-specific inhibition of Notch.

Maturation of pancreatic endocrine cells

The last step of human ESC differentiation into insulin-producing cells consists of directing the maturation of endocrine precursors into specialized and functional hormone-secreting cells. However, despite of the great number of biologically active compounds that have been used in published endocrine pancreas differentiation protocols, as yet an *in vitro* differentiation of ESCs into functional β-cells has not been achieved. D'Amour et al. [21] used a mix of different 'maturation factors' such as IGF1, Exendin-4, HGF and B27 supplement during terminal differentiation stages, but observed only minor effects on differentiation when these factors were omitted. On the other hand, Cho et al. [32] demonstrated that the application of betacellulin and nicotinamide to D'Amour's protocol resulted in sustained Pdx1 expression and led to subsequent insulin production. Nevertheless, insulin-producing cells obtained by *in vitro* differentiation protocols are commonly immature and non-functionally glucose-responsive. As a consequence, *in vitro* terminal differentiation steps were omitted from the protocol published by Kroon et al. [29], where pancreatic progenitors were allowed to mature into functional β-cell by *in vivo* maturation after transplantation in streptozotocin-induced hyperglycemic mice.

ALTERNATIVE STRATEGIES FOR PROTOCOL OPTIMIZATION

All the signaling pathways and factors described above are the result of more than ten years of research into ESCs differentiation with the aim of obtaining functional insulin-secreting cells. The fact that this aim has still not been achieved demonstrates the complexity of the differentiation process (Fig. 41.2). New factors and different culture conditions will be probably required to induce the complete differentiation and maturation of ESC-derived β-cells.

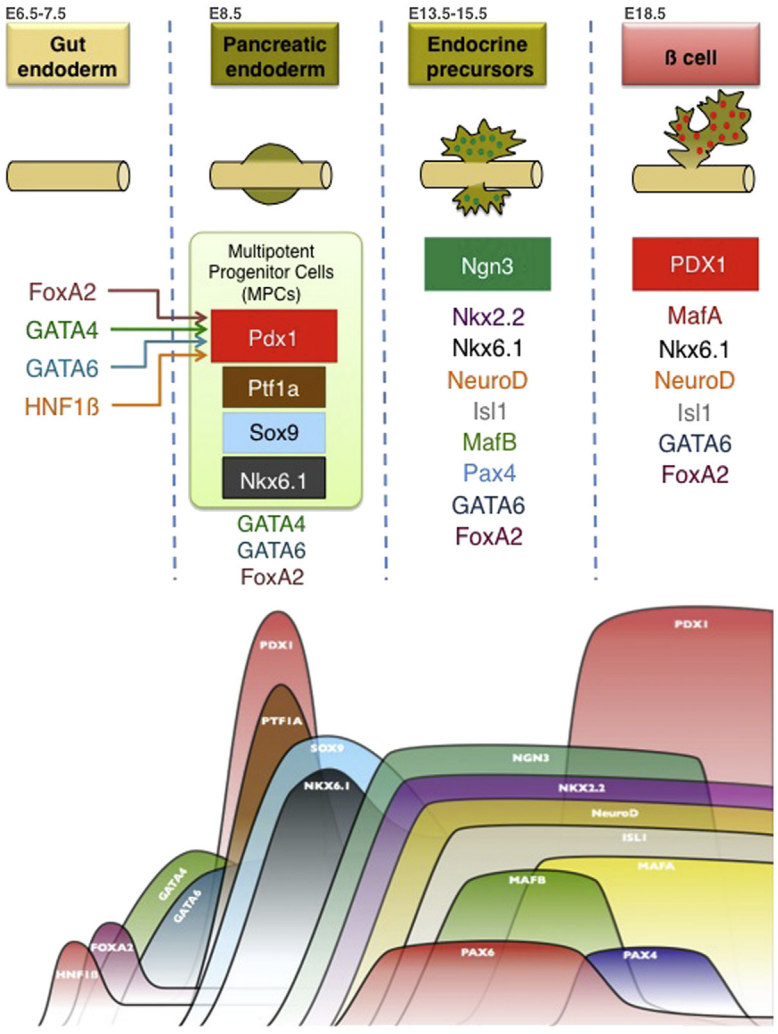

FIGURE 41.1
Schematic representation showing the transcription factors and signaling pathways identified in the development of mouse pancreatic β-cells.

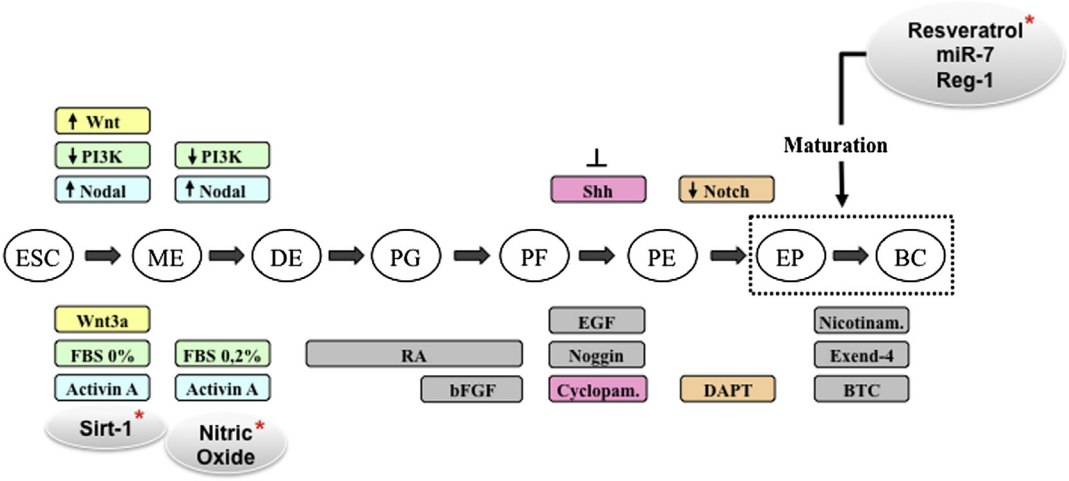

FIGURE 41.2
Overview of the signaling pathways and factors that have been shown to efficiently differentiate ESCs to a β-cell fate. Resveratrol, miR-7 and Reg-1 are proposed factors to improve the maturation stage. ESC: embryonic stem cells; ME: mesendoderm; DE: definitive endoderm; PG: primitive gut; PF: posterior foregut; PE: pancreatic endoderm; EP: endocrine precursors; BC: beta cells; DAPT: N-[N-(3,5-difluorophenacetyl)-L-alanyl-S-phenylglycine t-butyl ester; BTC: betacelulin. *Adapted from Champeris Tsaniras S et al. (2010). (*) Differentiation factors contributed by our group.*

Here we mention some novel approaches that could be useful in improving definitive endoderm generation, and the final maturation of the endocrine precursors, resulting in a more efficient insulin-secreting cell differentiation strategy. In addition, stem and somatic cells other than ESCs have been used to obtain a β-cell phenotype. Some of these strategies are overviewed below.

Increase of the glucose-stimulated insulin secretion pathway

Recent studies have shown the impact of Resveratrol (RSV) on insulin secretion and the way that this compound potentiates glucose-stimulated insulin secretion. RSV (3,5,4′-trihydroxy-trans-stilbene) is a polyphenol that has been shown to activate Sirt-1, a NAD+-dependent deacetylase [33]. Sirt-1 plays a role not only in the maturation process, but also in the initial differentiation process [34]. The effect of RSV on insulin secretion was studied for the first time by Zhang Y et al. [35] and recently by Vetteli et al. using the INS-1E cell line and human islets [36]. Bordone et al. demonstrated that Sirt-1 represses transcription of the mitochondrial uncoupling protein 2 (UCP2) by binding directly to its promoter [37]. Lower levels of UCP2, induced by Sirt-1 overexpression, result in increased ATP production and enhanced insulin secretion in INS-1E [38]. In humans, the transcriptional pathway regulating β-cell UCP2 gene expression is activated by the transcriptional cofactor peroxisome proliferator-activated receptor-γ coactivator-1 α (PGC-1 α) [39] which is another target of both Sirt-1 and RSV (Fig. 41.3). Hence RSV could be considered as a good candidate for improving the maturation process of human, ESC-derived, insulin-secreting cells.

Effects of new soluble factors on the maturation process

Of all the differentiation steps described above, the most difficult one to promote seems to be the maturation stage. Despite the large number of factors and their combinations that have been used in current protocols, functional β-like cells have not been produced. Screening for new active molecules to be used as 'maturation factors' could be helpful. In this context, a previous study described a fetal soluble factor, released by pancreatic buds, that has been used to induce *in vitro* endocrine pancreatic differentiation in mouse ESCs [40]. Subsequent proteomic studies (data not published) have demonstrated that one of the most abundant proteins present in the soluble factors released by pancreatic buds was Regenerating 1 (Reg-1). Reg-1 is normally induced in pancreatic β-cells and acts as an autocrine/paracrine growth factor for β-cell regeneration [41,42]. Based on this information, Reg-1 could be used in differentiation protocols to induce human ESC-derived β-cell maturation.

Nitric oxide and definitive endoderm induction

The relevant role of nitric oxide (NO) in developmental processes in the embryo has been previously described [43,44]. NO has also been reported to play a role in the induction of ESCs

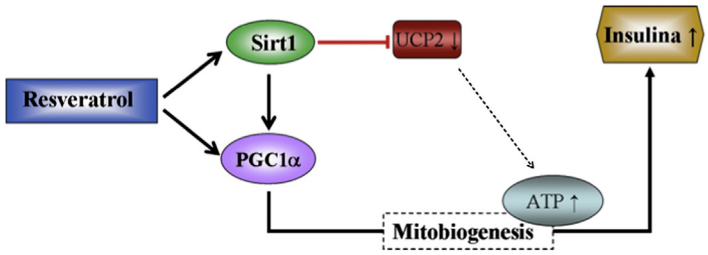

FIGURE 41.3

Proposed links beteen Resveratrol, Sirt1, UCP2 and insulin secretion. The indirect activation of Sirt1 by Resveratrol regulates insulin signaling pathways via repression of UCP2 transcription and through phosphorylation and subsequent deacetylation of PPARγ coactivator 1α (PGC1α), leading to mitochondrial function modulation, ATP increase and insulin secretion.

to differentiate into cardiomyocytes [45,46]. Recently the mechanism by which NO induces ESC differentiation has been described, and it has been observed that the exposure of ESCs to exogenous donors of NO like 1-[N-(2-aminoethyl)-N-(2-ammonioethyl)amino]diazen-1-ium-1,2-diolate (DETA-NO) for a short time induces early differentiation towards a definitive endoderm phenotype. Treatment with DETA-NO induced the expression of endoderm markers such as Pdx1 and GATA4 after a very short period of exposure (19 hrs): this is an interesting approach which could offer a suitable alternative for the generation of endoderm to the 3–5 days of Activin/Wnt3a treatment [47].

Endothelial cell co-culture

A less studied area in the field of pancreatic differentiation is the effect of endothelial cell signaling in β-cell maturation; this is increasingly being appreciated as an important contributing factor in *in vivo* pancreatic islet maturation. Recent studies have shown the effect of endothelial cell signaling in the maturation of human ESC-derived pancreatic progenitor cells into insulin-producing islet-like cells [48–50].

Microenvironment considerations

Despite the great influence of oxygen tension and extracellular matrix (ECM) on islet survival, the physiological environment has been largely ignored in β-cell differentiation protocols. Islet cells are extremely sensitive to both hypoxia and hyperoxia, and at the same time they need a three-dimensional (3D) cell-to-cell interaction structure to achieve a functional phenotype [51]. Unfortunately the *in vitro* condition used until now could not reproduce an optimal *in vivo* microenvironment, thus the 3D islet-like structure is not compatible with physiological oxygen distribution because of the lack of capillary vessels in the cluster structure. Novel differentiation approaches that take into account the role of both the ECM and oxygen distribution could be important for improving the maturation process of the endocrine precursors derived from human ESC differentiation. For these reasons, studies of the use of ECM components, such as laminins, and silicone rubber membranes to control oxygen tension are being carried out [52,53].

MicroRNAs

MicroRNAs (miRNAs) are non-coding small RNAs that regulate gene expression by post-transcriptional interference with specific messenger RNAs (mRNA). Study of miRNAs as regulators of complex gene expression networks is an emerging field that could be of great impact in both the differentiation and maintenance of cell phenotype. Studies in β-cell development demonstrate that miR-7 is highly expressed in both mouse and human developing pancreas [54], in the same way it contributes to *in vivo* β-cell development, consequentially miR-7 could be considered as an important player for the achievement of a complete differentiated human ESCs-derived β-cell.

ALTERNATIVE CELL SOURCES

Induced pluripotent stem cells

Induced pluripotent stem cells (iPSCs) are a new source of embryonic-like stem cells obtained by reprogramming somatic cells. Similar to ESCs, iPSCs can differentiate into many different cell types, including insulin-secreting cells [55], suggesting that patient-specific functional β-cells might be generated [56]. Furthermore, β-cells generated from iPSCs were able to reverse hyperglycemia after transplantation into diabetic mice [57]. One of the most important advantages of using patient-specific β-cells is that they avoid the risk of immunological rejection [58]. However, unexpectedly, rejection of autologous iPSCs transplanted in genetically identical mice has been observed [59] hence, further studies are required to ensure consistency and safety of iPSCs before they can be used in future cell regenerative therapy.

Mesenchymal stem cells

Mesenchymal stem cells (MSCs) are multipotent non-hematopoietic progenitor cells that are being explored as a promising new treatment for tissue regeneration. However, the ability of MSCs to differentiate into insulin-producing cells when treated with different soluble factors is still under question [60]. Nevertheless the efficacy of MSCs in the treatment of diabetes could derive from different abilities of these cells, such as their immunomodulatory properties or their capability to differentiate into endothelial cells, thus providing environmental support for pancreatic regeneration [61]. Actually several lines of evidence have demonstrated that cotransplantation of islets and MSCs exhibits a better outcome then islet transplantation alone, by promoting vascularization of the graft and hence preventing rejection [62,63].

Transdifferentiation

In addition to studies using stem cells and iPSCs, recent reports suggest that pancreatic duct cells, liver cells, acinar cells, and other mature cell types (Fig. 41.4) have the ability to trans-differentiate into insulin-producing cells [64–66]. Even adult monocytes retain this capability [67]. However is difficult to demonstrate that these 'insulin-producing cells' possess the criteria to be considered pancreatic β-cells. The difficulties of differentiating adult cells into insulin-producing pancreatic cells have been bypassed by using *in vivo* gene transfer of the pdx-1 gene into liver cells to induce hepatocyte transdifferentiation [68,69]. Experiments are not conclusive because cells generated in this manner are not true β-cells, but rather hybrids of hepatic and pancreatic cells. To avoid the problem of viral infection, a very recent study shows that is possible to induce liver transdifferentiation by using a hydrodynamic approach to deliver genes such as pdx1, ngn3 and mafA [70]. On the other hand, a more efficient attempt at transdifferention of non-endocrine tissue into β-cells has been achieved using exocrine cells as the starting material. In this context, it was feasible to reprogram pancreatic exocrine tissue into islet cell types using a combination of three genes (Pdx1, Ngn3, and MafA) [71,72]. Unlike in other transdifferentiation settings, the original exocrine phenotype appeared to be completely abrogated, and diabetic mice subjected to transplantation of these cells showed a significant and permanent improvement in blood glucose levels, even if their diabetes was not completely reversed.

De novo organ formation

While it has been shown that insulin-producing cells may benefit glucose homeostasis, in human physiology the actual micro-organs controlling blood glucose are the pancreatic islets.

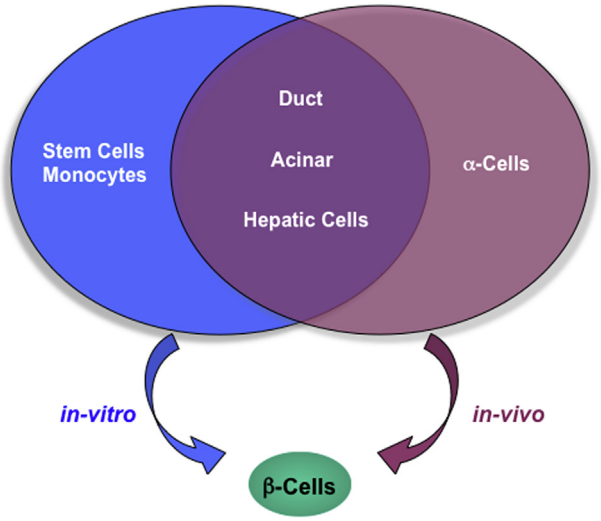

FIGURE 41.4
Cell sources that have been proved able to transdifferentiate into insulin-producing cells under in vitro and/or in vivo conditions.

Pancreatic islets are well-vascularized and innervated structures in which endocrine and non-endocrine cells are responsible for an integral response to blood glucose oscillations. Insulin-secreting β-cells respond in synchrony to stimulatory nutrient increases within the islet building a well-tuned response [73–75], simultaneously glucagon- and somatostatin-secreting cells modulate their activity to other nutrient ranges [76,77]. It is generally accepted that pancreatic islets better represent the overall physiology than isolated β-cells, but so far no-one has been able to produce a pancreatic islet *in vitro*. A complex and exciting strategy is appearing in the field of regenerative medicine which consists of the generation of entire transplantable organs. The complex cellular interactions among and within tissues that are required for organogenesis are extremely difficult to recapitulate *in vitro* so, as an alternative, promising new studies on blastocyst complementation are being undertaken [78]. The aim is to generate pluripotent stem cell (PSC)-derived donor organs *in vivo* by injection of PSCs into blastocysts obtained from mutant mice in which the development of a certain organ was precluded by genetic manipulation. The PSC-derived cells would developmentally compensate for the defect and form the missing organ [78]. Nakauchi's group has shown proof-of-principle findings for pancreas generation through the injection of PSCs into pancreas-deficient Pdx1(−/−) mouse blastocysts [79]. This innovative approach poses not only technical but ethical questions; for example, could the production of human organs in human-pig chimeras be an alternative approach? Obviously, we are still far from such an attempt.

CONCLUSION

Development of human ESC-based therapy for diabetes represents one of the most challenging areas of stem cell research. Mimicking the complex developmental processes of β-cell formation has been demonstrated to be the most promising and effective approach to obtaining insulin-secreting cells. However, our understanding of the signals which are important in the final phase of pancreatic endoderm specification is still incomplete. Study of endothelial cell-released factors and cell matrix interactions during pancreatic differentiation will be required to generate functionally competent insulin-secreting pancreatic cells. On the other hand, direct or indirect reprogramming of somatic cells through transdifferentiation or iPSCs derivation has been shown to be an effective strategy to produce β-cell surrogates. However, the problem of genetic manipulation that characterizes both these two techniques represents a safety concern that is still unlikely to be acceptable for clinical applications. In conclusion, despite all the investigations efforts and promising progress reported in this review, further studies are required to generate new transplantable insulin-producing cells that are safe and able to mimic extremely closely the complex functions of an endogenous β-cell.

CHAPTER 42

Bioartificial Pancreas

Athanassios Sambanis
School of Chemical & Biomolecular Engineering and the Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, Georgia

INTRODUCTION

Diabetes is a significant health problem affecting an estimated 25.8 million people (or 8.3% of the population) in the United States. Of these, 5–10% have autoimmune, or juvenile Type 1 diabetes, which results from the destruction of the insulin-producing β cells in the pancreas. Adult onset Type 2 diabetes has a more complicated etiology, which includes development of resistance to insulin, chronically elevated levels of insulin, and eventual damage to the pancreatic β cells. Although initially controlled by diet, exercise and oral medication, Type 2 diabetes often progresses towards insulin dependence. It is estimated that the diabetics who receive insulin either by itself or in combination with oral medication comprise 26% of the total population of diabetics, or approximately 6.7 million people in the US (CDC National Diabetes Fact Sheet, 2011; http://www.cdc.gov/diabetes/pubs/pdf/ndfs_2011.pdf).

Although insulin-dependent diabetes (IDD) is considered a chronic disease, even the most vigilant insulin therapy cannot reproduce the precise metabolic control present in the non-diseased state. The poor temporal match between glucose load and insulin activity leads to a number of complications, including increased risk of heart disease, kidney failure, blindness, and amputation due to peripheral nerve damage. Providing more physiological control would alleviate many of the diabetes-related health problems, as suggested by findings from the Diabetes Control and Complications Trial and its continuation study [1,2]. Cell and tissue-based therapies, which provide continuous regulation of blood glucose through the physiologic secretion of insulin, have the potential to revolutionize diabetes care.

Several directions are being considered for cell-based therapies of IDD, including the transplantation of immunoprotected allogeneic or xenogeneic islets, of continuous cell lines, or of cells engineered to acquire a β phenotype genetically or through differentiation. For allogeneic islet transplantation, a protocol developed by physicians at the University of Edmonton [3–6] has dramatically improved the survivability of grafts. The protocol uses human islets from cadaveric donors, which are transplanted in the liver of carefully selected diabetic recipients via portal vein infusion. The success of the Edmonton protocol is attributed to two modifications relative to earlier islet transplantation studies: the use of a higher number of islets and the implementation of a more benign, steroid-free immunosuppressive regimen. However, two barriers prevent the widespread application of this therapy. The first is the limited availability of human tissue, as generally more than one cadaveric donor pancreas is needed for the treatment of a single recipient. The second is the need for life-long immunosuppression, which, even with the more benign protocols, results in long-term side effects in the patients and may also negatively affect the transplanted islets themselves.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00042-2

A tissue-engineered pancreatic substitute aims to address these limitations by using alternative cell sources, relaxing the cell availability limitation, and by reducing or eliminating the immunosuppressive regimen necessary for survival of the graft. A number of significant challenges are facing the development of such a substitute, however. These include procuring cells at clinically relevant quantities; the immune acceptance of the cells, which is exacerbated in Type 1 diabetes by the resident autoimmunity in the patients; and the fact that diabetes is not an immediately life-threatening disease, so that any other therapy will have to be more efficacious and/or less invasive than the current standard treatment of daily blood glucose monitoring and insulin injections or infusions by a pump.

In general, developing a functional living tissue replacement requires advances and integration of several types of technology [7]. These are:

1) Cell technology, which addresses the procurement of functional cells at the levels needed for clinical applications.
2) Construct technology, which involves combining the cells with biomaterials in functional three-dimensional configurations. Construct manufacturing at the appropriate scale and preservation, as needed for off-the-shelf availability, also fall under this set of technologies.
3) Technologies for *in vivo* integration, which address the issues of construct immune acceptance, *in vivo* safety and efficacy, and assessing construct integrity and function post-transplantation.

The same three types of technology need also be developed for a pancreatic substitute. It should be noted, however, that the critical technologies differ depending on the type of cells used. With allogeneic or xenogeneic islets or beta cells, the major challenge is the immune acceptance of the graft. In this case, encapsulation of the cells within semipermeable barriers, which allow passage of low molecular weight nutrients and metabolites, including insulin, but exclude larger antibodies and cytotoxic cells of the host, assist the immune acceptance of the graft. With cell therapies based on potentially autologous non-pancreatic cells, targeted by gene expression vectors, transdifferentiated *in vivo*, or retrieved surgically, engineered *ex vivo* and returned to the host, the major challenge is achieving insulin secretion to the necessary level and in precise response to physiologic stimuli. Lastly, with stem or progenitor cells, the primary hurdle is their reliable, reproducible differentiation into cells of the pancreatic β phenotype. Fig. 42.1 shows schematically the two general therapeutic approaches based on allo- or xenogeneic cells (Fig. 42.1a) or autologous cells (Fig. 42.1b).

This chapter is therefore organized as follows. We first describe the types of cells that have been used or are of potential use in engineering a pancreatic substitute. We then discuss issues of construct technology, specifically encapsulation methods and the relevant biomaterials, manufacturing and preservation of the constructs. The challenges of *in vivo* integration and results from *in vivo* experiments with pancreatic substitutes are presented next. We conclude by offering a perspective on the current status and the future challenges in developing an efficacious, clinically applicable bioartificial pancreas.

CELL TYPES FOR PANCREATIC SUBSTITUTES

Islets

Despite several efforts, the *in vitro* expansion of primary human islets has been met with limited success. Adult human islets are difficult to propagate in culture, and their expansion leads to de-differentiation, generally manifested as loss of insulin secretory capacity. Although reports exist on the re-differentiation of expanded islets [8,9] and of non-islet pancreatic cells, which are discarded after islet isolation [10], the phenotypic stability and the *in vivo* efficacy of these cells remain unclear. Additionally, with expanded and re-differentiated islets, it remains unknown whether the insulin-secreting cells arose from

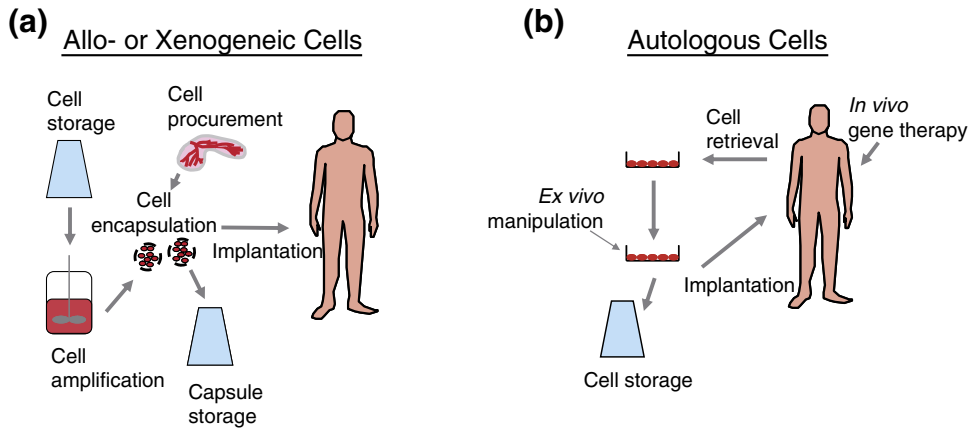

FIGURE 42.1

Approaches for bioartificial pancreas development using allo- or xenogeneic cells (a) and autologous cells (b). In (a), islets are procured from pancreatic tissue, or cells are thawed from cryostorage and expanded in culture; cells are encapsulated for immunoprotection before they are transplanted to achieve a therapeutic effect; encapsulated cells may also be cryopreserved for inventory management and sterility testing. In (b), cells are retrieved surgically from the patient; manipulated *ex vivo* phenotypically and/or genetically in order to express β cell characteristics, and in particular physiologically responsive insulin secretion; the cells are implanted for a therapeutic effect either by themselves or, preferably, after incorporation in a three-dimensional substitute; some of the cells may be cryopreserved for later use by the same individual. In *in vivo* gene therapy approaches, a transgene for insulin expression is directly introduced into the host and expressed by cells in non-pancreatic tissues.

the re-differentiation of mature endocrine cells or from an indigenous stem or progenitor cell population in the tissue isolate [10].

Animal, such as porcine, islets are amply available, and porcine insulin is very similar to human, differing only by one amino acid. Furthermore, use of closed, porcine endogenous retroviruses (PERV)-free herds is reasonably expected to alleviate the possibility of PERV transmission to human hosts. A difficulty with porcine tissue is the strong xenograft response elicited by the transplant. A combination of less immunogenic islets, islet encapsulation in semipermeable barriers, and host immunosuppression may accomplish long-term survival of the graft. Use of transgenic pigs that do not express the α-Gal (α[1,3]-galactose) epitope is one possible approach for reducing the immunogenicity of the islets. Studies also indicate that neonatal pig islets induce a lower T cell reactivity than adult islets [11], even though the α-Gal epitope is abundant in neonatal islets as well [12]. Furthermore, it is possible that the primary antigenic components in islet tissue are the ductal epithelial and vascular endothelial cells, which prominently express the α-Gal epitope; on the other hand, β cells express the epitope immediately after isolation, but not after maintenance in culture [13]. In spite of difficulties related to delayed insulin secretion as they undergo maturation, neonatal porcine islets are also receiving increased attention due to their natural resistance to hypoxia [14]. Lastly, it should be noted that the large-scale isolation of porcine islets under the conditions of purity and sterility that are necessary for their eventual clinical application pose some major technical hurdles, which have not been fully addressed yet.

β cell lines

Recognizing the substantial difficulties involved with the procurement and amplification of pancreatic islets, several investigators have pursued the development of continuous cell lines,

which can be amplified in culture, yet retain key differentiated properties of normal β cells. One of the first successful developments in this area was the generation of the βTC family of insulinomas derived from transgenic mice carrying a hybrid insulin-promoted simian virus 40 tumor antigen gene; these cells retained their differentiated features for about 50 passages in culture [15]. The hypersensitive glucose responsiveness of the initial βTC lines was reportedly corrected in subsequent lines by ensuring expression of glucokinase and of the high K_m glucose transporter Glut2, and no or low expression of hexokinase and of the low K_m transporter Glut1 [16,17]. A similar approach was used to develop the murine MIN-6 cell line that exhibits glucose-responsive secretion of endogenous insulin [18]. Subsequently, Efrat and co-workers developed the βTC-tet cell line, in which expression of the SV40 T antigen (Tag) oncoprotein is tightly and reversibly regulated by tetracycline. Thus, cells proliferate when Tag is expressed, and shutting-off Tag expression halts cell growth [19]. Such reversible transformation is an elegant approach in generating a supply of β cells via proliferation of an inoculum, followed by growth arrest when the desirable population size is reached. In any case, when retained in capsules, proliferating cells do not grow uncontrollably, since the dissolved oxygen concentration in the surrounding milieu supports up to a certain number of viable, metabolically active cells in the capsule volume. This number of viable cells is maintained through equilibration of cell growth and death processes [20–22]. Thus, growth arrest is primarily useful in preventing the growth of cells that have escaped from broken capsules *in vivo* and in reducing the cellular turnover in the capsules. The latter reduces the number or accumulated dead cells in the transplant and thus the antigenic load to the host due to antigens shed by dead and lysed cells, which pass through the capsule material.

In a different approach, Newgard and co-workers [23] carried out a stepwise introduction of genes related to β cell performance into a poorly secreting rat insulinoma (RIN) line. In particular, RIN cells were iteratively engineered to stably express multiple copies of the insulin gene, the glucose transporter Glut2, and the glucokinase gene, which are deemed essential for proper expression of β cell function. Although this is an interesting methodology, identifying and expressing all the genes necessary for reproducing β cell function in a host cell is a daunting task. Also, significant progress has been made towards establishing a human pancreatic β cell line that appears functionally equivalent to normal β cells [24]. This was accomplished through a complicated procedure involving retroviral transfection of primary β cells with the SV40 large T antigen and cDNAs of human telomerase reverse transcriptase. This resulted in a reversibly immortalized human β cell clone, which secreted insulin in response to glucose, expressed β cell transcriptional factors, prohormone convertases 1/3 and 2 that process proinsulin to mature insulin, and restored normoglycemia when transplanted in diabetic immunodeficient mice [24].

With regard to β cell lines capable of proliferation under appropriate conditions, key issues that remain to be addressed include their long-term phenotypic stability, their potential tumorigenicity, especially if cells escape from the encapsulation device, and their possible recognition by the immune system of the host.

Engineered non-β pancreatic cells

The use of non-β pancreatic cells from the same patient, engineered for insulin secretion, relaxes both the cell availability and immune acceptance limitations that exist with other types of cells. Experiments with an autoimmune diabetic mouse model indicate that such cells may not be recognized by autoimmunity [25]. The A-chain/C-peptide and B-chain/C-peptide cleavage sites on the proinsulin gene can be mutated so that the ubiquitous endopeptidase, furin, recognizes and completely processes proinsulin into mature insulin absent of any intermediaries [26]. Based on this concept, several non-endocrine cell lines have been successfully transfected to produce immunoreactive insulin, including hepatocytes, myoblasts and fibroblasts [27]. In a different approach, Lee and coworkers [28] expressed in hepatocytes

a synthetic single-chain insulin analog, which does not require post-translational processing. Although recombinant insulin expression is relatively straightforward, a key remaining challenge is achieving the tight regulation of insulin secretion in response to physiologic stimuli, which is needed for normoglycemia in higher animals and, eventually, humans.

One approach for regulating insulin secretion is through glucose control of biosynthesis at the gene transcription level, as realized in hepatocytes by Thulé et al. [29,30] and Lee et al. [28]. Besides the ability to confer transcriptional level regulation, hepatocytes are particularly attractive producers of recombinant insulin due to their high synthetic and secretory capacity and their expression of glucokinase and Glut2 [31,32]. Hepatic delivery by viral vectors and expression of the glucose-responsive insulin transgene in diabetic rats controlled the hyperglycemic state for extended periods of time [28,30,33]. Nevertheless, transcriptional regulation is sluggish, involving long time lags between stimulation of cells with glucose and induced insulin secretion, as well as between removal of glucose and downregulation of the secretory response [34]. The latter is physiologically more important, as continued insulin secretion following glucose downregulation results in potentially serious hypoglycemic excursions. Increasing the number of stimulatory glucose elements in a promoter enhances the cellular metabolic responsiveness *in vitro* [29]. With regard to secretion downregulation, Tang and Sambanis [34] hypothesized that the slow kinetics of this process following removal of the transcriptional activator are due to the stability of the preproinsulin mRNA, which continues to become translated after transcription has been turned off. Using a modified preproinsulin cDNA that produced an mRNA with two more copies of the insulin gene downstream of the stop codon resulted in preproinsulin mRNA subjected to nonsense mediated decay and thus destabilized. This significantly expedited the kinetics of secretion downregulation upon turning off transcription [34]. Thus, the combination of optimal transcriptional regulation with mRNA destabilization promises further improvements in insulin secretion dynamics from transcriptionally regulated hepatic cells. It should be noted, however, that despite the time delays inherent in transcriptional regulation, hepatic insulin gene therapy is sufficient to sustain vascular nitric oxide production and inhibit acute development of diabetes-associated endothelial dysfunction [35]. Hence, many promising aspects of the therapeutic potential of hepatic insulin expression remain to be explored.

Another appealing target cell type is endocrine cells, which possess a regulated secretory pathway and the enzymatic machinery needed to process authentic proinsulin into insulin. Early work in this area involved expression of recombinant insulin in the anterior pituitary mouse AtT-20 cell line [36], which can be subjected to repeated episodes of induced insulin secretion using non-metabolic secretagogues [37]. Co-transfection with genes encoding the glucose transporter Glut-2 and glucokinase resulted in glucose-responsive insulin secretion [38]. Limitations of this approach include possible instabilities in the cellular phenotype and secretion of endogenous hormones, such as adrenocorticotropic hormone from AtT-20 cells, which are not compatible with prandial metabolism.

In this regard, endocrine cells of the intestinal epithelium, or enteroendocrine cells, are especially promising. Enteroendocrine cells secrete their incretin products in a tightly controlled manner that closely parallels the secretion of insulin following oral glucose load in human subjects; and incretin hormones are fully compatible with prandial metabolism and glucose regulation [39,40]. As with β cells, enteroendocrine cells are polar, with sensing microvilli on their luminal side and secretory granules docked at the basolateral side, adjacent to capillaries. Released incretin hormones include the glucagon-like peptides (GLP-1 and GLP-2) from intestinal L cells and glucose-dependent insulinotropic polypeptide (GIP) from K cells, which potentiate insulin production from the pancreas after a meal [41]. The importance of enteroendocrine cells (and in particular, L cells) was first put forward by Creutzfeldt whose primary interest in these cells was for the prospect of using GLP-1 for the treatment of Type 2 diabetes [42]. Furthermore, ground-breaking work by Cheung et al. demonstrated that insulin

secreted by genetically modified intestinal K cells of transgenic mice prevented the animals from becoming diabetic after injection with streptozotocin (STZ), which specifically kills the β cells of the pancreas [43]. This is an important proof-of-concept study, which showed that enteroendocrine cell-produced insulin can provide regulation of blood glucose levels. Subsequent work with human and murine intestinal L cell lines demonstrated that these cells can be effectively transduced to express recombinant human insulin, which co-localizes in secretory vesicles with endogenous GLP-1 and is secreted with identical kinetics to GLP-1 in response to stimuli [44–47]. Furthermore, a combination of enteroendocrine L and hepatic cells, both engineered to express recombinant insulin, appears to better mimic the secretion kinetics of normal β cells than either cell type alone [48]. Although the intestinal tract is an attractive target for gene therapy because of its large size making it the largest endocrine organ in the body, enteroendocrine cell gene therapy faces several challenges. These are caused by anatomic complexity, with L cells being located at the base of invaginations of the gut mucosa called crypts, the harsh conditions in the stomach and intestine, and the rapid turnover of the intestinal epithelium.

Transdifferentation of adult non-β cells towards the β phenotype offers another promising approach towards replacing β cell function. This is generally accomplished by expressing β cell-related transcription factors in target cells. For example, expressing the pancreatic and duodenal homeobox gene 1 (PDX-1) in adult human liver cells reprogrammed them to express insulin, secrete it in response to glucose, and function *in vivo* in immunodeficient diabetic mice [49]. Reprogramming adult exocrine pancreatic cells towards the β phenotype was achieved *in vivo* in mice by adenoviral delivery of three transcription factors [50]. One of the challenges with cellular reprogramming is to express the requisite β cell function while stopping short of fully converting the target cell to a β cell that is then recognized by autoimmunity in Type 1 diabetics.

Contrary to direct *in vivo* gene delivery, *ex vivo* gene therapy involves retrieving the target cells surgically, culturing them and possibly expanding them *in vitro*, genetically engineering them to express the desired properties, then returning them to the host either as such or in a three-dimensional tissue substitute. It is generally thought that the *ex vivo* approach is advantageous, as it allows for the thorough characterization of the genetically engineered cells prior to implantation, possibly for the preservation of some of the cells for later use by the same individual, and, importantly, for localization and retrievability of the implant. However, the challenges imposed by the *ex vivo* approach, including the surgical retrieval, culturing and *in vitro* genetic engineering of the target cells, are significant, so such methods are currently under study.

Differentiated stem or progenitor cells

Naturally, throughout life, islets turn over slowly and new small islets are continually generated from ductal progenitors [51]. There exists also evidence that adult pluripotent stem cells may be a possible source of new islets [52–54]. Differentiation of human stem cells towards the b phenotype is actively being pursued by several groups, and recently success has been reported in deriving cells that secrete insulin in response to glucose from human embryonic stem cells [55,56]. Interestingly, these cells do not function well *in vitro*, but mature towards the β phenotype after transplantation into mice. Also, mouse embryonic stem cells transfected to constitutively express Pax4, a transcription factor essential for β cell development, differentiated into insulin-producing cells and normalized blood glucose when transplanted in STZ diabetic mice [57]. Overall, the existing results are quite promising but also point towards considerable additional work that needs to be done before stem or progenitor cells can be reliably differentiated into β cells in a safe way, ensuring absence of teratogenesis *in vivo*, and at a clinically relevant scale. Harnessing the *in vivo* regenerative capacity of the endocrine pancreas may also constitute a promising approach [58].

Engineering cells for enhanced survival *in vivo*

As islets or other insulin-secreting cells experience stressful conditions during *in vitro* handling and *in vivo* post-transplantation, several strategies have been implemented to enhance islet or non-islet cell survival in pancreatic substitutes. These generally focus on improving the immune acceptance of the graft, enhancing its resistance to cytokines, and reducing its susceptibility to apoptosis. Phenotypic manipulations include extended culturing of neonatal and pig islets at 37°C, which apparently reduces their immunogenicity, possibly by downregulating the major histocompatibility class 1 antigens on the islet surface; islet pretreatment with TGF-β1; and enzymatic treatment of pig islets with α-galactosidase to reduce the a-galactosyl epitope on islets [59]. However, the permanency of these modifications is unknown. For instance, a-galactosyl epitopes reappear on islets 48 hours after treatment with α-galactosidase. Surface engineering of islets by grafting of functional groups is also pursued to reduce procoagulation and proinflammatory responses post-transplantation by hepatic portal vein injection [60]. With proliferative cell lines engineered for recombinant insulin expression, selection of clones resistant to cytokines appears feasible [61].

Genetic modifications for improving survival *in vivo* may offer prolonged expression of the desired properties relative to phenotypic manipulations, but also presents the possibility of modifying the islets in additional, undesirable ways. Examples include the expression of the immunomodulating cytokines IL-4 or a combination of IL-10 and TGF-β, which promoted graft survival by preventing immune attack in mice [62]; the overexpression of the anti-apoptotic bcl-2 gene, which enhanced protection of islets when the adaptive immune response was inhibited by locally produced CTLA4Ig [63]; and the engineering of murine βTC3 insulinomas and of murine islets to express high levels of stromal cell derived factor-1 (SDF-1), which resulted in increased survival of the allografts in mice [64].

CONSTRUCT TECHNOLOGY

Construct technology focuses on associating cells with biocompatible materials in functional three-dimensional configurations. Depending on the type of cells used, the primary function of the construct can be one or more of the following: to immunoprotect the cells post-transplantation; to enable cell function; to localize insulin delivery *in vivo*; or, to provide retrievability of the transplanted cells.

Encapsulated cell systems

Encapsulation for immunoprotection involves surrounding the cells with a semipermeable barrier, in essence an ultrafiltration membrane, which allows passage of low molecular weight nutrients and metabolites, including insulin, but excludes larger antibodies and cytototoxic cells of the host. Fig. 42.2 summarizes the common types of encapsulation devices, which

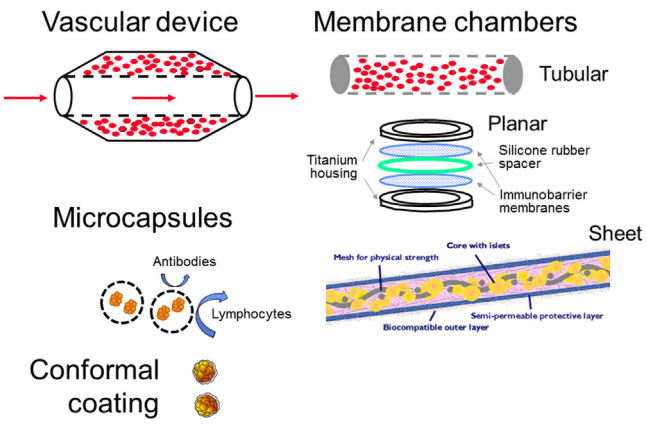

FIGURE 42.2
Schematics of commonly used encapsulation devices for islets and other insulin-secreting cells. Vascular devices and membrane chambers of tubular, planar or sheet architectures are generally referred to as macrocapsules, in distinction from the much smaller microcapsules.

include spherical microcapsules, tubular or planar diffusion chambers, thin sheets, and vascular devices.

Although several methods exist, encapsulation is generally pursued by one of two major approaches. With capsules fabricated using water-based chemistry, cells are first suspended in un-crosslinked polymer, which is then extruded as droplets into a solution of the cross-linking agent. A typical example here is the very commonly used alginate encapsulation. Alginate is a complex mixture of polysaccharides obtained from seaweeds, which forms a viscous solution in physiologic saline. Islets or other insulin-secreting cells are suspended in sodium alginate and droplets are extruded into a solution of calcium chloride. Calcium cross-links alginate instantaneously, trapping the cells within the gel. The size of the droplets, hence also of the crosslinked beads, can be controlled by flowing air parallel to the extrusion needle so that droplets detach at a smaller size than if they were allowed to fall by gravity; or, by using an electrostatic droplet generator, in which droplets are detached from the needle by adjusting the electrostatic potential between the needle and the calcium chloride bath. Capsules generated this way can have diameters from few hundred micrometers to a little over one millimeter. Alginate by itself is relatively permeable, and to generate the semipermeable barrier, beads are treated with a polycationic solution, such as poly-L-lysine or poly-L-ornithine. The reaction time between alginate and the polycation determines the molecular weight cutoff of the generated membrane. Poly-L-lysine is highly inflammatory *in vivo*, however, beads are coated with a final layer of alginate to improve their biocompatibility. Hence, calcium alginate/poly-L-lysine/alginate (APA) beads are finally formed. The permanency of the last alginate coat, however, is questionable. Treating the beads with a calcium chelator, such as citrate, presumably liquefies the inner core forming APA membranes. Other materials that have been used for cell microencapsulation include agarose, photocrosslinked poly(ethylene glycol), chitosan, and various copolymers [58,65,66]. The advantages of hydrogel microcapsules include a high surface-to-volume ratio and thus good transport properties, as well as ease of handling and transplantation. Small beads can be transplanted in the peritoneal cavity of animals simply by injection; without the need for incision. Other transplantation sites include the subcutaneous space and the kidney capsules. Disadvantages include the fragility of the beads, especially if the crosslinking cation becomes chelated by compounds present in the surrounding milieu or released by lysed cells, and the difficult retrievability once the beads have been dispersed in the peritoneal cavity of a host. Earlier problems caused by the variable composition of alginates and the presence of endotoxins have been resolved through the development and commercial availability of ultrapure alginates of well-defined molecular weight and composition [67,68].

Hydrogels impose little diffusional resistance to solutes, and indeed effective diffusivities in calcium alginate and agarose hydrogels are in the range of 50–100% of the corresponding diffusivities in water [69,70]. However, with conventional microencapsulation, the volume of the hydrogel contributes significantly to the total volume of the graft. For example, with a 500 μm microcapsule containing a 300 μm islet, the polymer volume constitutes 78% of the total capsule volume. Additionally, conventional microcapsules are not appropriate for hepatic portal vein infusion as, besides their higher graft volume relative to the same number of naked islets, they result in higher portal vein pressure and more incidences of blood coagulation in the liver. To address this problem, methods have been developed for islet encapsulation in thin conformal polymeric coatings. Materials that have been used for conformal coating include photopolymerized poly(ethylene glycol) (PEG) diacrylate [71,72], hydroxyethyl methacrylate-methyl methacrylate (HEMA-MMA) [73,74], and poly(L-lysine)-poly(ethylene glycol)(biotin) (PPB) and streptavidin (SA) in PPB/SA multilayers [75]. Conjugation of glucagon-like peptide 1 (GLP-1) to PEG hydrogels has been shown to reduce islet cell death due to photopolymerazation [76]; the antiapoptotic and insulinotropic effects of GLP-1 may also help islet survival and function *in vivo*. Conformal coatings offer a promising approach for islet encapsulation, however, the stability, continuity for complete islet coverage, and permeability

of the coatings remain to be addressed. Ultimately, the *in vivo* efficacy of conformal-coated islets needs to be established, as such data are mostly lacking.

Encapsulated cell systems can also be fabricated by preforming the semipermeable membrane in a tubular or disk-shaped configuration, filling the construct with a suspension of islets or other insulin-secreting cells in an appropriate extracellular matrix, and then sealing the device. This approach is particularly useful when organic solvents or other chemicals harsh to the cells are needed for the fabrication of the membranes. Membrane chambers can be of tubular or planar geometry (Fig. 42.2). The cells are enclosed in the semipermeable membrane and can be transplanted intraperitoneally, subcutaneously, or at other sites. Membrane materials used in fabricating these devices include polyacrylonitile-polyvinyl chloride (PAN-PVC) copolymers, polypropylene, polycarbonate, cellulose nitrate, and polyacrylonitrile-sodium methallylsulfonate (AN69) [65,67,77,78]. Typical values of device thickness or fiber diameter are 0.5 to 1 mm. Advantages of membrane chambers are the relative ease of handling, the flexibility with regard to the matrix in which the cells are embedded, and retrievability after transplantation. A major disadvantage is their inferior transport properties, since the surface-to-volume ratio is smaller than that of microcapsules and diffusional distances are longer.

Constructs connected to the vasculature via an arteriovenus (AV) shunt consist of a semipermeable tube surrounded by the cell compartment (Fig. 42.2). The tube is connected to the vasculature, and transport of solutes between the blood and the cell compartment occurs via the pores in the tube wall. A distinct advantage of the vascular device is the improved transport of nutrients and metabolites, which occurs both by diffusion and convection. However, the major surgery that is needed for transplantation and problems of blood coagulation at the anastomosis sites has reduced the enthusiasm felt for these devices.

Other construct systems

A common approach for improving the oxygenation of cells in diffusion chambers is to encourage the formation of neovasculature around the graft. This will be discussed in the 'In vivo transplantation' section. Other innovative approaches that have been proposed include the electrochemical generation of oxygen in a device adjacent to a planar immunobarrier diffusion chamber containing the insulin-secreting cells [79]; the co-encapsulation of islets with algae, where the latter produce oxygen photosynthetically upon illumination [80]; and the use of biomaterials that are hydrolytically activated to generate oxygen [81]. More work is clearly needed to evaluate whether these approaches can be translated into effective and clinically usable *in vivo* configurations.

In a different design, Cheng et al. combined constitutive insulin-secreting cells with a glucose-responsive material in a disk-shaped construct [82,83]. As indicated earlier, it is straightforward to genetically engineer non-β cells for constitutive insulin secretion; the challenge is engineering appropriate cellular responsiveness to physiologic stimuli. In this proposed device, a concanavalin A (con A)-glycogen material, sandwiched between two ultrafiltration membranes, acted as a control barrier to insulin release from an adjacent compartment containing the cells. Con A-glycogen forms a gel at low concentrations of glucose, which is reversibly converted to sol at a high glucose concentration as glucose displaces glycogen from the gel network. Since insulin diffusivity is higher through the sol than through the gel, insulin secreted by the cells during low glucose periods diffused slowly through the gel material; when switched to high glucose, insulin that had accumulated in the cell compartment during the previous cycle was released at a faster rate through the sol-state polymer. Overall, this approach converted the constitutive secretion of insulin by the cells to a glucose-responsive insulin release by the device [82]. However, these were *in vitro* studies, and the *in vivo* efficacy of such hybrid devices remains to be evaluated.

Construct design and *in vitro* evaluation

Design of three-dimensional encapsulated systems can be significantly enabled using mathematical models of solute transport through the tissue and of nutrient consumption and metabolite production by the cells. Beyond the microvasculature surrounding the construct, transport of solutes occurs by diffusion, unless the construct is placed in a flow environment, in which case convective transport may also occur. Due to its low solubility, transport of oxygen to the cells is the critical issue. Models can be used to evaluate the dimensions and the cell density within the construct so that all cells are sufficiently nourished and the capsule as a whole is rapidly responsive to changes in the surrounding glucose concentration [70]. Experimental and modeling methods for determining transport properties and secretion kinetics have been described [84]. Furthermore, models can be developed to account for the cellular reorganization that occurs in constructs with time as a result of cell growth, death, and possibly migration processes [20]. Such reorganization is significant when the encapsulated cells proliferate in the capsule environment [20,68,85] and it may result in changes in the secretory properties of capsules as the intracapsular environment remodels [86].

Pancreatic tissue substitutes should be evaluated *in vitro* prior to transplantation in terms of their ability to support the cells within over prolonged periods of time and to exhibit and maintain their overall secretory properties. Long-term cultures can be performed in perfusion bioreactors under conditions simulating aspects of the *in vivo* environment. In certain studies, the bioreactors and support perfusion circuits were made compatible with a nuclear magnetic resonance spectrometer. This allowed measurement of intracellular metabolites, such as nucleotide triphosphates, as a function of culture conditions and time without the need to extract the encapsulated cells [21,22,87,88]. Such studies produce a comprehensive understanding of the intrinsic tissue function in a defined and controlled environment prior to introducing the additional complexity of host-graft interactions in *in vivo* experiments.

The secretory properties of tissue constructs can be evaluated with low time resolution in simple static culture experiments by changing the concentration of glucose in the medium and measuring the secreted insulin. In general, a square wave of insulin concentration is implemented, from basal to inducing to basal conditions for insulin secretion. To evaluate the secretory response at a higher time resolution, perfusion experiments need to be performed, in which medium is made to flow around the tissue and secreted insulin is assayed in the effluent. Again, a square wave of glucose concentration is generally implemented. By comparing the secretory dynamics of free and encapsulated cells, one can ensure that the encapsulation material does not introduce excessive time lags compromising the secretory properties of the construct. Indeed, properly designed hydrogel microcapsules introduce only minimal secretory time lags [70,86,89]. Secretion measurements by perfusion on explanted capsules also shed light on changes that occur to the graft *in vivo*.

Manufacturing considerations

Fabrication of pancreatic substitutes of consistent quality requires the use of cells which are also of consistent quality. Although with clonal, expandable cells this is a straightforward issue, with islets isolated from human and animal tissues there can be significant variability in the quantity and quality of the cells in the preparations. With islets from cadaveric human donors, the quality of the isolates is assessed by microscopic observation, viability staining, and possibly a static insulin secretion test. It is generally recognized, however, that a quantitative, objective assessment of islet quality would help improve the consistency of the preparations. Assays evaluating mitochondrial function and oxygen consumption rate, especially when conducted with intact islets, are promising in evaluating their quality and are being established as standard tests prior to transplantation [90].

It is conceivable that encapsulated cell systems could be fabricated at a central location from which they would be distributed to clinical facilities for transplantation. In this scheme, preservation of the constructs for long-term storage, inventory management and, importantly, sterility control would be essential. Cryopreservation appears to be a promising method for maintaining fabricated constructs for prolonged time periods. Although there have been significant studies on the cryopreservation of single cells and some tissues, the problems pertaining to cryopreserving artificial tissues are in the process of being addressed. Cryopreservation of murine insulinomas and islets in microcapsules appears feasible [91–95], however, cryopreservation of macroencapsulated systems is expected to be particularly challenging.

IN VIVO TRANSPLANTATION

This section highlights results from *in vivo* experiments using the different configurations outlined above. Results with encapsulated cell systems are presented first. Since *in vivo* experiments with non-β cells engineered for insulin secretion are at present based mostly on *in vivo* gene therapy approaches, these are described next. Technologies for the *in vivo* monitoring of cells and constructs and graft retrievability are then discussed.

Encapsulated cell systems

In vivo experiments with pancreatic substitutes are numerous in small animals, limited in large animals, and few in humans. Allogeneic and xenogeneic islets in hydrogel microcapsules transplanted in diabetic mice and rats have generally restored normoglycemia for prolonged periods of time. In the early study of O'Shea et al. [96], islet allografts encapsulated in APA membranes were transplanted intraperitoneally in STZ-induced diabetic rats. Of the five animals which received transplants, three remained normoglycemic for more than 100 days, and one of these three remained normoglycemic 368 days post-transplantation. Microencapsulation in alginate crosslinked with barium without a traditional semipermeable barrier allowed prolonged survival of syngeneic and allogeneic transplanted islets in diabetic BALB/c and non-obese diabetic (NOD) mice for more than 350 days [97]. Interestingly, adult porcine islet (API) xenografts encapsulated in the same type of capsule also restored normoglycemia in STZ-induced diabetic mice for at least one month [98] or, in another study [99], for up to 190 days, the latter in spite of the presence of an antibody response.

On the other hand, with the NOD mouse model, it was found that encapsulation alone prolonged *in vivo* survival of APIs from less than one week to 35 ± 14 for microencapsulated APIs [100]. With continuous costimulatory blockade comprised of CTLA4-Ig and anti-CD154 monoclonal antibodies, non-encapsulated API functioned for 27 ± 4 days, whereas microencapsulated API functioned for more than 450 days [100]. Thus, microencapsulation and costimulatory blockade acted synergistically, at least for APIs in the NOD mouse model. Normoglycemia has also been restored in rodents transplanted with encapsulated cell lines, such as APA-encapsulated βTC6-F7 insulinomas in diabetic rats, where diabetes was reversed for up to 60 days [101], and APA-encapsulated βTC-tet insulinomas in NOD mice, where normoglycemia was restored for at least eight weeks [102]. With a human cell line [24], experiments were performed with un-encapsulated cells transplanted into STZ-induced diabetic severe combined immunodeficiency mice. Control of blood glucose levels started within two weeks post-transplantation, and mice remained normoglycemic for longer than 30 weeks [24]. Besides rodents, long-term restoration of normoglycemia with microencapsulated islets has been demonstrated in large animals, including pancratectomized dogs, where normalization of fasting blood glucose levels was achieved with encapsulated islet allografts in nine out of nine dogs for up to 214 days [103]. Also, in one study with porcine islet xenografts transplanted in spontaneously diabetic non-human primates (NHPs), animals became insulin independent for periods ranging from 120 to 804 days [104]. These results with NHPs, however, have not

been reproduced. Successful results with NHPs usually involve reduction of exogenous insulin requirements to maintain normoglycemia, as in the study of Elliott et al. with encapsulated neonatal porcine islets in cynomolgus recipients [105]. Also, in a study with non-diabetic NHPs transplanted with sub-therapeutic levels of alginate-encapsulated adult pig islets in NHPs, islet survival was reported for up to six months, even in the presence of antibody response [106]. Overall, in spite of certain promising results, correcting diabetes in NHPs by encapsulated islet grafts without exogenous insulin injections remains a daunting task.

Human studies with encapsulated islet transplants are few and far in between. In an earlier study involving encapsulated allogeneic islets, the graft reportedly provided tight glycemic control for nine months [107]; however, there is general skepticism about the validity of these results. In another study, also with encapsulated allografts transplanted intraperitoneally, Type 1 diabetic patients remained non-immunosuppressed, but exogenous insulin had to be provided [108]. Encapsulated neonatal porcine islets transplanted intraperitoneally in a Type 1 diabetic did not render the patient insulin independent, but reduced the exogenous insulin requirement and improved glycemic regulation, as evidenced by a reduction in total glycated hemoglobin [109]. Currently, Phase I and II clinical trials are ongoing in New Zealand and Russia by Living Cell Technologies Limited; in these, encapsulated neonatal porcine islets are transplanted intraperitoneally with laparoscopy.

In vivo results with vascular devices are mixed. Implantation of devices containing allogeneic islets as arteriovenous shunts in pancreatectomized dogs resulted in 20–50% of the dogs becoming normoglycemic for up to 10 weeks post-transplantation without exogenous insulin administration. When xenogeneic bovine or porcine islets were used, only 10% of the dogs remained normoglycemic 10 weeks post-transplantation. All dogs were reported to be diabetic or dead after 15 weeks [110]. A hollow fiber device composed of polyethylene-vinyl alcohol fibers and a poly-amino-urethane-coated, non-woven polytetrafluoroethylene fabric seeded with porcine islets provided normalization of the blood glucose levels in totally pancreatectomized pigs when connected to the vasculature of the animals [111]. It should be noted however, that the overall interest in vascular devices has faded due to the surgical and blood coagulation challenges that they pose.

Although several hypotheses exist, the precise cause of the eventual *in vivo* failure of encapsulated cell systems remains unclear. There exists increasing evidence that two possible causes for the gradual attrition and eventual failure of encapsulated grafts are small molecular weight cytotoxic compounds, including cytokines and nitrogen oxide, and hypoxia. Indeed, encapsulation does not completely prevent the immune recognition of the graft, and antigens shed by the encapsulated cells as a result of secretion and, more importantly, lysis eventually pass through the semipermeable barrier and are recognized by the antigen-presenting cells of the host. Passage of low molecular weight molecules cannot be prevented by immunoprotective membranes imposing a molecular weight cutoff on the order of 50 kDa. Overall, optimal properties of immunoprotective barriers remain largely unknown and may actually depend on the type of the host and the transplanted encapsulated cells. Transplantation sites, including the peritoneal cavity, are also intrinsically hypoxic, and transplantation of encapsulated insulin-secreting cells further reduces the dissolved oxygen concentration at the transplantation site, apparently as a result of the additional metabolic load to the host [112,113], to levels that affect secretion from pancreatic islets [114]. Sustained hypoxia also results in viability loss.

Non-specific inflammation may also occur around the graft and develop into a fibrous capsule, so reducing the oxygen available to the cells within. The fibrotic layer has been found to consist of several layers of fibroblasts and collagen with polymorphonuclear leukocytes, macrophages, and lymphocytes. The surface roughness of the membrane may also trigger inflammatory responses. In one study, membranes with smooth outside surfaces exhibit a minimal fibrotic reaction 10 weeks post-transplantation, regardless of the type of encapsulated cells, whereas

rough surfaces elicited a fibrotic response even one week post-transplantation [115]. Use of high purity materials also helps minimize inflammatory reactions. If a material is intrinsically inflammatory, such as poly-L-lysine, it can be coated with a layer of non-inflammatory material, such as alginate, to minimize the host's reaction. Such coverage may not be sufficiently permanent, though, resulting in the eventual fibrosis of the graft. Indeed, several investigators report improved results with plain alginate beads without a poly-L-lysine layer, especially when allogeneic cells are used in the capsules.

Provision of nutrients to and removal of metabolites from encapsulated cells can be especially challenging *in vivo*. Normal pancreatic islets are highly vascularized and thus well oxygenated. There exists evidence that un-encapsulated islets injected in the portal system of the liver become re-vascularized, which enhances their engraftment and function. On the other hand, encapsulation prevents re-vascularization, so the transplanted tissue is nourished by diffusion alone. Promotion of vascularization around the immunoprotective membrane increases the oxygenation of the transplanted islets [116]. Interestingly, transformed cells, such as the βTC3 line of mouse insulinomas, are more tolerant of hypoxic conditions than intact islets; such cells may thus function better than islets in transplanted capsules [117]. However, with transformed cells, too, enhanced oxygenation increases the density of functional cells that can be effectively maintained within the capsule volume. Vascularization is dependent on the microarchitecture of the material, which should have pores of 0.8–8.0 μm in size allowing permeation of host endothelial cells [118,119]. Vascularization is also enhanced by the delivery of angiogenic agents, such as Fibroblast Growth Factor-2 (FGF-2) and Vascular Endothelial Growth Factor (VEGF), possibly with controlled release devices [120]. Although vascularization can be promoted around a cell-seeded device, improved success has reported if a cell-free device is first implanted and vascularized, then the cells are introduced. An example of this procedure involved placing a cylindrical stainless steel mesh in the subcutaneous space of rats with the islets introduced 40 days later [121]. Replacement of a vascularized graft is challenging, however, due to the bleeding that occurs. A solution to this problem may entail the design of a device that can be emptied and refilled with a suspension of cells in an extracellular matrix without disturbing the housing and the associated vascular network.

Gene and cell-based therapies

In vivo efficacy studies with gene therapy and non-β cells genetically engineered for insulin secretion are generally limited to small animals. Intraportal injection of recombinant adenovirus expressing furin-compatible insulin under the control of a glucose-responsive promoter containing elements of the rat liver pyruvate kinase gene restored near-normal glycemia in STZ diabetic rats for periods of one to twelve weeks [30]. With hepatic delivery of a recombinant adeno-associated virus expressing a single-chain insulin analog under the control of an L-type pyruvate kinase promoter, Lee and coworkers [28] controlled blood glucose levels in STZ diabetic rats and NOD mice for periods longer than 20 weeks. However, transiently low blood glucose levels observed 3–5 hours after glucose loading indicated a drawback of the transcriptional regulation of insulin expression, which may result in hypoglycemic episodes [28]. Possible approaches towards ameliorating this problem include optimizing the number of glucose-regulatory and insulin-sensing elements in the promoter [122] and destabilizing the preproinsulin mRNA; the latter has been shown to significantly expedite the downregulation of secretion dynamics from transcriptionally controlled cells upon removal of the secretory stimulus [44].

In vivo gene therapy with small animals has also shown success when the target cells for insulin expression were intestinal endocrine K or gastric G cells. Using a transgene expressing human insulin under the control of the GIP promoter, Cheung et al. expressed insulin specifically in gut K cells of transgenic mice, which protected them from developing diabetes following STZ-mediated destruction of the native β cells [43]. Similarly, use of a tissue-specific promoter to

express insulin in gastric G cells of mice resulted in insulin release into circulation in response to meal-associated stimuli, suggesting that G cell insulin expression is beneficial in the amelioration of diabetes [123]. Translation of these approaches to adult and large animals and, eventually, humans, requires the development of effective methods of gene delivery to intestinal endocrine or gastric cells *in vivo* or the development of effective *ex vivo* gene therapy approaches.

In vivo monitoring

Monitoring of the number and function of insulin-secreting cells *in vivo* would provide valuable information directly on the transplant and possibly offer early indications of graft failure. Additionally, in animal experiments, the ability to monitor a transplant non-invasively reduces the number of animals that are needed in the experimental design and helps establish a critical link between transplantation and end-point physiologic effects, the latter commonly being blood glucose levels and animal weight and general well being.

Imaging techniques can provide unique insight into the structure/function relationship of a construct *in vitro* and *in vivo*. There are several imaging modalities that have been applied to monitor tissue-engineered constructs, including computed tomography (CT), positron emission tomography (PET), optical techniques and nuclear magnetic resonance (NMR) imaging and spectroscopy. Among these, NMR offers the unique advantage of providing information on both construct integrity and function without the need to genetically modify the cells (e.g., through the expression of green fluorescent protein or luciferase, used in optical methods) or the introduction of radioactive labels (e.g., PET agents). Furthermore, since magnetic fields penetrate uniformly throughout the sample, NMR is ideally suited to monitor constructs transplanted at deep-seated locations. Its disadvantage is its low sensitivity. Whereas optical and radionuclide techniques can detect tracer quantities, NMR detects metabolites that are available in the millimolar or, in some cases, sub-millimolar range. Nonetheless, NMR has been used successfully to monitor *in vivo* agarose disk-shaped constructs containing mouse insulinoma cells and transplanted in the peritoneal cavity of mice. Construct integrity was visualized by MR imaging and the metabolic activity of the cells within by water-suppressed ^{1}H NMR spectroscopy [124]. Labeling of cells or of the encapsulation matrix with magnetic nanoparticles which can be detected by magnetic resonance [125], and genetically engineering cells so that they express a fluorescent or luminescent marker that can be optically detected [126], are other methods being pursued to track the location and possibly viability and function of transplanted cells *in vivo*. Incorporation of a perfluorocarbon emulsion in the encapsulation matrix may also help assess the metabolic activity of a transplant through measurement of dissolved oxygen levels by ^{19}F NMR [113]. It is expected that development of robust monitoring methodologies will be helpful not only in experimental development studies but also in eventual clinical applications.

