FOREWORD

Robert Langer

Since the mid-1980s, tissue engineering has moved from a concept to a very significant field. Already we are at the point where numerous tissues, such as skin, cartilage, bone, liver, blood vessels and others, are in the clinic or even approved by regulatory authorities. Many other tissues are being studied. In addition, the advent of human embryonic stem cells has brought forth new sources of cells that are beginning to prove to be useful in a variety of areas of tissue engineering.

This fourth edition of *Principles of Tissue Engineering* examines a variety of important areas. In the introductory section, an important overview on the history and challenges of tissue engineering as well as a chapter on stem cells and the movement of engineered tissues into the clinic is examined. This is followed by an analysis of important areas in cell growth and differentiation including aspects of molecular biology, extracellular matrix interactions, cell morphogenesis, and gene expression and differentiation. Next, *in vitro* and *in vivo* control of tissue and organ development is examined. The involvement of biomaterials in tissue engineering is also addressed. Important aspects of polymers, extracellular matrix, materials processing, novel polymers such as biodegradable polymers as well as micro and nano fabricated scaffolds and three-dimensional scaffolds are discussed. Tissue and cell transplantation including methods of immunoisolation, immunomodulation, and even transplantation in the fetus are analyzed.

As mentioned earlier, stem cells have become an important part of tissue engineering. As such, important coverage of embryonic stem cells, adult stem cells, and postnatal stem cells are examined. Gene therapy is another important area, and both general aspects of gene therapy as well as intracellular delivery of genes and drugs to cells and tissues are discussed. Various important engineered tissues including breast tissue engineering; tissues of cardio vascular systems such as myocardium, blood vessels and heart valves; endocrine organs such as the pancreas and the thymus are discussed, as are tissues of the gastrointestinal system, such as liver and the alimentary tract. Important aspects of the hematopoietic system are analyzed as is the engineering of the kidney and genitourinary system.

Much attention is devoted to the muscular skeletal system including, bone and cartilage regeneration, and tendon and ligament placement. The nervous system is also discussed, including brain implants, and the spinal cord. This is followed by a discussion of the eye where corneal replacement and vision enhancement systems are examined. Oral and dental applications are also discussed as are the respiratory system and skin. The concluding sections of the book cover clinical experience in such areas as cartilage, bone, skin and cardiovascular systems as well as the bladder. Even tissue engineered food is evaluated. Finally, regulatory and ethical considerations are examined.

In sum, the 90 chapters in this third edition of *Principles of Tissue Engineering* examine the important advances in this burgeoning field of tissue engineering. This text will be very useful for scientists, engineers, and clinicians engaging in this important new area of science and medicine.

PREFACE

A lot has happened since the first edition of 'Principles of Tissue Engineering' was published sixteen years ago. Human embryonic stem cells had not yet been discovered. In fact, progress in the field has been so rapid that since the publication of the last edition of this book, the first clinical trials have been carried out using these cells. Indeed, scientists have not only figured out how to reprogram differentiated human cells into induced pluripotent stem (iPS) cells, but a Nobel Prize has already been awarded for the achievement.

The fourth edition of 'Principles' covers all of this recent progress as well as the latest advances in the biology and design of tissues and organs, from mathematical models to clinical reality. It has also been expanded to include the rapidly emerging field of brain-machine interfaces (BMI) for controlling bionic and prosthetic body parts, as well as a new section on the application of tissue engineering techniques for food production, another application of tissue engineering just in its infancy. As in previous editions, the book attempts to simultaneously connect the basic sciences with the potential application of tissue engineering to diseases affecting specific organ systems. While the fourth edition furnishes a much needed update of the rapid progress that has been achieved in the field in the last half decade, we have retained those facts and sections which, while not new, will assist students and general readers in understanding this exciting area of biology and medicine.

The fourth edition of *Principles* is divided into twenty-two parts, an introductory section, and an Epilogue. The organization remains largely unchanged, combining the prerequisites for a general understanding of cellular differentiation and tissue growth and development, the tools and theoretical information needed to design tissues and organs, as well as a presentation by the world's experts of what is currently known about each specific organ system. As in previous editions, we have striven to create a comprehensive book that, on one hand, strikes a balance among the diversity of subjects that are related to tissue engineering, including biology, chemistry, material science, and engineering, among others, while emphasizing those research areas that are likely to be of clinical value in the future.

While we cannot describe all of the new and updated material of the fourth edition, we have expanded and given added emphasis to stem cells, including adult, embryonic, and induced pluripotent stem cells and progenitor populations that may soon lead to new tissue engineering therapies for heart disease, diabetes, and a wide variety of other diseases that afflict humanity. This up-to-date coverage of stem cell biology and other emerging technologies is complemented by two new chapters on the challenges of tissue engineering for food and *in vitro* meat production, which someday may end up a routine part of our food system, potentially reducing environmental pollution and land use. The result is a comprehensive textbook that we believe will be useful to students and experts alike.

Joseph P. Vacanti

PREFACE TO THE THIRD EDITION

The third edition of *Principles of Tissue Engineering* attempts to incorporate the latest advances in the biology and design of tissues and organs and simultaneously to connect the basic sciences — including new discoveries in the field of stem cells — with the potential application of tissue engineering to diseases affecting specific organ systems. While the third edition furnishes a much-needed update of the rapid progress that has been achieved in the field since the turn of the century, we have retained those facts and sections that, while not new, will assist students and general readers in understanding this exciting area of biology.

The third edition of 'Principles' is divided into 22 parts plus an introductory section and an epilogue. The organization remains largely unchanged from previous editions, combining the prerequisites for a general understanding of tissue growth and development, the tools and theoretical information needed to design tissues and organs, and a presentation by the world's experts on what is currently known about each specific organ system. As in previous editions, we have striven to create a comprehensive book that, on one hand, strikes a balance among the diversity of subjects that are related to tissue engineering, including biology, chemistry, materials science, and engineering, while emphasizing those research areas likely to be of clinical value in the future.

No topic in the field of tissue engineering is left uncovered, including basic biology/mechanisms, biomaterials, gene therapy, regulation and ethics, and the application of tissue engineering to the cardiovascular, hematopoietic, musculoskeletal, nervous, and other organ systems. While we cannot describe all of the new and updated material of the third edition, we can say that we have expanded and given added emphasis to stem cells, including adult and embryonic stem cells, and progenitor populations that may soon lead to new tissue engineering therapies for heart disease, diabetes, and a wide variety of other diseases that afflict humanity. This up-to-date coverage of stem cell biology and other emerging technologies is complemented by a series of new chapters on recent clinical experience in applying tissue engineering. The result is a comprehensive book that we believe will be useful to students and experts alike.

PREFACE TO THE SECOND EDITION

The first edition of this textbook, published in 1997, was rapidly recognized as the comprehensive textbook of tissue engineering. This edition is intended to serve as a comprehensive text for the student at the graduate level or the research scientist/physician with a special interest in tissue engineering. It should also function as a reference text for researchers in many disciplines. It is intended to cover the history of tissue engineering and the basic principles involved, as well as to provide a comprehensive summary of the advances in tissue engineering in recent years and the state of the art as it exists today.

Although many reviews had been written on the subject and a few textbooks had been published, none had been as comprehensive in its defining of the field, description of the scientific principles and interrelated disciplines involved, and discussion of its applications and potential influence on industry and the field of medicine in the future as the first edition.

When one learns that a more recent edition of a textbook has been published, one has to wonder if the base of knowledge in that particular discipline has grown sufficiently to justify writing a revised textbook. In the case of tissue engineering, it is particularly conspicuous that developments in the field since the printing of the first edition have been tremendous. Even experts in the field would not have been able to predict the explosion in knowledge associated with this development. The variety of new polymers and materials now employed in the generation of engineered tissue has grown exponentially, as evidenced by data associated with specialized applications. More is learned about cell/biomaterials interactions on an almost daily basis. Since the printing of the last edition, recent work has demonstrated a tremendous potential for the use of stem cells in tissue engineering. While some groups are working with fetal stem cells, others believe that each specialized tissue contains progenitor cells or stem cells that are already somewhat committed to develop into various specialized cells of fully differentiated tissue.

Parallel to these developments, there has been a tremendous 'buy in' concerning the concepts of tissue engineering not only by private industry but also by practicing physicians in many disciplines. This growing interest has resulted in expansion of the scope of tissue engineering well beyond what could have been predicted five years ago and has helped specific applications in tissue engineering to advance to human trials.

The chapters presented in this text represent the results of the coordinated research efforts of several hundred scientific investigators internationally. The development of this text in a sense parallels the development of the field as a whole and is a true reflection of the scientific cooperation expressed as this field evolves.

Robert Lanza

Robert Langer

Joseph Vacanti

PREFACE TO THE FIRST EDITION

Although individual papers on various aspects of tissue engineering abound, no previous work has satisfactorily integrated this new interdisciplinary subject area. *Principles of Tissue Engineering* combines in one volume the prerequisites for a general understanding of tissue growth and development, the tools and theoretical information needed to design tissues and organs, as well as a presentation of applications of tissue engineering to diseases affecting specific organ system. We have striven to create a comprehensive book that, on the one hand, strikes a balance among the diversity of subjects that are related to tissue engineering, including biology, chemistry, materials science, engineering, immunology, and transplantation among others, while, on the other hand, emphasizing those research areas that are likely to be of most value to medicine in the future.

The depth and breadth of opportunity that tissue engineering provides for medicine is extraordinary. In the United States alone, it has been estimated that nearly half-a-trillion dollars are spent each year to care for patients who suffer either tissue loss or end-stage organ failure. Over four million patients suffer from burns, pressure sores, and skin ulcers, over twelve million patients suffer from diabetes, and over two million patients suffer from defective or missing supportive structures such as long bones, cartilage, connective tissue, and intervertebral discs. Other potential applications of tissue engineering include the replacement of worn and poorly functioning tissues; as exemplified by aged muscle or cornea; replacement of small caliber arteries, veins, coronary, and peripheral stents; replacement of the bladder, ureter, and fallopian tube; and restoration of cells to produce necessary enzymes, hormones, and other bioactive secretory products.

Principles of Tissue Engineering is intended not only as a text for biomedical engineering students and students in cell biology, biotechnology, and medical courses at advanced undergraduate and graduate levels, but also as a reference tool for research and clinical laboratories. The expertise required to generate this text far exceeded that of its editors. It represents the combined intellect of more than eighty scholars and clinicians whose pioneering work has been instrumental to ushering in this fascinating and important field. We believe that their knowledge and experience have added indispensable depth and authority to the material presented in this book and that in the presentation, they have succeeded in defining and capturing the sense of excitement, understanding, and anticipation that has followed from the emergence of this new field, tissue engineering.

INTRODUCTION

From the beginning, humans have yearned for a better existence for themselves, those they love, and for the human race. We have always sought ways to improve the human condition. Injury, disease and congenital malformation have always been part of the human experience. If only damaged bodies could be restored, life could go on for loved ones, as though tragedy had not intervened. In recorded history, this desire was first manifested through myth and magic as in the Greek legend of Prometheus and eternal liver regeneration. Then legend gave way to miracles with the creation of Eve in 'Genesis', or the miraculous transplantation of a limb by the Saints Cosmos and Damien. With the introduction of the scientific method came new understanding of the natural world. The methodical unraveling of the secrets of biology was coupled with the scientific understanding of disease and trauma. Artificial or prosthetic materials for replacing limbs, teeth and other tissues resulted in the partial restoration of lost function. Also the concept of using one tissue as a replacement for another was developed.

In the sixteenth century, Tagliacozzi of Bologna, Italy reported in his work 'Decusorum Chirurgia per Insitionem' a description of a nose replacement that he constructed from a forearm flap. In the nineteenth century, through the scientific understanding of the germ theory of disease and the introduction of sterile technique, modern surgery had its emergence. The advent of anesthesia by the mid-nineteenth century enabled the rapid evolution of many surgical techniques. With anesthetized patients, innovative and courageous surgeons could save lives by examining and treating internal areas of the body: the thorax, the abdomen, the brain, and the heart. Initially, surgical techniques were primarily extirpative — for example, removal of tumors, bypass of the bowel in the case of intestinal obstruction, and repair of life-threatening injuries. Maintenance of life without regard to the crippling effects of tissue loss or the psychosocial impact of disfigurement however was not an acceptable end goal. Techniques that resulted in the restoration of function through structural replacement became integral to the advancement of human therapy.

Now, whole fields of reconstructive surgery have emerged to improve the quality of life by replacing missing function through rebuilding the body's structures. In our current era, modern techniques of transplanting tissue and organs from one individual into another have been revolutionary and lifesaving. The molecular and cellular events of the immune response have been elucidated sufficiently to suppress the response in the clinical setting of

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00001-X

transplantation and to produce prolonged graft survival and function in patients. In a sense, transplantation can be viewed as the most extreme form of reconstructive surgery; transferring tissue from one individual into another. As with any successful undertaking, new problems have emerged. Techniques using implantable foreign body materials have produced dislodgment, infection at the foreign body/tissue interface, fracture, and migration over time. Techniques moving tissue from one position to another position have produced biologic changes because of the abnormal interaction of the tissue in its new location. For example, diverting urine into the colon can produce fatal colon cancers 20—30 years later. Making esophageal tubes from the skin can result in skin tumors 30 years later. Using intestine for urinary tract replacement can result in severe scarring and obstruction over time.

Transplantation from one individual into another, although very successful, has severe constraints. The major problem is accessing enough tissue and organs for all of the patients who need them. As of this writing in 2012, 115,940 people are on transplant waiting lists in the United States, and many will die while waiting for available organs. Also, problems with the immune system produce chronic rejection and destruction over time. Creating an imbalance of immune surveillance from immunosuppression can cause new tumor formation. The constraints have produced a need for new solutions to provide needed tissue.

It is within this context that the field of tissue engineering has emerged. In essence, new and functional living tissue is fabricated using living cells, which are usually associated in one way or another with a matrix or scaffolding to guide tissue development. New sources of cells, including many types of stem cells, have been identified in the past few years, igniting new interest in the field. In fact, the emergence of stem cell biology has led to a new term; regenerative medicine.

Progress in this field has been so rapid that the 2012 Nobel Prize in Physiology or Medicine was awarded to Drs. Gurdon and Yamanaka for their insights into re-programming of cells and for the production of induced pluripotent stem cells (iPS cells). The last edition of this book had no mention of this technology — such has been the progress.

Scaffolds can be natural, man-made, or a composite of both. A major advance in scaffolding has occurred with the description of gentle decellularization of vital organs with preservation of the architecture of the vascular supply by Harald Ott and colleagues. By perfusion through the skeleton of blood vessels in a bioreactor, cells can be reintroduced and therefore re-animate the organ before transplantation. Again, this technology was not described in our last edition. Living cells can migrate into the implant after implantation, or can be associated with the matrix in cell culture before implantation. Such cells can be isolated as fully differentiated cells of the tissue they are hoped to recreate, or they can be manipulated to produce the desired function when isolated from other tissues or stem cell sources. Conceptually, the application of this new discipline to human health care can be thought of as a refinement of previously defined principles of medicine. The physician has historically treated certain disease processes by supporting nutrition, minimizing hostile factors, and optimizing the environment so that the body can heal itself.

In the field of tissue engineering, the same thing is accomplished on a cellular level. The harmful tissue is eliminated; the cells necessary for repair are then introduced in a configuration which optimizes the survival of the cells in an environment that will then permit the body to heal itself. Tissue engineering offers an advantage over cell transplantation alone, in that organized three-dimensional functional tissue is designed and developed. This chapter summarizes some of the challenges that must be resolved before tissue engineering can become part of the therapeutic armamentarium of physicians and surgeons. Broadly speaking, the challenges are scientific and social.

SCIENTIFIC CHALLENGES

As a field, tissue engineering has been defined for barely two decades. As in any new undertaking, its roots are firmly implanted in what went before. Any discussion of when

the field began is inherently fuzzy. Much still needs to be learned and developed to provide a firm scientific basis for therapeutic application. To date, much of the progress in this field has been related to the development of model systems, which have suggested a variety of approaches. Also, certain principles of cell biology and tissue development have been delineated. The field can draw heavily on the explosion of new knowledge from several interrelated well-established disciplines, and in turn, may promote the coalescence of relatively new, related fields to achieve their potential. The rate of new understanding of complex living systems has been explosive in the past three decades. Tissue engineering can draw on the knowledge gained in the fields of cell and stem cell biology, biochemistry, and molecular biology and apply it to the engineering of new tissues. Likewise, advances in materials science, chemical engineering, and bioengineering allow the rational application of engineering principles to living systems. Yet another branch of related knowledge is the area of human therapy as applied by surgeons and physicians. In addition, the fields of genetic engineering, cloning, and stem cell biology may ultimately develop hand in hand with the field of tissue engineering in the treatment of human disease, each discipline depending on developments in the others.

We are in the midst of a biologic renaissance. Interactions of the various scientific disciplines can elucidate not only the potential direction of each field of study, but also the right questions to address. The scientific challenge in tissue engineering lies both in understanding cells and their mass transfer requirements and the fabrication of materials to provide scaffolding and templates.

CELLS

If we postulate that living cells are required to fabricate new tissue substitutes, much needs to be learned in regard to their behavior in two normal circumstances — namely, normal development in morphogenesis and normal wound healing. In both of these circumstances, cells create or recreate functional structures using pre-programmed information and signaling. Some approaches to tissue engineering rely on guided regeneration of tissue using materials that serve as templates for ingrowth of host cells and tissue. Other approaches rely on cells that have been implanted as part of an engineered device. As we understand normal developmental and wound healing gene programs and cell behavior, we can use them to our advantage in the rational design of living tissues.

Acquiring cells for creation of body structures is a major challenge, the solution of which continues to evolve. The ultimate goal in this regard — the large-scale fabrication of structures — may be to create large cell banks composed of universal cells that would be immunologically transparent to an individual. These universal cells could be differentiated cell types that could be accepted by an individual or could be stem cell reservoirs, which could respond to signals to differentiate into differing lineages for specific structural applications. Much is already known about stem cells and cell lineages in the bone marrow and blood. Studies suggest that progenitor cells for many differentiated tissues exist within the marrow and blood, and may very well be ubiquitous. Our knowledge of the existence and behavior of such cells in various mesenchymal tissues (muscle, bone and cartilage), endodermally derived tissues (intestine and liver), or ectodermally derived tissues (nerves, pancreas, and skin) expands on a daily basis.

The recent description of iPS cells is so promising that they may be the holy grail of therapeutic stem cells in unlimited numbers and with patient specificity to be immunologically neutral. These cells also avoid the ethical and regulatory pitfalls of embryonic stem cells. Much remains to be learned, but data continues to be positive.

As intermediate steps, tissue can be harvested as allograft, autograft, or xenograft. The tissues can then be dissociated and placed into cell culture, where proliferation of cells can be initiated. After expansion to the appropriate cell number, the cells can then be transferred to

templates, where further remodeling can occur. Which of these strategies are practical and possibly applicable in humans remains to be explored.

Large masses of cells for tissue engineering need to be kept alive, not only *in vitro* but also *in vivo*. The design of systems to accomplish this, including *in vitro* flow bioreactors and *in vivo* strategies for maintenance of cell mass, presents an enormous challenge towards which significant advances have been made. The fundamental biophysical constraint of mass transfer of living tissue needs to be understood and dealt with on an individual basis as we move toward human application.

MATERIALS

There are so many potential applications to tissue engineering that the overall scale of the undertaking is enormous. The field is ripe for expansion, and requires training of a generation of materials scientists and chemical engineers.

The optimal chemical and physical configurations of new biomaterials as they interact with living cells to produce tissue-engineered constructs are under study by many research groups. These biomaterials can be permanent or biodegradable. They can be naturally occurring, synthetic or hybrid materials. They need to be developed to be compatible with living systems or with living cells *in vitro* and *in vivo*. Their interface with the cells and the implant site must be clearly understood so that the interface can be optimized. Their design characteristics are major challenges for the field, and should be considered at a molecular chemical level. Systems can be closed, semi-permeable, or open. Each design should factor in the specific replacement therapy considered. Design of biomaterials can also incorporate the biologic signaling that the materials may offer. Examples include release of growth and differentiation factors, design of specific receptors and anchorage sites, and three-dimensional site specificity using computer-assisted design and manufacture techniques. New nanotechnologies have been incorporated to design systems of extreme precision. Combining computational modeling with nano-fabrication can produce microfluidic circulations to nourish and oxygenate new tissues.

GENERAL SCIENTIFIC ISSUES

As new scientific knowledge is gained, many conceptual issues need to be addressed. Related to mass transfer is the fundamental problem associated with nourishing tissue of large mass as opposed to tissue with a relatively high ratio of surface area to mass. Also, functional tissue equivalents necessitate the creation of composites containing different cell types. For example, all tubes in the body are laminated tubes composed of a vascularized mesodermal element such as smooth muscle, cartilage, or fibrous tissue. The inner lining of the tube, however, is specific to the organ system. Urinary tubes have a stratified transitional epithelium. The trachea has a pseudostratified columnar epithelium. The esophagus has an epithelium that changes along the gradient from mouth to stomach. The intestine has an enormous, convoluted surface area of columnar epithelial cells that migrate from a crypt to the tip of the villus. The colonic epithelium is, again, different for the purposes of water absorption and storage.

Even the well-developed manufacture of tissue-engineered skin used only the cellular elements of the dermis for a long period of time. Attention is now focusing on creating new skin, consisting of both the dermis and its associated fibroblasts, as well as the epithelial layer consisting of keratinocytes. Obviously, this is a significant advance, but for truly 'normal' skin to be engineered, all of the cellular elements should be contained, so that the specialized appendages can be generated as well. These 'simple' composites will indeed prove to be quite complex and require intricate designs. Thicker structures with relatively high ratios of surface area to mass, such as liver, kidney, heart, breast, or central nervous system, will offer engineering challenges.

Currently, studies for developing and designing materials in three-dimensional space are being developed utilizing both naturally occurring and synthetic molecules. The applications of computer-assisted design and manufacture techniques to the design of these matrices are critically important. Transformation of digital information obtained from magnetic resonance scanning or computerized tomography scanning can then be developed to provide appropriate templates. Some tissues can be designed as universal tissues that will be suitable for any individual, or may be custom-developed tissues specific to one patient. An important area for future study is the entire field of neural regeneration, neural ingrowth, and neural function toward end organ tissues such as skeletal or smooth muscle. Putting aside the complex architectural structure of these tissues, the cells contained in them have a very high metabolic requirement. As such, it is exceedingly difficult to isolate a large number of viable cells. An alternate approach may be the use of less mature progenitor cells, or stem cells, which not only would have a higher rate of survival as a result of their lower metabolic demand, but also would be more able to survive the insult and hypoxic environment of transplantation. As stem cells develop and require more oxygen, their differentiation may stimulate the development of a vascular complex to nourish them. The understanding of and solutions to these problems are fundamentally important to the success of any replacement tissue that needs ongoing neural interaction for maintenance and function.

It has been shown that some tissues can be driven to completion *in vitro* in bioreactors. However, optimal incubation times will vary from tissue to tissue. Even so, the new tissue will require an intact blood supply at the time of implantation for successful engraftment and function.

Finally, all of these characteristics need to be understood in the fourth dimension of time. If tissues are implanted in a growing individual, will the tissues grow at the same rate? Will cells taken from an older individual perform as young cells in their new 'optimal' environment? How will the biochemical characteristics change over time after implantation? Can the strength of structural support tissues such as bone, cartilage, and ligaments be improved in a bioreactor in which force vectors can be applied? When is the optimal timing of this transformation? When does tissue strength take over the biochemical characteristics as the material degrades?

SOCIAL CHALLENGES

If tissue engineering is to play an important role in human therapy, in addition to scientific issues, fundamental issues that are economic, social, and ethical in nature will arise. Something as simple as a new vocabulary will need to be developed and uniformly applied. A universal problem is funding. Can philanthropic dollars be accessed for the purpose of potential new human therapies? Will industry recognize the potential for commercialization and invest heavily? If this occurs, will the focus be changed from that of a purely academic endeavor? What role will governmental agencies play as the field develops? How will the field be regulated to ensure its safety and efficacy prior to human application? Is the new tissue to be considered transplanted tissue and, therefore, not be subject to regulation, or is it a pharmaceutical that must be subjected to the closest scrutiny by regulatory agencies? If lifesaving, should the track be accelerated toward human trials?

There are legal ramifications of this emerging technology as new knowledge is gained. What becomes proprietary through patents? Who owns the cells that will be sourced to provide the living part of the tissue fabrication?

In summary, one can see from this brief overview that the challenges in the field of tissue engineering remain significant. All can be encouraged by the progress that has been made in the past few years, but much discovery lies ahead. Ultimate success will rely on the dedication, creativity, and enthusiasm of those who have chosen to work in this exciting but still

unproved field. Quoting from the epilogue of the previous edition; 'At any given instant in time, humanity has never known so much about the physical world and will never again know so little.'

CHAPTER 2

The Challenge of Imitating Nature

Robert M. Nerem[1] and Stacey C. Schutte[2]
[1] Parker H. Petit Institute for Bioengineering and Bioscience, Georgia Institute of Technology, Georgia
[2] Department of Gynecology and Obstetrics, Emory University School of Medicine, Atlanta, Georgia

INTRODUCTION

Since the first author on this chapter wrote in the first edition of this book about 'the challenge of imitating nature', the field of tissue engineering has evolved considerably, into what many now call regenerative medicine [1]. This original chapter was written in the late 1990s, when stem cell research was just beginning to accelerate. Since then our knowledge of stem cells and also progenitor cells has greatly expanded, and we now are in a much better position to develop clinical therapies. As was stated then, through the imitation of nature this field has the potential to confront the transplantation crisis, i.e., the crisis caused by the shortage of donor tissues and organs. Data from the Organ Procurement and Transplantation Network indicates that there are more than 110,000 patients in the US waiting for organs, and in contrast in 2011 there were only 28,000 transplantation procedures performed. Compared to 20 years earlier, this represents a four-fold increase in the number of patients on the waiting list for an organ transplant and not even a two-fold increase in transplantation procedures. Perhaps even more important than addressing the transplantation crisis is that, through the imitation of nature, there is the potential for tissue engineering and regenerative medicine to address important, but currently untreatable patient needs. This may be the 'holy grail' for this field; however, if we are to be successful in this, there are a variety of issues that need to be faced.

An underlying premise of this field of tissue engineering and regenerative medicine is that the utilization of the natural biology of the system will allow for greater success in developing therapeutic strategies aimed at the replacement, maintenance, and/or repair of tissue and organ function. Another way of saying this is that just maybe the great creator, in whatever form one believes he or she exists, knows something that we mere mortals do not, and if we can only 'tap' into a small part of this knowledge base, if we can only imitate nature in some small way, then we will be able to achieve greater success in our efforts to address patient needs. It is this challenge of imitating nature that has been accepted by those who are providing leadership to this new area of technology originally called tissue engineering [2,3]. To imitate nature requires that we first understand the basic biology of the tissues and organs of interest, including developmental biology; with this we then can develop methods for the control of these biological processes; and based on the ability to control, we finally can develop strategies either for the engineering of living tissue substitutes or for the fostering of tissue repair or regeneration.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00002-1

It should be noted that the concept of a more biologic approach dates back more than 70 years [4]. Since then there has been a large expansion in research efforts in this field, and a considerable recognition of the enormous potential that exists. With this hope, there also has been a lot of hype; however, the future long term remains bright [5,6]. As the technology has become further developed, an industry has begun to emerge. This industry has been very much a fledgling one, with only a few companies possessing product income streams, largely in the skin and orthopedic area, an industry that the first author of this chapter has referred to in the past as being only 'skin deep'; however, from the 'go-go' years of the 1990s, to the more 'sobering years' at the beginning of this century, and then rebounding to today, there now is extensive industrial activity in progress [7]. More recently it has been estimated that there now are more than 175 products in the regenerative medicine pipeline [8]. These products are in various stages of development; however, at least 125 of these are cell-based. Furthermore, an update on 2008 Lysaght et al. study reports a three-fold growth in commercial sales, with 106 companies employing 14,000 employees [9].

Although research in what we now call tissue engineering began to accelerate more than a quarter of a century ago and there were references to tissue engineering in the early 1980s, the term tissue engineering only took on a 'life of its own' when it was 'coined' in 1987 by Professor Y. C. Fung from the University of California, San Diego — who suggested this name at a National Science Foundation meeting. This led to the first meeting called 'tissue engineering' that was held in early 1988 at Lake Tahoe, California [10]. More recently the term regenerative medicine has come into use. For some this is a 'code word' for stem cell technology, while for others regenerative medicine is the broader term, with tissue engineering representing only replacement, not repair and/or regeneration. Still others use the terms tissue engineering and regenerative medicine interchangeably. Whatever name you choose to use, what is important is that it is a more biologic approach that has the potential to lead to new patient therapies and treatments, in some cases where none are currently available.

Tissue engineering also can be viewed as being at the interface of the traditional medical implant industry and the biological revolution. By harnessing the advances of this revolution there will be an entirely new generation of tissue and organ implants as well as strategies for repair and regeneration. Already we are beginning to see increased investments in this field by the large medical device companies, and there has been in more recent years a recognition that there is a convergence of biologics and devices [11]. There also is an increased interest on the part of the pharmaceutical and biotech industries. Long term there is the potential for a literal revolution in medicine; however, this revolution will only occur if we successfully meet the challenge of imitating nature.

As has already been stated, there are a number of issues that need to be addressed. The fourth edition of this book examines these for a variety of enabling technologies and tissue/organ applications. The purpose of this chapter is thus to 'set the stage'; i.e., to provide a foundation for what is to come later in this book. This starts with the next section of this chapter focusing on the basic paradigm that underlies the different approaches that are being taken.

THE BASIC PARADIGM

Tissue engineering in its evolution to regenerative medicine now comprises replacement, repair and regeneration. It is the concept of replacement that dates back the furthest. In this one fabricates a replacement tissue or organ outside of the body which then is implanted within the body. Some of the initial successes were in this category of replacement. This includes such skin substitutes as Integra, a product of Integra Life Sciences and approved by Food and Drug Administration (FDA) in 1996; Apligraf, a product of Organogenesis approved by FDA in 1997; and Dermagraft, a product of Advanced Tissue Sciences approved by FDA in 1999. Dermagraft is now sold by Advanced Biohealing which has been acquired by Shire Medical. Using

Integra as an example, the research on this approach was published in a journal in 1982 [12]; however, as already noted, FDA approval did not come until 1996, a gap of 14 years. This indicates that this field is not only about patients, but that it also requires patience. Furthermore, although all three of these skin substitutes were developed as a 'replacement', these in fact were wound healing implants and were regulated by the US FDA through the Center for Devices and Radiological Health in the category of wound healing. Thus, they were really in the repair category and not replacement. Today these might well be regulated as biologics, and one can only speculate about the length of time today that would be required for FDA approval.

Of course there will be applications where the best approach will be one of replacement. An example of this is the need for a bioartificial pancreas for patients with Type 1 diabetes. Such an implant is under development, and it would involve cells that are glucose responsive and insulin secreting, encapsulated so as to provide immunoprotection since these in most cases would not be cells from the patient. The cells to be used might in fact be derived from embryonic stem cells. Although such a bioartificial pancreas would not have anywhere near all of the functional characteristics of the normal pancreas, it would be a major step forward. Another example would be the tissue engineering of a heart valve replacement. Here it is the pediatric population for whom the need is critical. If an infant has a heart valve defect and thus needs a replacement, as that infant grows into a child and ultimately an adult, there will need to be a series of surgeries so as to implant a prosthetic valve with an ever-increasing diameter. If one could tissue engineer a heart valve that would grow with the child, this would have a major impact on pediatric patients with heart valve defects.

There of course are other examples where replacement will be the preferred approach; however, for many applications the tissue or organ of interest is just so biologically complex that an approach of repair and/or regeneration might be a better strategy than one of replacement. This leads one to what might be considered a basic paradigm for tissue engineering and regenerative medicine. This is illustrated in Fig. 2.1 where the three 'pillars' are cells, scaffolds, and signals. The cells could be stem cells or progenitor cells or even fully differentiated cells. It might be a combination of cell types, even what might be called a primary cell with a partner cell. The scaffolds could either be made of a synthetic biomaterial or be a natural extracellular matrix. Whatever the scaffold, it might be needed in the fabrication of a replacement tissue or used as a delivery vehicle for the cells being used in a cell therapy. The signals could be a variety of types, including growth factors and chemotactic factors. These signals might be ones secreted by the cells employed; in fact, if one actually knew the signals that are necessary, perhaps one would not need cells as one could simply deliver the right signals, however, such a molecular therapy is long ways from being realized.

It should be noted that one of the most successful tissue-engineered products is the small intestine submucosa (SIS). This extracellular matrix product is porcine derived and acellular in nature. It has been used in a variety of applications including both rotator cuff and hernia repair [13,14]. Here SIS is providing the necessary signals to facilitate repair. To date more than two million patients have been treated.

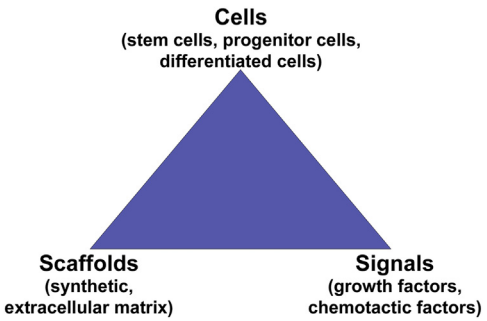

FIGURE 2.1
Illustration of the basic paradigm for tissue engineering and regenerative medicine showing the three 'pillars', i.e., cells, scaffolds, and signals.

If it is the signals that are important, then we need to think about these in a broader way, as the functional characteristics of cells are determined by the cues, i.e., the signals, which make up their microenvironment. This is true *in vivo*, where what might be called 'nature's orchestra' is made up of a 'symphony of signals'. What makes up this symphony? It includes soluble molecules, the extracellular matrix/substrate to which the cells are attached, cell-cell contact, and the mechanical/physical force environment in which the cell resides. Even though everyone recognizes that the *in vivo* microenvironment of a cell is extremely complex, most of the scientific literature does not investigate this 'symphony of signals' but rather is focused on 'soloists', i.e., a single growth factor or a single chemotactic factor. This might be viewed as the reductionist approach, but it does not help us understand the synergy between different signals. It is because of this synergy that we need to go beyond simply understanding 'soloists'. It may be unrealistic to investigate the entire 'symphony' to which cells are exposed, but we at least need to begin to understand how combinations of signals influence cell function. Initially it may not be a symphony that we investigate, but perhaps a 'duet' of signals, maybe even a 'quartet'.

This leads to one final consideration. In learning about 'nature's orchestra' perhaps we should start with what is known about developmental biology. Granted that what we want to do in tissue engineering and regenerative medicine in adults needs to take place on a geometric scale much larger than that in the embryo and with a timescale that will be much shorter. Still, we know that there are species that can regrow their tissues and organs. This has fascinated biologists for at least 200 years; however, for this to happen in a human has always appeared to be in the realm of science fiction. But is it? Perhaps we can learn the nature of the signaling molecules that result in the regeneration of the zebra fish's heart as opposed to the scarring that takes place in the adult human after a major wound. If we can, then we might better understand what the important 'players' are in what we want to do, what we need to do.

The models used in the study of developmental biology are simply one avenue that needs to be focused on in the future. There are other models as well, and these all can contribute to the understanding needed to more fully imitate nature in our therapeutic approaches. These various models are the subject of the next section of this chapter.

MODELING NATURE'S ORCHESTRA

Beyond learning from developmental biology, there are other avenues that need to be pursued by the tissue engineering and regenerative medicine community as it tries to better understand the 'symphony of signals' that are part of nature's orchestra and to address the challenge of imitating nature. This includes learning from those human tissues that do regenerate, the use of animal models, the employment of *in vitro* systems, and also computational approaches. These will be addressed here one by one.

Although most adult human tissues do not repair and/or regenerate, there are examples that in fact do. These include skin and liver, and also in the fetus [15]. For skin, the regenerative process [16] in the adult leads to a recovery of physiological anatomy that is imperfect. In contrast, healing in the early stages of fetal development appears to lead to complete restoration [17]. An entirely unique human tissue that regenerates once a month is the endometrium. It is an amazing tissue in many ways, especially when discussing liver regeneration.

The regenerative capacity of the liver has been known since the time of the ancient Greeks, and the fascination with this remarkable regenerative organ has resulted in a long history of research into the orchestration of liver regeneration. For reviews on liver regeneration see Micholopoulos and DeFrances [18] and Gilgenkrantz et al. [19]. Liver regeneration is possible when even up to 70 percent of the organ is damaged or removed; however, the regenerated tissue is not a recreation of the lost lobes but instead is a compensatory growth of the remaining tissue. Studies utilizing partial hepatectomy suggest that mature liver cells are responsible for growth of the tissue; however, more recent studies of chronic disease suggest

that progenitor cells are key players. The search for the symphony of signals that starts the regenerative process continues, and many of the important growth factors and cytokines in the orchestra have been identified, including hepatocyte growth factor, epidermal growth factor, interleukin-6, tumor necrosis factor-α and transforming growth factor-α.

The liver has a remarkable capacity for regeneration, but it is not unlimited. Liver failure during transplantation will occur when the graft weight to body weight ratio is less than 0.8% for the recipient, or the remaining donor tissue consists of less than 25% of the functional liver. In a chronically diseased liver, regeneration is often impaired in part due to mito-inhibitory factors. Much of what we have learned about the symphony of signals in liver regeneration and failure comes from animal models. Animal studies began in the late 1800s with canine models and has progressed using canine, rabbit, primate, feline, porcine and rodent animal models, with the latter two models being the most utilized today. An in depth review of the various animal models used to study liver regeneration is detailed by Mortenson and Revhaug [20].

As noted earlier, the human endometrium is an amazing tissue, one where rapid scarless regeneration occurs monthly [21]. The endometrium is the innermost layer of the uterus, and it consists of a basalis layer and a functionalis layer onto which an embryo implants. The functionalis layer makes up two thirds of the endometrium and is shed in the absence of pregnancy. In contrast to many other regenerative tissues such as the fetus, this amazing symphony of events takes place in a highly inflammatory environment. The 'conductors' of a woman's monthly endometrial cycle are the ovarian hormones, estrogen and progesterone. The rapid decrease of progesterone triggers a carefully conducted symphony of signals that results in menstruation. Regeneration occurs simultaneously with the tissue destruction making it difficult to study and detect [22]. Endometrial stromal cell proliferation, angiogenesis and the recreation of the microvasculature, and re-epithelialization of the ducts and the endometrial surface occur during the menstrual and proliferative phases of the cycle. Re-epithelialization of the surface by basal gland cells is completed by day two of the cycle, although it is unclear if the epithelial repopulation is due to migration and proliferation of mature epithelial cells or stem cells resident in the glands. While progesterone is a known conductor for the initiation of menstruation, it is unclear what role estrogen plays in regeneration. Estrogen levels increase in the proliferative phase, but there is evidence that estrogen is not essential for complete regeneration [23].

One reason for our limited knowledge on the mechanisms of endometrial regeneration is the lack of animal models. These are limited as menstruation is a rather unique process occurring only in women, a few old world primates, the elephant shrew, and fruit bats. The menstruation models that do exist are reviewed in Salamonsen and Guidice [24]. The macaque is the most utilized primate model due to the similarities in anatomy and menstrual cycle, while the baboon has been widely used in endometriosis studies. Rodent models are now available as menstruation has been induced in mice; alternatively, xenotransplants of human endometrium in a mouse model have been utilized under hormone regulated conditions. These models will help further our understanding of this scarless regenerative process, but none completely recreate the inflammatory human menstrual cycle.

Animal models of course are used in a wide variety of other ways. Such models range from small animals such as the mouse or the rat to large animal models such as non-human primates. Although small animal models do not in general predict what will happen in the human, they do lend themselves to carefully designed experiments that can lead to a better understanding of the signals involved in a particular cellular function. This includes the use of transgenic animals.

In vitro models have been and will continue to be a significant asset to our efforts to achieve a better understanding of signaling mechanisms. Such models already have contributed substantially to our knowledge. As an example, *in vitro* studies have made it clear that for most

cell types their characteristics in a three-dimensional structure can be very different from those when cultured in two dimensions. The exception is the vascular endothelial cell, which exists *in vivo* as a monolayer and thus has been studied successfully as a monolayer in culture. On the other hand, the vascular smooth muscle cell, which exists *in vivo* in a three-dimensional structure, has been demonstrated in culture to have very different characteristics in three dimensions as compared to two dimensions. *In vitro* studies do provide the opportunity to systematically investigate cell signaling [25]. Granted a majority of literature results are for studies of 'soloists'; however, the potential for studies of 'duets' and 'quartets' exists and has led to some relatively recent publications in this area.

As already noted, the endometrium regenerates once a month in the human female. This is a complex process, but one from which the tissue engineering and regenerative medicine community can learn. Because of the limitations of animal models and the difficulties in obtaining biopsies of proliferating endometrium, a hormonally responsive tissue-engineered *in vitro* model of the human endometrium is important if we are to understand the symphony of signals required for regeneration. The first report of a tissue-engineered endometrium was that by Bentin-Ley et al. [26]. This initial approach concentrated on replication of the tissue architecture including the establishment of a ciliated epithelial surface. Bentin-Ley et al. used a collagen I, Matrigel scaffold which is a popular choice for endometrial engineering. Fig. 2.2 shows how the collagen/Matrigel hydrogels are created; Fig. 2.3 shows the ciliated epithelial layer in a tissue-engineered endometrium created by Park et al [27] to study endometrial cancer.

Most of the groups involved in endometrial tissue engineering that have looked at tissue function have focused on receptivity and implantation [28]. Only recently has an engineered tissue been shown to respond to menstruation mimetic cues, where collagenase and MMP-2 activity increases in response to steroid withdrawal and where the shedding of cells occurs [29]. This is an important first step, necessary for the study of regeneration in an engineered tissue. Furthermore, the study of the menstrual and proliferative endometrial phases might help to define the important players in scarless regeneration.

One recent development is that of fabricating human organ-on-a-chip models. Such *in vitro* model systems are being developed for use in drug discovery, toxicity testing, and bioinfectious agents [30]. Just recently Defense Advanced Research Projects Agency (DARPA) made three five-year awards to develop up to 10 organ-on-a-chip models using human cells. A leader in this is the Wyss Institute at Harvard University. Already reported in the literature in 2010 is the development of a human 'lung-on-a-chip' model [31] and more recently a human 'gut-on-a-chip' model has been published [32]. With models such as these it is hoped that the use of animals in the development of a drug or agent might be considerably reduced. Not only are

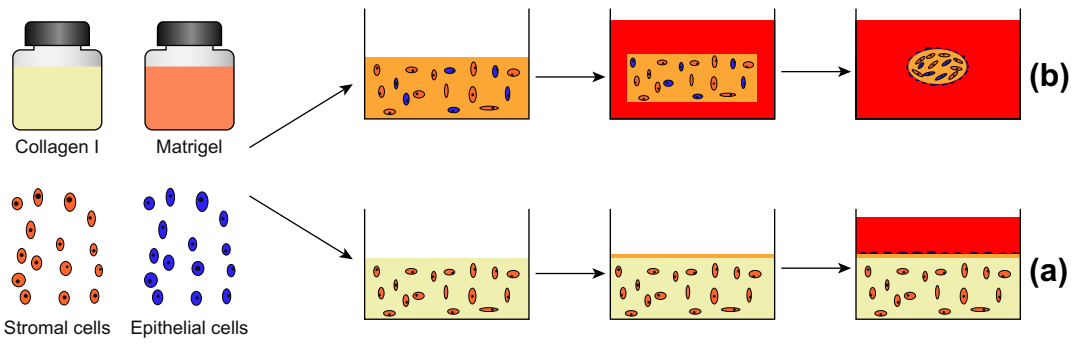

FIGURE 2.2

The most common current approach to creating a tissue-engineered endometrium is the creation of a collagen I and Matrigel cell-seeded hydrogel. A layered approach is shown (a) where collagen I and endometrial stromal cells are combined. After the solution gels a thin layer of Matrigel is added and the endometrial epithelial cells are added above. A combined approach (b) can be used where collagen I, Matrigel, and the endometrial stromal and epithelial cells are mixed together. When liberated from the well the gel will compact and the epithelial cells will eventually coat the outer surface of the tissue.

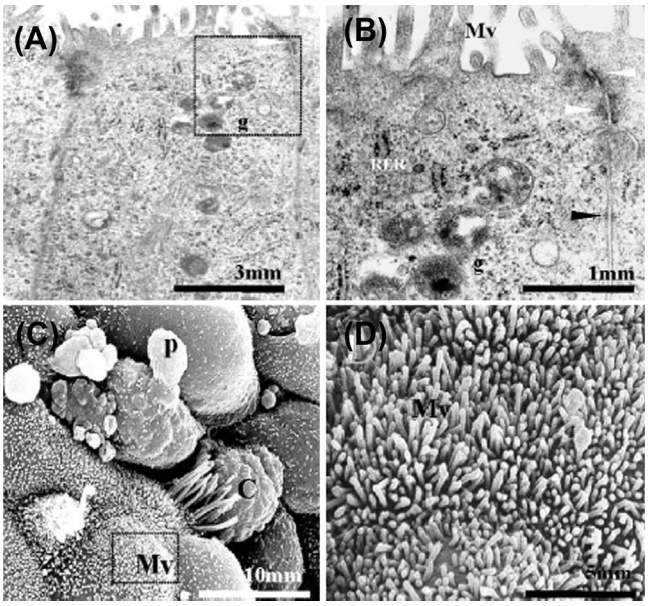

FIGURE 2.3
Electron micrographs of epithelial cell layer on a collagen/Matrigel engineered endometrium. Microvilli and tight junctions (open arrows) are seen in the transmission electron micrographs (A,B). Pinopodes (P), cilia (C) and microvilli (Mv) are seen in the scanning electron micrographs. *Reprinted from Park et al. (2003) with permission from Elsevier.*

animal studies labor intensive, time consuming, and costly, but as already noted, the results obtained also do not necessarily predict what will happen in the human.

Finally, a different kind of modeling that will become increasingly important if we are to understand nature's orchestra is that represented by computational approaches [33–35]. One of the early attempts at this for a eukaryotic cell was the computational model developed by Weisner et al. [36,37] to describe the dynamics in calcium that is observed when a vascular endothelial cell responds to the onset of flow and the associated shear stress. Since then, computational models have become much more sophisticated. Whatever the model being used in a computational approach, it will need to incorporate a hierarchy of time and length scales with many interconnected elements. Furthermore, the intracellular and extracellular dynamics may well be non-linear in nature, and a realistic model will need to include the external environment, transport phenomena, and membrane processes. In each of these not only will the chemistry be important, but also the mechanics. There also are additional complexities including genetic information and the role of miRNAs, as well as other epigenetic features. Clearly this requires a sophisticated model and with this the use of advanced engineering tools and an advanced knowledge of the biology. The development of such a sophisticated computational model initially will be based on experimental results; however, the results obtained from such a computational model can then drive the design of new experiments and may require new, innovative measurement techniques. These new experiments will then lead to an improvement in the computational model. It is this interplay of experiments and computational models that will lead to an improvement in our understanding of the signals that make up the symphony provided by nature's orchestra. And it is this improved understanding that will help us in our efforts to develop therapies that in some way imitate nature.

CELL TECHNOLOGY

The starting point for any attempt to engineer a cell-based therapy is a consideration of the cells to be employed. Not only will one need to decide whether the source to be employed is to be autologous, allogeneic, or xenogeneic, but one will need to ensure that the cells are free of pathogens and contamination of any type whatsoever. As is well known, there are both advantages and disadvantages to autologous vs. allogeneic vs. xenogeneic cells; however, it should be noted that one important consideration for any product or treatment strategy is its off-the-shelf availability. Only with this will the product find application for the wide variety of patients in need throughout the entire healthcare system including community hospitals.

The skin substitutes developed by Organogenesis (Canton, MA) and Advanced Tissue Sciences (La Jolla, CA) represented some of the first tissue-engineered products, and these in fact use allogeneic cells. The Organogenesis product, Apligraf, is a bilayer model of skin including both a dermis and an epidermis involving fibroblasts and keratinocytes that are obtained from donated human foreskin [38]. Apligraf is approved by the FDA. The first tissue-engineered product approved by the FDA was the Advanced Tissue Sciences product, TransCyte. Approved initially for third-degree burns, TransCyte is made by seeding dermal fibroblasts in a polymeric scaffold; however, once cryopreserved it becomes a non-living wound covering. Advanced Tissue Sciences also has a living cell product called Dermagraft. It is a dermis model, also with dermal fibroblasts obtained from donated human foreskin [39]. Even though the cells employed by both Organogenesis and Advanced Tissue Sciences are allogeneic, immune acceptance did not have to be engineered because both the fibroblast and the keratinocyte do not constitutively express major histocompatibility complex (MHC) II antigens.

The next generation of tissue-engineered products will involve other cell types, and the immune acceptance of allogeneic cells will be a critical issue in many cases. As an example, consider a blood vessel substitute that employs both endothelial cells and smooth muscle cells. Although allogeneic smooth muscle cells may be immune acceptable, allogeneic endothelial cells certainly would not be. Thus, for the latter, one either uses autologous cells or else engineers the immune acceptance of allogeneic cells, as will be discussed in a later section. Undoubtedly the first human clinical trials will be done using autologous endothelial cells; however, it would appear that the use of such cells would severely limit the availability of a blood vessel substitute, unless the host's own endothelial cells are recruited. Only by moving to off-the-shelf availability for the clinician does routine use become possible.

There is considerable interest in the use of stem cells, i.e., the 'mother' cells within the body, as a primary source for therapies based on cell and tissue replacement [40—42]. The excitement about stem cells reached a new height with two articles in 1998 [43,44]. These reported the isolation of the first lines of human embryonic stem cells (ESCs). Since then it has been demonstrated that one can reprogram a cell like the fibroblast into a pluripotent cell, what is called an induced pluripotent stem cell (iPS cell), first reported by Takahashi and Yamahaka [45] and further outlined by Takahashi et al. [46]. More recently, Yamanaka has provided an update [47]. Although iPS cells may not be exactly the same as ESCs, they still are of considerable interest, particularly since they can be derived from patients with various diseases and possibly even used as an autologous cell in the therapy for a specific patient. Disease-specific iPS cells also can be used to make novel cell types for drug discovery and screening. Still there are technical challenges to be addressed [48]. This includes new tools for genetic modification and reprogramming. Amniotic stem cell lines also are potentially of interest [49] as well as human umbilical cord blood [50]. The stem cell arsenal thus now includes not only ESCs, but also a variety of other stem cells types including mesenchymal stem cells and iPS cells.

In addition, there are progenitor cells of various types including ones circulating in blood. In some cases, stem cells are being used to derive progenitor cells. One example is the Geron clinical trial for spinal cord injury which, though now stopped, used progenitor cells derived from human ESCs. It may be that it is the use of progenitor cells that offers the best hope for a clinical cell-based therapy.

To take full advantage of stem cell technology, however, it will be necessary to more fully understand how a stem cell differentiates into a tissue-specific cell. This requires knowledge not just about the molecular pathways of differentiation, but even more importantly the identification of the combination of signals leading to a stem cell becoming a specific type of differentiated tissue cell. As an example, it is recognized that there are subtypes of human smooth muscle cells, and recently if was demonstrated how one could generate various human smooth muscle cell subtypes [51]. There also are recognized differences between different subtypes of endothelial cells, e.g., large vessel endothelial cells and valvular endothelial cells.

What are the signals that will drive the differentiation towards one type of endothelial cell versus the other? Only with this type of knowledge will we be able to realize the full potential of stem cells. In addition, however, we will need to develop the technology necessary to expand a cell population to the number necessary for clinical application and to do this in a controlled, reproducible manner. In addition, there are a variety of other issues related to the translation of bench-top science into clinical therapies. These will all be discussed in a later section of this chapter.

ENGINEERING FUNCTIONAL CHARACTERISTICS

Once one has selected the cell type(s) to be employed, then the next issue relates to the manipulation of the functional characteristics of a cell, i.e., the engineering of these characteristics, so as to achieve the behavior desired. This can be done either by manipulating a cell's microenvironment, e.g., its matrix, the mechanical stresses to which it is exposed, or its biochemical environment, or by manipulating a cell's genetic program. In regard to the latter, the manipulation of a cell's genetic program could be used as an ally to tissue engineering and regenerative medicine in a variety of ways. A partial list of possibilities includes the alteration of matrix synthesis; inhibition of the immune response; enhancement of non-thrombogenicity, e.g., through increased synthesis of antithrombotic agents; engineering the secretion of specific biologically active molecules, e.g., a specific insulin secretion rate in response to a specific glucose concentration; or the alteration of cell proliferation.

Much of the above is in the context of creating a cell-seeded construct that can be implanted as a tissue or organ substitute; however, the fostering of the repair or remodeling of tissue also is an essential component of tissue engineering and regenerative medicine. Here a critical issue is how to deliver the necessary biologic cues in a spatially and temporally controlled fashion so as to achieve a 'healing' environment. In the repair and/or regeneration of tissue the use of genetic engineering might take a form that is more what we would call gene therapy. An example of this would be the introduction of growth factors to foster the repair of bone defects. In using a gene therapy approach, it should be recognized that in many cases only a transient expression would be required. Because of this, the use of gene therapy as a strategy in tissue engineering and regenerative medicine may become viable prior to its wide employment in treating genetically related diseases.

With the selection of a source of cells, the next challenge in imitating nature is to develop an organized three-dimensional architecture, one with functional characteristics such that a specific tissue is mimicked. In this it is important to recognize the importance of a cell's microenvironment in determining its function. As already noted, *in vivo* a cell's function is orchestrated by a symphony of signals, a symphony that includes soluble molecules, the mechanical environment to which the cell is exposed, and the extracellular matrix. If we want an organized tissue substitute that replicates the characteristics of native tissue, then attention must be given to each of these components of a cell's microenvironment. If the approach is to seed cells into a scaffold, then a basic question is what type of scaffold? Also, for a given application will it be desirable for the cells to make their own matrix?

The design and engineering of a tissue-like substitute is a challenge in its own right. There are many possible approaches, and one of these, of course, is a cell-seeded polymeric scaffold, an approach pioneered by Langer and his collaborators [2,52]. This is the technology that was used by Advanced Tissue Sciences, and many consider this the classic tissue engineering approach. Another is the use of a cell-seeded collagen gel. This approach was pioneered by Bell in the late 1970s and early 1980s [53,54], and this is being used by Organogenesis in their skin substitute, Apligraf.

A rather intriguing approach is that of Auger and his group in Quebec, Canada [55,56]. Auger refers to this as cell self-assembly, and it involves a layer of cells secreting their own matrix,

which over a period of time becomes a sheet. Originally developed as part of the research on skin substitutes by Auger's group, it has been extended to other applications. For example, the blood vessel substitute developed in Quebec involves rolling up one of these cell self-assembled sheets into a tube. One can in fact make tubes of multiple layers so as to mimic the architecture of a normal blood vessel. A simpler version of this approach is being used to fabricate a tissue-engineered blood vessel at a company called Cytograft Tissue Engineering Inc. Here the initial application is for dialysis, and the blood vessel substitute only involves a single layer, one that is created from a fibroblast sheet. An expanded clinical study carried out by Cytograft was published a few years ago [57,58]. Cytograft is focusing its clinical trials in Europe and Asia, and the Phase III clinical studies for hemodialysis access employ both autologous and allogeneic grafts. Of interest is that the new allogeneic model has the potential of reducing the overall production time to three weeks. Furthermore, it allows thousands of grafts to be fabricated from a single master cell line, thus reducing cost. Cytograft indicates that they plan to have commercial sales and initial revenues in the next year or two (private communication 2012).

A different approach to the creation of a three-dimensional, functional tissue equivalent is the acellular one. Here the use of extracellular matrix as a scaffold represents an attractive approach [59]. An example of this is the use of SIS, which is an extracellular matrix that is porcine derived. As already noted in an earlier section, more than two million patients have been treated for a variety of conditions. SIS is successful because as an extracellular matrix product it provides a rich array of signals that facilitate repair. This has led to a strategy where one employs a decellularized tissue or organ as a scaffold that then can be repopulated with human cells [60,61]. In the last few years, a variety of organs have been 'fabricated' in this manner. Examples include the heart [62], the lung [63], and the liver [64].

In a recent study published by the company Humacyte [65], a tissue-engineered blood vessel (TEBV) showed good patency in both coronary and carotid bypass models. This TEBV was created by culturing human smooth muscle cells on a polyglycolic acid tubular scaffold. The cells secreted an extracellular matrix that, when the polymeric scaffold degraded away and the cells were removed, left a completely formed vascular graft. Perhaps the most important achievement in this study was to produce a small diameter human TEBV with a burst pressure in excess of 3000 mmHg. These vessels were produced in 10 weeks in a pulsating bioreactor and decellularized, and they showed a compliance better than that of a human saphenous vein, but still considerably less than that of human arteries. Humacyte plans to be in their first dialysis patients in Europe next year (private communication, 2011). Another strategy is used whereby the implant is without cells, i.e., acellular, and the cells are then recruited from the recipient or host. A number of laboratories and companies are developing this approach. One result of this approach is to, in effect, bypass the cell sourcing issue, and replace this with the issue of cell recruitment, i.e., the recruiting of cells from the host in order to populate the construct. Because these are the patient's own cells, there is no need for any engineering of immune acceptance.

Whatever the approach, the engineering of architecture and of functional characteristics that allows one to mimic a specific tissue is critical to achieving any success and to meeting the challenge of imitating nature. In fact, because of the interrelationship of structure and function in cells and tissues, it would be unlikely to have the appropriate functional characteristics without the appropriate three-dimensional architecture and the appropriate microenvironment for the cells. Thus, many of the chapters in this book will describe in some detail the approach being taken in the design and engineering of constructs for specific tissues and organs, and any further discussion of this will be left to those chapters.

An important issue, however, is how much of the 'maturation' of a substitute is done *in vitro* in a bioreactor as compared to what is done *in vivo* through the remodeling that takes place within the body itself, i.e., in the body's own bioreactor environment. An interesting approach

has been that of the Campbells and their co-workers, who use the peritoneal and pleural cavities as bioreactors to grow autologous tissues [66]. A bioreactor simply represents a controlled environment – both chemically and mechanically – in which a tissue-like construct can be grown. Although it is generally recognized that a construct, once implanted in the living system, will undergo remodeling, it is equally true that the environment of a bioreactor can be tailored to induce the *in vitro* remodeling of a construct so as to enhance characteristics critical for success to be achieved following implantation [67–70]. Thus, the manufacturing process can be used to influence directly the final product and is part of the overall process leading to the imitation of nature. Again, an important issue is how much of the 'maturation' of a substitute should be done *in vitro* in a bioreactor as compared to what will be done *in vivo* through the remodeling that takes place within the body itself.

TRANSLATION INTO THE LIVING SYSTEM

The final challenge for tissue engineering and regenerative medicine is presented by moving a bench-top concept into the living system. This of course starts with the selection of the cell type(s) to be employed and the processing strategy to be used to scale up to the number of cells required and with the correct phenotype. For a cellular therapy, is it undifferentiated stem cells, progenitor cells, or fully differentiated cells that will be used? Will this approach be an autologous one or an allogeneic one? Also, if the source is to be iPS cells, what will the reprogramming approach be? Can the cell processing strategy be automated?

Beyond the variety of issues related to the cells to be employed, next are the pre-clinical, animal experiments. Unfortunately, there is a lack of good animal models for use in the evaluation of tissue engineering and regenerative medicine therapies. This is despite the fact that a variety of animal models have been developed for the study of different diseases. However, these models are still somewhat unproved, at least in many cases, when it comes to their use in evaluating the success of a cell-based therapy.

In addition, there is a significant need for the development of methods to evaluate quantitatively the effectiveness of a therapy. This is not only the case for animal studies, but is equally true for human clinical trials. In regard to the latter, it may not be enough to show efficacy and long-term patency; it may also be necessary to demonstrate the mechanism(s) that lead to the therapy's success. Furthermore, it is not just in clinical trials that there is a need for more quantitative tools for assessment; it also would be desirable to have available technologies to assess periodically the continued viability and functionality of the treatment that the patient has received.

Important to the success of any tissue engineering or regenerative medicine approach is that it be immune acceptable. This comes naturally with the use of autologous cells; however, if one moves to non-autologous cell systems (as this author believes we must if we are to make these therapies widely available for routine use), then the challenge of engineering immune acceptance is critical to our achieving success in the imitation of nature. It should be recognized that the issues surrounding the immune acceptance of an allogeneic cell-seeded implant are no different than those associated with a transplanted human tissue or organ. Both represent allogeneic cell transplantation, and this means that much of what has been learned in the field of transplant immunology [71,72] can help us understand the immunology and the engineering of immune acceptance for tissue-engineered allogeneic implants and cell therapies. For example, it is now known that to have immune rejection there must not only be host cell recognition of a foreign body, there also must be present what is called the co-stimulatory signal, or sometimes simply signal 2. It has been demonstrated that, with a donated allogeneic tissue, if one can block the costimulatory signal, one can extend survival of the transplant considerably [73]. Thus strategies to do this are under development and may provide greater opportunities in the future for the use of allogeneic cells.

Furthermore, if the approach is one where there is to be an implant, then it must be biocompatible. Even if the implant is immune acceptable, there can still be an inflammatory response. This response can be considered separate from the immune response, although obviously there can be interactions between the two. In fact, it may be that the regeneration that takes place in a species like the newt as opposed to the scarring observed in the human is due to differences in the interaction of the inflammatory process with the immune system. In addition to any inflammatory response, for some types of implants thrombosis will be an issue. This is certainly an important part of the biocompatibility of a blood vessel substitute.

Finally, the challenge of imitating nature does not stop with the design and engineering of a specific treatment or therapy. This is because the patient's need cannot be met by making one construct at a time on a bench top in some research laboratory. Accepting the challenge of imitating nature must include the development of cost-effective manufacturing processes [74]. These must allow for a scale up from making one at a time to a production quantity of 100 or 1000 per week. Anything significantly less would not be cost-effective, and if a product cannot be manufactured in large quantities and cost-effectively, then it will not be widely available for routine use.

Once manufactured, a critical issue will be how the product is delivered and made available to the clinician. The Organogenesis product, Apligraf, is delivered fresh and has a 5-day shelf life at room temperature [38]. On the other hand, Dermagraft, the skin substitute developed by Advanced Tissue Sciences, is cryopreserved and shipped and stored at −70°C [39]. This provides for a much more extended shelf life, but introduces other issues that one must address. Ultimately, the clinician will want off-the-shelf availability, and one way or another this will need to be provided if a product is to have wide use. Although cryobiology is a relatively old field and most cell types can be cryopreserved, there is much that still needs to be learned if we are successfully to cryopreserve three-dimensional cell-based products.

Manufacturing also is an issue for therapies that involve cells without any construct. Whatever the way that cells are to be used, as one moves from bench-top research to a clinical study in a human, ultimately to clinical trials and approval by FDA, there are a variety of issues that will need to be addressed. Some of the needs are as follows:

- A processing system for massive cell expansion
- Systems for the homogenous differentiation of cells
- Methods for the assessment of genetic and epigenetic stability
- Real time in-process assays
- *In vitro* surrogate potency assays

Critical is the need to scale up the number of cells to the level needed for a human, the ability to provide a defined population of cells, i.e., with the appropriate phenotype, and having in place the quantitative assessments needed for quality control [75–78]. In this it would be desirable to automate such a cell manufacturing system.

Finally, the translation of bench-top science to a clinical therapy and ultimately commercialization will only take place if the business model is viable. Commercialization is important because only then can the widest population of patients in need be reached. Commercial successes to date have either been with acellular approaches, or with ones that use allogeneic cells. As attractive as an autologous cell approach is scientifically, in general it will be prohibitive in terms of cost as a clinical therapy, as every patient is an N of one. Even so, Genzyme's Carticel product was autologous, based on research in Sweden [79]; however, what Genzyme provided was a service, not a real product. In the earlier discussion of iPS cells it was commented that they could possibly be used to provide autologous cells for a therapy for a specific patient; however, from the viewpoint of a realistic business model, only an allogeneic iPS cell approach would appear to be viable for a cellular therapy. It is also for this reason that a majority of approaches being commercialized are of an allogeneic nature.

CONCLUDING DISCUSSION

As already noted, if we are to meet the challenge of imitating nature, there are a variety of issues. In this chapter, the authors have attempted to identify if not all, at least many of these. The purpose has been to provide a foundation for what will be discussed in the remainder of this fourth edition. As part of this, it is our hope that we have broadened the perspective of the reader.

Much of the discussion here may have appeared to be focused on the challenge of engineering tissue-like constructs for implantation. As noted earlier, however, equally important to tissue engineering and regenerative medicine are strategies for the fostering of remodeling and ultimately the repair and enhancement of function. As one example, consider a damaged, failing heart. Should the approach be to tissue engineer an entire heart for replacement, or should the strategy be to foster the repair of the myocardium? In this latter case, it may be possible to return the heart to relatively normal function through the implantation of a myocardial patch [80] or even through the introduction of growth factors, angiogenic factors, or other biologically active molecules. Because of the complexity of the heart, it appears to the authors of this chapter that the best strategy is one of repair and/or regeneration; however, to be successful in such an approach there is still much that needs to be done.

Since the first edition of this book, considerable progress has been made; however, at times the 'hype' appears to outpace the progress. The 'hype' is not only about the promise of stem cells. It at times has permeated much of the field. This is unfortunate for researchers speaking about tissue engineering and regenerative medicine need to balance the hope with realism, by making comments that indicate what it will take for the promise offered, i.e., the potential, to be realized.

Beyond the hype and if we are to realize the hope, then the approach of the tissue engineering and regenerative medicine community must be one that is very interdisciplinary. As advocated in the report from the National Research Council entitled 'A New Biology for the 21st Century' [81], this starts with breaking down the silos within the field of biology itself and then integrating into the field computational researchers, engineers, mathematicians, and physicists. As illustrated in Fig. 2.4, such an integration will lead to a deeper scientific understanding, and with the addition of clinicians one can then move to translating the science into therapies. Only with this final integration will our understanding of how to imitate nature lead to the therapies needed for the future.

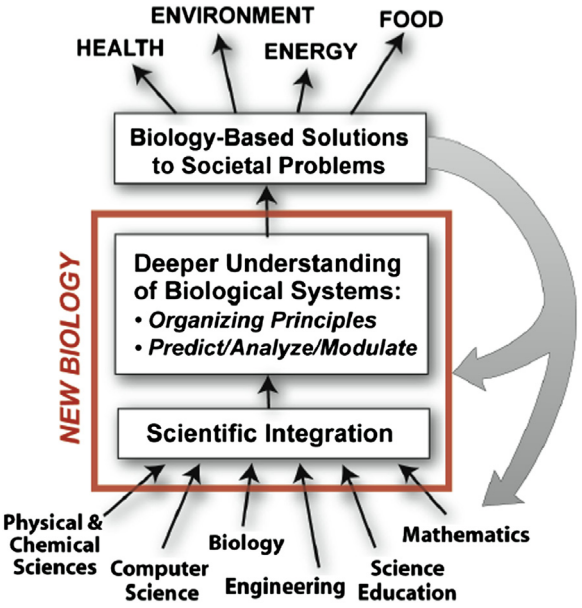

FIGURE 2.4
Illustration of the integration of computational researchers, engineers, mathematicians, and physicists will lead to a deeper biological understanding and provide for addressing the major needs of society. *Reprinted from the National Research Council Report entitled 'A New Biology for the 21st Century' (2009) with permission from the National Academies Press.*

INTRODUCTION

Tissue engineering aims to understand the principles of *in vivo* tissue growth and development and apply this understanding to the engineering of functional replacement tissue *ex vivo* for clinical use subsequent to disease or injury. However, tissue formation is an inherently complex process — involving multiple biological, chemical, and physical processes that interact on a variety of length- and time-scales — and deciphering general principles of tissue development is a challenging task [1]. Nevertheless, a deep understanding of these principles is necessary to efficiently engineer functional tissue *in vitro*. For this reason, tissue engineering approaches commonly coordinate techniques from a variety of different disciplines, including molecular, cell and developmental biology, chemical engineering and biophysics to dissect this complexity. Recent years have seen an increasing interest in applying tools from the mathematical and computational sciences to the design, development, and implementation of tissue engineering protocols [2,3].

Mathematical and computational models are routinely used to help understand complex systems and optimize industrial processes in the engineering and physical sciences. There are many remarkable examples of the longstanding use of quantitative methods in the cell and molecular biosciences [4]. Recent rapid advances both in available computational power and high-throughput experimental procedures have stimulated an extraordinary cross-fertilization of ideas from the mathematical, statistical, physical and life sciences, particularly within the areas of systems biology and bioinformatics [5]. Concurrently, much progress has also been made in recent years toward understanding the general principles of tissue growth and development. In this chapter we will explore how mathematical models, in collaboration with experimental studies, can help further understanding of these principles. Given the breadth and rapid growth of this field we will necessarily only focus on a few key areas, particularly: understanding molecular basis of stem and progenitor cell fate commitment; spatiotemporal regulation of cellular differentiation; and general principles of tissue morphogenesis.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00003-3

MODELING STEM CELL DYNAMICS

Stem cells are present during all stages of development and are uniquely characterized by their capacity to maintain their numbers by self-renewing, as well as differentiate along distinct lineages. Embryonic stem (ES) cells have the capacity to produce all somatic tissues, a property known as pluripotency, and there is much interest in elucidating the molecular mechanisms of pluripotency [6]. Following the seminal work of the Yamanaka group in demonstrating that adult fibroblasts could be reprogrammed to ES cell-like state by the forced expression of just four pluripotency-associated transcription factors (Klf4, c-Myc, Oct-3/4 and Sox2), there is hope of using adult somatic cell-derived induced pluripotent stem (iPS) cells as patient-specific, and less controversial, alternatives to human ES cells [7–9].

In contrast to ES and iPS cells, adult stem cells are typically lineage restricted and thereby constrained in their therapeutic potential (they are generally only multi- or uni-potent) [10]. Nevertheless, due to their regenerative capacities and the relative ease with which they may be obtained, there is also considerable interest in understanding the processes by which adult stem cells orchestrate tissue growth and development, and in applying this understanding to engineering functional replacement tissue in the laboratory [1]. A standard tissue engineering approach to this problem is to harvest appropriate stem cell populations and, using defined culture conditions (which include regulating the chemical, physical/mechanical and geometric properties of the growth environment), recapitulate *in vivo* regenerative processes to produce functional tissue *in vitro*. The ultimate success of this strategy relies on a clear understanding of the molecular mechanisms of stem cell self-renewal and differentiation and the spatiotemporal control of these processes.

Stem cell fate is critically dependent upon interactions with neighboring cells – including differentiated progeny [11] and other stem/progenitor cells [12] – and extracellular components that constitute the stem cell niche [13]. Stem cell interactions with the niche are mediated through intracellular molecular regulatory networks that include transcriptional, signaling, and epigenetic regulatory components [14]. These networks are highly complex, containing multiple feedback and feed-forward loops that allow the cell to respond dynamically to changes in its environment. These types of feedback-based mechanisms are reminiscent of control systems in engineering, and recent years have seen considerable interest in viewing cell fate decisions from a dynamical systems perspective [14]. In the field of synthetic biology, for instance, switches and oscillators have been implemented experimentally in model systems using rational designs based upon mathematical reasoning [15–17]. A general principle that emerges from this viewpoint is that the molecular switches that underpin stem cell fate decisions are ultimately dependent upon positive feedback loops in the cells' underlying intracellular molecular regulatory circuitry [18].

Positive feedback based molecular switches

Positive feedback based switches play a central role during development by initiating all-or-none commitment events in response to external stimuli, and commonly underpin stem and progenitor cell fate decisions, including during hematopoiesis [19]; neural development [20]; and human embryonic and mesenchymal and stem cell fate commitment [21,22]. In order to illustrate the general principle of a feedback-based switch, consider as an example the following dimensionless equations, which describe a simple 'toggle switch' consisting of two cross-inhibitory transcription factors, X and Y[15]:

$$\frac{dx}{dt} = \frac{\alpha_1}{1 + y^{\beta_1}} - x, \tag{1}$$

$$\frac{dy}{dt} = \frac{\alpha_2}{1 + x^{\beta_2}} - y. \tag{2}$$

Here x and y denote the intracellular concentration of X and Y. Equations (1)–(2) describe the rate of change in expression of X and Y over time and state that X and Y are synthesized with effective rates α_1 and α_2 respectively (first terms on the RHS) and decay with constant half-lives (second terms on RHS). The parameters β_1 and β_2 capture cooperativity in repression, allowing for repression by multi-protein complexes and/or binding of multiple regulatory sites on the respective promoters, for instance. Note that although this system is characterized by repressive interactions, it nevertheless represents a simple positive feedback loop since both factors indirectly activate their own expression via inhibiting expression of the other. This kind of switch has been engineered both in *E. coli* [15] and mammalian cells [23] and behaves as a genetic 'memory unit' [15] (indeed it behaves similarly to a SR flip-flop for memory storage in electronic systems).

The dynamics of this system may be explored by plotting changes in expression of X and Y against each other to form the system's *phase plane*. The phase plane for this system is shown in Fig. 3.1 (top row) for different parameter values. For appropriate regimes, this system supports stable expression of *either X or Y*, but not co-expression of both, as one might expect (Fig. 3.1 a, c). For instance, if the effective rate of synthesis of Y is higher than that of X, then Y is expressed whilst X is repressed (Fig. 3.1a); by contrast, if the effective rate of synthesis of X is higher than that of Y, then X is expressed whilst Y is repressed (Fig. 3.1c). In these cases, since only one stable equilibrium point is present the system is said to be *monostable*. In general

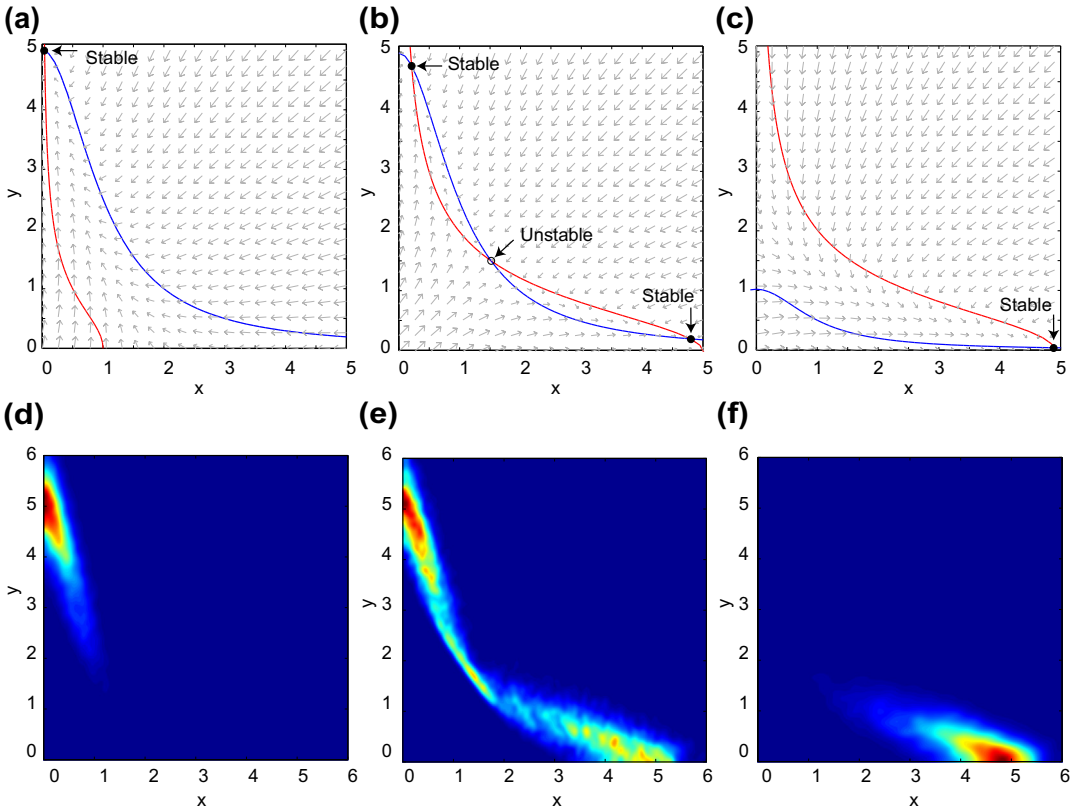

FIGURE 3.1

Bistability and monostability in a genetic toggle switch. (**a**–**c**) Phase planes for Eqs. (1)–(2) for different model parameters showing that this simple molecular switch supports both monostability (**a**, **c**) and bistability (**b**). Arrows show the direction field illustrating the flow towards the stable equilibria from different initial conditions. (**d**–**f**) Corresponding probability density functions, showing that expression variability can arise within a cellular population in the presence of molecular noise. Red shows regions of high probability of finding a cell; blue shows regions of low probability. Here stochasticity in expression of the two genes has been modeled as white noise process with amplitudes $\sigma_1 = 0.55$ (noise in expression of x) and $\sigma_2 = 0.75$ (noise in expression of y). Parameter values: (panels **a**, **d**) $\alpha_1 = 1$, $\alpha_2 = 5$; (panels **b**, **e**) $\alpha_1 = 5$, $\alpha_2 = 5$; (panels **c**, **f**) $\alpha_1 = 5$, $\alpha_2 = 1$. In all cases, $\beta_1 = \beta_2 = 2$.

monostability occurs in the absence of cooperativity ($\beta_1 = \beta_2 = 1$) or if the effective rates of synthesis of the two repressors are unbalanced ($\alpha_1 >> \alpha_2$ or $\alpha_1 << \alpha_2$). However, if the effective rates of synthesis of the two repressors are balanced ($\alpha_1 \approx \alpha_2$) and transcriptional repression is cooperative ($\beta_1, \beta_2 > 1$) then these two alternate states may stably coexist (Fig. 3.1b). In this case the system is said to be *bistable* and it is the capacity of this system to possess different equilibrium patterns of expression depending on parameter values that allows it to act as a switch. Particularly, this system is a *toggle* switch since expression of either of the repressors may be toggled 'on' and 'off' by transiently inducing changes in expression by varying the effective rates of synthesis α_1 and α_2 [15].

Ultimately, the toggle switch described above works since each factor directly represses transcription of the other while indirectly activating its own transcription. However, mutual cross-repression is by no means the only positive feedback motif that can give rise to molecular switches of this kind. For instance, direct auto-regulation, which is also common in eukaryotic genetic regulatory networks [16,24] can give rise to multistability and switching, either on its own [16] or in concert with other mechanisms. For example, if in addition to mutual cross-repression, each of the transcription factors in the toggle switch also directly positively regulates its own expression then a third 'primed' state, in which both factors are promiscuously co-expressed within individual cells, may also be supported resulting in a potentially *tristable* system. This occurs, for instance, during hematopoiesis: the lineage specifying master transcription factors GATA1 and PU.1 each enhance their own expression while repressing that of the other [25]. Since both GATA1 and PU.1 also regulate multiple downstream targets (GATA1 specifies the erythroid/megakaryocyte lineages; while PU.1 specifies the myelomonocytic lineage), the state of this motif affects widespread genetic programs and effectively defines a lineage choice. By differentially regulating multiple downstream targets, positive feedback-based switches such as this can act as input/output (I/O) devices within larger genetic regulatory networks [26]. In the context of development, positive feedback-based I/O devices are important since they provide a mechanism by which the cell populations can convert spatial information (for instance, an extracellular morphogen gradient) into defined commitment responses, resulting in spatial localization of widespread gene or protein expression patterns [16,27]. We will discuss further how spatial localization of intracellular feedback mechanisms can give rise to complex spatiotemporal patterns of expression in the section 'Pattern formation' below.

Variability in stem cell populations

Although useful, the toggle switch model given by Eqs. (1)–(2) is deterministic, and it does not account for environmental fluctuations or variability in gene expression that are inevitably present. Gene and protein expression are intrinsically stochastic processes, [28,29] and cell-cell variability may arise in isogenic cell populations either due to gene expression 'noise', or due to stochastic partitioning errors or asymmetry during cell division [30–32] (Fig. 3.2). For instance, if such expression noise is accounted for in the toggle switch model then cell-cell variability in expression patterns can naturally arise within a population of genetically identical cells (Fig. 3.1, bottom row). This variability is particularly evident in the bistable regime when expression fluctuations can induce transitions between the coexisting stable states (Fig. 3.1e). This kind of cell division-independent, non-genetic population heterogeneity is remarkably robust, and appears to be a relatively widespread feature of both prokaryotic and eukaryotic cell populations [33–35].

It has long been postulated that stochasticity may have an important role in stem cell fate commitment [36–39]. In the 1960s McCulloch, Till and Siminovitch assessed the colony forming ability of adult mouse bone marrow cells in the spleens of irradiated mice [36]. Using a serial transplantation assay they found that the number of colony forming units (CFUs) per colony varied considerably beyond that expected from sampling errors alone, in a manner

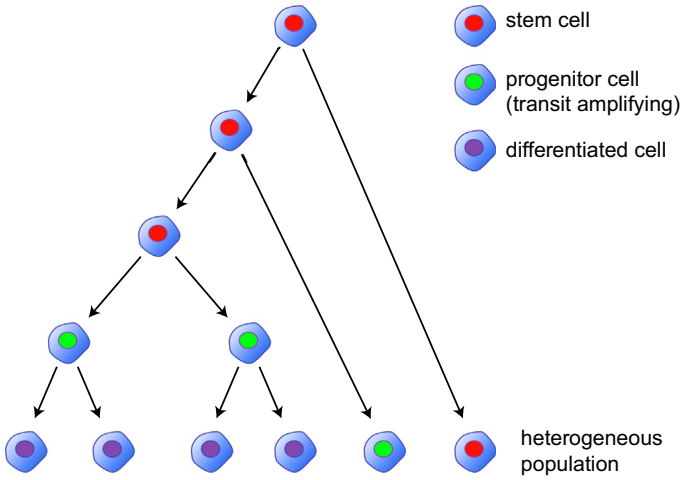

FIGURE 3.2

Heterogeneity in a hierarchically structured population of stem, progenitor and terminally differentiated cells. Stem cells maintain their numbers by symmetric and asymmetric divisions, and give rise to transit amplifying progenitor cells, which in turn produce terminally differentiated progeny. This hierarchy of divisions naturally produces a mixed population containing stem, progenitor and terminally differentiated cell types in proportions that vary with environment, age and disease or insult.

consistent with a 'birth-and-death' process (a simple Markov process, well studied in the statistical physics literature [40]), in which CFU self-renewal and differentiation occur stochastically with defined probabilities [36]. They confirmed this conclusion by numerically simulating colony formation using the birth-and-death model, providing a good early example of the use of computational simulations in stem cell biology. Similarly, Ogawa, Suda and co-workers came to related conclusions concerning the stochastic nature of stem cell fate commitment, in their studies of paired hematopoietic progenitor cells in the 1980s [37–39].

Within the last few years, studies have confirmed substantial variability both in equilibrium expression patterns in a variety of mammalian stem and progenitor cell populations [33,41–45] and the dynamics of cellular differentiation and reprogramming [21,46,47]. In our own recent work we have investigated variability in colony forming ability of primary human bone marrow stromal cell (HBMSC) populations using a two-stage colony forming assay [48]. We found considerable variability both in the sizes of primary (P0) colonies, seeded from single HBMSC cells, and secondary (P1) colonies, formed by detaching cells from P0 colonies and reseeding at clonal density, with apparently little correlation between primary and secondary colony sizes (dependent on the primary colony, transplanted cells produced either small secondary colonies or a wide range of disparate colony sizes). We also observed distinct spatial heterogeneities in expression of mesenchymal and niche-associated markers (including CD146, alpha smooth muscle Actin and Alkaline Phosphatase, see Fig. 3.3, top row) indicating spatial regulation of cell behavior within the colonies. Computational analysis, using a cellular automaton model that accounted for proliferation and migration of individual cells, showed that this behavior is consistent with tissue growth within a structured cellular hierarchy (consisting of stem, transit amplifying, and differentiated cell types, see Fig. 3.2), regulated by cell-cell interactions.

Taken together these results indicate that cell-cell variability in expression patterns and stochasticity in stem cell commitment may be closely related, with stochastic mechanisms allowing dynamic 'priming' of subpopulations of stem cells for different lineages prior to commitment [49]. These observations suggest that cell fate commitment events are regulated at the population, rather than individual cell, level. Thus, intracellular molecular regulatory networks may not control individual stem cell fate commitment *per se*, but rather control the overall structure of the cellular population [36], possibly by modulating molecular noise [50]. In this regard, a more probabilistic view of stem cell fate may be appropriate, in which statistical properties of ensembles of cells, rather than characteristics of individual cells (or averaged properties of populations of cells) are considered. An enhanced quantitative understanding of the intrinsic variability of stem cell populations will require developments

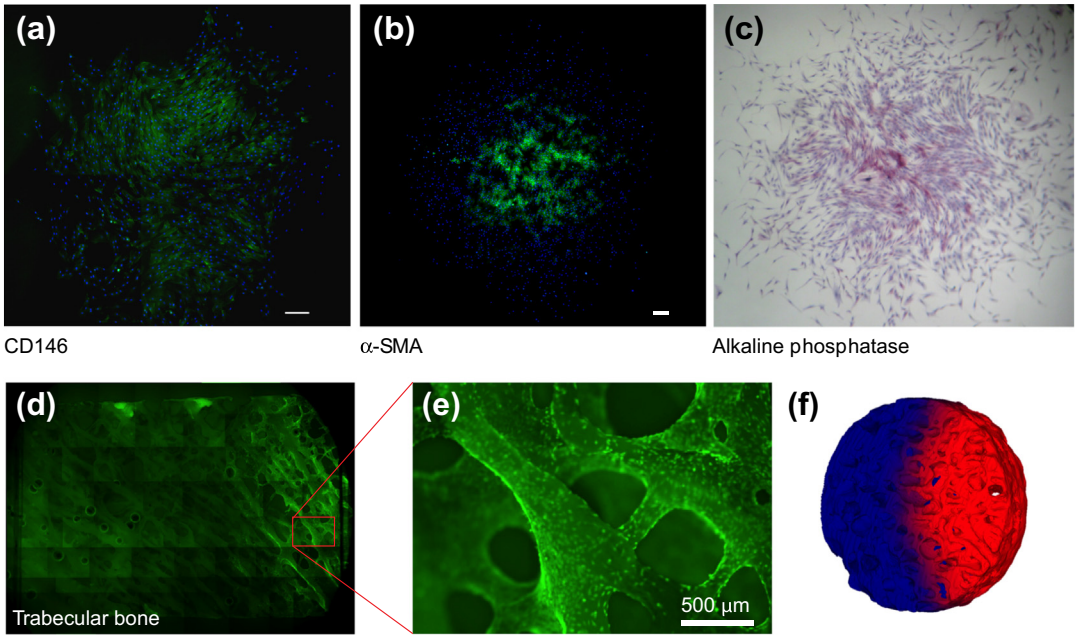

FIGURE 3.3

Tissue growth in monolayer and 3D culture. Panels (**a**—**c**) show intra-colony variability of differentiation and niche markers within primary human bone marrow stromal cell samples seeded at clonal density to form single cell derived colonies. P0 colonies were fixed and assessed for the following mesenchymal markers. (**a**) CD146 (Melanoma Cell Adhesion Molecule) expression measured using mouse monoclonal antibody, in combination with FITC conjugated anti-mouse Immunoglobulin G (IgG) secondary antibody. (**b**) Alpha smooth muscle Actin expression measured using mouse monoclonal antibody in conjunction with FITC conjugated anti-mouse IgG secondary antibody. (**c**) Alkaline Phosphatase activity in red, stained with Naphthol AS-MX Phosphate and Fast Violet B Salts. Staining of all three markers is strongest toward the center of the colony. Panels (**d**—**f**) show cell colonization of complex 3D geometries. (**d**) Slice of human trabecular bone used in a 3D colonization assay. (**e**) Primary human bone marrow stromal cells were seeded onto the trabecular bone sample and cell colonization was visualized over time using Cell Tracker Green labeling (bright green). (**f**) Typical simulation of corresponding mathematical model of cell proliferation and colonization of trabecular bone sample. Domain geometry was obtained from a μCT scan of the trabecular bone sample. Regions of high cell number density are in red; regions of low cell number density are in blue.

both in high-throughput single cell profiling procedures and the mathematical and statistical techniques needed to decipher the complex datasets that result from these experimental advances. Such advances will enable a better understanding of how variability can be controlled to produce more defined stem cell populations, which will ultimately lead to the development of more robust stem cell isolation and expansion protocols for tissue engineering and regenerative medicine applications.

MODELING TISSUE GROWTH AND DEVELOPMENT

Any success in engineering functional tissue *ex vivo* must rely not only on deciphering individual stem cell behavior, but also on developing an enhanced understanding of the mechanisms of morphogenesis *in vivo* including the environmental, chemical, mechanical, genetic and epigenetic processes involved in spatial regulation of cellular differentiation. There have been a number of remarkable recent successes in engineering complex, spatially structured and *functional* three-dimensional (3D) tissues in the lab, including: the optic cup [51]; the anterior pituitary (adenohypophysis) [52]; the trachea [53]; articular cartilage [54,55]; vascularized bone [56]; and, recently, allogeneic veins [57].

The generation of structure either during *in vivo* development or *ex vivo* tissue formation is dependent upon cells translating spatial information concerning their relative location within the developing organism or tissue into different patterns of gene and protein expression based upon their current genetic state and developmental history [58]. The extraordinary

reproducibility of development requires not only that positional information is precisely and robustly defined (that is, insensitive to environmental fluctuations) but also that cellular sensing of such information is correspondingly sensitive and appropriately coordinated. Spatial gradients have long been known to provide positional information for spatial patterning during development (for instance see the work of Wolpert, Tickle and colleagues [59–61]). Since spatial patterns emerge over relatively short length scales, Crick suggested that spatial information may be supplied by diffusion gradients [62], although local mechanisms, such as cell-cell communication, are also important [63]. Consequently, mathematical models of reaction-diffusion processes – which take into account both chemical diffusion, and cellular responses to evolving chemical gradients – have been widely used to study tissue growth and development.

Monolayer tissue growth *in vitro*

One of the simplest reaction-diffusion models is Fisher's equation, which was originally used to study the spread of a favored gene through a population [64], but serves as a good model for expansion of an *in vitro* monolayer cell colony due to proliferation and cellular migration. Denoting the cell number density (the number of cells/m^2 for monolayer culture) at position x and time t by $n(x,t)$, Fisher's equation reads:

$$\frac{\partial n}{\partial t} = rn(N-n) + D\nabla^2 n. \tag{3}$$

This equation describes the rate of change of cell number density in space and time. The first term on the RHS of Eq. (3) describes cellular proliferation. At low cell number densities proliferation is approximately exponential, with linear growth rate rn; however, as the cell number density reaches N, the maximum at confluence, the proliferation rate tends to zero accounting for inhibition of cell division due to cellular crowding. This model is known as logistic growth, and is a good first approximation to two-dimensional expansion of an unstructured population of identical cells. Hierarchically structured populations that contain subpopulations of stem, progenitor or transit amplifying cells may exhibit more complex patterns of proliferation not captured by the logistic model (Fig. 3.2). Mathematical models of growth kinetics in such heterogeneous populations have been considered by a number of authors [48,65–67]. The second term on the RHS of Eq. (3) describes random cell movement with motility coefficient D, similar to a diffusion coefficient. More complex forms of motility, including chemotaxis or haptotaxis, may be included by adapting this migration term [68]. In one spatial dimension, assuming appropriate initial conditions, Fisher's equation predicts that the colony advances as a 'traveling wave' (meaning that the invasion front maintains a constant shape, moving at a constant speed) with wave speed $v = 2\sqrt{rND}$ [64]. In the case that growth is spherical and axisymmetric (for instance, a radially expanding colony), the wave speed approaches this constant asymptotically for large radius [64]. Since the wave speed depends upon both the diffusion coefficient and the linear growth rate, reaction-diffusion fronts may advance much faster than by diffusion alone, and in a precisely quantifiable way. Consequently, Fisher's equation provides an illustrative example of how a simple mathematical model may be used to investigate the relationship between proliferative and migratory parameters and colony growth rate. If the linear growth rate is known (for instance from an independent proliferation assay), then cellular motility coefficients may be estimated using this relationship. For instance, Maini and co-workers have used this model to analyze an invasion front in a wound-healing assay for human peritoneal mesothelial cells [69,70] and we have previously used this relationship to estimate the migration rate of primary HBMSCs [71]. We found that for slowly proliferating migratory cell types, such as HBMSC populations, Fisher's equation provides a good model for colony growth; however for highly proliferative populations, such as the MG63 human osteosarcoma cell line, a sharp-front variation of Fisher's model is more appropriate [71].

Tissue growth on complex surfaces *in vitro*

Fisher's equation as outlined above describes monolayer growth. However, tissue engineering strategies commonly rely on seeding appropriate cell populations onto complex three-dimensional porous biomimetic scaffolds in order to provide geometric support for tissue development [1,72]. In this situation, while good peripheral tissue growth is usually observed, poor growth or necrotic cell death is often seen in the central regions of such constructs (though this is not always acknowledged). Spatial heterogeneity of this kind is usually related to inadequate nutrient supply and/or accumulation of toxic waste products at the scaffold interior, problems that we shall discuss in the following section. However, spatial tissue inhomogeneity may also arise from poor cellular ingrowth due to uneven initial seeding of cells and/or locally adverse scaffold geometries. Numerous groups have investigated the effects of seeding strategies, scaffold geometry, and nutrient supply on subsequent tissue growth, using both experimental and computational methods [73–75]. For instance, we have investigated HBMSC population ingrowth in a complex geometry using an experimental-computational approach which simulated Fisher's equation over a surface obtained from micro computerized tomography (μCT) scanning of trabecular bone [75] and compared simulations with experimentally-derived invasion fronts. We observed that despite the complex geometry, Fisher's equation described tissue ingrowth over the trabecular bone surface surprisingly well, with the average migration front advancing at an approximately constant speed dependent upon geometric properties of the bone surface, such as porosity and tortuosity [75] (see Fig. 3.3, bottom row). Applications of simple models of this kind are useful since they allow quantitative assessment of how scaffold architecture affects key proliferation and migratory parameters that govern the efficacy of tissue ingrowth.

Three-dimensional tissue growth *in vitro*

Nutrient-limited growth has been observed for a wide variety of engineered tissues including articular cartilage, intervertebral fibrocartilage and cardiac tissue [74,76,77]. In the absence of enhanced transport of nutrients and cellular waste products spatial heterogeneities in cell numbers rapidly develop: peripheral cells have access to ample nutrient that they consume, leaving those on the interior nutrient starved. Consequently diffusion-limited viable scaffold-based tissue growth is typically restricted to a few hundred micrometers (approximately the intercapillary distance *in vivo*). Spatial variability in cell numbers can also lead to variability in deposited extracellular matrix (ECM) components that can severely inhibit the formation of mechanically competent tissue (see Fig. 3.4). The problem of nutrient-limited growth and resultant tissue integrity has been examined from a computational perspective by numerous groups both in the context of tissue engineering [74,78–80] and avascular solid tumor growth [81].

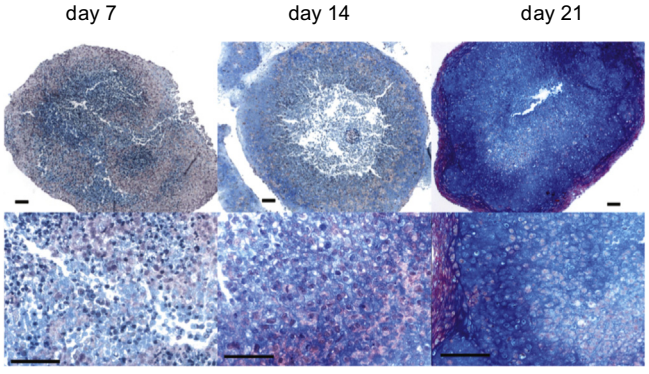

FIGURE 3.4

21-day pellet culture time-course of murine chondrocytic ATDC5 cells. Pellets were stained with Alcian blue and Sirius red to demonstrate presence of proteoglycans and collagenous ECM respectively. Spatial variability in cell numbers is apparent after 7 days and extends throughout the culture period. Cell number variability also leads to variability in deposited ECM components, which affects the structural properties of the engineered tissue. Scale bar: 100 μm.

For example, we used the following mathematical model to investigate the relationship between evolving oxygen concentration profiles and nutrient-limited tissue formation in the early stages of growth in developing engineered cartilage tissue [74]:

$$\frac{\partial c}{\partial t} = D\nabla^2 c - \alpha\beta cn, \tag{4}$$

$$\frac{\partial n}{\partial t} = \beta cn. \tag{5}$$

Here $c(x,t)$ and $n(x,t)$ represent oxygen concentration (mol/m^3) and chondrocyte cell number density (number of cells/m^3 for three-dimensional culture) at position x and time t respectively. These equations describe the rate of change of oxygen concentration and cell numbers both in space and time. The first describes the evolution of the oxygen concentration in the developing tissue: the first term on the RHS of this equation accounts for transport of oxygen which is assumed to occur by diffusion with constant diffusion coefficient D; the second term accounts for oxygen depletion and states that oxygen is consumed at a rate proportional to the local cell number density. The second equation describes changes in cell number density: the term on the RHS accounts for cellular proliferation at a rate proportional to the oxygen concentration (cell death and migration are assumed to be negligible during the initial phase of tissue growth which this model considers). The parameters α and β control the relative rates of cellular proliferation and oxygen consumption. Note that the cell number density and the oxygen concentration are intrinsically coupled to each other: changes in oxygen concentration affect cellular proliferation, which in turn effect changes in oxygen levels. To close the system we assume that oxygen levels are initially constant and the scaffold is uniformly seeded with chondrocytes; and take a no-flux boundary condition at the scaffold center and a continuity condition on the scaffold surface for the oxygen concentration. Although this model is somewhat simplified, it was nevertheless found to provide a good fit to experimentally-derived evolving oxygen and cell number density profiles, indicating that oxygen availability is a rate-limiting process during the early stages of *in vitro* cartilaginous tissue formation. Furthermore, this analysis indicated that in the absence of enhanced transport processes or regulation of cellular proliferation, spatial heterogeneities are inevitable: nutrient supply by diffusion alone will always result in proliferation-dominated peripheral regions that severely restrict viable tissue growth, and therefore the potential for clinical scale-up. This problem has been tackled both by enhancing nutrient transport, for instance using bioreactors in which transport is enhanced by advection or perfusion [82,83], or using printed scaffolds which possess an artificial 'vasculature' which can channel nutrients to the tissue center [84]; and by co-culture with endothelial cells in order to encourage the concomitant formation of *de novo* vasculature within the developing tissue [85].

Pattern formation

During development extraordinarily complex spatiotemporal structures emerge spontaneously, and it is these intricate 'patterns' that ultimately provide tissues and organs with the microscopic and macroscopic structure necessary to their function. Reproducing such pattern-forming processes *in vitro* is a major goal of tissue engineering, and a quantitative understanding of these self-organizing processes will be needed if we are to reproducibly and reliably engineer macroscopically structured functional tissues *ex vivo*. Remarkable progress has been made toward understanding the biochemical and biophysical basis of morphogenesis from both experimental and theoretical perspectives (see [86] and references therein for some examples).

In the 1950s, Alan Turing presented a simple chemical mechanism by which spatial patterns may arise spontaneously in biological systems [87] which has become acknowledged as a milestone in our understanding of development [88]. Turing's mechanism relies upon diffusion of a chemical 'morphogen' destabilizing a spatially homogeneous state, and driving

evolution toward a stable spatially heterogeneous, or patterned, state. This mechanism is both simple and remarkable, since diffusion usually has a homogenizing, or stabilizing, role. However, it can give rise to an extraordinary range of complex patterns. Consequently, it has received much attention in the mathematical biology literature [89]. The biochemical and biophysical basis of morphogenesis has developed considerably since Turing's initial work, and his concepts have been used to help understand a range of mammalian developmental systems including vertebrate limb bud development, angiogenesis and wound healing [64,89,90]. Recent developments have also begun to take into account both chemical mechanisms and biomechanical forces (which are known to play a critical part in the development of tissues such as bone [63]) in morphogenesis [91,92].

An archetypical model of pattern formation is the *activator-inhibitor* model of Gierer and Meinhardt [93]. The generalized Gierer-Meinhardt (GM) model consists of the following coupled equations, which describe reactions between an *activator* with concentration $u(x,t)(\text{mol/m}^3)$ and an antagonist, or *inhibitor*, with concentration $v(x,t)$ (mol/m^3) at position x and time t:

$$\frac{\partial v}{\partial t} = D_u \nabla^2 u + \rho_u + \frac{\rho_u}{(1+\kappa u^2)v} - \mu_u u, \tag{6}$$

$$\frac{\partial v}{\partial t} = D_v \nabla^2 v + \rho_v + \rho_{u^2} - \mu_v v. \tag{7}$$

These equations describe the rate of change of activator and inhibitor concentrations in space and time. Here $D_u, D_v, \rho_u, \rho_v, \rho, \mu_u$ and μ_v are positive constants which characterize the rates of diffusion, production and decay of the two species. The first terms on the RHS of Eqs. (6)—(7) account for diffusion; the second and third terms account for production: the activator enhances its own production (forming an autocatalytic positive feedback loop) and that of the inhibitor, while the inhibitor represses production of the activator; the fourth terms account for decay of both species with constant half-lives. If the inhibitor diffuses more quickly than the activator then this model can give rise to a variety of different spatially inhomogeneous patterns (including various types of spots and stripes, see Fig. 3.5 for some examples). The essential mechanism by which these patterns arise depends on spatial control of positive feedback: small fluctuations away from the spatially homogeneous state are initially strongly locally amplified by the positive feedback present in the system due to activator autocatalysis; however this amplification does not continue uninhibited but rather is spatially confined due to fast diffusion of the inhibitor away from regions of local activation. This type of

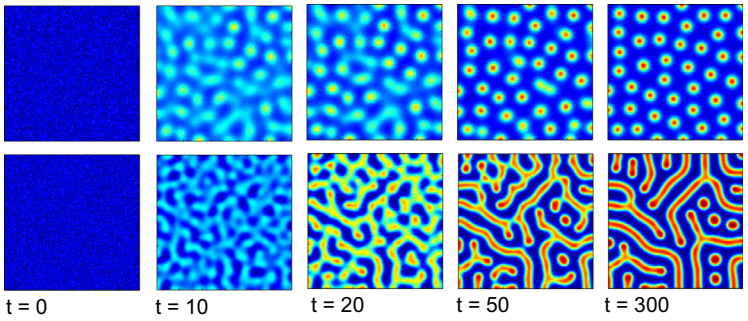

FIGURE 3.5

Spontaneous pattern formation in a simple reaction diffusion model. Simulations of the generalized Gierer-Meinhardt model [93], a classic activator-inhibitor reaction-diffusion process given by Eqs. (6)—(7), show how different kinds of spatial patterns can emerge spontaneously from the same model equations with different parameters. This model has been used to explain experimentally-observed patterns formed by adult vascular mesenchymal cells in culture [94] (**Top row**) Emergence of regular spots. (**Bottom row**) Emergence of stripes.

short-range activation and *long-range* inhibition underpins many examples of biological pattern formation. For instance, using a joint experimental-computational approach, Garfinkel and co-workers have recently shown that this mechanism can account for complex patterns formed by adult vascular mesenchymal cells (VMCs) in monolayer culture *in vitro* [94]. VMCs differentiate and self-organize into a variety of complex spatial patterns, similar to those seen in the GM model, during development, disease progression as well as *in vitro* culture. Garfinkel et al. reasoned that bone morphogenetic protein 2 (BMP-2), which is expressed by VMCs and positively regulates its own transcription, may act as a local activator; while matrix carboxyglutamic acid protein (MGP), a relatively small molecule which inhibits BMP-2 induced differentiation, may play the part of a fast diffusing long-range inhibitor (see [94] and references therein). They found that experimental culture of VMCs demonstrated good qualitative agreement with the patterns formed in a generalized GM model based on spatiotemporal interactions between BMP-2 and MGP. Additionally, their analysis predicted that different patterns would emerge from the same underlying mechanism if the kinetics of BMP-2 activation and MGP inhibition were perturbed. To test this they showed experimentally that addition of MGP to the media preparation shifted the observed pattern from labyrinthine stripes to spots; while addition of warfarin (which blocks MGP inhibition of BMP-2, see [94] and references therein) resulted in 'stripe-doubling', two changes which were predicted by their mathematical model.

Despite the relative success of activator-inhibitor models such as this, Turing-type patterns are difficult to engineer synthetically since they are sensitive to parameter changes and rely on particular disparities in kinetic and transport parameters. Consequently, the importance of these mechanisms in development has been long debated [95]. However, Turing did not intend his model to be an accurate description of any particular morphogenetic process, nor did he intend it to make hard biological predictions. Rather the power of his work was that it initiated a new way of thinking about how complex self-organizing patterns may arise when feedback is spatially controlled. Perhaps the greatest advantage to the tissue engineer of mathematical models of this kind is that they provide examples of how simple chemical, biological and physical processes can interact to spontaneously produce complex spatial patterns in ways that are hard to explore using experiment and intuition alone. In the long term, better understanding of the complex self-organizing mechanisms of tissue and organ morphogenesis from such a mathematical perspective may allow more efficient and reproducible engineering of macroscopically structured tissue.

FROM MATHEMATICAL MODELS TO CLINICAL REALITY

Mathematical methods are routinely used in engineering to optimize complex processes for industrial implementation. Similarly, we anticipate that as tissue engineering protocols make their way from development in the lab to routine use in the clinic, mathematical methods will play an increasingly central role in their optimization and scale-up. Mathematical optimization approaches are already being used to design custom scaffolds for tissue regeneration [72,96–98]. For example, Hollister and colleagues have outlined a strategy for the rational design of porous scaffolds with defined architectural properties that balance conflicting mechanical and transport requirements (reviewed in [72]). This strategy uses a set of mathematical tools from homogenization theory – which allow macroscopic material and transport properties to be inferred from scaffold microstructure – to aid scaffold design *in silico* for practical implementation using novel solid free-form fabrication techniques. Such custom approaches have been successfully used to design optimized scaffolds for bone tissue engineering in craniofacial reconstruction, for instance [97]. As another example, Unadkat and co-workers have recently outlined an algorithm-based strategy to design biomaterial surface micro-topographies that optimally regulate cell function [99]. It is likely that advanced multidisciplinary protocols such as these, which coordinate mathematical, computational,

chemical and materials engineering techniques, will lead to further advances in scaffold design in the near future. Indeed, design optimization is perhaps the area in which there is the most potential for genuinely productive application of mathematical and computational principles to tissue engineering and regenerative medicine. Such sophisticated design strategies are likely to become essential to the future of tissue engineering, and ultimately will help to take tissue engineering from experimental concept to clinical reality.

LIST OF ABBREVIATIONS

ESC – embryonic stem cell
HSC – hematopoietic stem cell
iPS – induce pluripotent stem cell
MSC – mesenchymal stem cell
ICM – inner cell mass

INTRODUCTION

A human being comes into existence by formation of the zygote, which gives rise to all human stem and non-stem cells. Stem cells are identifiable not only in the developing embryo and fetus, but also in postnatal tissues, thus ensuring the lifetime maintenance of their integrity and homeostasis by replacing the cells lost due to normal turnover, injury or disease [1]. As stem cells play a major role in the process of tissue repair, the concept of their manipulation for applications in tissue engineering and regenerative medicine has attracted considerable attention. The diversity of stem cells imposes difficulties in offering a single comprehensive definition that can be applied to all of these cells. As a general guide, stem cells are classically defined as cells with self-renewal and clonogenic properties capable of multi-lineage differentiation. Self-renewal is the capacity for extensive proliferation and generation of stem cells with the same properties as the parent cell; clonogenicity is the property of a single stem cell to produce a colony of cells through self-renewal [2]. On the other hand, the multi-lineage differentiation capability is the property of a single stem cell to generate different types of mature progenies. It should be noted that in some instances, such as spermatogonial stem cells [3], the cells only differentiate into one mature progeny, the male gamete in this case, and have limited self-renewal properties. These cells are considered as unipotent stem cells. Alternatively, these unipotent cells and other cells, such as neuronal restricted progenitor cells (NRP), with limited properties of self-renewal and multilineage differentiation are called progenitor cells [2].

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00004-5

Asymmetric cell division has been described in stem cells for a long time. Although this phenomenon has been mainly studied in invertebrates, there is evidence of asymmetric division in some mammalian stem cells, such as hematopoietic stem cells [4]. Asymmetric division gives rise to two daughter cells with different fates: one of them will remain a stem cell and the other differentiates. There are several distinct intracellular and extracellular mechanisms that contribute to asymmetric division. However, the exact nature and regulation of these mechanisms remain to be elucidated, especially in mammalian stem cells. According to recent evidence, mammalian stem cells undergo both asymmetric and symmetric divisions based on factors such as the developmental stage or the health and disease state of the tissue they are residing in [5].

DIFFERENTIATION POTENTIAL OF STEM CELLS

The differentiation potential of stem cells is described with different functional terminologies:

1) **Totipotent** stem cells, i.e., the zygote and its descendants up to the eight-cell stage in mammals, which can form the embryo and the trophoblast of the placenta [6];
2) **Pluripotent** stem cells, such as the inner cell mass of the blastocyst, embryonic stem cells and reprogrammed cells, such as induced pluripotent stem (iPS) cells that can differentiate into all the cells of the three embryonic germ layers;
3) **Multipotent stem** cells, such as mesenchymal stem cells and several other adult stem cells, which can differentiate into multiple cell lineages like osteoblast, chondroblast and adipocyte, but not all the lineages derived from the three germ layers;
4) **Bipotent** stem cells such as mammary gland epithelial stem cells, which can differentiate into two cell lineages such as myoepithelial and luminal cells [7];
5) **Unipotent** stem cells such as spermatogonial stem cells that can differentiate into only one mature cell lineage like male gamete [3].

STEM CELL NICHE

The fate of a stem cell depends not only on the genetics of the particular cell itself, but also on epigenetic cues; i.e., the signals it receives through the microenvironment. The interactions of these exogenous signals with intracellular signaling mechanisms determine a given stem cell's decision to remain quiescent, self-renew, differentiate, migrate, or even undergo apoptosis. The local microenvironment that provides the physical and chemical support for survival and the spatiotemporal cues for the regulation of stem cell function is called stem cell niche [8]. The structure and components of the niche vary in different tissues and are dependent on the developmental stage. For example, during migration of hematopoietic stem cells from fetal liver to fetal bone marrow, the expression pattern of a single hematopoietic stem cell changes according to the function of a given microenvironment and developmental stage [9]. Depending on the tissue and its developmental stage, a niche could be composed of any combinations of chemical, physical and cellular elements. Some of these elements directly interact with the stem cells, others affect the stem cells by modulating the activities of distinct local factors. For example, osteogenic differentiation of mesenchymal stem cells is enhanced by parathyroid hormone through fine-tuning of bone morphogenetic protein signaling [10]. Extracellular fluid and blood in the local vasculature play a significant role in transport of some of these elements, such as hormones and cytokines, to and from the niche.

In a typical stem cell niche (Fig. 4.1), chemical components such as cytokines and growth factors that affect stem cell function, can be secreted from neighboring 'bystander' cells, the stem cell itself or somatic cells located at a distance in the same tissue or other tissues. For example, interleukin-6 and insulin-like growth factor-I are paracrine cytokines and growth

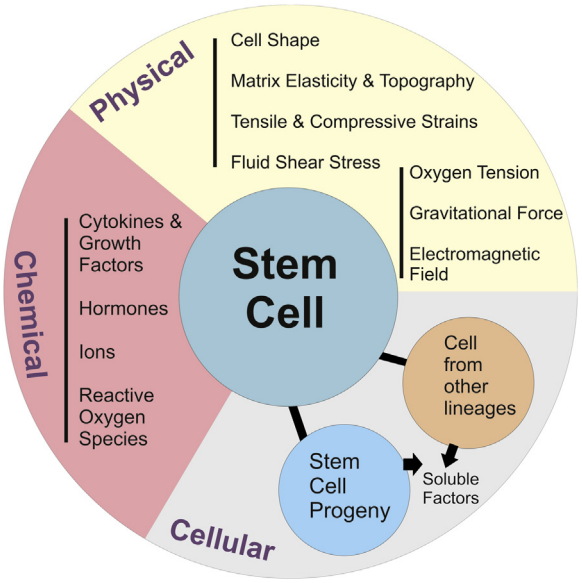

FIGURE 4.1
Composition of stem cell niche including physical, chemical and cellular components. All the components interact dynamically.

factors that promote self-renewal [11] and chondrogenic differentiation [12] of mesenchymal stem cells (MSCs), respectively. Examples of other chemical factors are:

1) Hormones, e.g., parathyroid hormone that increases osteogenic differentiation of mesenchymal stem cells [10];
2) Ions, such as calcium that increase homing of hematopoietic stem cells to bone marrow [13]; and
3) Reactive oxygen species (ROS) that, at low levels can promote self-renewal of neural progenitors [14].

Physical forces, which contribute to the formation of the stem cell niche, originate from different sources of which the extracellular matrix (ECM) plays a significant role as one of the major determinants of cell shape and phenotype. The viscoelasticity and surface topography of the ECM surrounding a stem cell can affect its fate decision *in situ* [15]. For example, differentiating MSCs choose different fates according to:

1) Cell shape, e.g., round morphology favors adipogenesis and flattened morphology osteogenesis [16];
2) Matrix elasticity, e.g., brain-tissue-like elasticity (in the range of several hundred Pascals) favors neurogenesis and bone-like elasticity (in the range of 10–100 kiloPascals) favors osteogenesis [17]; and
3) The matrix's surface topography, e.g., a particular nano-topographic surface pattern can induce the differentiation of MSCs into an osteogenic lineage [18].

The ECM's contribution to the stem cell niche includes its physical properties, structural support and its role as a reservoir of many biochemical cues and as a source for several ligands, which interact with stem cell surface receptors. For example, binding of laminin-5 found in ECM to laminin-specific integrin receptors on the surface of MSCs favors osteogenic differentiation of these cells [19]. Amongst the physical elements of a given niche that contribute to distinct stem cells differentiation are the following:

1) Tensile and compressive strains, e.g., differentiation of MSCs into a vascular smooth muscle phenotype is enhanced by a specific pattern of cyclic tensile strain [20], while their differentiation into a chondrogenic phenotype is enhanced by a certain pattern of dynamic compressive strain [21],
2) Fluid shear stress, which may enhance osteogenic differentiation of MSCs [22],

3) Gravitational force, e.g., simulated microgravity markedly increases the self-renewal capacity of MSCs [23],
4) Electromagnetic field, e.g., pulsed electromagnetic stimulation, which enhances osteogenic differentiation of MSCs [24] or cardiac differentiation of human embryonic stem (hES) cells upon electrical stimulation, [25] and
5) Oxygen tension, e.g., low oxygen tension favors self-renewal of hematopoietic stem cells [26] and endodermal differentiation of mES cells [27].

The cellular components of a particular stem cell niche comprise the stem cells themselves, their progenies and cells from other lineages [28]. For example, the hair follicle stem cell niche in the bulge contains both melanocyte stem cells (McSCs) and hair follicle stem cells (HFSCs). Progenies of the latter are incorporated into the structure of the hair follicle stem cell niche and contribute to the HFSCs' quiescence by secretion of factors such as Fgf18 and Bmp6 [29], while on the other hand, secreting soluble factors, such as TGF-β, that promote McSC self-renewal [30]. Some stem cells establish close interactions with their neighboring cells. For example, hematopoietic stem cells (HSCs) adhere to osteoblasts by activation of Tie2/angiopoietin-1 signaling, which maintains the HSCs in a quiescent state [31]. The establishment of gap junctional contacts between some stem cells and their neighboring cells has also been described. Gap junctions allow diffusion and exchange of small ions, amino acids, metabolites, and second messengers [32]. For example, human MSCs form gap junctions with endothelial cells, a feature which is important for the osteogenic differentiation of these MSCs [33]. The stem cells' response to the niche is highly influenced by the temporal and spatial pattern of expression of specific receptors. For example, in neural stem cells the expression of nuclear hormone receptors changes depending on presence of differentiating cues and the stage of differentiation, leading to a variable response to a particular stimulus at different stages of development [34]. Another important factor is the metabolic state of the stem cells. For instance, while hematopoietic stem cells reside in the bone marrow niche with low oxygen tension, they generate energy mainly via anaerobic metabolism and have low level of ROS, which promotes their self-renewal. Once recruited to the peripheral blood, however, the change of their metabolic state leads to the production of higher levels of ROS. The level of the latter can induce the cells to differentiate, undergo senescence, or lead to apoptosis [35]. Incorporation of some or all of these salient factors into an engineered stem cell niche will be of importance for maintaining the stemness of a particular (tissue-specific) stem cell population or for efficiently manipulating their directed differentiation into a desired (somatic) cell population.

DEVELOPMENTAL ORIGIN OF STEM CELLS

The process of stem cell behavior and differentiation can be understood in the context of the normal processes of development, especially during the embryonic period. Hence, regenerative tissue engineering requires good understanding and application of basic principles of developmental biology. In tissue engineering, stem cells are not just the sources for generation of the right type of somatic cells. Stem cells can also serve as key factors/building blocks for the development of tissues by organizing the stem cells into spatially appropriate models and subjecting them to specific physico-chemical cues. It is necessary to have a comprehensive understanding of the dynamics of early development together with the source and origin of stem cells in order to select the appropriate source of stem cells and design a specific suitable protocol for the use of these cells in specific applications of tissue engineering and regeneration [36]. A detailed review of the initial stages of development in humans is beyond the scope of this chapter and has recently been provided by Sadler, 2012 [37].

In humans, the first eight weeks of development is called the embryonic period. The subsequent intrauterine life after the end of embryonic period is called the fetal period. Most of the named structures of the body appear during the embryonic period. The fetal period is highlighted by maturation of tissues and organs and growth of the body. However, some

TABLE 4.1 Summary of main derivatives of embryonic germ layers

Endoderm	Mesoderm	Ectoderm
Gastrointestinal tract from pharynx to upper rectum	Muscles	Neural crest:
Liver	Bone and connective tissue (except in head)	Melanocytes
Pancreas	Urinary system	Ganglia of cranial nerves and spinal dorsal root
Respiratory epithelium	Reproductive system	Major part of autonomic nervous system
Middle ear epithelium	Circulatory system	Schwann and glial cells
Urinary bladder epithelium	Dermis (except in head and neck)	Adrenal medulla
Thyroid		Bone and connective tissue of head
Parathyroid		Dermis in head and neck
		Nervous system (see neural crest above)
		Sensory epithelium of eye, ear and nose
		Oral epithelium
		Epidermis
		Mammary gland

developmental processes, such as lung development, continue postnatally. An abridged summary of structures derived from each germ layer and neural crest is presented in Table 4.1; a more comprehensive list of the origins of human cell types is provided by Vickaryous and Hall, 2006 [38]. The fate of the differentiating cells is controlled by a set of interacting signaling mechanisms during embryonic development. The overall process of cell fate decision is determined by activation of a few well-known signaling pathways including notch, fibroblast growth factor (FGF), epidermal growth factor (EGF), Wnt/Wingless (Wg), Hedgehog (Hh), transforming growth factor β (TGFβ)/BMPs, non-receptor tyrosine kinase-signal transducers and activators of transcription (JAK-STAT), Hippo, JUN kinase (JNK), nuclear factor kappa B (NF-κB), and retinoic acid receptor (RAR). A particular cell fate decision is determined by the spatial and temporal activation and interaction of these pathways. See Perrimon et al., 2012 for a detailed review [39]. For details of the molecular mechanisms that control specification of endoderm see Grapin-Botton and Constam, 2007 [40]; for mesoderm see Lim and Thiery, 2012 [41]; and for ectoderm see Jiménez-Rojo et al., 2012 [42], for neural crest derivatives see Nelms and Labosky, 2010 [43].

Embryonic stem cells

In both mice and humans, embryonic stem (ES) cells are classically derived from the explanted ICM of the pre-implantation blastocyst. In mice, cultured ICM cells differentiate to early epiblast before giving rise to ES cells; i.e., in mice the origin of mouse ES cells is the early epiblast. Primordial germ cells (PGCs) have also been speculated as the secondary origin of mouse ES cells. It is believed that a longer term culture of ICM cells can lead to appearance of PGCs in the epiblast, which can subsequently give rise to pluripotent cells with the same phenotypic characterization as ES cells derived from early epiblast [44]. In humans, the phenotype of ES cells closely resembles the phenotype of stem cells derived from the post-implantation mouse epiblast (EpiSCs), and hence, it is believed that human ES cells originate from epiblast at a later stage of development i.e., the origin of human ES cells is the late epiblast [44]. More recent data show the possibility of capturing human cells also at the early epiblastic stage. For example, derivation of human ES cells under 5% oxygen tension generated human ES cells with two active X chromosomes, which is one of the characteristics of early epiblastic cells [45].

Non-embryonic stem cells

In terms of the origin of stem cells derived from the fetus proper, supportive fetal tissues, and postnatal tissues, three main theories are currently considered [46].

1) During development, stem cells undergo hierarchical differentiation by decreasing their differentiation potential so that pluripotent stem cells differentiate into multipotent and unipotent stem cells, which in turn, differentiate into the mature cells. Some of these multi- or unipotent cells, which have been developed after somatic lineage specification, escape further differentiation and remain in their respective tissues as stem cells. This is the most widely accepted theory for the origin of postnatal stem cells. For example pancreatic beta cells develop from progenitors, which were committed to be definitive endoderm, foregut endoderm, and endocrine precursor cells [47].
2) Some stem cells escape differentiation before or at early lineage specification, migrate to and colonize the differentiating tissues and acquire the specific tissue stem cell phenotype based on the signals in their niche. HFSCs could be the example of this hypothesis [48]. Another example would be tissue-specific differentiation of neural crest derived progenitor cells of the sympathoadrenal cells into chromaffin cells of the adrenal medulla [49].
3) In adults, there are rare populations of pluripotent stem cells, which can circulate in the body and acquire a particular tissue-specific stem cell phenotype upon integration into different tissues [50].

FETAL STEM CELLS

Detailed studies of stem cells in fetal tissues and their supporting structures, such as placenta, amniotic fluid and umbilical cord, suggest that these cells originate from specific embryonic germ layers. For example, mesenchymal stem cells isolated from chorionic villi [51] and amniotic membrane [52], which are of fetal origin, can be tracked to the chorionic and amniotic extraembryonic mesoderm, respectively. Similarly, stem cells isolated from the maternal part of the placenta, i.e., from decidual tissue, [53] are of maternal origin and from the embryonic mesoderm layer. Epithelial stem cells isolated from the amniotic membrane [54] originate from the epiblast. Amniotic fluid is a known source of stem cells. Amniotic fluid sampling is usually performed after 15th week of gestation for diagnosis of fetal diseases. The cellular composition of this sample depends on the presence or absence of congenital abnormalities, but in general most of these cells are derived from the fetal skin, pulmonary, digestive and urinary tracts and from the amniotic epithelium. Amniotic fluid may also contain cells originating from the mother and from trophoblasts. Amniotic fluid stem cells express both embryonic [55] and mesenchymal stem cell markers [56]. These markers are often expressed by the same cells [57]. Clonal derivatives of these cells can differentiate into cells of all three embryonic germ layers [58]. However, further studies are needed regarding the origin, characterization, maintenance, and differentiation potential of amniotic fluid stem cells before translation into any clinical applications can be considered [59].

Umbilical cord stem cells

The umbilical cord is of fetal origin and contains several types of stem cells. Stem cells have been identified in the umbilical epithelium, which is believed to be derived from the amniotic epithelium, and hence from the epiblast [60]. Stem cells with predominant mesenchymal properties have been isolated from subamnion [61], intervascular matrix known as Wharton's jelly [62], perivascular stroma [63] and subendothelium [64] of the umbilical cord. All these stem cells are believed to originate from extraembryonic mesoderm. The origins of hematopoietic and mesenchymal stem cells in cord blood are the same as of fetal blood, since the umbilical circulation is part of the fetal circulation. Cord blood hematopoietic stem cells are a mixed population of cells at different commitment stages, as characterized by the differential combination of CD34, CD45 and CD133 markers [65]. Other cells isolated from the umbilical cord blood, which reportedly have stem cell properties, include unrestricted somatic stem cells (USSCs) and very small embryonic-like stem cells (VSELs). USSCs are a CD45-negative population [66] with the ability to differentiate towards derivatives of all three germ layers. USSCs exhibit a high *in vitro* proliferation capacity, no spontaneous differentiation, and

immunophenotypic features that overlap with fetal MSCs [67]. There are speculations that these cells may represent the precursor cells for MSCs [66], but their precise developmental origin and molecular mechanisms of stemness remain to be elucidated. Initial studies suggest that their extensive differentiation capacity may be due to incomplete DNA methylation and reversible histone modification of key pluripotency genes including Oct4, Sox2, and Nanog, which epigenetically keep these cells in an uncommitted state [68]. Very small embryonic-like stem cells (VSELs) are cells of very small diameter (3–6 μm) with high nucleo-cytoplasmic ratio, which express the main pluripotency markers including Oct-4, Nanog, and SSEA-4 [69]. They are found in low abundance in human cord blood and are mobilized to peripheral blood as the result of specific conditions, such as skin burn injury [70]. Murine VSELs have the capability to differentiate into cells of all three germ layers and are believed to originate from early migrating primordial germ cell-like cells derived from epiblast [71]. Human VSELs may not show the same differentiation potential as their murine counterparts [72]. However, more studies are needed to define the molecular and cellular characteristics of these intriguing cells in humans.