Retrievability

The issue of construct retrievability needs to be considered for all pertinent applications. Useful lifetimes of constructs are limited, so repeated transplantation of cells will likely be required. Although guidelines have not been established, it can be reasonably expected that failed constructs will need to be removed periodically. Hence, technologies for graft retrieval under minimally invasive conditions are also likely to be needed.

Concluding Remarks

Tight glycemic regulation in insulin-dependent diabetics significantly improves their overall health and reduces the long-term complications of the disease. A pancreatic substitute holds significant promise at accomplishing this in a relatively non-invasive way. However, to justify the improved outcome, a substitute needs to be not only efficacious in terms of insulin

secretion, but also immunologically acceptable. A number of approaches are being pursued to address this obstacle and additionally develop constructs that can be manufactured at a clinically relevant scale. However, a number of challenges remain to be addressed before reproducible success in large animal models can be claimed and constructs can be moved to clinical trials. Encapsulation in semipermeable barriers improves the immune acceptance of allo- and xenografts, but it is quite doubtful that encapsulation will, by itself, ensure long-term survival and function of xenografts in non-immunosuppressed hosts. The development of specific, benign immune suppression protocols that work in concert with encapsulation appears necessary. Reducing the immunogenicity of transplanted cells and modifying them so that they better withstand the encapsulation and *in vivo* environment are appropriate strategies. To ensure that substitutes can be fabricated at the necessary scale, methods to expand pancreatic islets in culture, to produce β-like cells from stem or progenitor cells, or to generate expandable β cell lines with appropriate phenotypic characteristics need to be pursued. In alternative approaches involving genetic engineering of non-β cells towards the β phenotype, or transdifferentiation of adult non-β cells, the major problem is ensuring precise regulation of insulin secretion by glucose or other physiologic stimuli and phenotypic stability of the engineered cells. This poses a different set of problems which, however, are equally challenging to those of β cell procurement and immune acceptance. Methods for the preservation of substitutes and for the non-invasive monitoring of their integrity and functionality *in vivo* are integral parts of construct development and characterization in regards to construct manufacturing and assessment of *in vivo* efficacy, respectively.

As in many aspects of life, with challenges come opportunities. It is essential that multiple approaches be pursued in parallel, as it is currently unclear which ones will eventually develop into viable therapeutic procedures. If more than one method evolves into a clinical application, this would be welcome news, as it may allow flexibility in the personalization of therapy.

STRUCTURE AND MORPHOLOGY OF THE THYMUS

The mature thymus is a highly dynamic cellular environment, comprised of developing T lymphocytes [1–3] (thymocytes) – which make up over 95% of its cellularity – and a range of stromal elements that includes mesenchymal cells, bone marrow (BM) derived cells, vasculature, and the uniquely specialized thymic epithelium (TE) [4]. This complex cellularity, and the functional importance of the spatial organization of the different cellular components of the organ, present challenges for strategies aiming to generate a functional, self-tolerant T cell repertoire *in vivo* or to develop a functional thymus for transplantation.

The thymus is an encapsulated and lobulated organ, and contains three principal histologically defined regions, the cortex, the medulla and the subcapsule (Fig. 43.1). The capsule and trabeculae consist of a thick layer of connective tissue, and are separated from the cortex by a thin layer of simple epithelium, the subcapsule [4]. The cortex and medulla each contain open networks of epithelial cells, which are densely packed with thymocytes [4–6], and each of the cortical and medullary regions contains several different morphologically and phenotypically distinct epithelial subtypes (see below). These thymic epithelial cells (TEC) are a key element of the thymic stroma, providing many of the organ's specialist functions. The outer cortex also contains fibroblasts, and the organ as a whole is heavily vascularized. BM-derived stromal cells also exist and are found in both compartments, macrophages being distributed throughout the organ, while thymic dendritic cells – which are required for imposition of tolerance on the emerging T cell repertoire – are found predominantly at the cortico-medullary junction (CMJ) and in the medulla [4].

Thymus structure is intimately linked to its function, which is to support T cell development. This encompasses the linked processes of T cell differentiation and T cell repertoire selection, which together ensure that the peripheral T cell repertoire is predominantly populated by T cells that respond to antigens in the context of self-major histocompatibility antigens (MHC), but which are not activated by binding self-peptides. T cell development has been extensively reviewed elsewhere [7–14] and is not discussed in detail herein.

In brief, thymocyte progenitors enter the postnatal thymus at the CMJ, and subsequent T cell development is then regulated such that thymocytes at different stages of development are

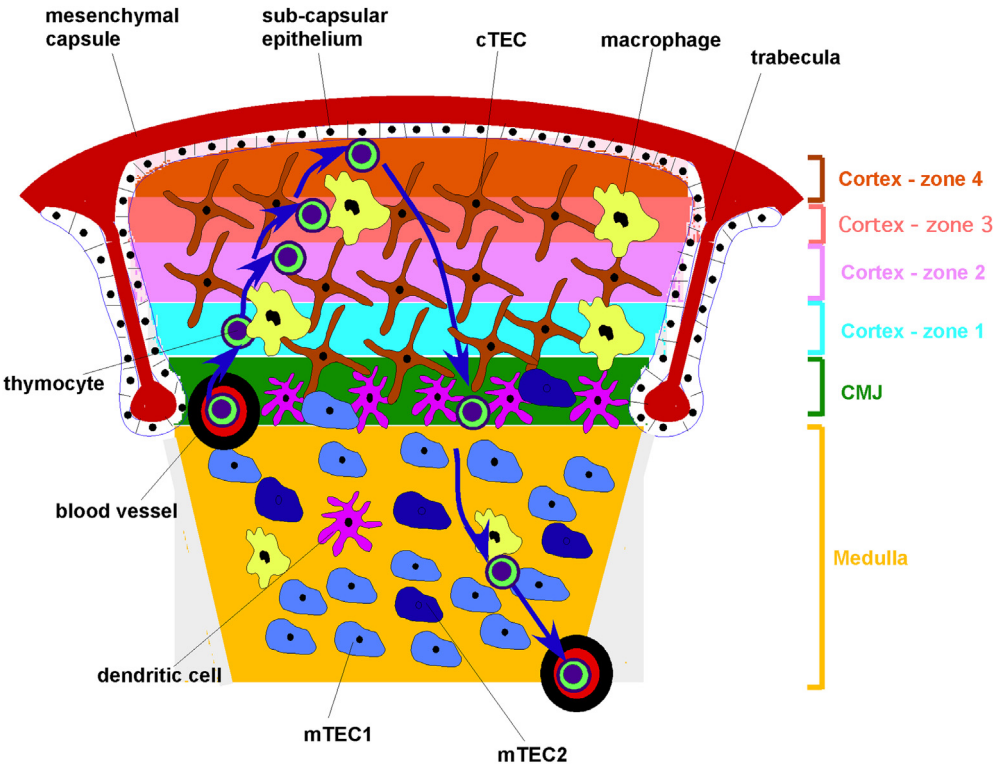

FIGURE 43.1

Histology of the postnatal thymus. The postnatal thymus is surrounded by a capsule consisting of mesenchymal cells and connective tissue, which penetrates into the thymus at regular intervals to form trabeculae. Underlying the capsule and trabeculae is the sub-capsular epithelium consisting of a layer of simple epithelium, which overlies the outer cortex. The cortex is populated with cortical thymic epithelial cells (cTEC), macrophages and developing thymocytes at the double negative (DN) and double positive (DP) stages of development. Thymocytes enter the thymus at the cortico-medullary junction (CMJ) via the vasculature and migrate through the cortex to the subcapsule as they differentiate. The cortex can be divided into four zones based on the differentiation status of thymocytes that reside within it. Thus, zone 1 contains the most immature DN1 thymocytes and zone 4 contains thymocytes undergoing the DN4-DP transition. DP thymocytes are then screened for propensity to recognize self-MHC, a process termed 'positive selection', and those selected to mature into $CD4^+$ or $CD8^+$ single positive (SP) cells migrate into the medulla, where they undergo the final stages of maturation before being exported to the periphery. Central tolerance is established by deletion of self-reactive thymocytes in a process termed 'negative selection', and occurs principally at the cortico-medullary junction and in the medulla: negative selection is mediated both by thymic dendritic cells and medullary TECs. Medullary TECs are also required for the generation of $CD4^+CD25^+$ T regulatory (Treg) cells and natural killer T cells, both of which actively repress self-reactive T cells.

found in different intrathymic locations. The earliest thymocyte progenitors do not express the CD4 or CD8 co-receptors and are referred to as double negative (DN) cells. DN thymocyte progenitors undergo a highly ordered series of maturation stages in the thymic cortex and upregulate expression of CD4 and CD8 to become the major double positive (DP) thymocyte subset. The cortex itself can be subdivided into four regions based on the localization of thymocyte populations at different stages of development. Thus, zone 1 contains the colonizing population of thymocyte progenitor cells; these early thymocytes undergo proliferative expansion in zone 2; T cell lineage commitment is completed in zone 3; and in zone 4, thymocytes differentiate to the DP stage of development, characterized by expression of both CD4 and CD8 co-receptors [15,16](see Fig. 43.1). Only DP thymocytes expressing T cell receptors that mediate low affinity interactions with self-peptide/MHC complexes, presented on cortical epithelial cells, are positively selected. These positively selected thymocytes survive and mature into $CD4^+$ or $CD8^+$ single positive (SP) cells. Thymocytes that have been positively selected then migrate into the medulla [17,18]. The remaining DP thymocytes, which fail positive selection, die by apoptosis [19].

In the medulla, a wide array of self-antigen/MHC complexes presented by epithelial cells and/or dendritic cells induce apoptosis of those SP thymocytes that express T cell receptors with high affinity for self-antigens [20,21]. This process, termed 'negative selection', is essential to reduce the frequency of autoreactive T cells in the peripheral T cell repertoire. SP thymocytes proliferate and undergo the final stages of T cell maturation in the medulla before emigrating from the thymus to enter into the peripheral immune system. Some high affinity self-reactive thymocytes escape negative selection and instead differentiate into T regulatory (Treg) cells, which suppress autoreactive T cells in the periphery and are therefore an important component of self-tolerance [22–24].

Intrathymic migration of thymocytes is at least partly a regulated process. Both the outward migration of thymocytes from the CMJ to the outer cortex [25], and the migration of positively selected cells from the cortex into the medulla [14,17,26–29] are controlled by chemokines.

Thymic epithelial cells

MORPHOLOGICAL AND PHENOTYPIC CLASSIFICATION

The TE within the sub-capsular/sub-trabecular, cortical and medullary regions is highly heterogeneous in terms of immnophenotype, morphological characteristics, and function. Ultrastructural and immunohistochemical analyses have revealed six different subtypes of TEC [30], assigned as 'clusters of thymic epithelial staining' [31–34]. Ultrastructural analysis also revealed large complexes of TECs and developing thymocytes [34], termed 'thymic nurse cells' (TNCs) [35,36]. In addition some epithelia identified in small isolated clusters at the corticomedullary junction were classified as undifferentiated cells [34] which were proposed to be precursors of differentiated epithelial cells [37]. These analyses give an indication of the complexity of the TE, but appear to underestimate the number of TEC subtypes present in the mature organ based on more recent immunophenotyping data.

The different TE subpopulations have now been defined by differential expression of cytokeratins (K) and other markers including MHC Class II. All TEC express MHC Class I, while MHC Class II expression is variable [38–41]. In both the cortex and the medulla, high levels of surface MHC Class II are thought to identify the most mature TECs [42–44].

Two cortical populations have been identified based on cytokeratin expression – a predominant $K5^{-}K14^{-}K8^{+}K18^{+}$ subset and a minor subset consisting of $K5^{+}K14^{-}K8^{+}K18^{+}$ cells that is found at the CMJ and scattered throughout the outer cortex [45]. Most if not all cortical (c) TECs also express the determinants recognized by mAbs Ly-51 [46], which recognizes the homodimeric cell surface glycoprotein BP-1, and CDR1 [47], the target of which is not yet biochemically defined. cTEC additionally express the endocytic receptor CD205 [48–50], and the TEC-specific catalytic proteasome subunit, β5t [51–53].

Most medullary (m) mTEC are $K5^{+}K14^{+}K8^{-}K18^{-}$ [45] and also bind mAb MTS10 [33], while a minor $K5^{-}K14^{-}K8^{+}K18^{+}$ $MTS10^{-}$ mTEC subset also exists [45]. mTECs also express high levels of epithelial cell adhesion molecule (EpCAM)[54], and bind the lectin *Ulex europeus agglutinin-1* (UEA-1)[55], with a subset of $K14^{-}$ mTECs binding UEA-1 at high levels. mTECs can be further subdivided based on CD80 expression, the level of which correlates with degree of functional maturation [42,56]. The lineage relationships between these different TEC subsets, and between cortical and medullary TECs are not well defined and this is a subject of much current investigation.

FUNCTIONAL DIVERSITY

The clear functional dichotomy between the cortical and medullary compartments of the mature thymus (see the section 'Structure and morphology of the thymus' above) is reflected in functional differences between the cortical and medullary TEC. cTEC express Delta-like 4 (Dll4), the Notch ligand required throughout the lifespan for commitment of thymocyte

progenitors to the T cell lineage [57–59], and the chemokine CXCL12 (also known as stromal cell-derived factor 1 alpha (SDF1α)), a regulator of the β-selection checkpoint which controls progression from the DN to the DP stage of thymocyte development [60–62]. Additionally, cTEC express ligands required for positive selection [63]. Notably, β5t is required for generating an optimally selected $CD8^+$ T cell repertoire. The β5t-containing 'thymoproteasome' generates a specific set of self-peptides for presentation by MHC Class I, and in the absence of β5t, a functionally deficient $CD8^+$ TCR repertoire is selected [52,64–66].

mTECs play an essential role in development central tolerance, by mediating both negative selection of the T cell repertoire and development of Tregs and natural killer T cells, both of which actively repress self-reactive T cells [24,67,68]. Additionally, they regulate migration of positively selected thymocytes into the medulla, via expression of CCL19 and 21 [27]. mTECs regulate central tolerance through expression of a broad repertoire of proteins, termed Tissue Restricted Antigens (TRAs), that are otherwise tissue or developmentally restricted [69–71]. Expression of a subset of these genes is regulated by the *Autoimmune Regulator, Aire*, which, within the thymus, is specifically expressed in mTEC [72–78]. In the absence of Aire, mice and humans develop the broad-spectrum autoimmune syndrome, APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy) [75,76]. Aire is expressed in $CD80^{hi}$ mTEC, and most Aire-dependent and Aire-independent TRAs are induced in the $CD80^{hi}$ population [70].

The medulla is also distinguished by corpuscular bodies of epithelial cells known as Hassall's corpuscles. These are particularly prevalent in human thymus and have been shown to express thymic stromal lymphopoietin, a signaling molecule that instructs closely associated dendritic cells in the medulla to induce Treg cells [22,23]. In this regard, mTEC also regulate the accumulation and positioning of dendritic cells in the medulla via secretion of the chemokine XCL1 [79].

IN VITRO T CELL DIFFERENTIATION

The high level of phenotypic and functional heterogeneity demonstrated above presents a significant challenge for attempts to support full T cell development, including proper repertoire selection, *in vitro* and is also pertinent to cell replacement or regenerative strategies for enhancing thymus activity *in vivo*. Currently, it is not possible to reconstitute full thymus function *in vitro* or on transplantation except in cultures based on *ex vivo* thymus tissue. However, *in vitro* systems that fully or partly support T cell differentiation are widely used as a tool for investigating regulation of this process [80] and recently, the use of *in vitro* culture of hematopoietic progenitors to enhance lymphohematopoietic reconstitution following bone marrow transplantation has been investigated. Current approaches to *in vitro* T cell generation are summarized below.

Fetal thymic organ culture (FTOC) utilizes *ex vivo* thymic lobes, usually derived from E15.5–E16.5 mouse embryos or second-trimester human fetuses, to support the differentiation of T cell progenitors from endogeneous or exogenous sources [81–85]. The technique of reaggregating fetal thymic organ culture (RFTOC), in which defined TEC subpopulations are obtained by cell purification techniques, reaggregated with fibroblasts and defined lymphocyte populations, and then cultured further *in vitro*, was developed as an extension of FTOC and has proved invaluable for assessing the role of individual stromal components during specific stages of T cell maturation [63,86]. This approach has also been combined with grafting, typically under the kidney capsule, as grafted RFTOC typically exhibit better cortical and medullary patterning than *in vitro* cultured RFTOC, and has been adapted for testing the potency of different fetal and adult TEC subpopulations from mouse, rat and human [87–93]. A recently developed protocol for generating RFTOC has improved the reproducibility of the technique and has also incorporated the capacity to control the juxtaposition of the different cell types included in the cellular reaggregate [94].

A related approach demonstrated generation of an *in vitro* 'thymic organoid' by seeding a tantalum-coated carbon matrix with *ex vivo* murine thymic stromal cells [95]. When these structures were co-cultured with human $CD34^+$ hematopoietic progenitors, efficient generation of mature CD4 and CD8 SP T cells was observed after 14 days. The T cells generated in this system were functional, as demonstrated by their proliferative response to mitogenic stimuli, and demonstrated a diverse TCR repertoire comparable to that of peripheral blood T cells [95]. These findings demonstrate that the utilization of three-dimensional matrices in conjunction with thymic stromal cells can provide an efficient and reproducible method of *in vitro* T cell generation. However, this approach relies on seeding with *ex vivo* thymus tissue and therefore is not highly scalable.

The demonstration that transfection of the BM stromal cell line OP-9 with the Notch ligand Delta-like 1 conferred the capacity to support T cell differentiation from a variety of hematopoietic progenitors in monolayer culture represented a major breakthrough [96]. Using this system, DP thymocytes can be generated efficiently from mouse fetal liver-, adult bone marrow-, or Embryonic Stem (ES) cell-derived hematopoietic progenitors; $CD8^+$ SP T cells are also produced inefficiently although $CD4^+$ SP T cells are largely absent [96,97]. This system was also shown to support T cell development from human cord blood- and human bone marrow-derived $CD34^+$ cells [98–101]. OP9 cells stably transfected with Dll4 also efficiently support generation of DP cells [102], and in this system lower levels of Dll4 than DL1 are required for T lineage commitment [102], consistent with the non-redundant role of Dll4 in T cell lineage commitment *in vivo* [57,58].

While neither the OP9-DL1 nor the OP9-Dll4 system represents a scalable means of supporting the *in vitro* generation of mature T cells for transplantation [103], due to their limited capacity to support positive and negative selection of the T cell repertoire, these systems have been widely used to dissect cellular and molecular regulation of T cell differentiation in mouse and human (see e.g., references [16,104]). Additionally, in a powerful recent development, they have been used to produce expanded pools of hematopoietic progenitors for transplantation [105–109]. In particular, adoptive transfer of OP9-DL1-produced $CD4^-CD8^-$ DN thymocytes in a mouse model of hematopoietic stem cell transplantation resulted in improved T cell reconstitution [105]. Similarly, transplantation of human $CD34^+CD7^{hi}$ cells produced by *in vitro* culture of umbilical cord blood or adult hematopoietic stem cells resulted in the efficient engraftment of the thymus of immunodeficient mice [106,108]. Furthermore, in preliminary clinical trial data, transplantation of OP9-DL1-cultured hematopoietic progenitors, together with a single unit of cord blood, resulted in more rapid recovery of neutrophil numbers following a myeloablative preparative regimen than the currently standard procedure of transplantation of a double unit of cord blood [107].

Thus, *in vitro* approaches based on generating and/or expanding hematopoietic progenitor cell types appear poised for translation. Progress towards the goals of generating transplantable T cell repertoires *in vitro*, however, is likely to require a combination of stem cell-based approaches coupled with tissue engineering to pattern the resulting organoid. Furthermore, while proof of principle studies have demonstrated the feasibility of restoring adaptive immunity in patients by thymus transplantation [110–112], this approach currently relies on transplantation of human neonatal thymus tissue. Stem cell and tissue-engineering technologies may thus provide an alternative source of cells, allowing thymus transplantation to be more widely adopted. In the following sections, we summarize current knowledge of molecular and cellular control of thymus development and maintenance as related to these aims. We focus primarily on the TEC compartment, based on the critical function of these cells in the thymus. We also discuss our current understanding of parathyroid development, since parathyroid replacement is also a clinically important goal.

THYMUS ORGANOGENESIS

Cellular regulation of early thymus organogenesis

The thymus arises in the pharyngeal region of the developing embryo, from a common primordium with the parathyroid gland. This common primordium develops from the third pharyngeal pouch (3PP), one of a series of bilateral outpocketings of pharyngeal endoderm that form sequentially in a rostral to caudal manner.

In the mouse, outgrowth of the 3PP occurs from approximately E9.0 [113]. At this stage, the epithelium of the 3PP consists of a single layer of columnar epithelium surrounded by a condensing population of neural crest cells (NCC) that will eventually form the capsule [114–117]. Overt thymus organogenesis is evident from between E10.5 and E11.0, at which stage the epithelium begins to proliferate, assuming a stratified organization [118]. At E12.5, the primordia separate from the pharynx and begin to resolve into discrete thymus and parathyroid organs. The thymus primordium subsequently migrates to its final anatomical location at the midline, following the path of the carotid artery and vagus nerve, while the parathyroid primordium associates with the lateral margins of the thyroid [119,120]. In the case of the thymus, this migration is active, and is regulated by NCC through EphB-ephrin-B2 interactions [121–123].

Within the common primordium, the prospective thymus is located in the ventral domain of the third pouch, and the prospective parathyroid in the dorsal aspect. Patterning of these prospective organ domains occurs early in organogenesis, as the parathyroid domain is delineated by the transcription factor Gcm2 as early as E9.5 (see the section Specification of the thymus and parathyroid).

The mesenchymal capsule surrounding the thymus primordium is derived from the migratory neural crest, a transient population formed between the neural tube and the surface ectoderm. In the mouse, NCCs migrate into the pharyngeal region from E9.0. Elegant chick-quail chimera studies provided the first evidence that NCCs are the source of mesenchymal cells in the thymus [115], which has been confirmed in the mouse by heritable genetic labeling *in vivo* [114,117,124].

Colonization of the mouse thymus with hematopoietic progenitor cells occurs between E11.25 and E11.5 [125–127]. As vascularization has not occurred by this stage, the first colonizing cells migrate through the peri-thymic mesenchyme into the TE. These cells have been reported to exhibit comparatively low T cell progenitor activity, while a second colonizing wave which arrives between E12 and E14 appears to display much higher levels of T cell potential upon *in vivo* transfer [128].

Following the formation of the thymic primordium and the commitment of the epithelial cells to the TEC lineage, the thymus undergoes a period of expansion involving both the proliferation of stromal cells and an increase in thymocyte numbers. *In vitro* experiments have demonstrated that both Fgf7 and Fgf10, which are expressed by the perithymic mesenchyme [129], can stimulate the proliferation of fetal TECs [130,131]. Furthermore, thymi in mice lacking *Fgfr2IIIb*, the receptor for Fgf7 and Fgf10, are severely hypoplastic although able to support T cell differentiation, and *Fgf10*$^{-/-}$ mutants also exhibit hypoplastic thymi [129]. Similarly, expression of a soluble dominant negative FgfR2IIIb fusion protein by thymocytes resulted in reduced thymic size and cellularity, although thymocyte development was unperturbed [132].

Concomitantly with this proliferation TEC differentiation commences, with the first evidence of differentiation into cortical and medullary cell types appearing by E12.5 [44,89]. Development of the two compartments then proceeds in a lymphocyte independent manner until E15.5 [133,134]. The expression of MHC Class II and MHC Class I on the surface of TEC is first detected at E12.5, and ~E16 respectively [41,44,135,136] and is followed by the appearance

of $CD4^+$ and $CD8^+$ SP thymocytes at E15.5 and E17.5 [41,135]. Although a functional thymus is present in neonates, the full organization of the stroma is not achieved until 2–3 weeks postnatally in the mouse.

We note that the precise timings of developmental events is known to vary between mouse strains, and the Blackburn lab has observed that the thymic primordium in C57BL/6 embryos is consistently developmentally retarded by at least 12 hours compared to CBAxC57BL/6 F1 embryos at E12.5. Hence, the timings reported for particular events in thymus organogenesis may vary slightly due to variations in genetic background.

Origin of thymic epithelial cells

The precise embryonic origins of the TE were a matter of long-standing controversy [88,126,137–142]. However, definitive evidence for a single endodermal origin in mice was provided through histological, fate and potency analysis of the pharyngeal region [113]. These data demonstrated that although the 3PP endoderm and third pharyngeal cleft ectoderm make contact at E10.5, these germ layers subsequently separate, with apoptosis occurring in the contact region. Furthermore, lineage tracing of pharyngeal surface ectoderm of E10.5 mouse embryos failed to find evidence for an ectodermal contribution to the thymic primordium and transplantation of pharyngeal endoderm isolated from E8.5–E9.0 embryos (i.e., prior to initiation of overt thymus organogenesis) indicated that the grafted endoderm was sufficient for complete thymus organogenesis [113], similar to previous results obtained using chick-quail chimeras [139]. Thus, pharyngeal endoderm alone is sufficient for the generation of both cortical and medullary thymic epithelial compartments.

Thymic epithelial progenitor cells (TEPC)

The phenotype of TEPC has been of considerable interest, and remains an area of on-going investigation. Analysis of a subset of human thymic epithelial tumors provided initial evidence supporting the existence of a common TEPC activity; these tumors contained cells that could generate both cortical and medullary subpopulations, thus suggesting that the tumorigenic targets were epithelial progenitor/stem cells [143]. In addition, ontogenic studies suggested that the early thymus primordium in both mouse and human might be characterized by co-expression of markers that later segregated to either the cortical or medullary epithelium [144].

The first genetic indication of a TEPC phenotype was provided by a study addressing the nature of the defect in *nude* mice [145], which fail to develop a functional thymus due to a single base deletion in the transcription factor Foxn1 [146,147]. Analysis of allophenic *nude*-wild-type aggregation chimeras demonstrated that cells homozygous for the *nude* mutation were unable to contribute to the major TE subsets, establishing that the *nude* gene product (Foxn1) is required cell-autonomously for the development and/or maintenance of all mature TEC [145]. However, a few *nude*-derived cells were present in the thymi of adult chimeras and phenotypic analysis indicated that these cells expressed determinants reactive to mAbs MTS20 [33] and MTS24, but did not express markers associated with mature TEC including MHC Class II. These findings suggested that in the absence of *Foxn1*, TE lineage cells underwent maturational arrest and persisted as $MTS20^+24^+$ progenitors [145]. This hypothesis was confirmed by an elegant study in which clonal reactivation of a conditional null allele of *Foxn1* in the neonatal thymus was shown to result in generation of functional thymus tissue containing organized cortical and medullary regions [148] – demonstrating unequivocally that in the absence of Foxn1, a common TEPC persists in the thymic rudiment.

Further data regarding the phenotype of TE progenitors came from analysis of mice with a secondary block in thymus development resulting from a primary T cell differentiation defect. The thymi of postnatal *CD3e26tg* mice, in which thymocyte development is blocked at the $CD44^+CD25^-$ TN1 stage [149,150], principally contain epithelial cells that

co-express K5 and K8 [45] — which, in the normal postnatal thymus, are predominantly restricted to the medulla and cortex respectively and are co-expressed by only a small population of TEC at the CMJ. In this study, Klug and colleagues demonstrated that transplantation of *CD3e26tg* thymi into *Rag1*$^{-/-}$ mice, which sustain a later block in T cell differentiation, resulted in the development of K5^{-}K8^{+} cells, suggesting that the K5^{+}K8^{+} cells are progenitors of cTEC [45].

The phenotypic and functional properties of MTS20^{+}24^{+} cells within the fetal mouse thymus were addressed directly in several studies. Analysis of the functional capacity of isolated MTS20^{+}24^{+} cells and MTS20^{-}24^{-} cells via ectopic transplantation demonstrated that MTS20^{+}24^{+} TEC were sufficient to direct establishment of a functional thymus containing both cortical and medullary TEC populations [89,90]. These studies clearly identified fetal MTS20^{+}24^{+} TEC as TEPC, but lacked clonal evidence for the existence of a common TEPC. Expression profiling subsequently identified the target of MTS20 and MTS24 as the orphan cell surface protein Plet1 [151].

Evidence for a common TEPC has been presented in two independent studies. A short-term retrospective clonal lineage analysis demonstrated the presence of both a common TEPC able to generate both cTEC and mTEC, and cTEC-restricted TEPC, in the neonatal thymus [148]. In an elegant extension of these experiments, clonal reversion of a *Foxn1* null allele resulted in the generation of small regions of thymus tissue that contained both cortical and medullary TEC [148], providing conclusive evidence for the existence of a common progenitor in *Foxn1*$^{-/-}$ mice, as discussed above. In a complementary study, the existence of a common TEPC in the E12.5 thymus was demonstrated by transplantation of single E12.5 Plet1^{+} TEC [92], establishing that the Plet1^{+} TEC population originally identified as TEPC indeed contains a common TEPC.

The view that Plet1 is a marker for TEPC was challenged in a recent report demonstrating, in contrast to initial conclusions [90], that at E14.5 both the Plet1^{+} and Plet1^{-} TEC compartments can form a functional thymus upon transplantation [152]. However, a key difference between these studies is that Gill and colleagues transplanted limiting numbers of Plet1^{+} TEC [90], whereas in the later study cell number was not limiting [152]. Furthermore, Rossi and colleagues did not provide phenotypic analysis of the input populations and therefore could not determine precursor:progeny relationships — a caveat of particular importance since the Plet1-negative TEC population at E14.5 and subsequent developmental stages is highly heterogeneous [44]. Rossi's findings are thus consistent with the existence of intermediate progenitor populations restricted to cortical and medullary TEC fates downstream of Plet1^{+} TEC in the thymic epithelial differentiation hierarchy, which can together generate a fully functional thymus. No information yet exists regarding the reversibility or otherwise of the early steps in thymic epithelial lineage differentiation, and therefore other alternative explanations for these findings are also possible.

Taken together, the available genetic and functional analyses strongly support Plet1 as a marker of the founder cells of the thymic epithelial lineage, and demonstrate loss of Plet1 expression with the onset of differentiation in the fetal thymus [44]. The functional relationship between fetal Plet1^{+} TEPC and the population of Plet1^{+} mTEC of the postnatal thymus is however not clear. While the Plet1^{+} TEC population isolated from the fetal thymus at stages up to and including E16.5 could initiate *de novo* thymus organogenesis upon ectopic transplantation, this capacity is lost by E18.5 [152,153], indicating a clear functional difference between the fetal and postnatal Plet1^{+} TEC populations. At the present time, both the function of postnatal Plet1^{+} TEC and the phenotypic identity of postnatal TEPC remain to be determined. Nonetheless, the identification of Plet1^{+} as a marker enabling isolation of the earliest fetal progenitor cells for the TEC lineage [44,89,90,151], coupled with the demonstrations that these cells are common TEPC [92] and can generate an organized, functional thymus upon

transplantation [89,90], points to the possibility of using these Plet1$^+$ TEPC as a source of TEC in generation of *in vitro* thymus organoids and in thymus transplantation.

The existence of intermediate mTEC- and cTEC-restricted progenitors in the fetal and postnatal thymus has now been demonstrated by a number of studies. Analysis of MHC Class II mismatched chimeras showed that the medullary epithelium initially forms as individual clonally-derived islets, and that these coalesce later in development [88]. This study demonstrated the presence of mTEC sub-lineage-restricted progenitors (mTEPC) until at least E15.5 [88]. Furthermore, medullary sub-lineage-restricted TEPC can be isolated from E13.5 fetal thymus based on expression of Claudin 3 (Cldn3) and Cldn4 [154], and the UEA1$^+$ subset of fetal Cldn3,4$^+$ TEC was shown to represent the precursor of the clinically important Aire$^+$ subset of mTECs [154]. Cldn4 co-localizes extensively with Plet1 at early developmental stages, and Plet1$^+$ cells are a minor subset of Cld4$^+$ cells in the postnatal thymus, potentially indicating a precursor-progeny relationship between Plet1$^+$ TEC and the broader Cld4$^+$ population [151]. A cTEC progenitor activity has also been identified within the CD205 TEC population of the fetal thymus [50], the descendants of which are suggested to acquire more differentiated characters in a stepwise fashion. CD205 is a broad marker of cTEC in the postnatal thymus and identification of cTEC progenitors within this population is therefore an area of current investigation.

Human thymus development

Early human thymus development closely parallels that of the mouse; the human thymus forms from the 3PP in a common primordium with the parathyroid gland. The 3PP is evident from early week 6 of human fetal development, and initially develops as a tube-like lateral expansion from the pharynx, which makes contact with the ectoderm of the third pharyngeal cleft [155,156]. A single endodermal origin has not been demonstrated directly for the human TE, however, since the thymus has a single endodermal origin in mice and avians [113,139] it is reasonable to assume that this is also the case in humans. Within the human common thymus/parathyroid primordia, the thymus and parathyroid domains are located ventrally and dorsally, and are surrounded by condensing NCC-derived mesenchyme from the onset of development [155]. The thymus component of this primordium begins to migrate ventrally from week 7 to mid-week 8, forming a highly lobulated, elongated, cord like structure. The upper part of this structure normally disappears at separation of the two organ rudiments, leaving the parathyroid in the approximate location in which it will remain throughout adulthood [155]. The bilateral thymic primordia continue to migrate towards the midline, where they eventually meet and attach at the pericardium — the permanent location of the thymus into adulthood — by mid-week 8 [155]. As in the mouse [89], the human early thymus primordium appears to contain undifferentiated epithelial cells which express some markers that are later restricted to either cortical or medullary compartments [144]. Nascent medullary development is evident from week 8, and by week 16 distinct cortical and medullary compartments are present. Other cell types penetrate the thymus from week 8, including mesenchymal, vascular and lymphoid cells, and mature lymphocytes begin to leave the thymus to seed the peripheral immune tissues between weeks 14 and 16 [157,158].

Cervical thymus in mouse and human

The presence of a cervical thymus in both animals [159] and humans has been recorded for some time [157,160,161], and recent publications indicate that an ectopic cervical thymus is also a common occurrence in at least some mouse strains [162,163]. In terms of size and cellularity, the cervical thymus is much smaller than the thoracic thymus, however, the morphology of the two structures is very similar, with organized cortical and medullary regions and similar expression patterns of cytokeratin molecules [162,163]. Furthermore, the cervical thymus expresses the transcription factors Foxn1 and Aire and can produce functional T cells

that are tolerant to self-antigens [162,163], although the range of self-antigens present may be more restricted than in the thoracic thymus [162].

The origin of the cervical thymus is at present unclear. A plausible hypothesis is that it may arise from remnants of the thymus domain of the 3PP that become detached from the organ during separation of the thymus and parathyroid domains. Several alternative explanations exist, and the identification of cervical thymi in mice will allow the embryonic origins of these structures to be addressed experimentally. It appears that in mice the cervical thymus may mature postnatally [163], while in humans, it is clearly present in second trimester of fetal development. The presence of Foxn1+ epithelial cells has not been reported in the cervical regions of developing mouse embryos. However, as it is now clear that cells specified to the TE lineage retain their identity in the absence of Foxn1 expression [148], it remains possible that thymus-fated cells that are Foxn1-negative may be present outside the thoracic thymus and serve as an origin for cervical thymi.

Molecular regulation of thymus and parathyroid organogenesis

Although the regulation of thymus organogenesis is incompletely understood, studies of classical and genetically-engineered mouse mutants have begun to reveal a network of transcription factors and signaling molecules that act in the pharyngeal endoderm and surrounding mesenchyme and mesoderm to regulate thymus and parathyroid organogenesis. Understanding of this network may facilitate the development of robust protocols to direct differentiation of embryonic stem cells or iPS cells *in vitro*. By recapitulating the stepwise restriction of differentiation potential observed *in vivo*, a highly enriched anterior foregut endoderm population can be obtained from pluripotent cell-derived definitive endoderm [164,165]. Further manipulation of these cells or cells isolated *ex vivo*, informed by the developmental events discussed below, may allow the controlled expansion and differentiation of functionally validated thymus and parathyroid progenitors isolated *ex vivo* or generated by differentiation of pluripotent stem cells *in vitro*. The principal components of this network are discussed below and summarized in Fig. 43.2.

MOLECULAR CONTROL OF EARLY ORGANOGENESIS

The T-box transcription factor Tbx1, retinoic acid (RA) signaling, and fibroblast growth factor 8 (Fgf8) signaling have been implicated as important regulators of the earliest events in thymus organogenesis, which occur prior to overt organ development and relate to molecular control of 3PP formation.

Tbx1 is the gene responsible for cardiovascular and glandular defects in *Df1* mice, which carry a large deletion of chromosome 16 [166]. *Df1* heterozygotes closely phenocopy a human condition known as 22q11.2 deletion syndrome (22q11.2DS, or DiGeorge Syndrome) in which a deletion in chromosome 22 covering an interval of approximately 30 genes [167], results in a range of defects including thymus aplasia or more frequently, hypoplasia [168,169].

During development, *Tbx1* is expressed in the pharyngeal endoderm and the core mesenchyme of the pharyngeal arches from approximately E7.5 and continues to be expressed in a variety of structures until E12.5 [170–172]. *Tbx1* mutants have severe defects throughout the pharyngeal region, including abnormal patterning of the first pharyngeal arch, hypoplasia of the second arch and absence of the third and fourth arches and pouches [173]. As a result, $Tbx1^{-/-}$ mutants lack both thymus and parathyroids and display a spectrum of cardiovascular abnormalities and craniofacial defects [173].

The phenotype of $Tbx1^{-/-}$ animals suggests an important role in segmentation of the pharyngeal region. Supporting evidence for this hypothesis was provided by an elegant study addressing the temporal requirement for *Tbx1* in the development of the pharyngeal region.

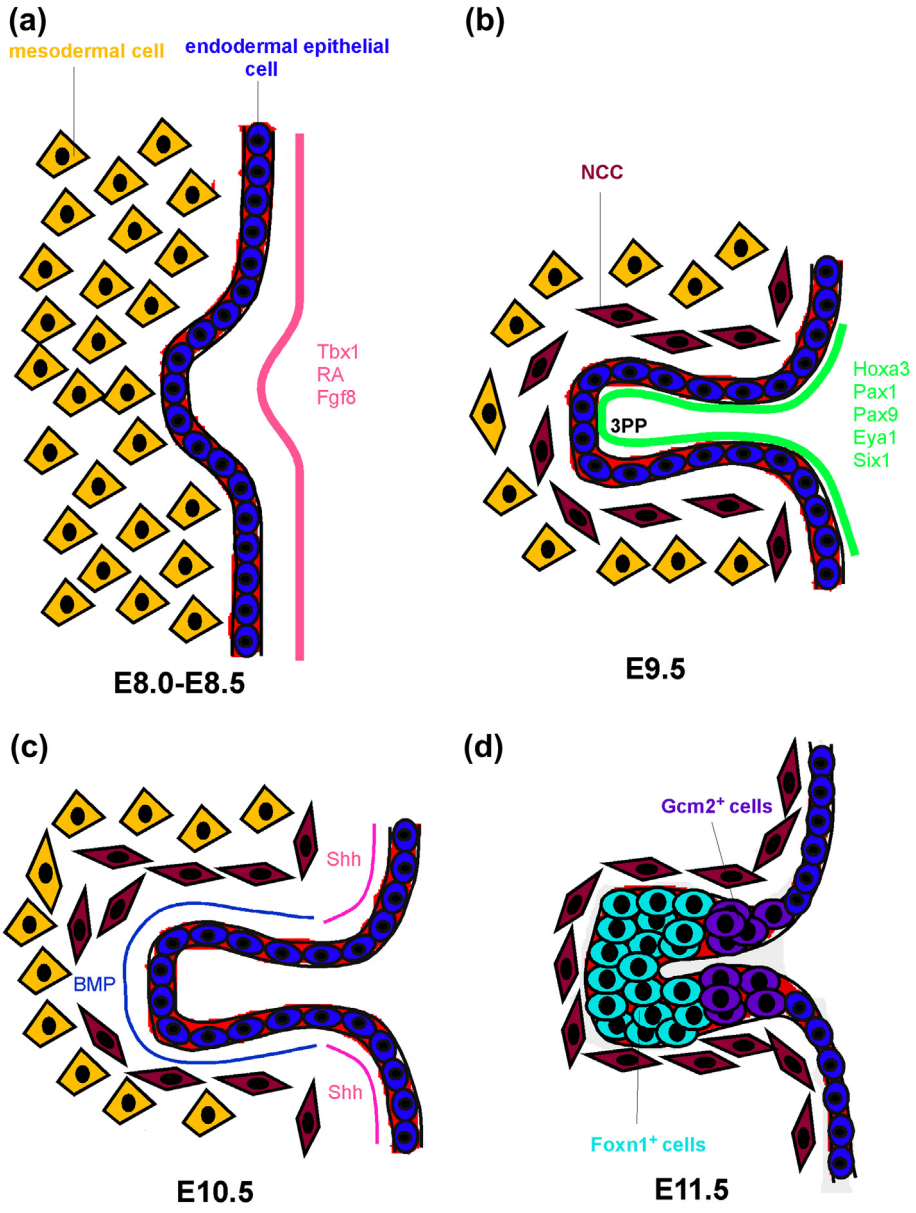

FIGURE 43.2

Molecular regulation of early thymus organogenesis. (a) At approximately E8.0-E8.5 the formation of the third pharyngeal pouch (3PP) is initiated in the pharyngeal endoderm and is dependent on the expression of Tbx1 and retinoic acid (RA), and on fibroblast growth factor 8 (Fgf8) signaling (pink). (b) At E9.5 the 3PP has formed and is surrounded by mesenchymal cells of mesodermal and neural crest cell (NCC) origin. Continued development is dependent on the expression of the transcription factors Hoxa3, Pax1, Pax9, Eya1 and Six1 (green). (c) Bone Morphogenetic Protein (Bmp) (blue) and Sonic Hedgehog (Shh) (pink) signaling occur at E10.5 in the 3PP endoderm in the ventral and dorsal aspects respectively. These factors may be involved in the specification of the 3PP into thymus and parathyroid specific domains. (d) At E11.5 epithelial cells in the ventral domain of the 3PP express the transcription factor Foxn1 (light blue) and will form the thymic epithelium. Epithelial cells in the dorsal domain express the transcription factor Gcm2 (purple) and will form the parathyroid gland. The differentiation and maintenance of both of these cell types are dependent on these factors. Note that throughout this figure, gene expression domains are annotated only for the endoderm. Many of the factors shown are also expressed in the mesoderm and/or mesenchyme of the pharyngeal arches, and/or in the pharyngeal ectoderm, as described in the text.

Deletion of *Tbx1* at E8.5, during the formation of the 3PP, resulted in complete absence of thymus and parathyroid, and complementary fate mapping experiments demonstrated that cells that express *Tbx1* at E8.5 contribute significantly to the thymic primordium [174]. However, although deletion of *Tbx1* at E9.5/E10.5 (after initial formation of the 3PP) caused

morphological defects in the thymus, these were not as severe as the aplasia seen after deletion at E8.5, and fate mapping of cells expressing *Tbx1* at E9.5/E10.5 revealed only a small contribution to the thymus [174].

Taken together, these data suggest that Tbx1 is required for establishment of the 3PP, but is not directly required for subsequent thymus development. Furthermore, although *Tbx1* is haplo-insufficient with respect to thymus development [175], the basis of this insufficiency remains to be determined and may result either from secondary effects resulting from mild defects in pouch formation, or dosage effects related to factor provision by non-NCC mesenchymal cells.

A role for RA in 3PP formation was suggested by experiments in which RA antagonist was administered to whole embryo cultures. Here, blockade of RA signaling at E8.0 resulted in the absence of the growth factors Fgf8 and Fgf3 in the 3PP endoderm, and impaired NCC migration to the third and fourth pharyngeal arches [176]. Expression of the transcription factor Pax9 (see below) was also absent in the 3PP, but was expanded in the 2PP endoderm. These data suggest that RA signaling is required for the specification of the 3PP, which confers subsequent competence to support NCC migration. *In vivo* evidence for a role for RA signaling was subsequently provided by the finding that fetal mice lacking RA receptors α and β display thymus agenesis and ectopia [177].

There is considerable evidence that Fgf8 is required during the early stages of thymus and parathyroid development. Fgf8 is expressed in the early gut endoderm and in the endoderm and ectoderm of the pharyngeal pouches and clefts. Mice carrying hypomorphic alleles of *Fgf8* show defects in thymus development ranging from hypoplasia to complete aplasia [178,179]: the initial impairment in thymus and parathyroid organogenesis is likely to occur at an early stage in development in these mice, as the third and fourth pharyngeal arches and pouches are usually hypoplastic/aplastic, in addition to other abnormalities in the pharyngeal region [178,179].

In terms of the cell types affected by impaired Fgf8 signaling, similarities between the phenotype of Fgf8 hypomorphs and the spectrum of abnormalities found during experimental NCC ablation [180,181] suggest that the glandular defects may result from defective NCC migration/differentiation or survival. In support of this, NCC of Fgf8 hypomorphs show increased levels of apoptosis [178,179] and reduced expression of *Fgf10*, which mediates expansion of the thymic primordium from E12.5 [129], in the neighboring NCC mesenchyme [179]. There is also a mild reduction in the expression of genes associated with differentiated NCC [178] suggesting that the maintenance of NCC is perturbed.

Taken together, these data implicate Fgf8 in maintaining a competent NCC population that can contribute to thymus organogenesis. However, Fgf8 may also act specifically on the 3PP endoderm, since ablation of Fgf8 in the endoderm and ectoderm, or ectoderm alone, results in different phenotypes. Ablation in the ectoderm alone causes vascular and craniofacial defects as seen in Fgf8 hypomorphs [182] whereas when Fgf8 is also deleted in the endoderm, glandular defects are evident, including thymus hypoplasia and ectopia [182]. The NCC defects were the same in both cases.

Further insight into the role of Fgf signaling in regulation of thymic primordium development was provided by a detailed study of Fgf signaling components during thymus organogenesis. This revealed a complex picture in which Fgf signaling is modulated by expression of Sprouty 1 and 2, such that although the 3PP expresses both Fgfs and FgfR, signaling in the endodermal component of the thymus is restricted by Sprouty 1 and 2 [183]. Thus, while the importance of Fgf8 signaling in regulating development of the 3PP is clear, further studies are required to understand the temporal requirements for this pathway and its interplay with other signaling pathways involved in thymus and parathyroid organogenesis.

TRANSCRIPTION FACTORS AND REGULATION OF 3PP OUTGROWTH

After initial 3PP formation, continued development of the common primordium is dependent on a complex networks of transcription factors, including Hoxa3, Pax1, Pax9, Eya1, Six1 and Six4; all of these factors are expressed in the 3PP endoderm from E9.5–E10.5 and, with the exception of Pax1 and Pax9, are also expressed in associated NCC and ectoderm.

Absence of functional Hoxa3 or Eya1 results in the failure to initiate overt thymus and parathyroid organogenesis once the 3PP has formed, revealing the essential roles of these factors [119,120,184,185]. *Tbx1* and *Fgf8* are both downregulated in the 3PP of *Eya1*$^{-/-}$ mice at E9.5 [185], indicating that Eya1 plays a role in regulation of these factors. Lack of Six1, Six1 and 4, Pax1 or Pax9 causes much less severe phenotypes. The common primordium begins to develop in *Six1*$^{-/-}$ mice, and patterning into thymus and parathyroid domains (see the section 'Specification of the thymus and parathyroid') is initiated. However, subsequent apoptosis of endodermally-derived cells in the common primordium leads to complete disappearance of the organ rudiment by E12.5 [185]. A similar phenotype is evident in *Six1*$^{-/-}$;*Six4*$^{-/-}$ embryos, though the size of the primordium is further diminished in the double mutants indicating synergy between these gene products [185]. *Pax9* loss of function mutations result in formation of ectopically located thymic primordia, which form within the laryngeal cavity, rather than within the pharyngeal arch mesoderm. These primordia fail to migrate to the mediastinum, and exhibit severe hypoplasia from E14.5. However, the thymic lobes are vascularized, contain both thymocytes and mesenchymal cells, and express Foxn1 [186]. *Pax1*$^{-/-}$ mutants show relatively mild thymus hypoplasia and aberrant TEC differentiation [187–189]. Since *Pax1* and *Pax9* are highly homologous, these phenotypes may reflect functional redundancy, as demonstrated in other tissues [190,191].

Expression of *Hoxa3*, *Eya1* and *Six1* in multiple germ layers complicates interpretation of the respective null phenotypes for these genes. However, Hoxa3 appears to regulate *Pax1* and *Pax9* either directly or indirectly, since *Pax1* and *Pax9* expression is initiated normally in *Hoxa3*$^{-/-}$ mutants but fails to be maintained at wild-type levels beyond E10.5 [120]. Furthermore, *Hoxa3*$^{+/-}$;*Pax1*$^{-/-}$ compound mutants show delayed separation of the thymus/parathyroid primordium from the pharynx, resulting in thymic ectopia and a more severe hypoplasia than that seen in *Pax1*$^{-/-}$ single mutants [121], indicating that these factors function in the same network.

It has been suggested that Eya1 and Six1 act downstream of the *Hox/Pax* genes, as *Eya1*$^{-/-}$ embryos show normal expression of *Hoxa3*, *Pax1* and *Pax9* but reduced expression of *Six1* in the endoderm of the third and fourth PP and ectoderm of the second, third and fourth pharyngeal arches [184]. However, while it is likely that Six1 acts downstream of Eya1, recent evidence indicates that Eya1 and Six1 do not act downstream of the Pax genes. This has been shown by analysis of *Pax9*$^{-/-}$ and *Pax1*$^{-/-}$*Pax9*$^{-/-}$ mutants, which show normal expression of *Eya1* and *Six1* in the 3PP, and *Eya1*$^{-/-}$;*Six1*$^{-/-}$ double mutants, which lack expression of *Pax1* in the E10.5 3PP [185]. Interestingly, *Pax9* expression is unaffected in *Eya1/Six1* double mutants [185]. However, it remains possible that *Eya1* and *Six1* may be regulated by Hoxa3 independently of Pax1 and Pax9 function.

A recent report has demonstrated that mice homozygous for a null mutation in *Ripply3*, a RA signaling target, have ectopic and hypoplastic thymi, with the thymic lobes being located in the oropharynx of *Ripply3*$^{-/-}$ embryos, similar to *Pax9* null thymi [192,193]. *Ripply3* was shown to repress *Tbx1* transcription in an *in vitro* Luciferase assay system, and the expression domain of *Pax9* was increased in the pharyngeal region of E9.5–E10.5 *Ripply3*$^{-/-}$ mice [192]. Furthermore, a 3.7kb promoter region of *Pax9* was shown to be Tbx1 responsive in a Luciferase assay. These studies together suggest that the expression of *Tbx1* may regulate *Pax9* expression.

The data reviewed above indicate the power of compound mutant analysis for unraveling genetic interactions. Overall, the complexity of these data suggests it is likely that all or some of these factors form a stable network, which is sustained by complex feedback and autoregulatory loops. Further work is required to elucidate exactly how these and other transcription regulators cooperate in the development of the 3PP endoderm, and to determine the precise role of each of these factors at the cellular level.

SPECIFICATION OF THE THYMUS AND PARATHYROID

Prior to the overt formation of the thymus and parathyroid primordia, the 3PP is specified into organ specific domains. At E9.5, epithelial cells within the anterior dorsal aspect initiate expression of Gcm2 [197], a transcription factor required for the development of the parathyroid [194]. Current evidence suggests that Gcm2 acts downstream of Eya1 and Hoxa3, as *Gcm2* is downregulated in *Hoxa3*$^{-/-}$, *Eya1*$^{-/-}$ and *Hoxa3*$^{+/-}$;*Pax1*$^{-/-}$ compound mutant mice [121,184,140]. *Gcm2* is also directly regulated by Gata3, with the result that in E11.5 *Gata3*$^{+/-}$ mice, a lower proportion of cells in the 3PP expresses *Gcm2* [195]. The first known thymus specific transcription factor, Foxn1, is expressed at functionally relevant levels in the ventral domain of the 3PP from approximately E11.25, although low levels can be detected by polymerase chain reaction (PCR) from E10.5 [196,197]. Foxn1, a forkhead class transcription factor, is required for TEC differentiation and hair development, and is discussed in more detail in the section 'Foxn1 and regulation of TEC differentiation'.

The expression patterns of *Foxn1* and *Gcm2* clearly define the thymus and parathyroid domains of the 3PP. However, these factors do not appear to be responsible for specification of their respective organs, indicating that specification must be mediated by an upstream factor or factors. With respect to Foxn1, this model is supported by the finding that, epithelial cells in the ventral domain of the E11.5 3PP express interleukin 7 (IL-7), a cytokine required for thymocyte differentiation [198,199], making IL-7 one of the earliest currently identified markers of thymus identity. In the thymus primordium *Foxn1*$^{-/-}$ embryos show normal *IL-7* expression [199], indicating that TE identity is specified in the absence of Foxn1. Transplantation experiments also support this model, as E9.0 pharyngeal endoderm, which does not express functionally relevant levels of *Foxn1*, gives rise to a functional thymus when grafted ectopically [113], indicating that at this developmental stage some pharyngeal endoderm/3PP cells are already specified to the TE lineage.

Similarly, our recent studies conclude that GCM2 is not required for specification of the parathyroid, as other parathyroid-specific markers including *Tbx1*, *Ccl21* and *CaSR* are initiated in *Gcm2*$^{-/-}$ mice, although this domain undergoes rapid and coordinated apoptosis in the absence of GCM2 [200]. Thus, *Gcm2* may play a somewhat analogous role in parathyroid development to that of *Foxn1* in the thymus, although the thymus rudiment does survive in the absence of *Foxn1*.

Upstream regulation of *Foxn1* is currently not understood, and analyses of mutations in potential upstream regulators have not been informative in this regard. *Hoxa3*$^{-/-}$ and *Eya1*$^{-/-}$ embryos do not express *Foxn1*, but this is likely due to the block in primordium formation prior to the onset of *Foxn1* expression in each of these mutants. Although *Foxn1* expression is unaltered in *Pax9*$^{-/-}$ and *Hoxa3*$^{+/-}$;*Pax1*$^{-/-}$ mutants [186,189], the possibility remains of functional redundancy between Pax1 and Pax9. Furthermore, while *Six1*$^{-/-}$ mutants display reduced *Foxn1* expression, the 3PP exhibits increased cell death in the absence of *Six1* [185], and therefore, the reduced expression of *Foxn1* may reflect poor survival of Foxn1^{+} cells rather than a direct interaction between *Foxn1* and Six1. Further studies are required to determine whether a regulatory relationship exists between these genes and *Foxn1*.

Several candidate regulators of thymus specification have, however, recently been identified based on their expression in the 3PP prior to initiation of *Foxn1* [201]. These include Nkx2.5,

Nkx2.6, Isl1, Gata3 and Foxg1. *Nkx2.5*, *Nkx2.6*, *Isl1* and *Gata3* are expressed in the developing 3PP at E9.5 and are restricted to the ventral portion of the 3PP endoderm at E10.5. *Foxg1* is not expressed in the 3PP at E9.5, but at E10.5 is expressed in two discrete regions, one dorsal and the other ventral. By E11.5, when *Foxn1* is first activated in the 3PP, *Foxg1* and *Isl1* are already restricted to the thymus domain. These factors continue to be expressed in TECs throughout late fetal and postnatal differentiation. However it remains unknown whether they transcriptionally activate *Foxn1* or instead regulate Foxn1-independent aspects of thymus development.

How then are the thymus and parathyroid domains within the 3PP established? Evidence suggests that opposing gradients of bone morphogenetic proteins (BMP) and sonic hedgehog (Shh) may play an important role in this process. During thymus development *Bmp4* expression is first detected at E9.5 when it is expressed by a small number of mesenchymal cells in the third pharyngeal arch [202]. By E10.5, the *Bmp4* expression domain has expanded to include the ventral 3PP endoderm and the adjacent mesenchyme, but remains absent from the dorsal 3PP. This expression pattern is maintained at E11.5 and by E12.5 *Bmp4* is expressed throughout the thymic primordium and the surrounding mesenchymal capsule [202].

In vivo evidence of a role for Bmps in thymus organogenesis was provided by a study in which expression of the Bmp inhibitor *Noggin* was driven by the *Foxn1* promoter, thus impairing Bmp signaling in the thymic stroma [203]. These mice developed hypoplastic and cystic thymi that failed to migrate to their normal position above the heart. It is highly likely that this is due to a direct effect on the thymic stroma, as impaired development is evident prior to lymphocyte immigration; mediators of Bmp signaling such as *Msx1* and phosphorylated Smad proteins were downregulated in both the epithelium and surrounding mesenchyme. Interestingly, *Foxn1* expression was only partially blocked in this transgenic model. However, *IL7* expression was also absent in the cells that had downregulated *Foxn1*, suggesting that thymus fate, rather than solely *Foxn1*, may have been affected [204]. A caveat for interpreting these data is that the inhibition of Bmp signaling was driven by the *Foxn1* promoter, and thus occurred after initiation of *Foxn1* expression. Furthermore, addition of a Bmp inhibitor did cause loss of *Foxn1* in a zebrafish model [204]. A more recent study showed that Bmp signaling is necessary for *Foxn1* initiation in co-cultures of qE2.5 quail pharyngeal pouch endoderm and chick mesenchyme. Bmp is required only during a narrow time window, however, as addition of Noggin has no effect on *Foxn1* initiation in co-cultures containing qE3 endoderm. *Gcm2*, in contrast to *Foxn1*, is initiated in the absence of mesenchyme and maintained in the presence of Noggin [205].

Conditional deletion of *Bmp4* in the pharyngeal endoderm (and, with variable efficiency, in the surrounding mesenchyme) using *Foxg1-Cre* indicates that Bmp4 is required for thymus and parathyroid morphogenesis. In E11.5 *Foxg1-Cre;Bmp4*$^{F/F}$ embryos, the thymus-parathyroid primordium is hypoplastic but expression of *Foxn1* and *Gcm2* is normal as detected by *in situ* hybridization, demonstrating proper specification and patterning of the thymus and parathyroid domains. However, delayed separation of the two organ primordia and reduced migration of the thymus primordia are evident at E12.5 and E13.5 [206]. *Wnt1-Cre* or *Foxn1-Cre* mediated deletion of *Bmp4* has no effect on thymus and parathyroid morphogenesis, suggesting that *Bmp4* signaling is required in the pharyngeal epithelium during a narrow time window prior to the onset of *Foxn1* expression. However, as the thymic primordium expresses Bmp2 and Bmp7 (CCB and NRM unpublished data), which signal through the same receptor as Bmp4, redundancy is an issue for interpreting these results.

During development of the 3PP, expression of the secreted glycoprotein sonic hedgehog (Shh) is restricted to the region of 3PP immediately adjacent to the pharyngeal endoderm at E10.5 and E11.5, although its receptor Patched1 is expressed by cells in close proximity to this region [207]. Analysis of *Shh*$^{-/-}$ embryos revealed expanded expression domains for both *Bmp4* and *Foxn1* in the 3PP, while the corresponding *Gcm2*$^{+}$ parathyroid domain was lost in these

mutants [207]. Consistent with these observations, cyclopamine treatment of chick embryos at HH14–16 blocked *Gcm2* initiation and led to enhanced *Bmp4* expression in the caudal pharyngeal pouches. However, loss of Shh signaling at a later stage (HH21) caused ectopic expression of *Gcm2* and *CaSR* in the anterior first ectodermal cleft and posterior second arch, and had no effect on *Gcm2* transcription in the 3PP [208]. Thus, at early developmental stages, the role of Shh in thymus organogenesis may be to oppose the action of Bmp4 to allow the specification and development of the parathyroid. At later stages, Shh signaling may also restrict parathyroid development to the caudal pharyngeal pouches.

Wnt glycoproteins may also be important in regulating *Foxn1* expression. Wnts are expressed by the thymic stroma and by lymphoid cells, although Wnt receptors are exclusively expressed by TECs [196]. The earliest reported expression of Wnt family members during thymus development is at E10.5, immediately prior to strong *Foxn1* expression, when the epithelium of the 3PP and adjacent cells express *Wnt4* [196]. Given this expression pattern and the finding that TEC lines that overexpress Wnt4 display elevated levels of *Foxn1* [196], it is possible that Wnt4 cooperates with Bmp4 to regulate *Foxn1*. *Wnt1*, *Wnt4* and $Wnt1^{-/-};Wnt4^{-/-}$ mice all exhibit hypoplastic thymi characterized by reduced T cell numbers but normal thymocyte developmental progression. As no histological analysis of the thymi in these *Wnt1* mutants has been presented, it is not possible to evaluate whether the primary effect is on the TE or on thymocytes [91,209]. However analysis of $Wnt4^{-/-}$ mice suggests that Wnt4 controls thymus size by modulating expansion of both TECs and immature thymocytes. By E15.5, $Wnt4^{-/-}$ thymi contain fewer TECs than wild-type, and at E18.5, histological analysis reveals smaller medullary areas, reduced expression of medullary markers and disorganization of the CMJ. In addition, loss of *Wnt4* results in a disproportionate decrease in the earliest thymic progenitors (ETPs) and DN2 thymocytes. This effect is likely to be direct, as OP9-DL1 cells modified to overexpress Wnt4 increase the expansion of ETPs and DN2s relative to OP9-DL1 cells [210]. As with Bmp family members, functional redundancy is again a possibility, as other Wnt family members are also expressed in the 3PP and surrounding mesenchyme [196,209].

A role for Wnt signaling in TEC is also suggested by deletion of the Wnt signaling repressor *Adenomatous Polyposis Coli* (*Apc*) in K14-expressing cells. $K14\text{-}Cre;Apc^{CKO/CKO}$ mice have a hypoplastic thymus characterized by variable disruption of epithelial organization, exclusion of lymphocytes, and the presence of enlarged structures expressing keratinocyte markers such as involucrin [211]. Similarly, expression of a stabilized form of beta catenin specifically in TECs resulted in thymus hypoplasia, restricted immigration of thymocytes, and a block in thymocyte development at the DN1 stage. The mutant TE contained a central core of cells that initially appeared committed to a thymus fate, but later downregulated expression of Foxn1, K8 and K5, and expressed involucrin [212]. Collectively, these data suggest that over-stimulation of canonical Wnt signaling in TEC perturbs thymus development and function, possibly by affecting TEPC and/or causing a fate shift in their differentiating progeny.

Recent evidence suggests that Wnt signaling is also required for maintenance of the postnatal thymus. Deletion of the Wnt antagonist Kremen resulted in the development of large epithelial-free zones in the TEC network [213]. Tetracyclin-regulated overexpression of the canonical Wnt inhibitor Dickkopf related protein 1 (encoded by *Dkk1*) in cortical and medullary TECs of postnatal mice resulted in dramatic thymus degeneration [214]. A decrease in the number of $K5^{+}K8^{+}$ cells at the CMJ and reduced proliferation in the MHC Class II^{lo} compartment was observed in this model, perhaps implicating Wnt in the regulation of progenitor TEC. Consistent with this idea, these phenotypes were reversed by withdrawal of Doxycyclin, and restoration of thymus size correlated with recovery of the $K5^{+}K8^{+}$ TEC population [214].

FOXN1 AND REGULATION OF TEC DIFFERENTIATION

The data discussed in the sections 'Origin of thymic epithelial cells' and 'Thymic epithelial progenitor cells (TEPC)' collectively establish that the thymus domain within the 3PP contains a common TEPC, able to generate all subtypes of cortical and medullary TECs. They further provide evidence for the existence of cortical and medullary thymic epithelial sub-lineage-restricted TEPC, which presumably arise downstream of the common TEPC in the fetal TE lineage hierarchy. Thus, in addition to TE lineage specification and expansion of the thymus primordium, mechanisms that support development of these sub-lineage restricted progenitors and their subsequent differentiation into c- and mTEC are an important component of thymus organogenesis. Of these, the mechanisms underpinning differentiation and expansion of mTEC are currently the best understood, and are discussed in detail in the section 'Medullary development and expansion' below; little information exists regarding mechanisms specifically regulating cTEC development.

In addition to sub-lineage specific mechanisms, Foxn1 regulates differentiation of TEC in both sub-lineages in the fetal and adult thymus. As discussed in the section 'Thymic epithelial progenitor cells (TEPC)', in Foxn1 null mice, TEC undergo developmental arrest at the founder/fetal progenitor cell stage of development [44,148], and chimera studies have demonstrated the cell-autonomous requirement for Foxn1 for development of all mature TEC subtypes [215]. The early thymic rudiment in *nude* mice also shows reduced proliferation [216]. Thus, while TEPCs form independently of Foxn1, their proliferation and differentiation into mature c- and mTEC is Foxn1-dependent. However, analysis of the *Foxn1*$^{-/-}$ fetal thymus revealed the presence of K5^{hi}Cldn4^{hi} regions corresponding to presumptive progenitor mTEC suggesting that, during organogenesis, Foxn1 is not required for divergence of the mTEC lineage from the common TEPC [44].

Foxn1 is expressed by most if not all differentiating and mature TECs throughout fetal development and, in the postnatal thymus, it is also expressed in most if not all TECs throughout the lifespan [147](CCB and NRM unpublished). The role of Foxn1 beyond the fetal TEPC stage is incompletely understood. However, our studies have indicated that Foxn1 regulates crosstalk between developing TEC and thymocytes, which is required for expansion and maturation of the medullary compartment [217,218]. Furthermore, we have recently shown that Foxn1 is required in a dosage-dependent manner to regulate multiple stages of differentiation in both the c- and mTEC sub-lineages in the fetal and adult thymus. In both sub-lineages, it is required throughout differentiation, from exit from the earliest TEPC state to terminal differentiation of both cTEC and Aire^{+} mTEC [44].