Fetal hematopoietic stem cells

Fetal hematopoietic stem cells are generated during the process of prenatal hematopoiesis, which takes place in several anatomical locations. In human, extraembryonic mesoderm surrounding the yolk sac is the first site of hematopoiesis. In this site, blood islands appear at about the day 17 of embryonic development [73]. After establishment of vascular connections between the yolk sac and the embryo, these yolk sac-derived hematopoietic cells enter the embryo and colonize the liver at day 23 (first hepatic colonization). Starting from day 27 of development, a few groups of hematopoietic stem cells are detected as the cells adhering to the aortic endothelium in the pre-umbilical area. These cells originate from intraembryonic splanchnic mesoderm [74] and lead to definitive hematopoiesis, which is characterized by differentiation into erythroid and myelolymphoid lineages. The liver is colonized by these cells at day 30 (second hepatic colonization) and bone marrow in the week 11. For detailed reviews, see Baron et al., 2012 [75].

MESENCHYMAL STEM CELLS

MSCs have been widely believed to be derived from embryonic mesoderm. However, a report published in 2007 suggested that these cells may originate from more than one embryonic layer [76]. So far, only a few follow-up experiments have been performed to elucidate the developmental origin of MSCs. These experiments suggested that the earliest MSC cells in the embryonic trunk are derived from the neural crest rather than the mesoderm [76] and identified neural crest derived stem cells in the embryonic circulating blood [77]. During later stages of development, these cells of neural crest origin are replaced with mesenchymal stem cells from other sources, but some of the neural crest derivatives persist in adult tissues. This hypothesis could explain the finding that, for example, bone marrow mesenchymal stem cells are not a homogenous population [78] and that some of these 'MSCs' may differentiate to cells outside the mesodermal lineage. The detailed description of different types of mesenchymal stem cells, their functions and applications for tissue engineering will be presented in Chapter 36.

It is important to apply the knowledge of the origin and development of stem cells in the design of protocols for engineering tissue constructs *in vitro* and also for the use in regenerative tissue repair, especially following a tissue loss. The latter process mimics some of the very early developmental events and involves a progressive remodeling of the existing tissue and progressive phenotypic characterization of stem cells. Consideration of this principle could help in designing and implementing a correct protocol, which stimulates stem cells to follow their normal developmental pathway and hence, enhance tissue repair through a remodeling process [79].

STEM CELL DIFFERENTIATION METHODS

When in their *in situ* microenvironment, stem cells are subjected to the physico-chemical cues and cellular elements of the niche. According to the specific physiological or pathological condition, a niche can have a spectrum of properties, which maintain stem cells in their undifferentiated state or coax them to differentiate into particular phenotypes. Niche elements and their unique properties have been extensively used for the design of protocols for the maintenance and differentiation of stem cells *in vitro*.

Soluble factors such as cytokines, growth factors, and hormones are the most widely used niche elements for *in vitro* differentiation of stem cells due to their relative ease of manipulation. In comparison to other methods that put stem cells in contact with other cells or their products or use genetic manipulation, it seems that the probability of inducing any aberrant phenotype in the differentiated cells is lower when using a soluble factor as the main method of differentiation. There are many examples for the use of this niche element. For instance, differentiation of embryonic stem cells to a distal pulmonary phenotype can be effectively directed by removal of inhibitory soluble factors in the serum [80], followed by a stepwise differentiation into definitive endoderm and distal lung epithelial cells using first activin A and wnt3a and then a cocktail of soluble factors including Fgf2 designed to mimic the natural microenvironment of mature distal lung cells [81]. A most recent variation to this protocol has shown that superior results can be obtained by a more refined stepwise direction of embryonic stem cells to distal lung epithelium by stepwise provision of niche-specific soluble factors and direction of ES cells into five distinct phases of induction of definitive endoderm, anteriorization of endoderm, induction of Nkx2-1+ foregut endoderm, proliferation and specification of lung progenitors, and their maturation [81].

Use of defined extracellular matrix (ECM) components or their ligand sequences is another strategy, which has been adopted to control the fate of differentiation of stem cells. For example, collagen type I promotes osteogenic differentiation of bone marrow mesenchymal stem cells by activations of $\alpha 1\beta 1$ and/or $\alpha 2\beta 1$ integrins [82]. Therefore, use of collagen type I for coating of 2D dishes or fabrication of 3D scaffolds is one of the effective methods for differentiation of MSCs into the osteoblast lineage. Furthermore, the DGEA (Asp-Gly-Glu-Ala) ligand sequence of collagen type I can be used instead of the whole type I collagen and can effectively induce osteogenic differentiation in mesenchymal stem cells [83]. However, Pimton et al. (2011) [84] recently showed that murine embryonic stem cells lack collagen integrin receptors and instead express $\alpha 5\beta 1$, the fibronectin receptors, which are subsequently further upregulated during the initial stages of meso-endodermal differentiation. Hence the choice of permissive ECM components to induce directed differentiation will depend on a clear understanding of the integrin profiling of naïve and differentiating stem cells, which may be stage- and species-specific. In addition to extracellular matrix proteins, synthetic materials that exhibit bioactive properties can also induce stem cell differentiation. For example, osteogenic differentiation of mesenchymal stem cells can be induced by many permissive scaffolds, such as a mixture of bioactive glass-polyvinyl alcohol [85] or hydroxyapatite-containing electrospun chitosan fibers [86].

As described above under the 'stem cell niche', differentiation of stem cells is also controlled by several physical factors. However, as in most cases, integration of these factors into the differentiation protocols needs special equipment and expertise. Physical stimuli including mechanical strain, fluid shear stress, hydrostatic pressure or electrical stimulation are not always in routine use in many stem cell laboratories. Specifically designed dynamic bioreactors are usually needed for subjecting the stem cells to physical factors. In addition to control of physical factors, some of these bioreactors will also enable control of the chemical micro-environment of the cells. For example, when murine embryonic stem cells are cultured in a low shear, low gravity, 3D rotating wall, bioreactor system, the efficiency of their differentiation into pulmonary epithelial cells is significantly enhanced in comparison to a static culture system [87]. This issue will be further discussed in Chapter 15.

To take advantage of the cellular component of the stem cell niche, *in vitro* co-culture of stem cells and other cells has been practiced for many years. The most widely used example of this method is the co-culture of embryonic stem cells (ESCs) and embryonic fibroblasts, which maintains the 'stemness' of ESCs and inhibits their spontaneous differentiation. Enhancement of the differentiation of ESCs into the distal pulmonary epithelial cell phenotype by co-culture of ESCs and embryonic mesenchyme is another example of this method [88]. Although the effectiveness of the co-culture method has been demonstrated in several studies, the difficulty of its administration has prompted the use of cell-conditioned media as an alternative. For example, a medium conditioned by A549 cells, an established cell line from a human lung adenocarcinoma with properties of type II alveolar epithelial cells, directs the differentiation of embryonic stem cells into type II pneumocytes [89]. A medium conditioned by particular 'mature' cell types contains the entire repertoire of soluble factors secreted by these cells ('secretome'), which can affect the process of differentiation of the target stem cells. In order to take full advantage of the competence of a mature cell to direct the fate of differentiation of stem cells, Quin et al. (2009) [90] used a method developed by Hakelien et al. (2002) [91] to permeabilize embryonic stem cells and expose them to the extracted cytoplasm of the mature A549 cells, and hence, effectively direct them to differentiate into type II pneumocytes [90]. This method exposes the stem cells to the whole gamut of intracellular signaling molecules of the mature cells and directs/induces the stem cells to differentiate along the mature cell's phenotype.

Genetic manipulation of stem cells is another means for induction and control of differentiation with high efficacy. This is usually achieved by transfecting the cells with a DNA construct, which encodes the expression of a certain protein. For example, over-expression of bone morphogenetic protein-2 in MSCs has been known to increase their osteogenic differentiation [92]. On the other hand, genetic manipulation can be used for purification of differentiated derivatives of stem cells. For example, Wang et al., (2007) [93] generated a pure population of lung alveolar epithelial type II cells derived from human ESCs using a unique human SPC promoter-neomycin transgene. Although many more successful examples of this approach have been reported so far, the potential risks of application of recombinant DNA technology in the clinical setting should always be considered. The concerns are the safety of the viral-based vectors, the risk of malignant transformation of the transfected cells and the possibility that over-expression of a particular protein may lead to unpredictable physiologic effects.

TRANSDIFFERENTIATION AND REPROGRAMMING

It has been known for many years that differentiation is not a one-way, terminal process. Under certain conditions, an adult differentiated cell can switch its phenotype to that of another mature cell type. This phenomenon is called transdifferentiation. For example, after near total destruction of pancreatic β cells in mice, pancreatic α cells spontaneously transdifferentiated into β cells [94]. Additionally, pancreatic exocrine cells can be transdifferentiated into insulin-producing β cells by over-expression of three genes involved in development of pancreatic β cells, including *Ngn3*, *Pdx1* and *Mafa* [95]. Transdifferentiation is highly facilitated when the cells are from closely related lineages or are derived from the same embryonic layer. For example, both the pancreas and liver are endoderm-derived organs. Hence, using the appropriate sets of lineage-specific reprogramming transcription factors, hepatocytes can be turned into pancreatic β cells and vice versa [96].

Transdifferentiation of one somatic cell into another is not the only strategy for turning an adult cell into one with another phenotype. Mature cells can be turned into pluripotent, ESC-like cells through a process called reprogramming. In addition to the scientific novelty and exciting possibility that they offer for answering specific mechanistic questions related to the process itself, reprogramming could yield patient-specific immunocompatible pluripotent cells on

demand. This opens up many potential clinical applications for these cells, while circumventing the ethical issues related to the use of ESCs. The first evidence of successful reprogramming was provided some 50 years ago by transfer of the nucleus of an intestinal cell of a frog to the enucleated fertilized egg of another frog, which led to the birth of live frogs [97]. This method, which is also known as cloning, is difficult to perform, has a very low efficiency, and needs availability of fertilized eggs, which in case of the human, imposes further practical and ethical restrictions. Also, cloned animals show phenotypic abnormalities which make cloning a challenging technique. In 2006, Yamanaka's group reported that retroviral insertion of a combination of genes for four key embryonic 'stemness' transcription factors Oct3/4, Sox2, c-Myc, and Klf4 could reprogram somatic cells into pluripotent cells, which are known as 'induced pluripotent stem (iPS) cells' [98]. However, the random integration of these transgenes and the risk of insertional mutagenesis raised concerns about the clinical safety of these cells. Hence, this technique is continually being improved upon to avoid random integration and overcome the low efficiency of the process. Although iPS cells are considered to be the surrogates of ES cells, emerging evidence shows a number of genetic and epigenetic differences between them. For example, mis-imprinting of the genes at the Dlk1-Dio3 locus on chromosome 12 has been reported in iPS cells [99]. These and other differences should be addressed by better definition of the epigenetics of pluripotent stem cells and by improving the methods of reprogramming. It should also be noted that iPS cells will be carriers of the same disease/genetic disorder as their somatic parental cells, which may limit their use, especially for treating conditions with significant genetic components. Reprogramming will be covered in detail in Chapter 35.

Finally, while the Yamanaka approach, recently recognized with the 2012 Nobel Prize for Medicine, is exciting in terms of generating quasi-embryonic stem cells, it may not be necessary to take reprogramming all the way back to first having to generate iPS cells, which then can be differentiated into the desired mature somatic cells. Recent studies suggest that essentially all mature somatic cells can potentially be transdifferentiated into any other cells in the body [100]. For example, using diverse combinations of cardiac-enriched defined transcription factors, mouse fibroblasts can be transdifferentiated into functionally mature cardiac myocytes [101]. If harnessed correctly and efficiently, transdifferentiation and/or reprogramming could be used as an additional strategy for the repair of damaged tissue using the patients' own mature cells, hence avoiding the need for the isolation and expansion of rare adult stem cells [102]. However, as the mechanisms and different aspects of this phenomenon are not yet very well understood, many more studies will be needed before this technology can be translated into the clinical arena.

CHALLENGES AND LOOKING FORWARD

Challenges

Although stem cell research offers many hopes for the better management of numerous human diseases, the progress of clinical applications of stem cells in the context of tissue engineering and regenerative medicine has been rather slow so far. This may be in part due to the fact that we still do not have a comprehensive understanding of the mechanisms, which lead to a particular disease and which we then hope to treat with stem cells. A clear definition of what we expect to be modulated and improved by stem cell therapy in different conditions will help us to design more suitable protocols for the clinical translation of stem cell research findings. On the other hand, there are also still many gaps in our knowledge of both the *in vivo* and *in vitro* biology of stem cells, including their microenvironment, signaling, differentiation and proliferation pathways, asymmetric cell division and response to stimuli. The potential safety risk of genetic manipulating stem cells for clinical applications is another issue that needs further in-depth study. More work needs to be done in the field of the *in vivo* biology of human stem cells. Specifically, in the natural *in vivo* setting, each stem cell resides in a niche, which is specific to that stem cell and given tissue. Unfortunately the routine culture of stem

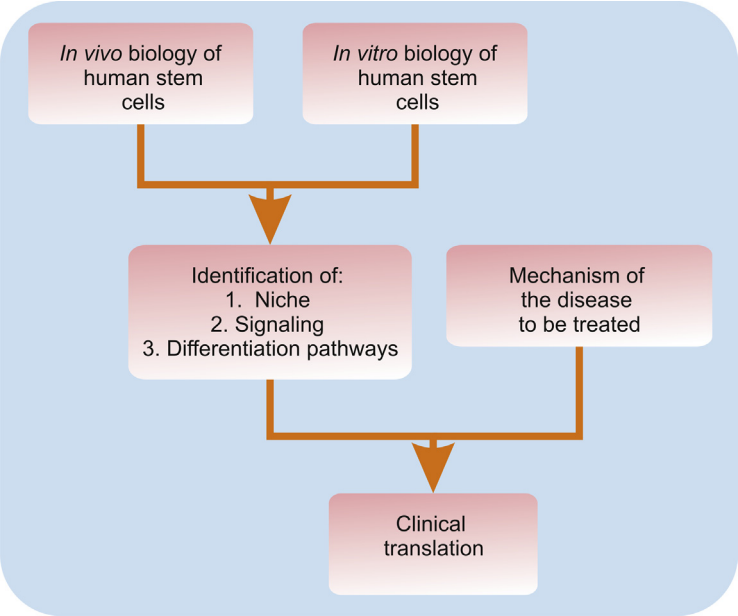

FIGURE 4.2
Major issues to be addressed for successful application of stem cells in tissue engineering and regenerative medicine.

cells in many laboratories is often performed under conditions that are quite distinct from the stem cell niche *in situ*. These differences can profoundly affect the behavior of stem cells not only *in vitro*, but also after implantation *in vivo*. It is therefore highly recommended to identify the natural stem cell niche at a specific developmental stage, from undifferentiated to fully differentiated, and provide the right niche during their *in vitro* manipulation (Fig. 4.2). Understanding the behavior of these cells in normal and pathological conditions *in vivo* will increase our ability to take full advantage of their therapeutic potential in different clinical scenarios.

Looking forward

Overall, there will be an increased demand for faster translational research in the coming years. Due to the technical complexities, interventions that involve a single cell lineage and their secretion products are expected to have a higher rate of progression in the translational phase. A stem cell therapy for restoring the dopaminergic system in Parkinson's disease is an example of such an intervention. We believe that both autologous and allogenic sources will find their ways into the stem-cell-mediated therapeutics. This is because genetic factors contribute to the pathogenesis of some diseases in the first place, and are retained in autologous cells, which continue to carry the same genetic risk factors. We are close to entering the logarithmic phase of growth in the clinical translation of stem cell research, hence we should be prepared for this new and challenging phase by clearly and comprehensively addressing the regulatory issues involved in the clinical application of stem cells as building blocks for regenerative engineering and cell-based therapies.

CHAPTER 5

Moving into the Clinic

Alan J. Russell[1] **and Timothy Bertram**[2]
[1] Disruptive Health Technology Institute, Carnegie Mellon University, Pittsburgh
[2] Tengion, Winston-Salem, North Carolina

INTRODUCTION

In the early 1930s Charles Lindbergh, who was better known for his aerial activities, went to Rockefeller University and began to study the culture of organs. After the publication of his book about the culturing of organs *ex vivo* in order to repair or replace damaged or diseased organs, the field lay dormant for many years. Indeed, delivering respite to failing organs with devices or total replacement (transplant) became far more fashionable. Transplantation medicine has been a dramatic success. But in the late 1980s scientists, engineers, and clinicians began to conceptualize how *de novo* tissue generation might be used to address the tragic shortage of donated organs. The approach they proposed was as simple as it was dramatic. Biodegradable materials would be seeded with cells and cultured outside the body for a period of time, before exchanging this artificial bioreactor for a natural bioreactor by implanting the seeded material into a patient. These early pioneers believed that the cells would degrade the material, and after implantation the cell-material construct would become a vascularized native tissue. Tissue engineering, as this approach came to be known, can be accomplished once we understand which materials and cells to use, how to culture these together *ex vivo*, and how to integrate the resulting construct into the body.

Most major medical advances take decades to progress from the laboratory to broad clinical implementation. Tissue engineering was such a compelling concept that the process moved much faster. As we will discuss later, the speed at which tissue engineering solutions can be implemented is inherently faster than traditional drug development strategies. For this reason, coupled with what was probably unexplained exuberance, business investors saw an immediate role for industry in delivering tissue-engineered products to patients.

Traditionally, new fields are seeded with foundational research, development, and engineering prior to implementation, but an apparent alignment of interests caused many to believe that companies could deliver products immediately and that the traditional foundational aspects could wait. The race to clinical implementation of a tissue-engineered medical product began with the incorporation of Advanced Tissue Science (ATS) in 1987. ATS and Organogenesis, an early competitor, began their quest by focusing on seeding biodegradable matrices with human foreskin fibroblasts. In the early days, Organogenesis, Integra, and Ortec focused on bovine-derived scaffolds, while ATS focused on human-derived scaffolds. Other companies focused on developing tissue engineering products using scaffold alone or cells alone. The path to implementation has been very different for each class of company, as will be summarized later. With hindsight, one might say that the choice of living skin equivalents as a first commercial product was probably driven by the willingness of the Food and Drug Administration (FDA) to regulate them as Class III devices rather than biologics. This attractive feature of the products was supplemented by large predicted market sizes and the ease of culturing skin cells.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00005-7

As these products moved from the laboratory to the clinic, development issues such as which cells, materials, and bioreactors were supplanted with industrial challenges such as scale-up and immunocompatibility. At the same time that ATS and Organogenesis were rapidly growing, the view emerged that delivery of tissue-engineered products to patients would require an allogeneic off-the-shelf solution with ease of use and long storage life in the United States — and this persists today. This business-driven decision predicated the development of allogeneic, cell-based therapies. Interestingly, in a study sponsored by the National Science Foundation, the World Technology Evaluation Center discovered that non-US investors were focused on autologous cell therapies resulting from a belief that allogeneic therapy would be unsuccessful because of the need to suppress the patient's immune system. This difference in emphasis between US and non-US investors continues today. Both approaches have genuine advantages and disadvantages. However, once it became clear that cell-seeded scaffolds could trigger dramatic changes in natural wound healing, thereby inducing *de novo* tissue formation and function, clinical implementation through industry progressed from skin to a wide array of tissues. In addition, pockets of excellence arose at major medical centers, where new innovations were tested clinically in relatively small numbers of patients.

So one is left with several questions: What have we learned from these early adoptions of tissue engineering? How can these lessons drive sustainable innovation that will both heal and generate a return on investment? Is broad clinical implementation of tissue engineering limited by the nature and structure of regulatory bodies? This chapter seeks to answer these questions by looking historically at selected high-profile clinical tissue engineering programs and looking forward with a suggested generic approach to rapid clinical translation in this new era of advanced medical therapies.

HISTORY OF CLINICAL TISSUE ENGINEERING

What is clinical tissue engineering?

As mentioned earlier, in the early 1990s the term *tissue engineering* was generally used to describe the combination of biomaterials and cells *ex vivo* to provide benefit once implanted *in vivo*. What emerged over the next decade, however, were biomaterials designed to alter the natural wound healing response and cell-only therapies. Lessons learned in the development of each led to the fusion of these tools under the rubric of tissue engineering. Today, there remains confusion about what the term *tissue engineering* truly encompasses. A related term, *regenerative medicine*, has emerged recently. The boundaries of what falls under each of these terms are unclear. We do not seek to provide a definitive answer in this chapter, but herein we discuss the use of biomaterials and cell-seeded biomaterials. We exclude the use of cell-only therapies.

Thus, we define *clinical tissue engineering* as:

> 'the use of a synthetic or natural biodegradable material, which has been seeded with living cells when necessary, to regenerate the form and/or function of a damaged or diseased tissue or organ in a human patient.'

We see clinical tissue engineering as a set of tools that can be used to perform regenerative medicine, but not all regenerative medicine has to be done with that set of tools.

Two-dimensional clinical tissue engineering

The earliest clinical applications of tissue engineering revolved around the use of essentially flat materials designed to stimulate wound care. Tissue-engineered skin substitutes dominated the market for almost a decade. Another small and slim tissue that found a clinical application was cartilage. Later in the 1990s, thin sheets of cells were produced in culture and then applied to patients using a powerful cell-sheet technology. In both the applications,

engineered tissue equivalent is relatively easy to culture *ex vivo* because oxygen and nutrient delivery to thin, essentially two-dimensional, materials is not challenging. In addition, once the construct has been cultured *ex vivo*, integration into the body is not an insurmountable barrier for thin materials.

TISSUE-ENGINEERED SKIN SUBSTITUTES

Since the inception of tissue engineering there has been a focus on the regeneration of skin. A number of drivers led to this early focus, not least of which was the mistaken assumption that skin is simple to reconstitute *in vitro*. Skin cells proliferate readily without signs of senescence. Indeed, fibroblasts and keratinocytes have been cultured *in vitro* for many years with ease. Interestingly, other highly regenerative tissues, such as the liver, are populated with cells that cannot be proliferated *in vitro*. The clinical need for effective skin wound healing was also a major driver. One in seven Medicare dollars is spent on treating diabetes-induced disease in the United States. The largest component of that cost goes toward treating diabetic ulcers. This attractiveness drew many tissue engineering efforts into the wound care market.

REGENERATIVE BIOMATERIALS

For almost two decades scientists have explored the use of processed natural materials as biodegradable scaffolds that induce improved healing from skin wounds. One of the first products to market was the INTEGRA® Dermal Regeneration Template. INTEGRA® is an acellular scaffold designed to provide an environment for healing using the patient's own cells. The INTEGRA® label describes the product as follows:

> INTEGRA® Dermal Regeneration Template is a bilayer membrane system for skin replacement. The dermal replacement layer is made of a porous matrix of fibers of cross-linked bovine tendon collagen and a glycosaminoglycan (chondroitin-6-sulfate) that is manufactured with a controlled porosity and defined degradation rate. The temporary epidermal substitute layer is made of synthetic polysiloxane polymer (silicone) and functions to control moisture loss from the wound. The collagen dermal replacement layer serves as a matrix for the infiltration of fibroblasts, macrophages, lymphocytes, and capillaries derived from the wound bed. As healing progresses, an endogenous collagen matrix is deposited by fibroblasts, simultaneously the dermal layer of INTEGRA® Dermal Regeneration Template is degraded. Upon adequate vascularization of the dermal layer and availability of donor autograft tissue, the temporary silicone layer is removed and a thin, meshed layer of epidermal autograft is placed over the 'neodermis'. Cells from the epidermal autograft grow and form a confluent stratum corneum, thereby closing the wound, reconstituting a functional dermis and epidermis. INTEGRA® is now one of many processed natural materials used to stimulate healing. Since the material is not vascularized at point of use, it is best used in thin (two-dimensional) applications. INTEGRA® is an FDA-approved tissue engineering material widely used in patients today. It does not, however, contain biological factors that are released during the tissue-remodeling process.

Another class of products, the thin extracellular matrix-based materials, does release natural factors as the material degrades, and these factors serve to reset the natural tissue-remodeling process, thereby producing a healing outcome. The most common Extra Cellular Matrix (ECM)-based material is derived from the submucosal layer of pig small intestine. The Cook OASIS® Wound Matrix label describes the product as follows:

> The OASIS® Wound Matrix is a biologically derived extracellular matrix-based wound product that is compatible with human tissue. Unlike other collagen-based wound care materials, OASIS is unique because it is a complex scaffold that provides an optimal environment for a favorable host tissue response, a response characterized by restoration of tissue structure and function. OASIS is comprised of porcine-derived

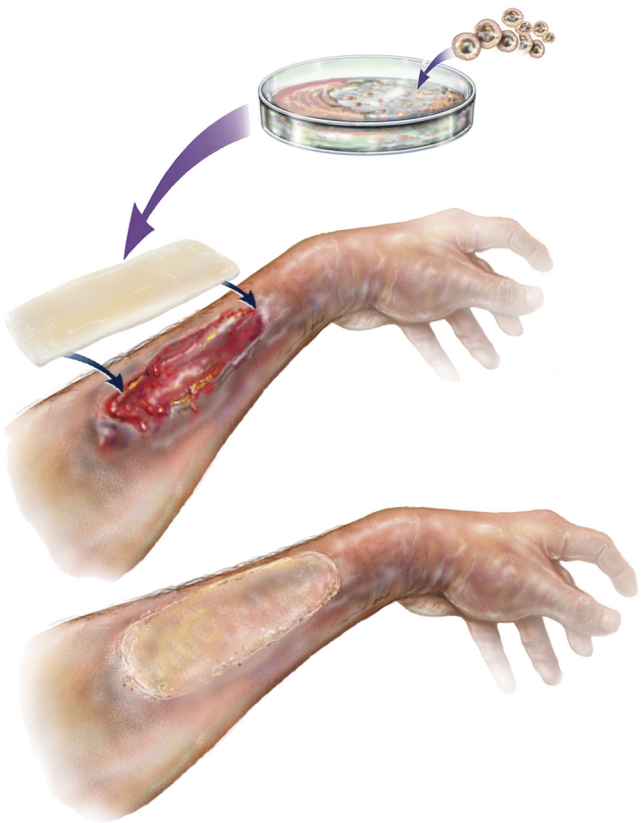

FIGURE 5.1

acellular small intestine submucosa. The OASIS Wound Matrix is indicated for use in all partial- and full-thickness wounds and skin loss injuries as well as superficial and second-degree burns.

Regenerative biomaterials, or materials designed to alter and enhance the natural tissue-remodeling process, are being used in hundreds of thousands of patients worldwide. These materials recruit a patient's own cells into the healing process post-implantation, and their relative simplicity makes them compelling clinical tools for indications where a thin, essentially two-dimensional material will achieve the desired result. In an elegant series of accomplishments, natural matrices have been applied for skin wounds and many other tissue-replacement therapies.

Cultured skin-substitute products (Fig. 5.1), where cells are seeded onto a biodegradable matrix and cultured *ex vivo* prior to shipment and use, have been extraordinarily difficult to market. Given this reality, it is interesting that the purveyors of the two leading skin equivalents are the true early pioneers of tissue engineering. Both Advanced Tissue Sciences and Organogenesis engaged in a valiant effort to use human fibroblasts and biomaterials to regenerate skin. They were challenged by a changing regulatory landscape, an ongoing struggle with reimbursement issues, and the highly complex need to manufacture and ship a living product. A full case study of ATS or Organogenesis would be of tremendous value to the next generation of tissue engineering companies, but is beyond the scope of this chapter. Dermagraft®, the Advanced Tissue Science product now manufactured by Shire, uses skin cells isolated from neonatal foreskins prior to seeding onto a polymeric scaffold. Apligraf®, Organogenesis' product, used similar technology to seed and culture cells on collagen-based scaffolds. Tissue-engineered skin equivalents continue to be developed. As technology improves and multilayer systems progress to broad clinical use, the market should also increase from today's anemic levels of $15 million/year. The FDA and reimbursement issues have greatly impacted clinical use of cultured skin equivalents. The FDA treated these products as devices yet held them to biologic standards, and this led inevitably to their being reimbursed as biologics.

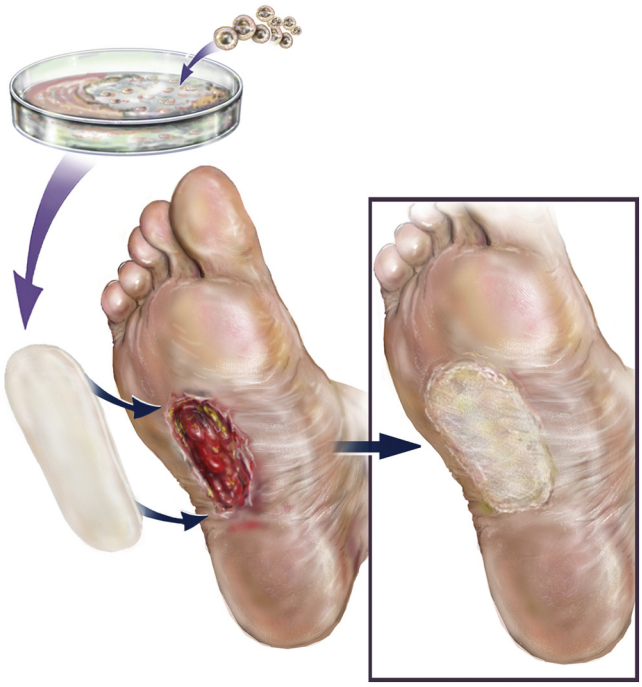

FIGURE 5.2

Another approach to clinical skin remodeling is the use of autologous cell-based therapies (Fig. 5.2). One attractive feature of using a patient's own cells is, of course, the lack of an immune response, but the manufacture of patient-specific yet inexpensive skin replacements is very complex. Epicel® from Genzyme Biosurgery uses irradiated mouse fibroblasts as a feeder layer from which to grow patient-specific keratinocytes. Co-culture with animal-derived cells may raise regulatory and infectious disease questions requiring manufacturing practices that increase the cost of goods. In 1995, Genzyme began expanding patient-specific chondrocytes (Fig. 5.3). Small biopsies were sent to Genzyme, where they were cultured and returned to the surgeon for implantation. The product, Carticel®, was approved as a biologic by the FDA in 1997. At time of treatment, a patient typically receives 10 million to

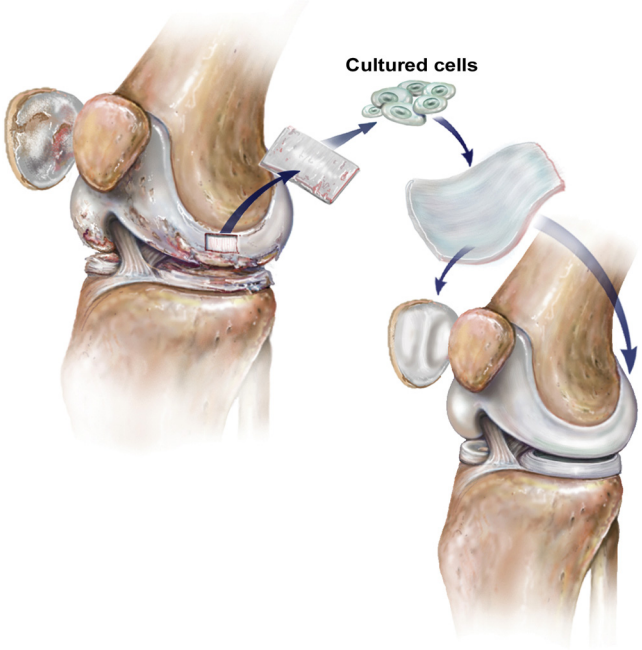

FIGURE 5.3

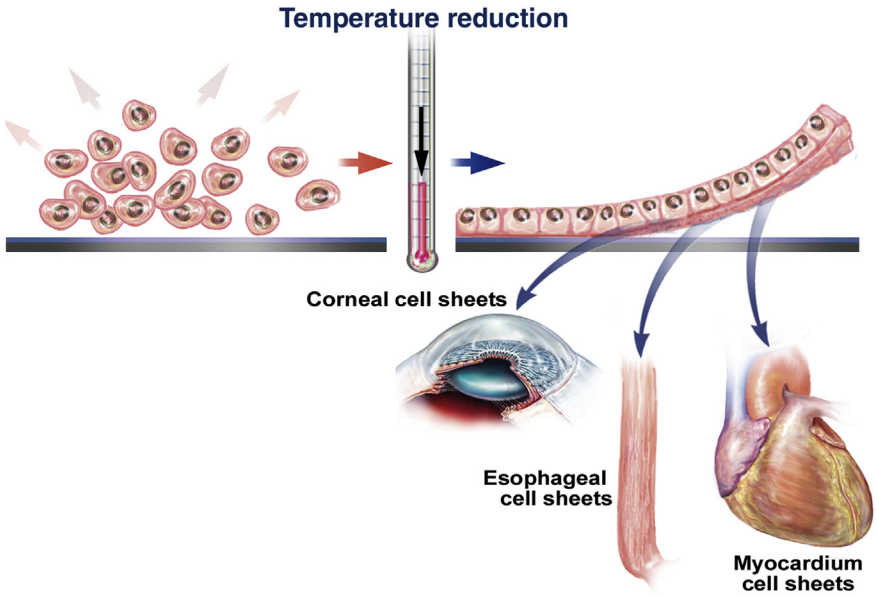

FIGURE 5.4

15 million cells after five weeks of custom *ex vivo* culturing. As with skin remodeling, a number of companies have focused on the use of acellular regenerative materials. Approved products are currently sold in many countries around the world that are based on collagen and/or extracellular matrices (ECMs). Thousands of patients around the world have benefited from orthobiologic approaches to cartilage replacement. Although patient-specific cartilage replacement therapy has also provided benefit, it is a good example of the difficulty of delivering individualized therapies while deriving a profit. The considerable infrastructure required to culture tissue safely in this manner presents unique challenges for the manufacturer to overcome.

Many research groups around the world have sought to improve on the efficacy of Carticel®, focusing on cell-based and regenerative material-based approaches. Although cartilage segments *in vivo* and *in vitro* are generally small and non-vascularized, the biomechanical properties of those tissue-engineered cartilage products have not overall achieved the standards required for clinical application (Fig. 5.4). Okano at Tokyo Women's Hospital has invented a remarkable technology that produces intact cell sheets for clinical applications. In general, when human cells are cultured *in vitro* they adhere to their culture dish substrate. Traditional culturing techniques extract cells by adding enzymes and other materials that digest cell-surface and cell-cell contacts. Cells processed in this manner are delivered as single cells for clinical application. Okano envisioned an alternative for removing cells that has had a dramatic clinical impact. Okano covalently bonds a layer of *N*-isopropylamide to the surface of the culture dish prior to adding cells and has shown that, under normal growth temperatures cells adhere, but when slightly chilled the entire sheet of cells is repelled from the dish without disrupting the cell-cell contacts and can be lifted from the surface rather like a Post-it note®. For a first clinical application, Okano's team cultured corneal epithelial cells and used the resulting sheets to replace the damaged corneal epithelia of dozens of patients. Okano has reported significant success and, although the number of patients in need of corneal epithelial replacement is limited, this cell-sheet technology has real potential for broader clinical tissue engineering application.

ENCAPSULATED PANCREATIC ISLETS

The use of biomaterials to immunoisolate pancreatic islets of Langerhans has been studied since the mid-1990s. If one could build a cage that surrounded the islet and had a mesh size

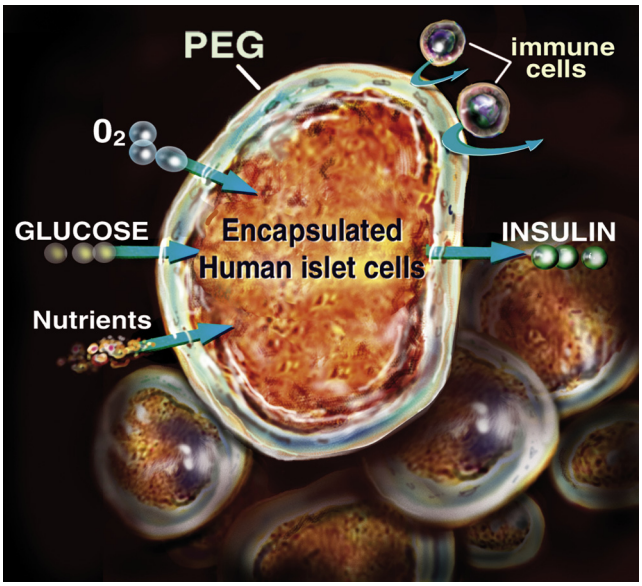

FIGURE 5.5

small enough to prevent the approach of antibodies to the islet but large enough to enable nutrient diffusion, it may be possible to diminish a patient's dependence on insulin, post-transplant. Alginate-encapsulated islets have been studied for many years, and an ongoing clinical trial (Novocell) is using interfacially polymerized Polyethylene Glycol (PEG)-encapsulated islets (Fig. 5.5). The success of these trials is not yet known, but porcine islets have already been shown to be protectable in a short-term discordant xenotransplantation model. Interestingly, our own work has shown that even a molecular-scale PEG cage can immunoisolate islets, and this has now been shown to eliminate insulin dependence in diabetic animals.

Three-dimensional clinical tissue engineering

BONE REGENERATION

Since the turn of the century, Dr. Yilin Cao has led a remarkable clinical tissue engineering approach to craniofacial reconstruction in Shanghai, China. Regeneration of craniofacial bone in patients has now been reported by using demineralized bone and autologous cells. Using tissue engineering to rebuild lost bone is novel, but it is not the only regenerative medicine approach being applied to the challenge.

Peptide-based therapy is an established treatment for stimulating bone formation. Bone morphogenetic protein (BMP) is the most common drug currently employed to induce bone growth. In a novel application of BMP, Medtronic developed a spine fusion device containing a collagen sponge infused with the peptide that is now in clinical use (Fig. 5.6). Deployed in the spine, the device and BMP induce native bone to fill the cavity within the device.

Although not often identified as such, this combination of a biodegradable material and a tissue-formation-inducing biologic molecule is clinical tissue engineering at its best.

BLADDER

Early successes in the tissue engineering field were gained in relatively simple tissue structures, organizations, or functions, such as chondrocytes, or two-dimensional cellular structures with limited organ function required. Tengion advanced a technology pioneered by Anthony Atala to augment or replace failing three-dimensional internal organs and tissues, requiring functionality and a vascularization platform using autologous progenitor cells, isolated and cultured *ex vivo*, and seeded onto a degradable biomaterial optimized for the body tissue it is

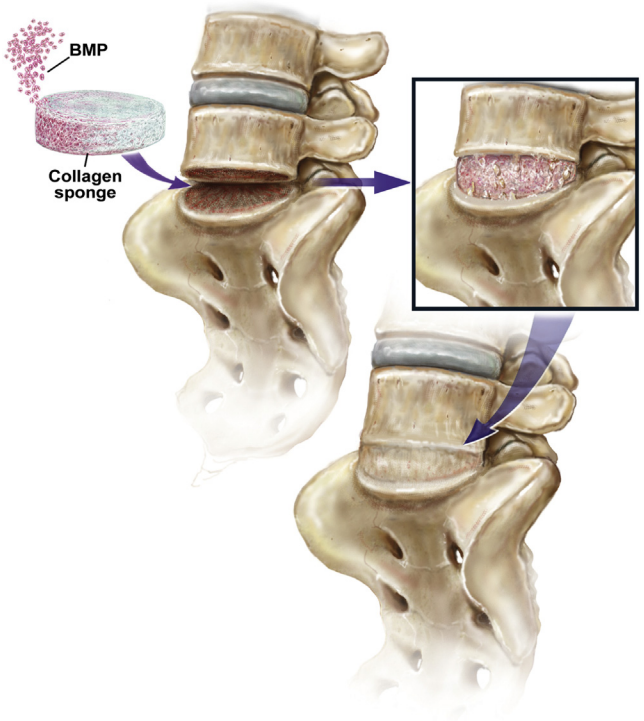

FIGURE 5.6

intended to augment or replace. This cell-seeded neo-organ construct is implanted into the patient for final regeneration of the neo-organ (Fig. 5.7). Using the neo-organ construct as a template, the body regenerates healthy tissue, restoring function to the patient's failing organ. This autologous organ and tissue regeneration avoids many of the negative implications of traditional donor transplantation techniques, such as requisite immunosuppression and limited donor supply. Tengion's initial focus on the genitourinary system was based on a bladder augmentation and ultimately an organ replacement for patients who have undergone radical cystectomy, or removal of the bladder. Tengion developed a robust focus on manufacturing capabilities to support neo-organ construct production in accordance with regulatory standards.

BLOOD VESSEL

At Tokyo Women's Hospital, Dr. Toshi Shin'Oka has used patient-specific tissue engineering to replace malformations of pediatric pulmonary arteries. Working with a biodegradable matrix designed by one of the 'fathers' of biomaterials, Dr. Ikada, Shin'Oka seeded a tubular material with the patient's own bone marrow cells at the time of vessel reconstruction (Fig. 5.8). In a series of clinical experiments, Shin'Oka demonstrated that the biodegradable scaffold's strength during the degradation period was sufficient to allow complete natural vessel replacement without rupture. This first successful clinical replacement of a pediatric blood vessel with a tissue-engineered construct designed to become as natural as the patient's own vasculature was performed in almost 50 patients. As one considers these historical events and the advances in tissue engineering over the past 80 years, we are seeing that tissue engineering is moving toward the regeneration and repair of increasingly complex tissues and even whole-organ replacement. This field holds the realistic promise of regenerating damaged tissues and organs *in vivo* (in the living body) through reparative techniques that stimulate previously irreparable organs into healing themselves.

Regenerative medicine also empowers scientists to grow tissues and organs *in vitro* (in the laboratory) and safely implant them when the body is unable to be prompted into healing itself. We have the technological potential to develop therapies for previously untreatable

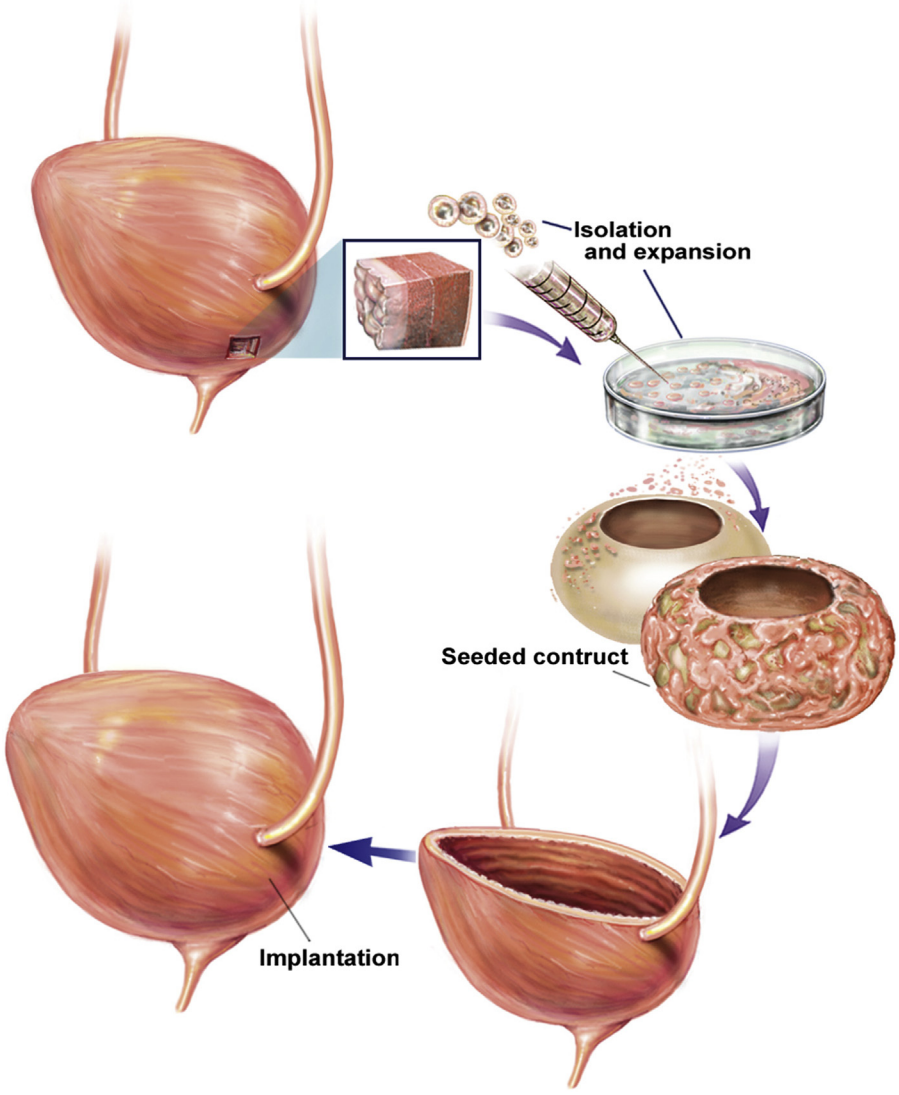

FIGURE 5.7

diseases and conditions. Examples of diseases regenerative medicine could cure include diabetes, heart disease, renal failure, and spinal cord injuries. Virtually any disease that results from malfunctioning, damaged, or failing tissues may be potentially cured through regenerative medicine therapies. Having these tissues available to treat sick patients creates the concept of *Tissues for Life* [1].

STRATEGIES TO ADVANCE TOWARD THE CLINIC

Since the mid-1980s we have had many opportunities to learn how one might quickly convert tissue engineering technology into regenerative medical products from the bench to the bedside. Establishing a plan to move toward clinical testing rests on a strategy of defining the unmet medical need (patient population), determining the intended use of the tissue-engineered/regenerative medical product (TERMP) that addresses the need, and defining the processes necessary to ensure that the product can be reproducibly manufactured to be both safe and effective once it is placed into the patient. A requisite scientific basis for partial or complete structural and/or functional replacement of a diseased organ or tissue requires a definition of what constitutes a successful outcome (i.e., primary clinical endpoint) in the appropriate patient population conducted under adequate and well controlled studies.

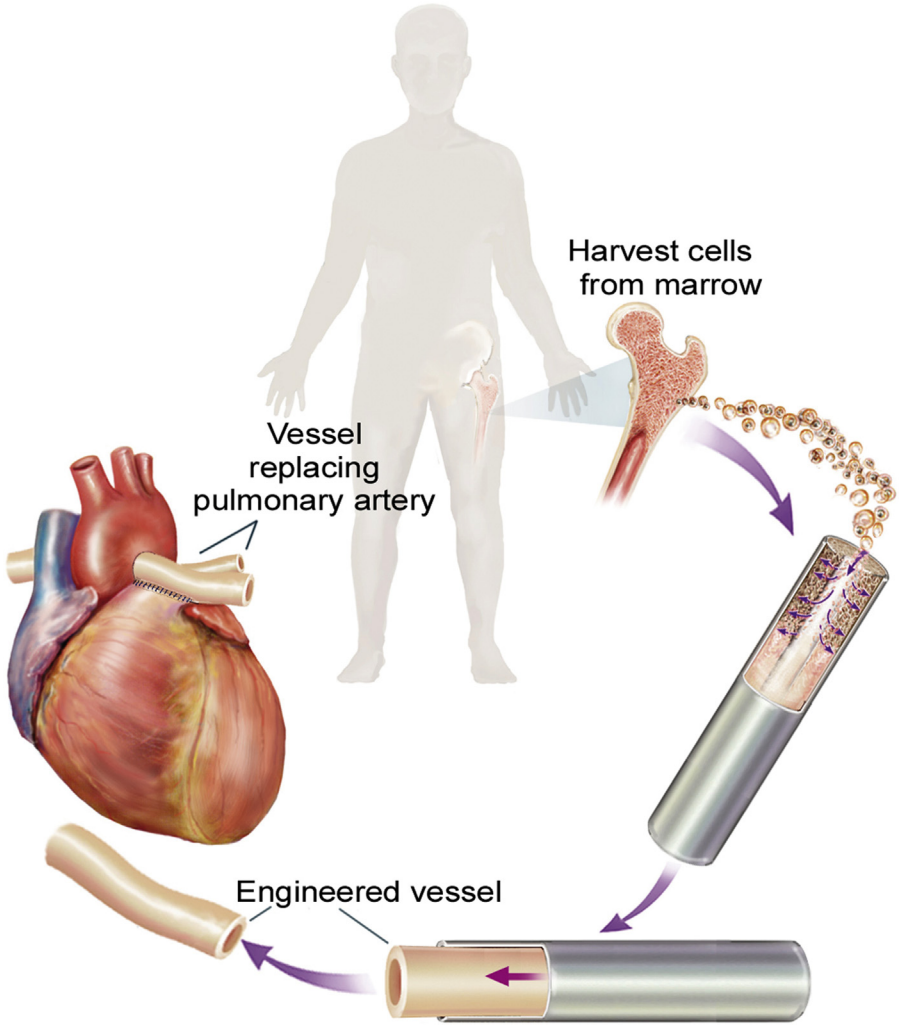

FIGURE 5.8

Ultimately, any clinical testing will require the application of existing regulatory guidelines for testing, clinical trial design and manufacturing a product prior to use in a human subject. With this information in hand, initial steps into clinical testing phases can be contemplated.

As we have already seen, sound scientific strategies are not effective in clinical translation unless there is a balancing sustainable business strategy. Naturally, the scientific data, clinical plan and business strategies must be woven together, in terms of both specific outcomes and timelines. As we will discuss in detail later, the significant differences between traditional drug therapies and tissue engineering therapies actually offer the opportunity to accelerate the bench-to-bedside process. We take the position that instead of a 10- to 15-year development cycle, tissue engineering therapies can be brought to market in 8—10 years, notably, when the product under development is for an orphan population. In considering the exploratory clinical testing phase (Phase I and II) with a scientifically based program, final product characteristics must be defined as well as standardizing the production processes and anticipating what justifications will indicate readiness for entering into the next phase of clinical testing (confirmatory studies). Table 5.1 presents an overview of a prototypical product development process.

Transitioning into an initial exploratory clinical evaluation rests on understanding the objectives for the first regulatory review as they relate to the specific product characteristic, the process to make the product, translational medical study results, and how preclinical

TABLE 5.1 Overview of a potential testing program to support clinical entry of a prototypical Tissue Engineered/Regenerative Medical Product (TERMP)

Cellular/chemistry manufacturing control
Define product production and early manufacturing processes
Establish cell, tissue and biomaterial sourcing for GMPs
Validate product processing and final product testing scheme
Characterize adventitious agents and impurities for each element
Define lot-to-lot consistency criteria
Validate quality control procedures
Translational medicine studies
Complete *in vitro* and *in vivo* testing
Define toxicity testing of raw materials composing the TERMP
Evaluate biomaterial biocompatibility
Establish immunogenic and inflammatory responses to each component
Develop rationale for animal and *in vitro* models to test product effectiveness
Define of endpoints for establishing TERMP durability
Clinical trials
Develop rationale for safety and clinical benefit (Risk/Benefit analysis)
Design exploratory and confirmatory trials
Select patient population and define inclusion/exclusion criteria
Identify investigational comparators and control treatments
Establish primary and secondary study endpoints
Consider options for data analysis and potential labeling claims

information demonstrates the desired clinical outcome [2,3]. In a rapidly changing field where regulatory agencies are still maturing in their decision-making processes, the decisions made during the initial clinical evaluation phase can have far-reaching impact. Table 5.2 provides an overview of data that will be needed prior to entering into an exploratory clinical trial. Regulatory considerations for the types of data required and bioprocess technologies must be in place prior to initiating clinical trials. Indeed, the regulatory environment is much more defined today than in the early days of tissue engineering because of scientific advances and

TABLE 5.3 Regulatory considerations for the development of a tissue engineered or regenerative medical product

	Description	Impact
Manipulation of cells	For structural and non-structural tissues, manipulation is minimal if it involves centrifugation, separation, cutting, grinding and shaping, sterilization, lyophilizing or freezing (e.g., cells are removed and reintroduced in a single procedure) Manipulation is not minimal if cells are expanded during culture or growth factors are used to activate cells to divide or differentiate Defined in 21 CFR 1271.3(f) – see also (FDA, 2005) 4	More extensive regulatory requirements applied to TERMP when manipulation is more than minimal
Cell source and application	Homologous use is interpreted as the augmentation tissue using cells of the same cellular origin. Examples include applying bone cells to skeletal defects and using acellular dermis as a urethral sling. Non-homologous use examples include using cartilage to treat bladder incontinence or hematopoietic cells to treat cardiac defects. Defined in 21 CFR 1271.3(c) – see also (FDA, 2001) 7	Non-homologous use triggers additional requirements for entering clinical trials
Scaffold characterization	Final scaffold composition and design determine whether the TERMP is characterized as a device, a biologic or a combination product. Defined in Quality Systems Regulations (QSRs) in 21 CFR 820 (FDA, 2005) 4 – see also (FDA, 1999) 11	Devices are held to the QSRs in 21 CFR 820 (FDA, 2005) 4, biologics are required to comply with Good Manufacturing Processes (GMPs) (FDA, 1991)12 and combination products are often required to comply with both sets of regulations and guidelines

insights gained from various attempts to commercially develop tissue engineering and regenerative medical products. Once again, understanding the regulatory environment is foundational to successfully implementing the development plan and using the scientific objectives laid out in Tables 5.1 and 5.2. Several regulatory considerations have significant impact on the development plan necessary to bring a TERMP to clinical testing: extent of cellular manipulation, cell source and use, and scaffold characteristics (Table 5.3). With a scientific foundation, an established product characterization, and application of appropriate regulatory considerations established, three additional considerations come into play for a particular technology to be transitioned from the bench to the bedside: raw materials testing, manufacturing process controls testing, and translational medicine.

Raw materials testing

CELLS

Cellular components of a TERMP are raw materials encompassing viable cells from the patient (autologous), other donors (allogeneic), or animals (xenogeneic). Standards for cellular quality have been extensively reviewed and considered by regulatory bodies and generally focus on controlling introduction of infectious diseases and cross-contamination from other patients. These standards also consider potential for environmental contamination from the

facility and equipment and the introduction of infectious agents from materials used to process cells (e.g., bovine-derived material that may contain infectious agents). For TERMPs that have cells placed onto a scaffold, scientific and regulatory considerations focus on ensuring that both the raw materials comprising the scaffold and its three-dimensional characteristics are biocompatible [4]. Biocompatibility testing involves evaluation of the scaffold's potential cytotoxicity to cells being seeded, potential toxicity that may be inflicted on the recipient's tissues once implanted, as well as the consequences of immune and inflammatory responses to the TERMP after implantation. Biocompatibility extends through the *in vivo* regeneration process; therefore, biocompatibility should be evaluated in parallel with demonstrating that the scaffold maintains the necessary biomechanical properties to support new tissue or organ growth.

SCAFFOLD

Synthetic, natural, or semisynthetic materials are readily available from various commercial sources, but the quality control of a material varies substantially between medical and research grades. As testing of a potential TERMP moves from research bench to clinical testing, scaffold composition and designs must be controlled for reproducibility of production and product characterization. Final production must consider quality management and organization, device design, production facility environmental controls, equipment, component handling, production and process controls, packaging and labeling control, distribution and shipping, complaint handling, and records management, as outlined in 21 CFR 820 [5]. However, during the exploratory phase and transition from bench to clinical testing, the most relevant of these guidelines are process validation and design controls. Typically, a design input phase is a continuum beginning with feasibility and formal input requirements and continuing through early physical design activities. Engineering input on final prototype specifications follow the initial design input phase and establish the design reviews and qualification. For a combination TERMP, defining quality for the chemical polymer (e.g., PGA) or natural material (e.g., collagen), including any residues introduced during machine processing (e.g., mineral oil), can require QSR integration into a product that would otherwise be regulated as a biologic. Since many TERMPs are combination products, testing of scaffold, cells, and the cell-seeded scaffold (i.e., construct) are required to ensure that, in exploratory clinical trials, the product is sterile, potent, fit for use, and composed of the appropriate raw materials to function properly following *in vivo* placement.

Manufacturing process controls and testing

CELLULAR PROCESSING

In-process controls generally focus on sterility, viability, and functional analysis of cells from isolation, through expansion and before they are placed on the scaffold. Release criteria generally ensure that cells remain viable and functioning properly after being attached to the scaffold. Functional evaluations of cells and potency assessments of their 'fitness for use' are performed after cells are combined with (or seeded onto) a scaffold. Taken together, these tests determine whether the final product can be released from the production facility for surgical implantation in the clinical setting.

BIOMATERIAL PROCESS AND TESTING

The focus of biomaterial process testing is to evaluate the *in vivo* behavior of the scaffold material following implantation. Characterizing the scaffold degradation profile ensures that breakdown time and other degradation attributes will support the regenerating tissue long enough for it to acquire the appropriate functional and structural integrity as the scaffold material degrades. Defining scaffold-breakdown products identifies the biochemical factors that may impact reparative, inflammatory, immunologic, and regenerative processes once the product is placed into the body. Measuring biomechanical properties such as stress-strain

relationships, Young's modulus, and other characteristics ensures that the scaffold portion of the combination product will perform properly during the *in vivo* regenerative phase.

Final combination product testing

Analytical methods for final product testing vary substantially, depending on the composition of the TERMP. In general, any product intended for customization to individual patients (e.g., autologous products) requires confirmation that release and potency standards are met via non-destructive test methods. Such test methods are typically novel and specific to each product type and are frequently based on a battery or 'matrix' of tests that evaluate cellular function and physical parameters of the scaffold. In contrast, lot-testing strategies, statistical sampling, and more routine analytical methods are available for scaffold-only products and cell-based products produced in large lots (e.g., allogeneic and xenogeneic cellular products). In the future we may see allogeneic therapies that are customized for patient-specific needs. Naturally, such innovations will require a combination of analytic approaches.

Translational medicine

Safety and efficacy evaluation of a TERMP is conducted in animals, and the findings are foundational to designing the first clinical trial protocol. These translational studies are the basis for safely transitioning a potential product into clinical testing. Since the regenerative process invoked by components product involve multiple homeostatic (e.g., metabolic), defense (e.g., immune), and healing (e.g., inflammation) pathways, animal studies provide an approach to understanding the inherent function of the TERMP (i.e., if the product contains cells, it can be considered a living 'tissue') and the inherent response of the body to a product composed of biomaterials with or without cells. Animal studies are a regulatory necessity, but we must also remind ourselves that many therapies function effectively in animals and fail in humans. The reverse is not often discussed.

Some therapies may fail preclinical testing and never enter clinical trials, but this is not to say that some of those therapies would not be excellent when applied in humans. An interesting example of this conundrum can be found in artificial-blood therapies. The US Army received approval for clinical use of a natural blood substitute in trauma applications during the recent war in Iraq. In a post-approval attempt to understand why the product worked so effectively in humans it was tested in a porcine model of hemorrhagic shock. The pigs did not do well with the therapy. The investigators proceeded to test the product in rodents and demonstrated that the rodents died when injected with the blood substitute that worked so effectively in the clinic. If preclinical animal testing had been performed first, this excellent product would never have been submitted for clinical evaluation.

Translational medical studies can be conducted in large animals (e.g., dog) or small (e.g., rat). Selection of the correct animal model should be based on the similarities of the pathophysiology, physiology, and structural components intended for treatment in the clinical setting. Exploratory clinical trials for most medical products utilize normal human volunteers as the first line of clinical testing. However, some products can be tested outside of the intended clinical population. As such, the animal model employed in translational medicine should resemble the human condition as closely as possible — immune status, inflamatory response, and healing pathways, as well as the medical approaches used to treat the human condition (e.g., surgical procedure) and monitoring methods to follow a clinical benefit or risk (e.g., imaging). Many pivotal preclinical experiments are performed in academia, and the importance of complying with the good laboratory, manufacturing, and tissue practice regulatory standards is critical at this phase. There is no such thing as Good Laboratory Practices/Good Manufacturing Practices/Good Tissue Practices (GLP/GMP/GTP)-light, and many academic animal facilities are not compliant to the degree needed by the FDA. This issue will increase in

TABLE 5.4 Test categories described in ISO10993-1

Local tolerance	

significance as the FDA increases its post-approval auditing of preclinical compliance. Since the regenerative response starts at the moment of TERMP implantation and concludes with the final functioning neo-tissue or neo-organ, animal studies provide an understanding of how to evaluate the early body responses, as well as longer-term outcomes reflecting the desired benefit — an augmented or replaced tissue or organ. Since most products are surgically implanted for the life of the patient, the duration of a translational study would extend to the time when final clinical outcome is achieved. Regulatory agencies have given considerable thought to the duration of translational studies, and many are of long duration — months to years. Nonetheless, since the final outcome is frequently achieved in a shorter period of time, the potential to conduct shorter-duration studies based on final patient outcome may present a rational solution to testing clinical utility in the shortest possible time while ensuring a high benefit:risk outcome. Understanding which endpoints are available and appropriate for clinical testing is achieved through translational studies. Standards are provided for the proper safety evaluation of TERMPs, whether they are regulated as a device [6] or a biological product (e.g., 351 or 361). Although the optimal testing strategy will typically be product specific [7], some basic guidelines for testing device-like products can be found in the ISO10993-1 guidance document. These testing guidelines cover a number of *in vitro* and *in vivo* assays (Table 5.4).

A scaffold-only product that is similar to an already tested material or medical device can be accelerated through the testing process using a 510K approach under an existing PMA [8]. Appropriate translational testing approaches will follow the biocompatibility flowchart for the selection of toxicity tests for 510(k)s [4]. If the device requires an IDE/PMA level of testing, then the translational studies will be more extensive and influenced by the length of time that the TERMP is in contact with the body of the recipient. As already mentioned, many regenerative medical devices or the tissues that replace the initial implant are in bodily contact for longer than 30 days and are therefore considered permanent devices. These products require a full range of *in vitro* and *in vivo* testing approaches prior to clinical testing. If the TERMP is cell-based or the primary mode of action is mediated through the cellular constituents of a scaffold-cell combination product, then the device requires an IND/BLA. The testing approach for these products will usually involve an assortment of studies that evaluate scaffold and cellular components through appropriate endpoint selection and experimental design for both *in vitro* and *in vivo* translational studies. An example of a preclinical development program for a cell-based product is presented in Table 5.5.

Although specific testing approaches are not defined absolutely, the scope and testing approaches for a specific TERMP can frequently be predicted by evaluating the development approach used for related technology platforms. A number of tissue engineering technologies can bridge from bench to clinical application. Testing a TERMP prior to moving into clinical evaluation is based on:

1) Scientific information demonstrating that the potential clinical product can invoke a response in the body of potential therapeutic benefit;
2) Demonstration of a controlled and reproducible manufacturing process; and
3) Demonstration of the safety of each component and the final product.

TABLE 5.5 General translational medicine testing paradigm for a cell-based tissue-engineered regenerative medical product

Cellular component	Scaffold	Combination
Phenotype characterization Genetic stability Biocompatability Biomechanical properties Degradation profile	Early stage (Acute) Late stage (Chronic)	Early stage (Acute toxicity) Late stage (Chronic toxicity)

This stage in the development of a prototypical clinical product is typically the first point of regulatory authority and governance body interactions and an area where procedural approaches for establishing controls are frequently reviewed and clarified.

BRINGING TECHNOLOGY PLATFORMS TO THE CLINICAL SETTING

General

Technology platforms that intend to recapitulate a tissue (e.g., skeletal muscle, bone, cardiac muscle) or an organ may address a range of unmet medical needs, from simple cosmetic defects in the body (tissue-focused technologies) to life-threatening maladies (organ and organ system replacement) (Fig. 5.9). Bringing a TERMP technology to clinical testing may rest on the scope of unmet medical need and the availability of alternative therapies. The array of available alternative therapies influences the early testing strategy of a particular product by

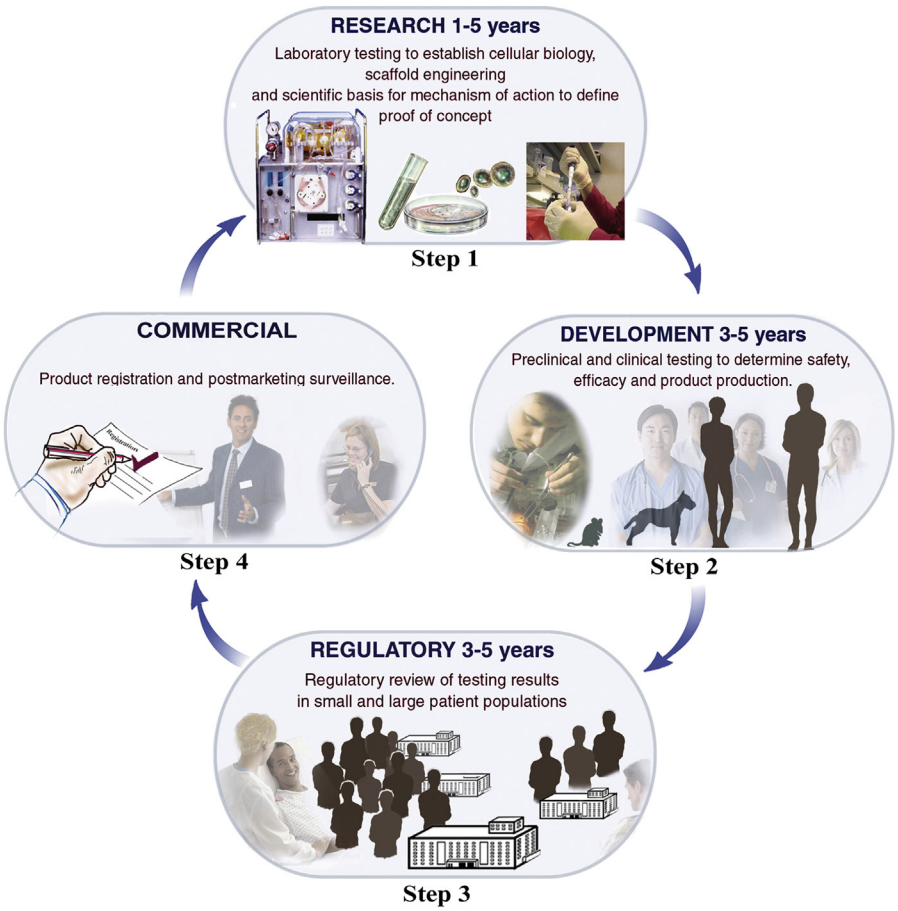

FIGURE 5.9

determining comparable products to be evaluated, selection of animal models, appropriate endpoints and amount of preclinical information needed to enter into clinical testing. Ultimately, the safety and efficacy of the prototype product are balanced by a risk-benefit analysis versus other available products, which directly influences the ability to test it in human trials.

Tissue-focused technologies

Tissue-focused technologies, such as bone and tendon repair, may move into clinical testing through routes that have been established by previous successes (e.g., Depuy's Restore®). If animal models and alternative therapeutic approaches are established, comparing the benefit of a proposed product to an existing therapy may be an appropriate approach to potential clinical testing. Ultimately, comparing the benefit of the TERMP versus the 'gold standard' commercial product or surgical therapy is the foundational rationale to evaluate potential human use. Depending on the raw materials composing the TERMP, the primary mode of action may drive the testing strategy for novel products. The primary mode of action is defined by the scientific studies demonstrating the range of bodily responses invoked by the product and the range of long-term outcomes. Products that elicit an immune response (e.g., allogeneic, xenogeneic, or genetically modified cells) will need to include an evaluation of immunotoxicity, immunomodulation, and/or potential for rendering the recipient sensitive to infectious diseases. Those products whose production employs animal materials will require testing for adventitious infectious agents or the use of materials from certified sources. Testing for potential endogenous infectious agents prior to clinical testing is especially relevant for products that contain, or whose production process includes, xenogeneic cells. Products using scaffold material for which there is little or no previous human testing will require testing that follows established FDA Guidelines (see G95-1) [4]. Biodegradable scaffolds have a testing paradigm similar to that used for a non-biodegradable material, with additional requirements for defining the degradation profile, breakdown products released, route of excretion, and response of the body to the material as it breaks down.

Ultimately, the final safety/efficacy testing strategy may rest with the regulatory pathway selected through a process established by the 'Office of Combination Products'.

Organ-based technologies

Tissue-engineered/regenerative medical technologies offer the promise of alleviating the vast organ shortage that exists worldwide. In spite of this great promise, the pathway to clinical testing with a product that replaces an entire organ is the least clearly defined. Although the clinical benefit of such a TERMP may be definitive, the endpoints readily discernible, and the animal models established, the delivery mechanism, procedures for connecting the neo-organ to other parts of the body, may pose substantial development hurdles and actually preclude clinical testing.

The complexity of whole-organ replacement by these types of products spans defining what is actually being replaced through defining what ancillary products may be needed if all organ functions are not included in the product characteristics. Traditional therapeutic approaches have generally focused on one pathway or target (e.g., pharmaceutical) or possibly two therapeutic benefits, such as structural and functional restoration (e.g., cartilage repair products). However, those products replacing an entire organ (e.g., kidney) or body part (e.g., limbs) will need to consider broad functional testing of both exocrine/excretory and endocrine functions before clinical testing can be considered. The transition to clinical testing of more complex TERMPs will have commensurate preclinical testing requirements to demonstrate not only the functionality of each component being replaced or augmented, but also the biological responsiveness of the integrated organ to native homeostatic mechanisms (e.g., integration with blood pressure or glucose control). Matters such as percutaneous conduits, skin infections, and controlling biofilms may be substantial development hurdles for the use

of products outside the body. For products intended to be used inside the body, solutions for vascular connections, waste product release pathways (e.g., urinary tract and GI), clinical monitoring of neo-organ development, and establishing how long it takes to achieve the desired clinical outcome may all need to be established before clinical testing can be considered. Biosensors and integration of biosensors with TERMPs replacing whole or major portions of an organ's function are becoming a reality. Moving into clinical testing with such products requires definition of *recovery pathways* in the event of product failure; definition of alternative therapies to be used in association with the product if not all organ functions are replaced; understanding TERMP longevity and how to replace the product if the product/neo-organ wears out; and understanding the rate of product failure for proper clinical management. In spite of these hurdles, the lure of replacing an entire organ is considerable. The benefit to society of replacing a kidney or pancreas is unimaginable. As scientific advances in *in vitro* organ growth are made and regenerative templates for entire organs are pioneered (e.g., through such technologies as organ printing), the potential to replace, regenerate, repair, and restore entire organ systems is being considered. Tissue engineering approaches may yield solutions for some of the most devastating human conditions, including congenital agenesis, cancer, degenerative disorders, and infectious diseases. However, entry into clinical testing with such products has not yet been defined.

TRANSITION TO CLINICAL TESTING

Defining and testing a prototype

Prior to beginning a clinical testing program, the TERMP's specific characteristics must be defined to the point that the product can be repeatedly and reproducibly manufactured for *in vitro* and *in vivo* testing as defined earlier. Product characteristics should be sufficiently stable to allow for data-driven demonstration of their clinical utility. Once a prototype is defined, its characteristics are evaluated in a series of tests to define the limits of the initial design criteria that allow for durability testing of the product design by establishing failure points, limits of TERMP application, and the achievement of design criteria. Anticipating the clinical conditions, complications, and untoward events that may arise during clinical testing also establishes a prototype's potential for clinical utility. A TERMP is seldom introduced as a final functioning neo-tissue; therefore, characterizing the pharmacological responsiveness, electrophysiological parameters, and phenotypic and structural features of the neo-tissue or neo-organ that emerges following implantation is key to demonstrating the product's ultimate clinical benefit.

Specific design elements of a final TERMP prototype that will be tested in humans are the culmination of a series of biological, physical, and chemical evaluations obtained during the prototyping phase. This characterization also defines sourcing and control of raw materials, assembly processes (aka: in-process testing) and release criteria.

Additionally, the product's shelf life, shipping conditions (temperature, humidity, nutrients, etc.), stability, sterility, and method of use are established before clinical testing. Any unique surgical procedures, clinical management practices during and after implantation, and recovery times are estimated based on the translational medical results using the final prototype product with the fully embodied characteristics.

Extending existing technology

Using previously tested technology platforms can accelerate the entry of any TERMP into clinical testing. Most products are combination products based on multiple technology platforms. Using one or more already-approved scaffold materials, cell-processing methods, culture media components, or transport containers greatly reduces the number of variables that need to be tested in product prototyping and preclinical testing phases. Additionally,

historical data available for any technology can help develop testing strategies for a final prototype and even establish early clinical phase designs.

Production of TERMPs in GMP facilities

With established product characteristics, standard operating procedures and clinical production processes, a GMP-qualified facility can be deployed to manufacture the first clinical prototype. GMP facilities not only meet GMP guidelines, but they have specialized facility designs and highly trained personnel to produce faithfully the first clinical prototypes in a controlled and reproducible fashion. Considerations for GMP facilities include capacity limitations, availability restrictions, and costs to build, operate, and maintain. Furthermore, utilization of a particular GMP facility may be constrained by the controls needed to generate a particular product. Deploying contract manufacturing is a strategy that can hasten product-prototype production in a manner that complies with regulatory guidelines. TERMP technologies can vary substantially, so it is not uncommon for small GMP facilities to be custom-built to meet the needs of a particular technology platform. Facility design considerations are outside of the scope of this chapter, but a GMP-qualified facility that can provide the required clean-room processing, shipping, and receiving procedures and Heating Ventilation Air conditioning (HVAC) systems for airflow maintenance should be identified before any consideration can be given to initiating clinical testing. This should be done as early as possible, but no later than the final stages of the prototyping phase, to ensure that the necessary facility design capable of producing products in compliance with GTPs and GMPs is available. Contract manufacturing operations (CMOs) have emerged that produce scaffold-only and scaffold-plus-cell products. These operations have staff skilled in various aspects of product manufacturing and generic facilities that can accommodate a variety of cellular methods and biomaterial-handling needs. A technology transfer plan [9] should be established before engaging a CMO, to ensure optimal product generation and the success of the first clinical trial.

Medical and market considerations

Entering clinical testing of TERMPs will not achieve the promise of impacting major unmet medical needs without consideration of market demands. These demands include third-party payers' willingness to support costs, follow-up care, and subsequent patient morbidity. The availability of lower-cost alternatives may be the most significant and practical barrier to clinical testing of a TERMP. Tissue engineering technologies address medical needs unmet by pharmaceutical agents or devices, but these needs may be met by the modification of medical practices, lower-cost alternatives (e.g., cadaveric skin), or currently accepted medical procedures (e.g., tissue transplantation). Exploratory clinical testing strategies can incorporate these alternative approaches to establish the comparative clinical benefit of a prototype product. As the science and technology of tissue engineering becomes more established and regulatory pathways are clarified, products will become more broadly applied. Strengths and limitations of TERMP technologies will determine market size and application to unmet medical needs. At present, products have few competitors in the market place, and the opportunities are driven largely by reducing a particular technology to practice.

Regulatory considerations and governance bodies

Multiple FDA review organizations oversee TERMPs, depending on their characteristics. For device-like products, Center for Device of Radiological Health (CDRH) is the regulatory center, for biological products it is Center for Biological Evaluation Research (CBER), and for combination products, the Office of Combination coordinates a time-bound process that begins with a Request for Designation to assign the combination product to the appropriate center. For example, scaffold and cell TERMPs having a cell-based primary mode of action would most likely be regulated by CBER's Office of Cellular, Tissue and Gene Therapies, with varying involvement from CDRH. These regulatory organizations conduct evaluations

TABLE 5.6 Regulated practices for consideration when taking a TERMP to clinical testing

Good tissue practices – 21 CFR 1271
Good manufacturing practices – 21 CFR 210 and 211
Good laboratory practices – 21 CFR 58
Good clinical practices – 21 CFR 50
Quality systems regulations – 21 CFR 820*

**Replaced cGMPs for TERMPs regulated as devices.*

under different regulatory authorities, depending on the designation of the product and the extent of clinical testing required. Lower-risk products that are minimally manipulated and intended for homologous use are considered under Section 361 of the Public Health Services Act and must comply with current good tissue practices (Table 5.6). Higher-risk products (e.g., cartilage that is implanted to provide bladder support) that are modified through tissue culture or genetic manipulation and not intended for homologous use are regulated under Section 351 of the Public Health Service Act and must comply with both the current good tissue practices and good manufacturing practices (Table 5.6) and go through a premarket approval review through an IND/BLA under 21 CFR 312/601 or IDE/PMA 21 CFR 812/814. In moving toward clinical testing, non-governmental groups guided by governmental regulations provide oversight of studies conducted in animals and humans. Animal care, use, and housing are governed by an institutional animal care and use committee (IACUC) whose operations are defined and established in 9 CFR 1–3. Although not a direct part of regulatory requirements to engage in clinical testing, institutions conducting animal studies in support of human trial testing are regulated by good laboratory practices (GLPs) and comply with United States Department of Agriculture (USDA) guidelines. Human subject testing is also governed by an institutional review board (IRB). IRB conduct and necessity are controlled by 21 CFR 56 whenever an application is submitted for a research and marketing permit. Specific IRB conduct may vary somewhat between institutions, but the IRB is consulted about necessary preclinical data prior to consideration of human subject testing in that institution.

CLINICAL TRIAL PLANNING

Clinical trials are human research studies designed to assess the effect of a new TERMP or treatments in study volunteers. The treatment may be a novel technology, application, or new use for a previously untreated or untreatable ailment. Trial design can vary substantially depending on the clinical hypothesis but can be classified as exploratory or first-in-human trial and confirmatory trial for product registration. Trials generally evaluate safety and efficacy in the defined human population, and frequently serve to compare the new technology with a current standard of care. These trials generally involve volunteer patients with specific health issues which the investigator believes will benefit from this new treatment.

In the US, the National Institutes of Health classifies clinical trials based on their purpose (http://www.ich.org/about/organisation-of-ich/coopgroup/pandrh/topics-under-harmonisation/article/good-clinical-practices.html). For example:

1. Compassionate use trial is a means to provide experimental medicinal products before the FDA has given final approval for use in humans. The FDA must approve compassionate use, usually only after a case-by-case analysis. This use is granted only for individuals who are very ill and have no other treatment options available to them.
2. Diagnostic trials are conducted to define tests or procedures that have better accuracy, sensitivity, or turn-around time for diagnosing a particular disease or condition than is currently available. This type of trial usually includes volunteers who exhibit symptoms of the disease or condition being studied.

3. Expanded access trials allow for the distribution of experimental drugs to participants who are not responding to currently available treatments for their illness and who are also unable to participate in ongoing conventional clinical trials.
4. Prevention trials are designed to discover better ways of disease prevention in people who have never had the disease or to prevent reoccurrence of a particular disease. These types of trials may include the use of medicines, vaccinations, dietary supplements such as vitamins and minerals, or changes in lifestyle.
5. Quality of life trials are sometimes referred to as supportive care trials. During these trials, ways to improve comfort and quality of life for individuals with a chronic illness are investigated.
6. Treatment trials test novel treatments which may include new combinations of drug therapies, new approaches to surgery or radiation therapy, or application of tissue-engineered and regenerative medicine products.
7. Screening trials are designed to address the best and most practical way to detect diseases or health conditions.

Principally, there are two main types of treatment studies; randomized and non-randomized. In a randomized controlled trial, abbreviated RCT, study volunteers are allocated at random to receive one treatment type over another. One of these treatments is the control, which is usually the standard of care. In some trials the control may be no treatment at all. The randomization is designed to prevent any bias that the investigator has from affecting the study results and their subsequent interpretation. Randomization procedures should include equal treatment group sizes to allow for adequate statistical powering, they should have low selection bias to prevent the investigator from inferring the next group which the next study volunteer will go to, and there should be a balance in covariates across the groups.

In a double-blind randomized trial, neither the study volunteers nor the clinical investigators know who belongs to the control group and the test group. Only upon completion of the study is this information revealed. Double-blind randomized studies have proven to be extremely successful towards eliminating subjective bias of both the study subjects and the clinical investigators, since neither knows to which group the study volunteers belong. In contrast, single-blind studies, in which the investigator knows but the study volunteer does not, runs the risk of the volunteer becoming biased as a result of their interaction with the investigator. When both investigators and study volunteers know to which group the volunteers are in, the RCT is called unblinded or open.

To alleviate as much bias as possible from these types of studies, it may be desirable to have the people assessing the data be blinded. Since the clinical outcomes are measured after the study participants receive the full course of the treatments, RCTs are quantitative studies, which make them one of the simplest and more rigorous ways of determining a cause-and-effect relationship between treatment and outcome in clinical research. Despite the widespread acceptance of the scientific merits of randomization, there may be reluctance to advocate such a trial in TERMP due to the lack of blinding for a surgically implanted product. Such experimental requirements are generally tested in the preclinical studies to allow TERMP to be tested in patients who may benefit from the therapeutic mechanism.

A non-randomized clinical trial is one in which the study volunteers are not assigned by chance to different treatment groups; they may choose which group they want to belong, or they may be assigned to the groups by the clinical investigator. The reporting of a non-randomized trial requires special care, especially when claims are made about efficacy. Reporting should address the potential biases that could affect the conclusions (Glossary of Clinical Trial Terms. http://clinicaltrials.gov/ct2/info/glossary). This is especially true for trials which use a comparison with a historical control group. Nonetheless, a non-randomized study is valid for evaluating pilot studies of novel therapies, provided that the potential biases are

recognized. Non-randomized studies are also compelling when the treatment outcome is so remarkable that it cannot be explained by the combination of the potential biases.

Clinical trials are typically divided into four phases, each of which is treated as a separate entity requiring its own clinical investigation. A description of each is provided below:

- Phase I – Initial studies on a small group of healthy volunteers to determine if there are any adverse effects of the treatment. These studies may include patients who do not have the disease for which the new medicinal product is designed to treat. At this phase, the overall safety of the treatment is unknown and the purpose of the study is to define safety.
- Phase II – This is a controlled clinical study to evaluate the effectiveness of the product for a particular illness in volunteers with the illness. Phase II can commence only after the safety of the treatment has been demonstrated during Phase I. The treatment group is generally larger than in a Phase I trial. The purpose is to determine if there are any common safety risks and establish early indications of potential efficacy.
- Phase III – Controlled and uncontrolled trials, often randomized and involving multiple centers, include a greater number of volunteers than in Phase II. The goal is to gather additional information to evaluate the overall effectiveness and benefit-risk relationship of the medicinal product, including any side effects, overall safety, and quality of life.
- Phase IV – After regulatory agency approval, this phase involves post-marketing studies to gather additional information regarding the product's risks, benefits, and optimal use. The purpose is to allow for detection of any rare or long-term adverse effects among a larger patient population which may not have been evident during the previous phase trials.

TERMP represent a relatively new therapeutic modality for clinical trial design and regulatory agency oversight. Although TERMP products are being actively developed and registered for commercialization, the number of examples for TERMP product-prototypes that have advanced to late stage clinical development remains relatively limited so generalizations on clinical development are not readily available. This has posed challenges not only for regulatory authorities in how these products are categorized but also in how manufacturers need to think about testing and characterizing their product. A recent publication by Lee et al. provides an excellent overview of the FDA process and some of the key scientific considerations, which may be applicable to developers of TE/RM products. These authors emphasize several key points to consider when planning to conduct clinical trials with TE/RM products:

1. The appropriate regulatory pathways need to be identified as early as possible during product development
2. Engage regulatory agencies, the example used being the FDA, early on during product development. The FDA encourages such informal exchanges so that they can have a preview of what they will be seeing during the anticipated formal filings. At the same time, the product developer can gain valuable insight into what the agency will be looking to see in the filing
3. Be up-to-date and well versed in all relevant agency guidance documents and regulations
4. Anticipate scientific and clinical questions that will be asked at the clinical phase of product development
5. Plan for changes in product design and manufacturing

A complete list of guidance documents from the three FDA centers in charge of regulating medicinal products can be found on their respective websites (CFR– Code of Federal Regulations, part 312 – investigational new drug application, subpart A– General provisions, Section 312.3 Definitions and interpretations. http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/CFRSearch.cfm?fr=312.3; Top contract research organization http://www.jazdhealthcare.com/healthtech/leaf/Health-Information/Clinical-Research/Contract-Research-Organizations-CROs.htm; Overcoming Cost Escalation with Design and Construction Strategies http://www.tradelineinc.com/reports/CCDDBD31-2B3B-B525-8E9C98EBAD6AE55F).

The actual clinical plan including protocol, clinical opinion leader network, clinical site identification, patient population to be tested and, initiation of the clinical trial can be based on established approaches for clinical trial conduct of approved medical products. However, the specific aspects unique to TERMPs require consideration prior to trial initiation.

Clinical design and protocol: Patient population, number of clinical sites, primary outcome, secondary outcome, I/E criteria, endpoint selection

The clinical trial design for a TERMP is generally composed of four major sections:

1) Study design including duration and randomization;
2) Patient population to be studied including controls;
3) Inclusion/exclusion criteria;
4) Outcome measures including safety and efficacy endpoints.

Logistics for setting up a clinical trial including identifying clinical centers, physician investigators, monitoring, data collection and reporting are beyond the scope of this chapter.

STUDY DESIGN

Study designs for TERMP remain an area of active evaluation and can include the use of single or multi-group studies, with or without randomization. As pointed out above, general study designs used for other medicinal products (e.g., devices) can serve as a basis for investigator selection and regulatory dialog.

PATIENT POPULATION

Establishing the most appropriate patient population for testing a TERMP is critical to advancing toward commercialization. Most TERMP trials will involve patients with the disease target. Such trials will have significant preclinical safety evaluation programs to ensure the patient volunteers are adequately protected and the product being tested can be safely administered. One approach not infrequently used with TERMPs is to identify a specific subpopulation that can be studied using adequate and well controlled trials. These 'orphan' populations are generally defined by US regulatory authorities as being composed of fewer than 200,000 patients/year, or when there are more than 200,000 patients/year, where the R&D costs will not be recovered upon sale of the product (http://www.tradelineinc.com/reports/CCDDBD31-2B3B-B525-8E9C98EBAD6AE55F).

INCLUSION/EXCLUSION CRITERIA

A key component of any clinical trial focuses on the criteria that will be used to screen subjects willing to enter it. These criteria require careful consideration with TERMP studies, because the first-in-human trials frequently are conducted in patients with the disease condition being targeted. Consequently, allowing patient volunteers who are insufficiently affected by the disease condition may prevent detection of either a safety or efficacy signal, especially in small studies with few patients; however, such patients are more capable of being treated in the event of an adverse outcome linked to the TERMP being tested. Conversely, allowing patient volunteers who are severely affected by the disease may provide results that are highly indicative of an effective treatment but equally sensitive to potential adverse effects of the TERMP understudy.

Inadequate definition of these criteria will lead to highly variable results that will not provide a successful outcome due to the inability to detect either a safety or efficacy signal. Balancing these type I and type II errors requires clear definition of the inclusion/exclusion criteria and establishing endpoints that are consistent with product evaluation and the patient population's response to both the disease and TERMP effects.

OUTCOME MEASURES — SAFETY AND EFFICACY ENDPOINTS

Selection of endpoints will vary between exploratory and confirmatory trials. All clinical trials must consider a robust evaluation of the safety for both the TERMP and product delivery approach being used. Safety outcomes can include symptomatology, hematology, and analysis of various body fluids and tissues. For TERMP, the use of imaging to evaluate both safety and efficacy is a common approach — safety might be biocompatibility and efficacy may be the appropriate tissue or organ structure. Additionally, patient quality of life, function of the TERMP once implanted and durability of the TERMP are key outcome measures.

ESTABLISHING A REGULATORY PATHWAY

Substantial clarification about appropriate regulatory pathways for evaluating TERMPs has occurred in recent years and is currently most advanced in the United States. Since several regulatory pathways exist for these products and most of the product characteristics consist of a scaffold and cells isolated from a specified source, the Office of Combination Products (OCP) serves as the most common entry point for establishing regulatory authority (21 CFR 3) [10]. Notably, some regenerative products may fit into existing regulatory pathways for drugs, devices, or biologics. Since regulatory pathways for individual products are well established, consideration here will focus on TERMPs composed of a combination of materials (biologics, drugs, and/or devices). A sponsor seeking to obtain regulatory guidance for a combination product prepares a Request for Designation (RFD) document laying out key information requested by the FDA (Table 5.7). This document presents the sponsor's recommendation and rationale for how the combination product should be regulated. The FDA's decision on how to regulate a combination product is based on the primary mode of action, a judgment that focuses on the scaffold and cellular components of the TERMP. If the product is sufficiently close to a product already regulated by a particular center and pathway, the FDA's decision about requirements for clinical trials may mirror that product's regulatory pathway. The FDA has 60 days from the time of RFD submission to render a decision. Once a pathway has been identified, the sponsor can engage that particular reviewing authority for the optimal study plan to support their first clinical trials.

Specific guidance on engaging the Office of Combination Products and establishing communications with the FDA can be found on the FDA website (FDA, updated regularly). Interacting with this office prior to clinical testing can assist in linking to the proper regulatory authority and necessary regulatory guidelines. For some products the primary mode of action is not readily apparent, and the primary mode of action assignment may be based on the most relevant therapeutic activity, intended therapeutic use, similarity of the product to an existing product, or the most relevant safety and efficacy questions. This designation is then used to establish the most relevant regulatory center and potential regulatory pathway for entry into the clinics and ultimate product registration. A current assignment algorithm and flowchart can be obtained on the FDA website.

CONCLUSIONS

It is inevitable that regenerative medicine-based products will represent an important class of treatments for future patients. These products have the potential to satisfy significant unmet medical needs with an almost unimaginable benefit — a cure, not just a treatment. Regenerative medicine products can be customized to heal the specific needs of the patient in need. Currently, many regenerative medical products have little downside risk, since they eliminate rejection — autologous products representing the clearest example. These products may offer unmatched benefit-risk profiles with the potential to be rapidly approved for introduction into the appropriate patient populations and bring reductions in health care costs and substantial patient benefits, particularly when there are no medically acceptable alternatives.

The path to clinical entry has already been paved for these breakthroughs, which emerge from applying established processes — in cell biology and scaffold engineering — in a knowledgeable way. It is possible that regenerative medical products can be brought to market more rapidly and efficiently than traditional medical products (e.g., pharmaceuticals).

The logistical advantages include development that can occur quickly with patient studies (rather than time-consuming and costly large-scale preclinical studies to define unknown risks), smaller trial sizes (customized nature of the products), and long-term follow-up that occurs post-registration (these products, once implanted, become part of the patient). One could easily envisage that once there is a dramatic success that combines effective therapy with compelling clinical data, industrial scale efforts will open the floodgates to developing treatments for diseases that today fill patients with fear and little hope. The responsibility of tissue engineers for today will be to deliver on the promise of the hope and bring forward the promise of their scientific endeavors.

Acknowledgments

The authors thank Randall McKenzie (rmac3@att.net) for his remarkable work to illustrate this chapter. AJR also thanks the Department of Defense for its support of the National Tissue Engineering Center through a series of grants.

CLINICAL NEED

Tissue engineering combines the principles of materials and cell transplantation to develop substitute tissues and/or promote endogenous regeneration. The approach was initially conceived to address the critical gap between the growing number of patients on the waiting list for organ transplantation due to end-stage failure and the limited number of donated organs available for such procedures [1–3]. This need continues to grow internationally [4]. Increasingly, tissue engineering, as a subfield of regenerative medicine, will also focus on even more prevalent conditions in which the restoration of functional tissue would answer a currently unmet medical need. The development of therapies for patients with severe chronic disease affecting major organs such as the heart, kidney, and liver, but not yet on transplantation waiting lists, would vastly expand the potential impact of tissue-engineering technologies. A notable example is congestive heart failure, with over 5 million patients in the United States alone, across all ethnic groups, who might benefit from successful engineering of cardiac tissue [5,6]. Similarly, diabetes mellitus is now recognized as an exploding epidemic with well over 16 million patients in the United States and more than 217 million worldwide [7]. Patients with type 1 diabetes have lost most or all of their pancreatic β cells due to autoimmune attack, and potentially could be treated by transplantation of surrogate β cells or neo-islets. However, a significant fraction of patients with type 2 disease, by far the more prevalent form, also have insufficient pancreatic β-cell mass, and might benefit from receiving β-like cells [8]. A recent report from the US National Academy of Sciences entitled *Stem Cells and the Future of Regenerative Medicine* highlighted these and other conditions, including osteoporosis (10 million US patients), Alzheimer's and Parkinson's Diseases (5.5 million patients each), severe burns (0.3 million), spinal cord injuries (0.25 million) and birth defects (0.15 million), as targets of regenerative medicine [9].

CURRENT STATE OF THE FIELD

Significant progress has been realized in tissue engineering since its principles were defined [10] and its broad medical and socioeconomic promise was recognized [11–13]. Yet to date only a handful of complex products incorporating cells together with scaffolds have gained regulatory approval; notably bioartificial skin grafts and replacement cartilage, and these have only achieved limited market penetration [14]. Nonetheless, recent clinical reports

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00006-9

with multiple years of patient follow-up document the maturation of the field and validate the development of neo-tissues and neo-organs. Furthermore, the tissue engineering and stem cell industry is rapidly becoming economically robust; annual commercial revenues and spending approached equivalence at about $3.5 billion in 2011 [15]. The combination of advances in both clinical development and commercialization indicates that these technologies will reach increasing numbers of patients in the years to come.

Studies in research models and humans have supported the principle that cell-seeded scaffolds generally perform much better than synthetic scaffolds alone [16]. In one early clinical study, tissue-engineered vascular grafts (TEVG), utilizing autologous bone marrow cells seeded onto biodegradable synthetic conduits or patches, were implanted into 42 pediatric patients with congenital heart defects [17,18]. Safety data were encouraging; there was no evidence of aneurysms or other adverse events after a mean follow-up of 490 days (maximum 32 months) post-surgery. The grafted engineered vessels remained patent and functional. Most importantly, the vessels increased in diameter as the patients grew. However, detailed analysis demonstrated that donor cells did not contribute directly to the long-term development of regenerated vascular tissue, but appeared to play a trophic role in mobilizing host cells from nearby vessels. The investigators who carried out this pioneering study on TEVG now hypothesize that comparable benefits might be obtained with cell-free vascular grafts that would elute cytokines from sophisticated scaffolds to enhance endogenous regenerative responses [19].

Studies of urinary bladder constructs in a canine model convincingly demonstrated the promise of whole organ tissue-engineering technology [20]. As with TEVG, tissue-engineered bladders grafted into juveniles responded to growth regulation as the host matured [21]. The first human studies of bladder augmentation with tissue-engineered constructs yielded very encouraging clinical data [22]. Seven pediatric patients in need of cystoplasty because of high-pressure or poorly compliant bladders received grafts comprising autologous urothelium and smooth muscle cells expanded *ex vivo* and seeded onto a biodegradable collagen or collagen-PLGA composite scaffold. Serial follow-up data obtained over 22 to 61 months (mean 46 months) post-surgery provided evidence for safety and efficacy of the procedure and highlighted advantages over previous surgical approaches. Some of the patients have now been followed for more than 11 years and continue to do well. More recently, 2 phase II clinical trials of tissue-engineered bladder augmentation were carried out under the sponsorship of Tengion Inc. Sixteen human subjects received neo-bladder constructs with autologous cells seeded on scaffolds (www.clinicaltrials.gov, NCT00512148 and NCT00419120). As of this writing, results from these trials have not yet been reported in the peer-reviewed literature.

The promise of tissue engineering in the field of urology has been amplified by a successful observational clinical trial of autologous, cell-seeded, tubularized urethral constructs in five boys with a mean age of 11 years [23]. Subjects were followed for at least 3 years to more than 6 years after surgery, and maintained wide urethral calibers without strictures.

Tissue-engineered bladders and urethras remain experimental, and considerable work remains to be done before they are likely to achieve regulatory approval and broad medical use. Nevertheless, advances in cell biology, biomaterials and bioreactor technologies, and improved understanding of basic regenerative mechanisms, bode well for future application to substantial numbers of patients [24,25]. The need for improved procedures to enable diversion of urine from the kidneys in patients with advanced bladder carcinoma is particularly acute [26]. A clinical trial is underway to test the safety and efficacy of a simpler construct, a tissue-engineered autologous neo-urinary conduit, in cancer patients after radical cystectomy (Tengion Inc., www.clinicaltrials.gov NCT01087697).

Tissue-engineered trachea and bronchi also have entered the early stages of clinical testing. A case report from 2008 describes the treatment of a subject with end-stage airway disease by

replacing the left main bronchus with a decellularized human trachea reconstituted by autologous epithelial cells and mesenchymal stromal cell (MSC)-derived chondrocytes [27]. Subsequent efforts focused on scaffold improvements and identification of an alternative cell source for seeding, as graft production for the initial subject had required almost 3 months [28,29]. Two further case reports document airway tissue engineering using scaffolds seeded with autologous bone marrow-derived cells. An adult subject with lung cancer received a tracheobronchial construct comprising a synthetic nanomaterial scaffold seeded with autologous marrow mononuclear cells [30]. At five months post-implantation the grafted airway appeared to function well and the subject was tumor-free. A 12-year-old child with a congenital tracheal defect was implanted on an emergency basis, after the failure of conventional stents, with a decellularized human tracheal scaffold seeded with autologous MSCs and epithelial patches [31]. Follow-up of each patient indicated that epithelial cells eventually covered the grafted scaffolds, albeit very slowly. Restoration of the epithelium was not apparent in the pediatric subject until a full year post-implantation, and biomechanical strength of the engineered trachea was poor until about 18 months. Nevertheless, the child's health improved significantly; at a two year follow-up, his airway was functional and he had returned to school.

CURRENT CHALLENGES

Observations from the limited numbers of human cases reported to date highlight the potential of tissue engineering to address unmet medical needs. However, both technical and economic hurdles must be overcome before therapies based on these technologies will reach the millions of patients who might benefit from them.

The bladder, urethra, and airways exemplify hollow or tubular structures with relatively thin walls. The engineering of tissues with more complex three-dimensional architectures remains a long-recognized challenge. Solutions will depend on advances in all of the key technologies of tissue engineering, including the design of scaffolds, the choice of cells and the methods for their culture and seeding onto the scaffolds, and maturation of constructs in bioreactors prior to implantation. A particularly critical issue will be to overcome the mass transport limit and provide sufficient oxygen to the engineered tissue prior to vascularization. One potential answer lies in the development of biomaterials that release oxygen at a controlled rate to sustain implanted cells until new blood vessels have formed [32,33]. In addition it will be important to enhance angiogenesis, to give the regenerating tissue access to sufficient oxygen and nutrients from the circulation as rapidly as possible. The use of angiogenic factors, improved scaffold materials, printing technologies, and accelerated *in vitro* maturation of engineered tissues in bioreactors may help to address this problem. Of particular interest is the invention of novel scaffold materials designed to serve an instructive role in the development of engineered tissues, both for parenchyma and vasculature. Another approach utilizes decellularized whole organs that retain the vascular channels and many extracellular matrix (ECM) components from the native tissues. Methods to prepare improved cell-scaffold constructs by growth in bioreactors before implantation will serve a complementary role in generating more robust clinical products.

A second key challenge centers on a fundamental dichotomy in strategies for sourcing of the live component of engineered tissues — the use of autologous versus allogeneic or even xenogeneic cells. It appears most cost-effective and efficient for manufacturing, regulatory approval, and wide delivery to end users to employ a minimal number of cell donors, unrelated to recipient patients (i.e., allogeneic), to generate an 'off-the-shelf' product. On the other hand grafts generated from autologous cells, obtained from a biopsy of each individual patient, in principle present no risk of immune rejection because of genetic mismatches, thereby avoiding the need for immunosuppressive drug therapy, with its attendant high cost and side effects. Thus, the autologous approach, though perhaps more laborious and costly, appears to have a major advantage. Nonetheless, there are many tissue-engineering

applications for which appropriate autologous donor cells may not be accessible by biopsy. Therefore, new sources of cells for regenerative medicine are being sought, mainly from among progenitor and stem cell populations. However, any use of unrelated donor cells inevitably raises the potential barrier of immune rejection, especially via the direct allorecognition pathway [34].

The path-breaking discovery that pluripotent stem cells can be generated by the reprogramming of normal adult cells, for which Shinya Yamanaka was awarded the 2012 Nobel Prize in Physiology or Medicine, in principle enables the production of autologous cells of virtually any type desired for tissue engineering [35]. Furthermore, evidence that some stem cell populations and tissues derived from them can be grafted successfully despite histocompatibility mismatches offers encouragement for allogeneic tissue-engineered products that could be delivered without immunosuppression.

Our goal here is to review recent advances in tissue engineering in light of the issues raised above. We will gaze into an admittedly imperfect crystal ball and attempt to highlight the technologies that will most profoundly impact medicine.

FUTURE DIRECTIONS

Smarter biomaterials

Scaffolds provide mechanical support and shape for neo-tissue construction *in vitro* and/or through the initial period after implantation as cells expand, differentiate, and organize [36]. Materials that mainly have been used to date to formulate degradable scaffolds include synthetic polymers such as poly(L-lactic acid) (PLLA) and poly(glycolic acid) (PLGA), and polymeric biomaterials such as alginate, chitosan, collagen and fibrin [37]. Composites of these synthetic or natural polymers with bioactive ceramics such as hydroxyapatite or certain glasses can be designed to yield materials with a range of strengths and porosities, particularly for the engineering of hard tissues [38]. Broadly, the conceptual understanding of biomaterials is evolving to include a wider range of substances such as biopolymers, nanoparticles, carbon nanotubes and quantum dots, and to focus increasingly on functional interactions with cells and tissues [39].

EXTRACELLULAR MATRIX

A scaffold used for tissue engineering can be considered an artificial ECM [40]. It has long been appreciated that the normal biological ECM, in addition to contributing to mechanical integrity, has important signaling and regulatory functions in the development, maintenance, and regeneration of tissues. ECM components, in synergy with soluble signals provided by growth factors and hormones, participate in the tissue-specific control of gene expression through a variety of transduction mechanisms [41–44]. Furthermore, the ECM is itself a dynamic structure that is actively remodeled by the cells with which it interacts [45,46]. An important future area of tissue engineering will be to develop improved scaffolds that more nearly recapitulate the biological properties of authentic ECM [47,48].

Decellularized tissues or organs can serve as sources of biological ECM for tissue engineering. The relatively high degree of evolutionary conservation of many ECM components allows the use of xenogeneic materials (often porcine). Various extracellular matrices have been utilized successfully for tissue engineering in animal models, and products incorporating decellularized heart valves, small intestinal submucosa (SIS), and urinary bladder matrix have received regulatory approval for use in human patients [49]. The use of decellularized matrices is likely to expand because they retain the complex set of molecules and three-dimensional structure of authentic ECM. The precise degree to which structural and signaling components are preserved depends on the choices of detergents and enzymes used to remove cells and the washing conditions used to clear these reagents. Despite many

advantages, there are also concerns about the use of decellularized materials. These include the potential for immunogenicity, the possible presence of infectious agents, variability among preparations, and the inability to completely specify and characterize the bioactive components of the material.

Decellularized scaffolds may serve as platforms for the engineering of whole organs [3,50]. A compelling demonstration was provided by the production of acellular hearts that retained patent vascular networks, functional valves, and normal chamber architecture [51]. When cardiomyocytes and endothelial cells were perfused back into the scaffolds and the constructs maintained in a bioreactor for several weeks, the partially reconstituted organs showed muscular contractions and detectable pump function. Similarly, whole organ decellularized liver scaffolds were produced with an intact vascular tree. Seeding of these scaffolds with endothelial cells and hepatocytes generated organoids with appropriate cellular organization, marker expression, and a degree of tissue-specific function [52]. A novel whole organ decellularization procedure designed to retain all collagen types, along with other structural proteins, proteoglycans, and ECM-bound cytokines and growth factors, yielded a liver scaffold that promoted the rapid differentiation of hepatic stem cells to mature hepatocytes and bile duct cells [53].

From a cellular perspective the heart and liver, are relatively homogeneous organs. Even so, the goal of attaining complete tissue reconstitution and function after seeding cells onto decellularized scaffolds from these organs remains to be achieved. Still greater challenges will be faced in the reconstruction of the kidney, with its multiplicity of cell types (up to 23 distinct classes) and complex physiology. As an initial step, decellularized renal scaffolds were re-implanted successfully into experimental animals, were readily reperfused, and sustained blood pressure [54].

ELECTROSPINNING

There would be significant advantages to synthetic scaffolds that closely mimic key features of the ECM, but might be manufactured more easily and reproducibly than decellularized organs. Electrospinning has enabled the production of a new generation of highly biocompatible micro- and nano-fibrous scaffolds from materials such as poly(epsilon-caprolactone), from diverse matrix proteins such as collagen, elastin, fibrinogen, and silk fibroin, from polysaccharides, and from carbon nanofibers [55–66]. Electrospun materials have fiber diameters in the range of those found in native ECM and generally display greater mechanical strength than hydrogels. The electrospun scaffolds may be assembled utilizing a variety of nano-fibrous structures and may incorporate additional important ECM components such as particular subtypes of collagen, glycosaminoglycans, and laminin, either in the spun fibers or as coatings, to promote cell adhesion, growth, and differentiation [55,64,67–69].

The use of specialized proteins such as recombinant silk fibroin offers the opportunities to design scaffolds with enhanced strength or other favorable features, for example controlled release of entrapped materials for drug or bioactive factor delivery [70,71]. The incorporation of plant materials such as wheat gluten and gliadin also may enable the cost-effective production of novel electrospun biomaterials [72,73].

It often proves problematic to introduce cells into a nanofibrillar structure in which pore spaces are considerably smaller than the diameter of a cell [74]. However, remarkably, it is possible to utilize electrospinning to incorporate living cells into a fibrous matrix. A proof-of-concept study documented that smooth muscle cells could be concurrently electrospun with an elastomeric poly(ester urethane)urea, leading to 'microintegration' of the cells in strong, flexible fibers with mechanical properties not greatly inferior to those of the synthetic polymer valone [75]. The cell population retained high viability and, when maintained in a

perfusion bioreactor, the cellular density in the electrospun fibers doubled over four days in culture. By electrospraying the smooth muscle cells concurrently with electrospinning a small-diameter conduit, the cells could be integrated efficiently into a biodegradable tubular matrix with properties favorable for a tissue-engineered blood vessel substitute [76].

BIOPRINTING

An equally surprising observation is that living cells can survive inkjet printing [77–79]. Modification of printers to add a z-axis allows the generation of three-dimensional structures. Thus, 'bioprinting' of cells together with matrix biomaterials and bioactive factors should enable the production of constructs that mimic the architectural complexity, signaling capacity, and cellular distribution of complex tissues [80–83]. Bioprinting can be applied even to highly specialized, fragile cells. For example, printed hippocampal and cortical neurons retained their characteristic phenotypes as judged by immunohistochemical staining and whole cell patch-clamping, a stringent functional test of electrical excitability [84].

Bioprinting technology for tissue engineering has developed rapidly, and will continue to do so [80,85–92]. Examples of applications under development include: directed differentiation of stem cells [93,94]; drug-screening in tissue-like contexts [95]; generation of tissue constructs with growth factor gradients [81] and tailored mechanical properties [89]; production of blood vessel substitutes [96]; and direct *in vivo* repair of tissues such cartilage and skin [97,98]. Eventually, bioprinting may prove the method of choice to generate whole organ constructs comprising multiple cell types and microenvironments.

SMART POLYMERS

Incorporation of cells by electrospinning or printing generates, in a sense, the ultimate 'smart' biomaterials. Even without cells, biomaterials can be produced that are capable of interactive behavior, both responsive to and able to modulate the local environment and cellular activities.

At the chemical level a number of groups have explored the production of biomaterials that unite the advantages of synthetic polymers with the biological activities of proteins. The notion of smart polymers initially described materials that undergo large conformational changes in response to environmental stimuli such small changes in temperature, ionic strength, or pH [99,100]. Light stimuli can activate crosslinking of polymers [90]. Ultrasound can be used to trigger nanobubble formation and facilitate DNA uptake [101]. The responses of a polymer may include precipitation or gelation, reversible adsorption on a surface, collapse of a hydrogel or surface graft, and alternation between hydrophilic and hydrophobic states [102]. In many cases the change in the state of the polymer is reversible.

Biological applications of smart polymer technology span diverse areas including bioseparation, drug delivery, reusable enzymatic catalysts, molecular switches, biosensors, regulated protein folding, microfluidics, and gene therapy [103,104]. In tissue engineering smart polymers offer promise for revolutionary improvements in scaffolds. Beyond the physical properties of polymers, a major goal is to invest smart biomaterials with specific properties of signaling proteins such as ECM components and growth factors.

One approach is to link smart polymers to proteins [103,102]. Conjugation can occur at random positions or in a site-specific manner, through engineering of the protein to introduce a reactive amino acid at a particular point in the primary sequence. If a conjugation site is introduced near the ligand-binding domain of a protein, induction of a change in conformational state of the smart polymer can serve to regulate the protein's activity [105]. This may allow selective capture and recovery of specific cells, delivery of cells to a desired location, and modulation of enzymes such as matrix metalloproteases that influence tissue remodeling.

PROTEINS AND MIMETICS

More broadly, the design of genetically modified proteins or of hybrid polymers incorporating peptides and protein domains enables the creation of a wealth of novel smart biomaterials [106]. These include: engineered mutant variants of natural proteins; semi-synthetic scaffold materials incorporating protein domains; scaffold materials linked to synthetic peptides; and engineered peptides capable of self-assembly into nanofibers.

Genetic engineering may improve on endogenous proteins for applications in tissue engineering [107]. For example, a collagen-like protein was generated by using recombinant DNA technology to introduce tandem repeats of the domain of human collagen II most critically associated with the migration of chondrocytes [108]. When coated onto a synthetic PLGA scaffold and seeded with chondrocytes, the engineered collagen was superior to wild-type collagen II in promoting artificial cartilage formation. Similarly, recombinant technology was employed to generate a series of elastin-mimetic protein triblock copolymers [109]. These varied broadly in their mechanical and viscoelastic properties, offering substantial choices for the production of novel materials for tissue engineering.

Bioactive signals can be incorporated into scaffold materials by the chemical linkage of proteins, protein domains, or synthetic peptides as tethered ligands. Integrins, transmembrane receptors that serve as adhesion molecules between cells and other cells and/or the ECM, are key targets for ligands used to modify scaffold surfaces. Numerous studies have confirmed that addition of the integrin-binding motif arginine-glycine-aspartic acid (RGD), first identified in fibronectin, enhances the binding of many types of cells to a variety of synthetic scaffolds and surfaces, including metals, polymers, potassium phosphate bone surrogates, and hydrogels [110–114]. The CS5 cell-binding domain of fibronectin also has been incorporated into scaffolds, and its activity is subject to regulation by sequence context [115]. Greater selectivity and potency in cellular binding and enhancement of growth and function can be achieved by taking advantage of additional binding motifs in concert with RGD, or independently of that tripeptide [116,117]. The integrin family comprises two-dozen heterodimeric proteins, so there remains great opportunity to expand the set of peptide binding motifs that could be utilized on tissue-engineering scaffolds, with the hope of achieving greater selectivity and control.

Even within the particular context of RGD-binding domains, scaffolds can be engineered with enhanced specificity for specific integrin heterodimers. For example, modification of a biomaterial by attachment of a fibronectin fragment containing both the RGD site and a so-called 'synergy site' (sequence proline-histidine-serine-arginine-asparagine [PHSRN]) promotes binding of cells via the integrin alpha(5)beta(1) [118]. A distinct synergy site promotes binding via a different integrin heterodimer, alpha(IIb) beta(3) [116]. Multiple chemical and biochemical approaches, including combinations of small protein fragments, peptide cyclization, peptide modification by N-methylation, linking of peptide motifs from different proteins, and use of small molecule peptide mimetics, are being explored to optimize specific cell-adhesive surfaces [119–123].

The modification of matrices with bioactive peptides and proteins can extend well beyond insertion of motifs to promote cell adhesion [124]. Cells also need to migrate in order to form remodeled tissues. Thus, the rate of degradation of scaffolds used for tissue engineering is a crucial parameter affecting successful regeneration [125]. Regulation of the degradation rate can be achieved by varying physical parameters of the scaffold. Alternatively, the scaffold can be engineered to contain target sites for proteolytic degradation [126,127]. For example, the incorporation into a crosslinked synthetic hydrogel of sequences cleaved by matrix metallopreases, known to play an important role in cell invasion, enhanced the migration of fibroblasts *in vitro* and the healing of bony defects *in vivo* [128]. Biodegradation of the synthetic matrix was efficiently coupled to tissue regeneration.

GROWTH AND ANGIOGENIC FACTORS

Factors that drive cell growth and differentiation can be added to the matrix in the form of recombinant proteins or, alternatively, expressed by regenerative cells via gene therapy. Growth factors of potential importance in tissue engineering and methods to deliver them have been reviewed [129]. Ideally, for optimized tissue formation without risk of hyperplasia, the growth factors should be presented to cells for a limited period of time and in the correct local environment. Biodegradable scaffolds produced by electrospinning or other methods are capable of sustained release of growth factors and cytokines, or small molecule drugs, over periods of weeks to months [130–135]). Biologically regulated release of growth factors from scaffolds appears particularly promising as a means to ensure that cells in regenerating neotissues receive signals at appropriate times and in physiological doses. For example, physical entrapment of recombinant bone morphogenetic protein-2 (BMP-2) in a hydrogel so that it would be released by matrix metalloproteases promoted excellent bone healing in a critical-size rat calvarial defect model [128]. Similarly, incorporation of a neurotrophic factor in a slowly degradable hydrogel promoted local extension of neurites from explanted retina, and gels were designed to release multiple neurotrophin family members at different rates [136].

The expression of recombinant growth factor domains and their immobilization to the matrix provides another means to control the presentation of biological signals in time and space. Model studies with epidermal growth factor (EGF) showed that oriented coupling to a scaffold via a protein coil domain provides an efficient means to preserve a high level of receptor-binding activity while localizing the signal to a desired scaffold region [137,138].

Using similar strategies, controlled presentation of angiogenic factors such as vascular endothelial growth factor (VEGF) should promote the well-regulated neovascularization of engineered, regenerating tissue [139,140]. Again, it is possible to covalently couple an angiogenic factor to a matrix and to regulate its release based on cellular activity and demand [141–144]). The selection of a sulfated tetrapeptide that mimics the VEGF-binding capability of heparin, a sulfated glycosaminoglycan, provides another potential tool for the construction of scaffolds able to deliver an angiogenic factor to cells in a regulated manner [145].

Spatial gradients can be generated in the presentation of growth factors within scaffold constructs [81,146–149]). By mimicking the distribution of normal developmental morphogens, graded signals from imprinted or bound factors may guide the formation of engineered complex tissues by directing both cellular migration and differentiation. For example, bioprinting of bone morphogenetic protein (BMP) and fibroblast growth factor (FGF) gradients can direct the formation of bone and tendon by stem and progenitor cells [81,93,150–152]). Similarly, gradients of neurotrophic factors and scaffold matrix components guide neuronal differentiation and the extension of nerve processes [153,154].

Gradients of scaffold-linked growth factor-binding motifs provide a generalized means to regulate the spatial distribution of signaling molecules [155]. The introduction of sophisticated manufacturing technologies, such as solid free-form fabrication, will allow the production of tissue-engineering constructs comprising scaffolds, incorporated cells, and growth factors in precise, complex three-dimensional structures [156].

DISCOVERY OF NEW MATERIALS

One potential next stage of smart biomaterial development extends to the design or discovery of truly novel bioactive matrices, not necessarily derived from naturally occurring carbohydrate and protein structures. At one level this may entail the relatively straightforward chemical synthesis of new materials. By adapting the combinatorial library approach already well established for synthetic peptides and drug-like structures, together with even moderately high throughput biological assays, thousands of candidate scaffold materials can be generated and tested. Thus, screening of a combinatorial library derived from commercially available

monomers in the acrylate family revealed novel synthetic polymers that influenced the attachment, growth and differentiation of human embryonic stem (ES) cells in unexpected ways [157]. As understanding of stem cell biology has become more sophisticated, comparable screening strategies have led to the discovery of an increasing number of biomaterials that mimic normal microenvironments in promoting the expansion and differentiation of various stem and progenitor cell populations [158–60].

Revolutionary developments in biomaterials are likely to arise at the interface of tissue engineering with nanotechnology. Basic understanding of the three-dimensional structure of existing biological molecules is being applied to a 'bottom-up' approach to generate new, self-assembling supramolecular architectures [161–164]. In particular, self-assembling peptides offer promise because of the large variety of sequences that can be made easily by automated chemical synthesis, the potential for bioactivity, the ability to form nanofibers, and responsiveness to environmental cues [165,166].

Pioneering studies have included the design of short peptides (e.g., heptamers) based on coiled-coil motifs that reversibly assemble into nanofilaments and nanoropes, without excessive aggregation [167]. These smart peptide amphiphiles can be induced to self-assemble by changes in concentration, pH, or the level of divalent cations [168,169].

As noted with electrospinning and bioprinting, tissue engineering will be facilitated greatly if cells can be incorporated readily into the biomaterial. An early proof-of-concept study showed that it is possible to entrap viable cells during the assembly of a nanofiber matrix [170]. The captured cells retained motility and the ability to proliferate. A subsequent report showed that specialized cells such as neural progenitors can be encapsulated by peptide amphiphiles, and their subsequent growth and differentiation influenced by incorporation of cell-adhesive ligands and other bioactive molecules [171].

Self-assembling amphiphilic peptides and, most broadly, rationally designed peptide and polypeptide-based hydrogels, will continue to serve as a platform and toolbox for a wide array of new biomaterials [172,173]. For example, branched structures can be designed to present bioactive sequences such as RGD to cells via nanofiber gels or as coatings on conventional tissue-engineering scaffolds [174,175]. Other features of the ECM, such as mechanical properties, sensitivity to enzymatic remodeling, and presentation of growth factor or cytokine signaling sequences can be selected or designed through the choice of peptide units, functionalization, and incorporation of bioactive macromolecules and small molecule drugs [176,177]. Other nanomaterials, such as carbon nanotubes and DNA polyplexes can be incorporated to add additional features and activities [178].

Further opportunities exist to expand the range of peptidic biomaterials by utilizing additional chemical components such as porphyrins, which can bind to peptides and induce folding [179]. Porphyrins and similar structures also may add functionality such as oxygen storage, catalysis or photosensitization of chemical reactions, or transfer of charge or molecular excitation energy. Peptide-porphyrin complexes thus offer promise of a new generation of regulated, photoelectronically active biomaterials that will be exquisitely sensitive to environmental stimuli [180,181].

Peptide-based nanofibers may be designed to present bioactive sequences to cells at very high density, substantially exceeding that of corresponding peptide epitopes in biological ECM. For example, a pentapeptide epitope of laminin, isoleucine-lysine-valine-alanine-valine (IKVAV), known to promote neurite extension from neurons, was incorporated into peptide amphiphiles (PA) capable of self-assembly into nanofibers that form highly hydrated (>99.5 weight % water) gels [182]. When neural progenitor cells capable of differentiating into neurons or glia were encapsulated during assembly of the nanofibers, they survived over several weeks in culture. Moreover, even without the addition of neurotrophic growth factors, they displayed neuronal differentiation as exemplified by the extension of large neurites, already

obvious after one day, and by expression of βIII-tubulin. The production of neuron-like cells from the neural progenitors, whether dissociated or grown as clustered 'neurospheres,' was more rapid and robust in the IKVAV-PA gels than on laminin-coated substrates or with soluble IKVAV. By contrast, the production of cells expressing glial fibrillary acidic protein (GFAP), a marker of astrocytic differentiation, was suppressed significantly in the IKVAV-PA gels even when compared to growth on authentic laminin, which also favors neuronal over glial differentiation. The ability to direct stem or progenitor cell differentiation via a chemically synthesized biomaterial, without the need to incorporate growth factors, offers many potential advantages in product development for regenerative medicine.

Combinations of the peptide amphiphile with other matrix components, such as collagen, and growth factors provide the basis for optimized smart scaffold biomaterials that ultimately should find medical application in tissue engineering [183]. For example aligned amphiphile nanofibers used as a scaffold and delivery system for Sonic hedgehog (SHH) have proven effective in an animal model of peripheral nerve regeneration, in part through modulation of the production of endogenous neurotrophic factors [184–186]).

Bioreactors

After seeding of cells onto scaffolds, a period of growth *in vitro* often is required prior to implantation. Static cell culture conditions generally have proven sub-optimal for the development of engineered neo-tissues because of limited seeding efficiency and poor transport of nutrients, oxygen, and wastes. Bioreactors systems have been designed to overcome these difficulties and to facilitate the reproducible production of tissue-engineered constructs under tightly controlled conditions [187–192]). Future advances will come through improved understanding of the requirements for tissue development coupled with increasingly sophisticated reactor engineering.

An important parameter that must be determined for the *in vitro* maturation of a tissue-engineered construct is the optimal level of oxygen. Contrary to conventional wisdom, for some tissues or cell types it appears that low oxygen tension is important for optimal growth and specialized function. For example, in tissue engineering of cartilage, while aerobic conditions are essential for adequate tissue production [193], cultivation in bioreactors at reduced oxygen tension (e.g., 5% instead of the 20% found in room air) improved the biosynthesis of glycoasminoglycans and the expression of additional characteristic phenotypic markers and functions [194–196]).

Regulation of oxygen tension also proves critical in handling many progenitor and stem cell populations in culture, particularly in bioreactors [197–201]. Physiological (i.e., reduced compared to ambient) oxygen generally mimics the normal microenvironment or 'niche' for stem cells, and enhances their growth and stability. Optimization of oxygen tension, sometimes at a low level sometimes at a significantly higher level than for stem cell proliferation, also frequently improves the production of particular differentiated derivatives [202–206].

It has become increasingly clear that, in addition to regulating mass transport, bioreactors may be used to enhance tissue formation through mechanical stimulation. For example, pulsatile flow helps the maturation of blood vessels [207,208]. Similarly, mechanical stretch strengthens engineered muscles, of both skeletal and smooth types [209–211]. Engineering of bone, cartilage, blood vessels, and both skeletal and cardiac muscle all will continue to advance in part through more sophisticated mechanical conditioning of developing neo-tissues.

A third area of great importance is the use of bioreactors to expedite the manufacture of engineered grafts for clinical use, at levels up to whole organ constructs [187,189,205,212–216]. Key goals will be to optimize the development of neo-tissues and neo-organs, and then to standardize production in order to eliminate wasted units and control

costs. Standardization also will help to meet regulatory requirements in the context of Good Manufacturing Practice (GMP).

The direct interface between man and bioreactors represents another significant challenge in the bioreactor field. On one hand, the patient is increasingly viewed as a potential *'in vivo* bioreactor,' providing an optimal environment for cell growth and differentiation to yield neotissues [217]. There also are circumstances in which a bioreactor may serve as a bioartificial organ, attached directly to a patient's circulation. There have been longstanding efforts to develop a bioartificial liver capable of sustaining life during acute liver failure, until the patient's endogenous organ regenerates or can be replaced by orthotopic transplantation [218–221]. Most designs to date have used hollow fiber bioreactors seeded either with human hepatic lineage cell lines or xenogeneic (e.g., porcine) hepatocytes. Despite intensive efforts over more than three decades, and multiple clinical trials, no bioartificial liver assist device has yet achieved full regulatory approval. Both bioreactor design and cell sourcing require further improvements before the hurdle of demonstrating safety and efficacy in human trials will be surmounted [222–228].

The creation of a robust bioartificial pancreas to provide a physiologically responsive supply of insulin to patients with diabetes represents a comparably significant challenge for bioreactor development. Again, no design has yet proved entirely successful [229–231]. Because pancreatic islets are among the most richly vascularized tissues in the body, providing sufficient oxygen appears to be one rate-limiting factor that may be addressed by improved bioreactor design [232,233]. Furthermore, although human islets can be isolated from pancreata obtained by organ donation, they are in scarce supply. Clearly, if bioartificial organ technology continues to advance, the demand for new sources of functional human cells such as hepatocytes and pancreatic β-cells will expand dramatically [234,235].

Cell sources

Choices of new sources of cells for tissue-engineered products hinge on two fundamental dichotomies: autologous *versus* allogeneic cells; and pluripotent stem cells *versus* adult multipotent or unipotent stem and progenitor cells (Fig. 6.1). Previous clinical and commercial experience sheds light on key differences between off-the-shelf products containing allogeneic cells and personalized products containing autologous cells. To date the vast majority of human studies have focused on tissue-engineered products in which the cellular component contains or derives from adult stem and progenitor cells. However, initial clinical trials of products derived from pluripotent stem cells have begun and may herald a dominant approach of the future.

The first clinical products of tissue engineering that achieved marketing approval from the US Food and Drug Administration (FDA) were skin substitutes used for wound healing. Both Dermagraft (Shire Regenerative Medicine) and Apligraf (Organogenesis) utilize cells expanded greatly from donated human foreskins to treat many unrelated patients. The cell types used to manufacture these products are fibroblasts for Dermagraft, and fibroblasts plus epithelial cells (keratinocytes) for Apligraf. Whereas fibroblasts had been grown *in vitro* since early in the 20th century [236], the successful cultivation of human keratinocytes represented an important breakthrough for regenerative medicine [237].

Despite the inevitable histocompatibility mismatches between donor and recipient, the off-the-shelf skin substitutes lack antigen-presenting cells and are not acutely rejected [238–241]. This stands in contrast to standard organ transplantation in which immune suppressive drug therapy generally is essential for allogeneic grafts [242]. Eventually, the cells in the skin substitutes may be rejected, but the grafts buy enough time for patients' own skin cells to regenerate.