Importantly, these studies demonstrate that a sub-functional thymus can be generated at sub-optimal levels of Foxn1 expression or function, indicating that full thymus function is generated only in a relatively narrow *Foxn1* dosage range [44,218–221]. This conclusion is also supported by analysis of Foxn1 function in the postnatal thymus, which shows it is required in a dosage-sensitive manner to maintain thymus homeostasis [222], and that complete loss of either Foxn1 expression or Foxn1-expressing TEC postnatally results in loss of thymus function [223–225]. Collectively, these data highlight the importance of understanding the intrinsic and extrinsic mechanisms that regulate Foxn1 expression, and the downstream mechanisms regulated by Foxn1, *in vivo*.

As discussed above, little information exists regarding the transcriptional regulation of *Foxn1* expression. However, direct or indirect transcriptional targets of Foxn1 have now been identified in a number of studies [22,44,219,222,223,226,227], although to date no putative Foxn1 targets in TEC have been verified by chromatin immunoprecipitation. However, since the set of Foxn1-regulated genes includes factors with diverse functions in thymus development and the TEC-mediated support of T cell development, Foxn1 can be considered a 'master regulator' of TEC differentiation, rather than a regulator of a specific aspect of thymus development.

In addition to its expression in TEC, Foxn1 is also expressed in skin and hair follicle keratinocytes, where it regulates normal development. In these cutaneous epithelial lineage cells, Foxn1 is believed to regulate the balance between proliferation and differentiation [228–230]. However, while some parallels may exist between Foxn1 function in skin and thymus, expression of Fgf2, a known direct target of Foxn1 in cutaneous epithelium [230], is not expressed in TEC [44], suggesting Foxn1 may regulate different target genes in the cutaneous and thymic epithelial lineages.

MEDULLARY DEVELOPMENT AND EXPANSION

The development of mature mTECs depends on activation of the non-canonical NF-κB-signaling pathway that culminates in RelB activation. mTEC development is severely compromised in RelB deficient mice [231,232]. In addition, a range of medullary defects occurs in mice that are deficient in various components upstream of RelB in the alternative NF-κB-activation pathway. Mice with a naturally occurring mutation in NF-κB-inducing kinase (*NIK*), and *Ikkα* knockout mice, display abnormal thymic architecture with small, hypocellular medullary regions associated with reduced *Aire* and TRA expression [233–235]. A similar phenotype is found in *TRAF6* knockout mice, indicating that the classical NF-kB-signaling pathway also plays a role in formation of functional medullary regions [236]. Interestingly, each of these mutant strains develops autoimmune manifestations consistent with a breakdown in the establishment of central tolerance due to a deficiency of Aire$^+$ mTECs.

Signals from positively selected thymocytes play an important role in expanding the medullary region in adult thymi, a mechanism often referred to as lympho-epithelial crosstalk. Small medullary regions containing sparse mTEC subsets are found when thymocyte development is blocked at the DP stage, as occurs in *TCRα* deficient mice or in mice lacking both MHC Class I and MHC Class II molecules [237,238]. Despite the paucity of mTECs, the medullary regions these mice nevertheless express *Aire* and TRAs, indicating that mTEC expansion is affected to a greater extent than differentiation. Positively selected DP thymocytes differentiate into SP thymocytes that migrate into the medulla, and these SP cells express various tumor necrosis factor superfamily (TNFSF) ligands, including receptor activator of NF-kB ligand (RANKL), CD40 ligand (CD40L), lymphotoxin-α and lymphotoxin-β [239–242].

Binding of these ligands to their receptors on mTEC activates NF-κB signaling, to promote mTEC proliferation and differentiation: ligand engagement of the TNFSF receptors activates NIK, which phosphorylates homodimers of the downstream kinase, Ikkα. Activated Ikkα in turn phosphorylates the C-terminal region of NF-κB2 (p100) leading to ubiquitin-dependent degradation and release of the N-terminal polypeptide, p52. The formation of RelB/p52 heterodimers permits shuttling of RelB from the cytoplasm into the nucleus where it functions as a transcriptional regulator [243]. Thus, *RANK* or *RANKL* deficient mice have small, poorly developed medullary regions in which mTEC cellularity is decreased and *Aire* expression is reduced [241,244]. Targeted disruption of the *LTβR* gene also results in disorganized medullary regions that contain reduced numbers of mTECs [242]. A recent study indicates that signaling via the LTβR is required to upregulate RANK expression on fetal TECs, implying cooperation between these two TNFSF receptors in mTEC development [245].

Interestingly, medullary region development is initiated in the fetal thymus prior to the appearance of SP thymocytes. This is at least partly due to the presence of lymphoid tissue inducer (LTi) cells that express RANKL, but not CD40L. RANKL signaling induces the generation of Aire$^+$ mTECs before fetal thymocytes of the αβ TCR lineage have matured to the SP stage [244,246]. The early fetal thymus also contains thymocytes expressing invariant Vγ5Vδ1 TCRs. These cells, which are present prior to the development of αβ lineage thymocytes, also express RANKL and play a role in development of Aire$^+$ mTECs [247].

SUMMARY

Thymus organogenesis is a complex process in which a dynamically regulated, three dimensional organ forms from the endoderm of the 3PP. The TE, a critical regulator of thymopoiesis, is comprised of many subtypes of TEC, all of which arise from a common progenitor. Importantly, T cell development depends on interactions with both cortical and medullary TEC subtypes, which mediate different aspects of T cell differentiation and repertoire selection. Therefore, development of functional *in vitro* or transplantable thymic organoids requires the ability to recapitulate all of these functions, with appropriate spatial and temporal constraints. Recent studies have begun to clarify the lineage relationships of the different TEC subtypes, and to unravel the molecular networks that govern thymus and parathyroid organogenesis. However, with respect to the goal of developing *in vitro* or transplantable thymi for therapeutic purposes, several significant questions remain unresolved:

- What factor or factors specify thymus and parathyroid lineages within the 3PP?
- How does the network of transcription factors and signaling molecules that are expressed in the endoderm and surrounding mesenchyme/mesoderm control subsequent thymus and parathyroid development, including the maintenance, proliferation and differentiation of thymic epithelial and parathyroid progenitor cells?
- How is *Foxn1* regulated in fetal and adult TEC?

In addition, further identification of Foxn1 targets in TEC, and the transcriptional networks in which Foxn1 operates to control development and function of c- and mTEC, is an important goal. The potential of factors downstream of Foxn1 to facilitate engineering of hematopoietic progenitor cell niches *ex vivo* has already been demonstrated by transgenic expression of varying combinations of *Ccl25*, *Cxcl12*, *Scf* and *Dll4* in *Foxn1*-deficient TE [248]. It is likely that knowledge of both additional Foxn1-regulated genes and proteins required in conjunction with Foxn1 to regulate specific functions in TEC may prove useful for manipulating or engineering thymus function(s) *in vitro* or *in vivo*.

Finally, important questions remain regarding homeostatic maintenance of the mature thymus, which are relevant to strategies for thymus regeneration or replacement. Of particular importance are the identification of both the stem/progenitor cell types responsible for replenishing TEC in the adult thymus, and of the mechanisms that operate on TEC to induce thymic involution. Progress in each of these issues is likely to facilitate rational design of strategies for therapeutic reconstitution of the adaptive immune system. The development of such strategies should significantly impact the health of the aging population, and other immunocompromised individuals.

Acknowledgments

We wish to thank Lucy Morris (Carnegie Institution of Washington and Howard Hughes Medical Institute, Baltimore, USA), for critical reading of the manuscript, and our funding bodies, Leukaemia and Lymphoma Research (CCB, CSN), the Biotechnology and Biology Research Council (CCB, KO'N), the EU (CCB, CSN) and the NIH (NRM, ER), for support.

INTRODUCTION

There has been a tremendous increase in interest in stem cell biology and its potential applications in recent years. Although this has been galvanized by the exploitation of research in pluripotent stem cells, it is interesting to note that what might be called the 'intestinal stem cell community', albeit small, has been working productively for some 40 to 50 years. With stem cells now claiming considerable attention, in retrospect, many of the basic tenets that govern our understanding of organ-specific stem cells have come from studies of the gastrointestinal tract and the hematopoietic system.

In the gastrointestinal tract, there is a large body of evidence that multipotent stem cells are found in specific zones, or niches, within gastric glands and intestinal crypts, composed of and maintained by myofibroblasts in the adjacent lamina propria. In this chapter, we review evidence that these multipotent stem cells generate all gastrointestinal epithelial cell lineages through committed precursor cells housed in the proliferative compartments of intestinal crypts and gastric glands, a concept that has had a long and difficult gestation [1]. Notwithstanding their obvious significance, the gastrointestinal stem cells remain elusive and unidentified, mainly because of a lack of accepted morphological and functional markers at the single cell level. We also explore concepts of stem cell number, location, and fate, and we touch on the ability of gastrointestinal stem cells to regenerate cell lineages of whole intestinal crypts and villi after damage. The luminal gut shows regional specializations of function — the stomach primarily for absorption and the intestinal mucosa for both absorption and secretion. This is reflected by variation in the adult cell lineages native to each tissue, and it is thereby consistent that stem cell fate within each tissue is also different. We are beginning to understand the mechanisms that govern such variation. Controversial recent findings regarding stem cell plasticity in the gastrointestinal tract are examined in this chapter.

Because of their longevity, putatively the same as that of the organism itself, stem cells are often viewed as the target cells for carcinogens and the cells of origin for spontaneous tumors. Recent thought on the location of stem cells in the colon has sparked debate concerning the possible pathways of morphological progression of transformed stem cells. This includes a *top-down* proliferation of mutated stem cells located within intercryptal zones on the mucosal surface,

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00044-6

downward into the adjacent crypts. Contrasting to this is a *bottom-up* theory of the upward proliferation of mutated stem cells in the crypt base to produce dysplastic crypts that replicate and expand by crypt fission. This brings other facets of gut biology into sharp focus — the mechanisms of crypt reproduction; the clonal architecture of normal and dysplastic gastric glands, intestinal crypts, and their derivative tumors; and the role that stem cells take in these events. Here, we propose that the stem cells accumulate the multiple genetic events leading to tumorigenesis, and we explore the manner by which such mutated clones spread in gastrointestinal epithelia. Many of these concepts are being explored at the level of molecular regulatory pathways, including the signaling pathways of Wnt and transforming growth factor β (TGFβ).

This is quite a brief, since several of the most common tumors originate in the gastrointestinal tract and with increasing incidence in Barrett's oesophagus. Our concepts of stem cell biology impinge considerably on our understanding of how these tumors arise.

GASTROINTESTINAL MUCOSA CONTAINS MULTIPLE LINEAGES

In the small intestine, the epithelial lining forms numerous crypts and larger, finger-shaped projections called villi. In the colon there are many crypts, which vary in size throughout the colon; the shortest is in the ascending colon. Overall, four main epithelial cell lineages exist in the intestinal epithelium. These are the columnar cells, the mucin-secreting cells, the endocrine cells, and Paneth cells in the small intestine. Other less common cell lineages are also present, such as the caveolated cells and membranous or microfold cells. Columnar cells, with apical microvilli, are the most abundant epithelial cells, termed enterocytes in the small intestine and colonocytes in the large intestine. 'Goblet' cells containing mucin granules — and thus producing swollen, goblet-shaped cells — are found throughout the colonic epithelium, secreting mucus into the intestinal lumen. Endocrine, 'neuroendocrine', or 'enteroendocrine' cells form an abundant cell population distributed throughout the intestinal epithelium; these cells secrete peptide hormones in an endocrine or paracrine manner from their contained dense core of neurosecretory granules. Paneth cells are located almost exclusively at the crypt base of the small intestine and ascending colon, contain large apical secretory granules, and express several proteins — including lysozyme, tumor necrosis factor, and the antibacterial cryptins (small molecular-weight peptides related to defensins).

In the stomach, the epithelial lining forms long, tubular glands divided into foveolus, isthmus, neck, and base regions. Gastric foveolar or surface mucus cells are located on the mucosal surface and in the foveola. They contain tightly packed mucous granules in the supranuclear cytoplasm and do not possess a theca. The mucus neck cells are situated within the neck and isthmus of the gastric glands and contain apical secretory mucin granules. The peptic-chief or zymogenic cells are located in the base of the glands in the fundic and body regions; they secrete pepsinogen from oval zymogenic granules. The parietal or oxyntic, acid-secreting cells are located in the body of the stomach in the base of the glands. These cells have many surface infoldings, or canaliculi, which form a network reaching almost to the base of the gland. Endocrine cell families include the enterochromaffin-like cells in the fundus or body that produce histamine; the gastrin-producing cells are a major component of the antral mucosa.

The intestinal crypts and gastric glands are enclosed within a fenestrated sheath of intestinal subepithelial myofibroblasts (ISEMFs). These cells exist as a syncytium that extends throughout the lamina propria and merges with the pericytes of the blood vessels. The ISEMFs play a vital role in epithelial–mesenchymal interactions. ISEMFs secrete hepatocyte growth factor (HGF), TGFβ, [2] and keratinocyte growth factor (KGF) [3], with the receptors for these growth factors are located on the epithelial cells. Thus, the ISEMFs are essential for the regulation of epithelial cell differentiation through the secretion of these and possibly other growth factors [3]. Platelet-derived growth factor-A (PDGF-A), expressed in the intestinal epithelium, acts by paracrine signaling through its mesenchymal receptor, PDGFR-α, to regulate

epithelial–mesenchymal interactions during development. Studies of mice with targeted deletions in the PDGF-A or PDGFR-α genes have shown defects in normal proliferation and differentiation of PDGFR-α positive mesenchymal cells [4]. Typically, ISEMFs are α-smooth muscle actin-positive (αSMA+) and desmin− [3], but some myofibroblasts also express myosin-heavy chains [5]. ISEMFs undergo proliferation despite this MyoD expression – unlike the skeletal muscle myoblast, which decycles once MyoD is expressed. It has been proposed that these cells form a renewing population, migrating upwards as they accompany the epithelial escalator [6]. Although they appear to proliferate and migrate, they move relatively slowly and then move off into the lamina propria to become polyploid [7].

A second myofibroblast population in the intestine is the interstitial cells of Cajal. These cells are located close to neurones in the muscular layers; they act as pacemakers for gastrointestinal smooth muscle activity, propagate electrical events, and modulate neurotransmission [8]. They are said to be αSMA+ and desmin+ and to immunostain for *c-kit* and CD45 [3].

EPITHELIAL CELL LINEAGES ORIGINATE FROM A COMMON PRECURSOR CELL

Little is known of the location and fate of the stem cells within the gastrointestinal tract because of the lack of distinctive and accepted stem cells markers, although they are usually said to appear undifferentiated and can be identified operationally by their ability to repopulate crypts and glands after damage.

The unitarian hypothesis states that all the differentiated cell lineages within the gastrointestinal epithelium emanate from a common stem cell origin [9]. Although widely propounded, until very recently little definitive evidence existed to underpin this hypothesis [10]. Moreover, Pearse and Takor famously proposed that gastrointestinal endocrine cells derive from migrating neuroendocrine stem cells in the neural crest [11], a concept that still has its adherents [12]. Although studies of quail neural crest cells transplanted into chick embryos [13], or experiments where the neural crest is eradicated [14], show gut endocrine cells to be of endodermal origin, Pearse [15] subsequently suggested that the endodermis is colonized by 'neuroendocrine-programmed stem cells' from the primitive epiblast, which generates gut endocrine cells. This hypothesis was not ruled out by chick-quail chimera experiments; therefore, other models must be used to ascertain the gut endocrine cell origins, such as the chimeric mouse studies described later.

Several lines of evidence suggest that stem cells reside in the base of the crypts of Lieberkuhn in the small intestine, just superior to the Paneth cells (approximately the fourth or fifth cell position in mice). In the large intestine, they are presumed to be located in the mid-crypt of the ascending colon and in the crypt base of the descending colon [1]. However, within the gastric glands, migration of cells is bidirectional from the neck-isthmus region to form the simple mucous epithelium of the foveolus or pit, and cells migrate downward to form parietal cells and chief cells. Therefore, the stem cells are believed to be within the neck-isthmus region of the gastric gland [16]. The unitarian hypothesis is now supported by a considerable body of research.

SINGLE INTESTINAL STEM CELLS REGENERATE WHOLE CRYPTS CONTAINING ALL EPITHELIAL LINEAGES

The ability of intestinal stem cells to regenerate epithelial cell populations of entire intestinal crypts and villi following cytotoxic treatment has been demonstrated using the crypt microcolony assay [17]. Four days after irradiation, sterilized crypts undergo apoptosis and disappear, but they can be identified by remaining radio-resistant Paneth cells at the crypt base. At higher radiation dose levels, only single cells survive in each crypt, since a unit increase in radiation leads to unit reduction in crypt survival. Survival of one or more clonogenic cells in a crypt after radiation ensures crypt persistence, and there is regeneration of all epithelial cell populations of that crypt

and, in the small intestine, of the overlying villi. Therefore, following cytotoxic damage, a single surviving stem cell can produce all cell types of the intestinal epithelium to reproduce a crypt [18].

MOUSE AGGREGATION CHIMERAS SHOW THAT INTESTINAL CRYPTS ARE CLONAL POPULATIONS

Mouse embryo aggregation chimeras are readily made, wherein the two populations can be readily distinguished. The lectin *Dolichos biflorus* agglutinin (DBA) binds to sites on the B6-derived but not on the Swiss Webster (SWR)-derived cells in C57BL/6J Lac (B6)×SWR mouse embryo aggregation chimeras, and it can be used to distinguish the two parental strains in gut epithelium. The intestinal crypts in each chimera studied were either positive or negative for DBA, and there were no mixed crypts in the tens of thousands studied [19] (Fig. 44.1A). Therefore, each crypt forms a clonal population. This is the case for Paneth, mucous, and columnar cells, although it was not possible to detect the markers in endocrine cells because of their inability to bind the lectin on their surface [20]. In neonatal C57BL/6J Lac (B6)×SWR chimeras, there were mixed (i.e., polyclonal) crypts for the first two weeks after birth,

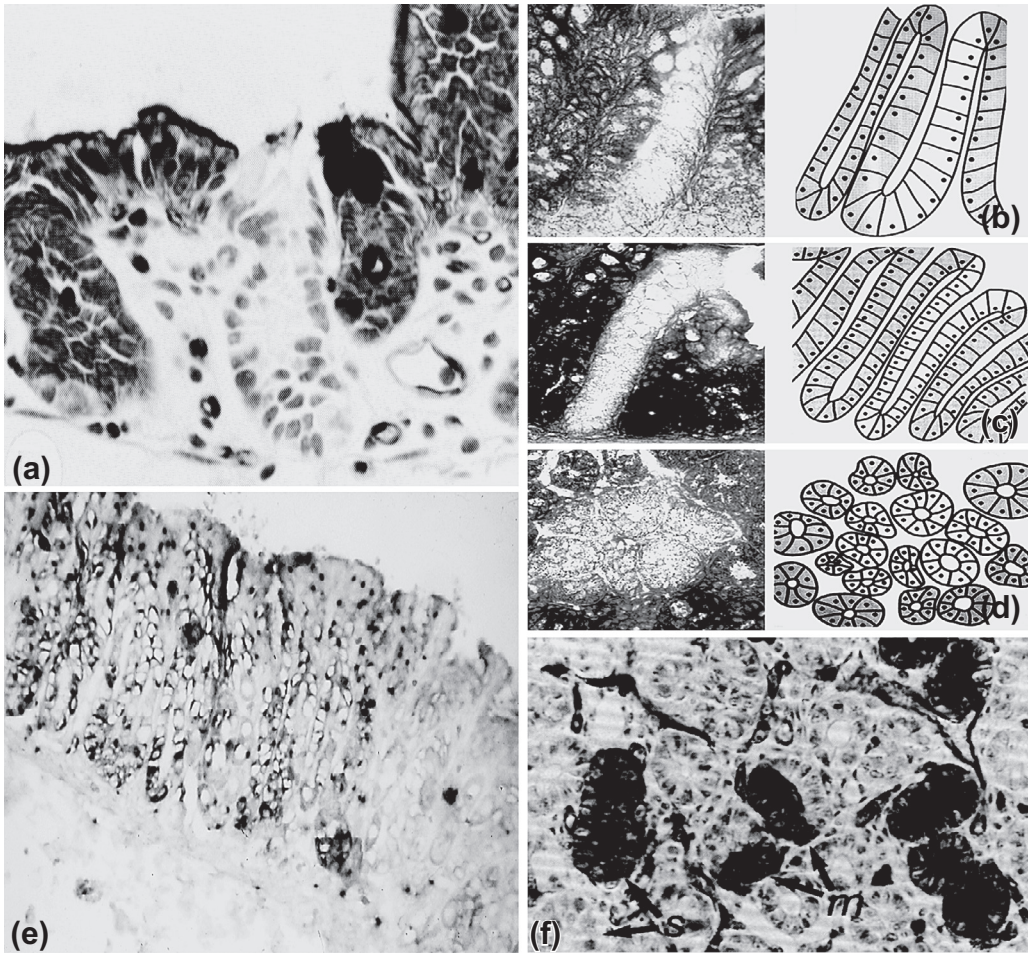

FIGURE 44.1

Gastrointestinal clonality studies. Mouse embryo aggregation chimeras, XX—XY chimeric mice, and X-inactivation mice. (a) DBA staining in the small intestine of ENU-treated (12 weeks) C57BL/6J-SWR F1 chimeras showing entire negative and positive (black) crypts. (b—d) G6PD histochemistry in frozen sections of colonic mucosa in an ENU-treated C3H mouse: (b) partially negative crypt, (c) completely negative crypt, and (d) cross section of an eight-crypt patch at 21 weeks. (e) Y-spot pattern in the gastric mucosa and underlying tissues of an XX—XY chimera. (f) Cross section through crypts in neonatal duodenum of B6-SWR chimera stained with DBA (B6 = black staining, SWR = unstained). A balanced contribution to mixed crypts (m), and monoclonal crypts (s) is seen. *Panel a reproduced with permission from Winton et al., [102] panel b with permission from Park et al., [22] panel e courtesy of E.M. Thompson, and panel f with permission from Schmidt et al. [21] (Please see CD-ROM for color version of this figure.)*

suggesting that multiple stem cells exist during development [21] (Fig. 44.1B through 44.1D). However all crypts ultimately become derived from a single stem cell between birth and postnatal day 14, so-called monoclonal conversion. This apparent cleansing or 'purification' of crypts could be caused by the stochastic loss of one stem cell lineage or by the segregation of lineages because of an extremely active replication of crypts by fission, which occurs at this developmental period[22,23]. To exclude the possibility that crypts from distinct strains segregate differentially during organogenesis, Griffiths et al. [24] confirmed the findings in mice bearing an X-linked defective gene for glucose-6-phosphate dehydrogenase (*G6PD*) (Fig. 44.1e and later sections of this chapter).

In the stomach, the situation is similar although more complex. Epithelial cell lineages in the antral gastric mucosa of the mouse stomach, including the endocrine cells, derive from a common stem cell. Identification of the Y-chromosome by *in situ* hybridisation in XX—XY chimeric mice showed that gastric glands were also clonal populations [21] (Fig. 44.1f). These findings were confirmed by Tatematsu et al. [25] in 1994 in CH3×BALB/c chimeric mice, where each gastric gland was composed of either CH3 or BALB/c cells; there were no mixed glands. Thus, we might advance the general hypothesis that gastric glands in the mouse, in addition to the intestinal crypts, are clonally derived. Additionally, by combining immunohistochemistry for gastrin, an endocrine cell marker, with *in situ* hybridization to detect the Y-chromosome, the male regions of the gastric glands were shown to be almost exclusively Y-chromosome positive with gastrin-positive endocrine cells, whereas the female areas in the chimeric stomach were gastrin positive and Y-chromosome negative [21] (Fig. 44.1d). These results finally negate the Pearse concept that gut endocrine cells originate from a separate stem cell pool.

Nomura et al. [26] used X-inactivation mosaic mice expressing a *lacZ* reporter gene to study clonality of gastric glands in the fundic and pyloric regions of the developing mouse stomach. As in the intestine, most glands are initially polyclonal, with three or four stem cells per gland, but they become monoclonal during the first six weeks of life — again either by purification of the glands, where division of one stem cell eventually overrides all other stem cells, or by gland fission. A population of approximately 5—10% of mixed, polyclonal glands persists into adulthood. The significance of these mixed glands with an increased stem cell number is not known, but it is possible that they do not undergo fission or have reduced fission rates; perhaps they even have an increased stem cell number during development and therefore maintain a higher number of stem cells after crypt fission.

SOMATIC MUTATIONS IN STEM CELLS REVEAL STEM CELL HIERARCHY AND CLONAL SUCCESSION

Somatic mutations at certain loci allow us to study stem cell hierarchy and clonal succession within the gastrointestinal tract. Mutations in the *DLb-1* gene on chromosome 11 are one good example of this; C57BL/6J×SWR F1 chimeric mice show heterozygous expression of a binding site on intestinal epithelial cells for the DBA lectin. This binding site can be abolished when the *Dlb-1* locus becomes mutated either spontaneously or by the chemical mutagen ethyl nitrosourea (ENU). After ENU treatment, crypts emerge that initially are partially and then are entirely negative for DBA staining [27]. Perhaps the simplest explanation for this phenomenon is that a mutation occurs at the *Dlb-1* locus in a stem cell within the small intestinal crypt. This mutated cell could expand stochastically to produce a clone of cells that cannot bind DBA and remain unstained [27] (Fig. 44.1ee). If this is the case, then a single stem cell can generate all the epithelial lineages within an intestinal crypt of the small intestine.

A 'knock-in' strategy at the *Dlb-1* locus can also be used to explain the preceding findings. If SWR mice do not express a DBA-binding site on their intestinal epithelial cells but can be induced to bind DBA by ENU treatment, wholly DBA+ or DBA− intestinal crypts would result. From the use of this model, Bjerknes and Cheng [23,28] proposed that 'committed epithelial

progenitor' cells exist in mouse intestinal crypts by visualizing the morphology, location, and longevity of mutant clones in crypts and villi of the mouse small intestine. These transitory committed progenitor cells — the columnar cell progenitors (C_o) and the mucus cell progenitors (M_o) — evolve from pluripotential stem cells and then differentiate further into adult intestinal epithelial cell types.

Not much is known about the mechanisms that regulate the proliferation of these progenitor cells, but administration of proglucagon-derived, glucagon-like peptide 2 (GLP-2) to SWR mice was found to induce intestinal epithelial growth and repair specifically by stimulating the columnar cell progenitors, resulting in increased crypt and villus size in the normal small intestine [28]. The receptor for GLP-2 (GLP2R) was recently shown to be located on enteric neurons [28] and not on the gut enteroendocrine cells and in the brain as previously thought [29]. GLP-2 activation of enteric neurons produces a rapid induction in *c-fos* expression, which signals growth of columnar epithelial cell progenitors and stem cells that generate adult columnar cell types. There is no stimulatory effect on the mucus cell lineage; instead, it is stimulated by KGF. Thus, the committed progenitor cells are involved in regeneration of damaged epithelia, possibly through a neural regulatory pathway (Fig. 44.2b).

There remains the possibility that cells from different parental strains of chimeric animals segregate independently during development to produce *monophenotypic* crypts and not *monoclonal* crypts. Mosaic expression of the electrophoretic isoenzymes PGK-1A and PGK-1B were analyzed in colonic crypts of mice heterozygous for the X-linked alleles *Pgk-1*^{a} and *Pgk-1*^{b} [19]. In agreement with the results from the chimeric studies, no mixed crypts were seen, thus eliminating the possibility that these crypts are monophenotypic and verifying that they are derived from a single progenitor cell. In a further model, mice that heterozygously express a defective *G6PD* gene have a crypt-restricted pattern of *G6PD* expression, thus confirming that the intestinal crypts are derived from a single stem cell [24]. Moreover, mice treated with the colon carcinogen dimethylhydrazine (DMH) or ENU also develop crypts that initially are partially and later are wholly negative for *G6PD*. The partially negative crypts could conceivably result from the

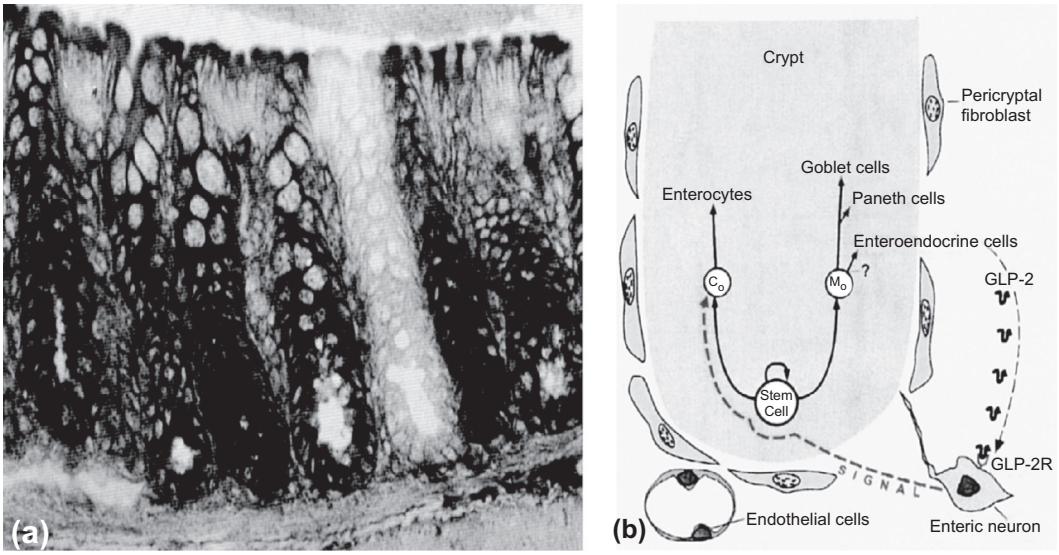

FIGURE 44.2

Stem cell niche hypothesis. (a) G6PD-stained frozen section of colonic mucosa from a CH3 mouse 14 days after a single dose of DMH, showing a single, wholly mutated crypt in which all cells have been replaced by a mutant phenotype. (b) Diagrammatic representation of the stem cell niche. An active, multipotent stem cell produces a daughter cell (C_o) generates enterocytic lineages and another that generates goblet, Paneth, and enteroendocrine cells (although it is not known whether all derive from M_o). GLP-2, produced by a subset of enteroendocrine cells, stimulates proliferation of the C_o daughter through an interaction with enteric nervous system neurons that express the GLP-2 receptor (GLP-2R). *Panel a reproduced with permission from Williams et al., [35] and panel b reproduced with permission from Mills et al. [165] (Please see CD-ROM for color version of this figure.)*

mutation of a cell in the dividing transit population of the crypt that lacks stem cell properties. This is supported by the observation that these partially negative crypts are transient and decrease in frequency parallel to an increase in wholly negative crypts. Conversely, such partially negative crypts could become wholly negative by stochastic expansion of a mutant stem cell. Wholly negative crypts would then be a clonal population derived from this mutant stem cell.

After administration of a mutagen, in both the Dlb-1 and the G6PD models, the time taken for the decrease in partially mutated crypts and the emergence of entirely negative crypts to reach a plateau is approximately four weeks in the small intestine and up to 12 weeks in the large intestine (Fig. 44.2a). This difference was initially thought to be because of cell cycle time differences between the two sites. However, a favored explanation can be found in the *stem cell niche hypothesis*. This hypothesis suggests that multiple stem cells occupy a crypt with random cell loss after stem cell division. It was originally formulated as the stem cell zone hypothesis by Bjerknes and Cheng (see Wright [1] for review and Bjerknes et al.[30–34]). The numbers of stem cells may be greater in the small intestine than in the large intestine, causing the difference in time taken for phenotypic changes following mutagen treatment as the mutant stem cell expands stochastically [35] (Fig. 44.2a). An alternative hypothesis might lie in crypt

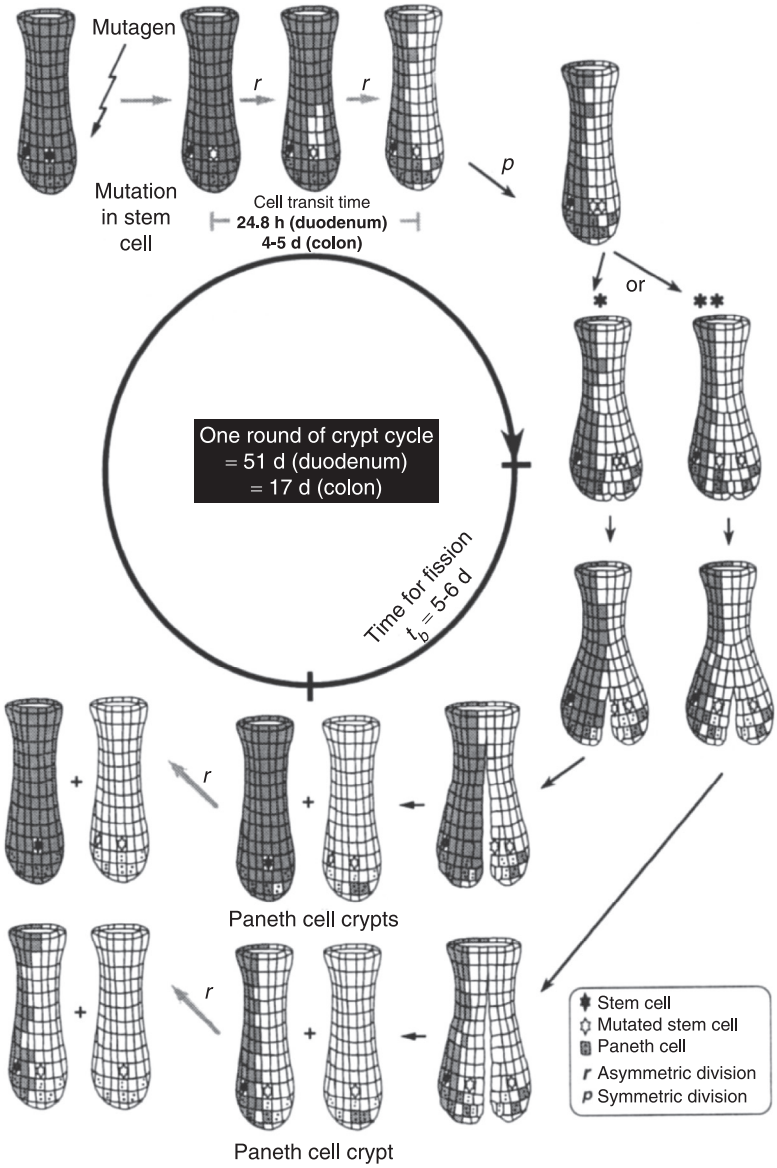

FIGURE 44.3
Crypt cycle. Emergence of transformed crypts after a single stem cell mutation. Crypt division is triggered by symmetric stem cell divisions (p), indicated by light-colored arrows, whereas dark arrows show asymmetric stem cell divisions (r). This is independent of the crypt cycle and enables individual crypts to maintain a constant number of stem cells and to continuously replace differentiated progeny over a crypt cell turnover time, on average. *Reproduced with permission from Park et al. [22] (Please see CD-ROM for color version of this figure.)*

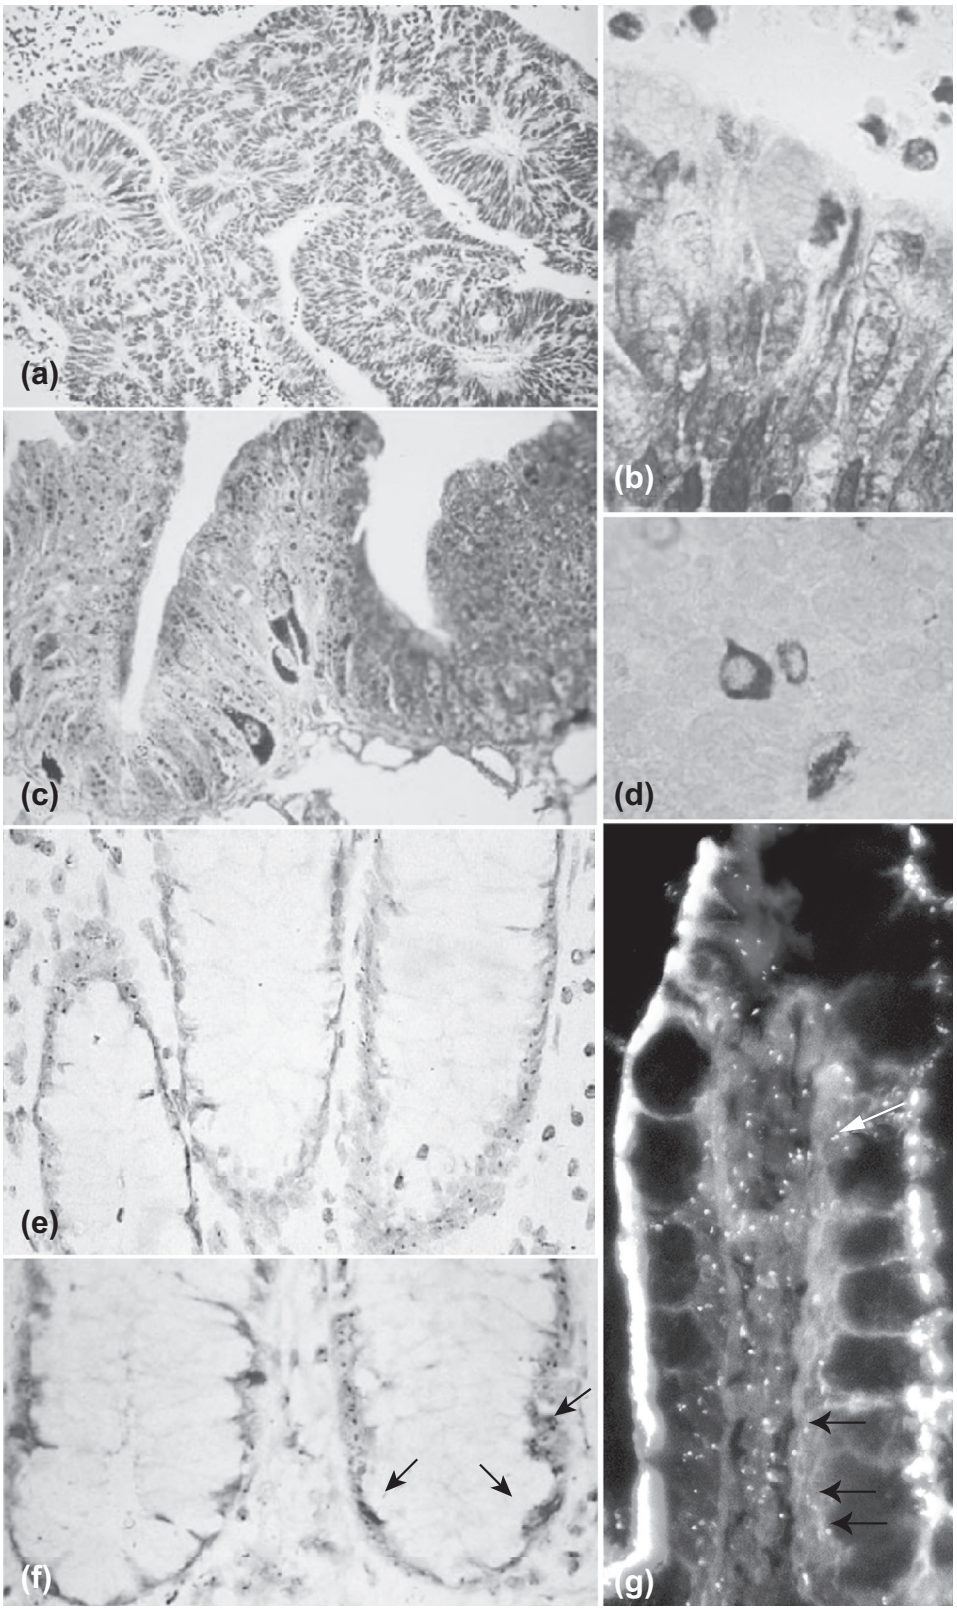

FIGURE 44.4

Monoclonal origin of human clonic crypts. (a) A tumor growing in a nude mouse derived from a single cell cloned human colorectal carcinoma cell line, stained (b) with Alcian blue to show goblet cells, and with (c) Grimelius and (d) an antibody against chromogranin A to demonstrate endocrine cells. (e) Monoclonal origin of human colonic crypts: normal colonic mucosa in an XO—XY mosaic individual stained by *in situ* hybridization for a Y-chromosome-specific probe showing an XO crypt (central) surrounded by two XY crypts. (f) Endocrine cells, highlighted by their chromogranin A content, also show clonality with the

fission: the rate of fission at the time of mutagen administration was higher in the colon than in the small intestine. During crypt fission, when crypts divide longitudinally, selective segregation of the two cell populations could occur, 'cleansing' the partially mutated crypts by segregating the mutated and non-mutated cells and by duplicating the wholly negative crypts to create monoclonal crypts [22] (Fig. 44.3). First proposed as a concept by Park et al. [22], this phenomenon was illustrated by Bjerknes and Cheng [23].

HUMAN INTESTINAL CRYPTS CONTAIN MULTIPLE EPITHELIAL CELL LINEAGES DERIVED FROM A SINGLE STEM CELL

The investigation of gastrointestinal stem cells in humans has proved difficult. The human colorectal carcinoma cell line HRA19 was derived from a primary adenocarcinoma of the rectum. A colony of single morphology was cloned and grown as a monolayer *in vitro* [36]. When engrafted subcutaneously into nude mice, these clones produce tumors histologically identical to the original tumor and contain columnar, goblet, and neuroendocrine cells (Figs. 44.4a through 44.4d). These malignant epithelial cells are therefore multipotent and can produce all differentiated cell types in the human colorectal epithelium [10]. However, these results cannot definitively be applied to normal human gastrointestinal epithelia.

In most of the human population, the colonic goblet cells secrete O-acetylated mucin. However, approximately 9% of the human Caucasian population have a homozygous genetic mutation in the enzyme O-acetyl transferase ($OAT^{-/-}$) and in goblet cells secreting this non-O-acetylated sialic acid; these are then positive when stained with mild periodic acid-Schiff (mPAS) stain[37,38]. In heterozygotes, which comprise approximately 42% of the population (OAT^{-}/OAT^{+}), O-acetylation proceeds, and crypts thereby stain negative for mPAS. Loss of the remaining active *OAT* gene converts the genotype to OAT^{-}/OAT^{-}, resulting in occasional, apparently randomly located, positive mPAS-stained crypts with uniform staining of goblet cells from base to luminal surface, an effect that increases with age [39]. This could be because of a somatic mutation or nondisjunction in a single crypt stem cell and subsequent colonization of the crypt by the mutated stem cell. The frequency of these events is racially determined [40] and increases after irradiation [41]. This has been interpreted as indicating an increased rate of stem cell mutation. Interestingly, there is no increase in the rate of apparent stem cell mutation in hereditary nonpolyposis carcinoma patients [42] or in the background mucosa of left- and right-sided carcinomas [43]. However, just as in the mouse stem cell mutation models, when patients are followed by the mPAS method over the period of time after irradiation, initially there is partial crypt staining, and then whole crypts appear where the goblet cells are mPAS+ [44]. The *clonal stabilization time* (defined as the period required for the emergence of most of such wholly stained crypts) in humans is approximately one year, a process we referred to previously as monoclonal crypt conversion.

These results have implications for the origins of goblet cell lineages in the gut: they indicate that they arise from crypt stem cells; however, they say little about the other cell lineages.

Perhaps the best evidence for the clonality of human intestinal crypts, and the stem cell derivation of all contained epithelial cell lineages, comes from studies of the colon of a rare XO—XY patient who received a prophylactic colectomy for familial adenomatous polyposis (FAP) [45,46]. Nonisotopic *in situ* hybridization (NISH) using Y-chromosome-specific probes showed the patient's normal intestinal crypts to be composed almost entirely of either Y-chromosome positive or Y-chromosome negative cells (Fig. 44.4e), with about 20% of crypts being XO. Immunostaining for neuroendocrine specific markers and Y-chromosome NISH

other crypt cell lineages in the same patient. (g) Villi, receiving cells from more than one crypt of different clonal derivation, show a polyclonal pattern in this XO—XY patient. Apart from the occasional Y-chromosome positive inflammatory cell (white arrow), most cells on the right of this villus are XO (black arrows); on the left side, the cells are XY. *Panels a—d courtesy of S. Kirkland, panels e and f courtesy of M. Novelli, and panel g courtesy of R. Poulsom. (Please see CD-ROM for color version of this figure.)*

used in combination showed that crypt neuroendocrine cells shared the genotype of other crypt cells (Fig. 44.4f). In the small intestine, the villus epithelium was a mixture of XO and XY cells, in keeping with the belief that the villi derive from stem cells of more than one crypt (Fig. 44.4g). Of the 12,614 crypts examined, only four crypts were composed of XO and XY cells, which could be explained by nondisjunction with a loss of the Y-chromosome in a crypt stem cell. Importantly there were no mixed crypts at patch boundaries. These observations agree with previous findings using chimeric mice; i.e., that intestinal crypt epithelial cells, including neuroendocrine cells, are monoclonal and derive from a single multipotent stem cell. Consequently, the hypothesis that enteroendocrine cells and other differentiated cell types within the colorectal epithelium share a common cell of origin (the unitarian hypothesis) appears to apply to both mice and humans. These observations have recently been confirmed in Sardinian women heterozygous for a defective *G6PD* gene [47].

It has been proposed that insight into stem cell organization can be gained from the study of the methylation pattern of nonexpressed genes in the colon. In the normal human colon, methylation patterns are somatically inherited endogenous sequences that randomly change and increase in occurrence with aging. Investigation of methylation patterns is a possible alternative to histological markers for investigating crypt histories, and should allow fate mapping. Examination of methylation tags of three neutral loci in cells from a normal human colon showed variation in sequences between crypts and in mosaic methylation patterns within single crypts. Multiple unique sites were present in morphologically identical crypts; for example, one patient had no identical methylation sequences of one gene within any of the crypts studied, even though all sequences were related [48]. This indicates that some normal human colonic crypts are quasi-clonal with multiple stem cells per crypt. Differences in methylation tags can highlight relationships among cells in a crypt where less closely related cells show greater sequence alterations and where closely related cells have similar methylation patterns. Sequence differences suggest that crypts are maintained by stem cells, which are randomly lost and replaced in a stochastic manner, eventually leading to a 'bottleneck' effect in which all cells within a crypt are closely related to a single stem cell descendant. This reduction to the most recent common crypt progenitor is predicted to occur several times during life, superficially resembling the clonal succession of tumor progression [49].

In situ analyses of glandular clonality in the human stomach have been more problematic. Nomura et al. [50] used X-chromosome-linked inactivation to study fundic and pyloric glands in human female stomachs. Studies using polymorphisms on X-linked genes, such as the androgen receptor (HUMARA) to distinguish between the two X-chromosomes, revealed that, although pyloric glands appear homotypic and thus monoclonal, about half of the fundic glands studied were heterotypic for the HUMARA locus and were consequently polyclonal. This finding suggests that a more complex situation occurs in humans than the studies of gastric gland clonality in chimeric mice indicate. However, we have seen that some glands in the mouse remain polyclonal throughout life [26].

BONE MARROW STEM CELLS CONTRIBUTE TO GUT REPOPULATION AFTER DAMAGE

The hematopoietic bone marrow stem cell is of mesodermal origin, and its functionality and cell surface markers have been well characterized [51]. When transplanted into lethally irradiated animals and humans, as in clinical bone marrow transplantation, it has been long considered that the hematopoietic stem cell colonizes host tissues to form only new erythroid, granulocyte-macrophage, megakaryocyte and lymphoid lineages [52]. Although earlier studies suggest that vascular endothelium could derive from transplanted donor marrow, more recent studies not only have confirmed these earlier proposals concerning endothelial cells [53,54] but also have indicated that adult bone marrow stem cells possess a considerable degree of plasticity and can differentiate into different cell types, including hepatocytes [55–59], biliary epithelial cells [56],

skeletal muscle fibers [60], cardiomyocytes [61], central nervous system cells [62], and renal tubular epithelial cells [63]. These pathways can be bidirectional, as muscle [64] and neuronal stem cells [65] can also apparently form bone marrow. Furthermore, it appears that selection pressure induced by target organ damage can intensify the efficacy of this process as bone marrow stem cells differentiate into cardiomyocytes, endothelial cells, and smooth muscle cells in mice, with ischemic cell death following myocardial infarction and coronary artery occlusion[61,66]. Bone marrow stem cells have also been shown to differentiate into pancreatic β-cells [67], and possibly more persuasively, fully differentiated cells can transdifferentiate into other adult cell types without undergoing cell division; for example, exocrine pancreatic cells can differentiate into hepatocytes *in vitro* [68]. Furthermore, isolated potential hepatic stem cells from fetal mouse livers, which differentiate into hepatocytes and cholangiocytes when transplanted into recipient animals, can form pancreatic ductal acinar cells and intestinal epithelial cells when transplanted directly into the pancreas or duodenal wall [69]. Thus, the conventional view that bone marrow stem cells generate cell types of a single lineage (i.e., all formed elements in the peripheral blood) has been rectified in favor of the findings that adult bone marrow stem cells are highly plastic and can differentiate into many cell types within various organs.

These observations have raised the possibility of regeneration of a failing organ by transplanting an individual's own bone marrow stem cells to colonize and repopulate the diseased tissue, thus avoiding the allograft reaction. In apparent proof of principle, fumarylacetoacetate hydrolase (FAH)-deficient mice, which resemble type 1 tyrosinaemia in humans, are rescued from liver failure by transplantation of purified hematopoietic stem cells that become morphologically normal hepatocytes, express the FAH enzyme, and therefore are functionally normal [59].

There are now several reports that bone marrow cells can repopulate both epithelial and mesenchymal lineages in the gut. Brittan et al. [70] analyzed the colons and small intestines of female mice that had received a bone marrow transplant from male mice donors and gastrointestinal biopsies from female patients with graft versus host disease following bone marrow transplant from male donors. Bone marrow cells frequently engraft into the mouse small intestine and colon and differentiate to form ISEMFs within the lamina propria. *In situ* hybridization confirmed the presence of Y chromosomes in these cells; their positive immunostaining for αSMA and negativity for desmin, the mouse macrophage marker F4/80, and the hematopoietic precursor marker CD34 determined their phenotype as pericryptal myofibroblasts in the lamina propria derived from transplanted bone marrow. This engraftment and transdifferentiation occurred as early as one week after bone marrow transplantation; almost 60% of ISEMFs were bone marrow-derived six weeks after the transplantation, indicating that transplanted bone marrow cells are capable of a sustained turnover of the ISEMF cells in the lamina propria (Fig. 44.5). Y-chromosome-positive ISEMFs were also seen in the human intestinal biopsy material [70]. Lethally irradiated female mice given a male bone marrow transplant and a subsequent foreign body peritoneal implant formed granulation tissue capsules containing myofibroblast cells derived from the hematopoietic stem cells of the transplanted bone marrow [71]. This suggests that myofibroblasts may generally derive from bone marrow cells.

There are a growing number of reports that bone marrow cells can repopulate gastrointestinal epithelial cells in animals and man. Krause et al. [72] found bone marrow-derived epithelial cells in the lung, gastrointestinal tract, and skin 11 months after transplantation of a single hematopoietic bone marrow stem cell in the mouse. In the gastrointestinal tract, engrafted cells were present as columnar epithelial cells in the oesophageal lining, a small intestinal villus, colonic crypts, and gastric foveola. No apparent engraftment into the pericryptal myofibroblast sheath was reported, and as only a single hematopoietic stem cell was transplanted, it is possible that the ISEMFs derive from mesenchymal stem cells within transplanted whole bone marrow. It is, however, generally believed that stromal cell populations do not survive following bone marrow transplantation — although if an empty niche exists, as after irradiation in the gut, engraftment might occur.

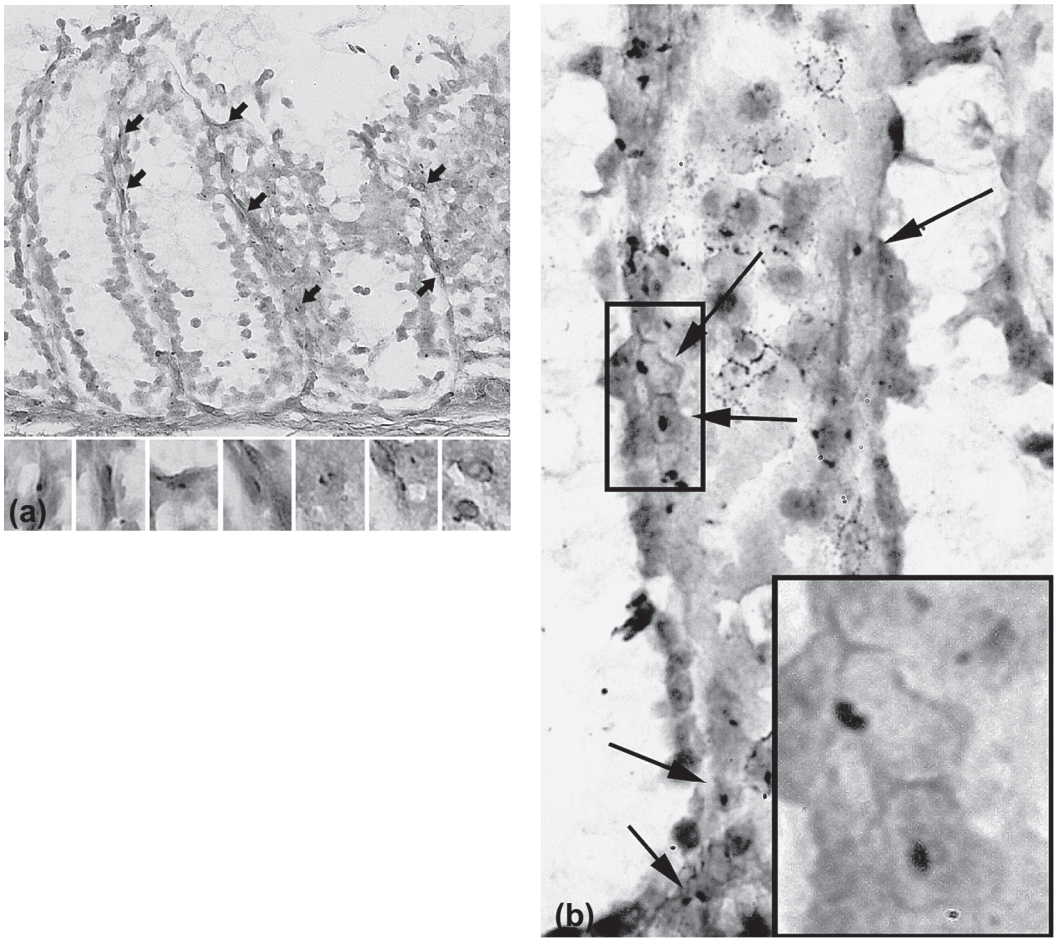

FIGURE 44.5

Bone marrow derived ISEMFs in the lamina propria of the mouse colon. Female mouse colon following a male whole bone marrow transplant. Bone marrow derived ISEMFs are present as Y-chromosome-positive cells, immunoreactive for α-SMA (a) two weeks after transplant (arrows and high-power inserts) and as columns reaching from crypt base to tip (b) six weeks after transplant (arrows and high-power inserts). The Y-chromosome is seen as a black punctate density, and cytoplasmic staining indicates immunoreactivity for α-SMA. *Courtesy of M. Brittan. (Please see CD-ROM for color version of this figure.)*

In biopsies from female patients who had undergone sex-mismatched hematopoietic bone marrow transplantation, *in situ* hybridization for a Y-chromosome-specific probe with immunohistochemical staining for cytokeratins demonstrated mucosal cells of donor origin in the gastric cardia [73]. Moreover, Okamoto et al. [74] reported four long-term bone marrow transplant survivors with multiple engraftment of oesophageal, gastric, small intestinal, and colonic epithelial cells by donor bone marrow cells up to eight years after transplantation, emphasizing the long-term nature of this transdifferentiation.

It would be impossible to finish even such a short section on this topic without mentioning the mechanisms and significance of such phenomena. At first considered to be caused by trans-differentiation or lack of lineage fidelity — commonly seen in invertebrates, during gastrulation, or during organogenesis — it is becoming clear that such changes are neither simple nor readily reproducible. Some labs have been unable to reproduce earlier findings [75,76], and there are claims that adult tissues are contaminated with bone marrow precursors [64]. Finally, the fusion of a transplanted bone marrow cell with an indigenous adult cell has been proposed as the mechanism by which bone marrow stem cells acquire the phenotype of target cell lineages. Initially, cell fusion was seen as a rare event, occurring only *in vitro* and under circumstances of extreme selection [77]. In the FAH model described previously, cell fusion was recently shown to be common, and it cannot be ruled out as the main mechanism by which bone marrow stem

cells transform to functional hepatocytes [78,79]. However, the genetic mechanisms whereby gene expression is switched off in the recipient cells — followed by clonal expansion to repopulate large areas of the liver, for example — are as yet unclear. We should also recall that several tissues in the mouse are polyploid, such as the liver and the acinar cells of the exocrine pancreas [80]. Other studies in which mixed-sex bone marrow transplants have been used to show plasticity have not reported evidence of cell fusion in animals or man. For example, bone marrow-engrafted cells in the human stomach, intestine, buccal mucosa, and pancreatic islet cells showed a normal complement of X and Y chromosomes [67,73,74,81]. Whatever the mechanism, it is clear that the most important criterion for altered lineage commitment, that of function [82], has only been fulfilled in a few models, such as the FAH model and possibly post-infarction cardiomyocyte engraftment. The future in this field will prove interesting.

In inflammatory bowel diseases, such as Crohn's disease, intestinal myofibroblasts are activated to proliferate and synthesize an extracellular matrix, and excessive collagen deposition causes fibrosis and post-inflammatory scarring in the lamina propria and muscularis layers of the gut wall. Intestinal inflammation is believed to be mediated by luminal bacteria and bacterial wall polymers [83], and tumor necrosis factor (TNF) plays a key role in the pathogenesis of intestinal inflammatory disease, since mice with targeted deletion of the AU-rich elements in TNF develop chronic ileitis resembling a Crohn's disease-like phenotype [84] (Figs. 44.6a through 44.6d). Moreover, a single dose of anti-TNF antibody to Crohn's disease patients can dramatically

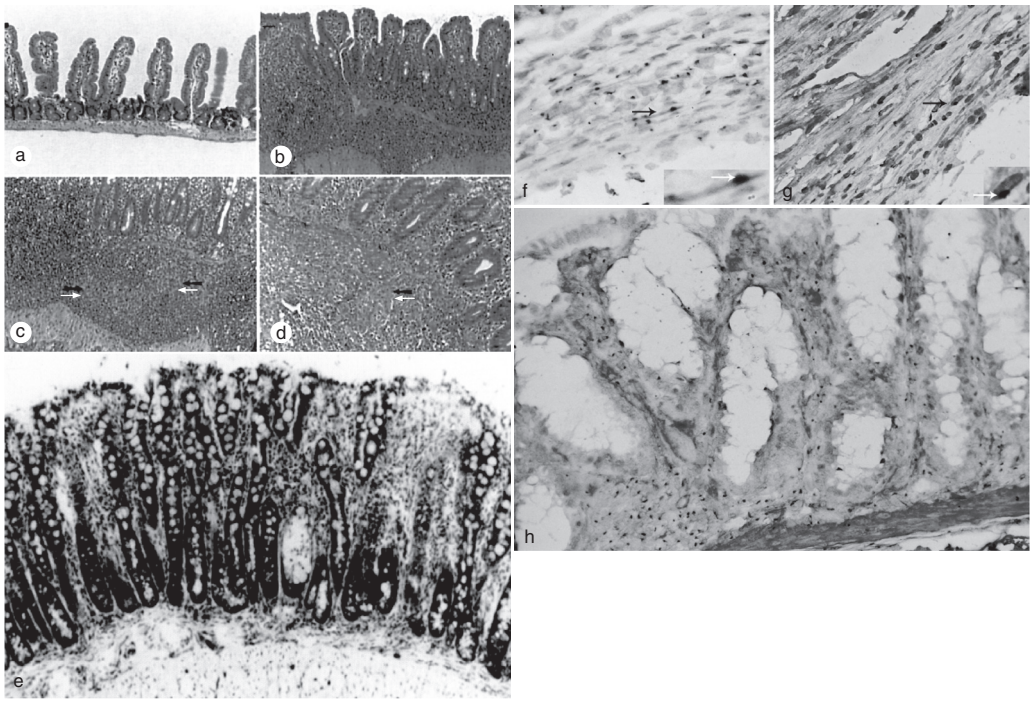

FIGURE 44.6

Murine models of fibrosis. Inflammatory bowel disease in TNFαARE and SAMP/Yit mouse ilea resembling human Crohn's disease. (a) Normal ileal morphology in an 8-week control mouse. (b) TNFαARE homozygous knockout at 7 weeks with blunt, distorted villi and increased inflammatory infiltrate. (c) TNFαARE heterozygote at 16 weeks with villus blunting and chronic inflammation. Direkze, and panel h courtesy of M. Brittan. (Please see CD-ROM for color version of this figure.)*

alleviate inflammation [85]. Other cytokines, including interleukin-10 [86] and TGFβ [87] are implicated in the development of fibrosis in inflammatory bowel disease.

It has previously been concluded that fibrotic reactions, which occur in inflammatory bowel disease, and other diseases are caused by the local proliferation of myofibroblasts and fibroblasts [88]. Our recent data showing that transplanted bone marrow contributes to the intestinal subepithelial myofibroblast population indicates that extraintestinal cells may have a role in fibrosis. In this respect, we have shown that cells with a fibroblast-fibrocyte phenotype can derive from transplanted bone marrow and contribute to fibrotic reactions in and around the intestinal wall [89] (Fig. 44.6f). The concept that cells of the lamina propria, other than the lymphoid and myeloid lineages, exist in equilibrium with bone marrow precursors is an interesting one and could provide an opportunity for therapeutic delivery of cytokines to the intestine to prevent the development of fibrosis, or even to treat it. Further recent data [90] show that many of the myofibroblasts and fibroblasts recruited to, or expanding in, the lamina propria and submucosa of mice with induced trinitrobenzene sulfonic acid (TNBS) colitis are bone marrow derived (Fig. 44.6g).

GASTROINTESTINAL STEM CELLS OCCUPY A NICHE MAINTAINED BY ISEMFs IN THE LAMINA PROPRIA

Stem cells within many tissues are thought to reside within a niche formed by a group of surrounding cells and their extracellular matrices, which provide an optimal microenvironment for the stem cells to function. The identification of a niche within any tissue involves knowledge of the location of the stem cells; as we have seen, this has proved problematical in the gastrointestinal tract. According to Spradling et al. [91], to prove that a niche is present, the stem cells must be removed and subsequently replaced while the niche persists, providing support to the remaining exogenous cells. Although this has been accomplished in *Drosophila* [92], such manipulations have not yet been possible in mammals. In this context, the survival of a single epithelial cell following cytotoxic damage to intestinal crypts in the microcolony assay is interesting, as many of the intestinal subepithelial myofibroblasts are also lost after irradiation [93], although sufficient numbers may remain or be replaced by local proliferation or migration from the bone marrow to provide a supportive niche for the surviving stem cell or cells. The ISEMFs surround the base of the crypt and the neck-isthmus of the gastric gland, a commonly proposed location for the intestinal and gastric stem cell niches, respectively. It is proposed that ISEMFs influence epithelial cell proliferation and regeneration through epithelial-mesenchymal crosstalk, and that they ultimately determine epithelial cell fate [3].

There has been a long quest for markers of stem cells in the intestine. The neural RNA-binding protein marker Musashi-1 (Msi-1) is a mammalian homolog of a *Drosophila* protein evidently required for asymmetrical division of sensory neural precursors. In the mouse, Msi-1 is expressed in neural stem cells [94,95] and has been proposed as the first intestinal stem cell marker because of its expression in developing intestinal crypts and specifically within the stem cell region of adult small intestinal crypts. This is further substantiated by its expanded expression throughout the entire clonogenic region in the small intestine after irradiation [94,95].

The regulatory mechanisms of stem cell division within the niche to produce, on average, one stem cell and one cell committed to differentiation is as yet unknown, although there is no shortage of potential models [96]. In the stem cell zone hypothesis, the bottom few cell positions of the small intestinal crypt are occupied by a mixture of cell types: Paneth, goblet, and endocrine. The migration vector is toward the bottom of the crypt [30–33]. Above cell position 5, cells migrate upward, although only the cells that divide in the stem cell zone beneath are stem cells. Other models envisage the stem cells occupying a ring immediately above the Paneth cells [97], although there is little experimental basis for such an assertion,

since 'undifferentiated' cells of similar appearance are seen among the Paneth cells in thin sections[31,32]. Moreover, there is no difference in the expression of Msi-1 and Hes1 — a transcriptional factor regulated by the Notch signaling pathway also required for neural stem cell renewal and neuronal lineage commitment — in undifferentiated cells located in either the stem cell zone or immediately above the Paneth cells [98]. This suggests that both populations may have the same potential as putative stem cells.

The number of stem cells in a crypt or a gland is presently unknown. Initially, all proliferating cells were believed to be stem cells [99]. Although clonal regeneration experiments using the microcolony assay indicated that intestinal crypts contained a multiplicity of stem cells, it was clear that this was less than the proliferative cellularity. Proposed stem cell numbers have varied from a single stem cell [100] to 16 or more [101]. Others have proposed that the number of stem cells per crypt varies throughout the crypt cycle, with the attainment of a *threshold number* of stem cells per crypt being the signal for fission to occur [102]. There is little experimental evidence to support these proposals. Although all cells in a crypt are initially derived from a single cell, as shown by the chimeric and X-inactivation experiments discussed previously, mutagenesis studies such as those shown in Fig. 44.1e and Fig. 44.2a argue strongly for more than one stem cell per crypt, with stochastic clonal expansion of a mutant clone. A three stem cell colonic crypt has been suggested by Williams et al. [35] on this basis.

In organisms such as *Drosophila* and *Caenorhabditis elegans* stem cell divisions are known to be asymmetric. We have no such firm concept in the mammalian gut, although there is some evidence to support the proposal [103,104]. By labeling DNA template strands in intestinal stem cells with tritiated thymidine during development or tissue regeneration, and by labeling newly synthesized daughter strands with bromodeoxyuridine, segregation of the two markers can be studied. The template DNA strand labelled with tritiated thymidine is retained, but the newly synthesized strands labeled with bromodeoxyuridine become lost after the second division of the stem cell. This indicates not only that asymmetric stem cell divisions occur but also that by discarding the newly synthesized DNA, which is prone to mutation, into the daughter cell destined to differentiate, a mechanism of stem cell genome protection is afforded [104].

When a stem cell divides, the possible outcomes are that two stem cells (P) are produced, that two daughter cells destined to differentiate (Q) cells are produced, or that there could be an asymmetric division resulting in one P and one Q cell. These are sometimes called p, q, and r divisions [102] or p and q divisions [107] (Fig. 44.7). If $p = 1$ and $q = 0$, then regardless of the number of stem cells per crypt, the cells are immortal and there will be no drift in the niche with time. Such a situation is called 'deterministic.' [48,105] However, if $p < 1$ and $Q > 0$ (i.e.,

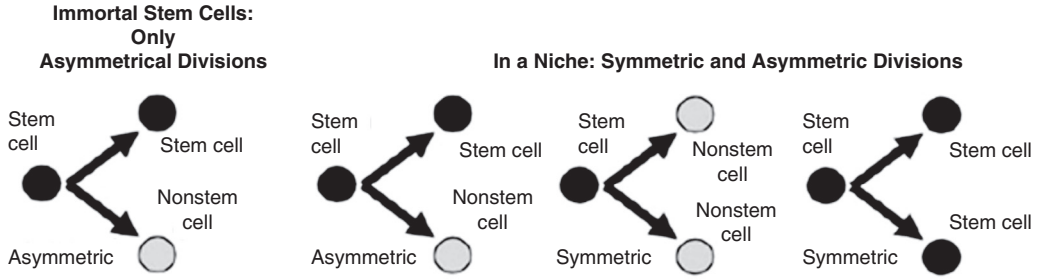

FIGURE 44.7

How stem cells divide in a niche. Classically, stem cells always replace themselves by asymmetrical division; therefore, their lineages never become extinct. However, although the stem cell number remains constant in a niche, both asymmetrical and symmetrical divisions occur. Symmetrical division can lead to one stem cell lineage becoming extinct as both daughters leave the niche, but to maintain a constant stem cell number in the niche, this loss is balanced by stem cell expansion, where both daughters remain in the niche as stem cells. Such stem cell loss with ensuing replacement can lead to the extinction of all lineages bar one, or clonal succession. *Reproduced with permission from Kim et al. [159] (Please see CD-ROM for color version of this figure.)*

a stochastic model), there will be eventual extinction of some stem cell lines and a drift toward a common stem cell from which all other cells derive. We previously described the variation in methylation patterns or 'tags' that occur in human colonic crypts [48,105] and explained that crypts apparently show several unique tags. The variance of these unique tags was compared with those expected using a variety of models, including no drift with aging (the deterministic model), drift with immortal stem cells with divergence (the numbers of unique tags are proportional to the stem cell number), drift with one stem cell per crypt, and a stem cell niche with more recent divergence (with loss of stem cells occurring proportional to the time since divergence). Multiple unique tags were found in some crypts, and the number of unique tags increased with the number of markers counted, which favors random tag drift and multiple stem cells per crypt. The variances were consistent with drift in immortal stem cells, where N (the number of stem cells) $= 2$, but favored a model where $0.75 < P < 0.95$ and $N < 512$. Thus, the data supported a stochastic model with multiple stem cells per crypt. However, as in many such attempts, there are several major assumptions necessary, such as a constant stem cell number. It is clear that variation in both P and N occur in this model. However, this analysis is consistent with the results of Campbell et al. [44], who deduced that the time taken for monoclonal conversion, or the 'clonal stabilization time', of $OAT^{+/-}$ individuals to convert to $OAT^{-/-}$ cells following irradiation was found to be about one year. Assuming 64 stem cells per niche and $P = 0.95$, the mean time for conversion should be some 220 days. The same assumptions suggest a bottleneck, where all stem cells are related to the most recent common ancestral cell, occurring every 8.2 years [104].

MULTIPLE MOLECULES REGULATE GASTROINTESTINAL DEVELOPMENT, PROLIFERATION, AND DIFFERENTIATION

Although the molecular mechanisms by which pluripotent stem cells of the gastrointestinal tract produce differentiated cell types are not clearly understood, an increasing number of genes and growth factors have been identified that regulate development, proliferation, and differentiation, as well as development of tumors. These are expressed by intestinal mesenchymal and epithelial cells and include members of the fibroblast growth factor family [106], epidermal growth factor family, TGFβ (reviewed by Dignass et al. [107]), insulin-like growth factors 1 and 2 [108], HGF-scatter factor [109], Sonic and Indian hedgehog [110], and PDGF-α [5], among others.

WNT/β-CATENIN SIGNALING PATHWAY CONTROLS INTESTINAL STEM CELL FUNCTION

The Wnt family of signaling proteins is critical during embryonic development and organogenesis in many species. There are 16 known mammalian *Wnt* genes, which bind to receptors of the frizzled (*Fz*) family, eight of which have been identified in mammals. The multifunctional protein β-catenin normally interacts with a glycogen synthase kinase 3-β (GSK3-β), axin, and adenomatous polyposis coli (APC) tumor suppressor protein complex [111]. Subsequent serine phosphorylation of cytosolic β-catenin by GSK3-β leads to its ubiquitination and to its proteasomal degradation, thereby maintaining low levels of cytosolic and nuclear β-catenin. Wnt ligand binding to its *Fz* receptor activates the cytoplasmic phosphoprotein *dishevelled*, which in turn initiates a signaling cascade resulting in increased cytosolic levels of β-catenin. β-Catenin then translocates to the cell nucleus, where it forms a transcriptional activator by combining with members of the T cell factor/lymphocyte enhancer factor (Tcf/LEF) DNA-binding protein family. This activates specific genes, resulting in the proliferation of target cells, for example, in embryonic development (Fig. 44.8). In addition to its role in normal embryonic development, the Wnt/β-catenin pathway plays a key role in malignant transformation [112,113]. Mutations of the *APC* tumor suppression gene are present in up to 80% of human sporadic colorectal tumors [114,115]. This mutation prevents normalβ-catenin

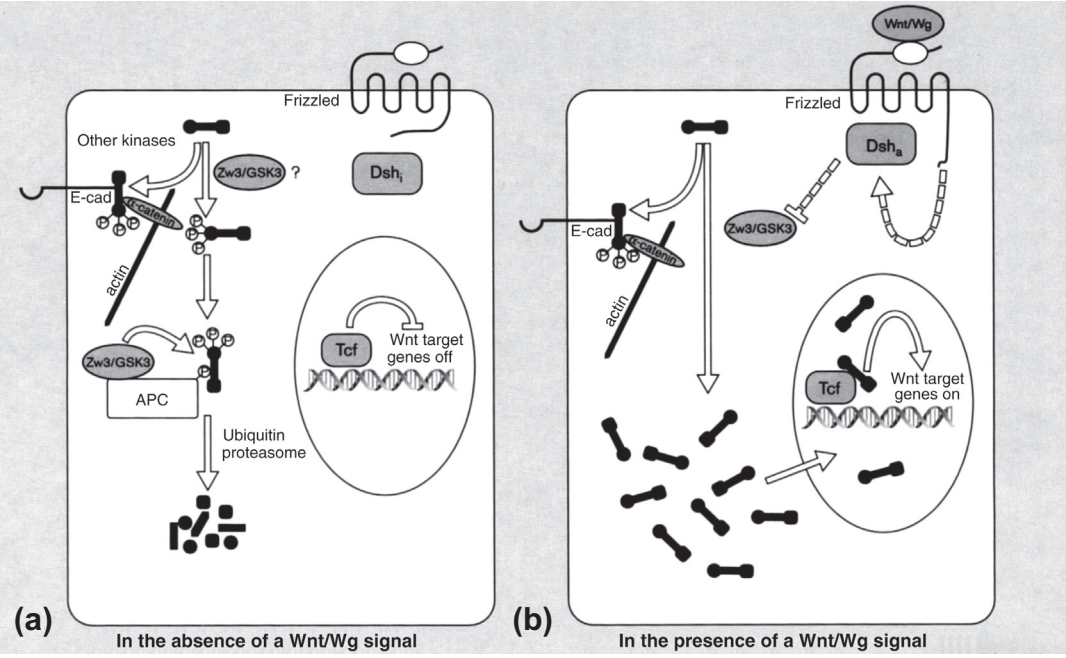

FIGURE 44.8

Wnt signaling pathway. (a) In the absence of Wnt signaling, *dishevelled* is inactive (Dshi), and Drosophila zeste-white 3 or its mammalian homolog glycogen synthase kinase 3 (Zw3/GSK3) is active. β-Catenin (black dumbbell), through association with the APC—Zw3/GSK3 complex, undergoes phosphorylation and. degradation by the ubiquitin-proteasome pathway. Meanwhile, T cell factor (Tcf) is bound to its DNA-binding site in the nucleus, where it represses the expression of genes such as Siamois in Xenopus. (b) In the presence of a Wnt signal, dishevelled is activated (Dsha), leading to inactivation of Zw3/GSK3 by an unknown mechanism. β-Catenin fails to be phosphorylated and is no longer targeted into the ubiquitin-proteasome pathway; instead, it accumulates in the cytoplasm and enters the nucleus by an unknown pathway, where it interacts with Tcf to alleviate repression of the downstream genes and provide a transcriptional activation domain. *Reproduced with permission from Willert et al. [113] (Please see CD-ROM for color version of this figure.)*

turnover by the GSK3β/axin/APC complex. This results in increased nuclear *β-catenin/Tcf/LEF* gene transcription and a subsequent increase in β-catenin-induced Tcf/LEF transcription [116,117]. One of the main functions of *APC* appears to be the destabilization of β-catenin. Free β-catenin is one of the earliest events, or perhaps even the initiating event, in tumorigenesis in the murine small intestine and in the human colon [118]. Many genes, including *c-myc*, *cyclin D1*, *CD44*, *c-Jun*, *Fra-1*, and urokinase-type plasminogen receptor have been identified as targets of the β-catenin/Tcf/LEF nuclear complex, although the precise mechanisms that lead to carcinogenesis are not entirely understood [118—122].

The Tcf/LEF family of transcription factors has four members; Tcf-1, LEF1, Tcf-3, and Tcf-4. Tcf-4 is expressed in high levels in the developing intestine from embryonic day (E) 13.5 and in the epithelium of adult small intestine, colon, and colon carcinomas. When there is loss of function of APC or mutations in β-catenin, increased β-catenin/Tcf-4 complexes are formed that lead to uncontrolled transcription of target genes [123,124]. Mice with targeted disruption of the *Tcf-4* gene have no proliferating cells within their small intestinal crypts and lack a functional stem cell compartment [124] (Fig. 44.9a through Fig. 44.9f). This suggests that *Tcf-4* is responsible for establishing stem cell populations within intestinal crypts; this in turn is thought to be activated by a *Wnt* signal from the underlying mesenchymal cells in the stem cell niche. Chimeric ROSA26 mice expressing a fusion protein containing the high mobility group box domain of Lef-1 linked to the transactivation domain of β-catenin (B6Rosa26<>129/Sv(Lef-1/β-cat) display increased intestinal epithelial apoptosis. This occurs specifically in 129/Sv cells throughout crypt morphogenesis, unrelated to enhanced cell proliferation. On completion of crypt formation and in adult mice, there is complete loss of all 129/Sv cells. Stem cell selection appears to be biased toward the unmanipulated ROSA26 cells in these

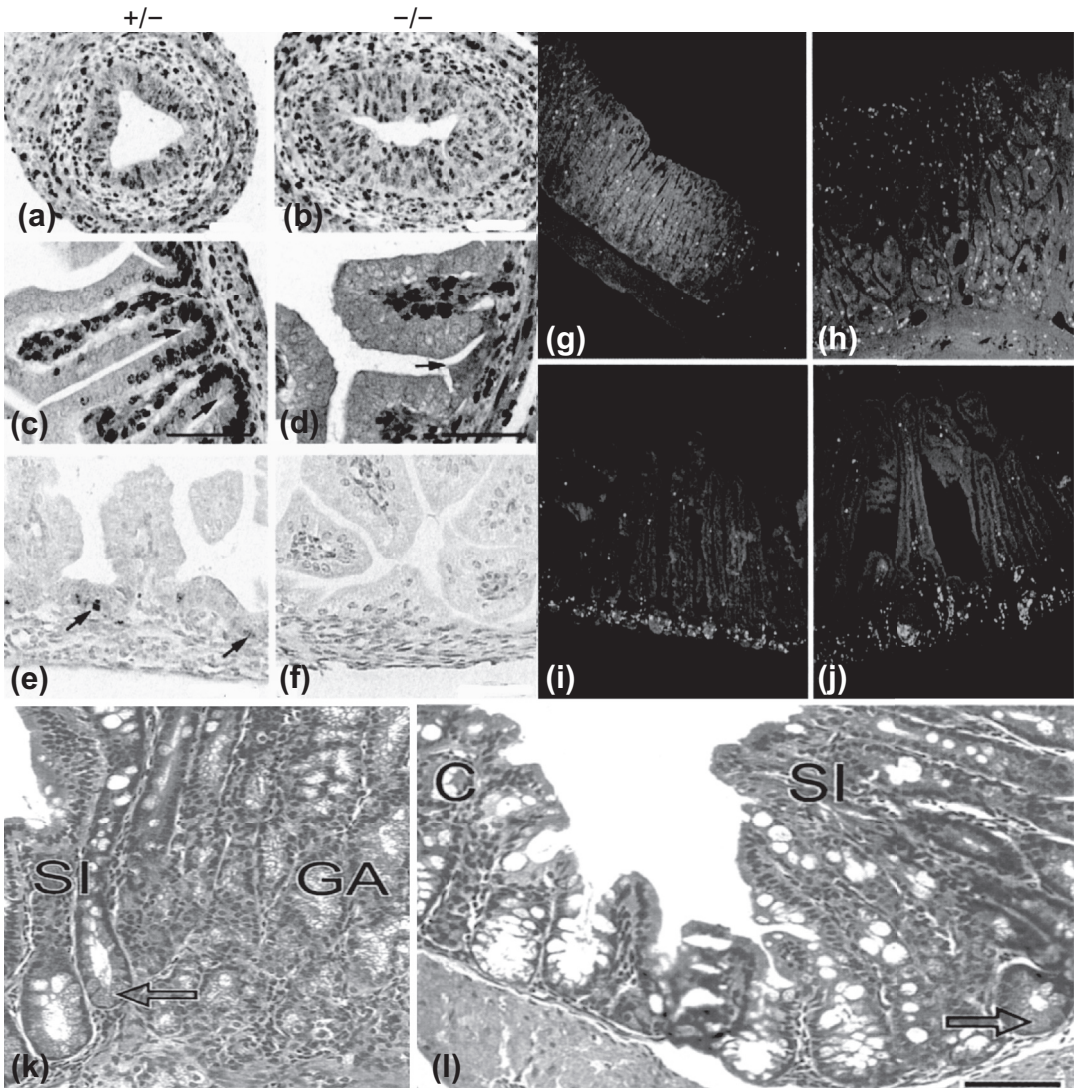

FIGURE 44.9

Tcf-4 knockout mice, Foxl1 knockout mice, and Cdx-2 knockout mice. (a–f) Small intestine from (a) E14.5 Tcf712+/– heterozygous, (b) Tcf712–/– homozygous, (c) E16.5 Tcf712+/–, and (d) Tcf712–/– embryos stained with Ki-67 antibody. (e) E17 heterozygous and (f) homozygous bromodeoxyuridine-labeled embryos stained with antibromodeoxyuridine. Numerous proliferating cells are present (a and b) throughout the epithelium at E14.5 in heterozygotes and homozygotes, but are restricted (c) to intervillous regions in E16.5 heterozygotes and absent (d) in E16.5 homozygotes. bromodeoxyuridine-labeled cells are present in intervillous regions of the (e) Tcf712+/– embryos (arrows), but are absent from (f) Tcf712–/– embryos. (g–j) Horizontal bars indicate 0.1 mm. Epithelial proliferation is increased in Foxl1 mutant mice shown by injection of bromodeoxyuridine 1.5 hours before sacrifice (g and h) in the stomach and (i and j) jejunum of (g and i) wild-type and Foxl1-null mice in increased levels (h and j) shown by immunofluorescence, where labelled nuclei represent proliferating cells. (k–l) The lateral edge of a colonic polyp in Cdx-2+/– mouse encompassing the gastric antrum (GA), small intestine (SI), and colon (C). Bar indicates 5.55 mm. (k) Goblet cells in the villi and Paneth cells (arrow) in the crypts adjacent to the branched mucus-secreting cells of the gastric antrum. (i) Transition from SI to C shows stunted villi with goblet cells and Paneth cells (arrow) in the crypts between villi. *Panels a–f reproduced with permission from Korinek et al., [124] panels g–j with permission from Perreault et al., [132] and panels k–l with permission from Beck et al. [127] (Please see CD-ROM for color version of this figure.)*

chimeras, suggesting that 'adequate threshold' levels of β-catenin during development permit sustained proliferation and selection of cells, establishing a stem cell hierarchy. Increased β-catenin expression appears to induce an apoptotic response, and thus the stem cell niche is unaffected by increased Lef-1/β-catenin during intestinal crypt development [125].

TRANSCRIPTION FACTORS DEFINE REGIONAL GUT SPECIFICATION AND INTESTINAL STEM CELL FATE

Hox genes define regional gut specification

The mammalian homeobox genes *Cdx-1* and *Cdx-2* display specific regional expression in developing and mature colon and small intestine. During embryogenesis, *Cdx-1* localizes to the proliferating cells of the crypts and maintains this expression during adulthood. The Tcf-4 knockout mouse does not express *Cdx-1* in the small intestinal epithelium, thus the Wnt/β-catenin complex appears to induce *Cdx-1* transcription in association with Tcf-4 during the development of intestinal crypts [126]. Mice heterozygous for a *Cdx-2* mutation develop colonic polyps composed of squamous, body, and antral gastric mucosa with small intestinal tissue (Fig. 44.9). Proliferation of *Cdx-2*colonic cells with low *Cdx-2* levels can produce clones of cells phenotypically similar to epithelial cells of the stomach or small intestine [127]. This could indicate a possible homeotic shift in stem cell phenotype. Region-specific genes such as *Cdx-1*, *Cdx-2*, and *Tcf-4* appear to define the morphological features of differential regions of the intestinal epithelium and regulate the proliferation and differentiation of the stem cells.

Forkhead family is essential for intestinal proliferation

The winged helix-forkhead family of transcription factors is essential for proper development of the ectodermal and endodermal regions of the gut. There are nine murine forkhead family members, which generate the forkhead box (Fox) proteins [128], three homologs of the rat hepatic nuclear factor 3 gene (*HNF3*α, -β, and -γ), and six genes referred to as forkhead homologs (*fkh-1* through *fkh-6*) [129]. *Fkh-6* is expressed in gastrointestinal mesenchymal cells [130] now reclassified as *Foxl1* [128]. *Foxl1* knockout mice have a dramatically altered gastrointestinal epithelium with branched and elongated glands in the stomach, elongated villi, hyperproliferative crypts, and goblet cell hyperplasia because of increased epithelial cell proliferation (Fig. 44.9g through 44.9j) [131]. They show upregulated levels of heparin sulfate proteoglycans (HSPGs), which increase *Wnt*-binding efficacy to the *Fz* receptors on gastrointestinal epithelial cells. This results in overactivation of the Wnt/β-catenin pathway and increased nuclear β-catenin [132]. The resultant β-catenin/Tcf/LEF complex activates target genes such as *cyclin D1* and *c-myc*, which increase epithelial cell proliferation. Therefore, *Foxl1* regulates the Wnt/β-catenin pathway in association with an increase in HSPGs, demonstrating epithelial cell regulation by mesenchymal factors during embryogenesis in the gastrointestinal tract. As *c-myc* is a known proto-oncogene, a mutation of *Foxl1* and the resultant increase in epithelial cell proliferation through inappropriate *c-myc* activation may lead to the development of colorectal cancers [122].

E2F transcription family is essential for development of the crypt proliferative zone

The E2F family of transcription factors regulates cell proliferation, allowing transit from the G_1 to the S phase. E2F4 is expressed in the proliferative regions of embryonic intestine and in the adult small intestine and colon. In E2F4-knockout mice, intestinal crypts fail to develop, and the lamina propria appears thickened. E2F4 is thus essential for the development of the proliferative compartment of the intestinal epithelium, although the molecular pathways that influence E2F4 during development are unknown [133].

MULTIPLE MOLECULES DEFINE STEM CELL FATE AND CELL POSITION IN THE VILLUS-CRYPT AXIS

The colonic crypt and the villus-crypt axis offer a system in which the fate of stem cell progeny is defined. Their position within this axis can readily be determined. The goblet cell number normally remains relatively constant, and Paneth cells derive positional information and use it

to remain in the crypt base. In mice, deletion of the *Math1* gene, a basic helix-loop-helix transcription factor and downstream component of the *Notch* signaling pathway, depletes goblet, Paneth, and enteroendocrine cell lineages in the small intestine. This indicates that Math1 is essential for stem cell commitment to one of three epithelial adult cell types. Math1 progenitors merely become enterocytes [134]. High levels of Notch switch on the Hes1 transcriptional repressor. This in turn blocks expression of *Math1* so that cells remain progenitors and ultimately become enterocytes. Conversely, low *Notch* expression increases levels of its ligand Delta, which induces *Math1* expression by blocking Hes1, causing cells to become goblet cells, Paneth cells, or enteroendocrine cells [135]. Hes1-null mice have elevated *Math1* expression, with increased enteroendocrine and goblet cells and fewer enterocytes. This supports the evidence that *Math1* regulates the determination of cell fate through a Notch-Delta signaling pathway [136] (Fig. 44.10).

Recent studies show that β-catenin and Tcf inversely control the expression of the EphB2/EphB3 receptors and their ligand ephrin-B1 in colorectal cancer and along the crypt-villus axis [137]. When the *EphB2* and *EphB3* genes are disrupted, cell positioning within the crypt is also disrupted. For example Paneth cells do not migrate downward to their normal position at the bottom of the crypt but scatter along crypt and villus. This indicates that β-catenin and Tcf contribute to the sorting of cell populations through the EphB/ephrin-B system.

In the future, it is clear that functional genomics will have an increasing role to play in the study and identification of intestinal stem cells. Stappenbeck et al. [138] studied a consolidated population of stem cells isolated by laser-capture microdissection from germ-free

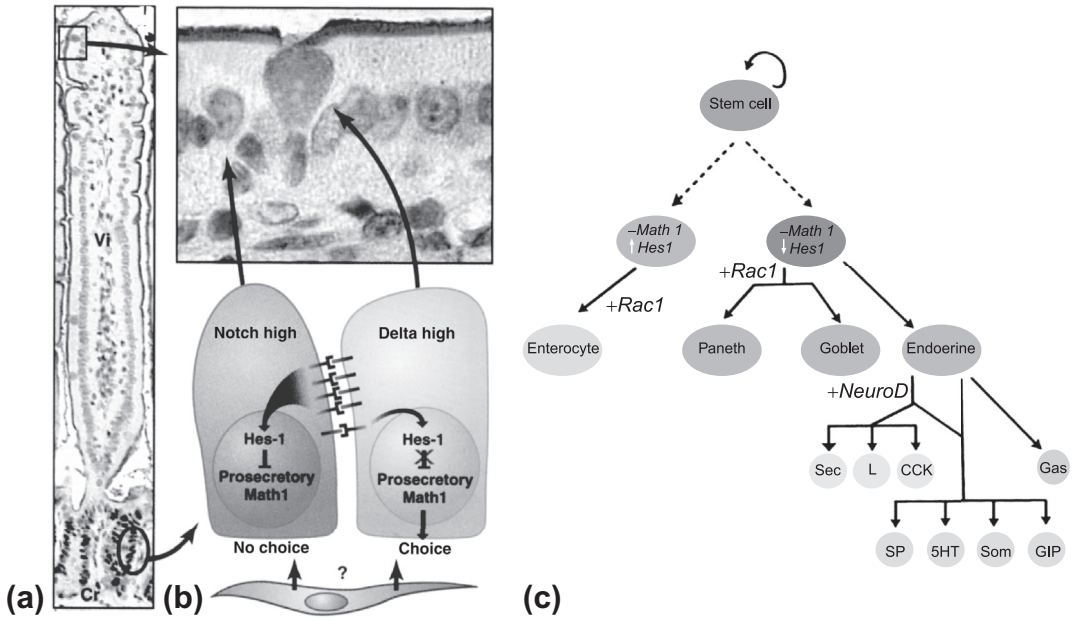

FIGURE 44.10

Math1 signaling pathway. (a) Low power section of adult murine small intestine. Precursor cells are stained for cyclin proliferating cell nuclear antigen, enterocytes express intestinal alkaline phosphatase, and goblet cells secrete mucins. Inset shows high-power image of small intestinal enterocytes and goblet cells. (b) Math1, a component of the Notch signaling pathway, influences intestinal epithelial cell fate decisions. In crypt progenitor stem cells that express high levels of Notch, the Hes1 transcription factor is switched on, and the expression of Math1 and of other 'prosecretory' genes is blocked. The result is that the precursor cells become enterocytes. In cells expressing low amounts of Notch, levels of Delta are high, production of Hes1 is blocked, and Math1 expression is induced. Production of the Math1 helix-loop-helix transcription factor allows precursor cells to make a choice: whether to become goblet cells, Paneth cells, or enteroendocrine cells (c) Math1 is essential for secretory cells. Whether Math1-expressing cells descend directly from stem cells or an intermediate progenitor remains unknown. (Vi: villus, Cr: crypt, Sec: secretin, L: glucagons—peptide YY, CCK: cholecystokinin, SP: substance P, 5HT: serotonin, Som: somatostatin, GIP: gastric inhibitory peptide, and Gas: gastrin). *Panels a and b reproduced with permission from van Den Brink et al., [135] and panel c reproduced with permission from Yang et al. [134] (Please see CD-ROM for color version of this figure.)*

transgenic mice lacking Paneth cells. There were no less than 163 transcripts enriched in these stem cells compared with normal crypt base epithelium, which contains a predominance of Paneth cells. The profile showed prominent representation of genes involved in *c-myc* signaling, as well as in the processing, localization, and translation of mRNAs. Similar studies in the mouse stomach showed that growth factor response pathways are prominent in gastric stem cells, examples including insulin-like growth factor [139]. A considerable fraction of stem cell transcripts encode products required for mRNA processing and cytoplasmic localization. These include numerous homologs of *Drosophila* genes needed for axis formation during oogenesis.

GASTROINTESTINAL NEOPLASMS ORIGINATE IN STEM CELL POPULATIONS

We can use the development of colorectal carcinoma as a paradigm. The concept of the adenoma-carcinoma sequence, whereby adenomas develop into carcinomas, is now widely accepted [140], and most colorectal carcinomas are believed to originate in adenomas. The initial genetic change in the development of most colorectal adenomas is thought to be at the *APC* locus, and the molecular events associated with these stages are clear: a second hit in the *APC* gene is sufficient to give microadenoma development, at least in FAP [141]. There are basically two models for adenoma morphogenesis, both of which closely involve basic concepts of stem cell biology in the colon: in the first, recently formulated, mutant cells appear in the *intracryptal zone* between crypt orifices, and as the clone expands, the cells migrate laterally and downward, displacing the normal epithelium of adjacent crypts [142]. A modification of this proposal is that a mutant cell in the crypt base, classically the site of the stem cell compartment [1], migrates to the crypt apex where it expands. These proposals are based on findings in some early non-FAP adenomas, where dysplastic cells were seen exclusively at the orifices and on the luminal surface of colonic crypts [142]; measurement of loss of heterozygosity (LOH) for *APC* and nucleotide sequence analysis of the mutation cluster region of the *APC* gene carried out on microdissected, well-orientated histological sections of these adenomas showed that half the sample had LOH in the upper portion of the crypts, most with truncating *APC* mutations. Only these superficial cells showed prominent proliferative activity, with nuclear localization of β-catenin, indicating an *APC* mutation only in these apical cells (Fig. 44.11c). Earlier morphological studies have drawn attention to the same appearances [143]. This top-down morphogenesis has wide implications for concepts of stem cell biology in the gut. It is clear that most evidence indicates that crypt stem cells are found at the origin of the cell flux, near the crypt base [23]. These proposals, however, either re-establish the stem cell compartment in the intracryptal zone or make the intracryptal zone a favored locus where stem cells, having acquired a second hit, clonally expand.

An alternative hypothesis proposes that the earliest lesion is the *unicryptal* or *monocryptal adenoma*, where the dysplastic epithelium occupies an entire single crypt. These lesions are common in FAP, and although they are rare in non-FAP patients, they have been described [144]. Here, a stem cell acquires the second hit, and then it expands, stochastically or more likely because of a selective advantage, to colonize the whole crypt. Such monocryptal lesions thus should be clonal [46]. Similar crypt-restricted expansion of mutated stem cells has been well documented in mice after ENU treatment [22] and in humans heterozygous for the *OAT* gene, where after LOH, initially half then the whole crypt is colonized by the progeny of the mutant stem cell [44]. Interestingly, OAT+/OAT$^-$ individuals with FAP show increased rates of stem cell mutation with clustering of mutated crypts. Thus, in sharp contrast the mutated clone expands not by lateral migration but by *crypt fission* in which the crypt divides, usually symmetrically at the base (Fig. 44.12a) or by budding (Fig. 44.11b). Several studies have shown that fission of adenomatous crypts is the main mode of adenoma progression — predominantly in FAP, where such events are readily evaluated [145,146], but also in sporadic

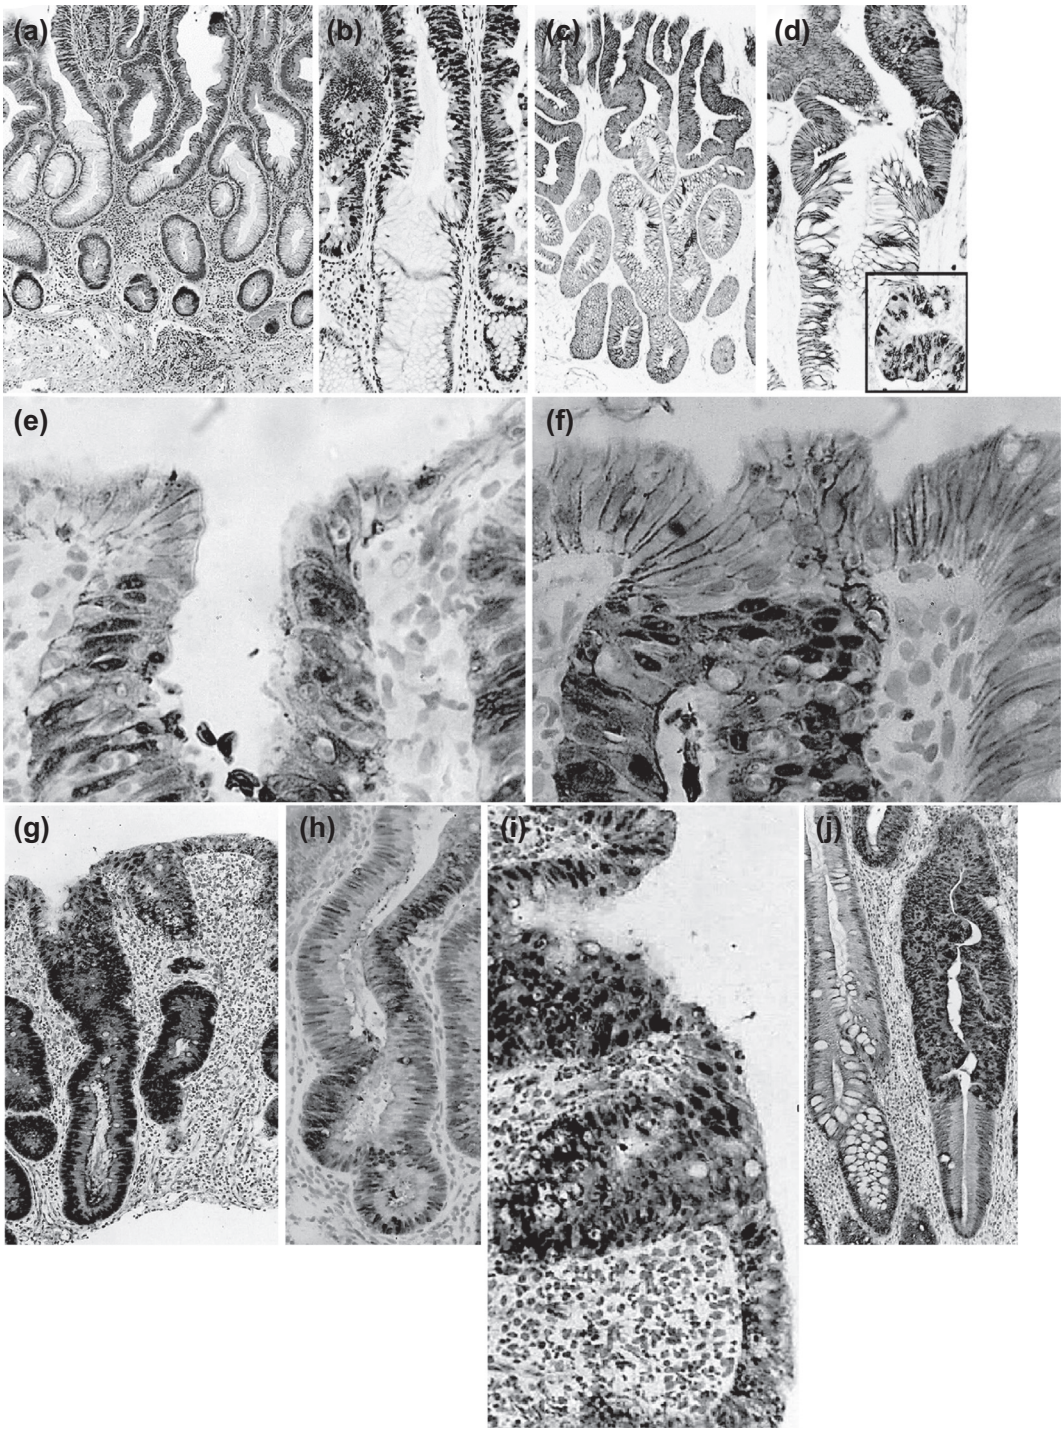

FIGURE 44.11

Contrasting theories for the morphogenesis of adenomas and the part played by stem cells. (a) Hematoxylin- and eosin-stained sections of a small tubular adenoma. Dysplastic epithelium is superficial within the crypts, with histologically normal underlying epithelium. (b) Abrupt transition between dysplastic and normal-appearing epithelial cells at the midpoint of this crypt. Proliferative activity assessed with the Ki-67 antibody, distributed throughout the dysplastic epithelium at the top of the crypts. (c) Nuclear β-catenin is highly expressed and distributed throughout the dysplastic epithelium at the top of the crypts but not in the crypt bases. (d) β-Catenin in the nuclei of adenomatous crypts from a tiny tubular adenoma. (e) Nuclear β-catenin extends to the bottom of crypts in early adenomas, including the very bases of the crypts. (f) β-Catenin staining in nuclei of budding crypts. (g) Junction between early adenomatous crypts, showing a sharp junction on the surface with accumulation of nuclear β-catenin giving way sharply to membranous staining in the normal surface cells. (h) High-power serial sections, demonstrating the sharp junction between nuclear staining in the adenomatous cells and membranous staining in normal surface epithelial cells. (i) Surface continuity between crypts showing nuclear β-catenin staining. (j) Crypts from a larger adenoma stained for β-catenin, showing invasion of adjacent crypt territories in a top-down fashion. *Panels a—d reproduced with permission from Shih et al., [142] and panels e—j reproduced with permission from Preston et al. [152] (Please see CD-ROM for color version of this figure.)*

adenomas [147]. The nonadenomatous mucosa in FAP, with only one *APC* mutation, shows a large increase in the incidence of crypts in fission [145]. Aberrant crypt foci, thought to be precursors of adenomas, grow by crypt fission [148,149], as do hyperplastic polyps [150]. This concept does not exclude the possibility that the clone later expands by lateral migration and downward spread into adjacent crypts, but with the initial lesion the monocryptal adenoma, this model of morphogenesis is conceptually very different.

Recent work supporting the bottom-up spread of colorectal adenomas looked at a number of small (< 3 mm) tubular adenomas. Here, nuclear accumulation of β-catenin (Fig. 44.11g) was seen, indicating loss of function of one of the genes in the Wnt pathway, most likely *APC*, with subsequent translocation of β-catenin to the nucleus. Serial sections (Figs. 44.11e and 44.11f) showed that the β-catenin nuclear staining extended to the bottom of the crypts and was present in crypts in the process of crypt fission (Fig. 44.11h). β-Catenin expression was particularly marked in the nuclei of buds. At the surface, there was a sharp cut-off between the adenomatous cells in the crypt that showed nuclear β-catenin and those surface cells that did not (Figs. 44.11e and 44.11f). The adjacent crypts were filled with dysplastic cells containing nuclear β-catenin, which were not confined to the upper portions of the crypts. In larger adenomas, there was unequivocal evidence of surface cells growing down and replacing the epithelium of normal-looking crypts (Fig. 44.11j). Crypt fission was rare in normal and noninvolved mucosa and usually began with basal bifurcation at the base of the gland (Fig. 44.12a), whereas in adenomas, fission was commonly asymmetrical (Fig. 44.12b) with budding from the superficial and mid-crypt (Fig. 44.12b). Multiple fission events were frequently observed in adenomas (Fig. 44.12c). The *crypt fission index* (the proportion of crypts in fission) in adenomas was significantly greater than that in noninvolved mucosa [150] (Fig. 44.12d).

It is usually stated that adenomas do not display a stem cell architecture, but recent observations [151,152] show that adenomatous crypts in early sporadic adenomas show superficial similarities to normal crypts in the distribution of their proliferative activity. Observations on possibly older adenomas have suggested that maximum proliferative activity is found towards the top of the crypts, indicating that that migration kinetics are reversed, with cells flowing toward the bottom of the crypt [153,154]. These observations are corroborated by the report of

increased apoptosis at the bottom of adenomatous crypts [155]. Such a distribution could support a top-down mechanism. But there is evidence from examining the methylation histories of cells in adenomas for a discrete stem cell architecture [156]; moreover, although crypt mitotic scores are significantly greater in adenomas than in noninvolved mucosa and normal controls, the zonal distribution of mitoses in adenomatous crypts mitoses is evenly distributed throughout the crypt, which does not suggest a concentration of dysplastic cells in the tops of adenomatous crypts.

Examination of the adenomas of an XO-XY individual with FAP showed none exceeded 2.5 mm in diameter [46].The monocryptal adenomas showed either the XO or the XY genotype and hence are clonal proliferations, as would be expected from the observation that crypts are clonal (Fig. 44.13a). Many microadenomas showed the XY genotype, and none of these early lesions showed mixture of XO and XY nuclei occupying the same crypt (Fig. 44.13b). It was shown that 76% of the microadenomas were polyclonal. There were also sharp boundaries at the surface between adjacent adenomatous crypt territories [152] (Fig. 44.3e).

What are the implications of these considerations upon our concepts of the single (stem) cell origin or clonality in colorectal adenomas? We have seen that crypts are clonal units; thus, these lesions would be polyclonal because of the mixture of clonal crypts and clonal adenoma — though in this instance, they have different clonal derivation. A study of both sporadic and FAP adenomas, using X-linked restriction fragment length polymorphisms, showed that such lesions were apparently monoclonal in origin [45]. On the other hand, the X-linked patch in the colon is large — and can be in excess of 450 crypts in diameter [47] (see Fig. 44.14). So, unless an adenoma grows over a patch boundary and involves crypts on either side of that boundary, X-inactivation analysis will always show that such lesions are monoclonal.

On the 'bottom-up' proposals, expansion of a clonal monocryptal adenoma by crypt fission would inevitably lead to a monoclonal microadenoma and thus adenoma. However, as

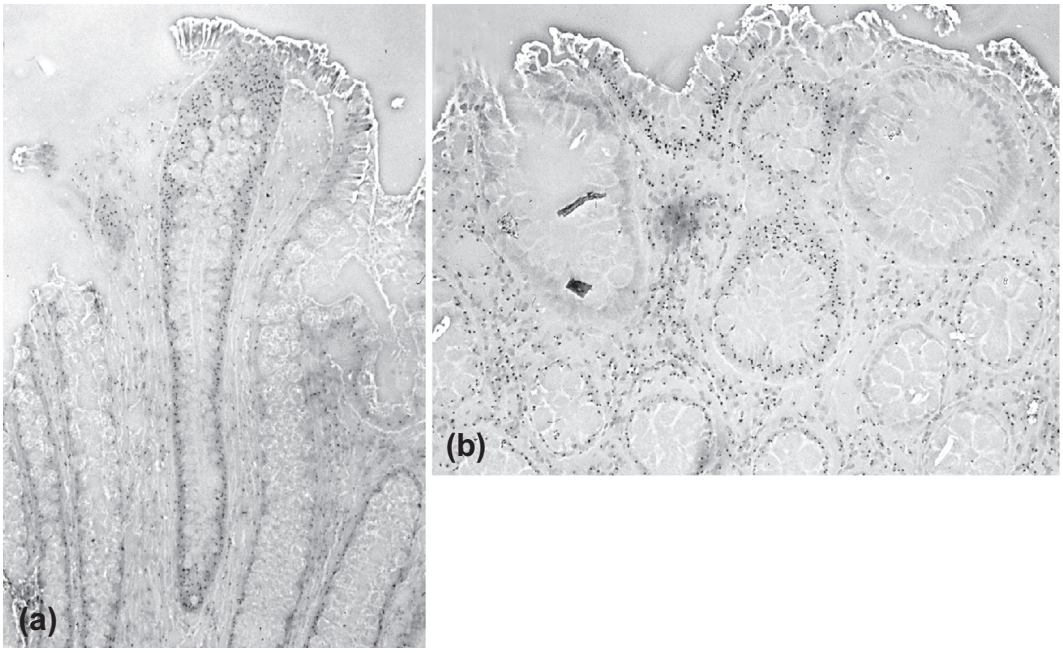

FIGURE 44.13
Adenomas from an XO—XY mosaic individual with FAP, stained by *in situ* hybridisation for a Y-chromosome—specific probe. (a) Clonal monocryptal adenoma. (b) Polyclonal adenoma, with a mixture of XO and XY crypts. Note that there is a sharp margin between the territories of XO and XY adenomatous crypts at the surface with no evidence of invasion. *Reproduced with permission from Preston et al. FIGURE 44.14
Visualization of X-inactivation patches directly by enzyme histochemistry in surgical resections from Sardinian females heterozygous for the G6PD Mediterranean mutation (563 C 3 T), previously shown to have reduced G6PD enzyme activity. Heterozygosity for the G6PD Mediterranean mutation was confirmed by polymerase chain reaction analysis of genomic DNA followed by MBOII restriction endonuclease. (a) G6PD staining in longitudinal sections of colonic crypts. In individual crypts, all epithelial cells show a similar staining pattern. (b) Longitudinal sections of crypts and villi in small intestinal mucosa stained for G6PD activity. Epithelial cells in individual crypts show a similar staining pattern, but the villous epithelium shows areas of positive and negative staining, confirming its polyclonal derivation. (c) G6PD staining in colonic patches in low power. (d) High-power view of large patches of crypts with irregular patch borders. Bar indicates 2 mm. *Reproduced with permission from Novelli et al. [47] (Please see CD-ROM for color version of this figure.)*

mentioned before, studies on the XO-XY individual, who has a mean patch size of 1.48 crypts, indicated that some 76% of adenomas were polyclonal [46], supported by observations in Rosa26-Min chimeric mice [157]. This could be explained by the transformation of noninvolved crypts by transformed stem cells.

So what is happening to the stem cells in the development of these early, monocryptal lesions? Bjerknes et al. [158] showed that adenomatous crypts in FAP contained two stem cell lines, $APC^{-/+}$ and $APC^{-/-}$, and interpreted this to mean that the $APC^{-/-}$ cells were expanding stochastically within the same crypt. There is good evidence that such monoclonal conversion occurs as a stochastic process [48,158]. It has previously been shown that a quantitative analysis of age-related methylation suggests that crypts are maintained by niches containing multiple stem cells [48]. Random stem cell loss with replacement suggests that all niche lineages except one will become extinct. It is fairly clear that clonal succession is related to tumor progression [48]. Although we have mentioned previously that Shibata has argued for clonal succession occurring in a stem cell niche without mutation, genetic alterations aiding clonal expansion of a mutant clone might confer a growth advantage [159]. Several mouse genotypes exist in which crypt morphology — and therefore implicitly stem cell proliferative behavior — is normal, such as $APC^{+/-}$, $TP53^{+/-}$, $Trp53^{-/-}$, $Apc^{+/-}$, $Trp53^{-/-}$, $MLH1^{-}/0$, $Apc^{+/-}$, $Mlh1^{-/-}$, and $Tgfbr2^{+/-}$. However, more subtle alterations, such as an increased incidence of crypt

fission that may be dependent upon stem cell behavior, might well be missed (see Wasan et al. [145], for example). These are special cases, so consider the situation in a normal individual, where stem cells are wild-type ($APC^{+/+}$) and one APC allele is lost in a single stem cell. This $APC^{+/-}$ stem cell, unless it possesses a growth advantage, could be lost by the stochastic ejection from the niche — indeed, it could be argued that this will happen in the overriding majority of instances [159], but the $APC^{+/-}$ cell could survive and the niche will be populated by progeny of this $APC^{+/-}$ cell, which will resemble an FAP crypt. A further hit in this crypt will lead to the formation of the monocryptal adenoma on the model proposed previously [152].

Others have also concluded that migrating crypt epithelial cells in the upper part of the crypt are the primary targets for transformation by *APC* mutation [160], and this has received some experimental support [161]. At the bottom of the crypt, progenitor cells accumulate nuclear β-catenin and express *Tcf* target genes as a result of *Wnt* stimulation from surrounding basal pericryptal myofibroblasts. In normal crypts, cells that reach the mid-crypt region down-regulate β-catenin/*Tcf*, resulting in cell cycle arrest and differentiation. Cells that bear a β-catenin or an *APC* mutation do not respond to signals controlling β-catenin/*Tcf* activity, and these cells continue to behave as crypt progenitor cells in the surface epithelium, generating microadenomas. Boman et al. [162] used computer modeling to suggest that an expansion in the crypt stem cell population explained the putative proliferative abnormality in FAP, namely an upwards shift in the proliferative compartment toward the top of the crypt [163]. Simulation of labeling index distribution curves from FAP crypts using a single mechanistic design was able to fit the data from both control and FAP crypts, indicating that the proliferative abnormality does not alter the rate of cell cycle proliferation, differentiation, or apoptosis of proliferating crypt cells. Instead, it suggests an expansion in the crypt stem cell population sufficient to explain the observed proliferative abnormality in FAP. Thus, β-catenin signaling in the colonic crypt controls the number of stem cells. The stem cell population is expanded in FAP crypts because of a germ line APC mutation activating Tcf-4. Any increase in the size of the stem cell population might be expected to result in an increase in the rate of crypt fission [164].

Crypt fission is therefore an essential event in the expansion of mutated clones in adenomas. Although the morphology of this process is distinct, the molecular mechanisms that govern it are far from clear. We further conclude that the initial event in the genesis of colorectal adenomas, of both sporadic and FAP adenomas, is the monocryptal adenoma; initial growth occurs through crypt fission, and spread into adjacent crypt territories is a later, secondary event.

SUMMARY

The cells of the gastrointestinal tract undergo constant renewal and respond to damage by regeneration and repopulation. Each region of the gastrointestinal tract is morphologically distinct with its own repertoire of cell types. Although the stem cells are the most important cells of the gastrointestinal tract, responsible for the production of every other cell type in the gastrointestinal mucosa, they have not yet been closely characterized. There is, initially at any rate, a single stem cell in every intestinal crypt or gastric gland that indirectly generates a clone containing further stem cells, transit amplifying and differentiated cells, through the production of committed progenitor cells. This cell also produces new crypts by crypt fission, repairs entire crypts and villi when damaged, and generates gastrointestinal tumors. The stem cell or cells occupy a niche, formed by mesenchymal cells such as the ISEMFs, and extracellular matrix molecules, which regulate epithelial stem cells through mesenchymal-epithelial crosstalk. The molecular events that regulate the development of the gastrointestinal tract and epithelial cell turnover in the normal tissue and in formation of carcinomas are beginning to be identified. It is clear that the Wnt/β-catenin signaling pathway and downstream molecules such as APC, Tcf-4, Fkh-6, Cdx-1, and Cdx-2 are vital for normal gastrointestinal stem cell function. We are beginning to identify molecular pathways that determine further

proliferation of committed progenitor cells into specific epithelial cell lineages: the Notch-Delta signaling pathways involving Hes1 and Math1 transcription factors regulate differentiation of goblet, Paneth, and enteroendocrine cells in the small intestine. Factors secreted and expressed by the mesenchymal cells (KGF, HGF, etc.) that regulate gastrointestinal mucosal development and epithelial proliferation are rapidly becoming identified. Epithelial and intestinal subepithelial myofibroblast lineages apparently derived from bone marrow, presenting the possibility of delivering therapeutic genes to the damaged lamina propria — for example, in diseases that cause fibrosis, such as Crohn's disease — and even repopulating the damaged gut. Finally, we conclude that the colonic stem cell is pivotal in understanding mechanisms of tumorigenesis in the colon. The isolation and characterization of gastrointestinal stem cells is a priority in gut biology.

CHAPTER 45

Liver Stem Cells

Rohan Manohar and Eric Lagasse
McGowan Institute for Regenerative Medicine, Department of Pathology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

INTRODUCTION

The hepatobiliary system consists of the liver, the intrahepatic bile ducts (IHBDs) and extrahepatic bile ducts (EHBDs) including the gallbladder. The identification of stem cells in the hepatobiliary system has importance for both basic biology and cell-based therapy. As candidate cell-based therapy, hepatobiliary stem cells could be an alternative to whole liver transplantation for patients suffering from chronic liver disease. However, the presence of stem cells in the adult liver remains a controversial concept, and there is a paucity of data regarding EHBD stem cells. The controversy surrounding the existence of liver stem cells is partially due to the extraordinary proliferative ability of adult hepatocytes, which are terminally differentiated cells that have a well-documented capacity for self-renewal and can accomplish regeneration of the liver after injury. In addition, there is a lack of clear evidence for the presence of a liver stem cell in the uninjured liver. However, there have been many recent reports of the prospective isolation of candidate stem cell populations in the liver and EHBD systems. Here we review recent literature regarding the lineage organization and self-renewal in liver and EHBD systems, as well as the studies evaluating presence of stem cells in both these systems.

DEFINITION OF A TISSUE-DERIVED STEM CELL

The classic definition of a tissue-derived adult stem cell comes from the study of hematopoietic stem cells. These stem cells have been defined as clonogenic cells capable of both self-renewal and colony formation, and differentiation to multiple committed progenitor cells that in turn proliferate and differentiate into functionally specialized mature cells [1]. In the search for hematopoietic stem cells, one which was initially driven by the need for bone marrow transplantation in patients, a hierarchical system organized around primitive stem cells, together with their committed progenitors and more mature cells, was uncovered [2–7]. With the prospective isolation of hematopoietic stem cells [6,7], it was possible to compare the regenerative abilities of these cells to all the other blood cells in mouse models of bone marrow transplantation. To the surprise of many, only the hematopoietic stem cells and not the more committed progenitor cells were able to sustain long-term engraftment *in vivo*. Thus, in the context of bone marrow transplantation, only the stem cells appeared important for the sustained regeneration of the hematopoietic system. This is in part due to the foremost characteristic of a stem cell: its capacity for self-renewal. Cells without long-term self-renewal potential, such as committed hematopoietic progenitor cells, would be capable of generating enough progeny for short-term engraftment, but would not be able to sustain long-term engraftment over many years. Therefore, self-renewal is a key function of stem cells.

Another property of stem cells is their multipotency, which is their ability to produce progeny of more than one lineage. Again, the best-known example of a multipotent tissue-derived stem cell is the hematopoietic stem cell. Hematopoietic stem cells have the capacity to give rise to many lineages, from short-term multipotent progenitor cells to more differentiated progeny [1]. Finally, clonality, i.e., the ability to self-renew from a single cell is probably the ultimate proof of the presence of stem cells. Clonal self-renewal allows one to demonstrate both self-renewal and mulitpotency at the single cell level. However, for stem cells to maintain their stemness, at least some of the cells must undergo division without differentiation while others will differentiate. Any claim for the isolation and identification of a resident tissue-specific stem cell has to satisfy two minimal requirements: the demonstration that it can be prospectively isolated and is capable of clonal self-renewal, and that it can differentiate to cell lineages of that tissue. Thus, a liver stem cell should be able to generate the two epithelial cells in the liver, namely the hepatocytes and the bile duct cells (Fig. 45.1). Multipotency in the EHBD system is harder to define, as the heterogeneity of epithelial cells has not been completely elucidated yet. In this chapter, we present a compilation of experiments that seek to identify liver stem cells as well as EHBD stem cells.

CELLULAR ORGANIZATION OF THE HEPATOBILIARY SYSTEM

Organization of liver and IHBD system

The liver is one of the largest organs of the body, composed of two epithelial cell types, the hepatocytes and IHBD cells. Both the hepatocytes and IHBD cells belong to the same hepatic lineage and are derived from a common stem cell during development (Fig. 45.1). The basic

functional unit of the liver is the *hepatic lobule*, which is demarcated by the portal triad and central vein. The portal triad is composed of the hepatic artery, portal vein and IHBD cells. Blood enters the liver from the portal vein and hepatic artery, and flows between liver sinusoids, which have a unique fenestrated endothelium, toward the central vein. Hepatocytes organized into hepatic plates are present between individual sinusoids, which allow the filtration of the blood. The junction of the hepatocytes and endothelial cells is their basolateral surface. The apical surface of hepatocytes is formed by bile canaliculi, which are spaces into which bile acids are pumped. Bile canaliculi form channels that drain bile secreted by hepatocytes into the bile ducts of the portal triad. In addition to hepatocytes and IHBD cells, sinusoidal endothelial cells, Stellate cells (formerly called *Ito cells*; resident fibroblasts found in the Space of Disse between hepatocytes and endothelial cells), Kupffer cells (resident macrophages of the liver), and leukocytes are also present in significant numbers in the liver.

There is functional heterogeneity of hepatocytes along the hepatic plate, from the portal triad to the central vein. Differences in heterogeneous biochemical properties as well as patterns of gene expression have been distinguished in periportal hepatocytes, i.e., those close to the portal triad and pericentral hepatocytes close to the central vein. Periportal hepatocytes are considered more primitive. This notion is reinforced by their proximity to the Canals of Hering, which represent the connection between the bile canaliculi and the bile ducts and is in the periportal zone and which have been proposed to be the site of the liver stem cells. Midacinar hepatocytes in the middle of the hepatic lobule and pericentral hepatocytes are considered more mature. However, these zonal differences depend on blood flow and more importantly, can be reversed when the blood flow through the liver is reversed [8].

Hepatocytes also exhibit heterogeneity in their ploidy. This is especially unique as hepatocytes are highly differentiated cells capable of multiple synthetic and metabolic functions. Hepatocytes can be diploid or polyploid, mononucleated or binucleated (Fig. 45.2). Newborn human or rat hepatocytes are exclusively diploid ($2n$) but will subsequently generate $4n$, $8n$, and eventually $16n$ mono- and binucleated hepatocytes. Aneuploidy is also frequently present in both human and mouse hepatocytes [9,10]. The mechanism for this polyploidization has been shown to be aborted cytokinesis, with mononucleated hepatocytes forming binucleated hepatocytes [11]. In rodents, studies of the transplanted hepatocytes separated by flow cytometry using the DNA profiles of diploid, tetraploid and octoploid liver cells, showed that all fractions could engraft, proliferate and regenerate liver tissues [12]. These data supported the conclusion that multiple hepatocyte ploidy classes can serve as progenitors for regenerating hepatocyte foci in damaged livers.

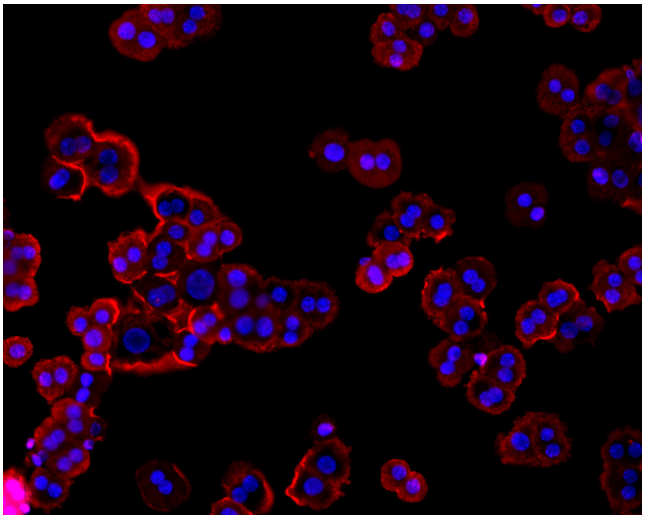

FIGURE 45.2
Cytospsin of mouse adult liver cells.
Hepatocytes are a heterogeneous population of cells: small and large, mono- and binucleated. Cells were stained with propidium iodide and counterstained with Hoechst.

Functional heterogeneity is also observed with IHBD cells. The bile ducts begin with the Canals of Hering within the hepatic lobule, and progressively increase in diameter into a system of interlobular, septal, area, segmental and hepatic ducts that eventually join with the EHBD system [13,14]. IHBD cells that line the Canals of Hering are small, cuboidal cells with a high nuclear to cytoplasmic ratio [15,16]. By contrast, larger bile ducts are lined with columnar epithelial cells that have low nuclear to cytoplasmic ratios, apical Golgi apparatus and relatively abundant rough endoplasmic reticulum. Beyond morphology, small and large IHBD cells differ by gene expression pattern and response to injury such as bile duct ligation (BDL) [17,18]. These data have led to the notion that small IHBD cells may represent committed bile duct progenitor cells that give rise to the large IHBD cells upon injury [16].

Organization of the EHBD system

The EHBD system consists of the common hepatic duct, gallbladder, cystic duct and common bile duct (CBD) [19,20]. Bile is concentrated and stored in the gallbladder, from where it is pumped through the CBD into the duodenum [21,22]. The gallbladder therefore plays an important role in the digestive process. However, this role appears to be dispensable, as cholecystectomy, or removal of the gallbladder, does not have major long-term consequences on the health of the organism. The epithelium of the EHBD system consists for the most part of a single layer of epithelial cells [23]. The CBD and Ampulla of Vater also consist of peribiliary glands (PBGs). PBGs are mucus secreting epithelial cells buried in the bile duct walls and are mostly found in the CBD and the Ampulla of Vater [24–26]. The gallbladder does not contain PBGs [20] but consists of Rokitansky-Aschoff (R-A) sinuses, which are invaginations of the epithelial cells through the muscle layer into the subserosal connective tissue have been identified by histology [27]. However, R-A sinuses are considered to represent early pathological changes in the gallbladder as their presence has been noted in gallbladder cancer [28, 29] and in gallstones [30,31]. Their existence in the uninjured gallbladder is controversial.

DEVELOPMENT OF THE HEPATOBILIARY SYSTEM

The liver, EHBD system and the ventral pancreas develop from the posterior ventral foregut endoderm [32–34]. Specifically, the liver primordium is formed by the closure of the lateral and medial endodermal domains [34], followed by its evagination into the septum transversum, which is the mesenchymal tissue located between the cardiac mesoderm and the ventral endoderm [33]. This induction requires Fibroblast Growth Factor (FGF) from the cardiac mesoderm and Bone Morphogenic Protein (BMP) from the septum transversum. At the same time, the ventral pancreas is induced in the lateral endodermal cells that are caudal to the hepatic endoderm [33]. Both these events occur at roughly embryonic day (ED) nine and three weeks post gestation in the mouse and human respectively.

The liver primordium is divided into cranial and caudal portions. The cranial portion of the liver primordium after its evagination into the septum transversum gives rise to the hepatocytes and the IHBD cells [32,35]. Hematopoietic cells migrate into the developing liver bud by ED 11 in the mouse. At this point, liver cells are referred as hepatoblasts and express liver specific genes like albumin (ALB), alpha-fetoprotein (AFP) and cytokeratin 19 (CK19) (Fig. 45.3). Hepatoblasts eventually give rise to mature hepatocytes and IHBD cells.

Developmental link between the EHBD system and ventral pancreas

The caudal portion of the liver primordium is thought to give rise to the EHBD system, including the gallbladder. However, this notion is based on histological data that show that EHBD and IHBD systems develop together. The exact mechanism of development and the cell-intrinsic factors by which the IHBD and EHBD segregate have heretofore been unclear.

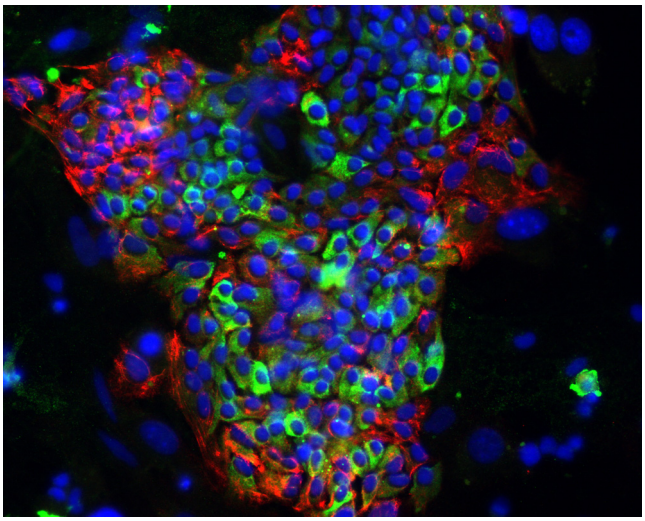

FIGURE 45.3
***In vitro* culture of human fetal liver cells.** Human fetal liver cells were cultured for several weeks on rat feeder cells. Colonies were stained with AFP, a marker for the hepatic lineage and CK19, a marker for bile duct cells. This colony contains a mix of cells positive for CK19 only (bile duct cells), AFP only (hepatoblasts and small hepatocytes) and for both (bipotent progenitor cells).

Sumazaki et al. [36] have noted gallbladder agenesis and ectopic pancreatic tissue in the common bile duct (CBD) in hairy and enhancer of split 1 (*Hes1*) deficient mice. Fukuda et al. [37] corroborated these data in a later study where they observed ectopic pancreatic tissue in the CBD of *Hes1*-knockout mice. In both reports, IHBD system development appeared normal though the connection to the CBD was lacking, suggesting a shared ontogeny between the EHBD system and ventral pancreas and one that is separate from the IHBD system. This shared ontogeny between the EHBD system and ventral pancreas has been much elucidated in a recent study by Spence et al. [38]. The authors used a pancreatic and duodenal homeobox-1 (PDX1)-Cre mouse to demonstrate that hepatocytes and IHBD cells derive from PDX1- cells while EHBD cells and ventral pancreas derive from PDX1+ cells. They found that SRY- (sex determining region)-box (SOX)-17 controlled the specification of the EHBD and pancreatic cells from PDX-1+ cells and this specification required HES-1. SOX-17 loss-of-function at ED 8.5 resulted in gallbladder agenesis and the presence of ectopic pancreatic tissue (PDX-1+ cells) in the EHBD. Conversely SOX17 gain-of-function at ED 9.5 resulted in ectopic ductal tissue (SOX-17+ cells) in the developing pancreas. In both the foregoing conditions, the IHBD system was not affected. The regulation of SOX-17 expression and its interaction with HES-1 and PDX-1 have yet to be completely understood. However, these data definitively demonstrate that during murine development, the IHBD and EHBD systems originate from distinct progenitor cells.

HEPATOCYTES: FUNCTIONAL UNITS OF THE LIVER WITH STEM CELL PROPERTIES

The liver is an amazing organ because it can regenerate

The Greek myth of Prometheus tells of the mortal who stole fire from Zeus and was punished by having his liver devoured by an eagle at dusk every day, only to have it regenerate by the following morning. The myth exaggerates the regenerative potential of the liver and the foregoing phenomenon was recognized much later in medicine. The classic experiment by Higgins and Anderson in 1931 demonstrated experimentally that surgical removal of two-thirds of a rat liver was possible without significant mortality, and more importantly resulted in regeneration of the remaining lobes of the liver within five to seven days by compensatory hyperplasia [39].