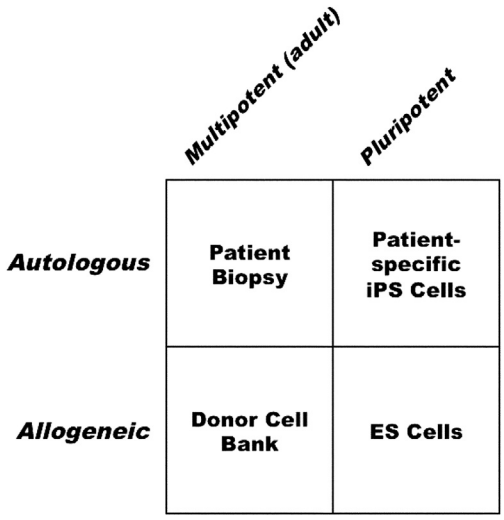

FIGURE 6.1

Four classes of stem cell sources for tissue engineering. Autologous cells are obtained in a biopsy sample harvested from the individual who will subsequently receive the engineered construct. Expansion of cells *in vitro* and regeneration and long-term maintenance of biopsy-derived cells *in vivo* often will depend on the presence of lineage-restricted stem cells in the biopsied tissue. In principle, any desired cell type also can be obtained for a patient by reprogramming to pluripotency cells from a readily obtained biopsy of cells from her/his blood, skin, hair, urine, etc. The iPS cells are then restricted to the desired lineage and used for the tissue-engineered construct. Allogeneic cells can be sourced from banked cells obtained from tissue donors. An already established example is banking of umbilical cord blood cells [501]. Pluripotent ES cell lines (or iPS cell lines) also can be used as a source to derive lineage-restricted cells for off-the-shelf products. Banking of primary donated cells and ES or iPS cell lines enables histocompatibility matching to varying levels of stringency. Strategies to achieve beneficial matching for large segments of a population from modest numbers of banked cell lines are discussed in the text.

Tissue-engineered products based on harvesting and expanding autologous cells containing stem and/or progenitor populations also have been developed successfully. Two examples, each marketed by Genzyme Biosurgery, are: Epicel, a permanent skin replacement product based on expanded keratinocytes for patients with life-threatening burns; and Carticel (Genzyme Biosurgery), a chondrocyte-based treatment for large articular cartilage lesions [243,244].

For some tissue-engineering applications, such as bladder augmentation, the ability to expand a sufficient number of autologous cells (in this case smooth muscle and urothelium) from a small biopsy is well established [245]. In other circumstances methods are not available to harvest and/or expand enough appropriate autologous cells to manufacture the needed neo-tissue or organ. Cardiomyocytes, neurons of the central nervous system, hepatocytes and other liver cells, kidney cells, osteoblasts, and insulin-producing pancreatic beta cells are examples of differentiated cell types for which new sources could enable novel therapies to address significant unmet medical needs.

Immature precursor cells present within tissue samples are essential for the expansion of cells from biopsies of skin, muscle, cartilage, or bladder to enable the engineering of the corresponding neo-tissues [246]. The extension of tissue engineering to other tissue and organ systems will depend greatly on finding sources of appropriate stem and progenitor cells. Three major stem cell sources are currently under intensive investigation:

1) ES cells, derived from discarded human embryos, or the essentially equivalent embryonic germ [EG] cells [247,248];
2) Induced pluripotent stem (iPS) cells derived by genetic reprogramming of somatic cells [249,250]; and
3) Adult tissue stem cells (so named regardless of sourcing from fetal, neonatal, pediatric, or adult donors), either autologous or allogeneic [251].

Shared features of all stem cells are their capacity self-renewal, that is, for extensive replication while maintaining 'stemness', and their ability to give rise to particular classes of differentiated cells. ES, EG and iPS cells can serve as precursors to any specialized cell type found in normal development and are termed pluripotent. Adult stem cells generally are restricted to limited sets of cell lineages. They are called multipotent or, if constrained to a single fate, unipotent. The restriction of the developmental fate of cells to a particular lineage is called commitment, and can refer to stem cells or to down-stream progenitors with lesser replicative capacity. It appears likely that multiple tissue-engineered products based on each class of stem cell source will be tested in the clinic in the coming years. The various stem cell types pose certain common challenges, and each also has specific drawbacks that must be overcome to achieve clinical utility. We will attempt to prognosticate future prospects for the three classes of stem cells in tissue-engineering applications, with particular attention to the implications of histocompatibility matching.

EMBRYONIC STEM CELLS

ES cells and EG cells will be treated together under the ES designation. ES cells indeed are quite similar to early germ cells [252]. They can self-renew apparently without limit in culture and are pluripotent. Their great degree of plasticity represents both the strongest attraction and a significant potential limitation to their use for tissue engineering. A major ongoing challenge lies in efficiently obtaining pure populations of specific desired specialized cell types from human ES cells [253–255].

Much recent work has yielded more robust methods to isolate and grow ES cells under conditions consistent with GMP, and to generate differentiated cell products that will pass stringent regulatory reviews [256,257]. While initial efforts have focused on cell therapies, the advances will have equal impact on the production of complex tissue-engineered constructs. Human ES cells are considerably more difficult to isolate and maintain stably in culture than the cell types that have previously entered clinical testing. However, they can now be derived, grown, and cryopreserved without exposure to non-human cells or proteins, in a GMP environment, and under conditions that appear to preserve genomic integrity [258–266]. The use of microcarriers and bioreactors, along with improved serum-free and xeno-free media, and possibly small molecules to inhibit spontaneous differentiation, will continue to facilitate the expansion of pluripotent stem cells to the population sizes required for product development and eventual broad medical application [267–273].

Even given clinical grade ES cells that can be produced at large scale, the manufacturing of specialized cell types derived from them for tissue-engineered products poses formidable challenges. Human tissues include more than 200 distinct cell types, and ES cells in principle can give rise to all of them. The historical approach of allowing ES cells to differentiate spontaneously after aggregation into embryoid bodies, followed by selection of a particular mature cell type, has largely been supplanted. Current strategies employ staged differentiation guided by knowledge of signaling events that regulate normal embryonic development [274]. A first step is to direct the pluripotent stem cells to one of the three germ layers, namely the ectoderm, mesoderm, or definitive endoderm, that form during the gastrulation stage of embryogenesis. For example, exposure of very early embryonic cells to the growth factor Nodal (a member of the TGF-β family) or its analog Activin A suppresses a default pathway of differentiation to ectoderm and favors the generation of mesendoderm, the immediate precursor of mesoderm and endoderm [275,276]. Fine tuning of the application of Nodal or Activin, in conjunction with other growth factors or small molecules, now allows the quantitative generation *in vitro* from ES cells of a reasonably homogeneous population with markers characteristic of definitive endoderm [277–281]. This is a key, albeit early, milestone in multi-step differentiation to cells that eventually may be used for tissue engineering of such organs as the liver and pancreas. Conversely, inhibition of Nodal/Activin signaling favors the

production of ectoderm, a precursor for ES cell-derived neural lineage cells [282,283]. The optimization of growth factor cocktails and the use of scale-up bioreactors will continue to make the initial steps of stem cell commitment to each germ layer more robust, as an important stage in the development of tissue-engineered products. This has been exemplified recently by scaled-up production of definitive endoderm [284].

Subsequent steps employed to drive differentiation to a desired lineage may be determined both by knowledge of normal development and by empirical observations, including screening for small molecule modulators. Increasingly, efforts to isolate a wide variety of specialized cells from human ES and iPS cells are approaching the goal of achieving differentiated populations in which high percentages of cells express morphological characteristics, biochemical and antigenic markers, and functional properties consistent with the desired cell types. Many of these differentiated cells have potential application in tissue engineering. Examples include: a number of classes of neurons [285–289] other cells of the nervous system including oligodendrocytes and subsets of astrocytes [290–296]; cardiomyocytes and endothelial cells [297–311]; mesenchymal stem and progenitor cells [312–316]; hepatocytes [277,317–321]; and endocrine cells of the pancreas, notably insulin-producing beta-like cells [322–326].

However, much remains to be accomplished in utilizing pluripotent stem cells as a source for future cell-based therapeutic products. Purity of differentiated cell populations and exclusion of potentially tumorigenic undifferentiated stem cells must be confirmed for every application. Furthermore, not surprisingly, the differentiated cells derived from ES cells in culture often more closely resemble those in embryonic and early fetal development than in adult or even neonatal human tissues. A recent report concludes that the gene expression profiles of ES cell-derived specialized cells retain many primitive features, and resemble those of cells in human fetuses at about six weeks of gestation. Detailed studies of various cell lineages, such as pancreatic β cells and hepatocytes, have highlighted the difficulty of achieving fully adult phenotypes from ES cells [323, 327–329]. The completion of development may actually require additional maturation for several months *in vivo*, as shown for endocrine pancreatic progenitors of insulin-producing β-like cells [330]. Therefore, while serving as useful models for human development, the immature cells derived from pluripotent stem cells may have significant limitations as components of safe and effective tissue-engineered therapies.

A particular safety concern is that undifferentiated pluripotent ES and iPS cells form teratomas *in vivo*. These tumors contain cell types representing each of the three embryonic germ layers [331]. The risk of tumorigenicity makes it essential to determine rigorously the residual level of undifferentiated stem cells in any therapeutic product derived from ES or iPS cells [332]. Assays for teratoma formation are being standardized, but currently have a lower sensitivity limit of about 100 stem cells [333]. It remains to be determined whether a small number of undifferentiated pluripotent stem cells can be introduced into humans without significant risk of tumor growth, and whether this threshold is influenced by immune suppressive drugs.

It should be possible to decrease risk of teratoma formation by introducing additional manufacturing steps to eliminate undifferentiated pluripotent stem cells from cell therapy or tissue-engineered products. For example, this might be accomplished by negative selection with antibodies to surface markers of pluripotent stem cells [334]. Another approach would be to facilitate elimination of any tumors that might actually arise in recipients of tissue-engineered products. One proposed strategy is to transduce into the stem cells a 'suicide' gene, such as one encoding a viral thymidine kinase that would serve as a fail-safe mechanism to allow eradication of any donor cell-derived tumors by treatment with ganciclovir [335]. However, the drug also would be expected to kill the therapeutically beneficial cells of the graft, unless it is placed under the control of a promoter expressed preferentially in pluripotent stem cells [336].

Despite substantial challenges, especially overcoming regulatory concerns over a first-in-class product with potential for tumorigenicity, the first ES cell-derived therapeutics entered clinical trials. Geron Corporation obtained approval to test hES cell-derived oligodendrocyte progenitor cells, thought capable of remyelinating axons and stimulating nerve process growth, in subjects with spinal cord injury [337,338]. Four patients were treated before the company elected for business reasons to drop its ES cell program.

Advanced Cell Technology has begun clinical trials of ES cell-derived retinal pigment epithelium (RPE) cells, implanted under the retina, in patients with Stargardt's macular dystrophy and dry age-related macular degeneration. The subretinal space is immune privileged, so the use of immune suppressive drugs was not considered necessary for this allogeneic cell therapy. Observations on two subjects at four months after cell transplantation were published in early 2012 [339]. Evidence for safety included absence of excess cell proliferation, ectopic tissue or tumor formation by grafted cells, or of immunological rejection. Vision apparently approved in at least one of the subjects. At the time of writing, this remains the only reported active clinical stage development program of an ES cell-derived product. Positive outcomes would undoubtedly stimulate future efforts to develop tissue-engineered products from pluripotent stem cells.

Two areas of clear medical need that might be addressed by stem cell-derived products are Parkinson's disease [340] and type 1 diabetes [234]. In each case the replacement of a specific cell type, dopamine-producing neurons for Parkinson's disease and insulin-producing pancreatic β cells for diabetes, would be potentially curative.

Significant advances have been made in the production of functional midbrain dopaminergic neurons by staged differentiation from ES cells [274,285,288,289,341,342–346]. Recent studies demonstrated the efficient grafting of these cells leading to physiological correction of symptoms in several animal models, including non-human primates, with chemical lesions that mimic the degenerative loss in Parkinson's disease [347,348]. The identification of conditions to more accurately replicate the normal developmental pathway, including the specification of the midbrain floorplate, proved crucial in generating neurons with the desired specific phenotype and a high capacity to engraft in the brain. Scale-up and the optimization of delivery should enable testing of dopaminergic cells in human subjects.

A team of scientists at Viacyte (formerly Novocell) similarly pursued the strategy of following a normal developmental sequence to produce progenitors of pancreatic endocrine cells from human ES cells [323]. They used transcription factors as stage-specific markers and induced stepwise advancement from pluripotent stem cells to definitive endoderm, primitive gut tube, posterior foregut, and pancreatic endoderm and endocrine precursors. As noted above, the progenitor cells from the final stage reached *in vitro* were able to mature further *in vivo* to yield glucose-responsive β-like cells [330,349]. Screening for small molecules that could replace growth factors or hormones in driving key steps in the differentiation sequence, e.g., the generation of definitive endoderm or pancreatic lineage specification, proved successful, and should facilitate the eventual development of cost-effective therapeutic products [350,351].

The production of ES cells and differentiation to pancreatic progenitors have been scaled-up under conditions compatible with GMP to support clinical testing [272]. It is anticipated that the grafted cells will be susceptible to acute immune attack, both by alloreactive T cells and by the autoimmune T cells that initially caused the patients' type 1 diabetes. Therefore, Viacyte proposes to deliver a tissue-engineered product with the therapeutic cells encapsulated in a semipermeable device designed to protect them from the immune system, while allowing exchange of nutrients and release of insulin to the circulation.

The need to protect grafts from the recipient's immune system is a fundamental problem for regenerative medicine and tissue engineering [34,352], aptly captured by the metaphor of 'the elephant in the room' [353]. The risk of immune rejection must be considered for any cell

therapy or tissue-engineered products based on ES cells, as these are genetically mismatched for all recipients. However, the situation appears more tractable than for classical whole organ transplantation. Tissue-engineered products generated *in vitro* will not contain the professional antigen-presenting cells and inflammatory cells that are present in donated cadaveric organs. Furthermore, undifferentiated human ES cells express very low levels of Class I Major Histocompatibility Complex (MHC) antigens, and do not express Class II MHC antigens (HLA-DR, -DQ, and -DP) [354]. Differentiated cells derived from the ES cells express higher levels of MHC Class I (human leukocyte antigens, HLA-A, -B, and -C), which can be induced further by interferon, but generally remain negative for Class II. One potential way to ensure successful allo-transplantation of these cells would be to modify ES cells genetically to knock out MHC Class I, and possibly Class II, expression [34].

Perhaps because of their relative immaturity and low MHC Class II expression, differentiated ES cell derivatives in fact display lower immunogenicity than do corresponding adult human cells, either *in vitro* or after implantation into mice with a 'humanized' immune system [355,356]. There has been a suggestion from transplantation of murine embryoid bodies in allogeneic mice that ES cells actually exert a local immunosuppressive effect [357], but this claim has been debated [358]. Others reported that various human ES cell-derived specialized cells are subject to immune rejection [359]. However, they found that transplantation tolerance could be induced readily by non-ablative treatment of the host with monoclonal antibodies to the T cell antigens CD4 and CD8. The investigators showed further that transplantation of ES cell-derived tissues across MHC Class I barriers also can occur spontaneously, and that this immune privilege depends on regulatory T cells (Treg) [360]. These observations imply that methods may be found to efficiently induce immunological tolerance in recipients of allogeneic stem cell-derived grafts [352,361–363]. Future developments in this arena could have major impact on the future of tissue engineering, as off-the-shelf therapies that could be employed without any immune suppression would lower both economic and safety barriers to widespread adoption in medical practice [14].

Another approach to enable the use of allogeneic human ES cells for tissue engineering with decreased, or zero, need for immune suppressive drugs rests on cell banking strategies. The simple expedient of deriving clinically intended ES cells only from blood group O donors obviates issues of ABO type compatibility [34]. More profoundly, while complete genetic matching can be achieved only with autologous cells or between identical twins, the establishment of GMP-grade ES cell line banks of relatively modest size, comprising from tens to under 200 lines from appropriately selected donors, would enable complete or 'beneficial' matching at the most important MHC loci (HLA-A, -B, and -DR) for the large majority of the population. Calculation of the numbers of lines that would be required depends on assumptions about the degree of matching that would be required, on the choices of cell line donors and methods of ES cell production, and on the genetic heterogeneity of various national populations [364,365]. In particular, derivation of ES cells from parthenogenetic embryos, which would be homozygous for HLA loci, or selection of rare HLA-homozygous donors from the general population to obtain pluripotent stem cell lines (more readily achieved for iPS than for ES cell banking), would significantly decrease the size of bank required to ensure matching of most potential recipients [364,365,366–369]. Stem cell line banking on a global scale seems an idealistic but potentially feasible goal for future development [370].

INDUCED PLURIPOTENT STEM (IPS) CELLS

At least superficially, the development of iPS cells offers the most direct way to ensure immune compatibility of tissue-engineered products, by allowing any individual to serve as her/his own donor. It also may enable the patient-specific correction of certain mutations that affect tissue development. The approach would be to isolate iPS cells and utilize a method such as

targeting with zinc finger nucleases to correct the genetic defect at the DNA level [371–377]. The genetically repaired cells would then be directed to an appropriate lineage for cell therapy or tissue engineering, and implanted to effectively cure the patient's condition. Clearly, such personalized therapies would demand a trade-off between perfect histocompatibility matching *versus* elevated costs and regulatory complexities [378,379].

Reprogramming of mature somatic cells to a pluripotent state was accomplished initially by the forced expression of four transcription factors common to murine [35] and human ES cells: *OCT4* and *SOX2*, together with either *KLF4* and c-*MYC* [249] or *NANOG* and *LIN28* [250]. The resulting iPS cells closely resemble ES cells in key properties such as the capacity for extensive self-renewal, ability to differentiate to many (presumably all) cell lineages derived from each of the three embryonic germ layers, and generation of teratomas *in vivo*. Initial studies on reprogramming of fibroblasts soon were extended to a variety of cell types that can be obtained with minimal invasiveness from large groups of human donors, such as peripheral blood cells, cord blood cells, keratinocytes from hair shafts, fat-derived MSCs, and cells present in urine [380–390].

Numerous developments have advanced reprogramming technology towards safer, more efficient translation to therapeutic products. Improved methods to deliver the pluripotency factors minimize the risk of inadvertent permanent genetic modification of iPS cells, particularly integration of an oncogene such as c-*MYC*, and thereby decrease the potential for tumorigenicity [391]. One approach is to transiently deliver the factors using various non-integrating viral or plasmid vector systems [392–399]. Reprogramming also can be achieved by direct delivery of either synthetic mRNA encoding the pluripotency factors or of the protein factors themselves [400,401]. Already a next generation of reprogramming methods has emerged in which drug-like compounds substitute for some of the transcription factors [402–407]. Indeed, efficient generation of iPS cells can be achieved with the single transcription factor *OCT4* and a cocktail of small molecules [408–410]. Another new method utilizes microRNA miR-302, which appears to regulate chromatin demethylation and other factors involved in global reprogramming [411–413].

For eventual clinical application, it is essential that reprogramming to generate iPS cells be carried out under GMP-compliant conditions. This has been accomplished [388,414]. Further scale-up and cell differentiation to yield clinical grade cell therapy and tissue-engineered constructs from iPS cells raises the same essential manufacturing and regulatory issues as already discussed above for ES cells. Demonstration projects with cell types including neurons and retinal pigmented epithelial cells support the feasibility of using iPS cells as a potential source of clinical grade products [415–417].

Nevertheless, questions remain about whether iPS cells are entirely equivalent to ES cells in their genomic state and pattern of gene expression, and in their potential to yield a full range of differentiated cell types [418–420]. Critical issues that must be addressed for the future therapeutic application of iPS cells center on the epigenetic mechanisms underlying the resetting of pluripotency [407,418,421,422], and the extent to which subtle variations in the genome and epigenome, which might persist through or be induced by the reprogramming process, influence the properties of iPS cells and of the mature, specialized cells to which they give rise [423–429]. As production methods improve, it is possible that best practices will become standardized and that iPS cell lines intended for clinical use will routinely meet high standards of uniformity and quality. However, it is likely that the reprogramming process itself causes some degree of genomic and epigenomic instability. If so, then to assure performance and safety it may be necessary to subject every line intended for therapeutic use to stringent, deep analysis of DNA sequence and methylation patterns.

One practical outcome that may result from more complete understanding of the mechanics of reprogramming will be the identification of preferred cell types from which to generate iPS

cells. For example, the epigenetic and gene expression signatures of peripheral blood mononuclear cells more closely resemble those of pluripotent stem cells than do those of fibroblasts, so that blood cells may be preferred starting material for the production of clinical grade iPS cell lines [430].

Furthermore, factors may be identified that protect genomic stability during reprogramming. Zscan4, a zinc finger protein that is expressed selectively in 2-cell embryos at the time when zygotic gene activation occurs, appears to have this property. The addition of Zscan4 to the 'Yamanaka' set of transcription factors decreased the DNA damage response during reprogramming of mouse somatic cells, and improved the yield of pluripotent cells [431]. Most tellingly, iPS cell lines produced using Zscan4 were of higher quality than those obtained with the standard factor set alone, as judged by significantly enhanced ability to give rise to live-borne mice derived entirely from the reprogrammed cells in a tetraploid complementation assay.

Important correlates of consistency in the genomic and epigenomic (i.e., DNA methylation and chromatin organization) patterns of reprogrammed cells will be increased predictability in their differentiation to desired lineages, and decreased likelihood of abnormal behavior, including tumorigenicity. A particular risk associated with the inadvertent introduction of changes in genomic DNA during reprogramming could be the creation of abnormal proteins and/or patterns of gene expression that might induce immune responses. This would defeat the purpose of utilizing autologous iPS cells as a putatively non-immunogenic 'self' cell source for tissue engineering. Indeed, experiments on cell transplantation in inbred C57BL/6 mice showed that iPS cells can be unexpectedly immunogenic [432]. Whereas, as expected, ES cells derived from this strain efficiently formed teratomas in syngeneic hosts, iPS cell lines derived from the same strain either failed to form tumors or formed teratomas that became strongly infiltrated by host T lymphocytes. The report's authors attributed the immune rejection of iPS cells to overexpression of multiple genes, compared to levels in ES cells. However, more encouragingly, an independent study in the same mouse strain provided no evidence for immunogenicity of differentiated skin or bone marrow tissues derived from either ES or iPS cells when transplanted to the syngeneic hosts [433]. These results are consistent with a test of immunogenicity of bovine cells derived after reprogramming by somatic cell nuclear transfer (i.e., development of an embryo after insertion of the nucleus of an adult tissue cell into an enucleated, activated egg cell — also known as cloning). Engineered constructs of multiple tissue types from developing cows cloned by this method were implanted into the animals that had served as donors of the nuclei, and there was no evidence for immune rejection [434]. Thus, the use of reprogrammed cells as a histocompatible source for tissue engineering has been established clearly in principle, but it remains possible for genetic or epigenetic aberrations to trigger unanticipated immune responses. This reinforces the importance of finding general means to induce immunological tolerance to tissue-engineered constructs [362], even if these are generated using reprogrammed autologous cells [435].

Much recent excitement in the reprogramming field has centered efforts to bypass the circuitous route of resetting cells to a pluripotent ground state and then inducing them to a desired lineage. Instead, may it be possible to achieve directed 'transdifferentiation' between cell lineages? A number of laboratories have indeed reported that fibroblasts or other adult cells can be reprogrammed directly to various specialized cell types such as neurons and neural progenitors, cardiomyocytes, endothelial cells, and hepatocytes [436–447]. Significant questions about direct lineage-to-lineage reprogramming still must be addressed. Does it generate cells that accurately mimic authentic gene expression patterns and differentiated function of the desired product, or is there carryover of residual signatures of the starting cells? Do the cells display fully adult phenotypes, or, like differentiated ES and iPS cells, do they more closely resemble relatively immature embryonic cells? Is the risk of introducing unwanted genetic or epigenetic abnormalities less or greater than in reprogramming to a pluripotent state?

The answers to these questions will clarify the value of direct cell lineage conversions for tissue engineering and regenerative medicine.

ADULT STEM CELLS

Despite the promise of ES and iPS cells, and of directly reprogrammed cell types, the challenges of controlling lineage-specific differentiation, eliminating residual pluripotent stem cells, and confirming the safety and accurate phenotypes of cell products are likely to extend the timeline for a number of tissue-engineering applications. By contrast, adult stem cells present in many tissues throughout fetal development and postnatal life are committed to restricted cell lineages, and they are not intrinsically tumorigenic [448–451]. The adult stem cells, therefore, provide a starting point for more rapid clinical development of tissue-engineered, cell-based products.

Today, by far the most commonly utilized cells for experiments in tissue engineering are mesenchymal stromal or stem cells (MSC), often isolated from bone marrow [452]. As presciently hypothesized by Caplan, MSC can give rise to a number of tissue types, mainly connective, including bone, cartilage, tendon, adipose, and some categories of muscle [453]. Essentially the same cell type can be harvested readily from fat tissue obtained by processing of suction-assisted lipectomy (liposuction) specimens [454,455]. It now appears that MSC comprise a subset of pericytes associated with vasculature throughout the body [454,455,500]. MSC have generated considerable interest for musculoskeletal and vascular tissue engineering [456–458]. For example, a large European consortium named Genostem (an acronym for 'Adult mesenchymal stem cells engineering for connective tissue disorders. From the bench to the bed side') seeks to develop MSC/scaffold combinations for bone, cartilage and tendon repair [459].

A broader use for MSC in regenerative medicine, distinct from their use as precursors of specialized connective tissues, followed from the unexpected discovery that they can be transplanted readily into allogeneic recipients [460]. The ability to escape immune rejection results from a variety of mechanisms, most notably the secretion of anti-inflammatory cytokines [461,462]. These constitute a subset of a large array of trophic growth factors, cytokines, and other molecules that collectively endow MSC with potent immunomodulatory, wound healing, and regenerative properties [463–466]. Advanced clinical trials have assessed MSC cell therapy to treat Graft versus Host Disease (GvHD) and various inflammatory or autoimmune conditions [467–469]. The first approvals for sale of a bone marrow-derived MSC product (Prochymal®, Osiris Therapeutics) were obtained for treatment of GvHD in Canada and New Zealand, and similar products from academic and commercial entities are in late stages of development and, in some cases, regulatory review around the world [470].

Cell therapy aimed primarily at immunodulation arguably falls outside of a strict definition of tissue engineering. The mechanistic contributions of MSC to regenerative therapies easily can be confounded, because this population also may give rise to cells expressing markers associated with various non-mesodermal lineages, including hepatocytes (endoderm) and neurons (ectoderm). However, the observations supporting the apparently extensive plasticity of MSC must be interpreted with caution [471,472]. 'Differentiation' events may be relatively rare, and in many cases the detailed phenotype of the resulting end cells has not been compared rigorously with authentic specialized cells of the lineage in question.

Certain cells originating in a developing fetus and isolated from amniotic fluid or chorionic villi share some properties with adult MSC, but are capable of more extensive proliferation in clonal cultures [473]. These so-called amniotic fluid-derived stem (AFS) cells could represent more primitive precursors of MSC, but also express some markers in common with ES cells, so that their precise lineage and physiological plasticity is not certain. However, like MSC the AFS cells possess immunomodulatory properties that could contribute to clinical utility [474].

Advances in MSC cell therapy for heart disease may point to an effective future role for these cells in tissue engineering, beyond the constellation of connective tissues for which the cells are direct progenitors. The delivery of either autologous or allogeneic MSC into the left ventricle wall using a transendocardial injection device has given promising indications for efficacy in the treatment of ischemic cardiomyopathy in a large animal (minipig) model and initial human trials [475–477]. A principal explanation for the beneficial action of the injected MSC appears to be trophic effects on endogenous cardiac stem and progenitor cells that can give rise to new cardiomyocytes [478,479]. The MSC also apparently contribute to reverse remodeling of damaged areas of the heart, even at long times after the initial insults [477]. Recently published data demonstrate that the combined delivery of isolated adult cardiac stem cells and MSC substantially improves outcomes in the porcine model of ischemic cardiomyopathy, as judged by infarct size and cardiac function [480]. It seems plausible that tissue-engineered constructs incorporating both stem cell types will evolve from these studies.

The long history of hematopoietic stem cell transplantation established that long-lived donor cells could permanently colonize bone marrow niches and continuously replenish the full array of mature blood cell type [481,482]. However, to date there has been remarkably little clinical experience with any other therapy based on the engraftment of a defined stem cell population and its differentiation to specialized cells that persist and function in a particular organ. Several years ago Stem Cells Inc. initiated human studies of a brain-derived neural stem cell preparation called HuCNS-SC in a handful of subjects with neurological degenerative conditions, namely, neuronal lipoid fuscinosis (Batten's Disease) and Pelizaeus-Merzbacher Disease (PMD) [483]. The cells were isolated by selection with antibodies to cell surface markers. They expand extensively as suspension aggregates ('neurospheres') in a defined culture medium containing EGF and FGF [484]. The clinical experiments provided preliminary evidence for safety of these stem cells [485]. MRI data demonstrated durable cell engraftment and suggested that donor-derived cells contributed to myelination in recipient brain. Compelling evidence for myelination was observed by transplantation of the human stem cells in mutant mice with a severe dysmyelination disorder [486]. Stem Cells Inc. recently began further clinical trials of the same neural stem cell product in subjects with spinal cord injury and dry age-related macular degeneration.

Another human adult stem cell population that gives rise to organ parenchymal cells was isolated from the liver [487]. These hepatic stem cells (HpSC) were enriched from cadaveric fetal, neonatal, or fully mature donors by selection with a monoclonal antibody to the surface marker CD326 (epithelial cell adhesion molecular, EpCAM), which constitute roughly 1 percent of cells in suspensions prepared from young or old postnatal livers. They can be maintained for more than 40 population doublings, corresponding to a potential expansion of one trillion-fold (1×10^{12}), with a doubling time of 36 to 40 hours, in a defined serum-free culture medium containing insulin and transferrin, but lacking classical growth factors [488,489]. If cultured as adherent cells on tissue culture plastic, the HpSC grow in cooperation with immature mesenchymal cells (e.g., angioblasts) that may provide elements of their normal stem cell niche [487,490,491]. Appropriate ECM molecules thought to be associated with that niche, type III collagen and/or weakly crosslinked hyaluronic acid hydrogels of appropriate mechanical stiffness, can replace the need for mesenchymal cells to assist the expansion of the stem cells [491–494]). Exposure to certain growth factors, for example EGF, and different collagens and tissue-specific matrix molecules (e.g., liver proteoglycans) induces efficient differentiation of the HpSC to either hepatocytes or cholangiocytes (bile duct cells) [53].

C.M. Habibullah and associates in Hyderabad, India initiated clinical assessment of CD326-positive hepatic stem and progenitor cells, selected from human fetal liver and used without expansion of the cell population in culture [495,496]. They found that delivery of these cells to the liver was best achieved by infusion via the hepatic artery. In a published report on

25 subjects with decompensated liver cirrhosis from various causes, at 6 months post-infusion improvements were observed in a number of objective clinical parameters, including a significant decrease in the mean Mayo End-stage Liver Disease (MELD) score ($P < .01$) [495]. It appeared important to identify patients whose initial status was not terminal, presumably to allow sufficient time (several weeks) for stem cells to differentiate to hepatocytes. Imaging studies with radiolabeled stem cells demonstrated retention of a significant fraction of the delivered cells in the liver, although, not surprisingly, a majority traveled through the circulation to distant sites such as the lung. The data were consistent with, but did not prove, differentiation of the stem cells to more mature parenchymal cells. Data from a subsequent clinical trial in over 250 subjects have not yet been published in the peer-reviewed literature. However, the results apparently were consistent with those reported for the initial clinical study, and have been submitted for regulatory review in India to support product approval.

Most remarkably, the encouraging clinical results with HpSC transplantation were achieved using allogeneic donors with no effort to match at HLA loci, and without the use of immune suppressive drugs. It is conceivable that the fetal liver-derived stem cells are particularly non-immunogenic; indeed, HpSC, like ES cells, express only low levels of MHC Class I and lack detectable MHC Class II [487]. Furthermore, it is possible that the liver is significantly immune privileged with respect to transplant rejection. Another possibility is that when HpSC are isolated by immunoselection with magnetic antibody-coated beads specific for CD326, some angioblast-like mesenchymal cells remain associated with them. Such cells, like MSC, might secrete immunomodulatory factors that could protect the HpSC and differentiated cells derived from them against immune rejection.

Future clinical trials based on HpSC may transition to cells sourced from neonatal livers obtained through organ donation. This would be facilitated by the relatively long survival of hepatic stem and progenitor cells under ischemic conditions, and the development of cryopreservation conditions for these cells [496,497]. Tissue engineering would appear a superior long-term option over simple cell therapy. One possible approach would utilize HpSC, probably in combination with endothelial progenitors such as the liver-derived angioblasts, to reconstitute whole-organ decellularized scaffolds [52,53]. A simpler strategy, more likely to be feasible in the near term, would be to deliver the HpSC in hyaluronan hydrogels, thereby minimizing escape of the cells to ectopic locations and encouraging local tissue development from cell aggregates confined in the matrix [498]. The addition of liver-specific matrix components and/or growth factors to the hydrogels might promote more rapid, robust differentiation to hepatocytes [53].

A newly discovered human stem cell population may prove to be a more readily isolated source for liver tissue engineering. Excitingly, these stem cells also offer hope for engineering of pancreatic islet-like structures to treat insulin-dependent diabetes. The cells were identified in peribiliary glands found in the extrahepatic biliary tree, ramifying ducts located between the liver and pancreas [499]. Analysis of cell surface marker and transcription factor expression *in situ*, along with the growth and differentiation potential of the cells, suggests that they include a population of more primitive endodermal stem cells than the HpSC identified within the liver. Some of these biliary tree stem cells do not express CD326, but appear to be precursors of the CD326-positive HpSC. Remarkably, these cells express detectable levels of transcription factors characteristic of both hepatic and pancreatic lineages; among the key pancreatic markers are *PDX1* and *NGN3*. A working hypothesis is that these stem cells serve as a potential source for cell turnover in both the liver and pancreas (at least the endocrine portion; their potential to differentiate to pancreatic exocrine cells has not yet been tested) throughout life.

The biliary tree stem cells proliferate extensively when cultured in the serum-free defined medium developed for HpSC. They could be induced to differentiate to either cholangiocytes or hepatocytes under conditions previously worked out for differentiation of HpSC. However, when exposed to soluble factors known to induce differentiation of pancreatic progenitors

to endocrine cells, and to ECM extracted from pancreatic islets of Langerhans, the stem cells gave rise to islet-like structures with cells expressing characteristic pancreatic hormones, most notably pro-insulin. Release of insulin was responsive to extracellular glucose.

In vivo studies supported the hypothesis that human biliary tree stem cells are multipotent for liver and pancreas lineages. Upon intrahepatic injection in immune-deficient mice, the stem cells gave rise to hepatocyte-like and cholangiocyte-like progeny. To assess endocrine pancreatic differentiation, islet-like structures were induced in culture and implanted into mouse fat pads. After several weeks the animals were treated with streptozotocin (STZ) at a concentration expect to destroy murine pancreatic β cells, but spare human ones, which are more resistant to the toxin. After the STZ treatment the mice that had received transplanted human islet-like clusters indeed became significantly less hyperglycemic than controls that had not received cell therapy. The presence of functional β-like cells derived from the biliary tree stem cells was supported by detection of human C-peptide in the circulation, and its level was regulated correctly in response to a glucose challenge [499]. Thus, it appears that biliary tree stem cells, which could be harvested from tissue frequently discarded after certain surgical procedures and should also be accessible by laparoscopy, represent a potential cell source for tissue engineering of islet-like structures for diabetes therapy.

Future challenges

The medical application of tissue engineering still lies largely ahead of us. Although a handful of products have achieved regulatory approval and entered the marketplace, many more are in the planning or proof-of-concept stage, or in relatively early clinical trials. In order to reach the large number of patients who might potentially benefit from bioengineered therapeutics, advances will be required in manufacturing and distributing complex products. This will be a fruitful area for engineers to address.

It also will be critical to develop closer partnerships among academic and industrial scientists and the regulatory agencies (e.g., the US FDA) that must assess new therapies for safety and efficacy. Products that may contain novel cellular components, biomaterials, and active growth or angiogenic factors will demand sophisticated, multifaceted review. Historically, regulatory agencies have had far greater experience with single drug entities or devices than with combination products. However, there is reason for optimism that the FDA's experiences to date with successful applications and early trials of products derived from both adult and embryonic human stem cells will pave the way to effective review of future bioengineered products.

CHAPTER 7

Molecular Biology of the Cell

J.M.W. Slack
Stem Cell Institute, University of Minnesota, Minneapolis, Minnesota

To a naïve observer the term 'tissue engineering' might seem a contradiction in terms. The word 'engineering' tends to conjure up a vision of making objects from hard components such as metals, plastics, concrete or silicon, which are mechanically robust and will withstand a range of environmental conditions. The components themselves are often relatively simple, and the complexity of a system emerges from the number and connectivity of the parts. By contrast, the cells of living organisms are themselves highly delicate and highly complex. Despite our knowledge of a vast amount of molecular biology detail concerning cell structure and function, their properties are still understood only in qualitative terms and so any application using cells requires a lot of craft skill as well as rational design. What follows is a very brief account of cell properties, intended for newcomers to tissue engineering who have an engineering or physical science background. It is intended to alert readers to some of the issues involved in working with cells, and to pave the way for an understanding of how cells form tissues and organs, topics dealt with in more detail in the later chapters. As it comprises very general material, it is not specifically referenced, although some further reading is provided at the end.

Cells are the basic building blocks of living organisms in the sense that they can survive in isolation. Some organisms, such as bacteria, protozoa or many algae, actually consist of single free living cells. But most cells are constituents of multicellular organisms, and although they can survive in isolation they need very carefully controlled conditions in order to do so. A typical animal cell suspended in liquid will be a sphere of the order of about 20 microns diameter (Fig. 7.1). Most cells will not grow well in suspension, and so they are usually grown attached to a substrate, where they flatten and may be quite large in horizontal dimensions but only a few microns in vertical dimension. All eukaryotic cells contain a nucleus in which is located the genetic material that ultimately controls everything that the cell is composed of and all the activities it carries out. This is surrounded by cytoplasm, which has a very complex structure and contains sub-structures called organelles which are devoted to specific biochemical functions. The outer surface of the cell is the plasma membrane, which is of crucial importance as it forms the frontier across which all materials must pass on their way in or out. The complexity of a single cell is awesome since it will contain thousands of different types of protein molecules, arranged in many very complex multimolecular aggregates comprising both hydrophobic and aqueous phases; and also many thousands of low molecular weight metabolites, including sugars, amino acids, nucleotides, fatty acids, phospholipids and many others. Although some individual steps of metabolism may be near to thermodynamic equilibrium, the cell as a whole is very far from equilibrium and is maintained in this condition by a continuous interchange of substances with the environment. Nutrients

are chemically transformed with release of energy which is used to maintain the structure of the cell and to synthesize the tens of thousands of different macromolecules on which its continued existence depends. Maintaining cells in a healthy state means providing them continuously with all the substances they need, in the right overall environment of substrate, temperature and osmolarity; and also continuously removing all potentially toxic waste products.

THE CELL NUCLEUS

The nucleus contains the genes that control the life of the cell. A gene is a sequence of DNA that codes for a protein, or for a non-translated RNA, and it is usually considered also to include the associated regulatory sequences as well as the coding region itself. The vast majority of eukaryotic genes are located in the nuclear chromosomes, although there are also a few genes carried in the DNA of mitochondria and chloroplasts. The genes encoding non-translated RNAs include those for ribosomal or transfer RNAs, and also for a large number of microRNAs that are probably involved in controlling the expression of protein coding genes. The total number of protein coding genes in vertebrate animals is about 25,000, and every nucleus contains all the genes, irreversible DNA modifications being confined to B and T cells of the immune system in respect of the genes encoding antibodies and T cell receptors.

The DNA is complexed into a higher order structure called chromatin by the binding of basic proteins called histones. Protein coding genes are transcribed into messenger RNA (mRNA) by the enzyme RNA polymerase II. Transcription commences at a transcription start sequence and finishes at a transcription termination sequence. Genes are usually divided into several exons, each of which codes for a part of the mature mRNA. The primary RNA transcript is extensively processed before it moves from the nucleus to the cytoplasm. It acquires a 'cap' of methyl guanosine at the 5' end, and a polyA tail at the 3' end, both of which stabilize the message by protecting it from attack by exonucleases. The DNA sequences in between the exons are called introns and the portions of the initial transcript complementary to the introns

are removed by splicing reactions catalyzed by 'snRNPs' (small nuclear ribonucleoprotein particles). It is possible for the same gene to produce several different mRNAs as a result of alternative splicing; whereby different combinations of exons are spliced together from the primary transcript. In the cytoplasm, the mature mRNA is translated into a polypeptide by the ribosomes. The mRNA still contains a 5′ leader sequence and a 3′ untranslated sequence flanking the protein coding region, and these untranslated regions may contain specific sequences responsible for translational control or intracellular localization.

Control of gene expression

There are many genes whose products are required in all tissues at all times; for example those concerned with basic cell structure, protein synthesis or metabolism. These are referred to as 'housekeeping' genes. But there are many others whose products are specific to particular cell types and indeed the various cell types differ from each other *because* they contain different repertoires of proteins. This means that the control of gene expression is central to tissue engineering. Control may be exerted at several points. Most common is control of transcription, and we often speak of genes being 'on' or 'off' in particular situations, meaning that they are or are not being transcribed. There are also many examples of translational regulation, where the mRNA exists in the cytoplasm but is not translated into protein until some condition is satisfied. Control may also be exerted at the stage of nuclear RNA processing, or indirectly via the stability of individual mRNAs or proteins.

Control of transcription depends on regulatory sequences within the DNA, and on proteins called transcription factors that interact with these sequences. The promoter region of a gene is the region to which the RNA polymerase binds, just upstream from the transcription start site. The RNA polymerase is accompanied by a set of general transcription factors, which together make up a transcription complex. In addition to the general factors required for the assembly of the complex, there are numerous specific transcription factors that bind to specific regulatory sequences that may be either adjacent to or at some distance from the promoter (Fig. 7.2). These are responsible for controlling the differences in gene expression between different types of cell.

TRANSCRIPTION FACTORS

Transcription factors are the proteins that regulate transcription. They usually contain a DNA-binding domain and a regulatory domain, which will either upregulate or repress transcription. Looping of the DNA may bring these regulatory domains into contact with the transcription complex with resulting promotion or inhibition of transcription. There are many families of transcription factors, classified by the type of DNA-binding domain they contain, such as the homeodomain or zinc-finger domain. Most are nuclear proteins, although some exist in the cytoplasm until they are activated and then enter the nucleus. Activation often occurs in response to intercellular signaling (see below). One type of transcription factor, the nuclear receptor family, is directly activated by lipid-soluble signaling molecules such as retinoic acid or glucocorticoids.

Each type of DNA-binding domain in a protein has a corresponding type of target sequence in the DNA, usually 20 nucleotides or less. The activation domains of transcription factors often contain many acidic amino acids making up an 'acid blob', which accelerates the formation of the general transcription complex. Some transcription factors recruit histone acetylases which open up the chromatin by neutralizing amino groups on the histones by acetylation, and allow access of other proteins to the DNA. Although it is normal to classify transcription factors as activators or repressors of transcription, their action is also sensitive to context, and the presence of other factors may on occasion cause an activator to function as a repressor, or vice versa.

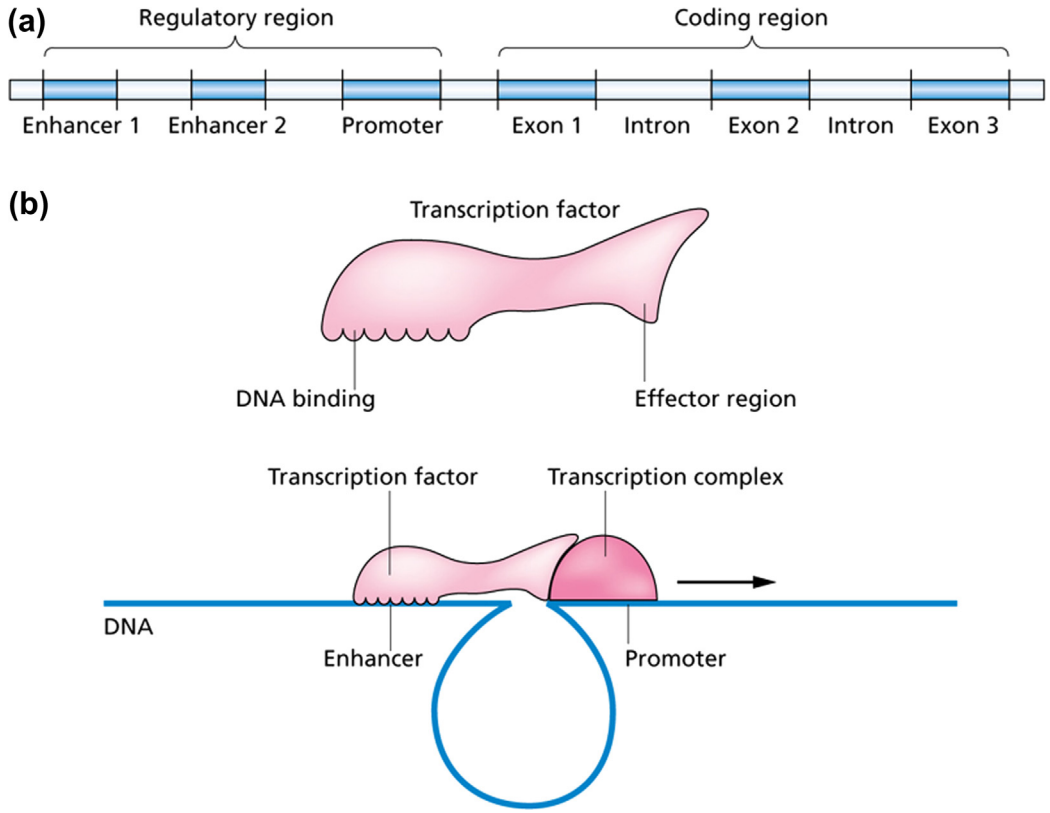

FIGURE 7.2
a) Structure of a typical gene. b) Operation of a transcription factor. *(From Slack 2012).*

OTHER CONTROLS OF GENE ACTIVITY

Some aspects of gene control are of a more stable and longer term character than that exerted by combinations of positive and negative transcription factors. To some extent this depends on the remodeling of the chromatin structure, which is still poorly understood. The chromosomal DNA is complexed with histones into nucleosomes and is coiled into a 30 nm diameter filament, which is in turn arranged into higher order structures. In much of the genome the nucleosomes are to some extent mobile, allowing access of transcription factors to the DNA. This type of chromatin is called euchromatin. In other regions the chromatin is highly condensed and inactive, then being called heterochromatin. In the extreme case of the nucleated red blood cells of non-mammalian vertebrates the entire genome is heterochromatic and inactive. Chromatin structure is regulated to some degree by protein complexes (such as the well known Polycomb and trithorax groups), which affect the expression of many genes but are not themselves transcription factors.

An important element of the chromatin remodeling is the control through acetylation of lysines on the exposed N-termini of histones. This partially neutralizes the binding of the histones to the negatively charged phosphodiester chains of DNA, so opens up the chromatin structure and enables transcription complexes to assemble on the DNA. The degree of histone acetylation is controlled, at least partly, by DNA methylation, because histone deacetylases are recruited to methylated regions and will tend to inhibit gene activity in these regions. DNA methylation occurs on cytosine residues in CG sequences of DNA. Because CG on one strand will pair with GC on the other, antiparallel, strand, potential methylation sites always lie opposite one another on the two strands. There are several DNA methyl transferase enzymes, including *de novo* methylases that methylate previously unmethylated CGs, and maintenance methylases that methylate the other CG of sites bearing a methyl group on only one strand.

Once a site is methylated, it will be preserved through subsequent rounds of DNA replication, because the hemimethylated site resulting from replication will be a substrate for the maintenance methylase.

There are many other chemical modifications of the histones in addition to acetylation, including methylation of sites within the histone polypeptides. It is probable that these modifications can also be retained on chromosomes when the DNA is replicated. So both DNA methylation and histone modifications provide means for maintaining the state of activity of genes in differentiated cells even after the original signals for activation or repression have disappeared.

THE CYTOPLASM

The cytoplasm consists partly of proteins in free solution, although it also possesses a good deal of structure that can be visualized as the cytoskeleton (see below). Generally considered to be in free solution, although probably in macromolecular aggregates, are the enzymes that carry out the central metabolic pathways. In particular the pathway called glycolysis leads to the degradation of glucose to pyruvate. Glucose is an important metabolic fuel for most cells. Mammalian blood glucose is tightly regulated at around 5–6 mM, and glucose is a component of most tissue culture media. Glycolysis leads to the production of two molecules of adenosine triphosphate (ATP) per molecule of glucose, with a further 36 molecules of ATP produced by oxidative phosphorylation, and this ATP is needed for a very wide variety of synthetic and biochemical maintenance activities. Apart from the central metabolic pathways, the cell is also engaged in the continuous synthesis and degradation of a wide variety of lipids, amino acids and nucleotides.

The cytoplasm contains many types of organelle which are structures composed of phospholipid bilayers. Phospholipids are molecules with a polar head group and a hydrophobic tail. They tend to aggregate to form sheets in which all the head groups are exposed on the surface and the hydrophobic tails associate with each other to form a hydrophobic phase. Most cell organelles are composed of membranes comprising two sheets of phospholipid molecules with their hydrophobic faces joined. The mitochondria are the organelles responsible for oxidative metabolism, as well as other metabolic processes such as the synthesis of urea. They are composed of an outer and an inner phospholipid bilayer. The oxidative degradation of sugars, amino acids and fatty acids is accompanied by the production of ATP. Pyruvate produced by glycolysis is converted to acetyl CoA, and this is oxidized to two molecules of CO_2 by the citric acid cycle, with associated production of 12 molecules of ATP in the electron transport chain of the mitochondria. Because of the importance of oxidative metabolism for ATP generation, cells need oxygen to support themselves. Tissue culture cells are usually grown in atmospheric oxygen concentration (about 20% by volume), although the optimum concentration may be somewhat lower than this since the oxygen level within an animal body is normally lower than the external atmosphere. Too much oxygen can be deleterious, because it leads to the formation of free radicals that cause damage to cells. Tissue culture systems are therefore often run at lower oxygen levels, such as 5%. The oxidation of pyruvate and acetyl CoA also results in the production of CO_2 which needs to be removed continuously to avoid acidification of the culture medium.

Among the organelles in the cytoplasm is the endoplasmic reticulum, which is a ramifying system of phospholipid membranes. The interior of the endoplasmic reticulum can communicate with the exterior medium through the exchange of membrane vesicles with the plasma membrane. Proteins that are secreted from cells, or that come to lie within the plasma membrane, are synthesized by ribosomes that lie on the cytoplasmic surface of the endoplasmic reticulum, and the products are passed through pores into the endoplasmic reticulum lumen. From here they move to the Golgi apparatus, which is another collection of internal membranes, in which carbohydrate chains are added. From there they move to the cell

surface or the exterior medium. Secretion of materials is a very important function of all cells and it needs to be remembered that their environment in tissue culture depends not only on the composition of the medium that is provided but also on what the cells themselves have been making and secreting.

The intracellular proteins are synthesized by ribosomes in the soluble cytoplasm. There is a continuous production of new protein molecules, the composition depending on the repertoire of gene expression of the cell. There is also a continuous degradation of old protein molecules, mostly in a specialized structure called the proteasome. This continuous turnover of protein requires a lot of ATP.

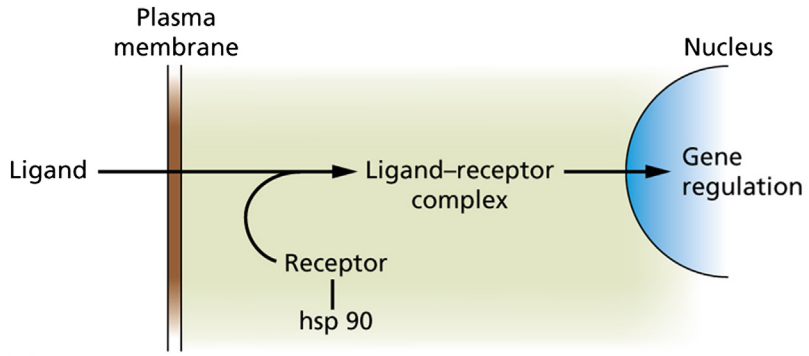
The cell surface

The plasma membrane is the frontier between the cell and its surroundings. It is a phospholipid bilayer incorporating many specialized proteins. Very few substances are able to enter and leave cells by simple diffusion; in fact this method is really only available to low molecular weight hydrophobic molecules like retinoic acid, steroids or thyroid hormones. The movement of inorganic ions across the membrane is very tightly controlled. The main control is exerted by a sodium-potassium exchanger known as the Na^+K^+ATPase, which expels sodium (Na) and imports potassium (K) ions. Because three sodium ions are expelled for every two potassium ions imported, this process generates an electric potential difference across the membrane, which is intensified by differential back diffusion of the ions. The final membrane potential is negative inside the cell and ranges from about 10 mV in red blood cells to about 70 mV in excitable cells such as neurons. This maintenance of membrane potential by the Na^+K^+ATPase accounts for a high fraction of total cellular ATP consumption. Calcium (Ca) ions are very biologically active within the cell and are normally kept at a very low intracellular concentration, about 10^{-7}M. This is about 10^4 times lower than the typical exterior concentration, which means that any damage to the plasma membrane is likely to let in a large amount of calcium which will damage the cell beyond repair.

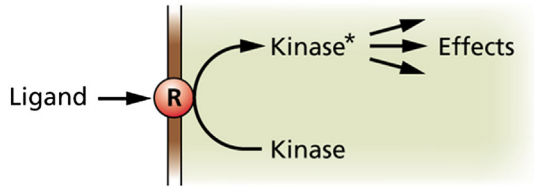
Some proteins of the plasma membrane are very hydrophobic molecules entirely contained within the lipid phase, but more usually they have hydrophilic regions projecting to the cell exterior or to the interior cytoplasm or both. These proteins have a huge range of essential functions. Some are responsible for anchoring cells to the substrate or to other cells through adhesion molecules and junctional complexes. Others, including ion transporters and carriers for a large range of nutrients, are responsible for transporting molecules across the plasma membrane. Then there are the receptors for extracellular signaling molecules (hormones, neurotransmitters and growth factors) which are critical for controlling cellular properties and behavior. Some types of receptor serve as ion channels, for example admitting a small amount of calcium when stimulated by their specific ligand. Other types of receptor are enzymes and initiate a metabolic cascade of intracellular reactions when stimulated. These reaction pathways often involve protein phosphorylation and frequently result in the activation of a transcription factor and thereby the activation of specific target genes. The repertoire of responses that a cell can show depends on which receptors it possesses, how these are coupled to signal transduction pathways, and how these pathways are coupled to gene regulation. It is sometimes called the 'competence' of the cell. The serum that is usually included in tissue culture media contains a wide range of hormones and growth factors and is itself likely to stimulate many of the cell surface receptors.

SIGNAL TRANSDUCTION

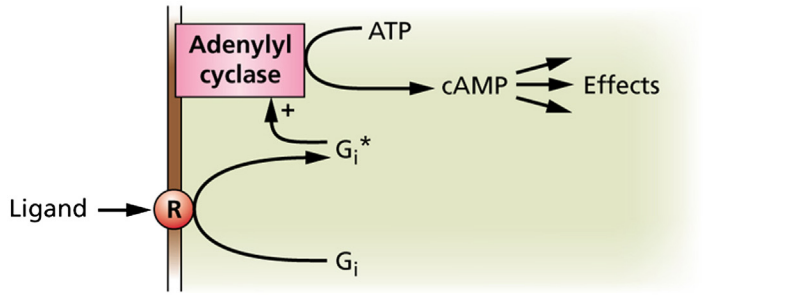
Lipid soluble molecules such as steroid hormones can enter cells by simple diffusion. Their receptors, called nuclear hormone receptors, are multidomain molecules that also function as transcription factors. Binding of the ligand activates the factor, in many cases also causing translocation to the nucleus where the receptor-ligand complex can upregulate its target genes (Fig. 7.3a).

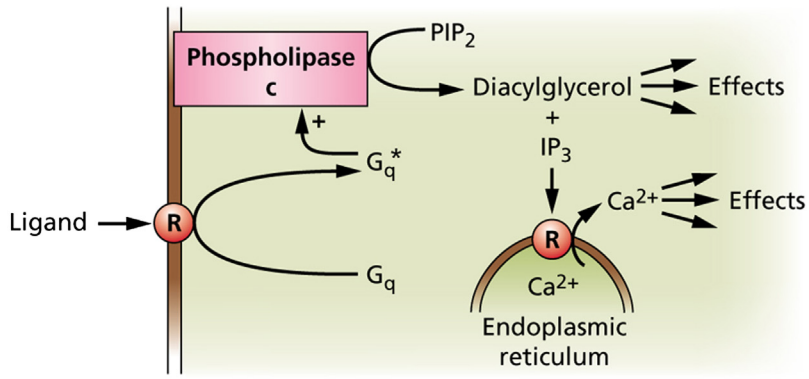


(a) Nuclear receptor

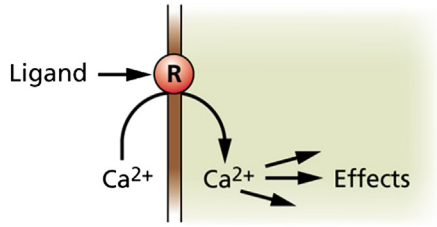


(b) Enzyme–linked receptor





(c) G protein–linked receptors



(d) Ion channel receptor

FIGURE 7.3
Different types of signal transduction. *(From Slack 2012).*

Most signaling molecules are proteins which cannot diffuse across the plasma membrane and so work by binding to specific cell surface receptors. There are three main classes of these: enzyme-linked receptors, Gprotein-linked receptors and ion channel receptors.

Enzyme-linked receptors are often tyrosine kinases or Ser/Thr kinases (Fig. 7.3b). All have a ligand-binding domain on the exterior of the cell, a single transmembrane domain, and the enzyme active site on the cytoplasmic domain. For receptor tyrosine kinases, the ligand-binding brings about dimerization of the receptor, and this results in an autophosphorylation whereby each receptor molecule phosphorylates and activates the other. The phosphorylated receptors can then activate a variety of targets. Many of these are transcription factors that are activated by phosphorylation and move to the nucleus where they upregulate their target genes. In other cases there is a cascade of kinases that activate each other down the chain, culminating in the activation of a transcription factor. Roughly speaking, each class of factors has its own associated receptors and a specific signal transduction pathway; however, different receptors may be linked to the same signal transduction pathway, or one receptor may feed into more than one pathway. The effect of one pathway upon the others is often called 'cross talk'. The significance of cross talk can be hard to assess from biochemical analysis alone, but is easier using genetic experiments in which individual components are mutated to inactivity and the overall effect on the cellular behavior can be assessed.

There are several classes of Gprotein-linked receptor (Fig. 7.3c). The best known are seven-pass membrane proteins, meaning that they are composed of a single polypeptide chain crossing the membrane seven times. These are associated with trimeric G proteins composed of α, β and γ subunits. When the ligand binds, the activated receptor causes exchange of guanosine diphosphate (GDP) bound to the α subunit for guanosine triphosphate (GTP), then the activated α subunit is released and can interact with other membrane components. The most common target is adenylyl cyclase, which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). cAMP activates protein kinase A (PKA) which phosphorylates various further target molecules affecting both intracellular metabolism and gene expression.

Another large group of Gprotein-linked receptors use a different trimeric G protein to activate the inositol phospholipid pathway (Fig. 7.3c). Here the G protein activates phospholipase Cβ which breaks down phosphatidylinositol bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol trisphosphate (IP_3). The DAG activates an important membrane-bound kinase, protein kinase C. Like protein kinase A, this has a large variety of possible targets in different contexts and can cause both metabolic responses and changes in gene expression. The IP_3 binds to an IP_3 receptor (IP_3R) in the endoplasmic reticulum and opens Ca channels which admit Ca ions into the cytoplasm. Normally cytoplasmic calcium is kept at a very low concentration of around 10^{-7}M. An increase caused either by opening of an ion channel in the plasma membrane, or as a result of IP_3 action, can have a wide range of effects on diverse target molecules.

Ion channel receptors (Fig. 7.3d) are also very important. They open on stimulation to allow passage of Na, K, Cl (chloride) or Ca ions. As mentioned above, Na and K ions are critical to the electrical excitability of nerve or muscle, and Ca ions are very potent, having a variety of effects on cell structure and function at low concentration.

GROWTH AND DEATH

Tissue engineering inevitably involves the growth of cells in culture, so the essentials of cell multiplication need to be understood. A typical animal cell cycle is shown in Fig. 7.4 and some typical patterns of cell division in Fig. 7.5. The cell cycle is conventionally described as consisting of four phases. M indicates the phase of mitosis, S indicates the phase of DNA replication, and G1 and G2 are the intervening phases. For growing cells, the increase in mass

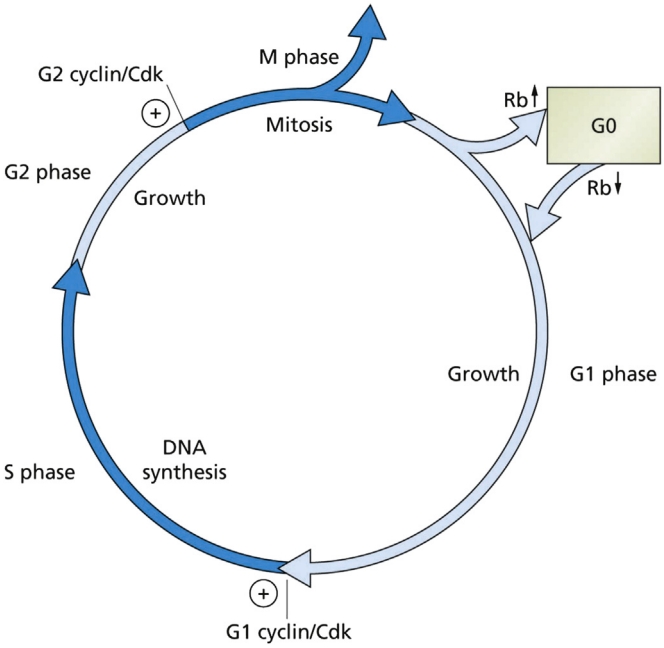


FIGURE 7.4
The cell cycle, with phases of growth, DNA replication and division. *(From Slack 2012).*

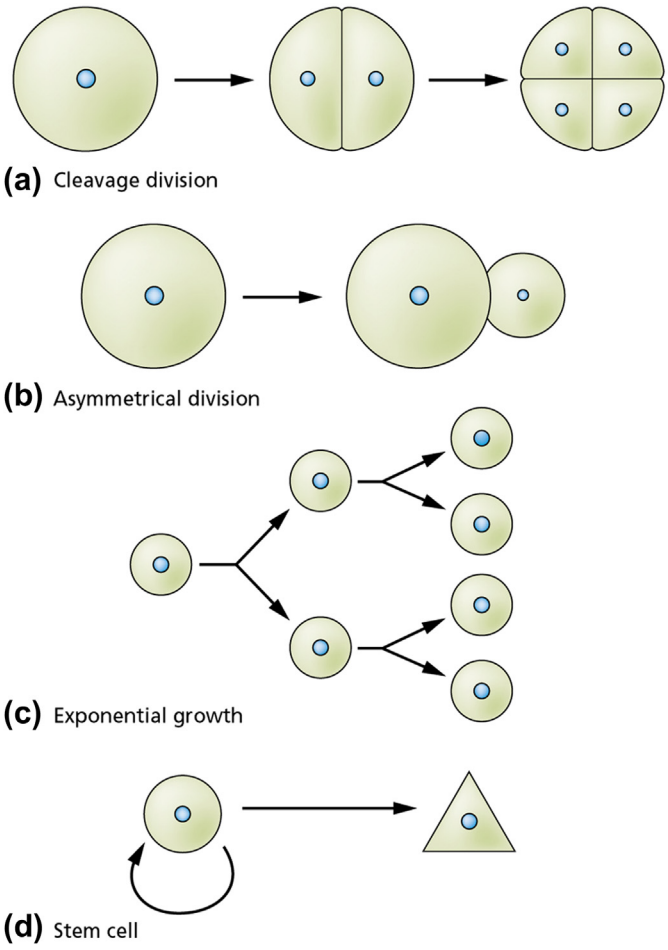

FIGURE 7.5
Types of cell division. a) Cleavage as found in early embryos. b) Asymmetrical division also found in some early embryos. c) Exponential growth found in tissue culture. d) Stem cell division found in renewal tissues in animals. *(From Slack 2012).*

is continuous around the cycle and so is the synthesis of most of the cell's proteins. Normally the cell cycle is coordinated with the growth of mass. If it were not, cells would increase or decrease in size with each division. There are various internal controls built into the cycle, for example to ensure that mitosis does not start before DNA replication is completed. These controls operate at checkpoints around the cycle at which the process stops unless the appropriate conditions are fulfilled.

Control of the cell cycle depends on a metabolic oscillator comprising a number of proteins called cyclins and a number of cyclin-dependent protein kinases (Cdks). In order to pass the M checkpoint and enter mitosis, a complex of cyclin and Cdk (called M-phase promoting factor, MPF) has to be activated. This phosphorylates and thereby activates the various components required for mitosis (nuclear breakdown, spindle formation, chromosome condensation). Exit from M phase requires the inactivation of MPF, via the destruction of cyclin. Passage of the G1 checkpoint depends on a similar process operated by a different set of cyclins and Cdks, whose active complexes phosphorylate and activate the enzymes of DNA replication. This is also the point at which the cell size is assessed.

The cell cycle of G1, S, G2 and M phases is universal although there are some modifications in special circumstances. The rapid cleavage cycles of early development have short or absent G1 and G2 phases and there is no size check, the cells halving in volume with each division. The meiotic cycles require the same active MPF complex to get through the two nuclear divisions, but there is no S phase in between.

In the mature organism most cells are quiescent unless they are stimulated by growth factors. In the absence of growth factors cells enter a state called G0, in which the Cdks and cyclins are absent. Restitution of growth factors induces the resynthesis of these proteins and the resumption of the cycle starting from the G1 checkpoint. One factor maintaining the G0 state is a protein called Rb (retinoblastoma protein). This becomes phosphorylated, and hence deactivated, in the presence of growth factors. In the absence of Rb, a transcription factor called E2F becomes active and initiates a cascade of gene expression culminating in the resynthesis of cyclins, Cdks and other components needed to initiate S phase.

Cells often have the capability for exponential growth in tissue culture (Fig. 7.5c) but this is very rarely found in animals. Although some differentiated cell types can go on dividing, there is a general tendency for differentiation to be accompanied by a slow down or cessation of division. In postembryonic life most cell division is found among stem cells and their immediate progeny called transit amplifying cells. Stem cells are cells that can both reproduce themselves and generate differentiated progeny for their particular tissue type (Fig. 7.5d). This does not necessarily mean that every division of a stem cell has to be an asymmetrical one, but over a period of time half the progeny will go to renewal and half to differentiation. The term 'stem cell' is also used for embryonic stem cells (ES cells) of early mammalian embryos. These are early embryo-type cells that can be grown in culture and are capable of repopulating embryos and contributing to all tissue types.

Asymmetric cell divisions necessarily involve the segregation of different cytoplasmic determinants to the two daughter cells, evoking different patterns of gene activity in their nuclei and thus bringing about different pathways of development. The asymmetry often arises from auto-segregation of a self-organizing protein complex called the PAR (partitioning defective) complex.

CYTOSKELETON

The cytoskeleton is important for three distinct reasons. Firstly, the orientation of cell division may be important. Secondly, animal cells move around a lot, either as individuals or as part of moving cell sheets. Thirdly, the shape of cells is an essential part of their ability to carry out their functions. All of these activities are functions of the cytoskeleton.

The main components of the cytoskeleton are microfilaments, microtubules and intermediate filaments. Microtubules and microfilaments are universal constituents of eukaryotic cells, while intermediate filaments are found only in animals. Microfilaments are made of actin, microtubule of tubulin, and intermediate filaments are composed of different proteins in different cell types: cytokeratins in epithelial cells, vimentin in mesenchymal cells, neurofilament proteins in neurons, and glial fibrilliary acidic protein (GFAP) in glial cells.

Microtubules

Microtubules (Fig. 7.6) are hollow tubes of 25 nm diameter composed of tubulin. Tubulin is a generic name for a family of globular proteins which exist in solution as heterodimers of α- and β-type subunits and is one of the more abundant cytoplasmic proteins. The microtubules are polarized structures with a minus end anchored to the centrosome and a free plus end at which tubulin monomers are added or removed. Microtubules are not contractile but exert their effects through length changes based on polymerization and depolymerization. They are very dynamic, either growing by addition of tubulin monomers, or retracting by loss of monomers, and individual tubules can grow and shrink over a few minutes. The monomers contain GTP bound to the β subunit and in a growing plus end this stabilizes the tubule. But if the rate of growth slows down, hydrolysis of GTP to GDP will catch up with the addition of monomers. The conversion of bound GTP to GDP renders the plus end of the tubule unstable and it will then start to depolymerize. The drugs colchicine and colcemid bind to monomeric tubulin and prevent polymerization and among other effects this causes the disassembly of the mitotic spindle. Because these drugs cause cells to become arrested in mitosis they are often used in studies of cell division kinetics.

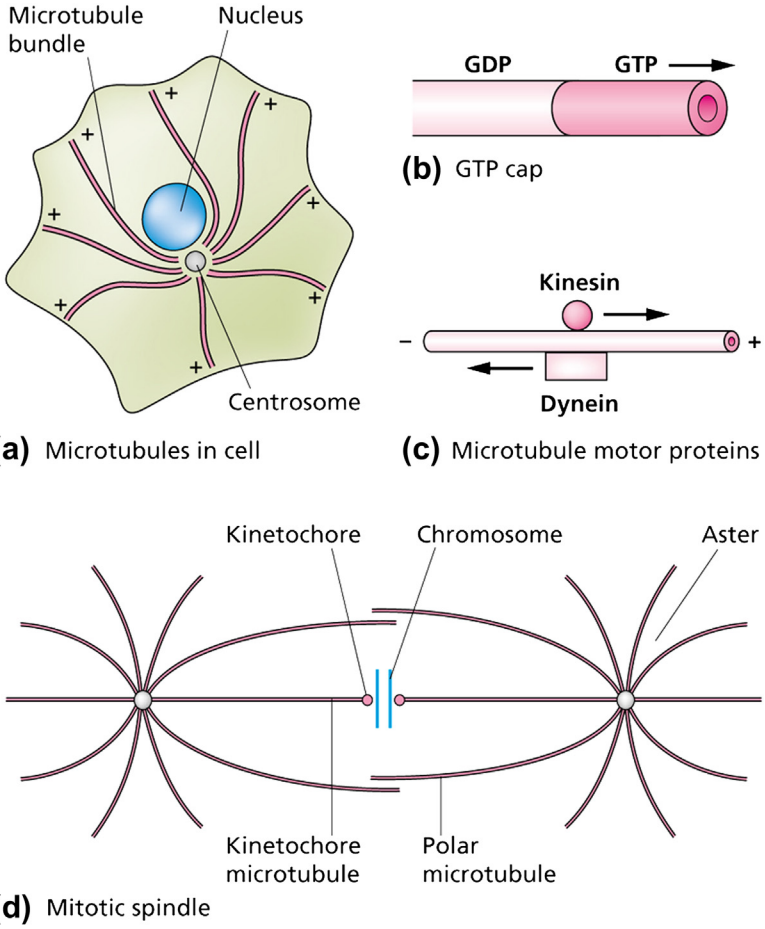

FIGURE 7.6
Microtubules. a) Arrangement in cell. b) The GTP cap. c) Motor proteins move along the tubules. d) Structure of the cell division spindle. *(From Slack 2012).*

The shape and polarity of cells can be controlled by locating capping proteins to particular parts of the cell cortex which bind the free plus ends of the microtubules and stabilize them. The positioning of structures within the cell also depends largely on microtubules. There exist special motor proteins that can move along the tubules, powered by hydrolysis of ATP, and thereby transport other molecules to particular locations within the cell. The kinesins move towards the plus ends of the tubules while the dyneins move towards the minus ends.

Microtubules are prominent during cell division. The minus ends of the tubules originate in the centrosome, which is a microtubule-organizing center able to initiate the assembly of new tubules. In mitotic prophase the centrosome divides and each of the radiating sets of microtubules becomes known as an aster. The two asters move to the opposite sides of the nucleus to become the two poles of the mitotic spindle. The spindle contains two types of microtubules. The polar microtubules meet each other near the center and become linked by plus-directed motor proteins. These tend to drive the poles apart. Each chromosome has a special site called a kinetochore which binds another group of microtubules called kinetochore microtubules. At anaphase the kinetochores of homologous chromosomes separate. The polar microtubules continue to elongate while the kinetochore microtubules shorten by loss of tubulin from both ends and draw the chromosome sets into the opposite poles of the spindle.

Microfilaments

Microfilaments (Fig. 7.6) are polymers of actin, which is the most abundant protein in most animal cells. In vertebrates there are several different gene products of which α actin is found in muscle and β/γ actins in the cytoskeleton of non-muscle cells. For all actin types the monomeric soluble form is called G-actin. Actin filaments have an inert minus end, and a growing plus end to which new monomers are added. G-actin contains ATP and this becomes hydrolyzed to adenosine diphosphate (ADP) shortly after addition to the filament. As with tubules, a rapidly growing filament will bear an ATP cap which stabilizes the plus end. Microfilaments are often found to undergo 'treadmilling' such that monomers are continuously added to the plus end and removed from the minus end while leaving the filament at the same overall length. Microfilament polymerization is prevented by a group of drugs called cytochalasins, and existing filaments are stabilized by another group called phalloidins. Like microtubules, microfilaments have associated motor proteins that will actively migrate along the fiber. The most abundant of these is myosin II, which moves toward the plus end of microfilaments, the process being driven by the hydrolysis of ATP. To bring about contraction of a filament bundle, the myosin is assembled as short bipolar filaments with motile centers at both ends. If neighboring actin filaments are arranged with opposite orientation then the motor activity of the myosin will draw the filaments past each other leading to a contraction of the filament bundle.

Microfilaments can be arranged in various different ways depending on the nature of the accessory proteins with which they are associated. Contractile assemblies contain microfilaments in antiparallel orientation associated with myosin. These are found in the contractile ring which is responsible for cell division, and in the stress fibers by which fibroblasts exert traction on their substratum. Parallel bundles are found in filopodia and other projections from the cell. Gels composed of short randomly orientated filaments are found in the cortical region of the cell.

Small GTPases

There are three well known GTPases that activate cell movement in response to extracellular signals: Rho, Rac and Cdc42. They are activated by numerous tyrosine kinase-, G-coupled-, and cytokine type receptors. Activation involves exchange of GDP for GTP and many downstream proteins can interact with the activated forms. Rho normally activates the

assembly of stress fibers. Rac activates the formation of lamellipodia and ruffles. Cdc42 activates formation of filopodia. In addition all three promote the formation of focal adhesions, which are integrin-containing junctions to the extracellular matrix. These proteins can also affect gene activity through the kinase cascade signal transduction pathways.

CELL ADHESION MOLECULES

Organisms are not just bags of cells, rather each tissue has a definite cellular composition and microarchitecture. This is determined partly by the cell surface molecules by which cells interact with each other, and partly by the components of the extracellular matrix (ECM). Virtually all proteins on the cell surface or in the ECM are glycoproteins, containing oligosaccharide groups added before secretion from the cell. These carbohydrate groups often have rather little effect on the biological activity of the protein but they may affect its physical properties and stability.

Cells are attached to each other by adhesion molecules (Fig. 7.7). Among these are the cadherins, which stick cells together in the presence of Ca, the cell adhesion molecules (CAMs), that do not require Ca, and the integrins that attach cells to the extracellular matrix. When cells come together they often form gap junctions at the region of contact. These consist of small pores joining the cytosol of the two cells. The pores, or connexons, are assembled from proteins called connexions and can pass molecules up to about 1000 molecular weight by passive diffusion.

Cadherins are a family of single-pass transmembrane glycoproteins which can adhere tightly to similar molecules on other cells in the presence of calcium. They are the main factors attaching embryonic cells together, which is why embryonic tissues can often be caused to disaggregate simply by removal of calcium. The cytoplasmic tail of cadherins is anchored to actin bundles in the cytoskeleton by a complex including proteins called catenins. One of these, β-catenin, is also a component of the important Wnt signaling pathway, providing a link between cell signaling and cell association. Cadherins were first named for the tissues in which they were originally found, so E-cadherin occurs mainly in epithelia and N-cadherin occurs mainly in neural tissue.

The immunoglobulin superfamily is made up from single-pass transmembrane glycoproteins with a number of disulfide-bonded loops on the extracellular region, similar to the loops

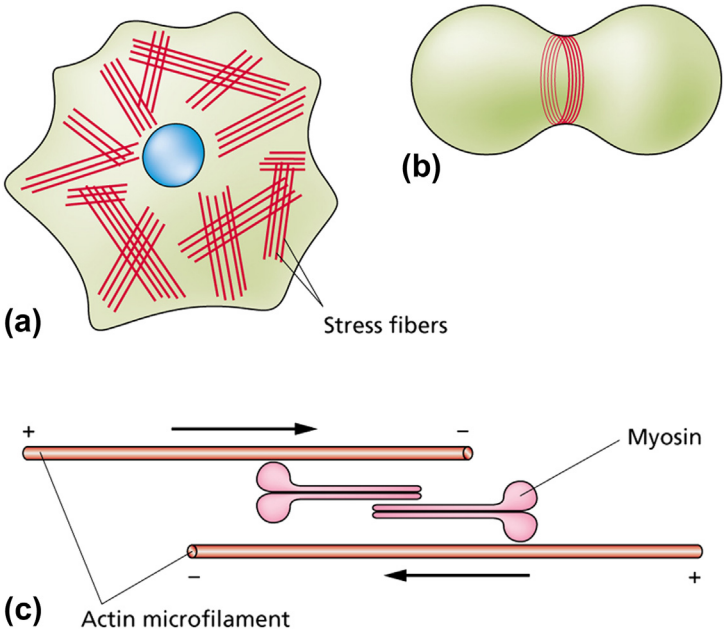

FIGURE 7.7
Microfilaments. a) Arrangement in cell. b) Role in cell division. c) Contraction achieved by movement of myosin along microfilament. *(From Slack 2012).*

found in antibody molecules. They also bind to similar molecules on other cells, but unlike the cadherins they do not need calcium to do so. The neural cell adhesion molecule (N-CAM) is composed of a large family of different proteins formed by alternative splicing. It is most prevalent in the nervous system but also occurs elsewhere. It may carry a large amount of polysialic acid on the extracellular domain, and this can inhibit cell attachment because of the repulsion between the concentrations of negative charge on the two cells.

The integrins are cell surface glycoproteins that interact mainly with components of the extracellular matrix. They are heterodimers of α and β subunits, and require either magnesium or calcium for binding. There are numerous different α and β chain types and so there is a very large number of potential heterodimers. Integrins are attached by their cytoplasmic domains to microfilament bundles, so, like cadherins, they provide a link between the outside world and the cytoskeleton. They are also thought on occasion to be responsible for the activation of signal transduction pathways and new gene transcription following exposure to particular extracellular matrix components.

EXTRACELLULAR MATRIX

Glycosaminoglycans (GAGs) are unbranched polysaccharides composed of repeating disaccharides of an amino sugar and a uronic acid, usually substituted with some sulfate groups. GAGs are constituents of proteoglycans, which have a protein core to which the GAG chains are added in the Golgi apparatus before secretion. One molecule of a proteoglycan may carry more than one type of GAG chain. GAGs have a high negative charge and a small amount can immobilize a large amount of water into a gel. Important GAGs, each of which have different component disaccharides, are heparan sulfate, chondroitin sulfate and keratan sulfate. Heparan sulfate, closely related to the anti-coagulant heparin, is particularly important for cell signaling as it is required to present various growth factors, such as the fibroblast growth factors (FGFs), to their receptors. Hyaluronic acid differs from other GAGs because it occurs free, and not as a constituent of a proteoglycan. It consists of repeating disaccharides of glucuronic acid and N-acetyl glucosamine, and is not sulfated. It is synthesized by enzymes at the cell surface and is abundant in early embryos.

Collagens are the most abundant proteins by weight in most animals. The polypeptides, called α chains, are rich in proline and glycine. Before secretion, three α chains become twisted around each other to form a stiff triple helical structure. In the extracellular matrix, the triple helices become aggregated together to form the collagen fibrils often visible in the electron microscope. There are many types of collagen, which may be composed of similar or of different α chains in the triple helix. Type I collagen is the most abundant and is a major constituent of most extracellular material. Type II collagen is found in cartilage and in the notochord of vertebrate embryos. Type IV collagen is a major constituent of the basal lamina underlying epithelial tissues. Collagen helices may become covalently crosslinked through their lysine residues, and this contributes to the changing mechanical properties of tissues with age.

Elastin is another extracellular protein with extensive intermolecular cross-linking. It confers the elasticity on tissues in which it is abundant, and also has some cell signaling functions. Fibronectin is composed of a large disulfide-bonded dimer. The polypeptides contain regions responsible for binding to collagen, to heparan sulfate, and to integrins on the cell surface. These latter, cell-binding domains are characterized by the presence of the amino acid sequence Arg-Gly-Asp (= RGD). There are many different forms of fibronectin produced by alternative splicing. Laminin is a large extracellular glycoprotein, found particularly in basal laminae. It is composed of three disulfide-bonded polypeptides joined in a cross shape. It carries domains for binding to type IV collagen, heparan sulfate and another matrix glycoprotein, entactin.

CULTURE MEDIA

Mammalian cells will only remain in good condition very close to the normal body temperature, so good temperature control is essential. Because water can pass across the plasma membranes of animal cells, the medium must match the osmolarity of the cell interior, otherwise cells will swell or shrink due to osmotic pressure difference. Mammalian cells media generally have a total osmolarity about 350 mOsm. The pH needs to be tightly controlled, 7.4 being normal. The pH control is usually achieved with bicarbonate-CO_2 buffers (2.2 gm/l bicarbonate and 5% CO_2 being a common combination). These give better results with most animal cells than other buffers, perhaps because bicarbonate is also a type of nutrient. The medium must contain a variety of components: salts, amino acids, sugars, plus low levels of specific hormones and growth factors required for the particular cell type in question. Because of the complexity of tissue culture media they are rarely optimized for a given purpose by varying every one of the components. Usually changes are incremental and the result of a 'gardening' type of approach rather than a systematic one.

The requirement for hormones and growth factors is usually met by including some animal serum, often 10% fetal calf serum. This is long standing practice but has two substantial disadvantages. Serum can never be completely characterized and there are often differences between batches of serum that can be critical for experimental results. Also there is currently a drive to remove serum from the preparation of cells that are intended for implantation into human patients. This is because of the perceived possibility, actually very remote, of transmitting animal diseases to patients.

Assuming cells are kept in a near optimal medium, they can in principle grow exponentially, with a constant doubling time. Indeed it is possible to grow many types of tissue culture cell in exponential cultures rather like microorganisms. In order to keep them growing at maximal rate they need to have their medium renewed regularly and to be subcultured and replated at lower density whenever they approach confluence, that is approach a density at which they cover all the available surface. Subculturing is usually carried out by treatment with the enzyme trypsin, which degrades much of the extracellular and cell surface protein and makes the cells drop off the substrate and become roughly spherical bodies in suspension. The trypsin is diluted out and the cells are transferred at lower density into new flasks. The cells take an hour or two to resynthesize their surface molecules and can then adhere to the new substrate and carry on growing.

CELLS IN TISSUES AND ORGANS

Cell types

On the basis of light microscopy it is estimated that there are about 210 different types of differentiated cell in the mammalian body. This number is certainly an underestimate since there are many subtypes of cells that cannot be seen via the light microscope, particularly the different types of neuron in the nervous system and different types of lymphocyte in the immune system. Cells types are different from one another because they are expressing different subsets of genes and hence contain different proteins. The products of a relatively small number of genes may dominate the appearance of a differentiated cell, for example the proteins of the contractile apparatus of skeletal muscle are very abundant. However a typical cell will express many thousands of genes, and its character will also depend on the genes that are not expressed. It is possible to control cell differentiation to some extent. There are special culture media that are favorable for differentiation of particular cell types, such as adipocytes, muscle or bone. In some cases differentiated cells can continue to grow in pure culture. But in many cases differentiation causes slowing or cessation of cell division.

From a morphological point of view most cells can be regarded as epithelial or mesenchymal (Fig. 7.8). These terms relate to cell shape and behavior rather than to embryonic origin. An

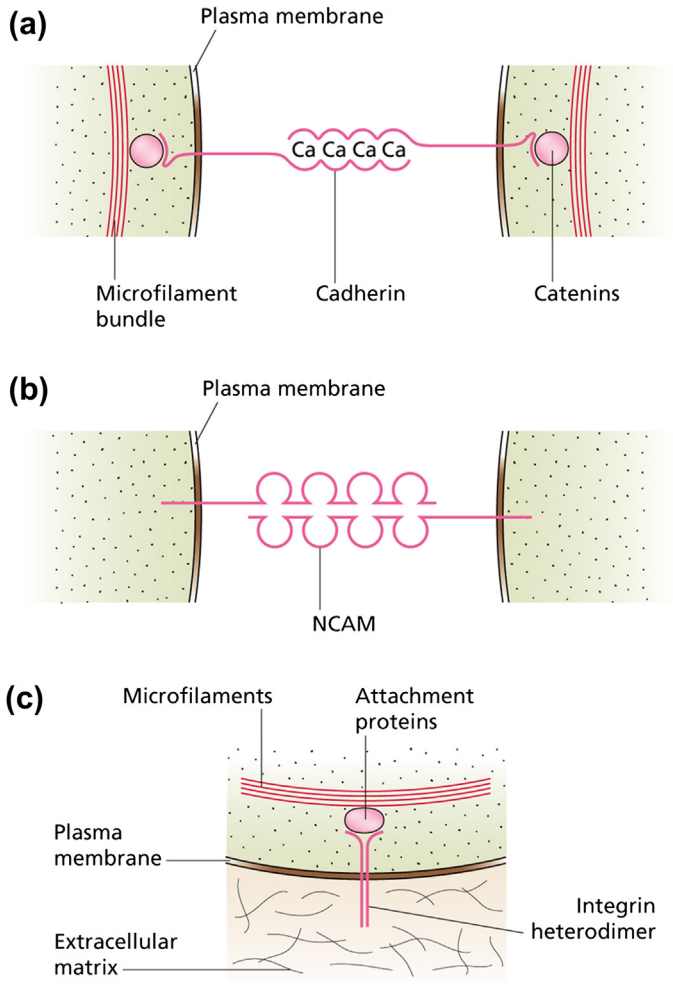

FIGURE 7.8

epithelium is a sheet of cells, arranged on a basement membrane, each cell joined to its neighbors by specialized junctions, and showing a distinct apical-basal polarity. Mesenchyme is a descriptive term for scattered stellate-shaped cells embedded in loose extracellular matrix. It fills up much of the space within the embryo and later forms fibroblasts, adipose tissue, smooth muscle and skeletal tissues.

Tissues

From a developmental biology standpoint, a tissue is the set of cell types arising from one sort of progenitor or stem cell. For example, the intestinal epithelium is a tissue. It is structured into crypts, containing undifferentiated cells, and villi covered with differentiated cells. There are four mature cell types: absorptive, goblet, Paneth and enteroendocrine cells. The stem cells are located at the crypt base and produce progenitor cells, called transit amplifying cells, which divide a few times before differentiating into one of the four mature cell types. The tissue comprises the stem cells, the transit amplifying cells, and the differentiated cells. This is an example of a renewal tissue, in which there is continuous production and replacement of differentiated cells. Not all tissues are renewal tissues although most display a small degree of renewal or the ability to replace the constituent cell types following damage. For example the central nervous system arises from the neuroepithelium of the early embryo and contains a variety of types of neuron together with glial cells, especially astrocytes and oligodendrocytes. There is only replacement of neurons in two regions of the brain and turnover of glial

populations is slow. But because it arises from a clearly identified progenitor cell population, the central nervous system can be regarded as one tissue.

In cases where differentiated cells are derived from different stem or progenitor cell populations, they cannot be considered as a single tissue. For example, the thyroid gland contains many follicles of thyroglobulin-producing epithelial cells. It also contains endocrine cells producing the hormone calcitonin. However, the latter do not arise from the same endodermal bud as the rest of the thyroid. Instead they arise from the neural crest of the embryo. Likewise, many tissues contain macrophages (histiocytes) derived from the hematopoietic stem cells of the bone marrow. These cells are properly considered to belong to the blood/immune tissue rather than the epithelia or connective tissues in which they reside.

Organs

Organs are the familiar structures in the body which are each associated with a particular function. They are typically composed of several tissue layers and arise from multiple developmental origins. For example, the stomach has the function of preliminary food digestion. The lining of the stomach is one tissue, the gastric epithelium, derived from gastric stem cells. The outer layers consist of smooth muscle and connective tissues, blood vessels, nerve fibers, and cells of the blood and immune system. Together these make up a discrete and integrated body part. A single named muscle contains many muscle fibers, which are postmitotic multinucleate cells. It also contains muscle satellite cells, which are stem cells that can regenerate fibers. The fibers and the satellite cells are one tissue, arising from the myotome of the somites of the embryo. Surrounding the bundles of fibers are connective tissue sheaths composed of fibroblasts and extracellular matrix derived from lateral plate mesoderm. Again, there are always blood vessels, nerve fibers and cells of the blood and immune system. A muscle is one organ, composed of several tissues, each consisting of more than one cell type (Fig. 7.9).

Organs often have an epithelial and mesenchymal component. The epithelium is usually the functional part, for example the epithelial lining of the various segments of the gut have specific properties of protection, absorption or secretion, while the underlying mesenchyme provides mechanical support, growth factors, and physiological response in terms of muscular movements.

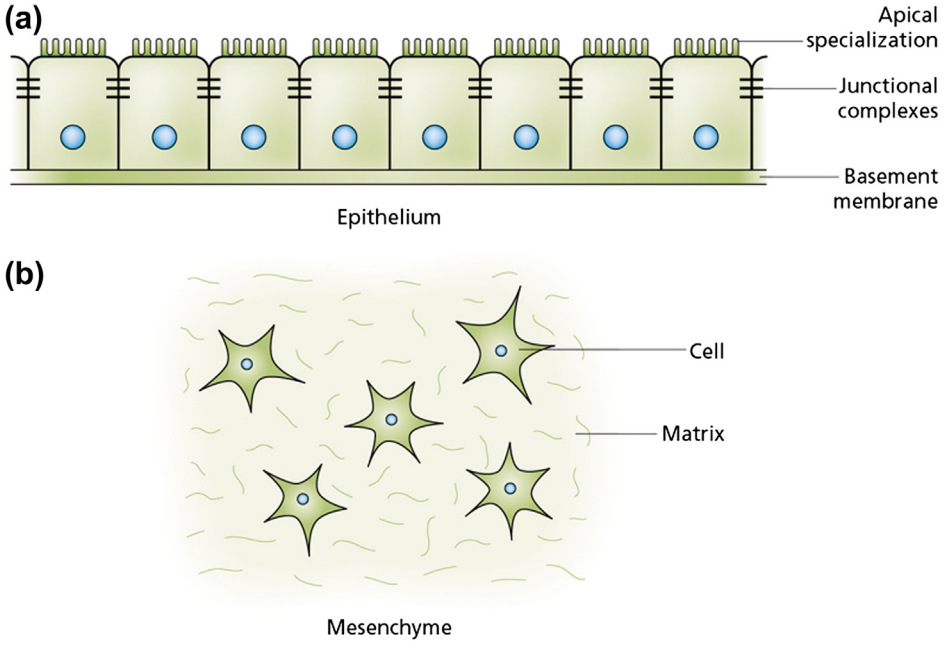

FIGURE 7.9
Most tissues are composed of epithelial (a) and mesenchymal (b) components. *From Slack (2012).*

With the exception of the kidney, all other organs draw their epithelium and mesenchyme from different germ layers of the embryo. The implication of this for tissue engineering is that it will probably be necessary to assemble structures from separate epithelial and mesenchymal cells, designed such that each population can support the other by secretion of appropriate factors.

The final consideration is that cells need a continuous supply of nutrients and oxygen and continuous removal of waste products. *In vivo* this is achieved by means of the blood vascular system which culminates in capillary beds of enormous density such that all cells are within a few cell diameters of the blood. For tissue engineering the lesson is clear: it is possible to grow large avascular structures only so long as they are two dimensional: for example large sheets of epidermis a few cells thick can be grown *in vitro* and used successfully for skin grafting. But any tissue more than a fraction of a millimeter thickness will need to be provided with some sort of vascular system.

Tissue engineering need not attempt to copy everything that is found in the normal body. However it is necessary to be aware of the constraints provided by the molecular biology of the cell. Factors to be considered include:

- How to keep cells in the desired state by providing the correct substrate and medium.
- How to create engineered structures containing two or more cell types of different origins which can sustain one another.
- How to provide a vascular system capable of delivering nutrients and removing waste products.
- How to control cell division to achieve homeostasis rather than uncontrolled growth or regression.

CHAPTER 8

Molecular Organization of Cells

Jon D. Ahlstrom
University of Utah and George E. Wahlen VAMC, Salt Lake City, Utah

INTRODUCTION

Multicellular tissues exist in one of two types of cellular arrangements; epithelial or mesenchymal. Epithelial cells adhere tightly to each other at their lateral surfaces and to an organized ECM (extracellular matrix) at their basal domain, thereby producing a sheet of cells resting on a basal lamina with an apical surface. Mesenchymal cells, in contrast, are individual cells with a bipolar morphology that are held together as a tissue within a three-dimensional ECM (see Fig. 8.1). The conversion of epithelial cells into mesenchymal cells, an 'epithelial-mesenchymal transition' (EMT), is central to many aspects of embryonic morphogenesis, adult tissue repair, as well as a number of disease states [1,2]. The reverse process, whereby mesenchymal cells coalesce into an epithelium is a 'mesenchymal-epithelial transition' (MET). Understanding the molecules that regulate this transition between epithelial and mesenchymal states offers important insights into how cells and tissues are organized.

The early embryo is structured as one or more epithelia. An EMT allows the rearrangements of cells to create additional morphological features. Well-studied examples of EMTs during embryonic development include gastrulation in *Drosophila* [3], the emigration of primary mesenchyme cells (PMCs) in sea urchin embryos [4], and gastrulation in amniotes (reptiles, birds, and mammals) at the primitive streak [5]. EMTs also occur later in vertebrate development, such as the emigration of neural crest cells from the neural tube, the formation of the sclerotome from epithelial somites, and during palate fusion [1]. The reverse process of MET is likewise crucial to development, and examples include the condensation of mesenchymal cells to form the notochord and somites, kidney tubule formation from nephrogenic mesenchyme, and the creation of heart valves from cardiac mesenchyme [1]. In the adult organism, EMTs and METs occur during wound healing and tissue remodeling. The conversion of neoplastic epithelial cells into invasive cancer cells has long been considered an EMT process [1]. However, there are also examples of tumor cells that have functional cell-cell adhesion junctions, yet are still migratory and invasive as a group. This 'collective migration' also occurs during development [2]. Hence, there is debate about whether an EMT model accurately describes all epithelial metastatic cancers. Similarly, the fibrosis of cardiac, kidney, lens, and liver epithelial tissue has also long been categorized as an EMT event [1]. However, recent research into the kidney *in vivo* shows that the myofibroblasts induced following kidney injury are derived from mesenchymal pericytes, rather than the proximal epithelial cells [6]. Therefore, the origin of the cells that contribute to fibrotic tissue scarring (epithelial or otherwise) may need to be carefully re-examined.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00008-2

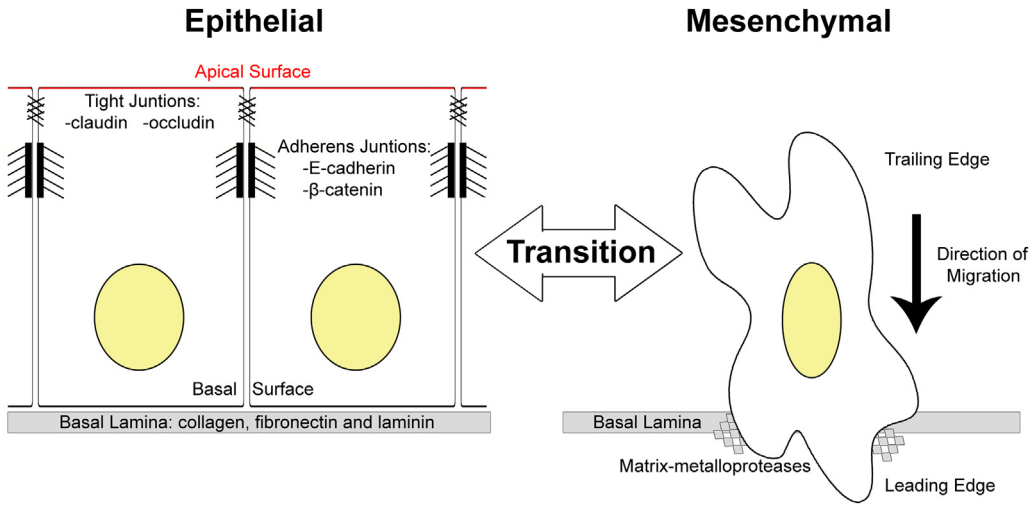

FIGURE 8.1
Epithelial vs. Mesenchymal. Epithelial cells adhere together by tight junctions and adherens junctions localized near the apical surface. Epithelial cells also have a basal surface that rests on a basal lamina (ECM). Mesenchymal cells in contrast do not have well-defined cell-cell adhesion complexes, have front-end/back-end polarity instead of apical/basal polarity, and mesenchymal cells are characterized by their ability to invade the basal lamina.

The focus of this chapter is on the molecules that regulate the organization of cells into epithelium or mesenchyme. We will first discuss the cellular changes that occur during an EMT, including changes in cell-cell and cell-ECM adhesions, changes in cell polarity, and the stimulation of invasive cell motility. Then we will consider the molecules and mechanisms that control the EMT or MET, including the structural molecules, transcription factors and signaling pathways that regulate EMTs.

MOLECULES THAT ORGANIZE CELLS

The conversion of an epithelial sheet into individual migratory cells and back again requires the coordinated changes of many distinct families of molecules.

Changes in cell-cell adhesion

Epithelial cells are held together by specialized cell-cell junctions, including adherens junctions, desmosomes, and tight junctions. These junctions are localized in the lateral domain near the apical surface and establish the apical polarity of the epithelium. In order for an epithelial sheet to produce individual mesenchymal cells, cell-cell adhesions must be disrupted. The principle transmembrane proteins that mediate cell-cell adhesions are members of the cadherin superfamily. E-cadherin and N-cadherin are classical cadherins that interact homotypically through their extracellular IgG domains with like-cadherins on adjacent cells. Cadherins are important mediators of cell-cell adhesion. For example, misexpression of E-cadherin is sufficient to promote cell-cell adhesion and assembly of adherens junctions in fibroblasts [5]. In epithelial cancers (carcinomas), E-cadherin acts as a tumor suppressor [7]. In a mouse model for β-cell pancreatic cancer, the loss of E-cadherin is the rate-limiting step for transformed epithelial cells to become invasive [8]. Although the loss of cadherin-mediated cell-cell adhesion is necessary for an EMT, the loss of cadherins is not always sufficient to generate a complete EMT *in vivo*. For example, the neural tube epithelium in mice expresses N-cadherin, but in the N-cadherin knockout mouse an EMT is not induced in the neural tube [9]. Hence, cadherins are essential for maintaining epithelial integrity, and the loss of cell-cell adhesion due to the reduction of cadherin function is an important step for an EMT.

One characteristic of an EMT is 'cadherin switching'. Often, epithelia that express E-cadherin will downregulate E-cadherin expression at the time of the EMT, and express different cadherins such as N-cadherin [2]. Cadherin switching may promote motility. For instance, in mammary epithelial cell lines, the misexpression of N-cadherin is sufficient for increased cell motility, and blocking N-cadherin expression results in less motility. However, the misexpression of N-cadherin does not result in the complete loss of epithelial morphology [10]. Hence, cadherin switching may be necessary for cell motility, but cadherin switching alone is not sufficient to bring about a complete EMT.

There are several ways that cadherin expression and function are regulated. Transcription factors that are central to most EMTs such as Snail-1, Snail-2, Zeb1, Zeb2, Twist, and E2A, all bind to E-boxes on the *E-cadherin* promoter and repress the transcription of *E-cadherin* [11]. Post-transcriptionally, the E-cadherin protein is ubiquitinated by the E3-ligase, Hakai, which targets E-cadherin to the proteasome [7]. E-cadherin turnover at the membrane is regulated by either caveolae-dependent endocytosis or clathrin-dependent endocytosis [12], and p120-catenin prevents endocytosis of E-cadherin at the membrane [13]. E-cadherin function can also be disrupted by matrix metalloproteases, which degrade the extracellular domain of E-cadherin [14]. Some or all of these mechanisms may occur during an EMT to disrupt cell-cell adhesion.

In summary, cell-cell adhesion is maintained principally by cadherins, and changes in cadherin expression are typical of an EMT.

Changes in cell-ECM adhesion

Altering the way that a cell interacts with the ECM is also important in EMTs. For example, at the time that sea urchin PMCs ingress, the cells have increased adhesiveness for ECM [4]. Cell-ECM adhesion is mediated principally by integrins. Integrins are transmembrane proteins composed of two non-covalently linked subunits, α and β, that bind to ECM components such as fibronectin, laminin, and collagen. The cytoplasmic domain of integrins links to the cytoskeleton and interacts with signaling molecules. Changes in integrin function are required for many EMTs, including neural crest emigration [15], mouse primitive streak formation [5], and cancer metastasis [16]. However, the misexpression of integrin subunits is not sufficient to bring about a full EMT *in vitro* [17] or *in vivo* [18].

The presence and function of integrins is modulated in several ways. For example, the promoter of the *integrin β6* gene is activated by the transcription factor Ets-1 during colon carcinoma metastasis [19]. Most integrins can also cycle between 'On' (high affinity) or 'Off' (low affinity) states. This 'inside-out' regulation of integrin adhesion occurs at the integrin cytoplasmic tail. In addition to integrin activation, the 'clustering' of integrins on the cell surface also affects the overall strength of integrin-ECM interactions. The increased adhesiveness of integrins due to clustering, known as avidity, can be activated by chemokines, and is dependent on RhoA and phosphatidylinositol 3' kinase (PI3K) activity [20].

In summary, changes in ECM adhesion are required for an EMT. Cell-ECM adhesions are maintained by integrins, and integrins have varying degrees of adhesiveness dependent upon the presence, activity, or avidity of the integrin subunits.

Changes in cell polarity and stimulation of cell motility

Cellular polarity is defined by the distinct arrangement of cytoskeletal elements and organelles in epithelial verses mesenchymal cells. Epithelial polarity is characterized by cell-cell junctions found near the apical-lateral domain (non-adhesive surface), and a basal lamina opposite of the apical surface (adhesive surface). Mesenchymal cells in contrast do not have apical/basal polarity, but rather front-end/back-end polarity, with actin-rich lamellipodia and Golgi localized at the leading edge [5]. Molecules that establish cell polarity include Cdc42, PAK1,

PI3K, PTEN, Rac, Rho, and the PAR proteins [21]. Changes in cell polarity help to promote an EMT. In mammary epithelial cells, the activated TGF-β receptor II causes Par6 to activate the E3 ubiquitin ligase Smurf1, and Smurf1 then targets RhoA to the proteasome. The reduction of RhoA activity results in the loss of cell-cell adhesion and epithelial cell polarity [22].

In order for mesenchymal cells to leave the epithelium, they must become motile. Many of the same polarity (Crumbs, PAR, and Scribble complexes), structural (actin, microtubules), and regulatory molecules (Cdc42, Rac1, RhoA) that govern epithelial polarity are also central to cell motility [23]. Cell motility mechanisms also vary depending on whether the environment is 2D or 3D [24]. Many mesenchymal cells express the intermediate filament vimentin, and vimentin may be responsible for several aspects of the EMT phenotype [25].

In short, a wide variety of structural, polarity, and regulatory molecules must be re-assigned as cells transition between epithelial polarity and mesenchymal migration.

Invasion of the basal lamina

In most EMTs the emerging mesenchymal cells must penetrate a basal lamina which consists of ECM components such as collagen type IV, fibronectin and laminin. The basal lamina functions to stabilize the epithelium and is a barrier to migratory cells [26]. One mechanism that mesenchymal cells use to breach the basal lamina is to produce enzymes that degrade it. Plasminogen activator is one protease associated with a number of EMTs, including neural crest emigration [26] and the formation of cardiac cushion cells during heart morphogenesis [27]. The type II serine protease, TMPRSS4, also promotes an EMT and metastasis when overexpressed *in vitro* and *in vivo* [1]. Matrix metalloproteases (MMPs) are also important for many EMTs. When MMP-2 activity is blocked in the neural crest EMT, neural crest emigration is inhibited, but not neural crest motility [28]. In mouse mammary cells, MMP-3 overexpression is sufficient to induce an EMT *in vitro* and *in vivo* [29]. Misexpressing MMP-3 in cultured cells induces an alternatively spliced form of Rac1 (Rac1b), which then causes an increase in reactive oxygen species (ROS) intracellularly, and Snail-1 expression. Either Rac1b activity or ROS are necessary and sufficient for an MMP-3-induced EMT [30]. Hence, a number of extracellular proteases are important to bring about an EMT.

While epithelial cells undergoing an EMT do eventually lose cell-cell adhesion, apical-basal polarity, and gain invasive motility, the EMT program is not necessarily ordered or linear. For example, in a study where neural crest cells were labeled with cell adhesion or polarity markers and individual live cells were observed undergoing the EMT in slice culture, neural crest cells changed epithelial polarity either before or after the complete loss of cell-cell adhesion, or lost cell-cell adhesions either before or after cell migration commenced [31]. Therefore, while an EMT does consist of several distinct phases, these steps may occur in different orders or combinations, some of which (e.g., the complete loss of cell-cell adhesion) may not always be necessary.

In summary, changes in a wide range of molecules are needed for an EMT as epithelial cells lose cell-cell adhesion, change cellular polarity, and gain invasive cell motility.

THE EMT TRANSCRIPTIONAL PROGRAM

At the foundation of every EMT or MET program are the transcription factors that regulate the gene expression required for these cellular transitions. While many of the transcription factors that regulate EMTs have been identified, the complex regulatory networks are still incomplete. Here we review the transcription factors that are known to promote the various phases of an EMT. Then we examine how these EMT transcription factors themselves are regulated at the promoter and post-transcriptional levels.

Transcription factors that regulate EMTs

The Snail family of zinc finger transcription factors, including Snail-1 and Snail-2 (formerly Snail and Slug) are direct regulators of cell-cell adhesion and motility during EMTs [11,32]. The knockout of *Snail-1* in mice is lethal early in gestation, and the presumptive primitive streak cells that normally undergo an EMT still retain apical/basal polarity, adherens junctions, and express E-cadherin mRNA [33]. Snail-1 misexpression is sufficient for breast cancer recurrence in a mouse model *in vivo*, and high levels of *Snail-1* predict the relapse of human breast cancer [1]. Snail-2 is necessary for the chicken primitive streak and neural crest EMTs [34]. One way that Snail-1 or Snail-2 causes a decrease in cell-cell adhesion is by repressing the *E-cadherin* promoter [11]. This repression requires the mSin3A co-repressor complex, histone deacetylases, and components of the Polycomb 2 complex [2]. Snail-1 is also a transcriptional repressor of the tight junction genes *Claudin* and *Occludin* [11] and the polarity gene *Crumbs3* [1]. The misexpression of Snail-1 and Snail-2 further leads to the transcription of proteins important for cell motility such as fibronectin, vimentin, and RhoB [11]. Further, Snail-1 promotes invasion across the basal lamina. The misexpression of Snail-1 represses laminin (basement membrane) production and indirectly upregulates *mmp-9* transcription [1]. Snail and Twist also make cancer cells more resistant to senescence, chemotherapy, apoptosis, and endow cancer cells with 'stem cell' properties [1]. Hence, Snail-1 or Snail-2 are necessary and sufficient for bringing about many of the steps of an EMT, including loss of cell-cell adhesion, changes in cell polarity, gain of cell motility, invasion of the basal lamina, and increased proliferation and survival.

Other zinc finger transcription factors important for EMTs are zinc finger E-box-binding homeobox 1 (Zeb1, also known as δEF1), and Zeb2 (also known as Smad-interacting protein-1, Sip1). Both Zeb1 and Zeb2 bind to the *E-cadherin* promoter and repress transcription [11]. Zeb1 can also bind to and repress the transcription of the polarity proteins Crumbs3, Pals1-associated tight junction proteins (PATJ), and lethal giant larvae 2 (Lgl2) [1]. Zeb2 is structurally similar to Zeb1, and Zeb2 overexpression is sufficient to downregulate E-cadherin, dissociate adherens junctions, and increase motility in MDCK cells [35].

The Lymphoid Enhancer-binding Factor/ T Cell Factor (LEF/TCF) transcription factors also play an important role in EMTs. For instance, the misexpression of Lef-1 in cultured colon cancer cells reversibly causes the loss of cell-cell adhesion [36]. LEF/TCF transcription factors directly activate genes that regulate cell motility, such as the L1 adhesion molecule [37], and the *fibronectin* gene [38]. LEF/TCF transcription factors also upregulate genes required for basal lamina invasion, including *mmp-3* and *mmp-7* [39].

Other transcription factors that have a role in promoting EMTs are the class I basic helix-loop-helix factors E2-2A and E2-2B [40], the forkhead box transcription factor FOXC2, the homeobox protein Goosecoid, and the homeoprotein Six1[1].

To summarize, transcription factors that regulate an EMT often do so by directly repressing cell adhesion and epithelial polarity molecules, and by upregulating genes required for cell motility and basal lamina invasion.

Regulation at the promoter level

Given the importance of the Snail, Zeb and LEF/TCF transcription factors in orchestrating the various phases of an EMT, it is essential to understand the upstream events that regulate these EMT-promoting transcription factors.

The activation of *Snail-1* transcription in *Drosophila* requires the transcription factors Dorsal (NF-κB) and Twist [11]. The human *Snail-1* promoter also has functional NF-κB sites [41] and blocking NF-κB reduces *Snail-1* transcription [42]. Additionally, a region of the *Snail-1* promoter is responsive to integrin-linked kinase (ILK) [11], and ILK can activate Snail-1

expression via poly-ADP-ribose polymerase (PARP) [43]. In mouse mammary epithelial cells, high mobility group protein A2 (HMGA2) and Smads activate *Snail-1* expression, and subsequently *Snail-2*, *Twist*, and *Id2* transcription [44]. For *Snail-2* expression, myocardin-related transcription factors (MRTFs) interact with Smads to induce *Snail-2* and MRTFs may play a role in metastasis and fibrosis [1]. There are also several *Snail-1* transcriptional repressors. In breast cancer cell lines, metastasis-associated protein 3 (MTA3) binds directly to and represses the transcription of *Snail-1* in combination with the Mi-2/NuRD complex [11], as also does lysine-specific demethylase (LSD1) [2]. The Ajuba LIM proteins (Ajuba, LIMD1 and WTIP) are additional transcriptional corepressors of the Snail family [1].

The transcription of LEF/TCF genes such as *Lef-1* is activated by Smads [5]. The misexpression of Snail-1 results in the transcription of *δEF-1* and *Lef-1* through a yet unknown mechanism [11].

Post-transcriptional regulation of EMT transcription factors

The activity of EMT transcription factors is also regulated post-transcriptionally, where alternative splicing, translational control, protein stability (targeting to the proteasome) and nuclear localization can all regulate an EMT.

One newly discovered layer of EMT regulation is the epithelial or mesenchymal specific expression of alternatively spliced transcripts. For example, epithelial splicing regulatory proteins 1 and 2 (ESRP1 and ESRP2) are two RNA-binding proteins that regulate the epithelial-specific expression of many molecules that are important to an EMT such as Rho regulators, integrins, and collagen [45]. Blocking ESRP1 and 2 expression changes the pattern of alternatively spliced transcripts and causes cultured epithelial cells to upregulate vimentin and fibronectin, to reduce E-cadherin at cell-cell contacts, and to increase protease activity [45].

Non-coding RNAs are also emerging as important regulators EMTs. In a breast cancer model, Myc activates the expression of microRNA-9 (miR-9), and miR-9 directly binds to and represses the *E-cadherin* promoter [2]. Members of the miR-200 family repress the translation of *Zeb1*, and the expression of these miR-200 family members are repressed by Snail-1. Additionally, *Zeb2* transcription can be activated by naturally occurring RNA antisense transcripts [1]. It is not yet known if there are non-coding RNAs that regulate Snail family members. However, the Y-box binding protein-1 (YB-1) is important for the selective activation of *Snail-1* translation [2].

Protein stability is another layer of EMT control. Snail-1 is phosphorylated by GSK-3β and targeted for destruction [1]. Therefore, the inhibition of GSK-3β activity by Wnt signaling may have multiple roles in an EMT, leading to the stabilization of both β-catenin and Snail-1. Some proteins that prevent GSK-3β-mediated phosphorylation (and thus promote Snail-1 activation) are lysyl-oxidase-like proteins LOXL2[1], and ILK [5]. A Snail-1 specific phosphatase (Snail-1 activator) is C-terminal domain phosphatase (SCP) [1]. Snail-2 is targeted for degradation by the direct action of p53 and the ubiquitin ligase Mdm2 [2].

In addition to protein translation and stability, the function of Snail-1 also depends upon nuclear localization mediated by Snail-1's nuclear localization sequence. The phosphorylation of human Snail-1 by p21-activated kinase 1 (Pak1) promotes the nuclear localization of Snail-1 (and therefore Snail-1 activation) in breast cancer cells [32]. In zebrafish, LIV-1 promotes the translocation of Snail-1 into the nucleus [1]. Snail-1 also contains a nuclear export sequence (NES) that is dependent on the calreticulin (CalR) nuclear export pathway [46]. This NES sequence is activated by the phosphorylation of the same lysine residues targeted by GSK-3β, which suggests a mechanism whereby phosphorylation of Snail-1 by GSK-3β results in the export of Snail-1 from the nucleus and subsequent degradation.

LEF/TCF activity is also regulated by other proteins. β-catenin is required as a co-factor for LEF/TCF-mediated activation of transcription, and Lef-1 can also associate with co-factor Smads to

activate the transcription of additional EMT genes [5]. In colon cancer cells, Thymosin β4 stabilizes ILK activity [1].

In summary, EMT transcription factors such as Snail-1, Zeb1 and Lef-1 are regulated by a variety of mechanisms, both at the transcriptional level, and post-transcriptional level by alternative splicing, non-coding RNA translation control, protein degradation, nuclear localization, and co-factors such as β-catenin.

MOLECULAR CONTROL OF THE EMT

The initiation of an EMT or MET is a tightly regulated event during development and tissue repair because deregulation of cellular organization is disastrous to the organism. A variety of external and internal signaling mechanisms coordinate the complex events of the EMT, and these same signaling pathways are often disrupted or reactivated during disease. EMTs or METs can be induced by either diffusible signaling molecules or ECM components. Below we discuss the role of signaling molecules and ECM in triggering an EMT, and then present a summary model for EMT induction.

Ligand-receptor signaling

During development, five main ligand-receptor signaling pathways are employed, namely TGF-β, Wnt, RTK, Notch, and Hedgehog. These pathways, among others, all have a role in triggering EMTs. While the activation of a single signaling pathway can be sufficient for an EMT, in most cases an EMT or MET is initiated by multiple signaling pathways acting in concert.

TGF-β PATHWAY

The transforming growth factor-beta (TGF-β) superfamily includes TGF-β, activin, and bone morphogenetic protein (BMP) families. These ligands operate through receptor serine/threonine kinases to activate a variety of signaling molecules including Smads, MAPK, PI3K and ILK. Most of the EMTs studied to date are induced in part, or solely, by TGF-β superfamily members [47]. During embryonic heart development, TGF-β2 and TGF-β3 have sequential and necessary roles in activating the endocardium to invade the cardiac jelly and form the endocardial cushions [48]. In the avian neural crest, BMP4 induces *Snail-2* expression [32]. In the EMT that transforms epithelial tissue into metastatic cancer cells, TGF-β acts as a tumor suppressor during early stages of tumor development, but as a tumor/EMT inducer at later stages [7,47]. TGF-β-signaling may combine with other signaling pathways to induce an EMT. For example, in cultured breast cancer cells, activated Ras and TGF-β induce an irreversible EMT [49], and in pig thyroid epithelial cells, TGF-β and epidermal growth factor (EGF) synergistically stimulate the EMT [50].

One outcome of TGF-β signaling is to immediately change epithelial cell polarity. In a TGF-β-induced EMT of mammary epithelial cells, TGF-βR II directly phosphorylates the polarity protein, Par6, leading to the dissolution of tight junctions [22]. TGF-β signaling also regulates gene expression through the phosphorylation and activation of Smads. Smads are important co-factors in the stimulation of an EMT. For example, Smad3 is necessary for a TGF-β-induced EMT in lens and kidney tissue *in vivo* [51]. Smad3/4 also complex with Snail-1 and co-represses the promoters of cell-cell adhesion molecules [1]. Further, TGF-βR I directly binds to and activates PI3K [52], which in turn activates ILK and downstream pathways.

ILK is emerging as an important positive regulator of EMTs [53]. ILK interacts directly with growth factor receptors (TGF-β, Wnt or RTK), integrins, the actin skeleton, PI3K, and focal adhesion complexes. ILK directly phosphorylates Akt and GSK-3β, and results in the subsequent activation of transcription factors such as AP-1, NF-κB, and Lef-1. Overexpression of ILK in cultured cells causes the suppression of GSK-3β activity [54], translocation of

β-catenin to the nucleus, activation of Lef-1/β-catenin transcription factors, and the down-regulation of E-cadherin [55]. Inhibition of ILK in cultured colon cancer cells leads to the stabilization of GSK-3β activity, decreased nuclear β-catenin localization, the suppression of *Lef-1* and *Snail-1* transcription, and reduced invasive behavior of colon cancer cells [56]. ILK activity also results in Lef-1-mediated transcriptional upregulation of MMPs [39]. Hence, ILK (inducible by TGF-β signaling) is capable of orchestrating most of the major events in an EMT, including the loss of cell-cell adhesion and invasion across the basal lamina.

WNT PATHWAY

Many EMTs or METs are also regulated by Wnt signaling. Wnts signal through seven-pass transmembrane proteins of the Frizzled family, which activates G-proteins, PI3K, inhibits GSK-3β and promotes nuclear β-catenin signaling. For example, during zebrafish gastrulation, Wnt11 activates the GTPase Rab5c, which results in the endocytosis of E-cadherin [57]. Wnt6 signaling is sufficient for increased transcription of *Snail-2* in the avian neural crest [58]. Snail-1 expression increases Wnt signaling [59], which suggests a positive feedback loop.

One of the downstream signaling molecules activated by Wnt signaling is β-catenin. β-catenin is a structural component of adherens junctions. Nuclear β-catenin is also a limiting factor for the activation of LEF/TCF transcription factors. β-catenin is pivotal for regulating most EMTs. Interfering with nuclear β-catenin signaling blocks the ingression of sea urchin PMCs [60], and in β-catenin mouse knockouts, the primitive streak EMT does not occur, and no mesoderm is formed [61]. β-catenin is also necessary for the EMT that occurs during cardiac cushion development [62]. In breast cancer, β-catenin expression is highly correlated with metastasis and poor survival [63], and blocking β-catenin function in tumor cells inhibits invasion *in vitro* [64]. It is unclear if β-catenin overexpression alone is sufficient for all EMTs. If β-catenin is misexpressed in cultured cells, it causes apoptosis [36]. However, the misexpression of a stabilized form of β-catenin in mouse epithelial cells *in vivo* results in metastatic skin tumors [65].

SIGNALING BY RTK LIGANDS

The receptor tyrosine kinase (RTK) family of receptors and the growth factors that activate them also regulate EMTs or METs. Ligand binding promotes RTK dimerization and activation of the intracellular kinase domains by auto-phosphorylation of tyrosine residues. These phosphotyrosines act as docking sites for intracellular signaling molecules, which can activate signaling cascades such as Ras/MAPK, PI3K/Akt, JAK/STAT, or ILK. Below we cite some examples of RTK signaling in EMTs and METs.

Hepatocyte growth factor (HGF, also known as scatter factor) acts through the RTK c-met. HGF is important for the MET in the developing kidney [66]. HGF signaling is required for the EMT that produces myoblasts (limb muscle precursors) from somite tissue in the mouse [7]. In epithelial cells, HGF causes an EMT through MAPK and early growth response factor-1 (Egr-1) signaling [1].

Fibroblast growth factor (FGF) signaling regulates mouse primitive streak formation [67]. FGF signaling also stimulates cell motility and activates MMPs [68,69].

EGF promotes the endocytosis of E-cadherin [70]. EGF can also increase Snail-1 activity via the inactivation of GSK3-β [71] and EGF promotes increased *Twist* expression through a JAK/STAT3 pathway [72].

Insulin growth factor (IGF) signaling induces an EMT in breast cancer cell lines through the activation of Akt2 and suppression of Akt1 [73]. In prostate cancer cells, IGF-1 promotes Zeb-1 expression [74]. In fibroblast cells, constitutively activated IGF-IR increases NF-κB activity and Snail-1 levels [75]. In several cultured epithelial cell lines, IGFR1 is associated with the complex of E-cadherin and β-catenin, and the ligand IGF-II causes the redistribution of

β-catenin from the membrane to the nucleus, activation of the transcription factor TCF-3, and a subsequent EMT [76].

Another RTK known for its role in EMTs is the ErbB2/HER-2/Neu receptor, whose ligand is heregulin/neuregulin. Overexpression of HER-2 occurs in 25% of human breast cancers, and the misexpression of HER-2 in mouse mammary tissue *in vivo* is sufficient to cause metastatic breast cancer [77]. Herceptin® (antibody against the HER-2 receptor) treatment is effective in reducing the recurrence of HER-2-positive metastatic breast cancers. HER-2 signaling activates *Snail-1* expression in breast cancer through an unknown mechanism [78]. The RTK Axl is also required for breast cancer carcinoma invasiveness [79].

Vascular endothelial growth factor (VEGF) signaling promotes Snail-1 activity by suppression of GSK3-β [80], and results in increased levels of *Snail-1*, *Snail-2*, and *Twist* [81]. Snail-1 can also activate the expression of VEGF [82]. In summary, RTK signaling is important for many EMTs.

NOTCH PATHWAY

The Notch signaling family also regulates EMTs. When the Notch receptor is activated by its ligand Delta, an intracellular portion of the Notch receptor ligand is cleaved and transported to the nucleus where it regulates target genes. Notch1 is required for cardiac endothelial cells to undergo an EMT to make cardiac cushions, and the role of Notch may be to make cells competent to respond to TGF-β2 [83]. In the avian neural crest EMT, Notch signaling is required for the induction and/or maintenance of *BMP4* expression [84]. Similarly, Notch signaling is required for the TGF-β-induced EMT of epithelial cell lines [85], and Notch promotes *Snail-2* expression in cardiac cushion cells [86] and cultured cells [87].

HEDGEHOG PATHWAY

The hedgehog pathway is also involved in EMTs. Metastatic prostate cancer cells express high levels of hedgehog and *Snail-1*. If prostate cancer cell lines are treated with the hedgehog pathway inhibitor, cyclopamine, levels of *Snail-1* are decreased. If the hedgehog-activated transcription factor, Gli, is misexpressed, *Snail-1* expression increases [88].

Additional signaling pathways

Other signaling pathways that activate EMTs include inflammatory signaling molecules, lipid hormones, ROS species, and hypoxia. Interleukin-6 (inflammatory and immune response) can promote Snail-1 expression in breast cancer cells [89], and Snail-1 in turn can activate Il-6 expression [90], providing a link between inflammation and EMTs [91]. The lipid hormone prostaglandin E2 (PGE2) induces Zeb1 and Snail activity in lung cancer cells [92], and Snail-1 can also induce PGE2 expression [93]. ROS species can also activate EMTs by PKC and MAPK signaling [2]. Hypoxia is important for initiating EMTs during development [94] and disease [91], often through hypoxia-inducible factor-1 (HIF-1), which directly activates *Twist* expression [95]. Hypoxia also activates lysyl oxidases (LOX), which stabilize Snail-1 expression [1] by inhibiting GSK-3β activity [96].

In addition to diffusible signaling molecules, extracellular matrix molecules also regulate EMTs or METs. This was first dramatically demonstrated when lens or thyroid epithelium was embedded in collagen gels, and then promptly underwent an EMT [5]. Integrin signaling appears to be important in this process [97], and involves ILK mediated activation of NF-κB, Snail-1, and Lef-1. Other ECM components that regulate EMTs include hyaluronan [98], the gamma-2 chain of laminin 5 [99], periostin, and podoplanin [1]. In summary, a variety of diffusible signals and ECM components can stimulate EMTs or METs.