Serial surgical resection of the liver (hepatectomy) is therefore possible in experimental animals, and each time results in the extraordinary compensatory growth of the remaining liver lobes. This model of hepatectomy has been extensively studied and, to the surprise of

many, is not dependent on resident stem cells in the liver. In contrast to other regenerative tissues like the bone marrow or the gut, mature cells — mostly hepatocytes — in response to specific stimuli like growth factors enter into cell cycle and drive liver regeneration. Hepatocytes have been shown to be the primary cell responsible for this enormous proliferation and regeneration of the liver. They are the most abundant epithelial cells in the liver (~60%) and represent most of the mass of the organ due to their large size. Hepatocyte proliferation starts in the periportal region and spreads to the pericentral region. In general, the regeneration of the liver mass requires each hepatocyte to undergo an average of 1.4 rounds of replication to restore the liver mass. Other type of cells including IHBD cells, stellate cells, endothelial cells and Kupffer cells are also involved in the process of liver regeneration [40].

HEPATOCYTES TRANSPLANTATION: 'PROOF-OF-CONCEPT' FOR CELL-BASED THERAPY FOR LIVER DISEASE

Our understanding of the potential of cell-based therapy for liver disease has come from studies of transplanted liver cells into animal models. The first such experiment described the transplantation and survival of hepatocytes in the spleen [41]. This work was followed by the demonstration that these ectopic hepatocytes were functional and could proliferate [42–44]. Hepatocyte transplantation has also been demonstrated in experimental animal models with inherited metabolic liver diseases [45,46]. These experiments established that allotransplantation of normal hepatocytes and autotransplantation of genetically modified hepatocytes can correct metabolic defects.

More recently, transgenic and knockout mice have provided excellent models of liver regeneration by cell transplantation. In these models, inherited chronic hepatocellular toxicity induces massive necrosis of the recipient's hepatocytes, and a quasi-clonal proliferation of the healthy donor hepatocytes.

The transgenic mouse containing the urokinase plasminogen activator (uPa) downstream of the albumin promoter was one of the first such genetic models used to study liver regeneration [47]. Albumin-driven uPa expression results in hepatotoxicity, and this confers a selective growth advantage to the transplanted donor hepatocytes, allowing their massive proliferation. The FAH knockout mouse is another genetic model of hepatocellular toxicity with the added advantage that it reproduces a lethal human inherited disease, Type 1 Tyrosinemia [48]. In this model, deletion of the fumarylacetoacetate hydrolase (*Fah*) gene, which encodes a key enzyme in the tyrosine metabolic pathway, results in the buildup of toxic metabolites. $Fah^{-/-}$ mice develop severe liver disease, but can be rescued by blocking the tyrosine pathway upstream of FAH by using the drug 2-(2-nitro-4-trifluoro-methyl-benzyol)-1,3 cyclohexanedione (NTBC). $Fah^{-/-}$ mice on NTBC can develop to adulthood, breed and remain healthy. Removal of NTBC results in liver failure within 6–8 weeks and subsequent death. When $Fah^{-/-}$ mice are transplanted intra-splenically with single cell suspensions of syngeneic hepatocytes from wild-type mice, the $Fah^{+/+}$ cells migrate to the liver, invade the hepatic lobules and divide until > 95% of the liver cell mass is replaced by the donor hepatocytes [49]. Repopulated animals are healthy and as few as 100 donor hepatocytes are sufficient to rescue the animal from tyrosinemia. Moreover, repopulating hepatocytes can be serially transplanted to measure their cell division capacity, which highlights their tremendous proliferative ability [50].

As hepatocytes are such terminally differentiated cells, it was originally thought they only had a limited capacity for proliferation. However, both the uPa transgenic and $Fah^{-/-}$ mouse models demonstrated the opposite. In the uPa transgenic mouse, 12 or more hepatocyte cell divisions were necessary for liver regeneration. Serial transplantations in $Fah^{-/-}$ mice showed that donor hepatocytes were capable of 69 cell doublings. This rather unique capacity of hepatocytes to regenerate the liver has two essential requirements: extensive and continuous liver injury and a strong selective advantage for the donor cells to survive relative to the recipient

cells. However, these conditions are usually not present optimally in situations involving transplantation of human hepatocytes, as will be discussed later.

LIVER STEM CELLS

The presence of a stem cell distinct from IHBD cells and hepatocytes in the uninjured liver is hotly debated. In part this is because during homeostasis in the uninjured liver, new hepatocytes and IHBD cells are thought to be generated by duplication of each respective epithelial cell type [51–54]. However, in a recent study Furuyama et al. [55] using the SOX9 transgenic mouse, which labels most of if not all IHBD cells, it was demonstrated that new hepatocytes derive from IHBD cells. These data were contradicted in another more recent paper that used an adenoviral labeling system in the adult mouse to specifically label hepatocytes. Malato et al. [56] determined that new hepatocytes derive from hepatocytes. Both these studies use state-of-the art tools such as transgenic mice and viral serotypes that afford good target cell specificity and low toxicity, and provide direct evidence for their respective conclusions. Yet the stark difference in these conclusions highlights much of the disagreement surrounding our current knowledge of liver homeostasis, which extends to studies of liver stem cells.

Hepatocytes and IHBD cells as facultative stem cells

TRANSDIFFERENTIATION OF HEPATOCYTES INTO IHBD CELLS

The ability of hepatocytes to proliferate extensively *in vivo* raises the possibility that they could be stem cells. Interestingly, hepatocytes have been reported to potentially transdifferentiate into biliary cells, both *in vitro* [57,58] and *in vivo* [59]. However, neither the prospective isolation of hepatocytes nor their clonal expansions were reported in these studies, making a definitive conclusion regarding their multipotentcy and consequently, stemness difficult. If these studies were confirmed though, it can be postulated that hepatocytes would behave like facultative stem cells, having both self-renewal and lineage commitment capacities. Last, hepatocytes are a heterogeneous population of cells (Fig. 45.2) containing small and large, mono- and binucleated cells. Therefore, it can be argued that only a distinct population of 'primitive hepatocytes' may have stem cell properties.

OVAL CELLS AND DUCTULAR REACTIONS

In rodent injury models, damage to the liver combined with an arrest in the proliferative capacity of hepatocytes leads to the proliferation of 'oval cells'. These cells are not small hepatocytes but a distinct population of liver cells, which differentiates into hepatocytes and restores the hepatic parenchyma [60,61]. A similar population of liver cells called 'ductular hepatocytes' has been reported in patients suffering a variety of liver diseases [62]. These cells have a gene expression associated with both hepatocytes and cholangiocytes, and their presence has been reported in histopathology of human diseases from fulminant hepatitis to primary biliary cirrhosis.

In rodent models, experimental studies suggest that oval cells derive from IHBD cells. Using models of injury that inhibit hepatocyte proliferation, the Canals of Hering have long been identified as a reservoir of what would be later characterized as oval cells [63]. Recent studies have described the Canals of Hering as the structures that penetrate deep inside the hepatic lobules and could be considered as a candidate stem cell niche [64]. Studies in the rat treated with partial hepatectomy followed by the administration of *N*-2 acetyl-aminofluorene (AAF), a protocol used to generate large populations of oval cells, have demonstrated that these cells are located in the Canals of Hering before differentiating into hepatocytes [65]. In a more recent report, Kuwahara et al. [66] use a label retention assay to identify the regenerative cells during liver injury. They find that all the candidate stem cell niches localize to or around the Canals of Hering. However, correlating these data to the uninjured liver and the subsequent identification of stem cells has proved difficult.

Prospective identification of fetal liver stem/progenitor cells

The first clonogenic liver progenitor cells to be prospectively isolated were from fetal rats [67]. Using an *in vitro* colony forming assay and flow cytometry, a population of fetal rat liver cells RT1A^{1}/ OX18^{low}/ ICAM-1^{+} was isolated at ED13. These cells were considered as hepatoblasts and were shown to be bipotent *in vitro* (by expression of hepatocyte and IHBD cell markers). This report was followed by the identification of a similar population of hepatoblasts in mouse fetal liver [68,69]. By combining a different culture system with flow cytometry, a more primitive fetal liver cell population capable of forming large colonies and long-term expansion was isolated from mouse fetal livers [70,71]. In these studies, the c-Met^{+}/CD49f$^{+/low}$/c-kit^{-}/ CD45^{-}/TER119^{-} fetal liver cells were clonally propagated in culture and were shown to continuously produce hepatocytes and IHBD cells, while remaining primitive. These clonally propagated cells were transplanted into mice and shown to morphologically and to some extent, functionally differentiate into hepatocytes and IHBD cells. Furthermore, these mouse fetal liver cells were capable of differentiating into pancreatic acinar cells, gastric as well as intestinal epithelial cells upon transplantation into these organs. Therefore, these cells were regarded as more of a general endodermal stem cell population [71]. More recently rodent studies have identified select markers that significantly enrich stem/progenitor cells. Using colony forming assays and flow cytometry, Kakinuma et al. [72] demonstrated that CD13^{+}/ Dlk^{+}/CD45^{-}/TER119^{-} cells at ED13.5 in mouse livers form the largest colonies *in vitro*, differentiate to produce ALB- and ck19-producing cells and engraft into recipient livers. Similarly, Oertel et al. [73] identified Dlk^{+} cells at ED14 in rat livers as being significantly enriched in liver stem/progenitor cells.

We know very little about the different progenitor populations in the human fetal liver. Recently, several isolations and characterizations of human fetal liver stem/progenitor cells were described. Using EpCAM and magnetic activated cell sorting (MACS), EpCAM^{+} hepatoblasts and hepatic stem cells were isolated from fetal, neonatal and adult liver and cultured in short-term (10 days) and long-term (20 days) assays [74]. EpCAM^{-} liver cells proved to be more than 95% diploid and polyploid hepatocytes. Hepatic stem cells were EpCAM^{+}, NCAM^{+}, CLDN-3^{+}, ck19^{+}, c-kit^{+}, aquaporin 4^{+} Alb^{low} and AFP^{-} while hepatoblasts were EpCAM^{+}, NCAM^{-}, CLDN-3^{-}, ck19^{low}, c-kit^{low}. In a later study, the authors localized the hepatic stem cells to the ductal plates in the human fetal livers and confirmed that they are capable of long-term expansion *in vitro* and are able to form hepatocyte-like cells (ALB^{+}/AFP^{+}/ Cytochrome P450-A7^{+}) and IHBD cells (ck19^{+}) [75]. In addition, transplantation into NOD-SCID mice showed that the hepatic stem cells could generate hepatocytes *in vivo*.

In another report, a multipotent progenitor population (hFLMPC) was reported to be capable of differentiating into liver and mesenchymal lineages [76]. Human fetal liver cells were maintained in culture on feeder cells and colonies were clonally isolated by serial dilution. These progenitor cells have the immunophenotype CD34^{+}, CD90^{+}, c-kit^{+}, EpCAM^{+}, c-met^{+}, SSEA-4^{+}, CK18^{+}, CK19^{+}, Albumin^{-}, alpha-fetoprotein^{-}, CD44h^{+} and vimentin^{+}. Placed in appropriate media, hFLMPC differentiated into hepatocytes and bile ducts as well as into fat, bone, cartilage, and endothelial cells. Similar to the findings of Schmelzer et al. [75], hFLMPCs in this study engrafted and formed hepatocytes *in vivo* when transplanted into animal models of liver disease. Dan et al. noted that hFLMPCs do not express hepatic markers like albumin, alpha-fetoprotein or primitive hepatic transcription factors (HNF1a, HNF3b, and HNF4a) in their undifferentiated state, but express mesenchymal markers. These results suggest that hFLMPCs are mesenchymal-epithelial transitional cells that could have a mesendodermal origin. In all, there is significant discrepancy between the foregoing reports regarding methods of *in vitro* culture, clarity of cell surface markers to identify stem cells, clonal expansion assays and *in vivo* transplantation experiments. For all these reasons, further analysis and characterization are necessary to determine the true origin of human fetal liver progenitor cells.

Prospective identification of adult liver stem/progenitor cells

Most studies of the identification of adult liver stem/progenitor cells in rodent systems focus on diseased liver conditions in which hepatocyte proliferation is blocked and oval cells emerge (see the section 'Oval cells and ductular reactions') [77–82]. As a result there are few reports of the presence of stem cells in the uninjured rodent and human livers. Suzuki et al. [78] and Qiu et al. [79] used CD133 and CD24 expression respectively, to isolate candidate stem cells from uninjured adult mouse livers. In both reports, the isolated cell populations expanded *in vitro* and appeared to differentiate into hepatocytes. Suzuki et al. [78] demonstrated that $CD133^+$ cells were capable of clonal self-renewal and gave rise to hepatocytes and IHBD cells *in vitro*. In both the foregoing reports, the authors determined that the candidate stem cell populations were capable of engraftment and differentiation into hepatocytes in $Fah^{-/-}$ mice. Suzuki et al. also observed that the frequency of $CD133^+$ cells increased upon DDC treatment.

Dorrell et al. [81] have used specific antibodies developed in-house [83] along with CD133 expression to identify a subpopulation of non-hepatocyte small liver cells capable of *in vitro* expansion and hepatocyte differentiation. They demonstrate that these candidate liver stem cell populations could engraft and differentiate into hepatocytes in $Fah^{-/-}$ mice. In addition, they determined that these stem cell populations were the most enriched for SOX9 expression, and were enriched upon DDC treatment.

While interesting, these studies suffer from the same general problems. The specific markers used usually co-stain with IHBD cells in the liver, confusing the interpretation of the results. Expansion of the stem cells was not completely homogeneous but contained contaminating mesenchymal cells, making the discernment of a resident epithelial stem cell difficult. Finally, the hepatocyte differentiation observed with these cells was inconclusive and occurred at very low frequencies. This could be for various reasons, beginning with the lack of a definitive *in vitro* hepatocyte differentiation protocol. However, it could also be because these candidate stem cells are not capable of *de novo* hepatocyte differentiation. In all, the identification of a liver stem cell is inconclusive and consequently, there are no specific markers for its isolation.

STEM CELLS IN THE EHBD SYSTEM

There are few reports of the identification of stem cells in the EHBD system, and specifically in the gallbladder. Irie et al. [84] observed c-kit^+ cells in the mouse CBD and gallbladder following BDL that expressed albumin and cytochrome P450 enzymes. These cells engrafted into livers of mice injured with carbon tetrachloride (CCl_4) and one-third partial hepatectomy, suggesting that they were capable of hepatocyte differentiation. However, this study does not mention the presence of c-kit^+ cells in the uninjured EHBD, which makes evaluating the origin of these cells difficult.

Recently, there have been reports indicating that PBGs in the EHBD system are a reservoir for multipotent stem cells that are capable of differentiation into hepatocytes, bile duct cells and pancreatic islets [20,85]. In a recent report, Cardinale et al. [20] demonstrate that the PBGs express the transcription factors SOX-9, SOX-17 and PDX-1 as well as EpCAM and CD133. They found that cells from the PBGs could expand *in vitro* long-term and when placed in the appropriate culture conditions or animal models, were capable of differentiating into hepatocytes, bile duct cells and glucose-responsive pancreatic islets *in vitro* and *in vivo* respectively [20]. However, these reports while interesting, fall short of definitively identifying the initial cell population isolated from the primary tissue and make no mention of separation of the PBGs from the luminal epithelium of the CBD. Furthermore, the gallbladder does not contain PBGs [20].

Our group has recently identified an $EpCAM^+/CD49f^{hi}/CD29^+/CD133^+/CD45^-/TER119^-$ epithelial subpopulation from adult mouse gallbladders that expanded *in vitro*, formed large colonies and exhibited single cell clonal self-renewal and differentiation to gallbladder-like

structures *in vitro* and *in vivo* [86]. The gallbladder stem cells also expressed the bile duct transcription factors SOX9 and SOX17. However, we did not observe any hepatocyte markers in these cells and were not able to obtain engraftment of the gallbladder stem cells in the livers of $Fah^{-/-}$ mice. Interestingly, we found that the transcriptional profiles of gallbladder stem cells and candidate IHBD stem cells were distinct from each other [86] corroborating the evidence that they descend from separate progenitors [38]. Functional annotation of differentially expressed genes suggested that lipid and drug metabolism are different in these two cell types, and consequently that their functions might be different as well. To our knowledge, this is the first direct comparison of the expression profiles of IHBD and gallbladder cells.

THERAPEUTIC APPROACHES FOR USING STEM CELLS IN THE HEPATOBILIARY SYSTEM

Treating orthotopic liver transplantation (OLT): searching for alternatives to hepatocyte transplantation

Liver disease affects a large part of western society and is among the top causes of death in the US [87]. Roughly 10% of all Americans suffer from liver disease. In addition, 170 million people worldwide and 4 million in the US are infected with Hepatitis C [88], which is a major cause of liver failure [89]. Currently the only widespread treatment for chronic liver disease is allogeneic orthotopic liver transplantation (OLT). However, OLT is hindered by the severe lack of donated livers. There are over 15,000 people on the waiting list for liver transplant and only 5,000 available donors [90]. Furthermore, this procedure requires the use of lifelong immunosuppressive drugs and is complicated by graft loss. In addition, OLT is an expensive procedure that not everyone can afford. As organ transplantation is unavailable for a large fraction of patients with acute and chronic liver disease, hepatocyte transplantation has become an increasingly attractive prospect. This foregoing need, along with the success of hepatocyte transplantation in animal models has resulted in several groups evaluating the efficacy hepatocyte-based cell therapy in a variety of human diseases [91–93]. Hepatocyte transplantation is less expensive and invasive than OLT, and unlike the whole organ, hepatocytes can be cryopreserved and stored.

Patients have undergone hepatocyte transplantation for inborn inheritable metabolic diseases. These surgeries have been performed in individual cases and in small, uncontrolled groups of patients [93,94]. Although the beneficial outcome in some of these liver cell transplantations has been very encouraging [95,96], the limited clinical experience with hepatocyte transplantation is still a problem. In addition, the single biggest obstacle to the widespread use of hepatocyte transplantation is the limited availability of donor liver tissue. Most hepatocytes used in clinical transplantation settings are obtained from donors that are deemed unsuitable for OLT and are subsequently of poor quality and viability. And it has been difficult to argue that an already limited donor pool should be shared between what is still an experimental cell transplantation protocol and the more established whole organ transplantation one. This problem of availability could be solved by alternative sources of hepatocytes, such as liver or EHBD stem/progenitor cells, pluripotent cell-derived hepatocytes or the transdifferentiation of other somatic cells such as fibroblasts into hepatocytes. The latter two options are discussed below.

Pluripotent cells as a candidate cell source of hepatocytes

Adult hepatocytes are scarce and refractory to *in vitro* expansion. For these reasons, embryonic stem cells (ESCs) and more recently induced pluripotent stem cells (iPSCs) are being evaluated as alternative cell sources for hepatocyte generation. iPSCs are better favored as their generation circumvents the ethical considerations that plague ESC generation and because of the possibility of autologous hepatocyte transplantation. A complete account of hepatocyte generation from pluripotent cells is beyond the scope of this chapter (see review in reference [97]).

We will instead focus on the seminal papers here and briefly discuss progress in and obstacles to this field.

Rambhatla et al. were the first to show that human ESCs could generate hepatocyte-like cells [98]. Since then various groups have reported the same result, specifically enhancing culture conditions to obtain a more homogenous and mature hepatocyte population [99–101]. Using similar protocols, a few groups have shown differentiation of iPSCs into hepatocyte-like cells [102–104]. However, in all these studies, the end products of differentiation are a heterogeneous population of cells including hepatocyte-like cells. Moreover, the hepatocyte-like cells are considered immature rather than terminally differentiated hepatocytes. Finally, only a few studies have evaluated these cells *in vivo*, and those that have, have observed teratoma formation, suggesting contamination of pluripotent cells in the donor cells. In all, there is currently no definitive protocol for the differentiation of pluripotent cells into terminally differentiated hepatocytes.

Non-hepatic somatic cells as a cell source of hepatocytes

Mouse gallbladder epithelial cells have been shown to differentiate into hepatocyte-like cells *in vitro* [105]. In this study, the authors cultured mouse gallbladder cells in transwell inserts above a layer of myofibroblast feeder cells, a technique that supports expansion of epithelial cells [106]. Following *in vitro* expansion, gallbladder epithelial cells were grown between collagen and matrigel in the presence of epidermal growth factor (EGF), hepatocyte growth factor (HGF) and dexamethasone (Dex). In these conditions, the authors noted the up-regulation of the hepatocyte markers HNF4α and ALB. The functionality of these hepatocyte-like cells was determined by bile acid synthesis, uptake of low-density lipoprotein and benzodiazepine metabolism [105]. In a later study, the same group observed engraftment of freshly isolated and *in vitro* expanded gallbladder epithelial cells in the livers of non-obese diabetic (NOD)/severe combined immunodeficiency (SCID) mice [107]. However, this engraftment was possible only with tremendous injury to the recipient liver. Even then reported engraftment was only 1.94% ± 2.18%, with the majority of donor cells engrafting in the IHBD system [107]. Therefore, the *de novo* differentiation of gallbladder cells into hepatocytes does not appear to be very frequent or robust. In all, these data establish the proof-of-concept for the differentiation of gallbladder cells into hepatocytes. In addition, the gallbladder is considered to be a non-vital organ and is routinely removed during surgery, with 500,000–600,000 surgeries every year [108]. This sheer volume of available tissue combined with the shared ontogeny of the liver and gallbladder presents exciting opportunities for candidate cell-based therapy.

Two more recent studies have detailed the reprogramming of mouse fibroblasts into hepatocyte-like cells using specific transcription factors [109,110]. In both reports, the authors began by over-expressing transcription factors that play a role in liver development, in mouse fibroblasts and eliminated those that did not give rise to a hepatic phenotype [33,111,112]. In the first study, Huang et al. [109] observed that over-expression of GATA4, HNF1α and Forkhead box A3 (FOXA3) in *p19*^{Arf}-null (p19^{Arf} is a cell cycle inhibitor) adult mouse fibroblasts, converted them into induced hepatocyte-like (iHep) cells. iHep cells exhibited hepatic morphology and expressed hepatic genes. Moreover, they were able to significantly (~80%) engraft and rescue five out of twelve *Fah*$^{-/-}$ mice.

In the second study, Sekiya et al. [110] observed that over-expression of combinations of two transcription factors – HNF4α and either FOXA1, FOXA2 or FOXA3 – in embryonic and adult mouse fibroblasts resulted in iHep cells. Similar to the previous study, the authors found that the iHep cells resembled hepatocytes in morphology and gene expression patterns and rescued significant (40%) numbers of transplanted *Fah*$^{-/-}$ mice. Both these studies confirm that somatic cells can be successfully reprogrammed into functional hepatocytes capable of engraftment *in vivo*. Furthermore, they suggest that reprogramming is more effective with specific transcription factors than defined culture conditions.

CONCLUSION

Major progress has been made in the identification of liver stem/progenitor cells. However more needs to be learned regarding the phenotypes and plasticity of these cells. So far only a few laboratories have prospectively isolated fetal liver stem cells, and as yet there is no consensus about their phenotypes. And in the adult liver, the presence of a stem/progenitor cell is still disputed. Finally, there is a clear paucity of data regarding EHBD including gallbladder stem/progenitor cells.

Transplantation of hepatocytes in small-animal models has demonstrated their ability to proliferate *in vivo*. Clinical trials for hepatocyte cell-based therapy to treat end-stage liver disease are subsequently underway (reviewed in reference [93]). But much remains to be discovered. Adult and fetal hepatocytes and fetal and adult liver stem/progenitor cells need to be compared to determine the most optimal cell for engraftment. This is especially important given the shortage of adult donor livers, and hepatocytes. Significant effort is necessary to demonstrate the reprogramming of fibroblasts and pluripotent cells into hepatocytes and the efficacy of this approach for cell-based therapy. Cell expansion will also be an issue for a viable therapeutic procedure. Finally, transplanted cells must have a clear selective advantage to engraft and repopulate the diseased liver. Starting points are the metabolic disorders that provide the necessary environment for efficient cell transplantation. However in acute and chronic liver disease where such an environment does not exist, a procedure similar to myeloablation would be necessary. In all, there is much more to learn about hepatobiliary stem cells. However, given the prevalence of liver disease, progress is necessary.

LIVER FAILURE AND CURRENT TREATMENTS

Liver disease afflicts over 600 million people worldwide, 30 million of whom are Americans. Liver disease leads to the death of over 40,000 individuals in the United States every year. Liver failure can be generally separated into two major categories: fulminant hepatic failure, also referred to as acute liver failure, and chronic hepatic failure resulting from chronic end-stage liver disorders. The term fulminant hepatic failure is utilized for cases in which hepatic encephalopathy and impaired synthetic function (i.e., coagulopathy) develops within 26 weeks of the initial onset of jaundice. Hepatic encephalopathy is a neuropsychiatric condition, which can be divided into four stages ranging from minor effects such as mild confusion and sleep disorder, to deep coma. Although fulminant hepatic failure is relatively rare, with approximately 2,000 cases in the United States per year, it exhibits a high mortality rate of approximately 28% [1]. The major identified causes of fulminant hepatic failure include acetaminophen overdose, idiosyncratic drug reactions, and viral hepatitis A and B [1]. Of note, a recent multicenter etiology study showed that 17% of fulminant hepatic failure cases remained of indeterminate origin [2]. In addition to hepatic encephalopathy, other clinical manifestations of fulminant hepatic failure include bacterial and fungal infection, coagulopathy, as well as metabolic, cardiorespiratory, and hemodynamic abnormalities. Though spontaneous recovery has been observed due to the regenerative capacity of the liver, this type of recovery is difficult to predict, and rarely occurs in various etiologies, such as idiosyncratic drug toxicity and hepatitis B [1]. Liver transplantation is currently the only therapy shown to directly alter mortality, and therefore, is the standard of care in most clinical settings. As a result, all fulminant hepatic failure patients that meet the criteria for orthotopic liver transplant are immediately listed as United Network for Organ Sharing Status 1 (highest priority) upon presentation. Factors that preclude this designation are irreversible brain damage, unresponsive cerebral edema, uncontrollable sepsis, malignancy, and multisystem organ failure. Despite the effectiveness of liver transplant in improving short-term survival of fulminant hepatic failure patients, the utility of this approach remains limited due to the scarcity of donor organs.

Liver failure due to chronic liver diseases, while exhibiting a longer time-course of disease pathogenesis, is much more common than fulminant failure, with chronic liver disease

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00046-X

and cirrhosis being the twelfth leading cause of death (1.3% of total deaths) in the United States in 2010 [3]. The most common causes of chronic liver disease are hepatitis B virus, hepatitis C virus, and alcohol-induced and non-alcoholic fatty liver disease (NAFLD) [4]. Other etiologies largely include metabolic and autoimmune etiliogies: primary sclerosing cholangitis, primary biliary cirrhosis, α_1-antitrypsin deficiency, autoimmune hepatitis, hereditary hemochromatosis, Wilson's disease, and liver cancer. The prevalence of hepatitis C infection in the United States population has been estimated at 1.8%, or nearly 4 million individuals [5]. Notably, cirrhosis initiated by hepatitis C infection is the most frequent cause for liver transplantation, accounting for 40–50% of both individuals who have undergone transplant and those on the waiting list [6]. In addition, the long-term inflammation precipitated by chronic hepatitis B and C infection can also promote the development of hepatocellular carcinoma. As a result, substantial efforts are focused on understanding hepatitis B and C viral pathogenesis and the development of approaches for the improved control of the viruses before and after transplantation. Taken together, so-called fatty liver diseases also comprise a major proportion of chronic liver disease patients [4]. In particular, NAFLD is an increasingly prevalent condition in the United States; present in approximately 20% of adults, of which a subset (2–3% of adults) exhibit non-alcoholic steatohepatitis (NASH), defined by the presence of characteristic injury and necroinflammatory changes in addition to excessive fat accumulation. NAFLD pathogenesis has been shown to be associated with risk factors and conditions such as obesity, type 2 diabetes mellitus, hyperlipidemia, hyperinsulinemia, and insulin resistance. Collectively, chronic liver disorders can progress towards the eventual development of cirrhosis and sequelae of decompensated cirrhosis: ascites, portal hypertension, variceal bleeding, and hepatic encephalopathy. Unfortunately, these complications represent decompensation of liver function and evidence of liver dysfunction. Medical management can minimize the impact on patient quality of life but transplantation is the only currently effective therapy. As a means to more accurately determine organ allocation to patients on the liver transplant waiting list the MELD (mathematical model for end-stage liver disease) system was implemented in 2002, which assigns a priority score based on three prognostic indicators, bilirubin level, creatine level, and INR (a measure of blood clotting time) [6]. Although overall improvements in liver allocation have been achieved following the introduction of the MELD system, regional variations in MELD scores exist, and the ability of this model to accurately predict outcomes across the entire score distribution and for distinct pathologies is less clear.

Unlike other major causes of mortality, liver disease death rates are rising rather than declining. Hepatitis B and hepatitis C virus infect 370 million and 130 million people, respectively. Current hepatitis B vaccination campaigns may help to decrease hepatitis B virus (HBV) associated morbidity although the rapid increase in HIV coinfected patients has represented a challenge for clinical management. The rising rates of obesity have also resulted in the rapid rise of NAFLD worldwide with recent epidemiologic studies suggesting a prevalence rate from 6% to 35% with a median of 20%. Up to 20% of patients with NAFLD may progress to cirrhosis, raising the possibility that liver disease may become one of the most common causes of mortality worldwide. Moreover, patients with cirrhosis or hepatitis B are at greater risk of developing hepatocellular carcinoma. Consequently, hepatocellular carcinoma is the third and sixth most common cause of cancer death among men and women, respectively.

Given the steady rise in patients with liver disease, the need for liver transplantation has continued to increase. However, the number of available donor livers has not changed significantly in five years. As a result several different approaches have been undertaken to address this growing of donor organs. Several surgical options have been pursued including the use of non-heart-beating donors or split liver transplants from cadaveric or living donors [7]. Split liver transplants depend on the significant regeneration capacity of the mammalian liver. This regenerative process has been extensively examined via experiments in rodent models, which demonstrate that partial hepatectomy or chemical injury induces the

proliferation of the existing mature cell populations within the liver including hepatocytes, bile duct epithelial cells, and others, resulting in the replacement of lost liver mass. However, liver regeneration is difficult to predict clinically, and although partial liver transplants have demonstrated some effectiveness, biliary and vascular complications are major concerns in these procedures [7]. In addition, the surgical risk to the living donors (which has included several donor deaths) has raised significant ethical questions. Furthermore, in spite of these surgical advances and improvements in organ allocation, the increasing divergence between the number of patients awaiting transplantation and the number of available organs suggests that it is unlikely that liver transplantation procedures alone will expand the supply of donor livers to meet the increasing demand. Alternative approaches are therefore needed and are actively being pursued. These include several non-biological extracorporeal support systems that will be discussed in more detail later in this chapter such as plasma exchange, plasmapheresis, hemodialysis, molecular adsorbents recirculation system, or hemoperfusion over charcoal or various resins. These systems have shown limited success likely due to the narrow range of functions inherent to each of these devices relative to the complex array of functions performed by the healthy liver, which include detoxification, synthetic, and metabolic processes. Recapitulation of a substantial range of liver functions will be required to provide sufficient liver support, and it is unclear which known liver functions (e.g., gluconeogenesis, serum protein production, coagulation factor production, toxin-mediating encephalopathy) should be prioritized to improve clinical outcomes. Given this complexity, extracorporeal support systems that do not incorporate a hepatocyte component may not be able to ameliorate and augment liver disease outcomes as illustrated by the failure of several non-biological extracorporeal support systems. In contrast, limited hepatocyte transplantation trials have been shown in some cases to ameliorate and improve liver function. These cellular therapies encompass approaches at providing temporary support such as extracorporeal bioartificial liver (BAL) devices as well as more permanent adjunct interventions such as cell transplantation, transgenic xenografts, and implantable hepatocellular constructs (Fig. 46.1). Collectively, the development of these types of cell-based therapies for liver disease is a major aim of liver tissue engineering, and fundamental advances and current status of these approaches are reviewed in this chapter.

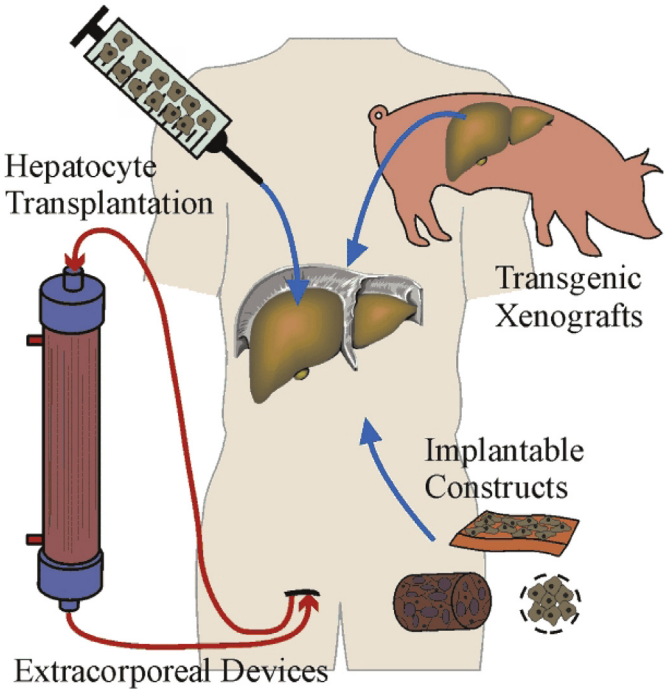

FIGURE 46.1
Cell-based therapies for liver disease. Extracorporeal devices perfuse patient's blood or plasma through bioreactors containing hepatocytes. Hepatocytes are transplanted directly or implanted on scaffolds. Transgenic animals are being raised in order to reduce complement-mediated damage of the endothelium [114].

CELL SOURCES FOR LIVER CELL-BASED THERAPIES

Cell-based therapies hold great promise, but their clinical use has been hindered by the inability of hepatocytes isolated from the *in vivo* hepatic microenvironment to maintain hepatocyte-specific phenotype and function *in vitro*. Due to the paucity of human liver tissue as a cell source, alternative cell sources have been explored (Table 46.1) with inherent strengths and drawbacks. However, the criteria to characterize these alternative cell sources as a hepatocyte or hepatocyte-like cells have not been standardized and vary greatly among different studies. No single test has been demonstrated to be sufficient to determine whether a particular cell type truly recapitulates hepatocyte function; as a result, several tests must be carried out to query various domains of hepatocyte function, including bile production, detoxification, metabolic, and synthetic functions (Table 46.2).

Cell lines

Immortalized hepatocyte cell lines such as HepG2 (human hepatoblastoma) [8], the HepG2 derived line C3A [9], HepLiu (SV40 immortalized) [10], or immortalized fetal human hepatocytes [11], have been utilized as readily available surrogates for hepatic tissue. However, these cell lines lack the full functional capacity of primary adult hepatocytes, and for clinical applications there is a risk that oncogenic factors or transformed cells could be transmitted to the patient. Thus, the generation of conditionally immortalized lines and the incorporation of inducible suicide genes have been considered as potential precautionary measures.

Primary cells

The use of primary hepatocyte-based systems could potentially eliminate the issues faced by immortalized lines, and provide the appropriate repertoire of liver functions. Primary porcine hepatocytes have been utilized in a range of BAL device configurations with some encouraging results. However, the utility of xenogeneic porcine cells for human liver therapies is restricted by immunogenicity and the potential for xenozoonotic transmission of infectious agents such as porcine endogenous retrovirus (PERV). Recognizing these concerns, recent efforts have led to the development of PERV-free pigs as well as genetically modified pigs that are transgenic for human proteins, thereby decreasing their immunogenicity.

Primary human hepatocytes are the ideal cell type for cell-based therapies, and the development of primary hepatocyte-based approaches is the focus of substantial ongoing research. However, progress has been hindered by the limited supply of primary human hepatocytes and the difficulty of maintaining hepatocyte function *in vitro*. Discussed in more detail later, hepatocytes exhibit a loss of liver-specific functions under many conditions *in vitro* and despite their significant proliferative capacity during regenerative responses *in vivo*, mature hepatocyte proliferation in culture is limited [12]. A variety of techniques have been developed

TABLE 46.1 Cell sources for liver therapies

Cell source	Critical issues
Primary hepatocytes Human adult and fetal, xenogeneic	Sourcing, expansion, phenotypic instability, immunogenicity, safety (xenozoonotic)
Immortalized hepatocyte lines Tumor-derived, SV40, telomerase, spontaneously immortalized	Range of functions, genomic instability, safety (tumorigenicity)
Stem Cells Embryonic, liver progenitors (hepatoblasts, oval cells), other lineages (HSC, MAPC), Induced pluripotent stem cells, direct reprogramming to hepatocytes	Sourcing, differentiation efficiency, phenotypic instability, immunogenicity, safety (tumorigenicity)

TABLE 46.2 Hepatic functions

Functional classification	Examples
Synthetic	Albumin Secretion Alpha-1-antitrypsin Secretion Coagulation Factor Production (II, IX, X) Lipoprotein and apoprotein synthesis Ceruloplasmin production Ferritin production Complement production
Metabolic	Ureagenesis and metabolism Bilirubin Metabolism Steroid Metabolism Gluconeogenesis/Glycogen Production Lipid metabolism
Detoxification pluripotent stem cells, direct reprogramming to hepatocytes	Metabolize, detoxify, and inactivate exogenous and endogenous compounds via cytochrome P450 enzymes, methyltransferases, sulfotransferases, acetyltransferases, UDP-glucuronosyltransferases, and Glutathione S-transferases
Bile Production	

to enable the cryopreservation of human hepatocytes [13]. This enables the large number of hepatocytes that are prepared from a single liver to be stored and thawed with reproducible cellular function. This option has opened the door to a variety of *in vitro* pharmacologic and infectious disease studies [14–16].

Due to the limitations in mature hepatocyte expansion *in vitro*, alternative cell sources are being pursued. These include various stem cell and progenitor populations, which can self-renew *in vitro* and exhibit multipotency or pluripotency and thereby serve as a possible source of hepatocytes, as well as other non-parenchymal liver cells.

Fetal and adult progenitor cells

A variety of fetal and adult progenitor cell types have been explored. Current investigations are focused on determining the differentiation potential and lineage relationships of these populations. Fetal hepatoblasts are liver precursor cells present during development that exhibit a bipotential differentiation capacity, defined by the capability to generate both hepatocytes and bile duct epithelial cells. Sourcing problems associated with fetal cells have led researchers to search for resident cells that have progenitor properties in the adult. Towards this end, a few groups have argued that rare resident cells (which may represent embryonic remnants) exhibit properties consistent with the hypothesized adult hepatic stem cells and share phenotypic markers and functional properties with fetal hepatoblasts. In adult animal livers suffering certain types of severe and chronic injury, such oval cells can mediate liver repair through a program similar to hepatic development. Whether or not these processes occur in normal human liver injury processes remains controversial. In either case, there is little evidence that cells other than adult hepatocytes participate in the daily turnover of healthy, undamaged rodent or human liver and therefore the existence and role of hepatic stem cells or progenitors in healthy rodent and human liver homeostasis remains controversial.

Along similar lines, Weiss and colleagues have demonstrated the development of bipotential mouse embryonic liver (BMEL) cell lines derived from mouse E14 embryos that exhibit characteristics comparable to fetal hepatoblasts and oval cells [17]. These BMEL cells are proliferative, can be induced to be hepatocyte-like or bile duct epithelial-like *in vitro*, and can

home to the liver to undergo bipotential differentiation *in vivo* within a regenerative environment. More recently, biopotential human embryonic liver cells have been isolated and, similar to mouse BMEL cells, are proliferative and capable of bipotential differentiation [18].

Pluripotent stem cells

Human embryonic stem cells (hES) first isolated by James Thomson in 1998 offer the ability to generate large numbers of pluripotent cells that have the potential to form all three germ layers and differentiated cells including hepatocytes. Subsequently, Yamanaka and colleagues demonstrated that fully differentiated adult cells, such as fibroblasts or skin cells, could be reprogrammed to a undifferentiated, pluripotent state similar to embryonic stem cells through the forced expression of reprogramming factors Oct3/4 and Sox2 along with either Klf4 or Nanog and Lin28. These reprogrammed cells are termed induced pluripotent stem (iPS) cells and highly resemble hES cells, sharing many characteristics such as self-renewal capabilities *in vitro* and pluripotent differentiation potential *in vitro* and *in vivo* (though epigenetic differences between hES and iPS have been identified). Since iPS cells are sourced from adult somatic cells unlike embryonic stem cells, ethical considerations associated with hES are eliminated. Moreover, iPS cells permit the generation of patient-specific cell populations, potentially enabling therapies to be developed according to the characteristics of an individual patient or to study a variety of metabolic disorders and genetic variations that only manifest in an adult.

Inspired by the understanding of how a totipotent stem cell proceeds to become a hepatocyte during normal development, multiple protocols have been described that enable hES cell differentiation into hepatocyte-like cells. Duncan and colleagues, as well as other researchers, demonstrated that through iPS reprogramming and a subsequent multistep differentiation protocol, skin fibroblasts can give rise to hepatocyte-like cells, which not only exhibit a variety of hepatocyte-specific functions *in vitro*, but can also be induced to generate intact fetal livers in mice *in vivo* via tetraploid complementation [19]. Pluripotent stem cell-derived hepatocytes exhibit both the phenotypic and functional characteristics associated with hepatocytes, though the resulting differentiated cells exhibit a more fetal state of maturation compared to adult human hepatocytes [20]. In addition, as with adult primary hepatocytes, it is not clear whether stem cell-derived 'hepatocyte-like cells' will maintain their phenotype *in vitro*. To date, only one example of *in vivo* engraftment of pluripotent stem cell-derived hepatocyte-like cells has been reported; this group utilized a unique and specific injury mouse model, and the authors noted little to no human-specific hepatic functions after engraftment [21]. Future studies will need to verify that pluripotent stem cell-derived hepatocyte-like cells can engraft *in vivo*, and will also need to address safety concerns, such as the potential for pluripotent cell-derived teratoma formation, and the oncogenic risks associated with integrating vectors used to generate some iPS lines. Human embryonic stem (ES) cells have recently been approved by the FDA (Food and Drug Administration) for safety trials to commence such studies.

Over the past few years a variety of lineages have been generated via the direct reprogramming of one adult cell type into another, without an undifferentiated pluripotent intermediate. Similar to the use of master transcriptional regulators in the reprogramming to iPS cells, the expression of a key sets of genes have been used to directly generate skeletal muscle tissue, cells that highly resemble β-cells, and neurons [22]. More recently, mouse fibroblasts have been directly reprogrammed to generate hepatocytes [23,24]. These findings raise future possibilities for deriving human hepatocytes directly from another adult cell type, although it is unclear how reprogrammed hepatocyte-like cells may behave compared to primary cells, or whether this approach will also be successful using human cells.

Ultimately, understanding the mechanisms governing the fates of stem and progenitor cell populations can empower the development of cell-based therapies. However, many challenges remain, including the ability to program differentiation completely, beyond a fetal hepatocyte stage. Furthermore, regardless of the cell source, phenotypic stabilization of

hepatocytes *ex vivo* remains a primary issue. Microenvironmental signals including soluble mediators, cell-extracellular matrix interactions, and cell-cell interactions have been implicated in the regulation of hepatocyte function. Accordingly, the development of robust *in vitro* liver models is an essential stepping-stone towards a thorough understanding of hepatocyte biology and improved effectiveness of cell-based therapies for liver disease and failure.

IN VITRO HEPATIC CULTURE MODELS

An extensive range of liver model systems have been developed, some of which include: perfused whole organs and wedge biopsies; precision cut liver slices; isolated primary hepatocytes in suspension or cultured upon extracellular matrix; immortalized liver cell lines; isolated organelles, membranes or enzymes; and recombinant systems expressing specific drug metabolism enzymes [25]. While perfused whole organs, wedge biopsies, and liver slices maintain many aspects of the normal *in vivo* microenvironment and architecture, they typically suffer from short-term viability (< 24 hours) and limited nutrient/oxygen diffusion to inner cell layers. Purified liver fractions and single enzyme systems are routinely used in high-throughput systems to identify enzymes involved in the metabolism of new pharmaceutical compounds; although they lack the complete spectrum of gene expression and cellular machinery required for liver-specific functions. In addition, cell lines derived from hepatoblastomas or from immortalization of primary hepatocytes are finding limited use as reproducible, inexpensive models of hepatic tissue. However, such lines are plagued by abnormal levels and repertoire of hepatic functions [26], perhaps most notably, the divergence of constitutive and inducible levels of cytochrome P450 enzymes [27]. Though each of these models has found utility for focused questions in drug metabolism research, isolated primary hepatocytes are generally considered to be most physiologically relevant for constructing *in vitro* platforms for a multitude of applications. However, a major limitation in the use of primary hepatocytes is that they are notoriously difficult to maintain in culture due to their precipitous decline in viability and liver-specific functions upon isolation from the liver [25]. Accordingly, substantial research has been conducted over the last two decades towards elucidating the specific molecular stimuli that can maintain phenotypic functions in hepatocytes. In subsequent sections, we present examples of strategies that have been employed to improve the survival and liver-specific functions of primary hepatocytes in culture.

In vivo microenvironment of the liver

In order to engineer an optimal microenvironment for hepatocytes *in vitro*, one can utilize as a guide the precisely defined architecture of the liver, in which hepatocytes interact with diverse extracellular matrix molecules, non-parenchymal cells, and soluble factors (i.e., hormones, oxygen) (Fig. 46.2). Structurally, the two lobes of the liver contain repeating functional units called lobules, which are centered on a draining central vein. Portal triads at each corner of a lobule contain portal venules, arterioles and bile ductules. The blood supply to the liver comes from two major blood vessels on its right lobe: the hepatic artery (one-third of the blood) and the portal vein (two-thirds). The intrahepatic circulation consists of sinusoids, which are small tortuous vessels lined by a fenestrated basement membrane lacking endothelium that is separated from the hepatocyte compartment by a thin extracellular matrix region termed the space of Disse. The hepatocytes, constituting $\sim$70% of the liver mass, are arranged in unicellular plates along the sinusoid where they experience homotypic cell interactions. Several types of junctions (i.e., gap junctions, cadherins, and tight junctions) and bile canaliculi at the interface of hepatocytes facilitate the coordinated excretion of bile to the bile duct and subsequently to the gall bladder. Non-parenchymal cells including stellate cells, cholangiocytes (biliary ductal cells), sinusoidal endothelial cells, Kupffer cells (liver macrophages), natural killer cells, and pit cells (large granular lymphocytes) interact with hepatocytes to modulate their diverse functions. In the space of Disse, hepatocytes are

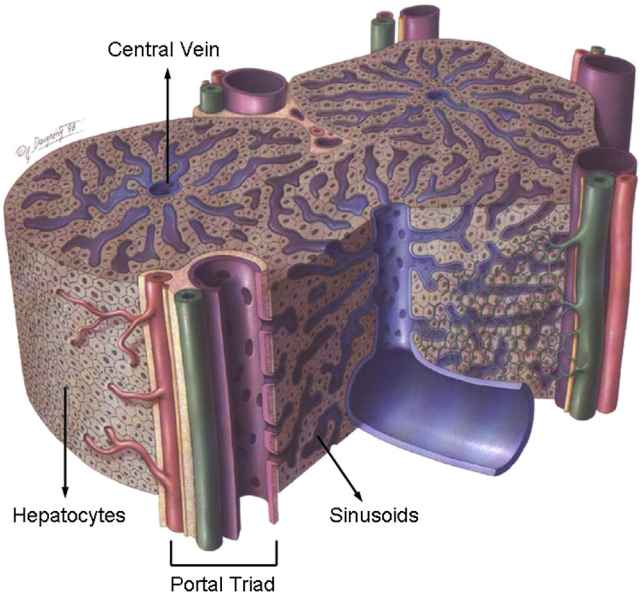

FIGURE 46.2
The precisely defined architecture of the repeating unit of the liver, the lobule. Hepatocytes are arranged in cords along the length of the sinusoid where they interact with extracellular matrix molecules, non-parenchymal cells and gradients of soluble factors. Nutrient and oxygen rich blood from the intestine flows into the sinusoid via the portal vein. After being processed by the hepatocytes, the blood enters the central vein and into the systemic circulation. *(Reproduced with permission from J. Daugherty.)*

sandwiched between layers of extracellular matrix (collagen types I, II, III, IV, laminin, fibronectin, heparan sulfate proteoglycans), the composition of which varies from the portal triad to the central vein [28].

Within the liver lobule, hepatocytes are partitioned into three zones based on morphological and functional variations along the length of the sinusoid (zonation). Zonal differences have been observed in virtually all hepatocyte functions. For instance, compartmentalization of gene expression is thought to underlie the capacity of the liver to operate as a 'glucostat'. Furthermore, zonal differences in expression of cytochrome-P450 enzymes have also been implicated in the zonal hepatotoxicity observed with some xenobiotics [29]. Possible modulators of zonation include blood-borne hormones, oxygen tension, pH levels, extracellular matrix composition, and innervation [30]. Therefore, a precisely defined microarchitecture, coupled with specific cell-cell, cell-soluble factor and cell-matrix interactions allows the liver to carry out its many diverse functions, which can be broadly categorized into protein synthesis (i.e., albumin, clotting factors), cholesterol metabolism, bile production, glucose and fatty acid metabolism, and detoxification of endogenous (i.e., bilirubin, ammonia) and exogenous (drugs and environmental compounds) substances.

Two-dimensional cultures

Numerous studies have improved primary hepatocyte survival and liver-specific functions *in vitro* through modifications in microenvironmental signals including soluble factors (medium composition), cell-matrix interactions as well as heterotypic cell-cell interactions with non-parenchymal cells (Fig. 46.3). The supplementation of culture media with

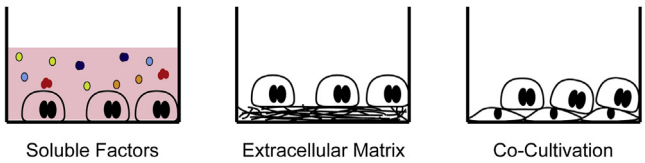

FIGURE 46.3
Cell sourcing of human hepatocytes. Approaches have focused on modulating *in vitro* culture conditions, such as the addition of soluble factors such as growth factors and small molecules, extracellular matrix proteins, heterotypic cell-cell interactions.

physiological factors such as hormones, corticosteroids, growth factors, vitamins, amino acids or trace elements [25,31], or non-physiological small molecules such as phenobarbital and dimethylsulfoxide [32,33] have been shown to modulate hepatocyte function. More recently, oxygen tension has also been shown to modulate hepatocyte function [34]. Certain mitogenic factors like epidermal growth factor and hepatocyte growth factor can induce limited proliferation in rat hepatocytes *in vitro*, but these mitogens result in negligible proliferation of human hepatocytes *in vitro* [35,36]. The impact of extracellular matrix composition and topology on hepatocyte phenotype is widely recognized. A variety of extracellular matrix (ECM) coatings (most commonly collagen type I) have been shown to enhance hepatocyte attachment to the substrate, but this usually occurs concomitantly with hepatocyte spreading and a subsequent loss of hepatocyte function [37]. Studies investigating the benefits of complex mixtures of ECM components have utilized strategies including Matrigel, liver-derived biomatrix [37–40], or bottom-up approaches such as a combinatorial high-throughput ECM microarray, where the latter has revealed specific combinations of ECM molecules that improve hepatocyte function compared to monolayer cultures on collagen I [41]. In contrast to culturing hepatocytes on a monolayer of ECM molecules, hepatocytes have also been sandwiched between two layers of type I collagen gel. In this classic 'sandwich' culture format, hepatocytes exhibit desirable morphology with polarized bile canaliculi, as well as stable functions for several weeks [42,43]. However, phase I/II detoxification processes have been shown to become imbalanced over time in this format [44]. Also, the presence of an overlaid layer of extracellular matrix may present diffusion barriers for molecular stimuli (i.e., drug candidates), and the fragility of the gelled matrix may hinder scale-up within BAL devices or multiwell *in vitro* models.

Heterotypic interactions between hepatocytes and their non-parenchymal neighbors are known to be important at multiple stages *in vivo*. Liver specification from the endodermal foregut and mesenchymal vasculature during development is believed to be mediated by heterotypic interactions [45,46]. Similarly, non-parenchymal cells of several types modulate cell fate processes of hepatocytes under both physiologic and pathophysiologic conditions within the adult liver [47,48]. Substantial work pioneered by Guguen-Guillouzo and colleagues has demonstrated that a wide variety of non-parenchymal cells from both within and outside the liver are capable of supporting hepatocyte function for several weeks in co-culture contexts *in vitro*, even across species barriers, suggesting that the mechanisms responsible for non-parenchymal cell-mediated stabilization of hepatocyte phenotype may be conserved [49,50]. Microfabrication approaches have been employed to control tissue microarchitecture in hepatic co-cultures so as to achieve an optimal balance of homotypic and heterotypic cellular interactions to promote hepatocyte function, which will be described in a later section. Hepatic co-cultures have been utilized to investigate various physiologic and pathophysiologic processes, including the acute phase response, mutagenesis, xenobiotic toxicity, oxidative stress, lipid and drug metabolism [50]. For example, co-cultures of hepatocytes and Kupffer cells have been used to examine mechanisms of hepatocellular damage [51,52], while co-cultures with liver sinusoidal endothelial cells (which are also phenotypically unstable in monoculture upon isolation from the liver) have highlighted the importance of hepatocyte-endothelial cell interactions in the bidirectional stabilization of these cell types [53,56]. Studies focused on the underlying mechanisms of hepatocyte stabilization in co-culture have identified several cell surface and secreted factors that play a role including T-cadherin, E-cadherin, decorin and TGF-β1, which demonstrate the potential for highly functional hepatocyte-only culture platforms [57,58].

Three-dimensional cultures

Culture of hepatocytes on substrates that promote aggregation into three-dimensional spheroids has also been extensively explored. Numerous technologies including non-adhesive surfaces (such as poly(2-hydroxyethyl methacrylate) and positively charged Primaria dishes),

rotational or rocking cultures, and encapsulation in macroporous scaffolds have been developed for hepatocyte spheroid formation [59–64]. Under spheroidal culture conditions, hepatocyte survival and functions are improved over standard monolayers on collagen [65]. Potential mechanisms underlying these effects include an increased extent of homotypic cell-cell contacts between hepatocytes, the retention of a three-dimensional cytoarchitecture, and the three-dimensional presentation of ECM molecules around the spheroids [59]. Some limitations of conventional spheroidal culture include a tendency for secondary aggregation of spheroids and the resultant development of a necrotic core in the larger aggregates due to diffusion-limited transport of nutrients and waste, and the lack of control over the cell numbers within each spheroid [25]. A variety of methods are being developed to prevent secondary aggregation of initially-formed spheroids and control cell-cell interactions, including microfabricated scaffolds, bioreactor systems, encapsulation techniques and synthetic linkers [26,66,67–73], which are discussed in further detail in the following sections.

Bioreactor cultures

A wide range of small-scale bioreactor platforms have been developed for *in vitro* liver applications. For example, perfusion systems containing hepatocellular aggregates exhibit desirable cell morphology and liver-specific functions for several weeks in culture [26,68,74–75], and the incorporation of multiple reactors in parallel has been explored as an approach for high-throughput drug screening studies [76–79]. In order to promote oxygen delivery while protecting hepatocytes from deleterious shear effects, gas-permeable membranes with endothelial-like physical parameters, grooved substrates and microfluidic microchannel networks have been integrated into several bioreactor designs [76,80–82]. *In vivo*, hepatocyte functions are heterogeneously segregated along the hepatic sinusoid, and this zonation is thought to be modulated by gradients in oxygen, hormones, nutrients and extracellular matrix molecules. Using a parallel-plate bioreactor, it was demonstrated that steady state oxygen gradients characteristic of those found in liver sinuosoids could contribute to a heterogeneous expression of drug metabolism enzymes CYP2B and CYP3A in hepatocyte-non-parenchymal co-cultures, which mimics the expression gradients present *in vivo* (Fig. 46.4) [83]. Furthermore, the localization of acetaminophen-induced hepatic toxicity in the region experiencing low oxygen in this model system recapitulates the perivenous location of toxicity *in vivo*. A zonal microbioreactor array based on microfluidic serpentine mixing regions feeding into several microbioreactors in parallel has also been designed for potential *in vitro* liver zonation applications (Fig. 46.4). Overall, the ability to decouple oxygen tension from gradients of other soluble stimuli and cell-cell interaction effects within this platform represents an important tool for the systematic investigation of the role of extracellular stimuli in zonation.

Bioreactors may also be used to study more dynamic physiological processes than is possible in conventional culture platforms. For example, a recent bioreactor device describes the ability to monitor invasion of metastatic cells into hepatic parenchyma by recreating relevant features of the liver tissue such as fluid flow and length scales [84]. Collectively, by providing dynamic control over hepatocyte culture parameters and hence hepatocyte function, bioreactors will continue to be useful in studying liver biology and facilitating drug development applications.

Microtechnology tools to optimize and miniaturize liver cultures

The ability to control tissue architecture along with cell-cell and cell-matrix interactions on the order of single cell dimensions represents another important tool in the investigation of mechanisms underlying tissue development, and ultimately, the realization of tissue-engineered systems. Semiconductor-driven microtechnology tools enable micrometer-scale control over cell adhesion, shape and multicellular interactions [85,86]. Thus, over the last decade, microtechnology tools have emerged both to probe biomedical phenomena at relevant length scales and to miniaturize and parallelize biomedical assays (e.g., DNA microarrays, microfluidics).

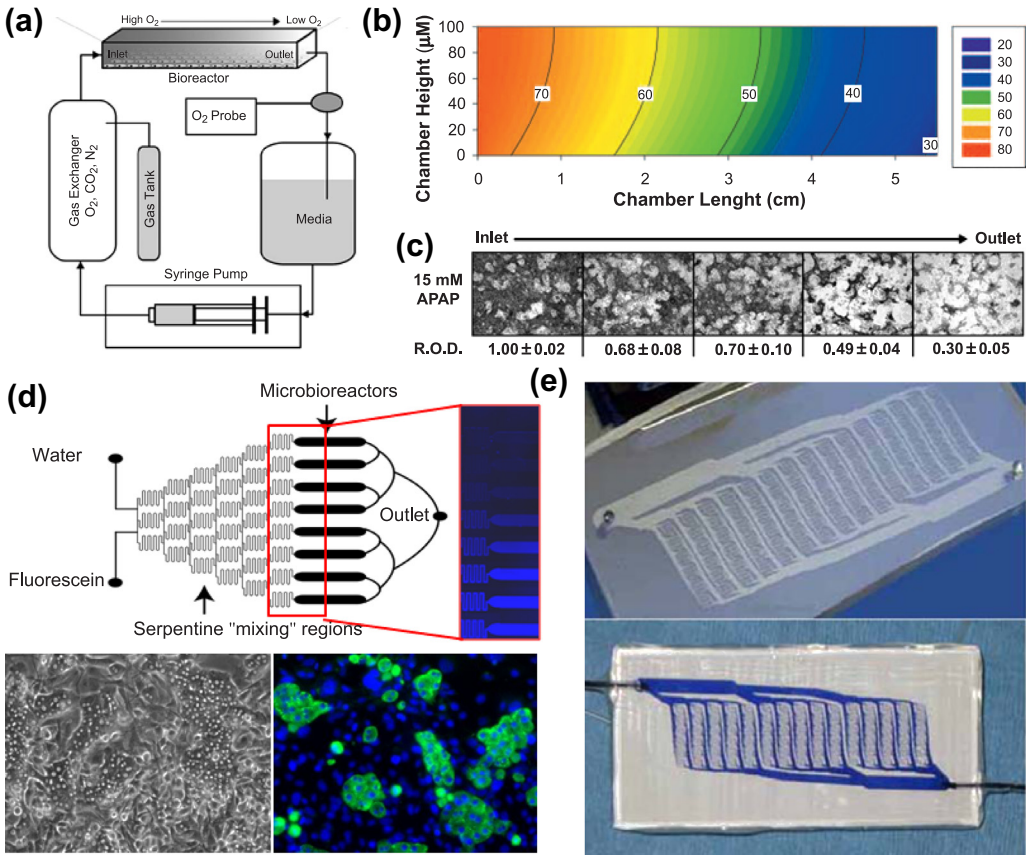

FIGURE 46.4

Bioreactors for *in vitro* liver applications. (a) Zonation and toxicity in a hepatocyte bioreactor. Co-cultures of hepatocytes and non-parenchymal cells are created on collagen-coated glass slides and placed in a bioreactor circuit where the oxygen concentration at the inlet is held at a constant value. Depletion of oxygen by cells creates a gradient of oxygen tensions along the length of the chamber, similar to that observed *in vivo*. (b) Two-dimensional contour plot of the medial cross section of the reactor depicting the cell surface oxygen gradient formed with inlet pO2 of 76 mmHg and flow rate of 0.3 mL/min. (c) Bright-field images of perfused cultures treated with 15 mM acetaminophen (APAP, a hepatotoxin) and stained with MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) as a measure of cell viability from five regions along the length of the bioreactor. The intensity of MTT staining is reported as relative optical density (R.O.D) values. The zonal pattern of APAP toxicity seen here is consistent with that observed *in vivo* [83]. (d) A zonal microbioreactor array that incorporates serpentine mixing regions and two sources is able to create a gradient of fluorescein (shown in blue on right) in an array of microbioreactors containing random co-cultures of hepatocytes and non-parenchymal cells (bottom). (e) A bilayer microfluidics device designed with a microchannel network that mimics liver vasculature so as to support the large metabolic needs of hepatocytes contained within an adjacent chamber. *(Figure panels reproduced with permission from [82].)*

In the context of the liver, a photolithographic cell patterning technique ('micropatterned co-culture') has enabled the optimization of liver-specific functions in co-cultures via engineering of the balance between homotypic (hepatocyte-hepatocyte) and heterotypic (hepatocyte-non-parenchymal) cell-cell interactions [50]. Specifically, micropatterned co-cultures were created in which hepatocyte islands of controlled diameters were surrounded by supporting non-parenchymal cells (Fig. 46.5). This pattern was miniaturized into a multiwall format using soft lithography techniques and has resulted in micropatterned co-cultures optimized for human hepatocyte function [14]. The maintenance of hepatic functions has been shown to be highly dependent upon precise optimization of island size in systems utilizing both rat and human hepatocytes. This platform has been utilized extensively for both drug development and pathogen model systems, as discussed in detail in the next section.

As described above, several culture techniques have been explored for the formation of hepatic spheroids. These methods exhibit certain limitations, including an inability to immobilize the spheroids at defined locations and the heterogeneity of the structures, which can result in

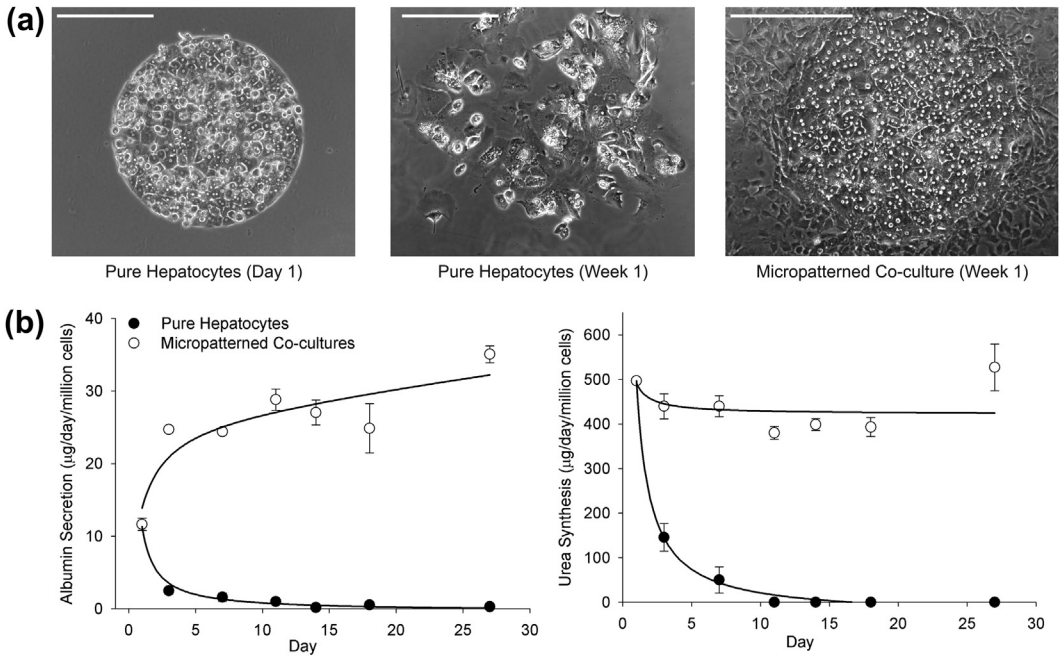

FIGURE 46.5
Micropatterned co-cultures. (a) Morphology of micropatterned co-cultures containing primary human hepatocytes (representative images at day 1 and week 1). Scale bars, 250 μm. (b) Albumin secretion and urea synthesis in micropatterned co-cultures and pure hepatocyte cultures [14].

cell necrosis at the core of large and coalesced spheroids due to depletion of oxygen and nutrients. Recently, microcontact printing, robot spotting techniques and micromolded hydrogels have been used to fabricate immobilized microarrays of hepatic cells or spheroids [41,73,87–90]. Hepatocytes in these platforms typically retain a liver-specific phenotype as assessed by the expression of liver-enriched transcription factors, secretion of albumin, and the presence of urea cycle enzymes. Microtechnological tools have also been applied to the analysis of dynamic processes related to hepatocyte biology. For example, microfluidic devices that recreate physiologically relevant fluid flows and lengths scales have been used to study drug clearance, toxicity and inflammation-mediated gene expression changes [78,91–93], and mechanically actuated, microfabricated substrates have been used to deconstruct the role of contact and short-range paracrine signals in interactions between hepatocytes and stromal cells or liver endothelial cells [53,94]. Overall, the fine spatial and temporal control of molecular signals provided by microtechnological approaches continue to reveal important mechanisms in liver biology and accelerate the development of therapeutic strategies.

Drug and disease model systems

Advances in the development of liver cell-based culture systems have begun to provide important insights into human-specific liver processes that were not previously accessible with standard *in vitro* models. Specifically, engineered tissue systems which promote long-term functional stabilization of human hepatocytes *in vitro* have enabled novel studies into drug-drug interactions and hepatocellular toxicity. For example, micropatterned co-culture-based platforms have been demonstrated to support human hepatocyte phenotypic function for several weeks, including maintenance of gene expression profiles, canalicular transport, phase I/II metabolism, and the secretion of liver-specific products [14,95]. Furthermore, drug-mediated modulation of CYP450 expression and activity, and resultant changes in toxicity profiles were observed, illustrating the utility of the platform for human ADME/Tox (adsorption, distribution, metabolism, excretion, and toxicity) applications (Table 46.3).

TABLE 46.3 Generation of major human drug metabolites by different *in vitro* systems [95,254]

	In Vivo	Microsomes[a]	S-9[b]	Hepatocyte suspension[b]	Micropatterned co-culture	
					48 h	7 Days
Excretory metabolites > 10% of dose

Several other engineered model systems incorporating 3D hepatocellular aggregates or perfusion methods have also been designed for drug screening purposes and tested with either rodent or human hepatocytes [26,68,96,97].

Engineered *in vitro* liver models can also facilitate studies into the behavior of pathogens that exclusively target human hepatocytes, including two such pathogens with profound global health implications, hepatitis C virus (HCV) and malaria. Early experiments examining HCV replication *in vitro* employed carcinoma cells stably transfected with a subgenomic viral replicon [98]. While these studies provided important information on viral replication and potential small molecule inhibitors of viral replicative enzymes, the entire viral life cycle could not be completed due to the absence of structural proteins. Furthermore, prior to 2005, there was no known viral genotype that could complete the viral life cycle *in vitro*. Following the identification of a genotype-2a strain of HCV responsible for fulminant hepatitis in a Japanese patient, termed JFH-1 [99], it was demonstrated that JFH-1 and a chimeric variant could complete a full viral life cycle in the Huh7 carcinoma cell line [100–102]. Subsequently, recent approaches have made it possible to examine HCV infection in primary human hepatocytes [16,103,104]. In particular, the stabilization of human hepatocytes in a micropatterned co-culture platform was demonstrated to allow the recapitulation of the full viral life cycle *in vitro* [16] (Fig. 46.6). In this platform, human hepatocytes expressed all known entry factors for HCV and supported viral replication for several weeks, illustrating the potential of such *in vitro* systems for screening drug candidates that suppress HCV replication, and the ultimate identification of non-hepatotoxic anti-HCV compounds. Furthermore, a recent study demonstrating HCV infection of human iPS-derived hepatocyte-like cells establishes a foundation for the development of personalized disease models that allow the study of the impact of host genetics on viral pathogenesis [105].

In vitro culture platforms have also been explored for the study of hepatocyte infection by *Plasmodium* sporozoites in order to model the liver stage of malaria. To date, the primary cell

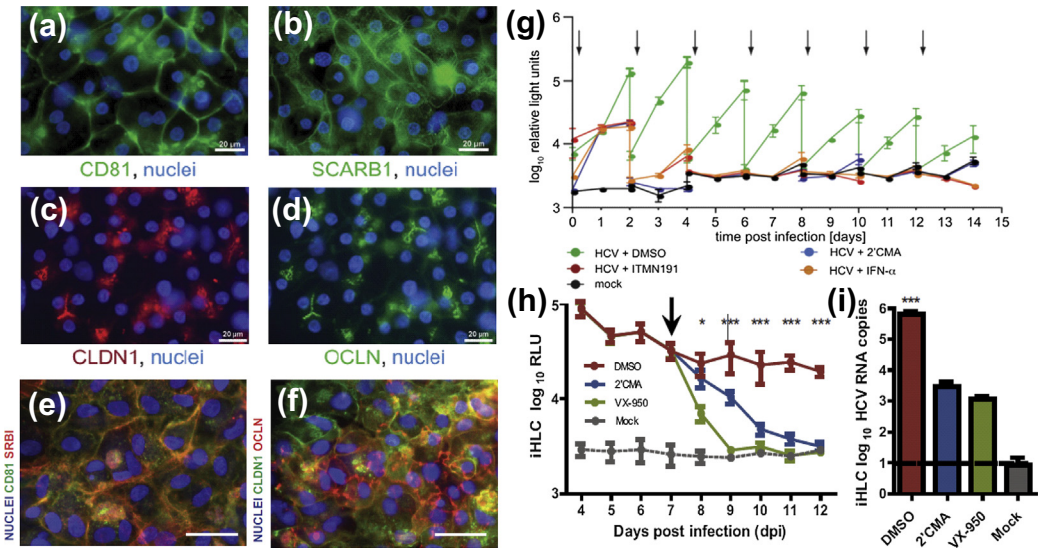

FIGURE 46.6

Modeling hepatotropic pathogenic diseases with human liver platforms. Primary human hepatocyte in micropatterned co-cultures express host entry factors for HCV (a) CD81, (b) SCARB1, (c) CDLN1 and (d) OCLDN, and (g) can be persistently infectible with HCV (green line), and is decreased by various inhibitors (orange, red, blue lines). Human iPS cell-derived hepatocyte-like cells (iHLCs) express host entry factors for HCV like (e) CD81, SRB1, (f) CLDN1 and OCLN. iHLCs are infectible with HCV (red) as determined by (h) a luciferase reporter assay and (i) RT-PCR, and infection can be inhibited with a polymerase inhibitor 2'CMA (blue) and a protease inhibitor VX-950 (green) [16,105].

culture models that have been utilized include primary human hepatocyte monolayers and human hepatoma cells [106–108], and have provided important information regarding hepatocyte invasion and the role of SR-BI and CD81 [109], and potential targets for attenuating parasite growth [110]. Recently, micropatterned co-cultures which support long-term functional maintenance of primary human hepatocytes have been shown to recapitulate the liver stage of two human malaria species, *Plasmodium falciparum* and *Plasmodium vivax, in vitro* [111]. By enhancing the efficiency and duration of *Plasmodium* infection *in vitro*, such engineered hepatocyte culture platforms could form the basis for drug screening and vaccine validation assays against *Plasmodium* in an era of renewed interest and focus on global malaria eradication.

The field of hepatic tissue engineering continues to evolve towards creating an optimal microenvironment for liver cells *in vitro*. Overall, it is evident that many different culture conditions can preserve at least some phenotypic features of fully functional hepatocytes. Since detailed differences can exist in these model systems, current strategies have focused on selecting a platform that is appropriate for a particular application. Although much progress has been made, further work is required to obtain a more complete picture of the molecular signals that provide phenotypic stability of liver cultures. Indeed, it is likely that many pathways contribute to the differentiated state of the hepatocyte via a systems-level network. Stimulation of this network via different inputs (e.g., using different culture systems) may result in distinct signal transduction trajectories, each of which could lead to a 'phenotypically stable' hepatocyte. It is also possible that differences between such stabilized hepatic populations will emerge as new methods to probe phenotype and function in greater detail (e.g., via epigenetics, proteomics, metabolomics) are utilized. Future challenges, therefore, will be to identify such differences and understand them in the context of network-level (*in vivo*) hepatic phenotype. The development of highly functional and systems-level [112,113] *in vitro* liver platforms will ultimately facilitate both the clinical effectiveness of cell-based therapies as well as enable high-throughput screening of candidate drugs for liver-specific metabolism and toxicity earlier in the drug discovery pipeline and for human hepatotropic infectious diseases such as HCV and malaria.

EXTRACORPOREAL BIOARTIFICIAL LIVER DEVICES

One promising approach for cell-based therapies for liver diseases is the development of extracorporeal support devices, which would process the blood or plasma of liver failure patients. These devices are principally aimed at providing temporary support for patients suffering from acute or acute-on-chronic liver failure, to enable sufficient regeneration of the host liver tissue, or serve as a bridge to transplantation. Early extracorporeal device designs utilized primarily non-biological mechanisms such as hemoperfusion, hemodialysis, plasmapheresis, and plasma exchange [114]. Hemoperfusion removes toxins, but also captures other useful metabolites, by passage of blood or plasma through a charcoal column. A modification of this approach, referred to as hemodiadsorbtion, reduces direct contact with charcoal components through the utilization of a flat membrane dialyzer containing charcoal and exchange resin particles [115]. In general, charcoal perfusion systems have been the most extensively studied non-biological configuration, including clinical evaluation in patients with acute liver failure, although no clear survival improvement has been observed [116]. More recent configurations of artificial support systems have focused on the elimination of albumin-bound toxins utilizing a method termed albumin dialysis. These devices, such as the Molecular Adsorbent Recirculating System (MARS®) and the Prometheus platform, clear albumin-bound toxins through interaction with an albumin impregnated dialysis membrane [117]. They have been shown to offer some clinical benefit by reducing plasma bile acids, bilirubin, and other albumin-bound toxins [118], but additional randomized controlled trials are required to fully evaluate their effectiveness.

In order to provide a more complete array of synthetic, metabolic, and detoxification functions, which are lacking in strictly artificial support systems, biological approaches including cross hemodialysis, whole liver perfusion, and liver slice perfusion have been explored [116]. While these methods have shown minor improvements for patients with acute hepatic failure, they have not demonstrated any clinically meaningful survival benefits. Consequently, substantial efforts have been placed towards the development of extracorporeal BAL devices containing hepatic cells. BAL devices can be categorized into four main types, summarized in Fig. 46.7: hollow fiber devices, flat plate and monolayer systems, perfusion bed or porous matrix devices, and suspension reactors. Broadly, several criteria have emerged as central to the design of an effective BAL device; these include issues of cell sourcing, maintenance of cell viability and hepatic functions, sufficient bidirectional mass transfer, and scalability to therapeutic levels. In this section, we discuss these issues and review recent advances in BAL device design.

Cell sourcing

As discussed earlier, the sourcing of hepatic cells is a fundamental challenge for all liver cell-based therapies. Most BAL devices are forced to employ xenogeneic sources (primarily porcine) or immortalized human hepatocyte cell lines [119–122]. Porcine hepatocytes are well studied, easily sourced, and offer a functional profile quite similar to human hepatocytes, but are limited by safety concerns, such as the possibility of transmitting pathogens like porcine endogenous retrovirus (PERV), across species. However, patients treated with porcine-derived therapies have all been negative for PERV infection [123]. Human hepatocyte cell

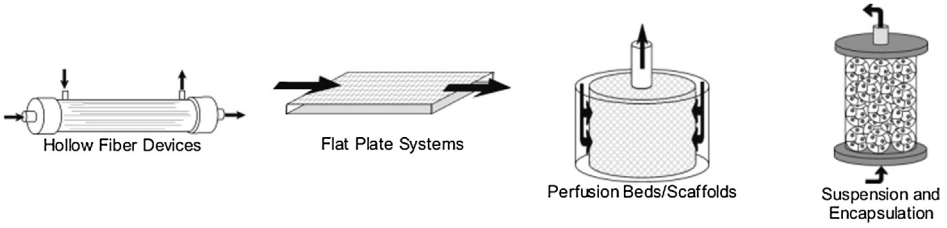

FIGURE 46.7
Schematics of cell-based bioreactor designs. The majority of liver cell-based bioreactor designs fall into these four general categories, each with inherent advantages and disadvantages [253].

lines, while expandable, exhibit an abnormal repertoire of liver functions, which limits their clinical impact. Primary human hepatocytes present the best functional output, but are scarce and rapidly lose viability and phenotype after procurement and isolation, although recent advances in cryopreservation, fetal cell procurement and stem cell differentiation have helped primary human cells become increasingly available [124–127]. Magnifying the cell sourcing challenge are scalability requirements for translation, which will be discussed in detail in the scale-up section of this chapter.

Cell viability and function

The development of effective BAL systems is dependent on the incorporation of appropriate environmental and organizational cues, which enable maximal survival and function of the hepatocellular component. Hollow fiber devices are the most common BAL design and contain hepatic cells within cartridge units similar to those utilized in hemodialysis systems [128]. The hollow fiber membranes serve as a scaffold for cell attachment and compartmentalization, although adequate nutrient transport and proper environmental stimuli are potentially limited in these configurations. Multiple modifications aimed at optimizing cellular performance have been explored. In particular, due to the enhanced function of hepatocyte spheroids relative to dispersed cells, many device configurations contain either attached or encapsulated hepatocyte aggregates [128]. For example, the original HepatAssist system previously developed by Circe Biomedical was a hollow fiber device containing microcarrier-attached porcine hepatocyte aggregates within the extracapillary space [129]. Collagen gel entrapment of hepatocyte aggregates has also been added to some hollow fiber designs to improve function, and many perfusion bed systems integrate hepatocyte aggregates within a polymeric network of pores or capillaries [120]. Furthermore, encapsulation of pre-formed hepatocyte spheroids within calcium-alginate beads has been explored as a means of promoting hepatocyte stability while simultaneously providing an immunoisolation barrier [128]. In the modular extracorporeal liver support (MELS) system (Charite, Germany) hepatocytes are aggregated in co-culture with non-parenchymal cells resulting in the formation of tissue-like organoid structures [130]. Bile canaliculi and bile duct structures as well as matrix deposition have been observed in this system, which utilized both porcine cells and primary human hepatocytes isolated from livers unsuitable for transplant [121]. Platforms based on collagen gel 'sandwich culture', a stable hepatocyte-only culture configuration, have also been developed recently [131]. Moreover, exposure of hepatocytes to the plasma or blood of a sick patient may necessitate alterations in hepatocyte culture conditions. Specifically, pre-conditioning with physiologic levels of insulin, lower than that present in normal culture medium, has been shown to prevent fat accumulation in hepatocytes upon exposure to plasma [132]. Additionally, the supplementation of plasma with amino acids has been demonstrated to increase albumin and urea synthesis [133].

Mass transfer

Bidirectional mass transfer is another primary consideration in the design of BAL systems and is required to provide vital nutrients to the incorporated cells and simultaneously allow export of therapeutic cellular products. Device configuration determines both the convective and diffusive properties of the system, thereby dictating the exchange of soluble components. In particular, diffusion resistance is often a major constraint in BAL devices. Factors commonly limiting diffusive transport are membrane structures, collagen gels, and non-viable cells. For example, semipermeable membranes are often utilized in BAL devices in order to enable selectivity in the size of exchanged factors. Inherent to most hollow fiber devices, but also utilized in some flat plate and perfusion bed systems, such membranes with a designated molecular weight cutoff act to prevent the transport of immunologic components and larger xenogeneic substances while maintaining transport of carrier proteins such as albumin. Although clearly not ideal, in order to maximize mass transfer, immunologic barriers have been eliminated from some device designs [134], with the assumption that the short duration

of contact with xenogeneic cells will result in minimal immunological complications. Perfusion bed systems allow for enhanced mass transfer due to the direct contact with the perfusing media, although fluid flow distribution is highly contingent on the type of packing material. Encapsulation of dispersed or aggregated cells represents another strategy for immunoisolation but can increase diffusion resistance [135,136]. The development of novel methods for the microencapsulation of hepatocytes is an active research area and is discussed in more detail in the implantable applications section of this chapter.

Oxygen tension is an important mediator of hepatocyte function [137–139]; thus, the improved regulation of oxygen delivery is a major goal of many recently developed BAL platforms. Strategies have included the incorporation of additional fiber compartments that carry oxygen directly into the device [140,141], and more recently, the incorporation of bovine red blood cells to the circulating culture medium [142]. Studies have confirmed that hepatocyte viability and function are more effectively maintained in devices with enhanced oxygen transport [143,144]. In contrast with other designs, flat plate geometries can be perfused in a relatively uniform manner, although this configuration may result in the exposure of cells to shear stress causing deleterious effects on cellular function [131,145–147]. Several approaches for minimizing shear stress exposure in the flat plate geometry have been explored, including the fabrication of grooved substrates for shear protection as well as the integration of adjacent channels separated by a gas-permeable membrane as a means to decouple oxygen exchange and volumetric flow rate [80,147,148]. Notably, as discussed earlier, oxygen has been implicated in the heterogeneous distribution of hepatocyte functions along the liver sinusoid, and this zonation can be recapitulated *in vitro* within a bioreactor system [149]. The eventual incorporation of oxygen gradients, as well as gradients of other diverse stimuli such as hormones and growth factors, into BAL designs could provide a means to more closely simulate the range of hepatocyte functions exhibited *in vivo* and further enhance the effectiveness of BAL devices.

Scale-up

The successful clinical implementation of any BAL device is dependent on the ability to scale the device to a level that provides effective therapy. It is estimated that such BAL devices would require approximately 1×10^{10} hepatocytes representing roughly 10% of total liver weight [150], although distinct categories of liver disease, such as acute liver failure, end stage cirrhosis, inherited metabolic disorders, will have varied scale requirements. Hepatocyte transplantation experiments in humans as well as rat models have demonstrated some improvement in various blood parameters following the transplantation of cell numbers representing 1–10% of total liver mass [151–154]. BAL devices that have been tested clinically have used approximately 0.5×10^9 to 1×10^{11} porcine hepatocytes or 4×10^{10} C3A hepatoblastoma cells [120]. Ultimately, to achieve clinical efficacy, approaches will require a) scaled-up systems with efficient nutrient transport and b) expandable cell sources, as discussed in earlier sections of this chapter. Accordingly, increasing cartridge size and use of multiple cartridges have been utilized as a means to scale-up hollow fiber-based systems. Perfusion systems [155] or devices utilizing encapsulated cells can be scaled fairly easily to the desired size; however such expanded configurations normally present a large priming or 'dead' volume. Stacked plate designs have been suggested as a means of scaling-up flat plate systems, although these modifications may introduce channeling effects and heterogeneous flow distribution [114]. Overall, the development of BAL devices exhibiting therapeutic levels of function is a major challenge and modifications aimed at further improving the capacity and efficiency of these systems is a central goal in the field.

Regulation and safety

Similar to other tissue-engineering-based therapies, the regulation of BAL devices is complex, due to the hybrid nature of these systems. Currently, BAL devices are being regulated as drugs

through the Center for Biologics Evaluation and Research of the Food and Drug Administration. The primary safety concerns for BAL systems are similar to those for other cell-based therapies, and include the escape of tumorigenic cells, immune reactions to foreign antigens and xenozoonosis. Other potential complications generally associated with extracorporeal blood treatment include hemodynamic, metabolic, and hypothermia-related abnormalities, as well as problems linked with catheterization and anticoagulation [118]. In order to explicitly prevent escape of tumorigenic cells, such as the C3A cell line used in the ELAD system, downstream filters have been added to BAL designs [119], an approach which is generally acknowledged as an adequate precautionary measure.

With regard to the utilization of porcine hepatocytes, there is some evidence for the presence of antibodies directed against porcine antigens in the serum of patients treated with BAL devices [156]. However, the clinical significance of these findings remains unclear, since high titers are not observed until one to three weeks, for IgM and IgG isotypes, respectively. These results suggest that immune rejection may not be a significant problem in the context of BAL therapy, except in cases of repetitive treatments. Still, appropriate modifications through cell sourcing or device design aimed at limiting immunologic complications would likely be important in expansion of BAL treatment options to chronic liver disease patients and patients with repetitive episodes of acute decompensation. As mentioned earlier, exposure to porcine cells can also represent a risk of xenozoonotic transmission of PERV, ubiquitous in the genome of bred pigs. PERV has been shown to infect human cell lines *in vitro* [157], although studies examining transmission to BAL-treated patients have not demonstrated any evidence of infection [158]. While specific transmission of PERV may not occur during the course of BAL therapy, the use of xenogeneic cells in BAL devices will always incur a note of caution.

Ongoing clinical trials

A number of BAL devices have been tested clinically, and the characteristics of these systems are provided in Table 46.4. Important practical issues include the use of whole blood versus plasma, and the type of anticoagulation regimen. The use of whole blood exhibits the advantage of including oxygen-containing erythrocytes; however, undesirable leukocyte activation and cell damage may arise. In contrast, perfusion of plasma prevents hematopoietic cell injury, but the solubility of oxygen in plasma devoid of oxygen carriers is quite low. Furthermore, heparin coagulation is normally used in BAL systems, although deleterious effects of heparin exposure on hepatocyte morphology and function have been suggested [159].

The design of clinical trials for BAL devices poses a significant challenge. In particular, liver failure progression is highly variable and etiology dependent. Additionally, hepatic encephalopathy, one of the major manifestations of liver failure is difficult to quantify clinically. As a result, patients in clinical trials must be randomized while still controlling for the stage at which support was initiated as well as individual etiology. Similarly, the determination of the relevant control therapy can be difficult. Ideally, in order to minimize non-specific effects of extracorporeal treatment, a non-biological control such as veno-venous dialysis would be utilized. Another challenge is the choice of clinical end point. Most clinical trials utilize end points of 30-day survival and 30-day transplant-free survival; however, trials can often be confounded by the fact that acute liver failure patients receive transplants variably depending on organ availability and the eligibility criteria in place at a given center. Furthermore, interpretation of the specific role of incorporated, live, functional hepatocytes can be complicated by the presence of non-biological adjuncts such as charcoal perfusion in some designs. A direct comparison of the effect of non-biological systems alone, dead or non-hepatocyte cells, and live hepatocytes would provide substantial insight concerning the effectiveness of the cellular components, particularly given that dead hepatocytes and non-hepatocyte cells have been shown to offer some survival benefit in various animal models of

TABLE 46.4 Characteristics of eight bioartificial liver systems

BAL system	Configuration	Cell source / amount	Trial phase	Comments
HepatAssist (Arbios, Waltham, MA)	Hollow fiber, polysulphone; microcarrier attached	Cryopreserved porcine (7×10^9)	II/IIIPrimary endpoint not reached	Plasma, citrate anticoagulation, 0.15–0.20 μm pore size, 7 h/session, daily
ELAD (Vital therapies, San Diego, CA)	Hollow fiber, polysulfone; cellulose acetate; large aggregates	C3A human cell line (200–400g)	II/III	Plasma, heparin anticoagulation, 0.20 um pores, continuous up to 107 h
MELS (Charite Virchow, Berlin, Germany)	Hollow fiber, interwoven, multicompartment; tissue organoids	Freshly isolated porcine or human (up to 650g)	I/II	Plasma, heparin anticoagulation, 400 kDa cutoff, continuous up to 6d
BLSS (Excorp Medical, Oakdale, MN)	Hollow fiber, cellulose acetate; collagen gel entrapped	Freshly isolated porcine (70–120 g)	II/III	Whole blood, heparin anticoagulation, 100-kDa cutoff, 12 h/session for up to 2 session
RFB-BAL (Univ. of Ferrara, Italy)	Radial flow bioreactor; aggregates	Freshly isolated porcine (200–230 g)	I/II	Plasma, heparin/citrate anticoagulation, 1 um polyester screen, 6–24 h treatments
AMC-BAL (Univ. of Amsterdam, Netherlands)	Non-woven polyester matrix, spirally wound; aggregates	Freshly isolated porcine ($10–14 \times 10^9$)	I	Plasma, heparin anticoagulation, direct cell-plasma contact, up to 18 h/session for up to 2 sessions
LiverX-2000 (Algenix Inc., Minneapolis, MN)	Hollow fiber; collagen entrapped	Freshly isolated porcine (40–80g)	I	Whole blood, heparin anticoagulation
HBAL (Nanjing Univ., Nanjing, China)	Hollow fiber; polysulfone; adsorption column	Freshly isolated porcine (10×10^9)	I	Plasma, 100k Da cutoff, one to two 60 h treatments

acute liver failure [160]. Notably, the ability to more accurately assess viability and function of cells during BAL treatment would be a major advance. Such information would be crucial in determining treatment time and the potential requirement for device replacement, both important considerations due to the instability of hepatocellular function in many contexts and the demonstrated detrimental effect of plasma from liver failure patients on cultured hepatocytes [161]. Finally, even if clinical trials of current BAL devices do not prove efficacy, information obtained from these studies coupled with improvements in cell sourcing and functional stabilization will represent the foundation for the next generation of devices.

IMPLANTABLE TECHNOLOGIES FOR LIVER THERAPIES AND MODELING

In addition to temporary extracorporeal support, the development of cell-based therapies for liver treatment aimed at the eventual replacement of damaged or diseased tissue is an active area of investigation. In many cases, hepatocytes have been injected into animal hosts and exhibit substantial proliferative capacity as well as the ability to replace diseased tissue and correct metabolic liver deficiencies in those models [162–165]. However, the clinical efficacy of these procedures is currently limited due in part to technical hurdles in cell delivery and animal models. These limitations might be addressed in part by engineering three-dimensional liver tissue *ex vivo* prior to implantation. Here we detail the state-of-art in cell transplantation in the context of applicable animal models as well as in the construction and application of engineered liver tissue.

Cell transplantation and animal models

Hepatocytes have been transplanted into rodents via injection into the spleen or splenic artery, intraperitoneal space, peripheral veins, or portal vein. Cell transplantation can improve host survival in animals with acute liver failure induced both chemically and surgically as well as end stage liver failure due to cirrhosis [165–169]. Transplantation also can correct metabolic deficiencies in several models of liver-based metabolic diseases [165,166]. Despite encouraging results in cell transplantation in animal models, translation of cell transplantation to the clinic has failed to result in sustained improvements in patient outcome. These results demonstrate the need for further improvements in cell delivery (e.g., through modalities such as tissue engineering) and/or better animal model systems.

Models of acute liver failure include administration of clinically relevant toxic doses of carbon tetrachloride (CCl_4) or acetaminophen, which can induce localized centrilobular necrosis, or surgical resection of two thirds of the liver in a partial hepatectomy model [170]. In these models, animals develop severe liver injury, but if animals can be kept alive for as little as 72 hours following injury, host regeneration can rapidly correct the damage. This observation is unlike the human situation, in which the repair of damage due to acute liver failure in patients has been estimated to take weeks or months [171,172]. This discrepancy could in part explain contradictory results in which animals can be 'cured' following acute liver failure after hepatocyte transplantation whereas humans are not; it is possible that injected hepatocytes are able to provide short-term support to animals but not the long-term replacement of hepatic function necessary for clinical therapy. Of note, parabiotic systems have demonstrated that after partial hepatectomy, factors regulating liver cell proliferation are present in the circulation [173,174]. Consequently, this model may serve as a well-controlled system to examine the importance of regenerative cues in the engraftment and proliferation of hepatic constructs implanted in extrahepatic sites.

Chronic liver failure represents a more substantial clinical burden, as outlined above. The most common animal models of experimental fibrosis are toxic damage due to CCl_4 administration and bile duct ligation [175]. In a rat cirrhosis model induced by CCl_4 treatment, hepatocytes transplanted into the spleen result in improved survival over controls for a period of months [176–178]. To date, hepatocyte transplantation has resulted in improvements in liver function and encephalopathy in some patients with acute and chronic liver failure, but no change in outcome and survival of these patients has been observed [179]. Engineering strategies to improve engraftment and survival in extrahepatic sites may improve the efficacy of these therapies.

Finally, hepatocytes have been transplanted into several animal models of metabolic liver diseases. In most cases, transplantation only partially corrected the genetic abnormalities. However, in the fumaryl acetoacetate hydrolase (FAH)-deficient mouse model of familial tyrosinemia [180], the albumin-uPA transgenic mouse [181], and in the transgenic mouse model of human alpha-1-antitrypsin deficiency [182], the inherited metabolic defect results in reduced survival of host hepatocytes and transplanted hepatocytes are able to engraft and replace the hepatocytes in the host liver over the course of weeks or months. These findings led to the generation of 'chimeric' mice, in which a substantial portion of the liver is composed of human hepatocytes (Fig. 46.8). For this reason, FAH-deficient and albumin-uPA transgenic mice are the most frequently used animal models for studying hepatocyte engraftment in host liver. Additionally, such mice promise to be useful as model systems for investigating human-specific drug metabolism and toxicity as well as infectious diseases that exhibit human tropism. The most convincing data for the therapeutic use of hepatocyte transplantation to date has been demonstrated in patients, primarily pediatric, with liver-based metabolic disorders. Patients with certain disorders such as urea cycle disorders experience greater improvement than others, but even in these cases, the function of hepatocytes deteriorates with time such that liver transplantation is typically necessary by six months [183].

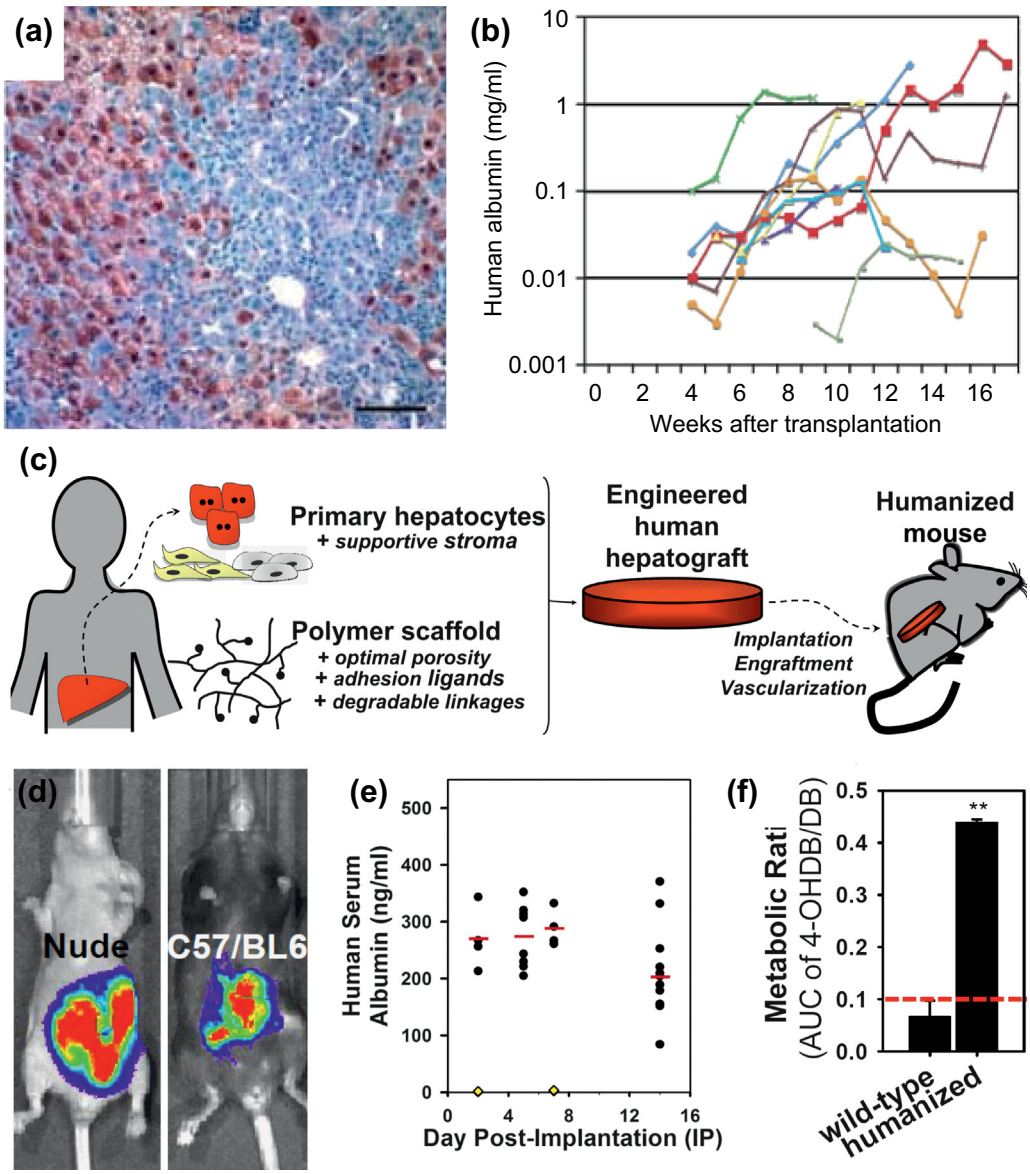

FIGURE 46.8

Mice with humanized livers. (a) FAH-positive human hepatocytes injected into the spleen of Fah$^{-/-}$ mice can engraft and integrate in the mouse livers, resulting in mice with 'humanized' livers. (b) Human albumin can be detected in the blood of these mice. (c) Engineered human liver tissue ('ectopic liver tissue') could also be constructed *ex vivo* and then implanted into mice. (d) Ectopic liver tissue can survive and function in mice that are both immunocompromised (left) and immunocompetent (right). (e) Human albumin can be detected in the blood of these mice. (f) Mice with ectopic human liver tissue can be used to identify disproportionate human drug metabolites that would not have been identified by wild-type mice. *(Reproduced with permission from [15,180].)*

In all of these animal models, a regenerative stimulation is provided by transgenic injury, partial hepatectomy, portocaval shunting, or the administration of hepatotoxic agents prior to cell transplantation. However, as evidenced by recent clinical trials that have seen limited success, these approaches are difficult to adapt to a clinical setting. Major limitations of isolated cell transplantation include the inefficient engraftment and limited survival of transplanted hepatocytes, which has been collectively reported at only 10–30% of injected cells [184]. Several studies have demonstrated methods to improve engraftment and enhance the selective proliferation of transplanted hepatocytes [185–187], although analogous to regeneration models, the clinical utility of these approaches remains to be determined. The time for engraftment and proliferation of transplanted hepatocytes also can create a

substantial lag time (48 hours in one study [152]) before clinical benefit is observed, which could restrict the utility of cell transplantation for certain clinical conditions, such as fulminant hepatic failure.

In summary, clinical trials of hepatocyte transplantation have recently demonstrated long-term safety, but donor hepatocyte engraftment and restoration of failing host livers has not been adequate to obviate the need for organ transplantation [188–190]. Additionally, only partial correction of metabolic disorders has been accomplished to date in the clinic [188–190]. Future studies that improve cell delivery, survival, and engraftment as well as reduce the time required for integration of the grafted cells with the host could greatly improve the effectiveness of cell-based therapies and animal model systems.

Implantable engineered tissue for humanized mouse models

Implantation of human engineered liver tissue into animal hosts may also provide alternative *in vivo* model systems for human disease. Despite their promise as model systems for investigating human-specific drug responses and infectious diseases with human tropism, current humanized mouse models (e.g., $FAH^{(-/-)}$ and albumin-uPA models detailed above) are limited in that animals must be both immunodeficient and exhibit significant host liver injury. Additionally, the process of human hepatocyte injection, homing to the liver, and expansion can take weeks to months; creating humanized mice using 'classic' cell transplantation is therefore tedious and time-consuming [15]. As one example of a candidate alternative, a recent study generated humanized mice by implanting hepatocytes and supporting non-parenchymal cells within a three-dimensional hydrogel scaffold into the intraperitoneal space of uninjured mice [15] (Fig. 46.8). The engineered human liver tissue synthesized human liver proteins as well as human-specific drug metabolism, drug-drug interaction, and drug-induced hepatocellular toxicity. The polyethylene glycol (PEG)-based engineered tissue was shown to survive and function within immunocompetent hosts for a period of time after implantation, suggesting that encapsulation of cells in this material system may have the potential to delay immune rejection and enable studies that require both human liver systems and intact immune processes.

Implantable therapeutic engineered liver tissue

The development of implantable engineered hepatic tissue is a promising strategy for the treatment of liver disease due to its potential to mitigate the limitations in current cell transplantation strategies, including inefficient seeding and engraftment, poor long-term hepatocyte survival, a required donor cell repopulation advantage, and the inherent lag phase before clinical benefit is attained [165,191]. Implantable engineered hepatic tissues are typically fabricated by immobilizing or encapsulating hepatic cells in biomaterial scaffolds in conjunction with strategies to optimize hepatocyte survival and function, leading to the generation of liver-like tissue *in vitro* prior to *in vivo* implantation.

Design criteria for implantable systems

To achieve therapeutic levels of liver function to treat liver failure, the development of engineered hepatic tissues that contain high densities of stable and functional hepatocytes with efficient transport of nutrients and secreted therapeutic factors is necessary. Furthermore, integration of the engineered tissue with the host upon implantation is critical in ensuring its long-term survival. The potential tunability of engineered implantable systems offers attractive prospects for the optimization of hepatocyte survival and function as well as subsequent host integration. Scaffold parameters that are customizable include porosity, mechanical and chemical properties, and three-dimensional architecture. Additionally, relevant microenvironmental cues like paracrine and juxtacrine cell-cell interactions, cell-matrix interactions and soluble factors can be incorporated into implantable engineered hepatic tissue

by translating either biological or biomimetic strategies from *in vitro* culture models so as to recapitulate important aspects of the *in vivo* hepatocyte microenvironment.

Natural scaffold chemistry and modifications

A wide variety of naturally-derived material scaffolds have been explored for liver tissue-engineering applications, including materials like collagen, peptides, fibrin, alginate, chitosan, hyaluronic acid, cellulose, decellularized liver matrix and composites of these [70,192–197] (Table 46.5). The choice of material determines the physicochemical and biological properties of the scaffold. For example, early efforts in developing implantable hepatic constructs utilized collagen-coated dextran microcarriers that enabled hepatocyte attachment since hepatocytes are known to be anchorage-dependent cells. The intraperitoneal transplantation of these hepatocyte-attached microcarriers resulted in successful replacement of liver functions in two different rodent models of genetic liver disorders [198]. Subsequently, collagen-coated or peptide-modified cellulose [196,199], gelatin [200], and gelatin-chitosan composite [201] microcarrier chemistries have also been explored for their capacity to promote hepatocyte attachment. On the other hand, materials that are poorly cell adhesive like alginate [70] have been exploited for their utility in promoting hepatocyte-hepatocyte aggregation (e.g., spheroid formation) and hence hepatocyte stabilization within these scaffolds. Collectively, the size of engineered tissues created by these approaches is limited by oxygen and nutrient diffusion to only a few hundred microns in thickness. To address this constraint, recent work has sought to use decellularized whole organ tissue as a matrix for liver tissue engineering (Fig. 46.9). The decellularization process removes cells from donor tissues but preserves the structural and functional characteristics of much of the tissue microarchitecture and vasculature of the underlying extracellular matrix. Decellularized liver matrices can be seeded with hepatocytes and vascular cells, exhibit liver-specific functions, and survive after transplantation into rodents [197,202]. Future work in this area will likely focus on improving cell seeding protocols, which to date have achieved only 20–40% of endogenous liver mass after recellularization, as well as co-seeding with a both hepatocytes and the various non-parenchymal cell types found in liver (e.g., stellate cells, Kupffer cells). In general, the advantages of biologically-derived materials include their biocompatibility, naturally occurring cell adhesive moieties, and, in the case of decellularization, native architectural presentation of extracellular matrix molecules.

Synthetic scaffold chemistry

In contrast to biologically-derived material systems, synthetic materials enable precisely customized architecture (porosity and topography), mechanical and chemical properties, and degradation modality and kinetics. Synthetic materials that have been explored for liver tissue engineering include poly(L-lactic acid) (PLLA), poly(D,L-lactide-co-glycolide) (PLGA), poly (ε-caprolactone) (PCL), and poly(ethylene glycol) (PEG) [15,71,203–207]. Polyesters like PLLA and PLGA are the most common synthetic polymers utilized in the generation of porous tissue-engineering constructs. These materials are biocompatible, biodegradable, and have been used as scaffolds for hepatocyte transplantation [203,208]. A key advantage of PLGA is the potential to finely tune its degradation time due to differences in susceptibility to

TABLE 46.5 Scaffolds utilized for hepatocellular constructs

Category	Composition
Natural	Collagen, chitosan, collagen/chitosan composites, alginate, alginate composites, liver-derived biomatrix, peptides, hyaluronic acid, fibrin, gelatin, agarose
Synthetic	PLLA, PLGA, PLLA/PLGA composite, PGA, PEG, PCL, PET, PVA

hydrolysis of the ester groups of its monomeric components (lactic acid and glycolic acid). However, the accumulation of hydrolytic degradation products has been shown to produce an acidic environment within the scaffold which initiates peptide degradation and stimulates inflammation, which may affect hepatocyte function [209]. Consequently, as alternatives to macroporous scaffold systems, approaches aimed at the efficient and homogeneous encapsulation of hepatocytes within a fully 3D structure have been explored. In particular, hydrogels that exhibit high water content and thus similar mechanical properties to tissues are widely utilized for various tissue-engineering applications including hepatocellular platforms. Synthetic, PEG-based hydrogels have been increasingly utilized in liver tissue-engineering applications due to their high water content, hydrophilicity, resistance to protein adsorption, biocompatibility, ease of chemical modification, and the ability to be polymerized in the presence of cells, thereby enabling the fabrication of 3D networks with uniform cellular distribution [210]. PEG-based hydrogels have been used for the encapsulation of diverse cell types, including immortalized and primary hepatocytes and hepatoblastoma cell lines [15,206,207]. The encapsulation of primary hepatocytes requires distinct material modifications (e.g., 10% w/v polyethylene glycol (PEG) hydrogel, inclusion of RGD adhesive motifs) as detailed below, as well as, analogous to 2D co-culture systems, the inclusion of non-parenchymal supporting cell types such as fibroblasts and endothelial cells [207].

Modifications in scaffold chemistry

The relatively inert nature of synthetic scaffolds allows for the controlled incorporation of chemical/polymer moieties or biologically active factors to regulate different aspects of cellular function. Chemical modifications like oxygen plasma treatment or alkali hydrolysis of PLGA [211,212], or the incorporation of polymers like poly(vinyl alcohol) (PVA) or poly(N-p-vinylbenzyl-4-O-β-D-galactopyranosyl-D-glucoamide) (PVLA) into poly(lactic-co-glycolic acid) (PLGA) or poly-l-lactide acid (PLLA) scaffolds [203,213,214] have improved hepatocyte adhesion by modulating the hydrophilicity of the scaffold surface [215]. Biological factors may include whole biomolecules or short bioactive peptides. Whole biomolecules are typically incorporated by non-specific adsorption of extracellular matrix molecules like collagen, laminin or fibronectin [211,216] and covalent conjugation of sugar molecules like heparin [217,218], galactose [71,219], lactose [217] or fructose [220], or growth factors like EGF [221]. Alternatively, short bioadhesive peptides that interact with cell surface integrin receptors have been extensively utilized to promote hepatocyte attachment in synthetic scaffolds.

For example, conjugation of the RGD peptide to PLLA has been shown to enhance hepatocyte attachment [222], whereas RGD modification significantly improved the stability of long-term hepatocyte function in PEG hydrogels [15,207]. The additional incorporation of adhesive peptides that bind other integrins may serve as a way to further modulate and enhance hepatocyte function within synthetic polymer substrates. Moreover, although not yet applied to hepatocellular systems, the integration of matrix metalloproteinase-sensitive peptide sequences into hydrogel networks as degradable linkages has been shown to enable cell-mediated remodeling of the gel [223–225]. The capacity to modify biomaterial scaffold chemistry through the introduction of biologically active factors will likely enable the finely tuned regulation of cell function and interactions with host tissues important for implantable systems.

Porosity

A common feature of many implantable tissue-engineering approaches is the use of porous scaffolds that provide mechanical support often in conjunction with cues for growth and morphogenesis. Collagen sponges, various alginate and chitosan composites, and PLGA are the most commonly used porous scaffolds for hepatocyte culture, and are generally synthesized using freeze-dry or gas-foaming techniques. Pore size has been found to regulate cell spreading and cell-cell interactions, both of which can influence hepatocyte functions [192], and may also influence angiogenesis and tissue ingrowth [226]. Porous, acellular scaffolds are normally seeded using gravity or centrifugal forces, capillary action, convective flow, or through cellular recruitment with chemokines, but hepatocyte seeding is generally heterogeneous in these scaffolds [227,228].

Controlling 3D architecture and cellular organization

Another approach to improving the functionality of tissue-engineered constructs is to more closely mimic *in vivo* microarchitecture by generating scaffolds with a highly defined material and cellular architecture, which would provide better control over the 3D environment at the microscale.

A range of rapid prototyping and patterning strategies have been developed for polymers using multiple modes of assembly including fabrication using heat, light, adhesives, or molding, and these techniques have been extensively reviewed elsewhere [229]. For example, 3D printing with adhesives combined with particulate leaching has been utilized to generate porous PLGA scaffolds for hepatocyte attachment [230], and microstructured ceramic [231] and silicon scaffolds [232,233] have been proposed as platforms for hepatocyte culture. Furthermore, molding and microsyringe deposition have been demonstrated to be robust methods for fabricating specified 3D PLGA structures towards the integration into implantable systems [234].

Microfabrication techniques have similarly been employed for the generation of patterned cellular hydrogel constructs. For instance, microfluidic molding has been used to form biological gels containing cells into various patterns [235]. In addition, syringe deposition in conjunction with micropositioning was recently illustrated as a means to generate patterned gelatin hydrogels containing hepatocytes [236]. Patterning of synthetic hydrogel systems has also recently been explored. Specifically, the photopolymerization property of PEG hydrogels enables the adaptation of photolithographic techniques to generate patterned hydrogel networks. In this process, patterned masks printed on transparencies act to localize the UV (ultraviolet) exposure of the pre-polymer solution, and thus, dictate the structure of the resultant hydrogel. The major advantages of photolithography-based techniques for patterning of hydrogel structures are its simplicity and flexibility. Photopatterning has been employed to surface pattern biological factors [237], produce hydrogel structures with a range of sizes and shapes [238,239], as well as build multilayer cellular networks [240,241].

Consequently, hydrogel photopatterning technology is ideally suited for the regulation of scaffold architecture at the multiple length scales required for implantable hepatocellular constructs. As a demonstration of these capabilities, photopatterning of PEG hydrogels was utilized to generate hepatocyte/fibroblast co-culture hydrogels with a defined 3D branched network, resulting in improved hepatocyte viability and functions under perfusion [206]. More recently, a 'bottom-up' approach for fabricating multicellular tissue constructs utilizing DNA-templated assembly of 3D cell-laden hydrogel microtissues demonstrates robust patterning of cellular hydrogel constructs containing numerous cell types [242]. Also, the additional combination of photopatterning with dielectrophoresis-mediated cell patterning enabled the construction of hepatocellular hydrogel structures organized at at the cellular scale (Fig. 46.8). Overall, the ability to dictate scaffold architecture coupled with other advances in scaffold material properties, chemistries, and the incorporation of bioactive elements will serve as the foundation for the future development of improved tissue-engineered liver constructs that can be customized spatially, physically, and chemically.

Host interactions

Further challenges in the design of therapeutic implantable liver devices are more specifically associated with the interactions with the host environment. These include issues related to vascularization, remodeling, the biliary system, and immunologic considerations. Notably, a significant challenge for the design of implantable liver constructs is the need to overcome transport limitations within the grafted construct due to the lack of functional vasculature. Within the normal liver environment, hepatocytes are supplied by an extensive sinusoidal vasculature with minimal extracellular matrix and a lining of fenestrated (sinusoidal) endothelial cells. Together these features allow for the efficient transport of nutrients to the highly metabolic hepatocytes. Strategies to incorporate vasculature into engineered constructs include the microfabrication of vascular units with accompanying surgical anastomosis during implantation [232,243]. For example, polymer molding using microetched silicon has been shown to generate extensive channel networks with capillary dimensions [244]. The incorporation of angiogenic factors within the implanted scaffolds has also been explored. Specifically, integration of cytokines important in angiogenesis, such as VEGF [208], basic fibroblast growth factor (bFGF) [245], and Vascular endothelial growth factor (VEGF) in combination with Platelet-derived growth factor (PDGF) [246], has been shown to promote the recruitment of host vasculature to implanted constructs. Furthermore, preimplantation of VEGF releasing alginate scaffolds prior to hepatocyte seeding was demonstrated to enhance capillary density and improve engraftment [247].

In addition to interactions with the vasculature, integration with other aspects of host tissue will constitute important future design parameters. For instance, incorporation of hydrolytic or protease-sensitive domains into hepatocellular hydrogel constructs could enable the degradation of these systems following implantation. Of note, liver regeneration proceeds in conjunction with a distinctive array of remodeling processes such as protease expression and extracellular matrix deposition. Interfacing with these features could provide a mechanism for the efficient integration of implantable constructs. Similarly to whole liver or cell transplantation, the host immune response following the transplant of tissue-engineered constructs is also a major consideration. Immunosuppresive treatments will likely play an important role in initial therapies, although stem cell-based approaches hold the promise of implantable systems with autologous cells. Furthermore, harnessing the liver's unique ability to induce antigen-specific tolerance [248] could potentially represent another means for improving the acceptance of engineered grafts. Finally, incorporation of excretory functions associated with the biliary system will ultimately be required in future designs. Towards this end, current studies are focused on the development of *in vitro* models which exhibit biliary morphogenesis and recapitulate appropriate polarization and bile canaliculi organization [249–251], as well as platforms for the engineering of artificial bile duct structures [252].

CONCLUSION

Although many challenges remain for the improvement of tissue-engineered liver therapies, substantial progress has been made towards achieving a thorough understanding of the necessary components. The parallel development of highly functional *in vitro* systems as well as extracorporeal and implantable therapeutic devices is based on contributions from diverse disciplines including regenerative medicine, developmental biology, transplant medicine, and bioengineering. In particular, novel technologies such as hydrogel chemistries, high-throughput platforms, and microfabrication techniques represent enabling tools for investigating the critical role of the microenvironment in liver function and, subsequently, the development of structurally complex and clinically effective engineered liver systems.

CHAPTER 47

Hematopoietic Stem Cells

Malcolm A.S. Moore
Moore Laboratory, Cell Biology Program, Memorial Sloan-Kettering Cancer Center, New York, New York

INTRODUCTION

Hematopoietic stem cells (HSCs) are characterized by their extensive self-renewal capacity and pluripotency. The probabilities of asymmetric versus symmetric division of HSCs can be stochastically determined or influenced by external signals. There are many *in vitro* systems involving either bone marrow (BM) stromal support or provision of a combination of recombinant hematopoietic growth factors, or both, that can maintain HSC proliferation and differentiation over many weeks. However, the goal of significant expansion of the HSC population *in vitro* has proved more elusive. There has been an explosive increase in knowledge of the cellular and molecular bases of HSC regulation with the identification of pathways implicating Notch, Wnt, and Hedgehog as well as cytokine signaling through the c-Kit, Flt3, IL-6-R, Mpl and Tie-2 receptors and downstream pathways involving Jak/STAT and homeobox proteins. There is considerable redundancy in pathways regulating HSCs, and both additive and synergistic interactions between different pathways determine the balance between self-renewal and differentiation. With the identification of specific niches within the BM including endosteal and endothelial, it is now recognized that intimate interactions between HSC and regulatory components of the marrow microenvironment (osteoblasts, osteoclasts, granulocytes, macrophages, mesenchymeal cells, endothelium) determine HSC proliferative status, pool size, differentiation and mobilization. The migration of HSCs between different niches and the vascular compartment is regulated by the chemotactic action of the stromally-derived chemokine SDF-1(CXCL12) acting through its receptor CXCR4, in combination with CD44 and hyaluronic acid. The release of various proteases within the marrow environment leads to cleavage of stromal and HSC-associated adhesion molecules, receptors, cytokines and chemokines, providing a further level of regulation.

HISTORICAL BACKGROUND

For more than a century, the nature and developmental potential of stem cells within the hematopoietic system has been debated. The concept of a self-renewing, pluripotent hematopoietic stem cell achieved experimental validation through the pioneering work of Till and McCulloch in the early 1960s, using the spleen colony-forming assay (CFU-s) in irradiated mice (reviewed in reference [1]). These authors undertook secondary passage of individually excised spleen colonies and observed a high variability in numbers of secondary colonies generated which fitted a skewed (gamma) distribution. The probability that a single CFU-s upon division would generate a new CFU-s (self-renewal) was calculated as 0.6 while production of a differentiated progenitor cell was 0.4. The conclusion was that this process was random or stochastic. Other studies at this time indicated the existence of 'hematopoietic inductive

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00047-1

microenvironments' that influenced the differentiation of HSCs. The relevance of stochastic processes versus external inductive signals in the regulation of HSC self-renewal and differentiation is still debated.

PROPERTIES OF HEMATOPOIETIC STEM CELLS (HSCs)

Asymmetric division

Recent genetic studies have provided important insight into the relation between the cell cycle activity and stemness of HSCs (reviewed in reference [2]). In HSCs, the cell cycle is tightly regulated by cyclins, cyclin-dependent kinases (CDKs), the retinoblastoma protein family, the transcription factor E2F and CDK inhibitors. Most, but not all, of these regulators are necessary for the maintenance of HSCs, with abnormal activation or suppression of the cell cycle resulting in HSC exhaustion [2,3]. HSC proliferation is also regulated by the ubiquitin proteasome pathway and by external factors such as cytokines, chemokines and morphogens produced by niche cells. The ability to isolate purified HSCs has led to the detailed analysis of their transcriptional and epigenetic status (reviewed in reference [4]). The undifferentiated state of an HSC is characterized by dynamic maintenance of chromatin structures and epigenetic plasticity, and the epigenetic chromatin states uniquely define the developmental plasticity of murine HSCs (reviewed in references [5,6]). HSCs can divide either symmetrically or asymmetrically depending on environmental, developmental or stochastic factors (Fig. 47.1). Using a Notch reporter mouse, in which green fluorescent protein (GFP) acts as a sensor for differentiation, imaging studies show that they undergo both symmetric and asymmetric division [7]. The balance between these divisions is not hardwired, but responsive to extrinsic and intrinsic signals. Murine HSCs in a pro-differentiation environment preferentially divide asymmetrically, whereas those in a pro-renewal environment primarily divide symmetrically [7]. The balance between the probability of symmetric versus asymmetric changes between fetal, neonatal, early postnatal (three weeks mouse, ~three months human), and adult hematopoiesis is biased toward symmetric HSC divisions allowing for expansion of the HSC population to match the expansion of the total lympho/hematopoietic system [8–10]. Asymmetric division can be governed by intrinsic partitioning of regulators of cell fate or by asymmetric exposure to extrinsic cues (reviewed in reference [11]). Symmetric divisions occur during hematopoietic expansion during development and in hematopoietic regeneration following myelodepletion or HSC transplantation. In the latter situations, there

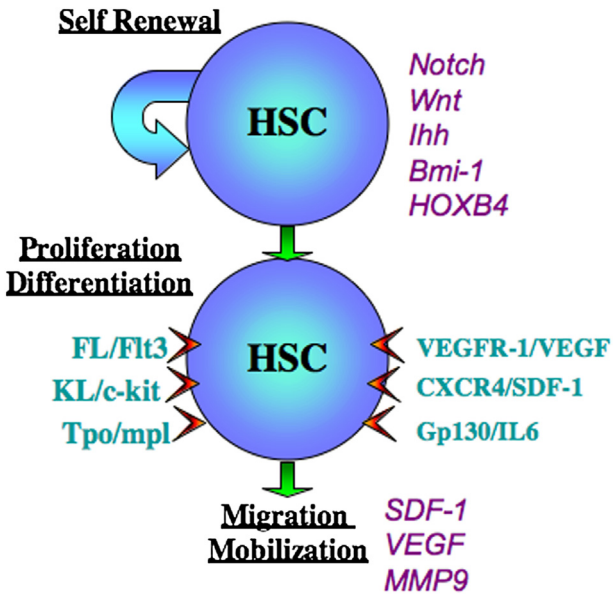

FIGURE 47.1
Model of HSC self-renewal and differentiation illustrating the role of key cytokines — Flt3 ligand (FL), c-Kit ligand (KL, also termed stem cell factor or Steel factor), thrombopoietin (Tpo) and Interleukin-6 (IL-6). The chemokine receptor CXCR4 and its ligand SDF-1 and the VEGF Receptor-1 (VEGFR-1) and its ligands are implicated in HSC migration and mobilization. The Notch, Wnt and Indian Hedgehog (Ihh) signaling pathways have also been implicated in HSC self-renewal as have the Polycomb group transcriptional repressor Bmi-1 and the HOX homeodomain protein HOXB4.

is well-documented data showing HSC expansion in murine models. For example after successive serial transfers of HSCs in irradiated mice, a cumulative 8,400-fold increase in HSC number was observed (reviewed in reference [12]). Extensive expansion of human HSCs was also observed following prolonged *in vitro* culture of hematopoietic precursors from umbilical cord blood [13]. There is less evidence of symmetrical HSC division either *in vitro* or *in vivo* in adult humans [14]. Beckmann et al. [15], identified four proteins (CD53, CD62L/L-selectin, CD63/lamp-3, and CD71/transferrin receptor) that segregate differentially in about 20% of human HSCs that divide in stroma-free cultures, indicating that HSCs/HPCs have the intrinsic capability to divide asymmetrically. Three of these proteins, the transferrin receptor and the tetraspanins CD53 and CD63, are endosomally-associated proteins, suggesting a link between the endosomal compartment and the process of HSC asymmetric cell division.

An intact p53 positively regulates HSC self-renewal independently from apoptosis, preventing gammaH2AX foci accumulation and ensuring optimal HSC self-renewal [16–18]. Constitutive DNA methylation is an essential epigenetic mechanism for protecting HSCs from premature activation of predominant differentiation programs, and methylation dynamics may determine HSC self-renewal [19]. Alternative functional programs of HSCs are governed by gradual differences in DNA methylation levels [20]. HSCs from mice with reduced DNA methyltransferase 1 activity cannot suppress key myeloerythroid regulators and thus can differentiate into myeloerythroid, but not lymphoid, progeny [20]. HSCs were thought to segregate chromosomes asymmetrically during self-renewing divisions so that older ('immortal') DNA strands are retained in daughter HSC whereas newly synthesized strands segregate to differentiating cells. Using definitive markers, Kiel et al. [21] demonstrated that HSCs do not asymmetrically segregate chromosomes or retain bromo-2-deoxyuridine (BrdU) and do not retain older DNA strands during division.

A promyelocytic leukemia (PML)-peroxisome proliferator-activated receptor δ (PPAR-δ) —fatty-acid oxidation (FAO) pathway has been identified which controls the asymmetric division and maintenance of HSCs [22]. PML exerts an essential role through regulation of PPAR signaling and FAO. Loss of PPAR-δ or inhibition of mitochondrial FAO induced the loss of HSC maintenance, whereas treatment with PPAR-δ agonists improved HSC maintenance [22]. The endocytic protein AP2A2, an agonist of mouse HSC activity, segregates asymmetrically during mitosis [23]. *In vivo* RNA interference has been used in mouse HSCs to inhibit a panel of genes with a role in HSC polarity and asymmetric cell division. Four important determinants of HSC behavior were identified, three being upregulated- Musashi2 (*Msi2)*, polarity-specifying PAR protein (*Pard6a)* and atypical protein kinase C homolog (*Prkcz*) and one downregulated (*Prox1*, an atypical homeodomain-containing transcription factor) [22]. A number of recent studies have convincingly shown a role for Msi2 independent of Msi1 in normal [24,338] and malignant [24,339] hematopoiesis. It was shown, using gain-of-function and loss-of-function strategies in mouse and human models, that Msi2 positively regulates HSC proliferation and, when overexpressed, impairs differentiation into mature blood cells [24]. Msi2 and the closely related Msi1 bind consensus motifs in mRNAs to inhibit their transcription. Msi2 has a role in determining binary cell fates during development by inhibiting Notch and Hedgehog signaling (reviewed in reference [25]). Known targets include developmental transcriptional factors, cell cycle regulators and Numb, a membrane-bound protein that has been shown to be a negative regulator of Notch and Hedgehog signaling via ITCH E3-mediated ubiquitination (Ub) and subsequent proteasome-mediated degradation of Notch intracellular domain (NICD) and the zinc finger transcription factor Gli that mediates Hedgehog signaling [22,25,338]. ITCH belongs to the HECT (homologous to E6AP C terminus) family of E3 ligases. It is proposed that it has more than 20 cellular targets including Notch (reviewed in reference [26]). In $Itch^{-/-}$ mice, the self-renewal capacity and absolute number of HSCs are increased without an increase in mature cell numbers. Under the physiological stress of myeloablation, $Itch^{-/-}$ cells show enhanced hematopoietic recovery. Knockdown of Notch, a known target of Itch, in

Itch-deficient progenitors has demonstrated a partial rescue, suggesting that the Itch$^{-/-}$ phenotype may in part result from increased stability of active intracellular Notch (ICN) [26]. It therefore appears that Itch, similar to c-Cbl, functions as a negative regulator of HSC self-renewal and proliferation. The HoxA9 binding element in the Msi2 promoter induces Msi2 reporter activity in HSCs and HoxA9$^{-/-}$ HSCs exhibited a substantial loss of proliferative capacity leading to diminished repopulation ability, very similar to what was found with Msi2$^{-/-}$ animals (reviewed in reference [25]). In this Hox—Msi2—Notch pathway, HoxA9 activates the expression of Msi2, which in turn inhibits the translation of Numb mRNA, resulting in activation of the Notch pathway. As NICD does not possess any DNA binding activity, it associates with recombination signal binding protein J (RBPJ), the primary transcriptional mediator of canonical Notch signaling (reviewed in reference [25]). By inhibiting the translation of Numb mRNA, Msi2 acts as a master switch that is 'on' in normal HSCs and leukemic stem cells (LSCs) [22,24,25,338]. After HSC asymmetric division, one daughter cell remains an HSC whereas the other becomes a non-self-renewing progenitor, with MSI2 downregulated and Numb upregulated (reviewed in reference [25]).

HSC transcriptome

The ability to isolate purified HSCs has led to the detailed analysis of their transcriptional and epigenetic status (reviewed in reference [4]). This detailed cellular picture of murine hematopoiesis combined with robust genetic approaches is beginning to unlock the molecular and biochemical pathways that underlie HSC function (reviewed in references [27,221]). Accumulating evidence indicates that the undifferentiated state of HSCs is characterized by dynamic maintenance of chromatin structures and epigenetic plasticity (reviewed in references [5,6]). Recent genetic studies in mice have provided insights into the regulation of the cell cycle in stem cells, including its potential modulation by the stem cell niche (reviewed in reference [27]). Bioinformatic analysis revealed HSCs were more transcriptionally active than their progeny, and identified a 'lineage fingerprint' of ~100—400 genes uniquely expressed in HSCs, with Wnt signaling being particularly enhanced [28]. Deneault et al. [29] developed a novel gain-of-function screen to identify 18 nuclear factors that were novel effectors of HSC activity. Overexpression of ten of these factors resulted in an increased repopulating activity compared to unmanipulated cells. Interestingly, at least four of the 18 factors, Fos, Tcfec, Hmgb1, and Sfpi1, show non-cell-autonomous functions. Novershtern et al. [30] reported a comprehensive transcriptome analysis of 38 distinct purified populations of human hematopoietic cells, combined with sophisticated bioinformatics analysis and high-throughput DNA binding data for multiple transcription factors. Large numbers of transcription factors were differentially expressed across hematopoietic states suggesting a more complex regulatory system for hematopoiesis than had been previously assumed. A genome-wide comparison of CpG methylation in human HSCs revealed a genome-wide undermethylation dip around the transcription start site and a hierarchical epigenetic plasticity [31]. Inhibition of chromatin condensation by chemical treatment (5-azacytidine, trichostatin A) enhanced the self-renewal of 'stimulated' HSCs in reconstituting BMs but not 'steady state' HSCs in stationary phase BM [31].

The gene expression profiles of steady state BM HSCs has been compared to HSCs treated with mobilizing drugs that expand the HSC pool and induce egress from the marrow, and to non-self-renewing multipotent progenitors [32]. The transcription factor Egr1, a regulator of HSC migration and location, was highly downregulated in mobilized HSCs. Likewise, the adhesion molecule Esam1, which was identified as a highly selective HSC marker [32]. Cell cycle and G_0 analysis indicates that the largest category of transcripts selective for normal HSC fall in the 'unknown' categories in cellular location and molecular function. Meta-analysis of differentially expressed gene sets defined a unique expression profile highly selective for quiescent HSC [32]. These 'HSC signature genes' likely include active regulators of controlled self-renewing divisions and interactions with the microenvironment which function to actively suppress differentiation, proliferation, and transformation.

HSC-associated genes

Aldehyde dehydrogenase (ALDH) was reported to be a key regulator of HSC differentiation [33]. Inhibition of ALDH with diethylaminobenzaldehyde (DEAB) delayed the differentiation of human HSCs that otherwise occurred in response to cytokines. Moreover, short-term culture with DEAB caused a 3.4-fold expansion in HSC [33]. The effects of DEAB on HSC differentiation could be reversed by the co-administration of the retinoic acid receptor agonist, all-trans-retinoic acid, suggesting that the ability of ALDH to generate retinoic acids is important in determining HSC fate. High levels of the aldehyde dehydrogenase isoform ALDH1A1 are expressed in HSCs, but loss of ALDH1A1 does not affect them [34]. ALDH1A1 deficiency is associated with increased expression of the ALDH3A1 isoform, suggesting its potential to compensate for ALDH1A1. Mice deficient in both ALDH3A1 and ALDH1A1 have reduced numbers of HSCs as well as aberrant cell cycle distribution, increased reactive oxygen species levels, p38 mitogen-activated protein kinase activity and sensitivity to DNA damage [34]. These findings demonstrate that ALDH3A1 can compensate for ALDH1A1 and both genes ALDH1A1 and 3A1 are important in HSC metabolism of reactive oxygen species and reactive aldehydes.