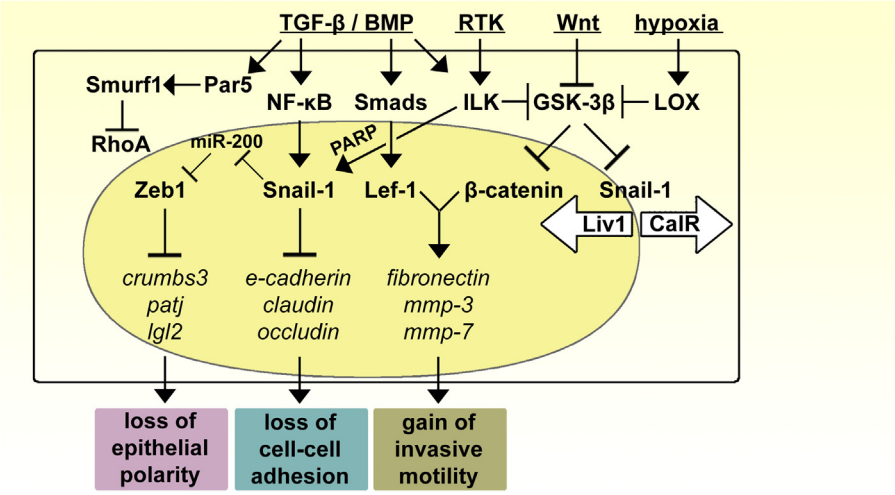

FIGURE 8.2
Induction of an EMT. This figure summarizes some of the important molecular pathways that bring about an EMT. Many of the signaling pathways converge on the activation of Snail-1 and nuclear β-catenin signaling to change gene expression, which results in the loss of epithelial cell polarity, the loss of cell-cell adhesion, and increased invasive cell motility.

A model for EMT induction

Many of the experimental studies on EMT mechanisms focus on one small part of the entire EMT process, and while great progress has been made in discovering EMT pathways, the entire EMT signaling network is still incomplete. The diagram (see Fig. 8.2) summarizes many of the various signaling mechanisms, although in actuality only a few of the inductive pathways will be utilized for a particular EMT. From experimental evidence to date, it appears that many of the EMT signaling pathways converge on ILK, the inhibition of GSK-3β, and stimulation of nuclear β-catenin signaling to activate Snail and LEF/TCF transcription factors. Snail, Zeb and LEF/TCF transcription factors then act on a variety of targets to suppress cell-cell adhesion, induce changes in cell polarity, stimulate cell motility, and promote invasion of the basal lamina.

CONCLUSION

Over the past 30 years since the term 'EMT' was coined [100], important insights have been made in this rapidly expanding field of research. EMT and MET events occur during development, tissue repair, and disease, and many molecules that regulate the various EMTs or METs have been characterized, thanks in large part to the advent of cell culture models. However, the EMT regulatory network as a whole is still incomplete. The improved understanding of EMT and MET pathways in the future will lead to novel therapeutic targets for the treatment of disease and more effective strategies for tissue engineering.

CHAPTER 9

The Dynamics of Cell-ECM Interactions, with Implications for Tissue Engineering

M. Petreaca[1] and M. Martins-Green[2]

[2] Department of Cell Biology and Neuroscience, University of California, Riverside, California

INTRODUCTION

Historical background

In the first part of last century, the extracellular matrix (ECM) was thought to serve only as a structural support for tissues. However, in 1966, Hauschka and Konigsberg [1] showed that interstitial collagen promotes the conversion of myoblasts to myotubes, and, shortly thereafter it was shown that both collagen and glycosaminoglycans are crucial for salivary gland morphogenesis. Based upon these and other findings, in 1977, Hay put forth the idea that the ECM is an important component in embryonic inductions, a concept which suggested the presence of binding sites (receptors) for specific matrix molecules on the surface of cells [2]. The stage was then set for further investigations into the mechanisms by which ECM molecules influence cell behavior. Bissell and colleagues [3] proposed the model of 'dynamic reciprocity'. In this model, ECM molecules interact with receptors on the surface of cells which then transmit signals across the cell membrane to molecules in the cytoplasm; these signals initiate a cascade of events through the cytoskeleton into the nucleus, resulting in the expression of specific genes, whose products, in turn, affect the ECM in various ways. Through the years, it has become clear that cell-ECM interactions can directly regulate cell adhesion, migration, growth, differentiation, and apoptosis, can also modulate the activities of cytokines and growth factors, and directly or indirectly activate intracellular signaling.

ECM composition

The extracellular microenvironment contains both traditional structural matrix components, such as hyaluronic acid, proteoglycans, collagens, glycosaminoglycans, and elastins, and non-structural matricellular proteins, including secreted protein acidic and rich in cysteine (SPARC), tenascin, osteopontin, and thrombospondins. The distribution and organization of these molecules is not static, but varies from tissue to tissue and, during development, from stage to stage, which has significant implications for tissue function. For example, mesenchymal cells are immersed in an interstitial matrix that confers specific biomechanical and

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00009-4

functional properties to connective tissue [4], whereas epithelial and endothelial cells contact a specialized matrix, the basement membrane, via their basal surfaces only, conferring mechanical strength and specific physiological properties to the epithelia [5]. This diversity of composition, organization, and distribution of ECM results not only from differential gene expression of the various molecules in specific tissues, but also from the existence of differential splicing and post-translational modifications of those molecules. For example, alternative splicing may change the binding potential of proteins to other matrix molecules or to their receptors, variations in glycosylation can lead to changes in cell adhesion and migration, and proteolytic cleavage can generate fragments with diverse biological functions [6–8].

The ECM harbors many non-matrix proteins, including growth factors, cytokines, and matrix-degrading enzymes and their inhibitors. Tissue-specific and developmental-stage-specific variation in matrix composition may determine the presence and localization of associated growth factors and cytokines. ECM molecules can influence the local concentration and biological activity of growth factors and cytokines by regulating their diffusion from their sites of origin, by protecting them from degradation, by presenting them more efficiently to their receptors, and by altering levels of their receptors [9–13]. Growth factor binding to intact ECM molecules or matrix fragments may also have inhibitory effects on growth factor signaling, by decreasing growth factor synthesis, impairing the interaction of these factors with their receptors, and/or decreasing levels of their receptors [7,12,14].

ECM/growth factor interactions can also involve the ability of specific domains of ECM molecules (e.g., laminin-332, tenascin-C, thrombospondin, and decorin) to activate growth factor receptors [15]. The EGF-like repeats of laminin and tenascin-C bind and activate the EGFR [16–18]. In the case of laminin, the EGF-like repeats interact with EGFR following their release by MMP-mediated proteolysis whereas tenascin-C repeats are thought to bind EGFR in the context of the full-length protein [17,18]. Decorin also binds and activates EGFR, although this binding occurs via leucine-rich repeats rather than EGF-like repeats [19]. In contrast, the EGF-like repeats of thrombospondin 1 appear to activate the EGFR in an indirect, MMP9-dependent manner, likely via MMP9-mediated release of heparin-binding EGF (HB-EGF) [20]. The ability of ECM molecules to activate growth factor receptors may facilitate a stable signaling environment for the associated cells due to the inability for the ligand to either diffuse or be internalized, thus serving as a long-term pro-migratory and/or pro-proliferative signal [15].

Receptors for ECM molecules

Integrins, a family of heterodimeric transmembrane proteins composed of α and β subunits, were the first ECM receptors to be identified. At least 18 α and 8 β subunits have been identified that pair in various combinations to yield 24 separate heterodimers, many of which recognize specific sequences on the ECM molecules (Fig. 9.1 [21]). Some integrin heterodimers exhibit a high degree of ligand specificity, while others are able to interact with a variety of epitopes (Fig. 9.1), facilitating plasticity and redundancy in specific systems [22]. Although the α and β subunits of integrins are unrelated, there is 40–50% homology within each subunit with the highest divergence in the intracellular domain of the α subunit. Apart from integrin β_4, the integrins have large extracellular domains and very small intracellular domains. Despite the small size of the cytoplasmic domains, integrins are able to bind to a variety of intracellular proteins, facilitating their interactions with the cytoskeleton and with signal transduction pathways [23].

Transmembrane proteoglycans, including syndecans, a receptor for hyaluronan mediated motility (RHAMM), and CD44, can also serve as receptors for ECM molecules, including collagen, fibronectin, laminin, and hyaluronan [21]. Syndecans 1–4, for example, mediate cell-ECM interactions via chondroitin- and heparan sulfate glycosaminoglycans, whose

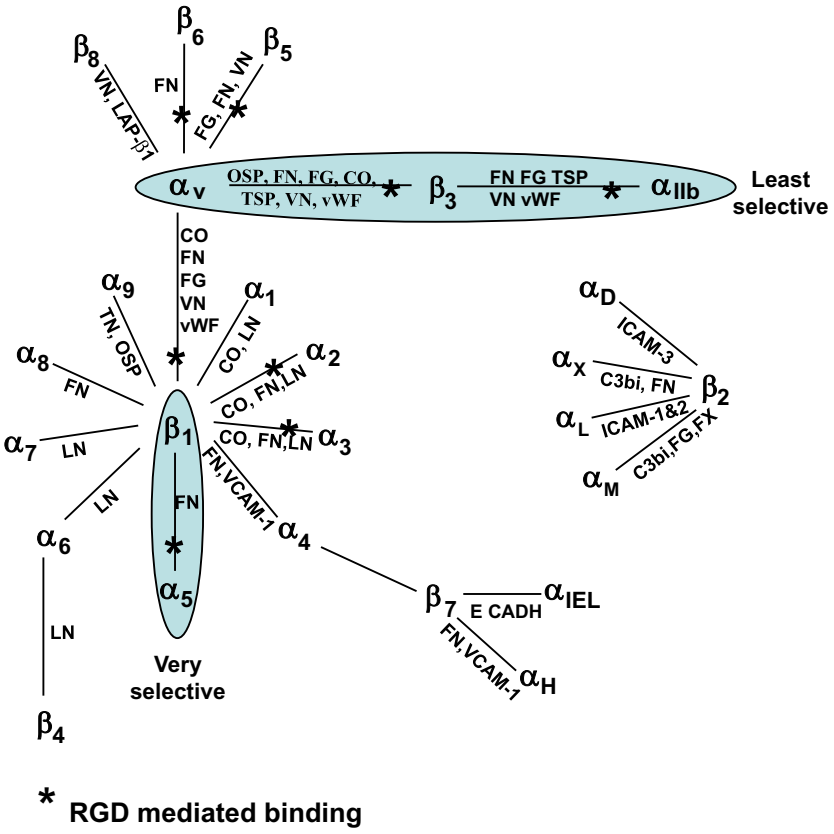

FIGURE 9.1

Members of the integrin family of ECM receptors and their respective ligands. These heterodimeric receptors are composed of one α and one β subunit, and are capable of binding a variety of ligands, including Ig superfamily cell adhesion molecules, complement factors, and clotting factors in addition to ECM molecules. Cell-cell adhesion is largely mediated through integrin heterodimers containing the β_2 subunits, while cell-matrix adhesion is mediated primarily via integrin heterodimers containing the β_1 and β_3 subunits. In general, the β_1 integrins interact with ligands found in the connective tissue matrix, including laminin, fibronectin, and collagen, whereas the β_3 integrins interact with vascular ligands, including thrombospondin, vitronectin, fibrinogen, and von Willebrand factor. Abbreviations: CO, collagens; C3bi, complement component; FG, fibrinogen; FN, fibronectin; FX, Factor X; ICAM-1, intercellular adhesion molecule-1; ICAM-2, intercellular adhesion molecule-2; ICAM-3, intercellular adhesion molecule-3; LN, laminin; OSP, osteopontin; TN, tenascin; TSP, thrombospondin; VCAM-1, vascular cell adhesion molecule-1; VN, vitronectin; vWF, von Willebrand factor.

composition varies based upon the type of syndecan and the tissue in which it is expressed. These differential glycosaminoglycan modifications alter the binding capacity of particular ligands, such as fibronectin and tenascin [24]. The short cytoplasmic domains of syndecans can interact with signaling proteins and the cytoskeleton, and thereby induce signal transduction upon binding to their ECM ligands, resulting in changes in cell adhesion and migration [24,25]. In addition to syndecan's function as a matrix receptor, the protein core can bind and activate some integrins directly, and activate other integrins indirectly, by facilitating their interactions with the matrix.

Another proteoglycan receptor, CD44, undergoes tissue-specific splicing and glycosylation to yield multiple isoforms [26]. CD44 has multiple ligands, including collagen IV, collagen XIV, fibronectin, osteopontin, and laminin among others, in addition to its primary ligand, hyaluronan [27]. CD44 can also interact with another hyaluronan receptor, RHAMM [27]. RHAMM, which is not an integral membrane protein, must bind transmembrane protein(s), such as CD44, integrins, and/or receptor tyrosine kinases, to transmit the signal from hyaluronan to intracellular signaling proteins [27,28]. Hyaluronan is present in most tissues in a high molecular weight, native form, but can be cleaved by various enzymes to generate lower molecular weight fragments; this cleavage is frequently associated with tissue damage. The native and cleaved forms of hyaluronan elicit different cellular responses, potentially due to differential receptor selectivity. CD44 binds more stably to high molecular weight hyaluronan than low molecular weight hyaluronan fragments [29,30]. In contrast, hyaluronan fragments, but not the native high molecular weight form, bind and activate toll-like receptors (TLRs), strongly suggesting that the fragments function as 'danger signals' that sense tissue damage and induce inflammatory responses [26,31].

Additional extracellular matrix receptors have also been identified, including the elastin/laminin receptor (ELR), CD36, annexin II, and receptor tyrosine kinases. The ELR is a complex

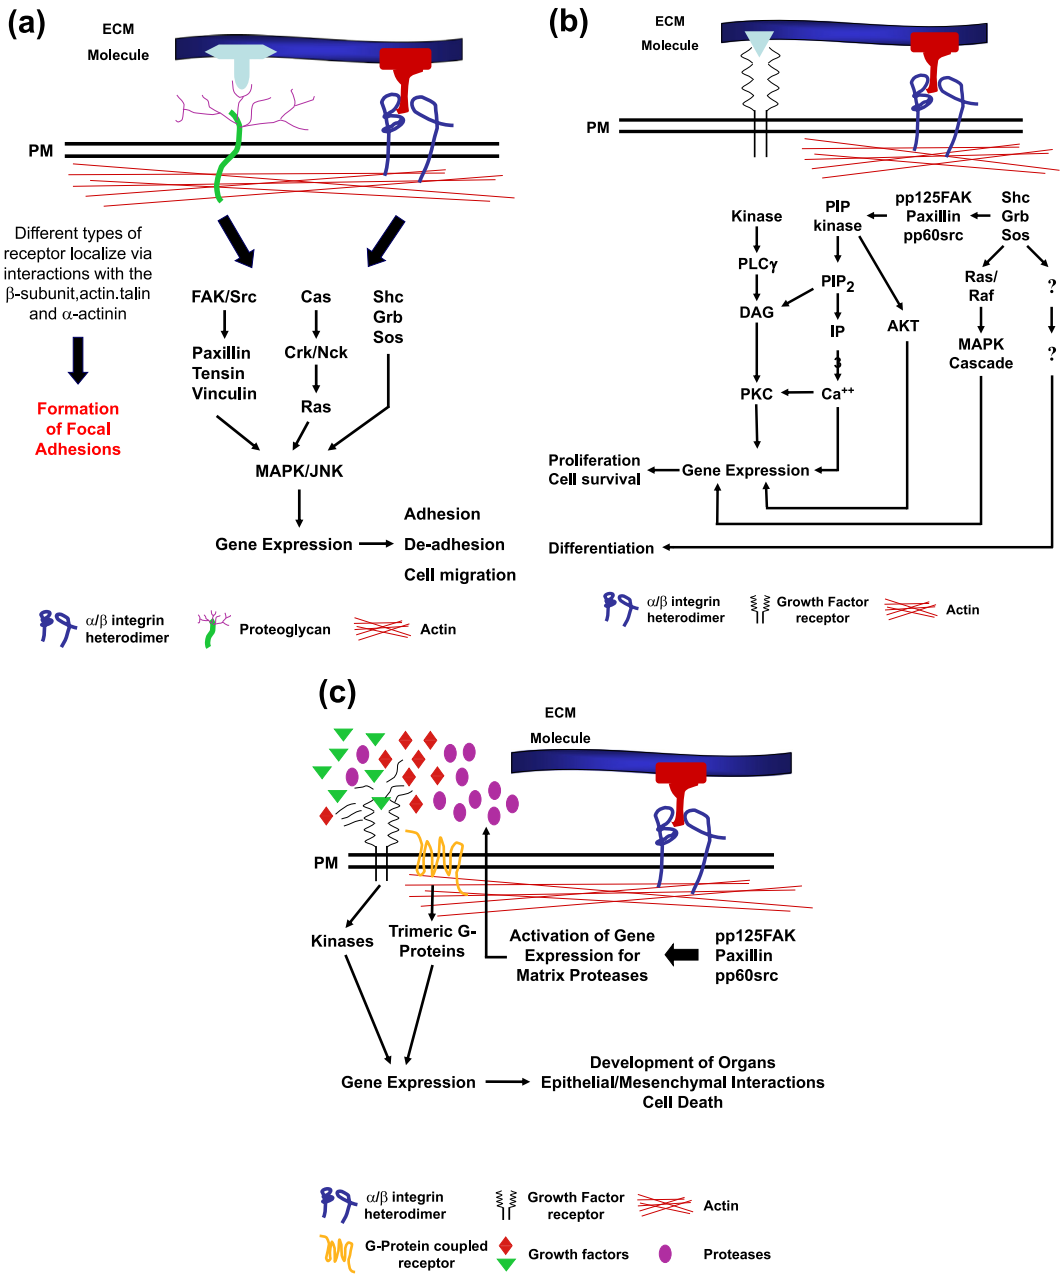

FIGURE 9.2

Schematic diagram of cell-ECM interactions present during healing and regenerative responses. Type I (a), type II (b) and type III (c). Such interactions between the ECM receptors and their respective ligands initiate signal transduction cascades culminating in a variety of cellular events important in repair and regeneration, including changes in cellular adhesion and migration and altered rates of proliferation and apoptosis. The presence and/or extent of such changes may influence the balance of repair and regenerative responses to favor one outcome over another; thus, interventions that alter ECM signaling events may shift this balance to favor tissue regeneration and thus decrease scarring.

of three proteins, including neuraminidase 1, cathepsin A, and the elastin-binding protein (EBP). The EBP binds specifically to the GXXPG sequence found in elastin, fibrillin, laminin, and fragments of these matrix molecules, and is critical for elastin deposition [32,33]. The ELR can also bind to the YIGSR sequence in the β1 chain of laminin-111 [34]. Elastin-derived peptides generated by proteases activated in response to tissue injury can promote proliferation and/or migration of fibroblasts, epithelial/endothelial cells, and monocytes downstream of the ELR [32]. These effects suggest that elastin-derived peptides are able to

promote wound healing; indeed, these peptides enhance the healing of burn wounds when used in conjunction with more conventional treatments [35].

CD36 can also function as a matrix receptor, despite its better-known role as a scavenger receptor, binding thrombospondin, collagen I, and collagen V [36]. In endothelial cells, thrombospondin binding to CD36 induces apoptosis, and is thus anti-angiogenic *in vivo* [37,38]. Another cell surface receptor, annexin II, is known to interact with alternative splice variants of tenascin-C, and mediates the cellular responses to these various forms of tenascin-C [39]. Tyrosine kinase receptors, including the EGFR and the discoidin domain receptors DDR1 and DDR2, can also function as matrix receptors. The EGFR can be activated by EGF-like domains or by MMP-mediated release of HB-EGF (see above), while DDR1 and DDR2 serve as collagen receptors [40]. Unlike most other receptor tyrosine kinases, which are activated by dimerization, DDR1 and DDR2 exist as constitutive homodimers, suggesting an alternative mechanism of activation [40]. Upon ligand binding, the DDRs undergo autophosphorylation and induce multiple downstream signaling pathways that ultimately alter cell adhesion and migration [40]. Several studies have suggested various roles for the DDR receptors in ECM remodeling. In smooth muscle cells, over-expression of DDR reduces the expression of several matrix molecules and receptors, including collagen, syndecan-1, and integrin α_3, while increasing MMP activity, resulting in degradation of collagen and elastin [41]. However, inhibition of DDR signaling in fibroblasts decreased collagen synthesis, suggesting that DDR may exert cell-type-specific effects on matrix deposition and remodeling [42,43].

Below, we will first discuss selected examples that illustrate the dynamics of cell-ECM interactions during development and wound healing, as well as the potential mechanisms involved in the signal transduction pathways initiated by these interactions. Finally, we will discuss the implications of cell-ECM interactions in tissue engineering.

CELL-ECM INTERACTIONS

Multiple biological processes, including those relevant to development and wound healing, require both interactions between cells and their environment and modulation of such interactions. During development, the cellular crosstalk with the surrounding extracellular matrix promotes the formation of patterns, the development of form (morphogenesis), and the acquisition and maintenance of differentiated phenotypes during embryogenesis. Similarly, during wound healing these interactions contribute to the processes of clot formation, inflammation, granulation tissue development, and remodeling. As outlined below, the current body of research in the fields of both embryogenesis and wound healing implicates multiple cellular behaviors, including cell adhesion/de-adhesion, migration, proliferation, differentiation and apoptosis, in these critical events.

Development

ADHESION AND MIGRATION

Today, there is a vast body of experimental evidence that demonstrates the direct participation of ECM in cell adhesion and migration, but some of the most compelling experiments came from studies in gastrulation, migration of neural crest cells (NCC), angiogenesis, and epithelial organ formation. Cell interactions with fibronectin are important during gastrulation; inhibition of fibronectin-integrin interactions in amphibian embryos by the introduction of blocking antibodies or RGD-containing peptides into their blastocoel cavities, which compete with integrins for ECM binding and disrupt normal cell movement leading to abnormal development [44]. Similarly, introduction of recombinant fibronectin lacking the RGD motif perturbs amphibian gastrulation [45]. These effects are not unique to fibronectin, as they can also be introduced by manipulation of other molecules, such as hyaluronan and heparan sulfate proteoglycans. Inhibition of hyaluronan synthesis in zebrafish embryos

interferes with cell movements in gastrulation, potentially due to a defect in Rac1 activation, as expression of constitutively active Rac rescued the observed migratory defects [46]. In the case of HSPG, degradation of HSPG by injection of the blastocoel with heparinitase interferes with gastrulation [47]. More recent studies suggest that the interaction between HSPG and fibronectin is critical for gastrulation. Binding of fibronectin to HSPG causes a conformational change in fibronectin, exposing growth factor binding sites that then bind PDGF-AA, generating a stable PDGF gradient that promotes the directional cell migration that is critical for gastrulation [48]. HSPGs are also necessary for FGF signaling during gastrulation, as inhibition of HSPG synthesis alters FGF localization, inhibits FGF signaling, and arrests embryonic development at gastrulation [49,50].

Cell-matrix interactions are also important for the migration of NCC, which develop in the dorsal portion of the neural tube just after closure of the tube, de-adhering from each other and then migrating extensively throughout the embryo in ECM-filled spaces, giving rise to a variety of phenotypes. The importance of cell-ECM interactions in NCC migration is supported by studies performed in the white mutant of Mexican axolotl embryos. The NCC that give rise to pigment cells fail to emigrate from the neural tube in these embryos, but when microcarriers containing subepidermal ECM from normal embryos are implanted into the appropriate area in these mutants, the NCC pigment cell precursors emigrate normally [51]. Laminin and fibronectin, the latter of which appears between chick NCC just prior to their emigration from the neural tube [52], play particularly critical roles in this process. Inhibition of fibronectin, laminin-111 (laminin-1), laminin-411 (laminin-8), or their integrin receptors using function-blocking antibodies, competing peptides, or antisense RNA prevents NCC migration, while exogenous laminin or fibronectin are sufficient to induce premature NCC migration [51,53]. More recent studies have identified different subsets of NCC, which may exhibit different responses to specific matrix molecules. For example, cranial NCC do not migrate in response to fibronectin, but do migrate on laminin [54,55]. Matrix remodeling may also contribute to NCC migration, as the matrix-remodeling protease MMP-9 is also required for NCC de-adhesion and migration, while exogenous MMP-9 induced premature de-adhesion and migration [56]. The role of MMP-9 in de-adhesion may be related to its ability to cleave the cell-cell adhesion molecule N-cadherin, while its role in migration may involve laminin degradation [56]. Proteoglycans also participate in the NCC migration process. Aggrecan, a proteoglycan that predominates in the notochord and cartilage tissue, inhibits NCC migration and may thus delimit NCC migration pathways [51]. The chondroitin sulfate proteoglycan versican may play a similar inhibitory role in NCC migration [57]. In contrast, syndecan-4 is not required for cell migration, but is necessary for directional migration. In conjunction with a non-canonical Wnt pathway, syndecan-4 inhibits Rac at the rear of the cell, restricting Rac activity to the leading edge of the migrating cell and facilitating directional migration [58].

Endothelial cell interactions with ECM molecules and the type and conformation of the matrix are also crucial in cell adhesion and migration during angiogenesis, a process in which new blood vessels form from pre-existing vessels [59]. Early indications of the role of ECM in angiogenesis were observed when human umbilical vein endothelial cells (HUVEC) were cultured on matrigel, a matrix synthesized by Engelbreth-Holm-Swarm (EHS) tumors. This specialized matrix has many of the properties of basement membrane; it consists of large amounts of laminin, as well as collagen IV, entactin/nidogen, and proteoglycans. When HUVEC are cultured on matrigel for 12 hours, they migrate and form tube-like structures. In contrast, when these cells are cultured with collagen I, they only form tube-like structures after they are maintained *inside* the gels for one week, at which time the cells have secreted their own basement membrane molecules [60]. The observation that tube formation occurs more rapidly on matrigel than within collagen gels strongly suggested an important role for one or more of the matrix molecules present within the basement membrane in the development of the capillary-like endothelial tubes. Indeed, laminin-111, the predominant matrix

molecule in matrigel, was later shown to participate in endothelial tube formation and angiogenesis. Purified or recombinant laminin-111 induce cell adhesion, migration, and tube formation *in vitro* and angiogenesis *in vivo*, while a mutation in laminin $\alpha 1$ leads to defective vessel formation [61]. Furthermore, studies in integrin α_7-deficient mice suggest that the laminin receptor integrin $\alpha_7\beta_1$ is necessary for appropriate pericyte interactions with blood vessels, and is thus important in vessel maturation and stability [62].

Recent studies have used knockout mice to implicate a number of ECM molecules in addition to laminin-111 in developmental blood vessel formation and maturation, including laminin $\alpha 4$, fibronectin, collagen IV, and the HSPG perlecan [59,63]. Mice deficient in laminin $\alpha 4$, fibronectin, or collagen IV exhibit defects in basement membrane formation, a process known to be critical in vessel maturation and stability, while the basement membranes in mice lacking perlecan form normally but have decreased ability to withstand mechanical stress [63,64]. Several integrin knockouts also exhibit defects in angiogenesis and vessel maturation. Like fibronectin, the fibronectin receptor integrin $\alpha_5\beta_1$ is necessary for angiogenesis, as shown by substantial angiogenesis defects in integrin α_5 and integrin β_1 endothelial cell-specific knockouts [62]. Abnormal pericyte-blood vessel interactions in integrin α_4 −deficient animals suggest the importance of integrin $\alpha_4\beta_1$ in this process, although in this case, the binding of this integrin to VCAM may be more important than its binding to fibronectin [61].

Some of the ECM effects on angiogenesis involve matrix cooperation with growth factors, such as vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF). VEGF and PDGF interact with HSPG, which can sequester them until their release by proteases, limit their diffusion, and/or function as co-receptors to promote receptor binding and activation [9]. Binding of VEGF to HSPG appears to be important in its localization during development. In mouse embryos, sole expression of a VEGF isoform that lacks the heparin-binding domain, VEGF121, increases diffusion of VEGF from the site of secretion and decreases blood vessel branching. This altered vascular patterning appears to result from impaired endothelial cell migration, as shown by decreased filopodia formation in the migrating 'tip cell' of nascent sprouts [65]. In embryos solely expressing the HSPG-binding VEGF isoform, VEGF188, branching of the blood vessels and filopodia formation by endothelial tip cells were increased when compared with wild type [65]. HSPG are also important for vessel stability and maturation, as HSPG are required for PDGF-BB-induced signaling, which, in turn, is important for pericyte migration and interaction with nascent blood vessels [65].

In contrast to the pro-angiogenic activities of many matrix molecules, fragments generated by their proteolysis can exert anti-angiogenic effects. The YIGSR peptide derived from laminin $\beta 1$, which binds the ELR rather than an integrin, prevents endothelial cell migration and angiogenesis [61]. YIGSR binding to the ELR promotes laminin cleavage by cathepsin-B [34]. This cleavage could reveal cryptic binding sites on laminin, altering its ability to bind specific receptors, leading to changes in cell signaling that, in turn, inhibit angiogenesis [61]. Another possibility is that the YIGSR peptides exert anti-angiogenic properties due to competition for receptor binding with the intact laminin present *in vivo*. Indeed, if YIGSR peptides can successfully compete with laminin, the displacement of the YIGSR sequence in the intact laminin molecule by soluble YIGSR peptides would alter the presentation of the ligand to its receptor, resulting in changes in mechanical resistance that alter signaling events downstream of the receptor, yielding different cellular responses. A similar hypothesis has recently been proposed for the interactions of integrins with soluble versus intact ligands [66]. Many soluble integrin ligands generated through proteolytic activity are anti-angiogenic, such as tumstatin and arresten (derived from collagen IV), endostatin (derived from collagen XVIII), and endorepellin (derived from perlecan), although their contribution to developmental angiogenesis remains unclear [7]. Although the mechanisms generating different cellular outcomes are not completely understood, the fact that soluble and intact ECM receptor ligands may, at times, lead to alternative outcomes is likely of importance *in vivo*

following matrix degradation. During angiogenesis, endothelial cell migration and invasion into surrounding tissues is accompanied by the activation of matrix-degrading enzymes, which then cleave the matrix and release both matrix-bound growth factors as well as ECM fragments, providing additional angiogenic or anti-angiogenic cues to further influence the process [10]. As such, matrix molecules that initially facilitate angiogenesis may be proteolytically cleaved to create anti-angiogenic matrix fragments, preventing additional blood vessel formation and/or resulting in vessel maturation. Thus, the temporal and spatial production and cleavage of matrix molecules may have important consequences for tissue homeostasis.

PROLIFERATION

Certain cell-ECM interactions modulate cell proliferation, with some matrix molecules inducing and others inhibiting proliferation. Tenascin-C stimulates cell proliferation *in vitro* via its EGF-like repeats, which bind and activate the EGFR [17]. Similarly, the EGF-like repeats of laminin stimulate proliferation of a variety of different cell lines, likely via EGFR activation [18]. Some of the ECM effects on cell proliferation involve matrix cooperation with growth factors. As mentioned above, under migration/adhesion, binding of growth factors to matrix molecules can affect their interactions with their receptors, limit their diffusion and/or sequester them until protease-mediated release. Several matrix-associated growth factors, including HB-EGF and TGF−β, can regulate cell proliferation during development.

Several studies have suggested that HSPG-associated molecules may regulate the proliferation of vascular smooth muscle cells (VSMC). Conditioned medium of aortic endothelial cells inhibits FGF-induced VSMC proliferation an effect that is abolished by pre-treatment with heparinase but not with proteases [67]. One possible explanation for this result is that heparan-type molecules may directly inhibit aortic VSMC proliferation. However, it is also possible that heparinase treatment may release pro-proliferative molecules interacting with heparin or heparan sulfate, thus allowing these factors to interact with their receptors and either promote proliferation or block any anti-proliferative effects. One such mitogenic heparin-binding ECM molecule is HB-EGF, which is known to promote VSMC proliferation *in vitro*, in cultured cells [68]. HB-EGF appears to regulate proliferation of additional mesenchymal cell types during development; a mouse embryo expressing of a mutant HB-EGF that could not be cleaved and released by HSPG showed defects resembling the HB-EGF knockout, suggesting that HB-EGF release is necessary for its function [69]. In contrast, embryos expressing a soluble version of HB-EGF that could not bind HSPG showed abnormal proliferation of multiple cell types, suggesting a role for soluble, and thus active, HB-EGF in regulating proliferation of these cell types during development [69].

Another heparin-binding ECM molecule that could induce VSMC proliferation is thrombospondin, which is known to exert its mitogenic activities on VSMC via its amino terminal heparin-binding domain [70,71]. Heparin blocks both thrombospondin binding to smooth muscle cells and its mitogenic effects [70]. These results suggest that interactions between heparin and thrombospondin may interfere with thrombospondin-induced smooth muscle cell proliferation, and that the observed increases in VSMC proliferation following heparinase treatment mentioned previously may result, at least in part, from the removal of such inhibitory interactions.

The effects of heparin on VSMC may also result from its regulation of TGF-β, an inhibitor of VSMC proliferation; heparin increases TGF-β activation, and heparin-mediated anti-proliferative effects are blocked by addition of a TGF-β antibody [71]. As such, heparinase treatment may prevent TGF-β activation, abolishing the anti-proliferative effects. To complicate matters further, thrombospondin can promote TGF-β activation as well [9], although the importance of thrombospondin binding to HSPG in TGF-β activation is unclear. However, if heparin's effects are exclusively mediated by the inhibition of HB-EGF or thrombospondin and/or activation of TGF-β, one would expect that treatment of the endothelial cell

conditioned medium with proteases should also eliminate the anti-proliferative effect. As the protease treatment does not prevent these effects, it is likely that heparin-like molecules also have a direct anti-proliferative effect [67].

TGFβ also cooperates with the ECM in the early developmental stages of the mammary gland during puberty [72]. During this period, inductive events take place between the epithelium and the surrounding mesenchyme that are mediated by the basement membrane (basal lamina and closely associated ECM molecules) and which play an important role in epithelial proliferation during branching of the gland. Endogenous TGFβ produced by the ductal epithelium and surrounding mesenchyme forms complexes with mature periductal ECM [73]. This TGF-β may participate in stabilizing the epithelium by stimulating expression of matrix molecules, by inhibiting cell proliferation, and/or by inhibiting matrix-degrading enzymes. In support of this possibility, the mammary gland epithelial cells in transgenic mice expressing a kinase-deficient TGF-β receptor showed excessive proliferation, whereas elevation of TGF-β decreased cell proliferation and increased matrix deposition [72]. In the branching areas, TGFβ is absent from newly synthesized ECM; thus, its inhibitory effects on epithelial cell proliferation and on production of matrix-degrading enzymes do not occur, allowing the basement membrane to undergo remodeling.

Along with the *in vivo* studies described above, *in vitro* studies using cultured cells suggest that various matrix molecules inhibit cell proliferation. For example, normal human breast cells do not growth arrest when cultured on plastic, but do so if grown in a basement membrane matrix [74]. More recent studies have shown that laminin-111 is particularly important in this inhibition of proliferation, as cells plated on this matrix molecule also stop dividing [75]. Laminin appears to suppress breast epithelial cell proliferation via expression of Id-2, a transcriptional regulator that binds and inhibits basic helix-loop-helix (HLH) transcription factors, leading to growth arrest of this cell type [76].

DIFFERENTIATION

Matrix molecules are critical in regulating the differentiation of keratinocytes, hepatocytes, and mammary gland epithelium. Keratinocytes form the stratified epidermal layers of the skin. The basal layer is highly proliferative, does not express the markers for terminal differentiation, and is the only cell layer in contact with the basement membrane. As these cells divide, the daughter cells lose contact with the basement membrane, move up to the suprabasal layers, and begin to express differentiation markers such as involucrin and keratins 1 and 10 [77]. This suggests that physical interaction with the basement membrane represses differentiation of the basal keratinocytes. Early studies implicated fibronectin and β_1 integrins in preventing differentiation; however, the later studies showed that the keratinocytes of a conditional integrin β1 skin knockout mouse and those of mice deficient lacking various β_1-associated α subunits do not undergo premature terminal differentiation. Additional studies investigating the importance of basement membrane components and basal keratinocyte integrins have found that these matrix-integrin interactions are critical in cell adhesion (and migration during wound healing), but do not appear to play an important role in differentiation [77]. These results suggest that further studies are necessary to better understand the contribution of the basement membrane in differentiation.

In the mouse mammary gland, the basement membrane and its individual components, in conjunction with lactogenic hormones, are responsible for the induction of the differentiated phenotype of the epithelial cells. When mid-pregnant mammary epithelial cells are cultured on plastic, they do not express mammary-specific genes. However, when the same cells are plated and maintained on basement membrane components (EHS), they form alveolar-like structures and exhibit the fully differentiated phenotype with expression of the genes encoding milk proteins, such as β-casein [78]. Function-blocking antibodies and conditional knockouts found that laminin-111 is the ECM molecule present in EHS ultimately responsible for the

observed differentiation, and that integrins β_1 and α_6 are critical in maintaining the differentiated state [78]. One role of laminin-111 in this process is in establishing mammary epithelial cell polarity, which re-distributes the prolactin receptor to the apical surface of the epithelium and facilitates ligand binding, receptor activation, and signaling necessary to induce expression of β-casein [79]. ECM molecules also regulate expression of another milk protein, the whey acidic protein (WAP). EHS decreases the production of TGF-α by mammary gland epithelial cells; this increases WAP expression, which is otherwise inhibited by TGF-α [80]. WAP may then participate in the maintenance of mammary epithelial differentiation by inhibiting the activity of laminin-degrading enzymes [81].

APOPTOSIS

Programmed cell death occurs during embryogenesis of higher vertebrates in areas undergoing remodeling, such as in the development of the digits, palate, nervous system, in the positive selection of thymocytes in the thymus, during mammary gland involution, and during angiogenesis. For example, intact basement membrane molecules suppress apoptosis of mammary epithelial cells, whereas matrix fragments are thought to induce apoptosis during the involution of the mammary gland [78]. The numerous alveoli that produce milk during lactation regress and are resorbed during involution due to enzymatic degradation of alveolar basement membrane and programmed cell death [82,83]. During this involution, apoptosis appears to proceed in two distinct phases, an early phase characterized by increased levels of pro-inflammatory and apoptosis-associated proteins, including several members of the tumor necrosis factor (TNF) and TNF receptor superfamilies and caspases, including caspase 1 [84], a protein known to be important in promoting mammary epithelial cell apoptosis [85]. This is then followed by a later apoptotic phase in which cell-ECM interactions are altered due to matrix degradation, preventing pro-survival integrin signaling and resulting in apoptosis [86]. The importance of integrin signaling is underscored by experiments in which mammary epithelial cells undergo apoptosis when an antibody is used to disrupt interactions between α_1 integrin and its ECM ligands [85]. This later phase of matrix degradation and apoptosis may be regulated, at least in part, by decreased production of WAP, a milk protein that can inhibit the activity of proteases that cleave laminin [81]. Decreased production of WAP by dying or de-differentiated cells could relieve WAP-mediated protease inhibition, promoting protease activation and matrix degradation. This, in turn, would decrease the interaction of intact matrix molecules with integrins, decreasing pro-survival signaling; it is also possible that integrins could then interact with soluble matrix fragments, which is known to induce apoptosis in endothelial cells (see below) [66].

In endothelial cells, $\alpha_v\beta_3$ integrin interactions with ECM play a crucial role in their survival during embryonic angiogenesis. Disruption of these interactions with an antibody to $\alpha_v\beta_3$ inhibits the development of new blood vessels in the chorioallantoic membrane (CAM) by inducing endothelial cell apoptosis [87]. In contrast, $\alpha_v\beta_3$ binding to tumstatin, a proteolytic fragment of collagen IV, induces endothelial cell apoptosis, preventing angiogenesis and/or promoting vessel regression [62]. This interaction may promote apoptosis by interfering with normal integrin-ECM binding, thus removing a critical survival signal. Tumstatin may also promote apoptosis through a separate mechanism, such as via the recruitment and activation of caspase 8, as has been suggested previously for such soluble ligands [66]. Taken together, these findings suggest that disruption of cell-ECM interactions may lead to an increase in the expression or activation of pro-apoptotic molecules, and may also lead to the removal of pro-survival signals, which then directly or indirectly cause apoptosis.

Wound healing

ADHESION AND MIGRATION

Early in the wound healing process, blood components and tissue factors are released into the wounded area in response to tissue damage, promoting both the coagulation cascade and

platelet adhesion and activation, resulting in the formation of a clot consisting of platelets, cross-linked fibrin, fibronectin, and vitronectin, along with lesser amounts of SPARC, tenascin, and thrombospondin [88]. Activated platelets, along with degranulating mast cells, release a number of cytokines and growth factors important in initiating the next phase of wound healing, the inflammatory response, and in regulating the wound healing process. The fibrin-fibronectin clot has functions in addition to hemostasis, sequestering cytokines and growth factors while providing a temporary extracellular matrix that facilitates the adhesion and migration of multiple cell types, particularly leukocytes, into the wounded area [89].

Leukocyte adhesion, migration, and secretion of inflammatory mediators are regulated by their interactions with various ECM molecules [90]. After initial interactions between neutrophil and macrophage integrins with non-matrix molecules ICAM and VCAM, these leukocytes interact with chemoattractants associated with HSPG, matrix molecules in the endothelial basement membrane, and the fibrin-based provisional matrix [88]. HSPG binding to chemokines can create a stable gradient to promote leukocyte chemotaxis into the injured area. This HSPG chemokine binding is critical for appropriate leukocyte recruitment, as shown by their defective recruitment by mutant chemokines lacking the ability to bind glycosaminoglycans, in mice deficient in heparan sulfate biosynthesis, or in mice lacking syndecan-4 [91,92]. Leukocyte adhesion to and migration through the basement membrane and provisional matrix are also mediated by matrix-receptor interactions. Neutrophils bind several matrix molecules, including fibronectin, vitronectin, laminin-511 (laminin 10), and the small leucine-rich proteoglycan (SLRP) lumican, and actively secrete laminin-411 (laminin 8) [93,94]. Both laminin-411 and lumican are necessary for neutrophil extravasation, the former via integrin $\alpha_6\beta_1$ and the latter via β_1 integrin(s) [93,94]. A proteolytic fragment of laminin-511 also promotes neutrophil migration, suggesting a potential role of proteases in this process as well [93].

Interaction with matrix molecules in the provisional matrix can also affect inflammatory cell adhesion, migration, and behavior. Integrin $\alpha_M\beta_2$ expressed by various inflammatory cells interacts with fibrin, urokinase plasminogen activator (uPA), and thrombospondin 4, inducing inflammatory cell adhesion and migration [95]. Binding of $\alpha_M\beta_2$ to uPA also promotes plasmin activation and thus fibrin degradation and removal of the provisional matrix [95]. Interactions between integrin $\alpha_M\beta_2$ and its ligands also promote pro-inflammatory cytokine production; in monocytes, fibrin binding induces expression of pro-inflammatory cytokines and chemokines, including IL-1β, IL-6, TNF-α, MIP-1, MIP-2, and MCP-1, and thrombospondin-4 binding in neutrophils induces secretion of the chemokine IL-8 and the respiratory burst [95,96]. Similarly, tissue macrophages release pro-inflammatory cytokines after TLR4 binding to low molecular weight hyaluronic acid. Due to the ability of matrix-leukocyte interactions to regulate the inflammatory process, the types of ECM molecules present in the injured area may greatly affect the inflammatory phase of wound healing.

During the re-epithelialization phase of cutaneous wound healing, keratinocytes migrate beneath the fibrin-rich provisional matrix, likely due, at least in part, to the fact that these cells do not express the fibrin-interacting integrin $\alpha_V\beta_3$ [89]. The keratinocytes do express multiple receptors for fibronectin, collagen, tenascin, and vitronectin, including the integrins $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, $\alpha_5\beta_4$, and α_v, and these receptor-matrix interactions, along with the activity of several proteases, promote keratinocyte migration and subsequent wound closure [88]. Keratinocyte migration requires the synthesis and deposition of laminin-332 and its interaction with integrin $\alpha_3\beta_1$, initiating signaling leading to Rac activation and protrusion formation [97]. Protease activity is also important in keratinocyte migration, likely through the release of HB-EGF from HSPG, which then induces keratinocyte migration through the EGFR [88].

Interactions between epithelial cells and ECM are also critical in the closure of other types of epithelial wounds. After wounding, retinal pigment epithelial cells exhibit a sequential pattern

of ECM molecule deposition that is critical in the epithelial cell adhesion and migration associated with wound closure. Within 24 hours of wounding, these epithelial cells secrete fibronectin, followed shortly by laminin and collagen IV; if the cell adhesion to these ECM molecules is blocked with either cyclic peptides or specific antibodies, the epithelial cells fail to migrate and close the wound, underscoring the importance of such interactions in wound closure [98,99].

During later stages of wound healing, macrophages and fibroblasts in the injured area deposit embryonic-type cellular fibronectin, which is important in the generation of the granulation tissue, a temporary connective tissue consisting of multiple types of ECM molecules and newly-formed blood vessels [88]. The cellular fibronectin provides a substrate for the migration of endothelial cells into the granulation tissue, thus forming the wound vasculature, and also facilitates the recruitment of fibroblasts, myofibroblasts, and lymphocytes stimulated by a variety of chemotactic cytokines, or chemokines, that are produced by tissue fibroblasts and macrophages [88,100]. Many chemokines have been characterized in multiple species, including humans, other mammals, and even birds, and have been grouped into a large superfamily which is further subdivided based upon the position of the N-terminal cysteine residues [101]. These chemokines, along with cell-ECM interactions, are critical in the adhesion and chemotaxis/migration of the cells that ultimately enter the wounded area and generate the granulation tissue [88,100].

One prototypical chemokine, IL-8, has several functions that are important in wound healing. Many of these functions have been elucidated in studies performed in the chick model system using chicken IL-8 (cIL-8/cCAF) [102]. After wounding, fibroblasts in the injured area produce large quantities of cIL-8, most likely resulting from their stimulation by thrombin, a coagulation enzyme activated upon wounding that is known to induce fibroblasts to express and secrete cIL-8. The initial rapid increase in cIL-8 generates a gradient that chemoattracts neutrophils [102]. These cells, in turn, produce monocyte chemoattractant protein, a potent chemoattractant for monocytes, which differentiate into macrophages in the wound environment. In addition, thrombin is able to induce IL-8 expression in cultured macrophages [103]; this, along with the additional IL-8 secreted from the endothelial cells of the wound vasculature and bound to various matrix components of the granulation tissue, further increases the presence of IL-8 in the granulation tissue. Indeed, IL-8 participates in granulation tissue formation by stimulating angiogenesis and matrix deposition [100,102,104]; therefore IL-8 not only functions in the inflammatory phase of wound healing by serving as a leukocyte chemoattractant, but also plays an important role in granulation tissue formation.

Angiogenesis relies heavily upon cell-ECM interactions, as described in detail earlier (under 'Development'). The localization of the matrix molecules and the proteases that degrade them both have critical roles in this process. In some cases, interaction of an angiogenic factor or its receptor with a matrix molecule is important in ligand-receptor interactions and/or downstream signaling, whereas in others, matrix fragments signal differently from the parent matrix molecule [105]. As mentioned earlier, many growth factors, including VEGF, bind HSPG, which can alter their diffusion and presentation to their receptors [9]. In addition to HSPG, VEGF-VEGFR signaling is heavily influenced by the presence of specific matrix molecules and integrins. Integrin $\alpha_v\beta_3$ is important in VEGFR2 activation and VEGF-induced angiogenesis, and a $\alpha_v\beta_3$ ligand, vitronectin, promotes the interaction of this integrin with VEGFR2 and enhances VEGF-induced VEGFR2 signaling [106]. Fibronectin simultaneously binds VEGF and integrin $\alpha_5\beta_1$, promoting VEGF-induced endothelial cell migration [106]. VEGF can also bind integrin $\alpha_9\beta_1$ directly, promoting VEGFR2-mediated signaling and endothelial cell migration [107]. In contrast, collagen I binding to β_1 integrins inhibits signaling downstream of VEGFR2 [107]. Taken together, these results underscore the importance of the microenvironment in regulation of VEGF-induced angiogenesis.

During angiogenesis, protease activity is needed for the endothelial cells to degrade and then migrate through the basement membrane and surrounding connective tissue [105]. These proteases can regulate endothelial cell adhesion and migration during angiogenesis by releasing matrix-bound factors, as mentioned earlier, and also by generating functional matrix fragments and exposing previously concealed matricryptic sites [7]. Some of these 'matricryptins' promote cell migration and angiogenesis. For example, a matricryptic site in collagen IV exposed by MMP-9-mediated proteolysis changes integrin binding from $\alpha_1\beta_1$ to $\alpha_v\beta_3$, and blocking this site with an antibody or inhibiting integrin $\alpha_v\beta_3$ prevents endothelial cell adhesion and migration *in vitro* and angiogenesis *in vivo* [107]. Many other matricryptins inhibit angiogenesis. For example, endostatin and tumstatin, matricryptins derived from collagen XVIII and collagen IV, respectively, inhibit VEGF-induced endothelial cell migration. These molecules may exert their inhibitory effects by binding VEGFR2 (endostatin) and/or integrin $\alpha_v\beta_3$ (endostatin and tumstatin), both of which are essential for VEGF-induced cell migration and angiogenesis, thereby blocking signaling downstream of the individual receptor(s) and the substantial crosstalk that occurs between them [62].

PROLIFERATION

After wounding, the keratinocytes alter their proliferation and migration in order to close the wound, a process known as re-epithelialization. As this process occurs, the cells at the edge of the wound migrate, whereas the cells away from the wound proliferate in order to provide the additional cells needed to cover the wounded area. The proliferative state of these latter keratinocytes may be sustained by interactions with the ECM of the remaining basement membrane. Indeed, during the remodeling of normal skin, the proliferation of the basal layer of keratinocytes needed to replace the upper keratinocyte layers requires the presence of fibronectin in the epithelial basal lamina (see above). In addition, ECM derived from the basement membrane, when present in a dermal wound model, can maintain keratinocytes in a proliferative state for several days. It is likely that laminins-511 and -521 (laminins 10 and 11), in addition to fibronectin, participate in keratinocyte proliferation, as previous data indicates that these molecules can promote proliferation *in vitro* [108]. Further studies have suggested important roles for integrins in regulating keratinocyte proliferation, although the functions of specific integrins remain unclear. For example, expression of integrin α_9 is increased upon wounding, and keratinocytes in mice lacking epithelial integrin α_9 or β_1 exhibit reduced proliferation, suggesting a potential role for integrin $\alpha_9\beta_1$ in keratinocyte proliferation; however, re-epithelialization is not substantially affected in these animals [77]. In contrast, integrin $\alpha_v\beta_8$ is expressed specifically in non-proliferating suprabasal keratinocytes and not in the proliferating basal cells, suggesting a possible role in inhibiting keratinocyte proliferation [77].

While re-epithelialization progresses, the granulation tissue begins to form. This tissue is composed of ECM molecules, including embryonic fibronectin, type III collagen, type I collagen, and hyaluronic acid, along with multiple cell types, such as monocytes/macrophages, lymphocytes, fibroblasts, myofibroblasts, and the endothelial cells of the wound vasculature. Growth factors released by these cells and platelets cooperate with the aforementioned surrounding ECM molecules to provide pro-proliferative signals to the granulation tissue fibroblasts and endothelial cells. Endothelial cells proliferate during angiogenesis, a process that is dependent upon growth factors, such as FGFs and VEGFs, and their interactions with matrix molecules. Signaling induced by both FGFs and VEGFs is enhanced by HSPG, as discussed earlier. In addition, VEGF binding to fibronectin or tenascin enhances its effect on endothelial cell proliferation [9]. Furthermore, some growth factors appear to promote proliferation only when specific ECM molecules are present, as is seen in the fibronectin requirement for TGF-β1-mediated fibroblast proliferation [109]. In contrast, SPARC and thrombospondin inhibit proliferation induced by VEGF and bFGF, indicating that interactions between growth factors and ECM can also be inhibitory [14,110]. While ECM-growth factor

interactions can significantly impact cell proliferation, specific ECM molecules, such as laminin, also affect proliferation directly [61]. Previous studies suggest that the proliferative ability of laminin is mediated by its EGF-like domains, implicating EGFR activation in its pro-proliferative effects [21]. In addition, certain ECM molecules and/or proteolytic fragments can inhibit proliferation; SPARC and decorin, as well as peptides derived from SPARC, decorin, collagen IV (tumstatin), and collagen XVIII (endostatin) are anti-angiogenic due to their inhibitory effects on endothelial cell proliferation [7,14].

DIFFERENTIATION

As the granulation tissue forms, some of the fibroblasts within the wounded area differentiate into myofibroblasts, cells that express the protein α-smooth muscle actin (αSMA) and thus function similarly to smooth muscle cells; they also secrete a number of matrix molecules, including fibronectin and collagen I [111]. Myofibroblast differentiation is influenced by various matrix molecules, such as heparin, which decreases fibroblast proliferation while stimulating αSMA expression *in vitro* [112]. The effects of heparin on myofibroblast differentiation and αSMA expression likely result from the ability of heparin and heparan sulfate proteoglycans to interact with cytokines and/or growth factors like TGF-β1, which then modulate myofibroblast differentiation [113]. TGF-β1-induced differentiation also requires the ED-A-containing form of fibronectin and the binding of the ED-A domain to integrin $\alpha_4\beta_7$ [111,114]. Maintenance of myofibroblast differentiation is mediated by hyaluronan, as shown by reduced differentiation when hyaluronan synthesis is inhibited [115]. Interstitial collagens, in conjunction with mechanical tension, also participate in the differentiation process. Fibroblasts cultured on relaxed collagen gels fail to differentiate, whereas fibroblasts grown on stiffened collagen matrices exhibit myofibroblast characteristics [116]. In addition, increased myofibroblast differentiation is observed when splints are used to increase mechanical tension in wounds, suggesting a role for mechanical tension in myofibroblast differentiation *in vivo* [111]. Tensile stress may regulate cell signaling and cell-matrix interactions by revealing cryptic sites in intact matrix molecules; for example, the ED-A domain of fibronectin, which is necessary for TGF-β-induced myofibroblast differentiation, could be exposed by mechanical stress [116]. Tensile stress exerted on the cell by the matrix may also induce the formation of stress fibers that exert intracellular tension on the integrin, changing its conformation and strengthening its adhesion to the matrix, promoting downstream signaling [117].

APOPTOSIS

Late in the wound healing process, the granulation tissue undergoes remodeling to form scar tissue. This remodeling phase is characterized by decreased tissue cellularity due to the disappearance of multiple cell types, including fibroblasts, myofibroblasts, endothelial cells, and pericytes, and by the accumulation of ECM molecules, particularly interstitial collagens. The observed reduction in cell numbers during the remodeling phase occurs due to apoptosis; many of these apoptotic cells are endothelial cells and myofibroblasts, as shown by studies using *in situ* DNA fragment end-labeling in conjunction with transmission electron microscopy [118]. Myofibroblast apoptosis is regulated by mechanical tension; using a splint to maintain tension in a healing wound inhibits myofibroblast apoptosis, whereas the release of tension in this model promotes apoptosis [116]. Apoptosis of fibroblasts and myofibroblasts may be important in preventing excessive scarring and facilitating the resolution of wound healing. Indeed, there is a decreased apoptosis of these cells in keloids and hypertrophic scars, leading to increased matrix deposition and scarring [111]. In keloids, reduced apoptosis may result from p53 mutations or growth factor receptor over-expression [119–121]. In hypertrophic scars, however, the reduced apoptosis may result from increased expression of tissue transglutaminase, resulting in enhanced matrix degradation and diminished collagen contraction [122].

SIGNAL TRANSDUCTION EVENTS DURING CELL-ECM INTERACTIONS

As discussed above, ECM molecules are capable of interacting with a variety of receptors. Such interactions activate signal transduction pathways within the cell, altering levels of both gene expression and protein activation, thus ultimately changing outcomes in cell adhesion, migration, proliferation, differentiation, and death. The signaling pathways linked to these specific outcomes have been studied for many of the ligand-receptor interactions, particularly those involving integrins [10]. In the case of integrins, it is important to remember that these receptors can participate in both 'outside-in' and 'inside-out' signaling. Outside-in signaling occurs when an extracellular ligand binds the receptor and initiates intracellular signaling, and in inside-out signaling, intracellular signaling increases the affinity of the receptor for its ligand. Binding of the receptor to the ligand, in turn, initiates outside-in signaling. Unless otherwise indicated, the signaling events discussed below refer to outside-in signaling.

Based upon the many studies that investigate matrix-induced signaling, we postulate the existence of three categories of cell-ECM interactions, namely type I interactions that are involved in adhesion and migration, type II interactions involved in proliferation, differentiation, and survival, and type III interactions involved in apoptosis and epithelial-mesenchymal transition.

Type I interactions

These are generally mediated by integrin and proteoglycan receptors, and are important in the adhesion/de-adhesion processes that accompany cell migration. These interactions are exemplified by fibronectin-mediated cell migration, which occurs when this matrix molecule simultaneously binds integrins and proteoglycan receptors, the latter via its heparin-binding domain [123]. These receptors then co-localize and interact at cell adhesion sites, where the microfilaments interact with the cytoplasmic domain of integrin β_1 through the structural proteins talin and α-actinin and the signaling molecule paxillin, which interacts with focal adhesion tyrosine kinase (FAK) [124]. Binding of an integrin to its ligand triggers auto-phosphorylation of FAK on tyrosine 397; this then serves as the binding site for the SH2 domain of the c-Src tyrosine kinase. This kinase subsequently phosphorylates multiple proteins present in the focal adhesion plaques, including FAK itself at position 925, which increases its activity, and paxillin, tensin, vinculin, and $p130^{cas}$ [125]. FAK PY925 binds the Growth factor receptor-bound protein 2 (Grb2)/Son of Sevenless (Sos) complex, thus promoting the activation of Ras GTPase and the MAP kinase cascade, which may be involved in cell adhesion/de-adhesion and migration events [126]. Paxillin may also participate in integrin-mediated signaling and motility, as evidenced by the reduced migration and decreased phosphorylation/activation of various signaling molecules observed in paxillin-deficient fibroblasts, and the impaired migration seen in cells over-expressing a paxillin mutant unable to be phosphorylated by FAK/Src [127]. Both phosphorylated paxillin and p130Cas bind Crk, an adaptor protein bound to DOCK180, a guanine nucleotide exchange factor (GEF) that activates Rac1, while paxillin is also able to recruit another Rac1/Cdc42 GEF, β-PIX, thereby inducing lamellipodia formation and cell migration [125,128]. Src-mediated signaling also activates another Rac GEF, Vav2, along with a Rho GTPase activating protein (GAP) that inhibits RhoA. Interestingly, integrin-induced Src can phosphorylate and trans-activate the EGFR, leading to additional pro-migratory signaling [128].

The contribution of tensin to cell adhesion and motility is poorly understood, although it is known to interact with the cytoskeleton and various phosphorylated signaling molecules via its SH2 domain; therefore, tensin may facilitate various signaling events downstream of integrin ligation [129]. In cancer cells, tensin-1 interacts with a RhoGAP, and tensin mutations that blocked RhoGAP interaction decreased levels of Rho-GTP and reduced cell migration, suggesting a potential role in normal integrin-mediated signaling [130].

To this point, we have discussed the roles of FAK and Src in outside-in, traditional receptor-mediated signal transduction. However, these kinases can participate in inside-out signaling as well; FAK/Src signaling stimulates integrin activation, cell adhesion to matrix molecules, and focal adhesion strengthening [131]. Integrin activation and matrix binding then initiates outside-in signaling, promoting FAK/Src activity, suggesting a positive feedback loop of integrins and FAK/Src kinases that may facilitate directional migration.

Matrix receptors other than integrins, such as proteoglycans and DDR1, are also important in cell adhesion and migration. Syndecans can function as co-receptors, associating with matrix molecules and integrins to promote cell adhesion and migration [24]. Syndecan-4, for example, can bind the heparin-binding domain of fibronectin and the fibronectin receptor integrin $\alpha_5\beta_1$, leading to activation of PKC and downstream activation of Rac and inactivation of RhoA, promoting migration [24,128,132]. Following fibronectin binding, syndecan-4-induced PKC and RhoG promote integrin $\alpha_5\beta_1$ internalization, thus inhibiting integrin-mediated signaling [25]. Proteoglycan receptors other than syndecans induce cell migration following ligand binding. For example, hyaluronan binding to CD44 induces phosphorylation of its intracellular domain, resulting in fibroblast migration, as inhibition of CD44 with blocking antibodies or by expression of phosphorylation-deficient CD44 blocked hyaluronan-induced fibroblast migration [26]. RHAMM, another hyaluronan receptor, facilitates fibroblast migration by regulating ERK1/2 activation downstream of CD44, and in smooth muscle cells, hyaluronan induces cell migration downstream of RHAMM via PI3K and Rac [26].

The roles of DDR1/2 in cell migration are less clear. DDR1 activation by collagen inhibits epithelial cell adhesion and migration induced by integrin ligation, likely through inhibition of Cdc42 and recruitment of the phosphatase SHP-2 [40]. In contrast, collagen-induced fibroblast migration depends upon DDR2 and downstream activation of MMP-2 and Erk1/2 [133].

Type II interactions

These involve processes in which the matrix-receptor interactions, in conjunction with growth factor or cytokine receptors, affect proliferation, survival, differentiation, and/or maintenance of the differentiated phenotype. These cooperative effects may occur in a direct manner, for example, by the direct interaction of EGF-like repeats present in certain ECM molecules with the EGF receptor, thereby promoting cell proliferation [15,17]. Indirect cooperative effects are better understood at this time, particularly with regards to the anchorage dependence of cell growth. S-phase entry, even when growth factors are present, requires the interaction of cells with a substrate, while detachment of cells from matrix promotes anoikis, a type of apoptosis, underscoring the critical role of cell-ECM adhesion in cell survival and proliferation [124]. The pro-survival function of matrix interactions is mediated by Fak signaling. In fibroblasts, Fak/Src-induced p130CAS activity leads to the activation of Rac, as mentioned above, which then promotes cell survival and proliferation via the JNK pathway [125,134]. In epithelial cells, Fak/Src complexes promote cell survival through PI3K-induced Akt activation [135,136]. Signaling downstream of Akt then increases levels of anti-apoptotic Bcl family members while decreasing levels of pro-apoptotic Bcl family members, resulting in cell survival [135]. In addition to promoting cell survival, integrin signaling can promote cell proliferation, either alone or in conjunction with growth factor signaling. Integrin-induced activation of the Rac/JNK pathway can induce cell proliferation by stimulating expression of cyclin D and by promoting the degradation of p21, a cell cycle inhibitor [137,138]. ERK1/2, also MAP kinases, can be activated by integrin ligation, which promotes the activation of Fyn and its binding to the Shc adaptor protein, which then recruits Grb2/Sos and activates the Ras/ERK pathway, resulting in the phosphorylation of the transcription factor Elk-1 and the activation of genes important in cell cycle progression [124,137].