The matricellular protein Nephroblastoma Overexpressed (Nov, CCN3) is essential for HSC functional integrity [35]. Forced expression of Nov or addition of recombinant Nov protein both enhance HSC and/or progenitor activity. Scl and Lyl1 encode two related basic-helix-loop-helix transcription factors, and single and double knockout studies in mice showed that expression of at least one of these factors is essential for maintenance of adult HSC function [36]. Lineage-specific transcription factors must be precisely regulated during HSC self-renewal and lineage commitment decisions. During embryogenesis, both Runx1/AML1 and Evi-1 are essential for HSCs, whereas in the adult Runx1 and Evi-1 regulate HSCs negatively and positively, respectively (reviewed in reference [37]). The tumor suppressor and mediator of cell contact inhibition Nf2/merlin is critical for maintaining the normal structure and function of the HSC niche [38]. HSCs in Nf2-deficient mice were increased in number and demonstrated a marked shift in location to the circulation, and this was associated with an increase in vascular endothelial growth factor (VEGF) and in both bone and vascular components [38]. Nf2 limits bone and vascular niche components, thereby constraining HSC number and position. Disruption of the c-myb proto-oncogene specifically in adult bone marrow resulted in a critical depletion of the HSC pool with impaired hematopoiesis and profound reductions of neutrophilic, monocytic, B lymphoid, erythroid, and megakaryocytic cells [39]. This transcription factor is an essential regulator of self-renewal and multilineage differentiation of adult long-term and short-term HSCs and multi-potential progenitors. The coexpression of lymphoid and myeloid genes is an early event detected in multipotent progenitors, but also in ~30% of short-term HSCs [40].

The proliferating cell nuclear antigen-associated factor (Paf) is highly expressed in cycling BM HSCs and plays a critical role as an essential regulator of early hematopoiesis [41]. Mice lacking Paf exhibited reduced BM cellularity and leukopenia with reduced numbers of HSCs and committed progenitors. These phenotypes are caused by a cell-intrinsic blockage in the development of long-term (LT)-HSCs into multipotent progenitors and preferential loss of lymphoid progenitors caused by markedly increased p53-mediated apoptosis [41]. In addition, LT-HSCs from Paf(−/−) mice had increased levels of reactive oxygen species (ROS), failed to maintain quiescence, and were unable to support long-term hematopoiesis.

Focal adhesion kinase (Fak) is a non-receptor protein tyrosine kinase that plays an essential role in many cell types, where its activation controls adhesion, motility, and survival. Fak expression is relatively increased in HSCs compared to progenitors and mature blood cells [42]. Widespread Fak inactivation in the hematopoietic system induces an increase in the numbers of activated HSCs, probably due to alterations in the reciprocal interactions between HSCs and their microenvironment [42]. The endoplasmic reticulum chaperone protein GRP94 has been reported to be essential for the expression of specific integrins, and is required for maintaining HSC interactions with the adult BM niche [43]. There was an increase in HSCs

and granulocyte-monocyte progenitors in Grp94$^{-/-}$ BM associated with loss of HSC quiescence and an increase in proliferation. This expansion of the HSC pool can be attributed to the impaired interaction of HSCs with their niche, as indicated by severely compromised HSC homing and lodging ability, and enhanced mobilization [43].

Endoglin is a transforming growth factor-beta (TGF-beta) accessory receptor recently identified as being highly expressed in long-term repopulating HSCs [44]. However, little is known regarding its function in these cells. Transplantation of BM enriched in HSCs and progenitor cells revealed that neither endoglin suppression nor endoglin overexpression affected the ability of stem cells to repopulate recipient marrow in either the short or long term [44]. Decreasing endoglin expression increased the clonogenic capacity of early blast-forming unit-erythroid progenitors, whereas overexpression compromised erythroid differentiation at the basophilic erythroblast phase, suggesting a pivotal role for endoglin at key stages of adult erythropoietic development [44].

It has recently been demonstrated that protein regulation via the ubiquitin proteasome system (UPS) is crucial for normal HSC function (reviewed in reference [26]). Casitas B cell lymphoma (c-Cbl), Itch and Fbw-7 have been termed the 'gatekeepers of quiescence' of the HSC population [26]. The proto-oncogene, c-Cbl, is a RING finger E3 ubiquitin ligase that is the cellular homolog of v-Cbl, a retroviral transforming gene c-Cbl is thought to regulate approximately 150 proteins either directly or indirectly and is a negative regulator of the activity of Notch1, c-Kit and signal transducer and activator of transcription (STAT)5 (an activator of c-myc expression) all of which contribute to HSC maintenance [26]. Cbl knockout mice exhibit a cell autonomous increase in the HSCs without an increase in mature cell output. Cbl$^{-/-}$ HSCs have increased concentrations of phospho-STAT5 and Myc mRNA suggesting Cbl deficiency stabilizes active STAT5. The E3 ligase activity of c-Cbl keeps the proliferative capacity of HSCs in check with loss of activity leading to enhanced self-renewal and aberrant proliferation in a normally quiescent adult HSC compartment [26]. Itch belongs to the HECT (homologous to E6AP C terminus) family of E3 ligases and, similar to c-Cbl, functions as a negative regulator of HSC self-renewal and proliferation via Notch, a known regulator of hematopoiesis [26]. Fbw-7 is a RING finger E3 ligase that plays a role in regulation of approximately 20 proteins including c-myc and Notch. Germline deletion of Fbw7 results in embryonic lethality around E10.5 due to vascular defects, which are attributed to the stabilization of Notch4 in the embryo. Conditional deletion of Fbw7 leads to an increase in the frequency of actively cycling HSCs with their eventual loss. Fbw7$^{-/-}$ HSC defects are cell autonomous and involve downregulation of genes involved in HSC quiescence, with global loss of quiescent characteristics [26].

USP1 is a cysteine protease DUB that deubiquitinates FANCD2 (Fanconi anemia group D2) which is a regulator of the Faconi anemia (FA) pathway. It is able to protect HSCs from DNA damage during the divisions that are necessary to maintain the stem cell pool (reviewed in reference [26]). RelB and nuclear factor κB (NF-κB2), main effectors of NF-κB non-canonical signaling, positively and intrinsically regulate HSC and progenitor cell self-renewal [45].

HSC assays

Recent developments and validation of phenotypic and functional assays for both murine and human HSCs have been extensively reviewed [4,46–50]. Human HSCs are enriched in Lin-CD34+CD38− cord blood (CB) and BM and express CD90. The Lin-CD34+CD38− fraction of cord blood and bone marrow can be subdivided into three subpopulations; CD90−CD45RA+, CD90−CD45RA+ and CD90+CD45RA−. In CB, the latter subpopulation is highly enriched in HSCs, with 10 purified cells detected in *in vitro* or *in vivo* HSC assays [51]. CB CD34+CD38−CD90+ long-term repopulating HSCs were further enriched by selection for integrin α2 receptor expression [53]. Primitive, highly proliferative potential progenitor (HPP-CFC) culture systems have been used as surrogate HSC assays [52]. More recent assays

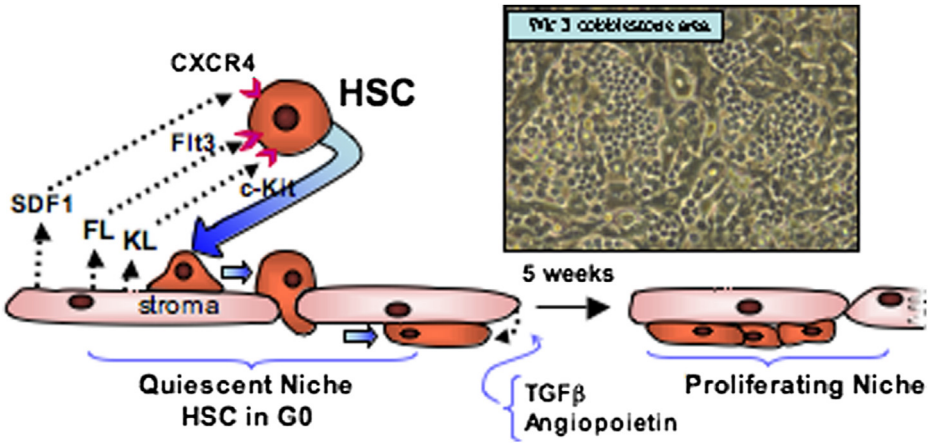

FIGURE 47.2
A model illustrating the concept of the 'late' cobblestone area -forming cell (CAFC)' and its interaction with bone marrow stromal elements. SDF-1 produced by the marrow stroma establishes a gradient that attracts CXCR4+ HSC that adhere via VLA-4-VCAM-1 mediated adhesion and then migrate beneath the stroma. Stromal membrane-associated c-Kit ligand (KL) and Flt3 ligand (FL) provide survival and proliferation signals to the HSC while negative regulatory influences from the stroma (TGFβ, Angiopoietin) override proliferative signals and place the HSC in a G0 state that persists for some weeks. Escape from quiescence may be a stochastic process or driven by an alteration in the balance between proliferation stimulating and inhibiting factors. At this stage the HSC proliferates and differentiates, forming colonies of 5–100 phase-dark cells by week 5. At this stage each cobblestone area contains on average of 1–4 HSC and 5–20 progenitors (CFU-GM, BFU-E).

involve the development of cobblestone areas of phase-dark cells that develop beneath BM stroma following 2–3 weeks (murine) or > 5 weeks (human) co-culture with BM or CD34+ cells [54] (Fig. 47.2). These cobblestone area forming cells (CAFCs) have self-renewal and pluripotent differentiation potential. A modification of this assay involves the quantitation of secondary, progenitor erythroid and myeloid colony formation (CFC) after five weeks (human) or three weeks (mouse) of stromal or cytokine-dependent culture (long-term culture-initiating cell assay – LTC-IC). The *in vivo* assays for murine HSCs involve limiting dilution, competitive (e.g., with addition of a genetically distinct marrow population) repopulation assay in irradiated recipients, with evaluation after 3–6 months. The immunodeficient SCID or NOD/SCID mouse supports human hematopoiesis following intravenous injection of $2 \times 10^4 - 2 \times 10^5$ CD34+ cells, and quantitation of engraftment by measuring human CD45+ cells in the murine femoral BM at five weeks and beyond can be used under limiting dilution conditions to quantify human HSCs (SCID Repopulating Cells – SRCs) (reviewed in reference [55]). Human HSCs with long-term engraftment of NOD/SCID mice are in the CD38−, CD34+ fraction [56]. Mazurier et al. [57] identified a new class of human HSC by direct intrafemoral injection in NOD-SCID mice. This CD34+, $CD38^{low}$, CD36− HSC was termed a 'rapid SCID repopulating cell' (R-SRC), since it rapidly generate high levels of human myeloid and erythroid regeneration within the injected femur and migrates to the circulation and colonizes individual bones within two weeks of transplantation. While the presence of CD34 and the absence of CD38 provide reliable markers for human HSCs, murine HSCs are routinely isolated as c-Kit+, Sca-1+, lineage negative (Lin−) populations with additional features such as Hoechst dye exclusion. CD34+ is expressed on long-term repopulating HSC of the murine fetus and neonate but decreases with age so that HSC of 10-week-old mice are CD34− [58,59]. The observations clearly demonstrate that CD34 expression reflects the activation/kinetic state of HSC, and that expression is reversible. In the murine system, the majority of HSCs are CD38+, and there is a reciprocal relationship between CD34 and CD38 expression [58]. Cell surface receptors of the SLAM family are differentially expressed among functionally distinct HSC and progenitor populations of the mouse and HSC are CD150+, CD244−, CD48−, while multipotent progenitors are CD244+, CD150−, CD48− [60].

HSC numbers and proliferative status

It has been suggested that HSC numbers are conserved in mammals, with cats, mice and rats having comparable numbers (~11–12,000) [19,61]. If extrapolated to humans, the frequency of HSCs would be 0.7–1.5/10^8 marrow cells, a frequency that is 20-fold less than estimated by the NOD/SCID repopulating assay. Granulocyte telomere length measurements have been used to estimate human HSC kinetics, and the results showed that replication is infrequent, on average once every 45 weeks, substantially slower than the average rates estimated for mice (once per 2.5 weeks) or cats (once per 8.3–10 weeks) [62]. Catlin et al. [63] analyzed the changes in this ratio with age of maternal/paternal X-chromosome phenotypes in blood cells from females and concluded that human HSCs replicate on average once every 40 weeks (range 25–50 weeks). They also provide evidence that the human HSC pool increased from birth until adolescence and then plateaued, and that the ratio of contributing to quiescent HSCs in humans significantly differs from that in the mouse. Long-term HSCs (LT-HSCs) can fully reconstitute all the hematopoietic lineages of a lethally irradiated host for the life span of that host, and represent 1/10^4 to 1/10^5 cells in the BM [27,64]. In addition, these cells can be serially transplanted, although, for reasons that are unclear, repopulation capacity is entirely lost after four to five passages through irradiated hosts, even when telomere length is maintained by overexpression of telomerase.

LT-HSCs develop into short-term (ST)-HSCs that are capable of reconstituting all the lineages of the hematopoietic system, but have limited self-renewal capacity, providing 'short-term' reconstituting cells able to sustain clones of differentiating cells for only 4–6 weeks and not able to sustain serial repopulation (reviewed in reference [46]). The Shelterin component Pot1b plays an essential role in HSC survival [65]. Its deletion in mice, in the setting of telomerase haploinsufficiency, results in rapid telomere shortening and increased apoptosis, leading to fatal BM failure due to severe depletion of the HSC reserve [65]. Benzeniste et al. [66] identified a numerically dominant 'intermediate-term' multipotent HSC stage in mice, whose clones persist for 6–8 months before becoming extinct and that are separable from both short-term as well as permanently reconstituting 'long-term' HSCs. The authors proposed that the first step in HSC differentiation consists not in the loss of initial capacity for serial self-renewal divisions, but rather in the loss of mechanisms that stabilize self-renewing behavior throughout successive future HSC divisions.

HSC quiescence

Quiescence of HSCs is critical for sustaining the HSC pool over long periods, and protecting them by minimizing their accumulation of replication-associated mutations (reviewed in reference [67]). The balance between quiescence and proliferation is tightly controlled by both HSC-intrinsic and -extrinsic mechanisms. In recent years, a wide variety of positive and negative regulatory molecules or pathways critical for HSC quiescence regulation have been identified (reviewed in reference [67]). Although HSCs divide infrequently, it is thought that the entire HSC pool turns over every few weeks, suggesting that HSCs regularly enter and exit cell cycle (reviewed in reference [68]). Quiescent mouse HSCs are lin(−) Sca1+ c-Kit+ CD150+ CD48(−) CD34(−) and give rise to an active self-renewing CD34(+) HSC population [68]. Computational modeling suggests that quiescent murine HSCs divide about every 145 days, or five times per lifetime [68]. The quiescent HSC population contains the vast majority of multilineage long-term self-renewal activity that can be rapidly activated to self-renew in response to BM injury or G-CSF stimulation. After re-establishment of homeostasis, activated HSCs return to dormancy, suggesting that HSCs are not stochastically entering the cell cycle but reversibly switch from dormancy to self-renewal under conditions of hematopoietic stress [68]. Quiescent HSCs reside in individual niches that preserve their dormancy via signaling molecules such as thrombopoietin, angiopoietins, and stem cell factor (c-Kit Ligand). A series of intracellular regulatory molecules, including FoxOs, mTORC1, Fbw7, Egr1,

Pbx1, pRb, c-Cbl, Myc, and Bmi1 mediate the processes of HSC dormancy, cycling, self-renewal, differentiation and survival [68].

Deletion of Cited2, a transcriptional modulator involved in fetal liver hematopoiesis, resulted in increased HSC apoptosis, loss of quiescence, and increased cycling, leading to a severely impaired HSC reconstitution capacity [69]. Transcriptional profiling revealed that multiple HSC quiescence- and hypoxia-related genes such as Egr1, p57, and Hes1 were affected in Cited2-deficient HSCs. Because Cited2 is a negative regulator of HIF-1, which is essential for maintaining HSC quiescence, Cited2 and HIF-1α double knockout mice showed partial rescue of impaired HSC quiescence and reconstitution capacity [69]. At the transcriptional level, deletion of HIF-1α restored expression of p57 and Hes1 but not Egr1 to normal levels. Results suggest that Cited2 regulates HSC quiescence through both HIF-1-dependent and HIF-1-independent pathways [69]. Rho GTPase Cdc42 is a critical coordinator of HSC quiescence maintenance [70]. Cdc42$^{(-/-)}$ HSCs enter the active cell cycle, resulting in a significantly increased number and frequency of the stem/progenitor cells in the BM. Cdc42 deficiency also causes impaired adhesion, homing, lodging, and retention of HSCs, leading to massive egress of HSCs from the BM [70]. These effects are intrinsic to the HSCs, and are associated with defective actin organization and deregulated c-Myc, p21(Cip1), N-cadherin and beta1-integrin expression [70]. Vascular niche E-selectin in the vascular niche also regulates HSC self-renewal and chemoresistance [71].

The importance of the p53 protein in the cellular response to DNA damage is well known, but its function during steady state hematopoiesis is less clear. Liu et al. [72] have defined a critical role of p53 in regulating HSC quiescence, especially in promoting the enhanced quiescence seen in HSCs that lack the MEF/ELF4 transcription factor. Transcription profiling of HSCs isolated from wild-type and p53 null mice identified Gfi-1 and Necdin as p53 target genes of importance in regulating HSC quiescence [72]. Necdin, a growth-suppressing protein, functions as a molecular switch in adult hematopoiesis, acting in a p53-like manner to promote HSC quiescence in the steady state [73]. Necdin suppresses p53-dependent apoptosis in response to genotoxic stress via both cell-cycle-dependent and cell-cycle-independent mechanisms, with the latter occurring in a Gas2L3-dependent manner [73]. Necdin (Ndn) plays an important role in restricting excessive HSC proliferation during hematopoietic regeneration and is preferentially expressed in HSC by gene expression profiling [74]. Mice deficient in Necdin had no overt abnormality in steady state hematopoiesis but show accelerated recovery of the hematopoietic system after myelosuppressive injury [74]. These findings suggest that Necdin functions in a negative feedback loop that prevents excessive proliferation of HSCs during hematopoietic regeneration. The Mixed Lineage Leukemia (MLL) gene is a homolog of Drosophila Trithorax which is commonly rearranged in infant leukemia. It is essential for embryonic and adult HSC and progenitor development, with fatal BM failure occurring within three weeks of Mll deletion [75,76]. Mll plays a dual role within the hematopoietic system, maintaining quiescence in HSCs and promoting proliferation in progenitors. Mll-deficient cells fail to self-renew even in an intact BM environment and exhibit ectopic cell cycle entry, resulting in the depletion of quiescent HSCs [75,76]. Committed lymphoid and myeloid cells no longer require Mll, defining the early multipotent stages of hematopoiesis as Mll dependent.

BM regeneration critically depends on the release of soluble factors from cells such as stromal cells, a process regulated by proteases. Two proteolytic systems, the fibrinolytic system and the matrix metalloproteinases (MMPs), have recently been shown to be involved in this process [77]; reviewed in reference [78]. The plasminogen/plasmin system is mostly recognized for its fibrinolytic activity, but it is also involved in processes such as cell invasion, chemotaxis, growth factor activity modulation, and tissue remodeling (reviewed in reference [78]). Plasminogen (Plg), a classical fibrinolytic factor, is a key player in controlling the hematopoietic stress response (e.g., myelosuppression) [77,78]. Deletion of Plg in mice prevented HSCs from

entering the cell cycle and undergoing multilineage differentiation after myelosuppression, leading to the death of the mice. Activation of Plg by administration of tissue-type plasminogen activator promoted matrix metalloproteinase-mediated release of Kit ligand from stromal cells, thereby promoting HSC/HPC proliferation and differentiation (reviewed in reference [78]).

The expression of thioredoxin-interacting protein (TXNIP) is essential for maintaining HSC quiescence and the interaction between HSCs and the BM niche. It is decreased during HSC activation and in Txnip$^{(-/-)}$ mice, the long-term reconstituting HSC population is decreased and progressively exhausted and its capacity to repopulate is rapidly lost [79]. These effects are associated with stress-induced cell cycling, reduced p21 expression and hyperactive Wnt signaling. Txnip deficiency reduced the CXCL12- and osteopontin-mediated interaction between HSCs and the BM, and impaired homing and retention in the osteoblastic niche, resulting in mobilized HSCs [79].

Hypoxia signaling in HSC

Although HSCs are thought to reside in hypoxic niches, the significance of hypoxia signaling in HSCs is still under active investigation. In particular, the question of how chronic local hypoxia influences HSC fate and how the cells adapt to a low oxygen environment needs to be addressed. HSCs are distributed in the BM according to regional hypoxia and are predominantly located at the lowest end of an oxygen gradient, with the implication that regionally defined hypoxia plays a fundamental role in regulating their function [80,81]; reviewed in reference [82]. The slow-cycling/quiescence balance of HSCs is related to the physiological gradient of oxygen [83], and hypoxic *in vitro* conditions maintain the quiescent phenotype of mouse HSCs [81]. Culture of human CD34$^+$ cells at low O_2 concentrations ($O_2 < 3\%$) maintains stem cell engraftment potential better than at 20% O_2 (NOD/Scid xenograft model) [84]. Very low O_2 levels ($< 1\%$) induce CD34$^+$ quiescence but progenitors disappear from cultures. Hypoxia also induced hypophosphorylation of pRb and increased the expression of p27^{KIP1}, the two proteins that have a major role in the control of G_0 and G_1 to S-phase transition [84]. HSCs in the hypoxic niche have low concentrations of ROS, and these increase as proliferating and differentiating HSC move out of the niche. ROS is a DNA damage signal that leads to the activation of p53 (reviewed in reference [82]). MDM-2 is a RING finger E3 ligase that targets p53 for degradation, as well as represses the accumulation of p53 by binding to its N terminus, inhibiting its transcriptional activity (reviewed in reference [26]). Loss of MDM-2 activity leads to stabilized p53, which induces cell cycle arrest, senescence and ultimately cell death in HSCs and progenitors. This is a cell-intrinsic defect that is completely dependent on p53 and is alleviated by treatment with antioxidants, demonstrating the necessity of ROS to induce p53. HSCs express multiple isoforms of NADPH oxidase, and a positive feedback mechanism of NOXs activation enables fine tuning of the ROS levels and redox-mediated signaling involved in growth and differentiation of HSCs [85].

HIF-1a is an essential regulator of HSC quiescence and strict regulation of HIF-1a is pivotal for the long-term maintenance of HSCs [86,87]. Hypoxia regulates the metabolic state of HSCs and protects their integrity by controlling HIF-1a (an alpha subunit of HIF-1). Adult HSCs have elevated levels of HIF-1a and increased expression of hypoxia-inducible genes, including those controlling glycolysis [87]. As a consequence, HSCs adapt to the hypoxic microenvironment within stem cell niches by altering their metabolism. They utilize glycolysis with increased glucose consumption and lactate production instead of mitochondrial oxidative phosphorylation with decreased oxygen consumption compared to mature BM cells [87]. This metabolic balance promotes HSC maintenance by limiting the production of reactive oxygen species, but leaves HSCs susceptible to changes in redox status (reviewed in reference [88]). Delete of HIF-1a in HSC results in loss of quiescence, increased cell cycling rate and progressive loss of long-term repopulation capacity in serial transplantation assays [86]. Interestingly, although HIF-1a is critical for HSC maintenance under conditions of hematopoietic stress,

under physiological conditions HIF-1a-deficient HSCs sustain hematopoiesis for a prolonged period. The homeodomain protein Meis1, which is essential for hematopoiesis and markedly enriched in LT-HSCs, directly activates HIF-1a expression [87]. Meis1 regulates the metabolic phenotype and oxidant defense of HSCs [89]. Loss of Meis1 resulted in down-regulation of both Hif-1alpha and Hif-2alpha in HSCs. This resulted in a shift to mitochondrial metabolism, increased reactive oxygen species production, and apoptosis of HSCs.

The effect of Meis1 knockout on HSCs is entirely mediated through reactive oxygen species since treatment of the *Meis1* knockout mice with the scavenger N-acetylcystein restores HSC quiescence and rescues HSC function [89]. Von Hippel-Lindau (VHL) protein is an E3 ubiquitin ligase that mediates HIF-1a degradation, and its monoallelic deletion stabilized HIF-1a and increased the fraction of quiescent HSCs [86] resulting in their expansion in transplanted recipients. However, ablation of both alleles of VHL and overstabilization of HIF-1a enhanced the quiescence of HSCs, but resulted in loss of HSC activity upon transplantation [86]. Conditional deletion of Cited2, a negative regulator of HIF-1a mediated transcription, results in dramatic loss of HSCs [90]. A direct target gene of HIF-1, Foxo3a, is essential for the quiescent phenotype of HSCs [91]. In addition to genes regulating energy metabolism, HIF-1 controls transcription of more than 100 genes involved in multiple cellular processes including the cell cycle, differentiation, autophagy and survival, suggesting that hypoxia signaling may also be critical for HSC fates other than quiescence (reviewed in reference [92]). A central role for the Lkb1 (Stk11) metabolic sensor has been identified in restricting HSC entry into the cell cycle and in broadly maintaining energy homeostasis in hematopoietic cells through a novel metabolic checkpoint (reviewed in references [93–96]). Upon *Lkb1* ablation there was an immediate loss of HSC quiescence and increased HSC/multipotent progenitor cell proliferation [96]. The overall increase in progenitor numbers was transient and was followed by a progressive depletion of HSCs and eventual pancytopenia [96]. The effect of *Lkb1* deletion is cell autonomous, as mutant HSCs failed to rescue lethally irradiated recipients and were outcompeted by *Lkb1*-replete HSCs in competitive reconstitution assays. The metabolic profiles of $Lkb1^{-/-}$ HSCs displayed elevated fatty acid levels, suggesting LKB1 regulates additional aspects of cellular metabolism [95]. $Lkb^{-/-}$ HSCs displayed decreased AMP-activated protein kinase (AMPK) activity resulting from loss of AMPKα phosphorylation, with increase in phospho-S6 levels and mTORC1 activity. LKB1 regulates HSC quiescence through an AMPK–, mTORC1–, and FoxO–independent mechanism. Transcriptome analysis of $Lkb1^{-/-}$ HSCs revealed enrichment for genes involved in the PPARγ metabolic pathway, with downregulation of PPARγ coactivators *Pgc-1*α and *Pgc-1*β [94]. LKB1-deficient cells exhibited defects in mitosis, characterized by supernumerary centrosomes and aberrant mitotic spindles. These cells became aneuploid and underwent apoptosis in an AMPK-independent manner [96], suggesting that LKB1–mediated regulation of mitosis and genome stability account for HSC loss.

ONTOGENY OF HSCs

Yolk sac (YS) phase

The ontogeny of hematopoiesis has been studied extensively in mice and man and also in the xenopus and zebrafish. A number of recent reviews are available [97–100]. In the mouse, hematopoiesis is initiated in the visceral yolk sac (YS) with generation of a non-self-renewing progenitor with limited multilineage differentiation potential termed the erythromyeloid progenitor (EMP). These progenitors develop before definitive HSCs, and are the source of primitive erythroblasts, megakaryocytes, and macrophages, which emerge on embryonic day (E)7.0 [101,102]. The YS blood islands have long been recognized as the first site for blood cell emergence during embryonic development. Much of our understanding of how blood islands form is derived from studies conducted in chick embryos. Similar processes are thought to be active during murine blood island development. But, the strength of the evidence that the process of blood island formation in the chick coincides with that documented in the

mouse (reviewed in reference [103]). The onset of definitive hematopoiesis at E8.25 in the murine conceptus is marked by high-level CD41 co-expressed with CD31, CD34, and Flk1 in some intraluminal, round, hematopoietic cells that appeared to arise from flattened endothelial cells lining YS capillary vessels [104]. CD41 expression marks the onset of primitive and definitive hematopoiesis in the murine conceptus, and persists as a marker of some HSC and progenitor cell populations in the fetal liver and adult marrow, suggesting novel roles for this integrin. CD41 serves as the earliest marker of primitive erythroid progenitor cells at E7.0 in the YS and high-level expression identifies essentially all E8.25 YS definitive hematopoietic progenitors [104]. Some definitive hematopoietic progenitor cells in the fetal liver and BM also express CD41. HSC competitive repopulating ability is present in CD41(dim) and CD41(lo/−) cells isolated from BM and fetal liver cells, however, activity is enriched in the CD41(lo/−) cells [104]. Pure populations of primary endothelial cell monolayers isolated from E9.5 YS and P-Sp were cocultured with murine BM Sca-1+c-K-it+lin- cells for seven days resulting in a three- to 10-fold expansion of long-term (> 6 months) HSC with competitive repopulating ability [105].

Aorta-Gonad-Mesonephros (AGM) and onset on intra-embryonic hematopoiesis

The first mouse adult-repopulating (definitive) HSCs emerge in the aorta-gonad-mesonephros (AGM) region at E10.5. Their numbers in this region increase thereafter and begin to decline at E12.5, thus pointing to the possible existence of both positive and negative regulation of emerging HSCs (reviewed in reference [100]). At E8.5, expression of Runx1, a pivotal transcription factor required for HSC generation in the vascular regions of the mouse conceptus, is observed in hematopoietic and endothelial cells within the blood islands of the YS (reviewed in reference [100]). A strong lymphoid potential of the pre-circulation embryo proper suggests that definitive HSC precursors segregate *in situ* from the para-aortic-splanchnopleuric (P-Sp) mesoderm that precedes the appearance of the aorta hemogenic endothelium (reviewed in references [106,107]). Slightly later, Runx1 expression is seen in the endothelial cells and underlying mesenchymal cells of the ventral portion of the dorsal aorta and the endothelial cells of the vitelline and umbilical arteries and placenta (reviewed in reference [100]). With further maturation, Runx1 expression appears in the hematopoietic cells that closely adhere to these endothelial structures. Runx1 is also expressed at high levels in the hematopoietic cells that develop within the fetal liver, spleen and bone marrow in later stage embryos and adult animals.

Several lines of evidence suggest that definitive HSCs derive from the transitory subset of endothelial cells, termed hemogenic endothelium, that express VE-cadherin, a specific marker of endothelial lineage, and Runx1 [108]. In the mouse, lineage tracing of endothelium, via an inducible VE-cadherin Cre line, indicated an endothelial origin of HSCs in the AGM region [108]. These HSCs subsequently migrated to the fetal liver, and later, to the BM and were capable of expansion, self-renewal, and multilineage hematopoietic differentiation [108]. AGM mesenchyme, as selectively traced via a myocardin Cre line, was reported to be incapable of hematopoiesis.

It has been thought that HSCs emerge from vascular endothelial cells through the formation of intra-arterial clusters, and that Runx1 functions during the transition from 'hemogenic endothelium' to HSCs (reviewed in reference [97]). Boisset and Robin [98] reviewed their use of time-lapse confocal imaging and a new dissection procedure to visualize the dynamic *de novo* emergence of phenotypically defined HSCs (Sca1+, c-kit+, CD41+) emerging from murine ventral aortic hemogenic endothelial cells at E10.5 and budding directly into the lumen from the aortic wall. Compared to the zebrafish, hematopoietic cell emergence in the mouse aorta was rare, with just 1.7 events per cultured E10.5 embryo over the course of 15 hr (as opposed to three events/hr in zebrafish). Previous quantification of c-kit+ cells in the

dorsal aorta of mouse embryos has identified hundreds of these cells in small and larger clusters (reviewed in reference [97]). In the light of recent demonstrations that blood flow augments Runx1 expression and blood formation [109] (reviewed in reference [97]), the low number of events observed *ex vivo* may be due to the absence of flow in the culture system. Selective deletion of Runx1 in VE-cadherin+ cells resulted in the ablation of all hematopoietic progenitors including HSCs with a complete lack of development of fetal liver hematopoiesis [110]; reviewed in reference [97]. Haploinsufficiency of Runx1 results in a dramatic change in the temporal and spatial distribution of HSCs, leading to their early appearance in the AGM and also prematurely in the E10 YS [110]; reviewed in reference [100]. E10 Runx1+/− YS cells are fully potent HSCs that can be serially transplanted, and can repopulate all hematopoietic tissues and lineages of adult recipients. The appearance of abundant HSC activity in the YS may be explained if this site is capable of autonomous HSC generation, producing more HSCs under non-physiologic Runx1 concentrations. Alternatively the YS could be seeded prematurely by HSCs generated in the AGM region [110]. E9.5 P-Sp/AGM explant cultures fail to produce definitive HSCs [110], an observation that is not consistent with a role for the P-Sp/AGM region as a site for *de novo* HSC origin. The earliest definitive HSCs are also found in other vascular territories at similar frequencies and at the same time as in the AGM region. These observations imply that there exists an early anatomical source of definitive HCS that enter the P-Sp after E9.5. This source might be located in the visceral YS, as was first proposed by Moore in avian [111–114] and murine [113,115] studies (reviewed [116,336]). High levels of persistent adult marrow chimerism were first demonstrated, using sex chromosome markers, in marmosets and freemartin cattle (reviewed in reference [116]). In both species, synchorial twinning and embryonic interchange of blood are of frequent occurrence. In avian studies using fertile double yolk eggs or vascular parabiosis established between chick embryos at of opposite sex at day 6–10 of development, Moore and Owen [111,113,114] undertook a cytogenetic analysis of primary lymphoid organs (thymus, bursa of Fabricius) and the hematopoietic organs (spleen and bone marrow) at intervals up to the time of hatching. This revealed extensive chimerism, with approximately equal proportions of male and female metaphases, indicating that these organs were all colonized by circulating HSC/HPCs that equilibrated between the embryos. The YS was proposed as the unique initial source of the HSCs that colonized the developing lymphohematopoietic organs and persisted through hatching and into adult life [114]. Moore and Metcalf [115] used whole E7–7.5 mouse conceptus cultures to monitor *in vitro* the transition between YS hematopoiesis and onset of intra-embryonic hematopoiesis over a period of 3–4 days. When embryos were cultured after removal of the developing YS, intra-embryonic hematopoiesis was not initiated, and neither CFU-S nor CFC was detected. In contrast, a culture of YS in the absence of the embryo resulted in robust hematopoiesis with CFU-S and CFC production and expansion. Subsequent studies concluded that, in addition to its well-known role in the establishment of 'primitive' hematopoiesis, the visceral YS served as an independent source of some 'definitive' hematopoietic stem/progenitor cells but not adult-type HSCs as defined by ability to repopulate adult, irradiated mice [117,118]. Cell-transplantation studies [119,118] have shown that YS precursor cells contribute to adult hematopoiesis. Yoshimoto et al. [120] showed the existence of T cell-restricted progenitors in the E9.5 YS that directly engraft in recipient immunodeficient mice. T cell progenitors were also produced *in vitro* from both YS and para-aortic splanchnopleura hemogenic endothelial cells, and these T cell progenitors repopulated the thymus and differentiated into mature T cell subsets *in vivo* on transplantation [120].

Cell tracing experiments have reported direct cell-lineage relationship between the YS precursor cells and adult hematopoiesis [121]. YS cells expressing Runx1 at embryonic day 7.5 developed into fetal lymphoid progenitors and adult HSCs. During midgestation (E7.5) the labeled YS cells colonized the umbilical cord, the AGM region and subsequently the embryonic liver. This indicated that at least some HSCs associated with major embryonic vasculature are derived from YS precursors. In more recent studies by this group to address the

issue of ultimate origin of HSCs, Tanaka et al. [122] designed an embryo rescue system in which the key hematopoietic factor Runx1 is reactivated in Runx1-null conceptuses at specific developmental stages. These investigators concluded that specification of the HSC lineage takes place early in ontogenesis, immediately after the start of gastrulation. The demonstration of this VE-cadherin+ definitive hematopoietic precursor in the proximal YS is consistent with a close ontogenic relationship between extra-embryonic hemogenic endothelium and hemangioblasts or nascent lateral mesoderm as a major source of the HSC precursors [122–124]. These findings must be compared with data on avian hematopoietic ontogenesis [125]; reviewed in reference [106]. The histogenesis of the bursa of Fabricius and of bone marrow was studied by a biological cell marking technique based on differences in the nuclear structure of two species of birds; the Japanese quail and chick [126]. By grafting bursal rudiments and limb buds of the quail into the chick, and the reverse, it was possible to demonstrate that the whole hematopoietic population of the bursa of Fabricius and of the BM was derived from blood-borne extrinsic stem cells. It remains to be determined whether mammalian and avian *de novo* hematopoiesis differ significantly, or whether a closer look at the presumed sites of blood cell generation in chickens would reveal a more prominent role for the avian YS [127], as first suggested by Moore and Owen [111,113,114]. An alternative concept, based on analysis of morphologically distinct chick/quail hybrids, relegated the YS to be a transient source of hematopoiesis of no relevance to subsequent *de novo* emergence of HSCs in the AGM region of the embryo [126,128,129]; reviewed in reference [100]. Specifically, HSC appeared to arise by budding from the floor of the dorsal aorta and other major arterial regions of the mouse embryo (reviewed in reference [97]).

It has been proposed that during embryonic development hematopoietic cells arise from a mesodermal progenitor with both endothelial and hematopoietic potential called the hemangioblast [130,131]; reviewed in reference [106]. An alternative theory is that hematopoietic cells originate from a specific type of endothelium designated as hemogenic. Indeed, transient, time-specific, hemogenesis arising at the floor of the aortic endothelium is prominent in embryos of many vertebrate species. Support for the hemangioblast concept was initially provided by the identification, during mouse embryonic stem cell differentiation to the blast colony-forming cell (BL-CFC) stage, of the development of blast colonies with both endothelial and hematopoietic components [130]. A VEGF-R2-positive progenitor, capable of differentiating into either endothelial or hematopoietic cells, depending on the growth factors in the culture medium, can indeed be isolated from the caudal mesoderm of the gastrulating avian embryo [133], or gastrulating mouse embryo [134]. Lancrin et al. [124] demonstrated that the hemangioblast, likely of mesenchymal or mesodermal origin, generates hematopoietic cells through the formation of a hemogenic endothelium intermediate. At the molecular level, the transcription factor Tal1 (also known as Scl) is indispensable for the establishment of this hemogenic endothelium and the upregulation of c-Kit and Tie2, whereas the core binding factor Runx1 (also known as AML1) is critical for generation of definitive hematopoietic cells from hemogenic endothelium characterized by CD41 expression and Tie2 downregulation [124]. It would appear that development of HSCs from an aortic hemangioblast (although this cell so far has proven elusive) must occur in a linear fashion that involves an endothelial intermediate, similar to what was recently reported for embryonic stem (ES) cell-derived blood cells [124,133]. Three-dimensional whole embryo immunostaining and live-imaging techniques have allowed quantitation and cartographic mapping of intravascular hematopoietic cell clusters developing in association with the midgestation mouse aorta, umbilical and vitelline arteries [135]. The data indicate that definitive HSCs and early progenitors (visualized as clusters) are generated from hemogenic endothelium. By continuous, long-term, single-cell observation of mouse mesodermal cells generating endothelial cell and blood colonies, it was possible to detect hemogenic endothelial cells giving rise to blood cells [133]. Living endothelial and hematopoietic cells were identified by simultaneous detection of morphology and multiple molecular and functional markers. Detachment of nascent blood cells from endothelium was not directly linked to asymmetric cell division, and hemogenic

endothelial cells were specified from cells already expressing endothelial markers [133]. Although some authors have presented evidence that HSCs may arise directly from the aortic floor into the dorsal aortic lumen, others support the notion that HSCs first emerge within the underlying mesenchyme (reviewed in reference [101]).

Zebrafish have been used to determine the function of a gene during embryonic-to-adult transition of hematopoiesis, since bloodless zebrafish embryos can develop normally into the early larval stage by obtaining oxygen through diffusion (reviewed in references [136,137]). Runx1 truncation mutant zebrafish embryos developed CD41+ HSCs in the AGM region, which later migrated to the kidney, the site of adult hematopoiesis, suggesting that in zebrafish adult HSCs can be formed in the absence of a functioning Runx1 [136]. The zebrafish embryo can be imaged directly using combinations of fluorescent reporter transgenes, confocal time-lapse microscopy and flow cytometry. This method was used to demonstrate aortic hemogenic endothelium in the ventral wall of the dorsal aorta transitioning to nascent HSCs [101,102]. These authors also used a permanent lineage tracing strategy to demonstrate that the HSCs generated from hemogenic endothelium are the lineal founders of the adult hematopoietic system, forming a large majority of kidney marrow cells in adult zebrafish, consistent with what was previously demonstrated in mouse (reviewed in references [97,108,137,138]). Kissa and Herbomel [139] showed by non-invasive, high-resolution imaging of live zebrafish embryos that HSCs emerge directly from the aortic floor, through a stereotyped process that does not involve cell division but a strong bending process involving a single endothelial cell on the floor of the dorsal aorta that is polarized not only in the dorso-ventral but also in the rostro-caudal versus medio-lateral direction, and depends on Runx1 expression. This single endothelial cell then egresses from the aortic ventral wall into the sub-aortic space, assumes a rounded morphology and transforms into a hematopoietic cell, apparently without a cell division. This new type of cell behavior was termed 'endothelial hematopoietic transition' [139]. These nascent hematopoietic cells transiently occupy the sub-aortic space and then migrate to and subsequently enter the caudal vein, and then migrate to and colonize the kidney, which is a hematopoietic site in zebrafish. Lam et al. [140] used time-lapse microscopy of Runx1-enhanced GFP transgenic zebrafish embryos to capture a subset of cells within the ventral endothelium of the dorsal aorta as they acquire hemogenic properties and directly emerge as presumptive HSCs. Cell tracing showed that these cells enter the circulation via the caudal vein and subsequently populate the sites of definitive hematopoiesis (thymus and kidney), consistent with an HSC identity [140].

In parallel to the AGM region, a number of intra and extra-embryonic sites in the E10.5–E11.5 mouse harbor definitive HSCs, as defined by long-term, high-level, multilineage reconstitution and self-renewal capacity in adult recipients. The murine placenta contains a large population of HSCs during midgestation within the vascular labyrinth region [129,141,142]. Tracking developing HSCs via their expression of Runx1-lacZ and CD41 revealed that they emerge in large vessels in the placenta and appear as early there as they do in the AGM region and before any HSCs had colonized the liver or were circulating in the blood. The placental HSC pool continues to expand until E12.5–E13.5, ultimately containing 15 times more HSCs than the AGM. As the placental HSC population declines, the liver HSC pool expands, suggesting that the placenta may be a major source of the HSCs that seed the liver [142]. However, these studies did not determine whether the placenta is capable of producing HSCs *de novo* or whether it functions solely as a niche for the maturation and expansion of HSCs originating from other sites. Once a heartbeat is initiated at E8.5, any cell within the vasculature may be released into circulation. Although free distribution of progenitors is delayed until E10.5 [118], adult repopulating HSCs are found only after this time, and may therefore have circulated. The emergence of HSCs in the placental vasculature was reported to occur in the absence of a circulation [143].

Probing the hematopoietic potential of cells from different anatomic locations in mammalian conceptuses has led to conflicting views on blood origin (reviewed in

reference [100]). Other vascular regions of the conceptus, such as the umbilical and vitelline arteries and the vascular labyrinth region of placenta, also harbor the earliest HSCs (reviewed in references [97,141]) although their role in the generation of these stem cells is less clear. Earlier studies on quail-chick chimeras showed that the avian allantois is a source of definitive hematopoietic cells [144]. Recently, the hematopoietic potential of the mouse chorionic and allantoic mesoderm was assessed by *in vitro* culture of the tissues explants that were harvested prior to chorioallantoic fusion and circulation [129,145]. Strikingly, these studies documented myeloerythroid hematopoietic potential in both the allantoic and chorionic mesoderm, supporting the hypothesis that HSCs may be generated in the placenta. Yet, these studies did not define lymphoid potential of the rudiments. Of note, one study in 1979 described B lymphoid potential in the midgestation placenta, however, the origin of these cells was not defined [146]. Hematopoiesis is also initiated in the midgestation E10.5—E11.5 mouse head, as indicated by the appearance of intravascular cluster cells and the blood-forming capacity of a sorted endothelial cell population preceding the entry of HSCs into the circulation [147]. A spatially restricted VE-cadherin-Cre lineage labeling system revealed a physiological contribution of cerebrovascular endothelium to postnatal HSCs and multilineage hematopoiesis [147].

To define the sites of origin of the HSC, it has been necessary to develop methods to circumvent the onset of blood cell redistribution via the circulation. Two novel model systems have been utilized to address the problem. The first method involves the use of the VE-cadherin$^{-/-}$ embryo lacking proper development of vasculature [148]. While the heart does beat in these embryos, the lack of interconnection between the embryo and the yolk sac via the vitelloembryonic stalk prevents the mixture of cells. The number of primitive erythrocytes present in the VE-cadherin$^{-/-}$ YS was not significantly different from wild-type. The presence of multipotent hematopoietic stem/progenitors in the YS in the absence of a contribution of cells from the embryo suggested the YS as their site of origin. These results were validated by lineage-specific gene expression analysis [148]. There was no evidence of lymphoid potential through E10.5 in this model system. An alternative approach is to leave the vascular network intact, but block the initiation of the fetal heartbeat. Ncx1 is a sodium calcium exchanger initially expressed exclusively in the fetal heart that facilitates cardiac muscle fiber contraction. When the Ncx1 gene was disrupted by targeted gene knockout, the resultant phenotype of homozygous mutant offspring was found to be unchanged until day 8.25 at which time the heart failed to commence beating, a phenotype which is ultimately fatal [118]. As Ncx1 is not expressed in cells thought to contribute to hematopoietic development, the mutant phenotype should only effect cellular distribution via the circulation. At E9.5, Ncx1$^{-/-}$ embryos had an intact vascular system, both *intra-* and *extra*-embryonically, in contrast to E9 wild-type embryos that had vessels full of primitive erythrocytes [118]. Cross sections of the E9.25 mutant embryo proper revealed an intact vasculature devoid of luminal blood cells. Plating of cells in blood colony-forming assays revealed the presence of both primitive and definitive progenitor lineages in the YS of the Ncx1 mutant, but both were nearly absent in the embryo proper [118]. The total number of hematopoietic progenitors in the conceptus was not significantly altered, suggesting that cells that would typically be distributed to the embryo proper by the circulation remained in the YS.

These results support a model in which both the mammalian primitive as well as the definitive hematopoietic progenitor cells originate entirely in extra-embryonic tissues and it is this population of myeloerythroid progenitor cells that first seeds the fetal liver [118]. A caveat to conclusions based on either the Ncx1$^{-/-}$ or VE-cadherin$^{-/-}$ model is that HSCs (or possibly hemogenic endothelium or hemangioblasts) may migrate considerable a distance outside the vasculature, as was shown in zebrafish where CD41+, cmyb+ hematopoietic precursors colonize the pronephros by a novel extravascular migration route along the pronephric tubules to initiate adult hematopoiesis in the developing kidney, the teleostean equivalent of mammalian BM [1]. In this context, during early embryogenesis in mice,

primordial germ cells (PGCs) arise in an extra-embryonic region near the YS, at E7–7.25. They then migrate to the endodermal epithelium of the hindgut as embryogenesis advances, and then separate from the gut epithelium to enter the dorsal mesentery, through which they finally migrate to form the gonadal anlage at E10.5 [150]. The PGCs move actively by amoeboid movements to transit their migratory pathway in response to attraction by chemotactic factors, substrate-guidance, and interaction with extracellular matrix molecules. This migration occurs over the same time period as the development of HSCs in the YS and establishment of definitive hematopoiesis in the AGM region at E10.5. In marked difference from the mammalian model, in birds, PGCs use the anterior vitelline veins to enter the embryonic circulation and migrate to the gonadal ridges. In both avian and murine systems, migration is driven by the CXCR4/CXCL12 gradient [150].

Analysis of the hematopoietic potential in extra-embryonic and intra-embryonic tissues in *Ncx1* mutant embryos verified myeloid and lymphoid potential not only in the AGM and the placenta but also the YS, suggesting that all three sites may independently generate HSCs [143]. These data, combined with evidence from literature [117,118,151,152], support a model of at least three waves of hematopoiesis during embryogenesis. The first, primitive wave, occurs in the YS, and generates a burst of primitive erythroid cells. The second wave involves production of transient definitive progenitors and is initiated in the YS, after which the progenitors circulate into the liver and give rise to definitive erythroid and myeloid cells that are the first mature blood cells released by the liver. The third wave, formation of HSCs, occurs in the large arteries, but is not only confined to the AGM but most likely also occurs within the umbilical and vitelline arteries, the placenta and the YS. These programs are regulated in part by different mechanisms since Notch1 signaling is not required for generation of the primitive or the transient definitive progenitors in the YS, but it is essential for formation of HSCs in the P-Sp/AGM [151]. Yoshimoto et al. [153] used the $Ncx1^{(-/-)}$ mice to demonstrate that the E9 YS and the intra-embryonic P-Sp tissues independently give rise to AA4.1(+)CD19(+)B220 (lo-neg) B progenitor cells that preferentially differentiate into innate type B-1 and marginal zone (MZ) B cells but not into B-2 cells upon transplantation. They further demonstrated that these B-1 progenitor cells arise directly from YS and P-Sp hemogenic endothelium. These results document an initial wave of innate B lymphopoietic progenitor cells available for seeding the fetal liver at E11. The results of these studies expand understanding of hemogenic endothelial sites specifying distinct B-1 and MZ cell fates apart from B-2 cells and independent of an HSC origin during development. Analysis of $Ncx1^{(-/-)}$ embryos, verified that HSC development is initiated in the placental vasculature independent of blood flow [142]. However, fewer CD41+ hematopoietic cells were found in $Ncx1^{(-/-)}$ placentas than in controls, implying that some HSCs/progenitors colonize the placenta via circulation and/or HSC emergence is compromised without blood flow [142]. Interestingly, the $\mathbf{Ncx1}^{-/-}$ placentas frequently displayed large aggregates of CD31+ cells that were protruding into the lumen, possibly precursors to definitive hematopoietic cells that were stalled during their emergence into the vascular lumen. Indeed, the CD31+ aggregates consist of round cells that are morphologically similar to hematopoietic cells, and cells in one of the clusters in the umbilical cord also expressed CD41+. As these aggregates were not found in the controls, it is likely that they form due to lack of developmental signals normally conveyed by blood flow [142]. Alternatively, they may represent endothelial cells that are unable to organize properly in the absence of blood flow. Mechanical forces created by circulation promote a response through mechanosensory receptor complexes in the endothelial cells to release angiogenic factors, such as VEGF [154,155], which are also essential for hematopoiesis. Therefore the absence of blood flow may impair both vasculogenesis and hematopoiesis. Of note, newly formed HSCs are not equivalent to adult HSCs, as they require a maturation process before they can engraft into adult BM and self-renew (reviewed in references [104,105,118,120,153,156]). Furthermore, in contrast to relatively quiescent adult HSCs, fetal HSCs are highly proliferative as they expand to establish a supply of HSCs for adult life [8,157,158].

Human hematopoietic ontogeny

Hematopoiesis in the human conceptus progresses similarly to that in the mouse conceptus; in a wave-like manner in several different embryonic sites in a sequence of hematopoietic migratory events. Blood generation begins at day 16 of development in the YS with the production of primitive erythroid cells. At day 19, the intra-embryonic splanchnopleura becomes hematopoietic. The emergence of multipotent progenitors and HSCs, organized in clusters of cells closely adherent to the ventral wall of the dorsal aorta, starts at day 27 in the developing splanchnopleura/AGM region. Starting at day 30, the first erythroid progenitors (BFU-E, burst forming unit-erythroid) are found in the liver, with multilineage hematopoietic progenitors (CFU-Mix or -GEMM; colony-forming unit-granulocyte, erythroid, macrophage, megakaryocyte) appearing in this tissue at week 13. The human placenta contains fetal-derived immature hematopoietic progenitors and HSCs from gestation week 6 onwards, and these differentially express CD34 through ontogeny [143,159]. Furthermore, pericyte-like mesenchymal stromal cells, isolated from human placenta throughout development, can support the *in vitro* maintenance of human cord blood hematopoietic progenitors [143]. Also, in cultures supporting osteogenic differentiation, placenta mesenchymal lines (second trimester and term) were positive for alkaline phosphatase and mineralization, and most cell lines also could be differentiated into adipocytes. This placenta mesenchyme also possessed endothelial potential, forming endothelial tubules in Matrigel [160]. Thus, the human placental cell lines have the same mesenchymal potential as reported previously in hematopoietic supportive AGM [161]. Robin et al. [160] showed, over a range of developmental times including term, that the human placenta contains hematopoietic progenitors and HSCs. Moreover, stromal cell lines generated from human placenta at several developmental time points are pericyte-like cells and support human hematopoiesis. Immunostaining of placenta sections during development localizes hematopoietic cells in close contact with pericytes/perivascular cells [160]. Thus, the human placenta is a potent hematopoietic niche throughout development.

Mammalian fetal liver

Johnson and Moore [162] first demonstrated the migration of HSCs from the YS and p-Sp region to the fetal liver. At E12, HSC were first detected in the murine liver (50 HSC repopulating units per liver) [163]. The number of HSC per liver increased 10-fold and 33-fold by day 14 and day 16 of gestation, and decreased thereafter, suggesting a single wave of HSC development in the fetal liver. Robin et al. [164] performed a complete *in vivo* transplantation analysis with YS, aorta, placenta, and fetal liver cells, sorted based on CD41 expression level. The data show that the earliest emerging HSCs in the aorta express CD41 in a time-dependent manner. In contrast, placenta and liver HSCs are CD41-negative. Thus, differential and temporal expression of CD41 by HSCs in the distinct hematopoietic territories suggests a developmental/dynamic regulation of this marker throughout development.

Zeb2 (Sip1/Zfhx1b) is a member of the zinc finger E-box-binding (ZEB) family of transcriptional repressors that regulate epithelial-to-mesenchymal transition processes during embryogenesis and tumor progression and high Zeb2 mRNA expression levels were reported in HSCs [165]. Conditional deletion of Zeb2 showed it to be dispensable for hematopoietic cluster and HSC formation in the AGM region but is essential for normal HSC/HPC differentiation [165]. In addition, Zeb2-deficient HSCs fail to properly colonize the fetal liver and/orBM.

Ghiaur et al. [166] studied the role of the Rho GTPases Rac1 in HSC migration during ontogeny and seeding of fetal liver. Using a triple-transgenic approach, they deleted Rac1 in HSC during very early embryonic development and showed a decrease in circulating HSCs in the blood of E10.5 embryos, while YS definitive hematopoiesis was quantitatively normal. Intra-embryonic hematopoiesis was significantly impaired in Rac1-deficient embryos, with absence of intra-aortic clusters and fetal liver hematopoiesis. These data suggest that Rac1 plays

an important role in HSC migration during embryonic development and is essential for the emergence of intra-embryonic hepatic hematopoiesis.

Late fetal/neonatal hematopoiesis

Lin28b is specifically expressed in mouse and human fetal liver and thymus, but not in adult BM or thymus. Ectopic expression of Lin28 reprograms HSCs from adult BM, endowing them with the ability to mediate multilineage reconstitution that resembles fetal lymphopoiesis, including increased development of B-1a, marginal zone B, gamma/delta (γδ) T cells, and natural killer T (NKT) cells [167].

The Sox17 transcriptional regulator is specifically expressed in fetal and neonatal but not adult HSCs and is required for the maintenance of fetal hematopoiesis, thus distinguishing fetal/neonatal HSC transcriptional regulation from that of adult HSCs [157]. Germline deletion of Sox17 led to severe fetal hematopoietic defects, including a lack of detectable definitive HSCs. Conditional deletion of Sox17 from hematopoietic cells led to the loss of fetal and neonatal but not adult HSCs [157]. HSCs stopped expressing Sox17 approximately four weeks after birth. During this transition, loss of Sox17 expression correlated with slower proliferation and the acquisition of an adult phenotype by individual HSCs [157].

MIGRATION, MOBILIZATION AND HOMING OF HSC

Bone marrow (BM) homing of HSCs

Large numbers of HSC move into and out of the circulation on a daily basis. Homing of HSC to the BM is rapid (hours) involving cells traversing across the BM sinusoidal endothelium that presents adhesion molecules and chemokines facilitating the process (reviewed in reference [168]). These circulating HSCs develop low affinity contacts with cell adhesion molecules E- and P-selectin on the endothelium in a process called 'rolling' that precedes firm adhesion via ICAM-1 and VECAM-1 (reviewed in reference [169]). Upon egress from the vasculature, HSC reside in, or adjacent to, specialized microenvironments in the BM. The endothelial or (peri)vascular niche is adjacent to BM endothelial sinuses and its perivascular stromal cells produce the HSC chemo-attractant CXCL12 while the endothelium provides the HSC survival and proliferation-inducing factor c-Kit ligand/SCF (Figs. 47.3, 47.4). The seeding efficiency of HSC to the BM as determined by secondary passaging has generally been accepted as 10—20% by 24 hours. However, Benveniste et al. [170] using competitive repopulation and tracking of a single purified HSC in mice concluded that HSCs engraft with near absolute efficiency. This view has been challenged by Camargo et al. [171], who reported that individual HSC (SP cells) could only engraft one in three mice. The transition from quiescence to active cell cycling of HSC was associated with significant loss of engraftment potential [172] that was not associated with loss of expression of the integrins VLA-4, VLA-5 or the chemokine receptor CXCR4.

The SDF-1/CXCR4 chemokine pathway in HSC homing and migration

The chemokine SDF-1 (CXCL12) is expressed on BM vascular endothelium, immature osteoblasts in the endosteal region and marrow stromal cells, while its receptor, CXCR4, is expressed on HSC and progenitors (Figs. 47.2, 47.3). The SDF-1/CXCR4 pathway plays a major role in regulating the mobilization, migration and retention of HSCs (reviewed in reference [168,173]). This chemokine pathway is essential for HSC seeding from the fetal liver to the BM during development, however, CXCR4 deficient HSCs can, with reduced efficiency, engraft adult irradiated mice [174]. Elevation of plasma levels of SDF-1 occurs following intravenous injection of an adenovector expressing SDF-1, and the consequent reversal of the SDF-1 gradient from blood to marrow leads to the mobilization of HSCs and progenitors [175]. Overexpression of CXCR4 on human CD34+ cells by gene transfer increased their proliferation, migration and NOD/SCID engraftment potential (reviewed in reference [168]). CXCR4 neutralization abolished human intravenous or intrafemoral CD34+ engraftment in

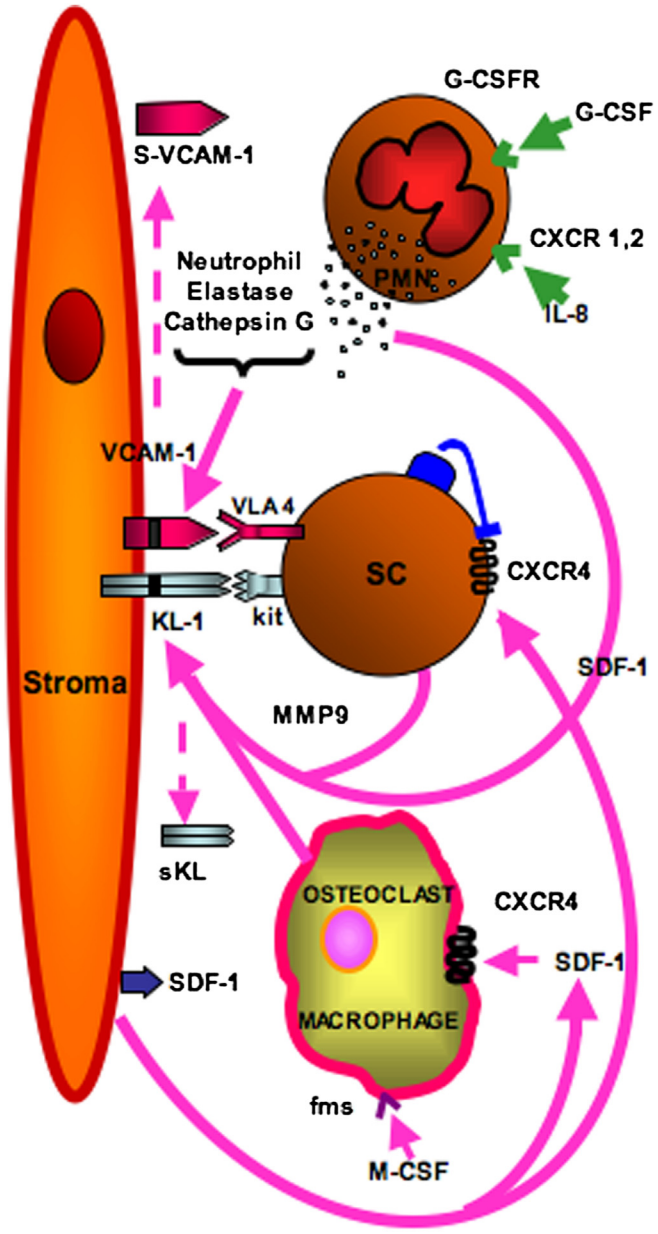

FIGURE 47.3
Model illustrating HSC adherence to bone marrow stromal cells via VLA4 binding to VCAM-1 and c-Kit binding transmembrane c-Kit ligand (KL-1). SDF-1 produced by the stroma induces matrix metalloproteinase-9 (MMP9) production by HSC and macrophages and this in turn cleaves the transmembrane KL-1, releasing soluble active ligand (sKL). The HSC mobilizing role of G-CSF is explained in part by increased numbers and activation of neutrophils within the bone marrow with secretion of a number of proteases (elastase, cathepsin G) that cleave VCAM-1 and 'untether' HSC. Protease activity is also implicated in cleavage and inactivation of SDF-1. HSC express the membrane-bound ectopeptidase CD26 that removes dipeptides from the amino-terminus of proteins and acts as a negative regulator of the SDF-1-CXCR4 axis.

NOD/SCID mice, indicating the essential role of this receptor in BM seeding and colonization, as well as in homing (reviewed in reference [168]).

The adhesion receptor CD44 and its major ligand, hyaluronic acid, are essential for HSC homing to BM and spleen. HSCs express CD44 and migrate on hyaluronic acid towards a gradient of SDF-1, acquiring a polarized morphology with CD44 concentrated at the leading edge of pseudopodia [176]. Since hyaluronic acid is expressed on both BM endothelium and endosteum, it is likely that CD44 plays a key role in SDF-1-mediated trans-endothelial migration and localization in specific BM niches.

HSC mobilization

Beginning in the mid 1980s, autologous peripheral blood was used for transplantation, particularly after chemotherapy at the rebound in hematopoietic regeneration. The availability of two hematopoietic growth factors, G-CSF and GM-CSF, in recombinant form, led to their use

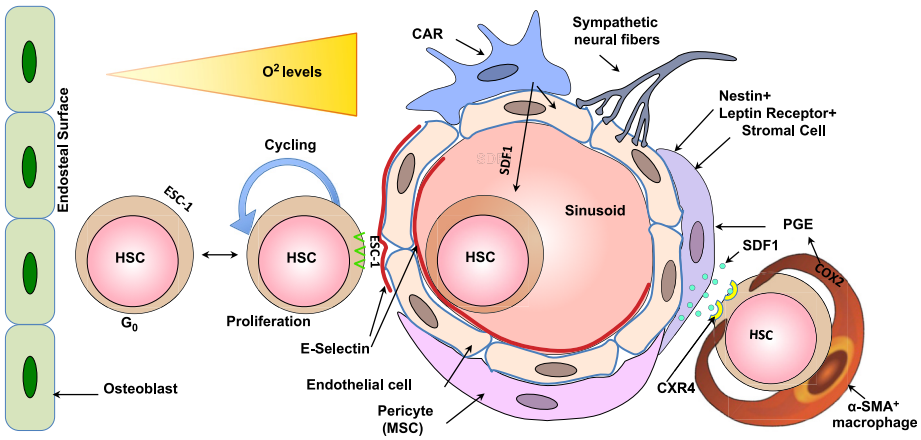

FIGURE 47.4

Hematopoietic stem cells in the bone marrow vascular niche. The endothelial sinusoid is surrounded by mesenchymal stromal cells (MSCs) identified as pericytes, and a subpopulation that can be further identified by expression of Nestin and/or Leptin receptors. CAR cells are MSCs characterized by high expression of the chemokine CXCL12 that is a chemo-attractant for CXCR4-expressing hematopoietic stem cells (HSCs). Sympathetic neural fibers also connect with the niche and may provide negative proliferative signals [184]. E-selectin is expressed exclusively on the endothelial cells of the niche and can bind HSCs expressing an appropriate ligand. ESC-1 is shown here as a candidate ligand that is binding to E-selectin is required for circulating HSC to attach and roll on the sinusoidal endothelium prior to their firm attachment and egress. In addition, the attachment induces HSC proliferation, self-renewal and chemo- and radio-sensitivity [71]. HSC close to the bone endosteal surface are in a hypoxic environment and are in a quiescent state. The extent of migration of these quiescent HSC into the proliferation-inducing environment of the E-selectin-expressing vasculature niche is dependent on demand for production of mature blood cells. Macrophages express α-smooth muscle actin are shown preserving HSCs in the BM adjacent to sinusoids [292].

as HSC and progenitor mobilizing agents [177]. G-CSF treatment for mobilization of HSC, peaking at 5–6 days, is currently the most efficient strategy for clinical HSC collection. A number of chemokines (IL-8, MCP-1, MIP-1α, Groβ, SDF-1) also induce rapid HSC mobilization in murine models with peak HSC and progenitor mobilization in a few hours, in contrast to the days required with CSF's [79,175,178]. Movement of HSCs between endosteal, perivascular and intravascular sites is influenced by G-CSF activation of marrow neutrophils with resulting protease release and cleavage and inactivation of SDF-1 (Fig. 47.3). One mechanism proposed to explain the ability of G-CSF treatment to mobilize HSCs involves a reported reduction in SDF-1, possibly due to degradation by neutrophil protease activity and an increase in its receptor CXCR4 in the bone marrow [177]. Activated neutrophils release matrix metalloproteinase 9 (MMP-9) and lactoferrin from specific granules, and neutrophil elastase, cathepsin G and proteinase 3 from azurophilic granules (Fig. 47.3) (reviewed in reference [179]). The release of multiple proteases within the BM can lead to cleavage or degradation of vascular cell adhesion molecule 1 (VCAM-1), membrane-bound c-Kit Ligand (KL), SDF-1(CXCL12) and its receptor CXCR4 – all events that can 'untether' HSC's from their niches and facilitate their proliferation, differentiation and mobilization (Fig. 47.3) [180]. Studies in genetic models of protease deficiency, including models with multiple prostease deficiencies, surprisingly did not show impaired G-CSF-induced HSC mobilization (reviewed in reference [179]). Thus, the contribution of a single protease to mobilization may not be critical, but multiple proteases acting in a cell-context-specific manner appear important. Targeting and reduction of SDF-1, or its receptor, may be common denominators of proteases implicated in HSC mobilization. HSCs express the membrane-bound ectopeptidase CD26 that removes dipeptides from the amino-terminus of proteins and CD26 null mice have an attenuated response to G-CSF [181].

CD26 expression on HSCs negatively regulated their homing and engraftment, and by inhibiting or deleting CD26 it was possible to greatly increase the efficiency of engraftment [181]. CD26 expression may regulate HSC engraftment potential by inactivating SDF-1 produced by marrow stroma. CXCR4 antagonists such as AMD3100 have also been shown to be

effective in mobilized HSCs with long-term repopulating capacity in mice [182], humans and non-human primates [183]. Signals from the sympathetic nervous system also regulate HSC egress from bone marrow [184]. Pharmacologic or genetic ablation of adrenergic neurotransmission resulted in failure of HSC and progenitors to egress the marrow following G-CSF stimulation while a β2 adrenergic agonist enhanced HSC mobilization in both control and norepinephrine-deficient mice [184]. Kollet et al. [168,178] have linked bone remodeling with regulation of stress-induced mobilization of HSC and progenitor cells. They showed that an increase in osteoclast numbers is associated with mobilization. RANK ligand (RANKL) is a member of the TNF family of cytokines that is necessary for the production of osteoclasts. It is a product of osteoblasts and is responsible for the balance between bone production and destruction in skeletal remodeling [178]. RANKL altered osteoclast expression of MMP-9 and cathepsin K, which cleaved membrane-bound KL resulting in decreased osteoblast KL and the production of osteopontin [168,178]. Inhibition of osteoclasts with calcitonin reduced G-CSF stem/progenitor mobilization. Mice deficient in the protein tyrosine phosphatase-ε (PTP-ε) have dysfunctional osteoclasts and HSC in these mice did not mobilize upon treatment with either RANKL or G-CSF [178].

Grassinger et al. [185] analyzed the proportion and number of murine HSC in the endosteal and central bone marrow regions after four days of G-CSF administration. They demonstrated that the number of HSCs, defined as CD150+CD48- LSK cells, increased within the central BM region in response to G-CSF, but not within the endosteal BM region. This study provided evidence that HSC in the BM respond differently to G-CSF and this is dependent on their location [185]. These findings may lead to development of new agents to specifically mobilize HSC from the endosteal BM region-an HSC population with significantly greater hematopoietic potential compared to their phenotypically identical counterparts located in other regions of the BM [185].

The Rho guanosine triphosphatases, Rac1 and Rac2, play distinct roles in actin organization, hematopoietic cell survival and proliferation. Deletion of both Rac1 and Rac2 murine alleles led to a massive egress of HSC from the marrow to blood, and Rac1−/− mice showed profound defects in engraftable HSC [186]. Rac2 deficient HSC showed defective adhesion, motility and interaction with the hematopoietic microenvironment and had a significant competitive repopulation defect [187].

HSC PROLIFERATION AND EXPANSION *IN VITRO*

The *in vitro* maintenance and potential expansion of HSCs has been the subject of extensive investigation over the last 30 years, beginning with murine long-term bone marrow co-cultures with murine bone marrow stroma ('Dexter cultures') [188] and subsequent adaptation of this system to primates [189] and humans [14,190–194], using both human and murine stroma or endothelium [195]. With the discovery of a number of hematopoietic growth factors (interleukins, colony stimulating factors) and their availability as recombinant proteins, *in vitro* culture systems were developed that supported extensive cell and progenitor expansion in the absence of stroma but in the presence of combinations of cytokines [13,14,52].

Stromal-based cultures

With adult human long-term bone marrow stromal co- culture (LTBMC), hematopoiesis was generally limited to 5–8 weeks and there was continuing decay in repopulating HSC and progenitors over time [14,193]. Several protocols for the expansion of HSCs and progenitor cells *in vitro* have been developed, such as the use of cytokine cocktails, co-culture with mesenchymal stem cells as feeder cells, and cell culture in bioreactors (reviewed in reference [199]). Frequent re-addition of fresh media and cytokines ranging from one exchange per week up to total daily feeding resulted in increased CFC and LTC-IC output and led to the development of clinical scale flat-plate perfusion bioreactors [196].

Unfortunately, the use of media exchange alone has not translated into an expansion of repopulating adult HSCs. CB CD34+ cells have been expanded in transwell culture systems (non-contact cultures) above AFT024 mouse fetal liver stromal cells with additional cytokines (Flt3 ligand [FL], c-Kit Ligand [KL], thrombopoietin [Tpo] and IL-7) [197]. In stromally supported cultures of CB CD34+ cells and cytokine (FL, Tpo, KL +/−IL-6), enhanced production of CAFC (11−89-fold over 6 weeks) was noted, while NOD/SCID repopulating cells increased 10−14-fold by 2 weeks but were absent by week 5 [198]. Expanded cells engrafted primary and secondary NOD/SCID mice and day 7 expanded cells engrafted primary, secondary and tertiary retransplanted fetal sheep. The murine OP9 stromal cell line derived from osteopetrotic op/op mice has been used to support long-term murine hematopoiesis in the absence of added cytokines, however it is not supportive of human CD34+ cells [193]. The addition of Tpo to the stromal co-culture system or transduction of OP9 with an adenovector expressing Tpo permitted very efficient long-term (16+ weeks) human hematopoiesis initiated with cord blood CD34+ cells, with sustained generation and extensive cumulative expansion of LTC-IC [13,200]. In a comparable system of co-culture of OP9 transduced with adenovectors expressing Tpo, KL and FL, but using adult bone marrow or G-CSF-mobilized blood CD34+ cells, hematopoiesis was sustained for 12 weeks but a much lesser degree of LTC-IC expansion was noted (3−4-fold) [193]. In the latter system addition of human (but not murine) M-CSF or CD14+ monocyte/macrophages to the cultures substantially decreased progenitor and HSC expansion, indicating that accumulation of differentiated cells, particularly macrophages, exerted a negative influence on HSC proliferation. *Ex vivo* expansion of human HSCs has been obtained by the use of osteoblast-differentiated mesenchymal stem cells (MSCs) acting as a feeder layer, and likely operates through the CXCL12 chemokine signaling pathway [194].

Due to progress in the understanding of the molecular and cellular mechanisms regulating HSPCs maintenance and expansion, more recent approaches have involved transcription regulation, cell cycle regulation, telomerase regulation, and chromatin-modifying agents. *In vitro* maintenance of HSC has been reported using Wnt5a-secreting AGM and embryonic liver-derived stromal cell line [201]. Human BM-derived MSCs have been used as feeder cells to expand CB HSCs and progenitors in a serum-free culture system [202]. CD34+ cells increased 43-fold while GM and erythroid progenitor increased 3.3- and 4.7-fold respectively, while HSCs capable of *in vivo* engraftment were maintained [202]. Culturing mouse or human hematopoietic cells on tropoelastin, a uniquely elastic biomaterial substrate, led to a two- to three-fold expansion of murine HSC [203]. Treatment with cytokines in the presence of tropoelastin had an additive effect on this expansion. These biological effects required substrate elasticity, as neither truncated nor crosslinked tropoelastin reproduced the phenomenon. The recent emerging technology which uses nanofibers as a supporting matrix, in combination with growth factors, has made a significant improvement in HSC self-renewal and expansion *in vitro* [205]. FGF-2 was reported to expand murine HSCs and progenitor cells via proliferation of stromal cells, c-Kit activation, and CXCL12 downregulation [204].

Cytokine-supplemented cultures

It was found that direct contact between stromal cells and hematopoietic cells was not necessary for long-term *in vitro* hematopoiesis [197] and hematopoiesis could be maintained in cultures fed with media conditioned by stromal feeders. This information suggested the feasibility of using stromal-free cytyokine supplemented cultures for expanding HSCs and progenitors *in vitro*. Over the years, the use of phenotypic and functional assays has identified a number of cytokines that have distinct stimulatory effects on primitive hematopoietic cells, particularly when used in various combinations (Fig. 47.1). These include FL, KL, Tpo, IL-1, IL-3, IL-6, IL-11, IL-12, G-CSF, and GM-CSF [52]; reviewed in references [14,206,207]. Using limiting dilution assays for competitive repopulating cells, modest degrees of HSC expansion have been reported in murine *in vitro* expansion systems using combinations of KL, FL and

IL-11. Optimal growth factor combinations are required to achieve *in vitro* HSC expansion and while KL and FL are sufficient to maintain survival and proliferation, retention of HSC function requires activation of additional pathways, for example gp130, stimulated via IL-6 or IL-11 (reviewed in reference [12]).

Haylock et al. [208] were first to report a CFC expansion of 66 fold in human CD34+ cultures stimulated with IL-1, IL-3, IL-6, G-CSF and GM-CSF. Subsequent studies showed the importance of specific cytokines for expansion of defined progenitor cell types. In a human CD34+ expansion system, IL-6 plus soluble IL-6 receptor (to maximize IL-6 signaling where IL-6 receptor density could be limiting), together with FL, KL and Tpo resulted in a ~4-fold expansion of HSCs, as determined by NOD/SCID limiting dilution repopulation [209]. Both FL and IL-6/sIL-6 are important for expanding CB CD34+-derived LTC-IC, while the addition of KL to either of these factors enhances generation of CFCs [210]. In contrast, FL, KL and IL-3 most efficiently stimulated BM LTC-IC proliferation, whereas the addition of IL-6/sIL-6R or Tpo to this combination was required for expansion of CFCs [210]. Regardless of the cytokine combination used, rigorous limiting dilution engraftment studies in NOD/SCID mice have shown, in the majority of studies, that cytokine-supplemented cultures generally showed a loss, maintenance or modest (2–4-fold) expansion of human SRC [209].

In contrast, Piacibello's group [13], reviewed in reference [14], reported a major expansion of LTC-IC and progenitors (3,000-fold) and a 70-fold expansion of NOD/SCID engrafting HSCs (SRC) in cultures of CB CD34+ cells with FL, KL, Tpo and IL-6. Under similar conditions but with CD34+ cells from adult BM and mobilized peripheral blood (MPB), *ex vivo* expansion was shorter in duration and extent, with SRC expansion of only six-fold by three weeks [13]. In a modified stromal-free culture system with CB-derived CD34+ cells and a cocktail of four cytokines (KL, FL, Tpo and IL-6), with CD34+ re-isolation at monthly intervals, continuous expansion of HSCs was observed over 16–20 weeks by *in vitro* CAFC and LTC-IC assays, and by NOD/SCID engraftment and secondary and tertiary passaging [13] (Table 47.1). Despite extensive proliferation, the telomere length of cultured hematopoietic cells initially increased and it was only at late stages of culture that telomere shortening was detected. Telomere length stabilization correlated with high telomerase levels (Table 47.1).

TABLE 47.1 Stem and progenitor cell production, telomere length and telomerase activity of CB CD34$^+$ cells generated after repeated expansion-isolation procedures 'Fractionated' LTC*

	Input	1st isolation wk 4	2nd isolation wk 8	3rd isolation wk 12	4th isolation wk 16	5th isolation wk 20

**Modified from Gammaitoni et al., 2004.*

In contrast, cytokine-stimulated adult CD34+ cells from BM or G-CSF mobilized blood showed CD34+ and NOD/SCID engrafting HSC expansions of six-fold over 3–4 weeks, with telomere shortening and low levels of telomerase activity. Human fetal liver-derived HSCs with NOD/SCID repopulating capacity have been expanded 10–100-fold (net expansion) over 28 days of culture with FL, Tpo, KL and IL-6 and 8% human AB plasma [211]. The CD133+ G0 cell subpopulation from CB is enriched for HSCs and progenitors (CFC), with an LTC-IC incidence of 1 in 4.2 cells and a CFC incidence of 1:2.8 cells [212]. These cells could be expanded with cytokines in a serum-free, stromal-free culture system for up to 30 weeks, resulting in a 100-million-fold amplification of progenitors. Quantitation of HSC expansion *in vitro* is complicated by divergence in results when *in vitro* HSC assays (CAFC, LTC-IC) are used as an end point, versus *in vivo* (SCR). While this has lead to considerable debate as to the validity of the assays, the issue is probably related to the efficiency of the respective systems. Clearly, the *in vivo* assay requires HSC survival and homing to the HSC niches of the mouse BM and there is evidence that *in vitro* culture or cycling HSC may be less efficient *in vivo* while retaining potential to self-renew and form CAFC/LTC-IC *in vitro*. In this context, Liu et al. [213] cultured CB CD34+ cells for up to five days with a cocktail of cytokines, labeled the cells with 111-Indium and determined recovery at 48 hours following intravenous injection into NOD/SCID mice. Cultured, cycling HSCs and progenitors showed a reduction of marrow homing (from 11.3% to 5.4%) with reduced homing to spleen, liver and lung. Acute cytokine deprivation in the *in vivo* environment and Fas/CD95-mediated cell death may be responsible for the reduced engraftment efficiency of cultured HSCs [213]. *Ex vivo* expansion may be enhanced by manipulating intracellular mediators and morphogen signaling pathways to increase the probability of symmetric division, which favors HSC expansion at the expense of differentiation (reviewed in reference [214]).

Pleiotrophin, a secreted neurite outgrowth factor with no known function in hematopoiesis, efficiently promotes HSC expansion *in vitro* and HSC regeneration *in vivo* [207]. Treatment of murine HSCs with pleiotrophin caused a marked increase in long-term repopulating HSC numbers in culture, as measured in competitive repopulating assays. *In vitro* culture of human CB CD34+CD38-Lin- cells with pleiotrophin also substantially increased the numbers of xenograft SCID repopulating HSCs recovered compared to input and cytokine-treated cultures. The chromatin-modifying agents 5-aza-2′-deoxycytidine (5azaD) and trichostatin A (TSA) have been used to ameliorate epigenetic alteration of CB HSCs during *ex vivo* culture [215]. The sequential addition of 5azaD followed by TSA was crucial for retention of *in vivo* engraftment of cytokine stimulated HSC.

Members of the angiopoietin-like (Angptl) family of growth factors have been shown to expand both murine and human HSCs, and Angptl5 has been implicated in the expansion of human NOD/SCID repopulating cells (SRCs) *ex vivo* [216]. Angptl4 maintained the *in vivo* repopulation capacity of CD34+ human CB cells, and both Angptl4 and Angptl5 can increase the engraftment capacity of SRCs [216]; but more frequently, these factors are associated with maintenance of SRC activity during *ex vivo* culture.

An unbiased screen with primary human HSCs identified a purine derivative, StemRegenin 1 (SR1), that promotes the *ex vivo* expansion of CD34+ cells [217]. Culture of HSCs with SR1 led to a 50-fold increase in cells expressing CD34, and a 17-fold increase in cells that retain the ability to engraft immunodeficient mice. Mechanistic studies show that SR1 acts by antagonizing the aryl hydrocarbon receptor (AHR) [217].

MORPHOGENS AND HSC REGULATION

In addition to the classic hematopoietic growth factors, signaling pathways implicated in general development have also been shown in various models to influence HSC proliferation and differentiation (Fig.47.1).

Notch

The transcription factors hepatic leukemia factor (HLF) and Notch target Hes1 were initially identified by gene expression profiling of $CD34^{+}CD38^{-}$ cells from human fetal liver, CB, and adult BM [218]. Overexpression of Hes1 or HLF conferred increased repopulation potential; however, their activity in clonal assays or serial transfer was not tested [218]. Canonical Notch signaling is initiated by their binding Jagged or Delta-like, which leads to proteolytic cleavage of the intracellular domain of Notch (ICN) by gamma secretase and ICN translocation to the nucleus, where it participates in transcriptional activation [219]. Interestingly, CCN3 (NOV), an extracellular modulator of Notch signaling, is also linked with human HSC function. NOV binds to the extracellular domain of Notch and increases expression of Hes1 [220]. The Notch pathway in murine HSCs has been widely studied. Recent evidence suggests that Notch does not have an obligate function in adult HSCs [341], but constitutive activation of Notch can block differentiation and promote HSC expansion [222]. Thus, while it seems that Notch has a conserved role in mouse and human, additional studies should examine the requirement for Notch in human systems via loss-of-function or dominant-negative approaches.

In differential gene display, Notch1 has consistently been shown to characterize the murine and human HSC. Notch1 null mouse embryos showed defective hematopoietic (and vascular) development and were devoid of HSC. Retrovirus-mediated expression of activated Notch 1 enhanced HSC self-renewal and a similar effect of differentiation inhibition and progenitor/HSC expansion was reported with activated Notch4 (Int3) [222]. The Bernstein group [222,223] showed that incubation of murine BM precursors with the Notch ligand Delta1 extracellular domain fused to the Fc portion of human IgG1, together with cytokines (KL, IL-6, IL-11 and Flt3L) inhibited myeloid differentiation and promoted several log increases in precursors capable of short-term lymphoid and myeloid repopulation. Addition of IL-7 promoted T-lymphocyte development whereas GM-CSF induced myeloid differentiation. It has been shown that Notch signaling mediated by both Delta and Jagged ligands expands the HSC compartment while blocking or delaying terminal myeloid differentiation. The quantitative aspects of Notch signaling in determining hematopoietic precursor fate has been demonstrated by Delaney et al. [223] who showed in CD34+ CB cultures that low densities of the Notch ligand Delta1 enhanced *in vitro* generation of CD34+ cells as well as CD14 and CD7 cells consistent with myeloid and lymphoid differentiation whereas higher concentrations induced apoptosis of CD34+ cells but not CD7 T cell precursors. A role for combinatorial effects of Jagged stimulation of Notch and cytokine-induced signaling pathways (Kit, Flt3, Mpl) was reported in murine HSC cultures, with a 10—20 fold expansion of HSC with long-term repopulating potential [224]. Inhibition of Notch signaling leads to accelerated differentiation of HSC *in vitro* and depletion of HSC *in vivo* [225]. However, using a Cre-LoxP-mediated inactivation system, mice with simultaneous inactivation of Jagged and Notch1 survived normally, even following chemotherapy-induced myelosuppression [226]. HSC regulation is complex, cell-context dependent and plagued by potential compensation systems and while the study excludes an essential role for Jagged1 and Notch1 during hematopoieis, there are 4 Notch receptors and five ligands and the Notch pathway cross-talks with the Wnt pathwy with more than nine frizzled receptors and 12 ligands [225]. The Drosophila hairy and enhancer of split (Hes) 1 basic helix-loop-helix protein is a major downstream effector of the Notch pathway and is expressed at high levels in HSC-enriched CD34+, CD38- subpopulations. Conditional expression of Hes1 in murine and human HSC inhibited cell cycling *in vitro* and cell expansion *in vivo* with preservation of long-term reconstituting function.

Wnt

The Wnt pathway has been implicated in HSC proliferation but its function in HSC biology is still controversial (reviewed in references [227—230]). Notch signaling was required for Wnt-mediated maintenance of undifferentiated HSC but not for their survival or entry into the

cell cycle [225]. Wnt signaling represses glycogen synthase kinase-3β (GSK3β), leading to accumulation of β-integrin but also accumulation of intracellular fragments of Notch and activation of Notch target genes such as Hes1. Hematopoietic repopulation by mouse or human HSCs was augmented by administration of a GSK-3 inhibitor to recipient mice [231]. The inhibitor improved neutrophil and megakaryocyte recovery, mouse survival and enhanced sustained long-term repopulation. The GSK-3 inhibitors modulated gene targets of Wnt, Hedgehog and Notch pathways in primitive hematopoietic cells, without affecting mature cells. Wnt-5A injected into immunodeficient mice enhanced engraftment by human CD34+ cells [232]. Reya et al. [227] showed that overexpression of activated β-catenin expanded the pool of HSC in long-term culture. Activation of Wnt signaling in HSC increases expression of HOXB4 and Notch1, both implicated in HSC self-renewal. Ectopic expression of axin or the frizzled ligand-binding domain, both inhibitors of the Wnt signaling pathway, inhibited HSC growth *in vitro* and reduced *in vivo* engraftment. Wnt3a palmitolylated protein has been purified and shown to induce self-renewal of HSC [233].

Induction of BMP or Wnt in zebrafish hematopoietic cells after irradiation led to increased gene expression of key hematopoietic genes, suggesting that regulation of blood genes may be important for BMP and Wnt effects during regeneration (reviewed, [230]). The ultimate effectors of Wnt signaling pathways are TCF/LEF transcription factors [230]. In hematopoietic development in the early embryo, HSCs are maintained by secretion of Wnt5a by AGM stromal cells [201]. In a 'lineage fingerprint' of ~100–400 genes uniquely expressed in HSCs, Wnt signaling was particularly enhanced [28]. During hematopoietic regeneration, both hematopoietic and stromal cell elements within the bone marrow microenvironment show increased expression of Wnt10b, which can function to enhance the growth of HSCs [234]. In mice, Wnt3a deficiency irreversibly impairs HSC self-renewal and leads to defects in progenitor cell differentiation [340]. Studies in zebrafish showed that Wnt activation in HSCs required prostaglandin E2 (PGE2) [337]. Although a central role for the canonical Wnt signaling pathway has been suggested in HSC self-renewal, as well as in the development of B and T cells, conditional deletion of beta-catenin (which is considered to be essential for Wnt signaling) had no effect on hematopoiesis or lymphopoiesis [235,236]. The combined deficiency of beta- and gamma-catenin in HSCs also did not impair their ability to self-renew and to reconstitute all myeloid, erythroid, and lymphoid lineages [236]. These results would appear to exclude an adult HSC cell autonomous role for canonical Wnt signaling (as mediated by beta- and/or gamma-catenin) during hematopoiesis and lymphopoiesis.

However, there is a distinct mode of Wnt/beta-catenin signal that can stabilize beta-catenin in the BM stromal cells, thus promoting maintenance and self-renewal of HSCs in a contact-dependent manner, whereas direct stabilization in hematopoietic cells caused loss of HSCs [237]. Wnt/β-catenin activity is needed for the emergence but not the maintenance of HSCs in mouse embryos, since it is transiently required in the AGM to generate long-term HSCs and to produce hematopoietic cells *in vitro* from AGM endothelium [238].

Hedgehog

The Hedgehog pathway has been implicated in HSC proliferation but its function in HSC biology is still controversial. Sonic Hedgehog (Shh) treatment in CD34+ cultures induced expansion of human HSCs, and Noggin, a specific inhibitor of bone morphogenic protein-4 (BMP-4) inhibited Shh-induced proliferation, indicating that Shh regulates HSC via mechanisms that are dependent on downstream BMP signals [239]. Indian hedgehog (Ihh)-expressing human stromal cells supported CD34+ cells with markedly enhance production of progenitor CFCs above the stroma, but no change in long-term cobblestone formation [240]. Despite these reports indicating that Hh signaling is an important regulator of HSC maintenance and differentiation, Gao et al. [241] reported that Hedgehog signaling is dispensable for adult HSC function. Gain- and loss-of-function Hh genetic models demonstrate that

conditional Smoothened (Smo) deletion or overactivation has no significant effects on adult HSC self-renewal and function. Transcriptome analysis reveals that silencing of Hh signaling does not significantly alter the HSC-specific gene expression 'signature' [241]. Moreover, there was a lack of synergism between the Notch and Hh pathways in HSC function.

Bone morphogenic protein

CD34+, CD38− HSC express the bone morphogenic protein type 1 (BMP-1) receptors activin-like kinase (ALK-3 and ALK-6) and their downstream transducers SMAD-1, -4 and -5 (reviewed in reference [230]). Like TGFβ, high concentrations of BMP-2, -4 and -7 inhibited HSC proliferation but maintained their long-term survival and repopulating potential whereas low concentrations of BMP-4 induced HSC proliferation and differentiation [242]; reviewed in reference [230].

MOLECULAR PATHWAYS IMPLICATED IN HSC SELF-RENEWAL

Jak-STAT

Transduction of mouse HSCs with constitutively activated STAT3 enhanced HSC self-renewal under stimulated, but not homeostatic conditions, while a dominant-negative form of STAT3 suppressed self-renewal [243]. Cytokine receptor signals through c-Kit and c-Mpl can modulate HSC quiescence and engraftment, acting in part through STAT5, a transcriptional regulator and mitogenic factor in hematopoietic progenitors that is also required for maintenance of HSC quiescence during steady state hematopoiesis [244]. Conditional deletion of STAT5 rapidly decreased quiescence-associated c-Mpl downstream targets (Tie-2, p57), increased HSC cycling, and gradually reduced survival and depleted the long-term HSC pool [244]. The STAT5 pathway is strongly activated following ligand binding to the erythropoietin and IL-3 receptors, and weakly following FL binding to Flt3. However, constitutively activating mutants of Flt3, found in ∼25% of human acute myeloid leukemias, are associated with strong activation of STAT5 (reviewed in reference [14]). A constitutively activated double mutant of STAT5a [STAT5a(1*6)] transduced into CD34+ cells promoted enhanced HSC self-renewal, as measured by CAFC assay, and promoted enhanced erythroid differentiation relative to myeloid [245]. This was causally linked to downregulation of C/EBPα, a transcription factor uniquely associated with granulocytic differentiation.

Polycomb group (PcG) proteins

PcG proteins are required for the maintenance of embryonic as well as a broad range of adult stem cells, including HSCs (reviewed in reference [246]). PcG proteins play a role in the self-renewal capacity of HSCs by repressing tumor suppressor genes through histone modifications and keeping differentiation programs poised for activation by repressing hematopoietic developmental regulator genes (reviewed in references [246,247]). PcG proteins also maintain redox homeostasis to prevent premature loss of HSCs. These findings established PcG proteins as epigenetic regulators of the self-renewal capacity and multipotency of HSCs. (reviewed in reference [246]). The Polycomb group transcriptional repressor gene Bmi-1 has been implicated in HSC maintenance, and loss-of-function studies showed profound defects in HSCs [247,248]. Bmi-1 overexpression downregulated the expression of p16 and p19Arf, which are encoded by ink4a, and enhanced HSC symmetrical division, resulting in the expansion of multipotent progenitors *in vitro* and enhanced HSC repopulation *in vivo* [249]. Enforced expression of Bmi-1 augments the self-renewal capacity of HSCs. Transcriptional comparison of HSCs and MPPs identified a number of transcription factors associated with the HSC state, including ID genes, SOX8, SOX18, and Bmi-1 [247,250].

The polycomb group (PcG) gene Bmi-1 has been identified as one of the key epigenetic regulators of cell fates during different stages of development in multiple murine tissues. In a clinically relevant model, enforced expression of Bmi-1 in CB CD34+ cells resulted in

long-term maintenance and self-renewal of HSC and progenitor cells [247,250]. Long-term culture-initiating cell frequencies were increased upon stable expression of Bmi-1 and these cells engrafted more efficiently in NOD-SCID mice [247,248,250]. Week 5 CAFCs were replated to give rise to secondary CAFCs. Serial transplantation studies in NOD-SCID mice revealed that secondary engraftment was only achieved with cells overexpressing Bmi-1. Importantly, Bmi-1-transduced cells proliferated in stroma-free cytokine-dependent cultures for more than 20 weeks, while a stable population of approximately 1% to 5% of CD34+ cells was preserved that retained colony-forming capacity [247,250]. Control cells lost most of their NOD-SCID engraftment potential after 10 days of *ex vivo* culture in the absence of stroma, NOD-SCID multilineage engraftment was retained by overexpression of Bmi-1. These data indicate that Bmi-1 is an intrinsic regulator of human HSC self-renewal [250,251]. Down-modulation of Bmi-1 in CB CD34+ cells impaired long-term expansion and progenitor-forming capacity, both in cytokine-driven liquid cultures as well as in bone marrow stromal co-cultures [251]. In addition, LTC-IC frequencies were dramatically decreased upon knock-down of Bmi-1, indicating an impaired maintenance of HSC and progenitor cells [251]. The reduced progenitor and HSC frequencies were associated with increased expression of p14ARF and p16INK4A and enhanced apoptosis, which coincided with increased levels of intracellular reactive oxygen species and reduced Foxo3A expression [251]. Bmi-1 overexpression is associated with poor prognosis in leukemia and down-modulation of Bmi-1 in AML CD34+ leukemic stem cells impaired their self-renewal and long-term expansion [251]. In addition to a role in bypassing senescence and the orchestration of the symmetry of HSC, it has recently become clear that Bmi-1 also functions in the protection against oxidative stress [247]. In the absence of Bmi-1, reactive oxygen species accumulate, associated with activation of DNA damage response pathways and increased apoptosis. Bmi-1-mediated control over reactive oxygen species levels can occur independently of the INK4a/ARF pathway, by impaired mitochondrial functions [247]. In human hematopoietic malignancies, Understanding molecular mechanisms by which Bmi-1 affects stem cell fate will increase our insights into the biology of HSCs and will also aid in understanding the process of leukemic transformation and ultimately in the identification of drugable targets that might facilitate the eradication of leukemic stem cells.

The HOX family of hematopoietic regulators

The Homeobox (HOX) transcription factors are important regulators of normal and malignant hematopoiesis because they control the proliferation, differentiation and self-renewal of hematopoietic cells at different levels of the hematopoietic hierarchy. *HOX* genes are expressed at various stages during hematopoietic development. Mounting evidence suggests that *HOXA9* plays an important role in normal hematopoiesis. Targeted disruption of *HOXA9* in mice severely reduces the number of HSC and progenitor cells, while enforced expression of *HOXA9* promotes proliferative expansion of HSC and progenitor cells and subsequently inhibits their differentiation [252]. These data highlight the importance of precise control of HOXA9 protein levels during hematopoiesis.

HOXB4 plays critical role in promoting HSC self-renewal, and engraftment [253]; as reviewed in references [12,14]. Combinations of early acting cytokines increased HOXB4 promoter activity in primitive hematopoietic cells and Tpo acting via Mpl and p38MAPK increased HOXB4 expression 2–3-fold in primitive hematopoietic cells [254]. In $Tpo^{(-/-)}$ mice, hematopoietic HoxB4 expression was 2–5-fold lower than in wild-type animals [254]. Wnt signaling in primitive hematopoietic cells also induces HOXB4 expression [255]. HOXB4 null mice had reduced numbers of HSC and progenitor cells due to impaired proliferative capacity, but did not show perturbed lineage commitment. Retroviral-mediated ectopic expression of HOXB4 resulted in a rapid increase in proliferation of murine HSC both *in vivo* (1,000-fold increase in transduced HSC in a murine transplant model), and *in vitro* (40-fold expansion of murine HSC), with retention of lympho-myeloid repopulating potential and enhanced

regenerative capability in mice (reviewed in reference [12]). However, high levels of HOXB4 expression in human CB $CD34^+$ cells were recently reported to either increase the proliferation of HSCs and inhibit differentiation [253], or direct the cells toward a myeloid differentiation program, rather than increasing proliferation [256]. HoxB4 has been ectopically expression in human embryonic stem cells (hESCs) and did not affect ESC features [257]. However, HoxB4-expressing, hESC-derived, CD34+ hematopoietic cells generated higher numbers of erythroid and blast-like colonies than controls. The number of CD34+ cells increased but CD45+ and KDR+ cell numbers were not significantly affected. When the hESC-derived CD34+ cells were transplanted into NOD/SCID beta $2m^{(-/-)}$ mice, the ectopic expression of HoxB4 did not alter their repopulating capacity [257]. Ectopic expression of HOXB4 in combination with MS-5 stroma exerts different effects in HSC-enriched, primitive (CD34+ CD38-) and HSC depleted (CD34+CD38+) progenitor-enriched human CB cells, resulting in an enhanced proliferation of early CD34+CD38− cells in the absence or presence of serum-sustained MS-5 stroma and an impaired output of late committed CD34(+) cells on MS-5 stroma [258].

These studies suggest that in human hematopoietic progenitors, HOXB4 affects cell fate decisions (self-renewal, differentiation, or a differentiation block) in a concentration-dependent manner. Therefore, like HOXA9, the relative abundance of HOXB4 requires precise regulation. Molecular mechanisms and target genes responsible for HOXB4-induced HSC expansion remain to be elucidated. Overexpression of HOXB4 point mutations lacking the capacity to bind DNA (HOXB4(N^{51}->A) failed to enhance the proliferative activity of transduced BM populations whereas mutants that blocked the capacity of HOX to cooperate with the transcription factor PBX in DNA-binding (HOXB4 (W->G) conferred a pronounced proliferative advantage *in vitro* and *in vivo* to transduced BM populations [259]. This mutant was comparable to wild-type HOXB4 in that its elevated level promoted a comparable degree of HSC expansion. This was distinct from results obtained by knocking down the expression of PBX in HOXB4-overexpressing BM cells using lentivector transduction with a PBX antisense construct. In this system, the HSCs were > 20 times more competitive than HSCs overexpressing HOXB4 with PBX levels intact which were, in turn, 20−50 times more competitive that wild-type BM [260]. It appears that the likely explanation for these observations is that HOXB4 and PBX genes act on distinct pathways in the HSC, the former promoting self-renewal and the latter inhibiting it. A developmentally important mechanism for regulating HOX gene expression was identified by Davidson et al. [261]. Cdx4 belongs to the caudal family of homeobox genes that have been implicated in antero-posterior patterning of the axial skeleton and regulation of HOX gene expression. A Cxc4 mutation in zebrafish causes severe anemia with complete absence of Runx1 in blood cells [261]. Injection of mutants with HOXB7 and HOXA9 mRNA almost completely rescued Cdx4 mutants. Retroviral transduction of mouse ES-derived embryoid body cells with Cdx4 increased expression of HOXB4 (30×), HOXB3 (19×), HOXB8 (5×) and HOXA9 (4×) − all implicated in HSC or progenitor expansion. Cdx4 was more potent than HOXB4 in stimulating hematopoiesis and CFU-GEMM production [261].

The abundance of a given cellular protein is regulated by the interplay between its biosynthesis and degradation. During normal hematopoietic development, *HOXA9* is strongly expressed in the $CD34^+$ populations enriched in early myeloid progenitors, and is turned off when cells exit the $CD34^+$ compartment and undergo terminal differentiation. In conjunction with decreased biosynthesis, rapid turnover of HOXA9 would ensure low steady state levels, which is necessary for proper execution of differentiation into myeloid lineages. HOXB4 is also expressed at high levels in HSC/progenitor compartments, and is downregulated, but maintains low-level expression during differentiation. The studies of the biochemical mechanisms controlling the activities of HOXA9 and HOXB4 thus far have been focused primarily on transcriptional regulation. Little is known about the way that their cellular abundance is controlled at the post-translational level. Identification of proteins involved in the removal of HOXA9 and HOXB4 will be necessary for understanding the elaborate regulatory circuitry governing hematopoiesis.

Post-translational regulation of HOX protein levels has been linked to their ubiquitin-dependent proteolysis by the CUL-4A ubiquitin ligase [262]. Some transcription factors travel between cells because they contain protein domains that allow them to do so. This is the case for the HIV transcription factor TAT and for several homeoproteins, such as Engrailed, HOXA5, HOXB4, HOXC8, EMX1, OTX2 and PAX6. Direct paracrine homeoprotein activity has not been considered, yet in theory it would represent a way for neighboring hematopoietic cells to exchange proliferative and differentiative signals. Bone marrow stromal cells (murine MS-5 stroma) have been lentivector transduced with a vector expressing HOXB4 linked to an immunoglobulin kappa chain leader sequence (signal peptide) that is cleaved during protein secretion [192]. Co-culture of human CB CD34+ cells on this stroma resulted in a 2−3-fold greater expansion of cells and progenitors (CFC), a 4−10-fold greater expansion of LTC-IC, and a 2.5-fold expansion of NOD/SCID repopulating cells relative to controls over five weeks of culture [192]. A biologically active TAT-HOXB4 fusion protein has been produced and expressed as a recombinant protein that upon purification could be added to murine HSC cultures [12]. Since the half life of intracellular HOXB4 was approx. one hour, TAT-HOXB4 was added to cell culture every three hours for four days together with cytokines (KL, IL-6, IL-3) resulting in a 5−6-fold expansion of HSCs as measured by competitive repopulation. Ectopic overexpression of HOXB4 in murine BM produced HSCs that were ~40-fold more competitive than non-transduced cells in mouse repopulation assay, and by 3−5 months the HSC pool size of reconstituted mice equaled, but never exceeded, that of untreated control mice [12]. High-level ectopic expression of HOXB4 in human CB CD34+ cells had a selective growth advantage in NOD/SCID mice but with substantial impairment in myeloerythroid differentiation and B cell development. In non-human primate competitive repopulating transplantation models, HOXB4 overexpressing CD34+ cells had a 56-fold higher short-term, and 5-fold higher long-term (six months), engraftment than control cells [263]. HOXB4-transduced and expanded non-human primate CB cells resulted in superior engraftment of all hematopoietic lineages in pigtailed macaques over non-expanded controls [264].

HOXC4, a protein encoded by a HOXB4 paralog gene, has also been implicated in HSC expansion [265]. In co-cultures of HOXC4-producing stromal cells with human CB CD34+HSCs, the HOXC4 homeoprotein expanded immature hematopoietic cells by three to six times, significantly improving the level of *in vivo* engraftment. Comparative transcriptome analysis of CD34+ cells subjected to HOXB4 or HOXC4, or not, demonstrated that both homeoproteins regulate the same set of genes, some of which encode key hematopoietic factors and signaling molecules [265].

HOXA10 is a critical regulator of HSCs erythroid/megakaryocyte development and induced a 15-fold increase in the repopulating capacity of HSCs after 13 days of *in vitro* culture [266]. The HOXA10-mediated effects on hematopoietic cells were associated with altered expression of genes that govern stem cell self-renewal and lineage commitment such as HLF, Dickkopf-1 (Dkk-1), growth factor independent-1 (Gfi-1), and Gata-1.

NEGATIVE REGULATION OF HSC

Members of the transforming growth factor-beta (TGF-β) superfamily of growth factors have been shown to regulate the *in vitro* proliferation and maintenance of HSCs [267]. The TGF-β/Smad signaling pathway is active in dormant HSCs, and loss of the TGF-β type II receptor reduces long-term repopulating activity in HSCs. TGF-β maintains HSCs in a quiescent, or slowly cycling state and this cell cycle arrest was linked to upregulation of the cyclin-dependent kinase inhibitor p57KIP2 in primary human hematopoietic cells (Fig.47.2) [268]. Fortunel et al. [269] attributed the TGF-β affect in part to downmodulation of cell surface expression of tyrosine kinase receptors c-Kit, Flt3, IL-6R and the Tpo receptor Mpl. This negative regulatory role of TGFβ has been challenged by Larsson et al. [270], who showed that TGF-β type I receptor-deficient mice had normal *in vivo* hematopoiesis, a normal HSC cell cycle

distribution and did not differ in long-term HSC repopulating potential compared to wild-type animals. TGF-β type II receptor-deficient HSCs showed low-level Smad activation and impaired long-term repopulating activity, suggesting a critical role for TGF-β/Smad signaling in HSC maintenance [271].

TGF-β is produced in a latent form by a variety of cells, and so it is necessary to identify activator molecules for latent TGF-β. Non-myelinating Schwann (glial) cells maintain HSC dormancy in the bone marrow niche by activating latent TGF-β [271] (Fig. 47.4). These glial cells ensheath autonomic nerves, express HSC niche factor genes, and are in contact with a substantial proportion of HSCs [271]. Autonomic nerve denervation reduced the number of these active TGF-β-producing glial cells and led to rapid loss of HSCs from BM. The Smad signaling pathway, which operates downstream of the TGF-beta superfamily of ligands, regulates a diverse set of biological processes, including proliferation, differentiation and apoptosis, in many different organ systems. The self-renewal capacity of HSCs is promoted *in vivo* upon blocking of the entire Smad pathway. Working at a common level of convergence for all TGF-beta superfamily signals, Smad4 is key in orchestrating these effects and is critical for self-renewal of HSCs [267]. Enforced expression of Smad4 revealed a role for TGF-beta in human CB HSCs, suggesting that the Smad pathway regulates HSC self-renewal independently of differentiation, and demonstrating that the Smad signaling circuitry negatively regulates the regeneration capacity of human HSCs *in vivo* [271]. Systemic induction of Smad4 deletion was incompatible with survival four weeks after induction because of anemia and histopathological changes in the colonic mucosa [272]. Restriction of Smad4 deletion to the hematopoietic system via several transplantation approaches demonstrated a role for Smad4 in the maintenance of HSC self-renewal and reconstituting capacity, leaving homing potential, viability, and differentiation intact [272]. Furthermore, the observed downregulation of notch1 and c-myc in Smad4$^{(-/-)}$ primitive cells places Smad4 within a network of genes involved in the regulation HSC renewal [272].

HSCs overexpressing Smad7 have an unperturbed differentiation capacity, as evidenced by their normal contribution to both lymphoid and myeloid cell lineages, suggesting that the Smad pathway regulates self-renewal independently of differentiation (reviewed in reference [273]). The data reveal an important and previously unappreciated role for the Smad signaling pathway in the regulation of self-renewal of HSCs *in vivo* [273]. He et al. [274] showed that the ubiquitious nuclear protein Transcriptional Intermediary Factor 1gamma (TIF1gamma/TRIM33) selectively binds receptor-phosphorylated Smad2/3 in competition with Smad4. Rapid and robust binding of TIF1gamma to Smad2/3 occurs in hematopoietic, mesenchymal and epithelial cell types in response to TGF-beta. In human HSCs/HPCs, where TGF-beta inhibits proliferation and stimulates erythroid differentiation, TIF1gamma mediates the differentiation response while Smad4 mediates the antiproliferative response with Smad2/3 participating in both responses [274]. Thus, Smad2/3-TIF1gamma and Smad2/3-Smad4 function as complementary effector arms in the control of hematopoietic cell fate by the TGF-beta/Smad pathway. Distinct HSC subtypes are differentially regulated by TGF-beta1. Myeloid-biased HSCs (My-HSCs) and lymphoid-biased HSCs (Ly-HSCs) phenotypes are stable under natural (aging) or artificial (serial transplantation) stress but respond differently to TGF-β1, presenting a possible mechanism for differential regulation of HSC subtype activation [275].

Two cyclin-dependent kinase inhibitors, (CKI), p21 (Cip1/Waf1) and p27kip1, have been shown to govern the pool size of HSCs and progenitors, respectively [276]. Enforced expression of the HOXB4 transcription factor and downregulation of p21 (Cip1/Waf) can each independently increase murine HSC proliferation [256]. When p21 knockdown and HOXB4 overexpression were combined in HSC, long-term competitive repopulating cells expanded 100-fold in five days, compared to wild-type HSC, and three-fold greater than HOXB4 alone [256]. The transcription factor MEF (or EL4F) regulates quiescence of primitive

hematopoietic cells [278]. MEF null HSC display increased residence in G0 with reduced 5-bromodeoxyuridine incorporation *in vivo* and impaired cytokine proliferation *in vitro*. MEF null mice are consequently relatively resistant to the myelosupressive effects of chemotherapy or radiation.

Bone marrow adipocytes as negative regulators of the hematopoietic microenvironment

Adult BM contains adipocytes, the number of which correlates inversely with hematopoietic activity [277]. HSCs and short-term progenitors are reduced in frequency in the adipocyte-rich vertebrae of the mouse tail relative to the adipocyte-free vertebrae of the thorax [277]. In the mouse, the marrow of long (tubular) bones (made of compact cortical bone and medullary cavity) remains hematopoietically active for the animal's lifespan. In humans, in contrast, life-long hematopoiesis becomes restricted, in the third decade, to the axial skeleton and portions of long bone metaphyses, whereas it is reversibly lost in the rest of the marrow (reviewed in reference [279]). Adipose conversion is reversible, and so is the block of hematopoiesis in yellow marrow. Regional adipose conversion of the marrow would *per se* suggest that physiologically, the HSC niche might be a flexible entity in mammals. In lipoatrophic A-ZIP/F1 'fatless' mice, which are genetically incapable of forming adipocytes, and in mice treated with the peroxisome proliferator-activated receptor-gamma inhibitor bisphenol (a diglycidyl ether which inhibits adipogenesis), marrow engraftment after irradiation is accelerated relative to wild-type or untreated mice [277]. These data implicate adipocytes as predominantly negative regulators of the bone marrow microenvironment, and indicate that antagonizing marrow adipogenesis may enhance hematopoietic recovery in clinical bone marrow transplantation.

HEMATOPOIETIC STEM CELL NICHES

Niches in the BM provide specialized microenvironments for the regulation of HSCs. The strict control of HSCs by the niche coordinates the balance between the proliferation and the differentiation of HSCs required for maintaining the homeostasis of the blood system in steady states and during stress hematopoiesis. There are number of recent reviews on the BM niche(s) [179,279–284c]. Multiple cells in the BM, including osteoblasts, vascular endothelia, stromal cells (i.e., reticular cells, perivascular mesenchymal cells) are of mesenchymal lineage. An increased understanding of the role of HSC niche cells has been obtained from studies on the role of osteoprogenitor cells (mesenchymal stem cells, skeletal stem cells). MSCs, identified using Nestin expression, constitute an essential HSC niche component [285]. Nestin+ MSCs in BM can be identified by their ability to form fibroblast colonies (CFU-F) and can be propagated as non-adherent 'mesenspheres' that can self-renew and expand upon serial transplantations [285]. HSCs home near Nestin+ MSCs and adrenergic nerve fibers in the BM of lethally irradiated mice (Fig. 47.4). Nestin+ MSCs highly express HSC maintenance genes and others that trigger osteoblastic differentiation and these are selectively downregulated during enforced HSC mobilization or beta3 adrenoreceptor activation [285]. Nestin+ cell depletion of the BM *in vivo* rapidly reduces its HSC content and significantly reduces homing of HSCs. HSC dysregulation has been linked to the dysregulation of osteoprogenitors (reviewed in reference [279]). As preosteoblastic, periendothelial cells residing at the sinusoid wall, MSCs reconcile the notions of 'osteoblastic' and 'sinusoidal' niches with one another. In addition, MSCs have provided insight into the cross-regulation of skeletal and hematopoietic physiology mediated by the interplay of two stem cells (hematopoietic and skeletal) sharing a single niche. Skeletal progenitors have emerged as pivotal organizers of a complex, highly plastic niche and are direct regulators of hematopoietic space formation, sinusoid development, and hematopoietic function(s), as well as direct progenitors of positive and negative regulators of HSCs such as osteoblasts and adipocytes (reviewed in reference [279]). An intrinsic BM hematopoietic niche occupancy defect of HSC in scid mice has been reported

which facilitates exogenous HSC engraftment and provides a conducive BM niche environment for xenotransplantation [286].

Various types of lympho/myeloid cells can promote the retention of HSCs in the BM by modulating the abundance of CXCL12 and other adhesive molecules in the bone marrow niches [287–290]. Activated regulatory T cells can maintain the quiescence of HSCs in the BM niches by participate in creating a localized zone where HSCs reside and where T(reg) cells are necessary for allo-HSPC persistence. In addition to supporting HSC function, the niche provides a relative sanctuary from immune attack [290]. The BM has a reservoir of monocytes and macrophages that have a major role in host defense throughout the body and function cooperatively as niche cells to regulate HSCs (reviewed in reference [279]). BM macrophages play a critical role in maintaining osteoblasts, bone formation and the expression of CXCL12, Kit ligand, and angiopoietin-1 necessary to HSC maintenance [291]. In transgenic mice, in which expression of the G-CSFR is restricted to cells of the monocytic lineage, G-CSF-induced HSPC mobilization, osteoblast suppression, and inhibition of CXCL12 expression in the BM are intact [288]. This demonstrates that G-CSFR signals in monocytic cells are sufficient to induce HSC mobilization. G-CSF treatment of wild-type mice is associated with marked loss of monocytic cells in the bone marrow and G-CSFR signals in BM monocyte/macrophage cells inhibit the production of trophic factors required for osteoblast lineage cell maintenance, ultimately leading to HSC mobilizatio [288]. HSCs can be mobilized into the blood in mice by depleting macrophages with clodronate-loaded liposomes [289,291]. Two antagonistic, tightly balanced pathways regulating maintenance of HSCs/progenitors in the niche during homeostasis have been identified. In one, sympathetic nervous system (SNS) signals enhance HSC egress, while in the other, macrophages cross talk with the Nestin(+) niche stromal cells to promote HSC retention [287] (Fig. 47.4). Reductions in BM mononuclear phagocytes led to reduced BM CXCL12 levels and the selective downregulation of HSC retention genes in Nestin+ niche cells, and egress of HSCs/progenitors to the bloodstream. Specific depletion of CD169+ macrophages was sufficient to induce HSC/progenitor egress and enhance mobilization induced by a CXCR4 antagonist or G-CSF [287]. Ludin et al. [292] recently identified a previously unknown BM subset of activated monocyte/macrophages that expressed α-smooth muscle actin (α-SMA) and cyclooxygenase (COX-2). These myeloid cells were adjacent to HSC/HPCs and were radio-resistant and further upregulated COX-2 expression under stress conditions [292]. The upregulated COX-2 produced sufficient PGE2 to counteract HSC exhaustion during alarm situations by limiting the production of ROS via inhibition of the kinase Akt, and producing higher stromal cell expression of CXCL12, which is essential for stem cell quiescence [292].

Endosteal niche

Dexter et al. [188] were the first to demonstrate that *in vitro* hematopoietic cell cultures were able to sustain primitive cells only in the presence of a bone marrow stromal feeder layer. Studies in the 1970s using the CFU-S assay indicated that these stem-like cells are localized close to the endosteal bone surface, while differentiated cells move toward the central axis of the marrow [293]. Subsequently, the concept of a stem cell niche was first proposed by Schofield [295], who laid out the basic concepts of a stem cell niche as a defined anatomic site where HSCs could be sustained and reproduce and where differentiation was inhibited. A niche had a limited space that also limited the numbers of HSC and was a place where reversion to an HSC phenotype could be induced in a slightly more mature cell type. Only the latter observation remains controversial.

Long-term bromodeoxyuridine (BrdU)-label-retaining cells reside in the hypoxic areas distant from the endothelial-lined microvasculature and sinusoidal blood vessels of the bone marrow and closely attached to the non-endothelial extracellular matrix of the trabecular endosteum (Fig. 47.4). A similar spatial distribution of HSCs was observed near the endosteal region by 15

hours after bone marrow transplantation [296]. Subsequent studies using live microscopy techniques and genetic manipulations identified the endosteal region of the BM as a preferential site of residence for the most potent HSC with serial transplantation potential [297]. As discussed in the next section, opposite results were obtained by Kiel et al. [60]. Both CD105+Thy-1- and CD146+ mesenchymal cells have been shown to produce reticular and endosteal components of the endosteal reguion [138]. Osteoblasts and their progenitors lining the trabecular bone surfaces within the BM cavity can modulate the activity of HSCs and have been considered critical cellular elements of an 'endosteal' or 'osteoblastic' niches [297–297b]. Osteoblasts support the maintenance of long-term culture-initiating cells (LTC-IC) *in vitro* by produce factors that have the ability to regulate quiescence and maintenance of HSCs [298–298a].

Osteopontin is a niche component that negatively regulates stem cell pool size [299]. SDF1 (CXCL12) binds to its receptor CXCR4 expressed on HSCs and various progenitors, and has a multifaceted role in regulating HSC migration from, or homing to, BM niches. G-CSF induces stem cell mobilization by decreasing bone marrow SDF-1 and upregulating CXCR4 [177]. Low levels of calcium, detected by calcium-sensing membrane receptors in the parathyroid stimulate the release of parathyroid hormone (PTH) that increases the number and activity of osteoclasts to release calcium from bone, and thus stimulates bone resorption. Receptor activator of NF-kappa B ligand (RANKL)-activated osteoclasts, decreases the expression of CXCL-12, osteopontin and c-Kit ligand (KL, also known as stem cell factor -SCF) in the endosteum, and caused the egress of HSCs from the niche [178]. Hematopoiesis is severely altered in mice with an induced osteoblast deficiency [300] whereas expression of constitutively active PTH/parathyroid hormone-related protein (PTHrP) receptor increased trabecular osteoblast numbers, which caused an expansion of LT-HSC [301].

Angiopoietin-1 (Angpt1) signaling via the Tie2 receptor regulates vascular and hematopoietic systems and regulates HSC quiescence in the bone marrow niche [302]. Enhanced Angpt1-Tie2 signaling affects the differentiation capacity of hematopoietic lineages during development and increases the repopulation ability of HSCs [303]. However, heterogeneous cell populations were found in endosteal regions that included mature bone lining cells, osteoblasts, and preosteoblasts (reviewed in reference [304]). Moreover, endosteal regions are highly vascularized [305] raising the possibility that vascular structures, in addition to osteoblasts, could also participate in the endosteal niche.

Vascular and perivascular niches

In addition to endosteal cells, other cell types likely participate in the regulation of HSCs, and more recent studies have pointed to the possibility of a vascular niche for HSCs. The observation that HSCs also reside at a distance from the endosteum triggered the concept of the vascular niche as alternative niche in BM [60,306]. Analyses of BM sections using SLAM family markers (CD150+CD244−CD48−CD41−) showed that about 60% of SLAM family HSCs were localized in the vicinity of sinusoidal endothelial cells (SECs) suggesting the presence of an additional niche in the vascular area [60,306] (Fig. 47.4). Interestingly, the majority (95%) of perisinusoidal HSCs was located within a five cell layer of the sinusoidal endothelium; in contrast only 8–20% of HSCs were located within a corresponding distance of the endosteum [60]. Additional evidence for the vascular niche was provided from a study using the GFP reporter in the CXCL12 locus [307]. The study identified a specific population of CXCL12-abundant reticular (CAR) cells that secreted high levels of CXCL12, that interacted with over 90% of the HSCs Xie. CAR cell constitute the subendothelial (adventitial) layer of sinusoidal walls projecting a reticular process that is in close contact with HSCs [308] (Fig. 47.4). CXCL12 release from BM stromal cells to the circulation emerges as a pivotal mechanism essential for steady state egress and rapid mobilization of HSC and hematopoietic progenitor cells, but not mature leukocytes [309]. Neutralizing antibodies against CXCR4 or CXCL12 inhibited both steady state and AMD3100-induced CXCL12 release and reduced

egress of murine HSC. Norepinephrine treatment, mimicking acute stress, rapidly increased CXCL12 release and HSC mobilization, whereas β2-adrenergic antagonist inhibited both steady state and AMD3100-induced CXCL12 release and HSC mobilization [309].

Previous data had already supported important interactions between the BM vascularity and hematopoietic progenitors. A number of studies have shown that endothelial cells are as capable as MSC stromal cells in supporting the long-term maintenance of HSCs *in vitro* [310−314a]. Endothelial disruption resulted in impaired thrombopoiesis under physiologic and stress conditions and Tpo is one of the critical regulators of HSC self-renewal [315]. Studies have also revealed that HSCs are localized differentially in the niches with respect to their distinct functional status, and that the biological activity of each niche is differentially influenced by extrinsic conditions (reviewed in reference [284]). Using a combination of confocal microscopy and video imaging, Lo Celso et al. [316] determined the spatial fate of transplanted hematopoietic cells and demonstrated that osteoblasts are surrounded by microvessels. They concluded that the endosteal niche is indeed perivascular (reviewed in references [317,318]). The above studies lend support to the concept of a vascular niche for HSCs. Hooper et al. [319] used a combination of immunohistochemistry on BM sections and polyvariate flow cytometry on bone marrow cells using VEGFR3 and Sca1 to distinguish the BM arterioles from SECs. They showed that SEC marker expression is unique and does not overlap with osteoblastic or hematopoietic cells. BM SECs are localized in close proximity to osteoblasts, suggesting that endosteal and vascular niches may not be distinct, as previously proposed models suggested.

Ding et al. [320] found perivascular cells throughout the BM expressed c-Kit ligand. HSC frequency and function were not affected when KL was conditionally deleted from hematopoietic cells, osteoblasts or Nestin-expressing stromal cells. However, HSCs were depleted from BM when KL was deleted from endothelial cells or leptin receptor (Lepr)-expressing perivascular stromal cells. Most HSCs were lost when KL was deleted from both endothelial and Lepr-expressing perivascular cells [320]. Within the BM, the c-Kit-expressing HSCs were positioned in proximity to Kit ligand (KL)-expressing niche cells [321−321a]. This c-Kit-mediated cellular adhesion was essential for long-term maintenance and expansion of HSCs. Conditional deletion of c-Kit resulted in hematopoietic failure and splenic atrophy both at steady state and after marrow ablation leading to the demise of the treated adult mice [321]. Thus, HSCs reside in a perivascular niche in which multiple cell types express factors that promote HSC maintenance.

Murine SLAM CD150-expressing HSC localize in various sites after *in vivo* injection, including endothelial niches provided by the sinusoids of spleen and BM, as well as endosteal niches [60,321b] (Fig. 47.4). The presence of the glycosaminoglycan hyaluronic acid on HSC appears critical for the spatial distribution of transplanted HSCs *in vivo* [298a]. Furthermore, binding of hyaluronic acid by a surrogate ligand results in marked inhibition of HSC proliferation and granulocyte differentiation. A unique feature of the bone niche for HSCs is the high concentration of calcium ions at the endosteal surface. HSCs express a calcium-sensing receptor (CaR), and mice deficient in CaR had normal numbers of HSCs in the fetal liver, but were highly deficient in HSCs localizing to the endosteal niche [322]. Further evidence for the importance of the osteoblast niche has been provided by studies in mice with genetic modifications leading to increased numbers of osteoblasts. Mice with constitutively activated parathyroid receptors have enhanced numbers of osteoblasts associated with a doubling of BM Sca-1+c-Kit+Lin− cells and increased LTC-IC and long-term repopulating HSCs [301]. Osteoblasts with activated receptors produced high levels of the Notch ligand Jagged 1 which may be responsible for HSC expansion, since HSC expansion was abrogated following treatment with a gamma secretase inhibitor that blocked Notch activation.

Mutant mice with conditional inactivation of the BMP receptor 1A had an increase in the number of spindle-shaped N-cadherin+, CD45- osteoblasts [262]. This was linked to a

2.4-fold increase in quiescent HSC and competitive repopulating cells in the marrow. β-catenin forms a complex with N-cadherin and this interact may play a role in retaining HSC in osteoblastic niches (Fig. 47.4). c-Myc was also reported to control the balance between HSC self-renewal and differentiation, possibly by regulating the interaction between HSCs and their niches (reviewed in references 323–325). Conditional elimination of c-Myc activity in BM resulted in severe cytopenia, and accumulation of self-renewing HSCs *in situ* with impaired differentiation. The c-Myc deficient HSC appear trapped in stem cell niches, possibly due to upregulation of N-cadherin and a number of adhesion molecules [324,325]. Enforced c-Myc expression in HSC repressed N-cadherin and integrins leading to loss of self-renewal at the expense of differentiation. The role of the cell adhesion molecule N-cadherin in HSC maintenance has been controversial. Some studies reported that N-cadherin was expressed in HSCs and played a critical role in the regulation of HSC engraftment (reviewed in reference [326]).

Overexpression of N-cadherin in HSCs was claimed to promote quiescence and preserved HSC activity during serial BM transplantation, and inhibition of N-cadherin by the transduction of N-cadherin shRNA was reported to reduce the lodgment of donor HSCs to the endosteal surface, resulting in a significant reduction in long-term engraftment. shN-cadherin-transduced cells were maintained in the spleen for six months after BM transplantation, indicating that N-cadherin expression in HSCs may be specifically required only in the BM (reviewed in reference [326]). However, the consensus is that HSCs do not depend on N-cadherin to regulate their maintenance [306,327–329]. Greenbaum et al. [327] conditionally deleted N-cadherin in osteoblasts, and showed that basal hematopoiesis, HSC number, cell cycle status, long-term repopulating activity and self-renewal capacity were normal. These mice responded normally to G-CSF and engraftment of wild-type cells into N-cadherin-deleted recipients was normal. Thus N-cadherin expression in osteoblast lineage cells is dispensable for HSC maintenance in mice. Bromberg et al. [328] also used a murine model in which deletion of N-cadherin had been targeted to cells of the osteoblastic lineage. This resulted in an age-dependent bone phenotype, ultimately characterized by decreased mineralized bone, but there was no difference in steady state HSC numbers or function at any time tested, and recovery from myeloablative injury was normal.

Gomes et al. [330] demonstrated that hypercholesterolemia in mice for 30 days induces dramatic alterations in hematopoiesis through CXCL12-mediated enhanced interaction of the hematopoietic cells with specialized BM sinusoidal endothelial cells. This results in thrombocytosis, lymphocytosis, and increased mobilization of HSC and progenitor cells to the peripheral circulation, possibly contributing to atherosclerosis.

The extracellular matrix (ECM) is a major anatomical component of the hematopoietic microenvironment of the BM niches and comprises fibrous proteins, such as types I and IV collagen and fibronectin (FN), and non-fibrous proteins, such as tenascin-C (TN-C). The expression of tenascin-C (TN-C) is dramatically upregulated in stromal cells and endothelial cells during hematopoietic recovery after myeloablation [331]; reviewed in reference [280]. TN-C expression is limited to the endosteal regions and functions by binding with high affinity to specific integrins such as integrin α9 or to other matrix proteins such as FN. TN-C stimulates proliferation of HSCs in an integrin α9-dependent manner and upregulates the expression of the cyclins (cyclinD1 and cyclinE1) and downregulates the expression of the cyclin-dependent kinase inhibitors [p57(Kip2), p21(Cip1), p16(Ink4a)]. Mice lacking TN-C showed normal steady state hematopoiesis; however, they failed to reconstitute hematopoiesis after BM ablation and showed high lethality [331].

A quiescent state is probably critical for the maintenance of HSCs (reviewed in reference [332]). HSCs expressing the Tie2 receptor are quiescent, anti-apoptotic and comprise a side population that adheres to osteoblasts in the BM niche [302]. The Tie-2 ligand, angiopoietin-1, induced HSC quiescence, their adherence to the endosteal surface, cobblestone formation and

retention of long-term repopulating activity. Disruption of gp130 in Tie-2 expressing cells resulted in dilatation of the vascular sinusoids and BM dysfunction [333]. This phenotype was reproduced when wild-type hematopoietic cells were transplanted into gp130$^{-/-}$ mice, indicating their microenvironmental origin in endothelial components [333].

The matrix glycoprotein, osteopontin (OPN), acts as a negative regulatory restraining factor on HSC within the osteoblast niche [299,334]. Osteoblasts at the endosteal bone surface produce varying amounts of osteopontin in response to stimulation and HSC specifically bind to OPN via β1 integrin. Exogenous OPN potently suppresses the proliferation of HSC *in vitro* and OPN-deficient mice have increased numbers of HSC with markedly enhanced cycling.

Using a combination of confocal microscopy and video imaging Lo Celso et al. [316] determined the spatial fate of transplanted hematopoietic cells, demonstrated that osteoblasts are surrounded by microvessels and concluded that the endosteal niche is indeed perivascular (reviewed in reference [317]). The above studies further support the concept of a vascular niche for HSCs. Hooper et al. [319] used a combination of immunohistochemistry on BM sections and polyvariate flow cytometry on bone marrow cells using VEGFR3 and Sca1 to distinguish the BM arterioles from SECs. This SEC phenotype was unique and did not overlap with that of the osteoblastic or hematopoietic cells [316]. Since the BM SECs are localized in close proximity to osteoblasts, it would suggest that endosteal and vascular niches are not as distinct as previously proposed models have suggested.

CONCLUSION

The current dogma recognizes that specific factors determine specific cell fates, ranging from stem cell (HSC) self-renewal through commitment to common myeloid (CMP) or common lymphoid progenitors (CLP) to lineage restricted progenitor differentiation. A contrary hypothesis to current dogma recognizes that HSC fate may instead be governed by (small) quantitative shifts in the relative activation of known signaling pathways [335]. Alterations in the relative levels of pathway activation may arise from dynamic shifts in the expression of signaling components (e.g., receptors, ligands). As extracellular conditions vary over small ranges, cells are induced to overcome signaling threshold barriers, and as a consequence, adopt new, stable cell fates. *Ex vivo* HSC culture systems can be manipulated:

1) Quantitatively, e.g., by varying the magnitude of signaling pathway activation influencing cell fate decisions;
2) Temporally, e.g., be defining windows of opportunity for stimulation;
3) Spatially, e.g., by fixed location-dependent signaling (niches).

While there has been remarkable progress over the last five years in increasing our understanding of the nature of HSCs, many questions still remain. The answers may come from in depth analysis of gene expression using RNA deep sequencing and mass Spec-based proteomic strategies that are able to extract data from small cell samples. These methods may be applied to HSC from multiple sources, highly enriched by improvements in multiparameter fluorescence activated cell sorting, and better *in vitro* HSC expansion strategies.