Integrin signaling can also induce cell proliferation in conjunction with growth factor receptor signaling [9]. Angiogenesis induced by the growth factors bFGF and VEGF requires the presence and activation of integrins $\alpha_v\beta_3$ and $\alpha_v\beta_5$, respectively [59]. In both cases, integrin signaling and FAK are necessary for activation of Erk1/2, but Erk1/2 activation by bFGF/$\alpha_v\beta_3$ is dependent upon Pak-1-induced Raf phosphorylation but not Ras, while Erk1/2 activation by VEGF/$\alpha_v\beta_5$ requires Ras [139]. Furthermore, cell-ECM interactions are critical for the efficient and prolonged activation of MAPK by growth factors, likely participating in MAPK-induced proliferation [140]. Cell-matrix interactions can also facilitate proliferation through transactivation of growth factor receptors, as in fibronectin-induced, Src-mediated EGFR activation [124]. This EGFR transactivation is required for fibronectin-induced Erk activation, regulating genes involved in cell cycle progression, including Rb and cyclin D; however, fibronectin-induced EGFR transactivation is not sufficient for cell division, but requires growth factor-induced signaling to induce expression of genes necessary for S phase [141].

Cell-matrix interactions can also regulate growth factor receptor signaling through integrin or matrix binding to growth factors or their receptors and by modulating downstream signaling [22]. Multiple VEGF isoforms bind and activate integrin $\alpha_9\beta_1$, which, along with VEGFR2, is necessary for VEGF-induced paxillin and Erk phosphorylation and angiogenesis [142]. Similarly, integrin $\alpha_v\beta_3$ interacts with both IGF-1 and FGF-1 and is required for proliferation induced by both growth factors [124]. Several growth factor receptors interact with integrins, including VEGFR2 and EGFR, and integrin-mediated adhesion can regulate growth factor-induced proliferation [124]. Growth factor signaling, in turn, can activate associated integrins and promote matrix adhesion. For example, VEGFR2 signaling induces phosphorylation of integrin β_3, leading to activation of Fak and p38 as well as VEGFR2-integrin binding and enhanced VEGFR2 signaling [106].

As mentioned earlier, matrix molecules themselves can interact with growth factors and/or their receptors [9]. Fibronectin and collage interact with VEGF; binding to fibronectin increases VEGFR activation and endothelial cell proliferation, whereas binding to collagen activates a phosphatase and thus decreases VEGFR activity [106]. HSPG can interact with many growth factors, including FGF and VEGF, limiting their diffusion, sequestering them until enzyme-mediated release, or promoting their receptor binding. FGF and VEGF binding to HSPG facilitates binding to their respective receptor and activates mitogenic signaling [64]. Matrix molecules can also bind growth factor receptors and activate them directly; for example, the EGF-like domains of laminin and tenascin-C bind and activate the EGFR, which may promote cell proliferation [9]. In contrast, decorin binding to the EGFR promotes EGFR internalization, and thus inhibits mitogenic signaling downstream of this receptor [64].

Activation of several non-integrin matrix receptors, including CD44, RHAMM, and DDR2, are associated with cell survival and proliferation. Hyaluronan promotes Erk activation and fibroblast proliferation through RHAMM and endothelial cell proliferation through CD44 [26,27]. Low molecular weight hyaluronan fragments also activate CD44, leading to Erk activation, cyclin expression, and proliferation in smooth muscle cells [143]. In addition, the collagen receptor DDR2 promotes fibroblast and chondrocyte proliferation, although the signaling that underlies this mitogenic effect has not been elucidated [133].

Similarly, cellular differentiation also relies upon cell interactions with ECM molecules, hormones, and growth factors. For example, the binding of laminin to integrin $\alpha_2\beta_1$ in endothelial cells promotes the formation of capillary-like structures [61], whereas the binding of fibronectin to integrin $\alpha_5\beta_1$ in these cells leads to cell proliferation [124]. Additional signaling molecules are required to generate the capillary-like tubes; one such molecule is integrin-linked kinase (ILK), which, when over-expressed, rescues capillary-like tube formation in the absence of ECM molecules [144], while expression of a dominant negative version of ILK blocks tube formation even when ECM and VEGF are present [145]. Once nascent vessels are formed, smooth muscle cells called pericytes are recruited to stabilize the

endothelium and promote synthesis of the basement membrane. Pericyte differentiation relies upon cell-matrix interactions, as shown by impaired differentiation and vessel stabilization/maturation in a mural cell-specific integrin β_1 knockout [146]. TGF-β-induced myofibroblast differentiation depends upon integrin $\alpha_4\beta_7$ binding to the EDA domain of fibronectin and downstream activation of FAK, PI3K, and associated signaling pathways [8].

Non-integrin receptors such as CD44 also regulate cellular differentiation. Hyaluronan induces keratinocyte differentiation *in vitro* in a CD44-dependent manner, and CD44 deficiency inhibits keratinocyte differentiation *in vivo*, suggesting a role for hyaluronan in this process [147]. Similarly, TGF-β-induced myofibroblast differentiation requires hyaluronan [26].

Type III interactions

Type III interactions primarily involve processes leading to apoptosis and epithelial-to-mesenchymal transitions (Fig. 2 III). Normally adherent cells that fail to interact with matrix molecules undergo anoikis, a form of cell death. Anoikis results from a lack of pro-survival Fak/Src-induced PI3K/Akt or Erk signaling, coupled with pro-apoptotic signaling that inhibits anti-apoptotic Bcl family members, increases expression/activity of pro-apoptotic Bcl family members, and recruits and activates caspase 8 [147]. The mechanism involved in caspase 8 recruitment and activation by unligated integrins is unclear; one possibility is that caspase 8 is normally phosphorylated and inhibited by Src, and that the absence of integrin-activated Src signaling relieves caspase 8 inhibition [148]. In many cases, integrins that do interact with ligands can still promote apoptosis. For example, CCN1 binding to syndecan-4 and integrin $\alpha_6\beta_1$ induces expression of Bax, which promotes cytochrome C release from the mitochondria and subsequent caspase 9 activation, leading to fibroblast apoptosis [149]. In endothelial cells, thrombospondin interaction with CD36 induces a pro-apoptotic pathway culminating in Fas ligand (FasL) expression; FasL then binds Fas, a death domain receptor that induces apoptosis [110].

Alterations in the ligand presentation by ECM can also regulate apoptosis. Studies have suggested that integrin ligation by soluble, rather than intact, ligands can function as integrin antagonists and promote apoptosis rather than survival or proliferation [66]. Many of these soluble ligands can be created by matrix degradation during tissue remodeling. Endostatin, derived from collagen XVIII, and tumstatin, derived from collagen IV, promote endothelial cell apoptosis by interacting with $\alpha_5\beta_1$ and $\alpha_v\beta_3$ integrins, respectively [150]. The apoptosis stimulated by soluble ligands or other antagonists appears to occur via the recruitment and activation of caspase 8 by clustered integrins and decreased expression of pro-survival Bcl family members, without any requirement for death receptors [150].

Although these three categories may not be exhaustive of the general types of cell-ECM interactions that occur during development and wound healing, they encapsulate the major interactions documented to date. Each category has its place in many developmental and repair events, and they may operate in sequence. A compelling example of the latter is the epithelial-to-mesenchymal transition and morphogenesis of the NCC system [52]. These cells originate in the neural epithelium that occupies the crest of the neural folds. After the delamination event that separates the neural epithelium from the epidermal ectoderm [151], the folds fuse to form the tube. At this time, the NCC occupy the dorsal-most portion of the tube, they are not covered by basal lamina, and the subepidermal space above them contains large amounts of fibronectin [152]. Just before the NCC emigrate from the neural tube, fibronectin appears between them, they separate from each other, and migrate away carrying fibronectin on their surfaces [153]. During the period of emigration at any particular level of the neural tube, basal lamina is deposited progressively toward the crest from the sides of the tube [152,154]. NCC emigration terminates as deposition reaches the crest of the tube. The NCC then follow specific migration pathways throughout the embryo, arriving at a wide

variety of locations where they differentiate into many different phenotypes in response to external cues [51].

The appearance of fibronectin between the NCC just before emigration must be the result of secretion by the adjacent cells or introduction from the epithelial cells after loss of cell-cell adhesions. In keeping with the cell-ECM interaction mechanism of type III, either alternative could initiate a positive feedback loop and release the NCC, leading to emigration: Enzymatic degradation of the stabilizing domain of fibronectin above the tube could cause enhanced secretion of specific enzymes by the NCC in response to the effect of the cell-binding domain acting alone, thus severing the cell adhesions and producing additional fibronectin fragments containing the cell-binding domain. These fragments, in turn, would bind to adjacent cells and stimulate further enzymatic secretion that would be self-perpetuating. NCC emigration occurs in an anterior-to-posterior wave, thus, once enzymatic activity were initiated in the head of the embryo, it could propagate in a posterior direction, triggering NCC emigration in a wave from head to tail.

Clearly some controlling event(s) must terminate NCC emigration at each location along the neural tube. Such an event has already been identified. At the time of NCC emigration, the ventral and lateral surfaces of the neural tube are covered by an intact basal lamina, which stabilizes the epithelium and separates it from the fibronectin layer around the tube [154]. During the few hours of emigration at any one site, as the NCC are leaving from the dorsal-most portion of the neural tube, basal lamina deposition progresses quickly up the sides of the tube and terminates local emigration when it becomes complete over the crest of the tube [152,154]. After they have emigrated from the neural tube, the NCC find themselves in an extracellular space filled with intact fibronectin and other ECM molecules that stimulate the focal adhesions of cell-ECM interactions of type I, thereby providing the substrate for migration. Upon arrival at their final destination, further interactions of type II stimulate differentiation into a wide range of phenotypes [51].

RELEVANCE FOR TISSUE ENGINEERING

Designing tissue and organ replacements that closely simulate normal physiology is a challenging endeavor. One avenue to achieve this goal is to study how tissues and organs arise during embryogenesis and during normal processes of repair, and how those functions are maintained. When developing tissue replacements, one needs to consider the following (Fig. 9.3).

(1) Avoiding an immune response that can cause inflammation and/or rejection. One possibility would involve using autologous cells; however, it is time-consuming and labor-intensive to collect and expand autologous cells for use in engineered tissues, decreasing the practicality of this approach. Alternatively, engineered tissues could incorporate progenitor cells that may suppress host immune responses directly or indirectly through decreased expression of MHC; these cells could be induced at a later time to differentiate into various cell types [155]. One example of a progenitor cell that appears to decrease immune responses and also maintains a broad differentiation capacity is the mesenchymal stem cell, which is capable of differentiating into multiple cell types, and may thus prove to be an invaluable asset in tissue engineering [155].

(2) Creating the proper substrate for cell survival and differentiation. One of the strategies to fulfill this goal is the use of biocompatible implants composed of extracellular matrix molecules seeded with autologous cells or with heterologous cells in conjunction with immunosuppressant drugs. Addition of growth and differentiation factors to these matrices as well as agonists or antagonists that favor cell-ECM interactions can potentially increase the rate of successful tissue replacement. However, growth factor activity in the engineered tissue is dependent upon its stability and its ability to diffuse both within

the engineered tissue and in peripheral host tissue. In normal tissue, VEGF has a short half-life (30 minutes), so it would be useful to increase the half-life, and thus activity, in an engineered tissue [156]. There are several methods that have been used to increase the duration and activity of growth factors: by adding components of the normal ECM that stabilize these factors and/or promote their activity, by covalently coupling the growth factors to a matrix molecule or biomaterial, and by removing proteolytic cleavage sites from growth factors to inhibit their degradation [59]. In the case of VEGF, covalent linkage to a fibrin matrix or addition of heparin and/or fibronectin fragments to the matrix promotes angiogenesis to a greater extent than addition of VEGF to a fibrin matrix alone [59]. In addition to restricting VEGF diffusion, heparin and fibronectin fragments likely promote VEGF signaling [92,106]. Preventing proteolytic cleavage of VEGF also increases its half-life and activity. Chronic wounds frequently exhibit excessive protease levels that would cleave wild type VEGF and limit its activity; in a mouse model of impaired healing, VEGF lacking proteolytic sites promoted VEGF duration and activity, leading to improved angiogenesis and healing [59]. It is possible that combinations of matrix molecules/fragments and inhibition of proteolytic activity could be even more effective in stimulating angiogenesis and wound healing in impaired wounds.

While the foregoing examples show that ECM molecules can be used successfully in tissue engineering, the use of natural ECM molecules in engineered tissue has several disadvantages, including the possibility of generating an immune response, possible contamination, and ease of degradation. Likewise, artificial biocompatible materials have drawbacks in that, unlike ECM, they are generally incapable of transmitting growth and differentiation cues to cells. Much attention is now devoted to the design of 'semi-synthetic biomaterials' in which functional regions of ECM molecules, including those that interact with receptors or growth factors or those that are cleaved by proteases, are incorporated into artificial biomaterials to impart additional functionality [59]. The inclusion of ECM-like cell-binding sites that promote cell adhesion, growth, and/or differentiation into such biomaterials may be critical in developing and maintaining functional engineered tissues by providing the appropriate cellular microenvironment. For example, because many integrins interact with the RGD motif on matrix molecules, it can be used as an agonist to make synthetic implants more biocompatible and to allow the development of tissue structure, or as an antagonist to prevent or moderate unwanted cell-ECM interactions. Similarly, collagen, fibronectin, and gelatin have been used to coat synthetic biomaterials to increase their biocompatibility and promote successful biological interactions [157]. However, the use of these biomaterials in engineered tissues requires additional knowledge regarding the types of cell-ECM interactions that result in the desired cellular effects.

(3) Providing the appropriate environmental conditions for tissue maintenance. To maintain tissue homeostasis, it is crucial to create a balanced environment with the appropriate cues for preservation of specific cell function(s). It is important to realize that such stasis on the level of a tissue is achieved via tissue remodeling — the dynamic equilibrium between cells and their environment. However, relatively little is known about the crosstalk between cells and ECM under such 'normal' conditions. As indicated above, the same ECM molecule may have multiple cellular effects; the ultimate cellular outcome likely depends upon the combination of variables, such as the domain of the molecule involved in the cellular interactions, the receptor used for these interactions, and the cellular microenvironment. These variables can, in turn, be influenced by matrix remodeling, as enzymatic degradation of the ECM can release functional fragments of ECM that then alter cell-ECM interactions by removing certain binding sites while exposing others. Another important consideration is the role of mechanical tension on matrix signaling, and, depending upon the desired effect, it may be necessary to control the stiffness and pore size of the biomaterial. One biomaterial that is 'tunable' in terms of stiffness and pore size is starPEG, which can use heparin as a functional crosslinker.

Altering the concentration or molecular weight of the starPEG changes its stiffness and pore size, and can thus change the mechanical tension exerted on cells, while the use of heparin as a crosslinker yields additional functionality due to its ability to bind growth factors and enhance their signaling [158]. Combinations of this hybrid biomaterial with RGD and growth factors increased endothelial cell survival and tube-like organization, suggesting the potential of this approach in designing engineered tissues [158].

Because organ transplantation is one of the least cost-effective therapies and is not always available, tissue engineering offers hope for more consistent and rapid treatment of those in need of body part replacement, and therefore has greater potential to improve patient quality of life. The selected examples presented above illustrate that further advances in tissue engineering require additional knowledge of the basic mechanisms of cell function and of the ways they interact with the environment. The recent surge in research on ECM molecules themselves and their interactions with particular cells and cell-surface receptors has led to realization that these interactions are many and complex, allow the modulation of fundamental events during development and wound repair, and are crucial for the maintenance of the differentiated phenotype and tissue homeostasis. As such, the manipulation of specific cell-ECM interactions has the potential to modulate particular cellular functions and processes in order to maximize the effectiveness of engineered tissues.

CHAPTER 10

Matrix Molecules and Their Ligands

Bjorn Reino Olsen
Department of Developmental Biology, Harvard School of Dental Medicine
and Department of Cell Biology, Harvard Medical School, Boston, Massachusetts

INTRODUCTION

Cellular growth and differentiation, in two-dimensional cell culture as well as in the three-dimensional space of the developing organism, requires the presence of a structured environment with which the cells can interact. This extracellular matrix (ECM) is composed of polymeric networks of several types of macromolecules in which smaller molecules, ions and water are bound. The major types of macromolecules are polymer-forming proteins, such as collagens, elastin, fibrillins, fibronectin and laminins, and hydrophilic heteropolysaccharides, such as glycosaminoglycan chains in hyaluronan and proteoglycans. It is the combination of protein polymers and hydrated proteoglycans that give extracellular matrices their resistance to tensile and compressive mechanical forces.

The macromolecular components of the polymeric assemblies of the ECM are in many cases secreted by cells as precursor molecules that are significantly modified (proteolytically processed, oxidized and cross-linked) before they assemble with other components into functional polymers (Fig. 10.1). The formation of matrix assemblies *in vivo* is therefore in most instances a unidirectional, irreversible process and the disassembly of the matrix is not a simple reversal of assembly, but involves multiple, highly regulated processes. One consequence of this is that polymers reconstituted in the laboratory with components extracted from extracellular matrices do not have all the properties they have when assembled by cells *in vivo*. The ECM *in vivo* is also modified by cells as they proliferate, differentiate, and migrate, and cells in turn continuously interact with the matrix and communicate with each other through it [1].

The ECM is therefore not an inert product of secretory activities, but influences cellular shape, fate, and metabolism in ways that are as important to tissue and organ structure and function as the effects of many cytoplasmic processes. This realization has led to a reassessment of the need for a detailed molecular understanding of ECM. In the past, the ECM was primarily appreciated for its challenge to biochemists interested in protein and complex carbohydrate structure; a detailed characterization of ECM constituents is now considered essential for understanding cell behavior in the context of tissue and organ development and function. Some of these constituents are obviously most important for their structural properties (collagens and elastin), while others (fibronectin, fibrillin, laminin, thrombospondin, tenascin, perlecan and other proteoglycans) are multidomain molecules that are both structural constituents as well as regulators of cell behavior (Fig. 10.1). In a third category are matrix-bound signaling molecules (such as matrix-bound fibroblast growth factors (FGFs), transforming growth factor-β (TGF-β) and bone morphogenetic proteins (BMPs)).

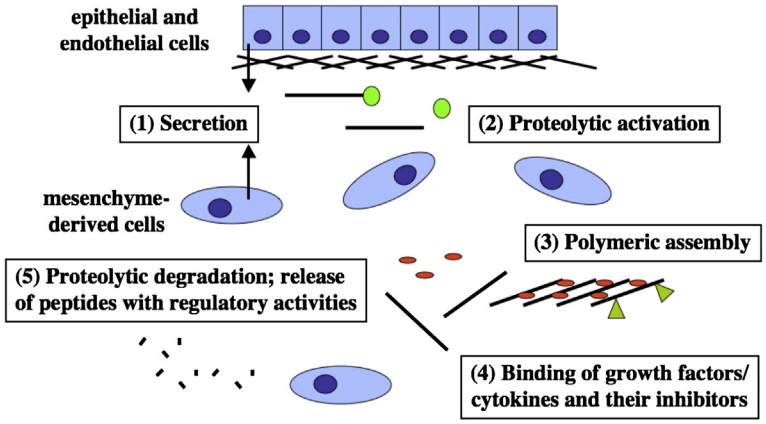

FIGURE 10.1

The life cycle of extracellular matrix molecules. Soluble matrix molecules are secreted by cells, modified by proteolysis, and assembled into polymeric complexes. These complexes serve as scaffolds for cells and as binding sites for small molecules such as growth and differentiation factors. Depending on the growth factor and cellular context, this may either inhibit or stimulate growth factor activity. Degradation of the scaffolds, during normal tissue turnover or during wound healing, may release bound growth factors and/or release peptide fragments from the larger scaffold proteins; such fragments may bind to cellular receptors and regulate cellular behavior.

COLLAGENS — MAJOR CONSTITUENTS OF ECM

Fibrillar collagens are major tissue scaffold proteins

Collagens constitute a large family of proteins that represent the major proteins (about 25%) in mammalian tissues [2]. A subfamily of these proteins, the fibrillar collagens, contains rigid, rod-like molecules with three subunits, α-chains, folded into a right-handed collagen triple helix. Within a fibrillar collagen triple-helical domain, each α-chain consists of about 1,000 amino acid residues and is coiled into an extended, left-handed polyproline II helix; three α-chains are in turn twisted into a right-handed superhelix (Fig. 10.2). The extended conformation of each α-chain does not allow the formation of intrachain hydrogen bonds; the stability of the triple helix is instead due to interchain hydrogen bonds. Such interchain bonds can only form if every third residue of each α-chain does not have a side chain and is packed close to the triple-helical axis. Only glycine residues can therefore be accommodated in this position. This explains why the amino acid sequence of each α-chain in fibrillar collagens consists of about 300 Gly-X-Y tripeptide repeats, where X and Y can be any residue, but Y is frequently proline or hydroxyproline. It also provides an explanation for why mutations in collagens that lead to a replacement of triple-helical glycine residues with more bulky residues can cause severe abnormalities.

Fibrillar collagen molecules are the major components of collagen fibrils. Their α-chains are synthesized as precursors, pro-α-chains, with large propeptide regions flanking the central triple-helical domain. The carboxyl propeptide (C-propeptide) is important for the assembly of trimeric molecules in the rough endoplasmic reticulum (RER). Formation of C-propeptide trimers, stabilized by intra- and interchain disulfide bonds, is the first step in the intracellular assembly and folding of trimeric procollagen molecules [3–5]. The folding of the triple-helical domain at body temperature requires post-translational hydroxylation of about 50% of the prolyl residues by prolyl hydroxylases, and this proceeds in a zipper-like fashion from the carboxyl towards the amino end of procollagen molecules. Mutations in fibrillar procollagens that affect the structure and folding of the C-propeptide domain are therefore likely to affect the participation of the mutated chains in triple-helical assemblies. In contrast, mutations upstream of the C-propeptide, such as in-frame deletions or glycine substitutions

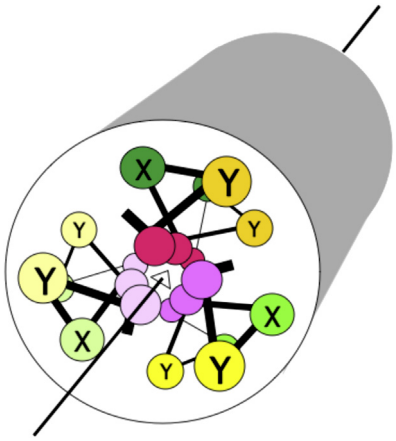

FIGURE 10.2
Diagram showing a segment of a triple-helical collagen molecule. The triple helix is composed of three left-handed helices (α-chains) that are twisted into a right-handed superhelix. The sequence of each α-chain is a repeat of the tripeptide Gly-X-Y. The Gly residues are packed close to the triple-helical axis (indicated by a line through a triangle). Only glycine (without a side chain) can be accommodated in this position. Although any residue can fit into the X- and Y-positions, Pro is frequently found in the Y-position.

in the triple-helical domains, exert a dominant negative effect, in that the mutated chains will participate in trimer assembly, but will interfere with subsequent folding of the triple-helical domain.

Fibrillar procollagen chains are the products of 11 genes. The similarities between these genes suggest that they arose by multiple duplications from a single ancestral gene. Despite their similarities and the high degree of sequence identity between their protein products, they exhibit specificity in the interactions of their C-propeptides during intracellular trimeric assembly in the RER. Thus, a relatively small number of chain combinations are found among triple-helical procollagens; these combinations represent fibrillar collagen types.

Collagens V/XI — regulators of fibril assembly, spatial organization and cell differentiation

Some collagen types are heterotrimers (types I, V, and XI), while others are homotrimers (types II, III, XXIV, and XXVII). Some chains participate in more than one type: For example, the α1(II) chain (encoded by the COL2A1 gene) forms the homotrimeric collagen II, but is also one of three different chains in collagen XI molecules. Between collagens V and XI there is extensive sharing of polypeptide subunits, and fibrillar collagen molecules previously described as belonging to either collagen V and XI are now referred to as belonging to the V/XI type. Thus, fibrillar procollagen molecules secreted by cells are members of a group of homologous proteins. They all contain a C-propeptide that is completely removed by an endoproteinase (BMP-1/tolloid) after secretion, and their triple-helical rod-like domains polymerize in a staggered fashion into fibrillar arrays (Fig. 10.3). They differ, however, in the structure of their amino propeptide (N-propeptide) domains and in the extent to which this domain is proteolytically removed. For some collagen types such as collagens I and II, the N-propeptide processing (by ADAMTS2, ADAMTS3 and ADAMTS14 proteinases) is complete in molecules within mature fibrils. For other types, such as collagens V/XI this is not the case, in that a large portion of the N-propeptides in these molecules remain attached to the triple-helical domain (Fig. 10.3). The incomplete processing of type V/XI molecules allows them to serve as regulators of fibril assembly. Collagen fibrils are heterotypic, i.e., they contain more than one collagen type, such that collagen I fibrils in skin, tendon, ligaments and bone contain 5—10% collagen V and collagen II fibrils in cartilage contain 5—10% collagen XI. The presence

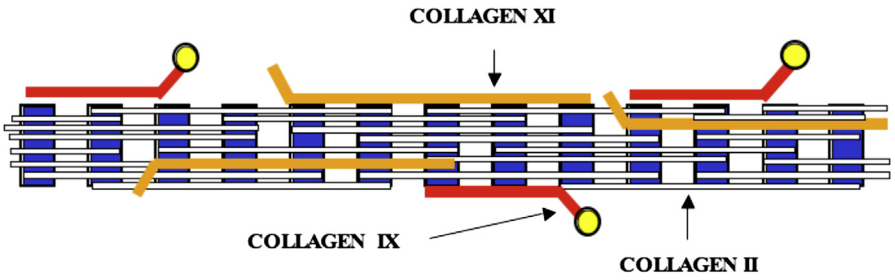

FIGURE 10.3
Diagram of a cartilage collagen fibril. Collagen II molecules are the major components. Molecules of collagen XI and IX are located on the surface. Collagen XI molecules, heterotrimers of three different α-chains, have amino-terminal domains that are thought to sterically block the addition of collagen II molecules at the fibril surface.

of N-propeptide domains on V/XI molecules represents a steric hindrance to addition of molecules at fibril surfaces. This heterotypic/steric hindrance model predicts that collagen fibril diameters in a tissue are determined by the ratio of the 'minor' component (V/XI) to the 'major' component (I or II). A high ratio results in thin fibrils; a low ratio results in thick fibrils. Direct support for this comes from studies of mutant and transgenic mice. For example, mice that are homozygous for a functional null mutation in α1(XI) collagen and transgenic mice overexpressing collagen II have cartilage collagen fibrils that are abnormally thick [6,7].

A characteristic feature of collagen fibrillar scaffolds is their precise three-dimensional patterns. These patterns follow mechanical stress lines and ensure a maximum of tensile strength with a minimum of material. Examples are the criss-crossing lamellae of collagen fibers in lamellar bone or in cornea, the arcades of collagen fibrils under the surface of articular cartilage and the parallel fiber bundles in tendons and ligaments. Ultimately, cells are responsible for establishing these patterns, but the cellular mechanisms involved are only beginning to be understood. A study by Canty et al. [8] suggests that the orientation of collagen fibrils in the extracellular space is linked to the cytoskeletal organization induced by cellular responses to mechanical stress. In tendon fibroblasts, Golgi-to-plasma transport carriers of collagen are formed on the exit side of the trans-Golgi network and move along cytoskeletal 'tracks' into long cytoplasmic extensions. Collagen fibrils, forming inside the carriers, are oriented along the longitudinal axis of the carriers. When the membrane at the distal tip of the carrier fuses with the cell membrane covering the tip of the extension, the space within the carrier becomes continuous with the extracellular space and the fibrils are, in effect, moved from an intracellular to an extracellular compartment. Thus, the parallel orientation of collagen fibrils in a tendon is a consequence of the polarized structure, intracellular movement, and polarized exocytosis of fibril-containing Golgi-derived transport carriers. This cellular mechanism for orientation of collagen fibrils is consistent with data showing that the same kind of heterotypic fibril can be part of scaffolds with very different spatial organization. Transgenic mice with an alteration in the N-propeptide region of collagen V molecules show a disruption of the lamellar arrangement of fibrils in the cornea of the eye, suggesting a role for fibril surface domains in generating and/or stabilizing the spatial pattern [2,9]. Finally, members of a unique subfamily of collagens, FACIT collagens (see below), are good candidates for molecules that modulate the surface properties of fibrils and allow tissue-specific fibril patterns to be generated and stabilized by cells.

The phenotypic consequences of mutations in fibrillar collagen genes indicate that a major function of these proteins is to provide elements of high tensile strength at the tissue level. Thus, mutations in COL1A1 or COL1A2, the human genes encoding the α1 and α2 subunits of fibrillar collagen I (in bone, ligaments, tendons and skin), cause osteogenesis imperfecta (brittle bone disease) or clinical forms of Ehlers-Danlos syndrome, characterized by skin hyperextensibility and fragility and joint hypermobility, with or without bone abnormalities [10,11]. Mutations in COL2A1, the gene encoding the α-chains of collagen II (in cartilage) cause a spectrum of human disorders, ranging from lethal deficiency in cartilage formation to relatively mild deficiencies in cartilage mechanical properties and function. Fibrillar collagens also have regulatory functions. For example, mutations in collagen V/XI genes suggest that

fibrillar collagen scaffolds are essential for normal cellular growth and differentiation. A functional null mutation in α1(XI) collagen, resulting in complete lack of collagen XI in cartilage, causes a severe disproportionate dwarfism in mice and perinatal death of homozygotes [7]. Histology of mutant long bone growth plates reveals a disorganized spatial distribution of cells and a defect in chondrocyte differentiation to hypertrophy. The explanation for this is likely related to the fact that proliferation and differentiation of chondrocytes in growth plates is regulated by locally produced growth factors and cytokines. Cells that produce these factors are localized close to cells that express the appropriate receptors. Lack of collagen XI may disrupt this relationship since it results in a dramatic decrease in cohesive properties of the matrix and a loss of cellular organization. Transgenic mice with a mutation in α2(V) collagen have a large number of hair follicles of unusual localization in the hypodermis; this may be related to a defect in the mechanical properties of the fibrillar collagen scaffold but could also be mediated by an effect on extracellular signaling molecules [9].

FACIT collagens — modulators of collagen fibril surface properties

Molecules that are associated with collagen fibrils, contain two or more triple-helical domains, and share characteristic protein domains (modules) with each other as well as with other non-collagenous matrix molecules (thrombospondin-1, fibronectin, von Willebrand factor) are classified as FACIT collagens [2,12]. Of the eight known members in the group (collagens IX, XII, XIV, XVI, XIX, XX, XXI, and XXII), collagen IX is the best characterized both structurally and functionally. Collagen IX molecules are heterotrimers of three different gene products [13]. Each of the three α-chains (α1(IX), α2(IX) and α3(IX)) contains three triple-helical domains separated and flanked by non-triple-helical sequence regions (Fig. 10.4). Between the

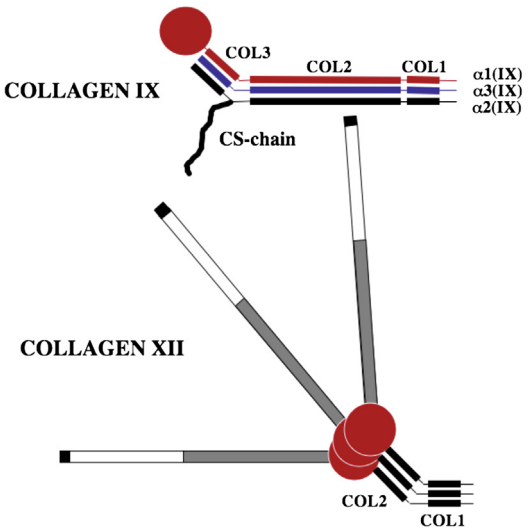

FIGURE 10.4

Diagrams of collagen IX and XII (long form) molecules. Collagen IX molecules contain the three chains α1(IX), α2(IX, and α3(IX). Each chain contains three triple-helical domains (COL1, COL2, COL3), interrupted and flanked by non-triple-helical sequences. In cartilage, the α1(IX) chain contains a large globular amino-terminal domain. The α2(IX) chain serves as a proteoglycan core protein in that it contains a chondroitin sulfate (CS-) side chain attached to the non-triple-helical region between the COL2 and COL3 domains. Collagen XII molecules are homotrimers of α1(XII) chains. The three chains form two short triple-helical domains separated by a flexible hinge region. A central globule is composed of three globular domains that are homologous to the amino-terminal globular domain of α1(IX) collagen chains. The amino-terminal region of the three α1(XII) chains contain multiple fibronectin type 3 repeats and von Willebrand factor A-like domains. These regions form three 'fingers' that extend from the central globule. Through alternative splicing a portion of the 'fingers' (white region in diagram) is spliced out in the short form of collagen XII. Hybrid molecules with both long and short 'fingers' can be extracted from tissues.

amino-terminal and central triple-helical domains a flexible hinge gives the molecule a kinked structure with two arms. The hinge region in the α2(IX) chain contains a sequence for attachment of a chondroitin sulfate glycosaminoglycan side chain, making type IX collagen both a collagen and a proteoglycan (see below) matrix component [14]. The use of two alternative promoters in the α1(IX) collagen gene gives rise to two alternative forms of the protein, one containing a thrombospondin-like module in the amino-terminal region and one without this module [15].

Type IX molecules are located on the surface of type II/XI-containing fibrils with the long arm parallel to the fibril surface and the short arm projecting into the perifibrillar space [16] (Fig. 10.3). Collagen IX functions as a bridging molecule between fibrils, between fibrils and other matrix constituents and between fibrils and cells. Transgenic mice with a dominant-negative mutation in the α1(IX) chain [17], as well as mice that are homozygous for null alleles of the gene (Col9a1) coding for α1(IX) [18], exhibit osteoarthritis in knee joints and mild chondrodysplasia. In humans, mutations in the α1(IX), α2(IX) or α3(IX) collagen chains cause a form of multiple epiphyseal dysplasia, an autosomal dominant disorder characterized by early onset osteoarthritis in large joints associated with short stature and stubby fingers [19].

Molecules of collagens XII and XIV are homotrimers of chains that are made up of several kinds of modules. Some modules are homologous to triple-helical and thrombospondin modules found in collagen IX, while others show homology to von Willebrand factor A domains and fibronectin type 3 repeats. Both types of molecules contain a central globule with three finger-like extensions and a thin triple-helical tail attached (Fig. 10.4). For collagen XII, two forms that differ greatly in the lengths of the finger-like extensions are generated by alternative splicing of RNA transcripts. Variations in the carboxyl regions also occur [20]. Both collagens XII and XIV are found in connective tissues containing type I collagen fibrils, except mineralized bone matrix, and immunolabeling studies show a fibril-associated distribution. Type XIV collagen can bind to heparan sulfate and the small fibril-associated proteoglycan decorin [21,22]. This would suggest an indirect fibril-association. A direct association is also possible, since collagen XII molecules form copolymers with collagen I even in the absence of proteoglycans. A functional interaction between fibrils and collagens XII and XIV is implied by studies showing that addition of the two collagens to type I collagen gels promote gel contraction mediated by fibroblasts [23]. The effect is dose-dependent and can be prevented by denaturation or addition of specific antisera. The association of collagens XII and XIV with fibrils may therefore modulate the frictional properties of fibril surfaces. The synthesis of different isoforms could be important in this context, since they could bind to fibrils with different affinities. Also, since the long form of collagen XII is a proteoglycan with heparan sulfate side chains, whereas the short form is not, variations in the relative proportion of the two splice variants may serve to modulate the hydrophilic properties of interfibrillar matrix compartments. Finally, the discovery that the collagen I N-propeptide processing enzyme (see below) binds to collagen XIV and can be purified as part of a complex with antibodies against collagen XIV, suggests that the FACIT collagens provide binding sites for fibril-modifying extracellular matrix enzymes [24].

Thus, FACIT collagens have multiple functions is a variety of tissues. For example, collagen XVI [25] connects and organizes fibrillar networks in cartilage and skin, but may also serve as substrate for adhesion and migration of cells, including tumor cells [26]. Collagen XIX [27] is expressed in skin and muscle cells [28] and it contributes to synapse-formation in the hippocampus [29]. Collagen XX [30], smaller but similar in structure to collagens XII and XIV, is present in several connective tissues, including cartilage, tendon and cornea, and collagen XXI [31] is expressed in heart, stomach, kidney, skeletal muscle and placenta. Collagen XXII is located in basement membrane zones of myotendinous junctions in skeletal and heart muscle, at hair follicles and at articular cartilage/synovial membrane junctions [32].

Basement membrane collagens and associated collagen molecules

At epithelial- and endothelial-stromal boundaries, basement membranes serve as specialized areas of ECM for cell attachment. Collagen IV molecules form a network-like scaffold in basement membranes by end-to-end and lateral interactions [33]. The products of the six different collagen IV genes (in mammals) interact to form at least three different types of heterotrimeric collagen IV molecules. These different isoforms show characteristic tissue-specific expression patterns. The physiological importance of collagen IV isoforms is highlighted by Alport syndrome [34]. This disease, characterized by progressive hereditary nephritis associated with sensorineural hearing loss and ocular lesions, can be caused by mutations within α3(IV) and α4(IV) collagen genes (autosomal Alport syndrome) or mutations in α5(IV) collagen (X-linked Alport syndrome). In cases of large deletions including both the α5(IV) and the neighboring α6(IV) collagen gene, renal disease is associated with inherited smooth muscle tumors.

Within basement membranes, the collagen IV networks are associated with a large number of non-collagenous molecules, such as various isoforms of laminin, nidogen, and the heparin sulfate proteoglycan perlecan (Fig. 10.5 [33]). Additional collagens are also associated with basement membranes. These include the transmembrane collagen XVII in hemidesmosomes and collagen VII in anchoring fibrils [2]. Collagens XVII and VII are important in regions of significant mechanical stress, such as skin, in that they anchor epithelial cells to the basement membrane (collagen XVII) and strap the basement membrane to the underlying stroma (collagen VII) (Fig. 10.6). In bullous pemphigoid, autoantibodies against collagen XVII cause blisters that separate epidermis from the basement membrane; dominant and recessive forms of epidermolysis bullosa can be caused by mutations in collagens VII and XVII [35,36].

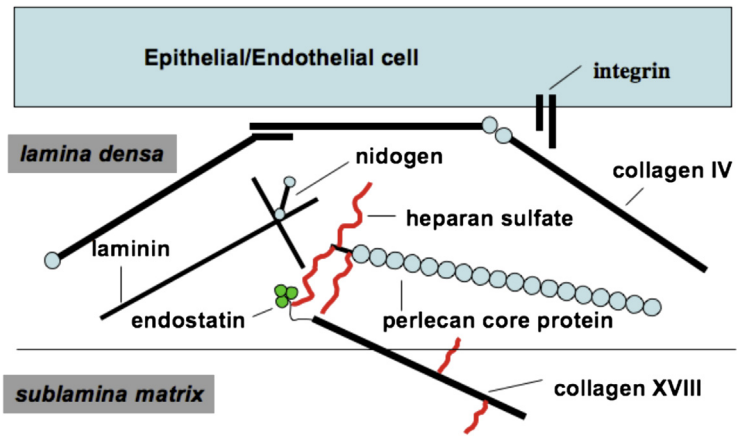

FIGURE 10.5
Components of basement membranes. Basement membranes contain interconnected networks of collagen IV and laminin polymers, together with nidogen, perlecan and collagen XVIII. Collagen XVIII molecules are located at the boundary between the lamina densa and the sublamina matrix, with their carboxyl endostatin domain within the lamina densa and the amino end projecting into the underlying matrix.

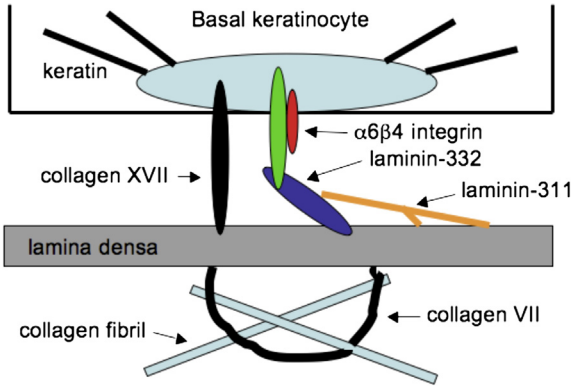

FIGURE 10.6
Epidermal basement membrane and associated collagens and laminins. Basal portion of a keratinocyte with hemidesmosome, anchoring filaments of collagen XVII and anchoring fibril of collagen VII. A complex of laminin-332, laminin-311 and integrin α6β4 provides further strength to the cell-basement membrane junction.

Two additional basement membrane-associated collagens, collagen VIII and collagen XVIII, are of interest because of their function in vascular physiology and pathology. Collagen VIII [2] is a short-chain, non-fibrillar collagen with significant homology to collagen X [37], a product of hypertrophic chondrocytes in long bone growth plates and cartilage growth regions (synchondroses) at the skull base. Mutations in collagen X cause metaphyseal dysplasia in mice and humans [38,39], likely as a result of endoplasmic reticulum stress [40].

Collagen VIII expression is upregulated during heart development [41], in human atherosclerotic lesions [42] and following experimental damage to the endothelium in large arteries [43]. Collagen VIII facilitates migration of smooth muscle cells from the medial layer into the intima during neointimal thickening following endothelial cell injury. Collagen VIII molecules are also major building blocks of Descemet's membrane, the thick basement membrane that bridges the corneal stroma with the corneal endothelium on the inside of the cornea [44]. Mutations in collagen VIII can cause clouding of the cornea and blurred vision (corneal dystrophy) in humans [45,46].

Collagen XVIII, together with collagen XV, belongs to a distinct subfamily of collagens called *multiplexins* because of their multiple triple helix domains and interruptions [47,48]. Because of the alternative utilization of two promoters and alternative splicing, the COL18A1 gene gives rise to three different transcripts that are translated into three protein variants. These are localized in various basement membranes (Fig. 10.5), including those that separate vascular endothelial cells from the underlying intima in blood vessels. Collagen XVIII α-chains contain several consensus sequences for attachment of heparan sulfate side chains and studies have, in fact, confirmed that collagen XVIII forms the core protein of a basement membrane proteoglycan [49]. Proteolytic processing of the carboxyl non-triple-helical domain of collagen XVIII in tissues leads to the release of a heparin-binding fragment with anti-angiogenic activity.

This fragment, named *endostatin*, represents the carboxyl-terminal 20 kDa portion of collagen XVIII chains (Fig. 10.5) [50]. Endostatin has been shown to inhibit the proliferation and migration of vascular endothelial cells, inhibit the growth of tumors in mice and rats, and cause regression of tumors in mice. The anti-tumor effects are mediated by inhibition of tumor-induced angiogenesis. The X-ray crystallographic structure of mouse and human endostatin proteins [51,52] shows a compact structure, consisting of two α-helices and a number of β-strands, stabilized by two intramolecular disulfide bonds. A coordinated zinc atom is part of the structure and on the surface a patch of basic residues forms a binding site for heparin. Studies of mutant endostatins have shown that specific arginines within this patch are required for heparin-binding [53].

The physiological function of collagen XVIII is highlighted by the consequences of loss-of-function mutations in this basement membrane component [54]. In humans, collagen XVIII mutations cause Knobloch syndrome, a recessive eye disorder in which affected individuals lose their eyesight at an early age because of degeneration of the retina and the vitreous [55]. Mice with inactivated collagen XVIII genes exhibit age-dependent changes in the retina and the pigment epithelial layer behind the retina. These changes are similar to what is seen in age-dependent macular degeneration in humans and lead (as in humans) to gradual loss of eyesight [54].

Of considerable interest is the finding that proteolytic fragments of basement membrane components other than collagen XVIII also have anti-angiogenic properties [56]. Molecules that give rise to such fragments include collagen IV and perlecan, the major heparan sulfate proteoglycan in basement membranes. The fragments involved show no sequence homology with endostatin, so it is likely that the molecular mechanisms underlying the anti-angiogenic effects are different. For example, endostatin is a heparin-binding molecule and its ability to inhibit angiogenesis is in many contexts heparan sulfate-dependent. In contrast, the fragment from perlecan, called *endorepellin*, does not bind to heparin and its inhibitory effects on

vascular endothelial cells are heparan sulfate-independent. In any case, release of such fragments as vascular basement membranes are degraded at sites of sprouting angiogenesis are likely to provide a local mechanism of negative control to balance the effects of factors that stimulate angiogenesis.

Bioactive fragments released by proteolytic cleavage of extracellular matrix proteins are not restricted to collagens. The recognition that such fragments may play an important role in both normal and pathological processes has led to the classification of such fragments as *matricryptins* [57]. A number of matricryptins have been identified as products of several collagens and proteoglycans [2].

ELASTIC FIBERS AND MICROFIBRILS

Collagen molecules and fibers have evolved as structures of high tensile strength, equivalent to that of steel when compared on a cross-sectional area basis, but three times lighter on a per-unit weight basis. In contrast, elastic fibers, composed of molecules of elastin and associated proteins, provide tissues with elasticity so that they can recoil after transient stretch [58,59]. In organs such as the large arteries, skin and lungs, elasticity is obviously crucial for normal functioning [60]. Elastic fibers derive their impressive elastic properties, an extensibility that is about five times that of a rubber band with the same cross-sectional area, from the structure of elastin molecules. Each molecule is composed of alternating segments of hydrophobic and α-helical Ala- and Lys-rich sequences. Oxidation of the lysine side chains by the enzyme lysyl oxidase leads to formation of reactive aldehydes and extensive covalent crosslinks between neighboring molecules in the fiber. It is thought that the elasticity of the fiber is due to the tendency of the hydrophobic segments to adopt a random-coil configuration following stretch.

On the surface of elastic fibers one finds a cover of microfibrils; beaded filaments with molecules of fibrillin as their major components [61,62]. The fibrillins, products of genes on chromosomes 5 (*FIB5*), 15 (*FIB15*) and 19 (*FIB19*) in humans, also form microfibrils that are found in almost all extracellular matrices in the absence of elastin. Fibrillin molecules are composed of multiple repeat domains, the most prominent being calcium-binding EGF-like repeats; similar repeats in latent TGF-β binding proteins indicate that the fibrillins belong to a superfamily of proteins. The physiological importance of fibrillin is highlighted by mutations causing the Marfan syndrome and congenital contractural arachnodactyly in humans [63]. The Marfan syndrome, caused by mutations in FIB15, is characterized by dislocation of the eye lens due to weakening of the suspensory ligaments of the zonule, congestive heart failure, aortic aneurysms, and skeletal growth abnormalities resulting in a tall frame, scoliosis, chest deformities, arachnodactyly and hypermobile joints [64]. In patients with congenital contractural arachnodactyly, mutations in FIB5 lead to similar skeletal abnormalities and severe contractures, but no ophthalmic and cardiovascular manifestations [65]. The tall stature and arachnodactyly seen in patients with the Marfan syndrome suggest that FIB15 is a negative regulator of longitudinal bone growth. Since fibrillin microfibrils are found in growth plate cartilage, it is conceivable that they affect chondrocyte proliferation and/or maturation.

A regulatory role for fibrillin in growth plates would be consistent with the function of fibrillin in other tissues [66]. In lung tissue and blood vessel walls, fibrillin functions as a regulator of TGF-β activity. Fibrillin mutations in mouse models of Marfan syndrome are associated with increased TGF-β activity in lungs and the aorta, causing impaired alveolar septation in lungs and widening and weakening (aneurysms) of the aorta. Inhibition of TGF-β largely prevents these defects [67,68]. Some of the major clinical abnormalities in patients with Marfan syndrome are therefore likely a consequence of altered fibrillin-mediated control of TGF-β activity and not loss of fibrillin as a structural molecule. The current data suggest that drugs to inhibit TGF-β activity may be useful in preventing early death caused by aortic aneurysms in Marfan syndrome patients. This represents a good example of how a genetic disease may be

effectively treated by pharmacological modulation of pathogenetic consequences of the mutation, without correcting the mutation.

A number of other proteins are associated with microfibrils or elastin [59]. These include MAGPs (microfibril-associated glycoproteins), fibulins, EMILIN as well as members of the lysyl oxidase (LOX) family, which catalyze the formation of covalent crosslinks between the proteins within elastic fiber networks. The importance of these different proteins for normal tissue formation and function is illustrated by the consequences of mutations in humans and experimental animals. For example, mice lacking the elastin gene die within a few days after birth due to obstruction of blood vessels as a result of increased proliferation of smooth muscle cells in vessel walls. Mice lacking fibrillin-1 (FIB-15) die within 2 weeks after birth because of aortic rupture and lung abnormalities. Mice lacking fibulin-1 die shortly after birth with kidney, lung and capillary defects; fibulin-4- or -5-deficient mice die either at birth (fibulin-4) with severe defects in lungs and blood vessels or exhibit loose skin and elastic fibers in abnormal aorta. Finally, several disease states have been linked to alterations in LOX activity (see reference [59]). Mutations in fibulin-4 and -5 have been associated with cutis laxa (loose skin, emphysema and aortic aneurysm) in humans (see reference [59]).

OTHER MULTIFUNCTIONAL PROTEINS IN ECM

Several proteins in the extracellular matrix contain binding sites for structural macromolecules and for cells, thus contributing both to the structural organization of ECM and its interaction with cells. The prototype of these adhesive proteins is fibronectin.

Fibronectin is a multidomain, multifunctional adhesive glycoprotein

Fibronectin is a disulfide-bonded dimer of 220–250 kDa subunits [69,70]. Each subunit is folded into rod-like domains separated by flexible 'joints'. The domains are composed of three types of multiple repeats or modules, Fn1, Fn2, and Fn3. Fn1 modules are found in the fibrin-binding amino- and carboxyl-terminal regions of fibronectin and in a collagen (gelatin)-binding region (Fig. 10.7). Single copies of Fn1 modules are also found in other proteins, such as tissue-type plasminogen activator (t-PA) and coagulation factor XII [71].

NMR and crystallographic studies of Fn1 modules demonstrate the presence of two layers of anti-parallel β-sheets (two strands in one layer and three strands in the other) held together by hydrophobic interactions [72,73]. The structure is further stabilized by disulfide- and salt-bridges. Fn2 modules are found together with Fn1 modules in the collagen-binding region of fibronectin and in many other proteins. Their structure, two double-stranded anti-parallel β-sheets connected by loops, suggests that a ligand such as collagen may bind to this module through interactions of hydrophobic amino acid side chains with its hydrophobic surface [74].

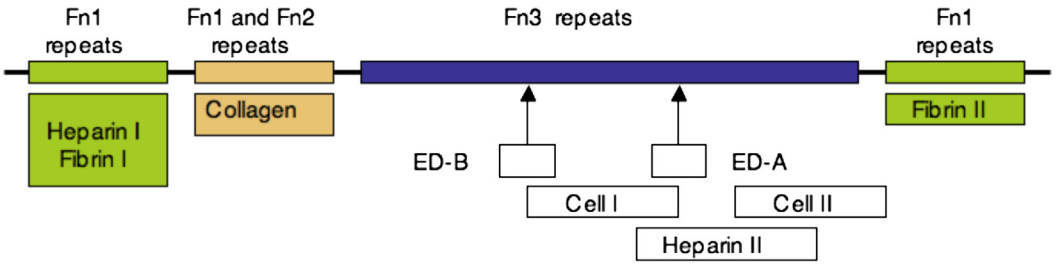

FIGURE 10.7

Diagram of a fibronectin polypeptide chan. The polypeptide chain is composed of several repeats (Fn1, Fn2, and Fn3) and contains binding sites for several matrix molecules and cells. Two regions can bind heparin and fibrin and two regions are involved in cell binding as well. By alternative splicing, isoforms are generated that may or may not contain certain Fn3 domains (labeled ED-A and ED-B in the diagram). Additional splice variations in the second cell-binding domain (Cell II) generate other isoforms.

Fn3 modules are the major structural units in fibronectin and are found in a large number of other proteins as well. Some of these proteins (for example, the long splice variant of collagen XII) contain more Fn3 modules than fibronectin itself. The structure of Fn3 is that of a sandwich of anti-parallel β-sheets (three strands in one layer and four strands in the other) with a hydrophobic core [75]. The binding of fibronectin to some integrins involves the tripeptide sequence Arg-Gly-Asp in the tenth Fn3 module; these residues lie in an exposed loop between two of the strands in one of the β-sheets [71].

Fibronectin can assemble into a fibrous network in the ECM through interactions involving cell surface receptors and the amino-terminal region of fibronectin. A fibrin binding site is also contained in this region; a second site is in the carboxyl domain. The ability to bind to collagen ensures association between the fibronectin network and the scaffold of collagen fibrils. Binding sites for heparin and chondroitin sulfate further make fibronectin an important bridging molecule between collagens and other matrix molecules (Fig. 10.7).

Transcripts of the fibronectin gene are alternatively spliced in a cell- and developmental stage-dependent manner. As a result there are many different isoforms of fibronectin [70]. The main form produced by the liver and circulating in plasma lacks two of the Fn3 repeats found in cell- and matrix-associated fibronectin. One alternatively spliced domain is adjacent to the heparin binding site, and this region binds to integrins α4β1 and α4β7. Thus, there is a mechanism for fine tuning of fibronectin structure and interaction properties. Not surprisingly, mice that are homozygous for fibronectin null alleles die early in embryogenesis with multiple defects [76].

The most important activity of fibronectin in biological terms is its interaction with cells. The ability of fibronectin to serve as a substrate for cell adhesion, spreading, and migration is based on the activities of several modules. The Arg-Gly-Asp sequence in the tenth Fn3 module plays a key role in the interaction with the integrin receptor α5β1, but synergistic interactions with other Fn3 modules are essential for high affinity binding of cells to fibronectin.

Laminins are major components of basement membranes

Laminins are trimeric basement membrane molecules of α, β, and γ chains [33]. With a large number of genetically distinct chains, more than 15 different trimeric isoforms are known from mice and humans. Based on a systematic approach to naming the different trimers, they are now named according to their chain composition (i.e., α1β1γ1) or by numbers only without the Greek letters (i.e., 111 instead of α1β1γ1) [77]. Several forms have a cross-shaped structure as visualized by rotary shadowing electron microscopy; some forms contain T-shaped molecules (Fig. 10.8).

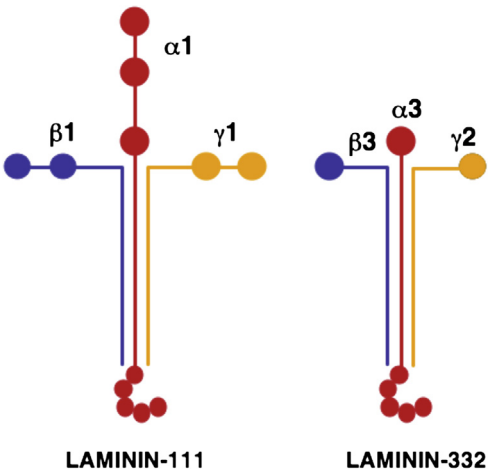

FIGURE 10.8
Diagrams of two types of laminins. Laminin-111 has a cross-shaped structure, while laminin 332 is T-shaped, due to a shorter α-chain.

In basement membranes, laminins provide interaction sites for many other constituents, including cell surface receptors. The functional and structural mapping of these sites and the complete sequencing of laminin chains has provided detailed insights into the organization of laminin molecules. Within the cross-shaped laminin-111 molecule, three similar short arms are formed by the N-terminal regions of the α1, β1, and γ1 chains, whereas a long arm is composed of the carboxyl regions of all three chains (Fig. 10.8). The three chains are connected at the center of the cross by interchain disulfide bridges. The short arms contain multiple EGF-like repeats of about 60 amino acid residues, terminated and interrupted by globular domains. The long arm consists of heptad repeats covering about 600 residues in all three chains folded into a coiled-coil structure. The α1 chain is about 1,000 amino acid residues longer than the β1 and γ1 chains and forms five homologous globular repeats at the 'base' of the cross; these globular repeats are similar to repeats found in the proteoglycan molecule perlecan, also a component of basement membranes (Fig. 10.5) [33].

Calcium-dependent polymerization of laminin is based on interactions between the globular domains at the N-termini and is thought to be important for the assembly and organization of basement membranes. Of significance for the assembly of basement membranes is also the high affinity interaction with nidogens (nidogen-1 and -2) [33]. The binding site in laminin for nidogen is on the γ1 chain, close to the center of the cross (Fig. 10.5). On nidogen, a rod-like molecule with three globular domains, the binding site for laminin is in the carboxyl globular domain, while another globular domain binds to collagen IV. Thus, nidogen is a bridging molecule that connects the laminin and collagen IV networks, and is critical for the assembly of normal basement membranes. Mice that are deficient in both nidogens or have the nidogen binding site in laminin γ1 deleted, have multiple defects and die before or at birth.

Laminin does not bind directly to collagen IV, but has binding sites for several other molecules besides nidogen. These are heparan sulfate, perlecan, and fibulin-1, which bind to the end of the long arm of the laminin cross. However, the biologically most significant interactions of laminin involve a variety of both integrin and non-integrin cell surface receptors. Several integrins show distinct preferences for different laminins and recognize binding sites on either the short or long arms of laminin molecules.

The different laminin genes likely arose through duplication of a single ancestral gene [78]. The laminins that are most closely related to this ancestral gene, laminin-111 and laminin-511, are crucial for early steps in development, including gastrulation, placentation and neural tube closure. In contrast, laminins that have evolved more recently are adapted to more specialized functions in the development and function of specific organs. For example, laminin-211 is a major laminin in the basement membranes surrounding skeletal muscle fibers where it provides binding sites for the dystroglycan-dystrophin complex, linking the muscle cell cytoskeleton to the basement membrane. In skin, a disulfide-linked complex of laminins-332 and -311 is crucial for the firm attachment of keratinocytes to the basement membrane by its interaction with α6β4 integrins in hemidesmosomes (Fig. 10.6). Mutations in any one of the genes encoding the subunits of laminin-332 cause autosomal recessive junctional epidermolysis bullosa, a lethal skin blistering disorder in which the epidermal cell layers are separated from the underlying epidermal basement membrane. Loss-of-function mutations in the laminin α2 gene cause congenital muscular dystrophy both in mice and humans.

Mice with targeted disruption of the laminin α3 gene develop a blistering skin disease similar to the disorder in human patients. In addition, the kidneys of the mutant animals show arrested development of glomeruli with a failure to develop glomerular capillaries with fenestrated endothelial cells, and lack of migration of mesangial cells into the glomeruli [79]. In humans, mutations resulting in laminin β2-deficiency cause a syndrome of loss of albumin and other plasma proteins through the glomerular basement membrane (congenital nephrotic syndrome), combined with sclerosis of the glomerular mesangium and severe impairment of vision and neurodevelopment [80].

Other modulators of cell-matrix interactions

Whereas proteins such as fibronectin and laminin are important for adhesion of cells to extracellular matrices, other ECM molecules function as both positive and negative modulators of such adhesive interactions. Examples of such modulators are thrombospondin [81] and tenascin [82]. Thrombospondins (TSPs) are a group of homologous trimeric (TSP-1 and TSP-2) and pentameric (TSP-3, TSP-4 and TSP-5/COMP) matrix proteins composed of several Ca^{++}-binding (type 3) domains, EGF-like repeats, (type 2) as well as other modules (Fig. 10.9). Different members of the group show differences in cellular expression and functional properties. The most highly conserved regions of the different thrombospondins are the carboxyl halves of the molecules, all consisting of a variable number of EGF-like domains, 7 Ca^{++}-binding TSP type 3 repeats and a C-terminal globular domain. In contrast, the N-terminal regions are quite variable, but all members have a short coiled-coil domain of heptad repeats in this region that is crucial for oligomerization into trimers in TSP-1 and TSP-2 or pentamers in TSP-3, TSP-4 and TSP-5/COMP. These oligomerization domains are stabilized by interchain disulfide bonds, but are quite stable even with the disulfides reduced. Since the subunits are held together at the coiled-coil domains, the assembled molecules have a flower-like appearance with three or five 'petals' extending out from the center, available for binding to cell surface receptors and other ECM molecules. The crystal structure of the five-stranded coiled-coil domain of TSP-5 shows that it forms a hydrophobic channel with some similarity to ion channels and can bind vitamin D and all-trans-retinoic acid. One function of pentameric thrombospondins may therefore be to store small hydrophobic signaling molecules in the ECM.

Interestingly, TSP type 1 repeats are found in many other proteins, including the large family of matrix metalloproteases called ADAMTS enzymes; in some members of this family, there are more copies of TSP type 1 domains than in TSP-1 or TSP-2 themselves. Members of the ADAMTS family have important biological functions [83]. For example, ADAMTS2, ADAMTS3 and ADAMTS14 are procollagen propeptidases, responsible for processing the amino propeptide in fibrillar procollagens (see above), and ADAMTS4 and ADAMTS5 are aggrecanases, able to degrade the major proteoglycan component of cartilage.

The carboxyl regions of thrombospondins can bind to a variety of ECM molecules, extracellular proteases and cell surface components such as integrins. Their oligomeric structure enable thrombospondins to be involved in multiple interactions and modulate both cellular behavior and ECM assembly. All thrombospondins support attachment of cells in a Ca^{++}-dependent manner and stimulate cell migration, proliferation, chemotaxis and phagocytosis. Trimeric thrombospondins (TSP-1 and TSP-2) have additional activities associated with the type 1 domains within their N-terminal regions. These activities include inhibition of angiogenesis through mechanisms by which thrombospondin induces endothelial cell apoptosis and inhibits mobilization of vascular endothelial growth factor (VEGF). The two

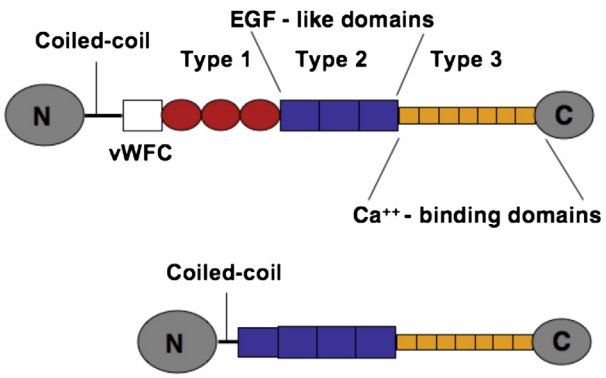

FIGURE 10.9
Diagram of thrombospondins. Diagram of trimeric thrombospondins (TSP-1 and TSP-2) on top showing the multidomain structure and the location of the coiled-coil domain important for trimerization. Diagram of pentameric thrombospondins (TSP-3, TSP-4 and TSP-5/COMP) at bottom, showing the lack of von Willebrand factor C-like domain (vWC) and type 1 repeats in this group of thrombospondins.

trimeric thrombospondins have also been shown to promote the formation of synapses in the central nervous system [84].

Cartilage oligomeric matrix protein (TSP-5/COMP) is thought to have evolved from the TSP-3 and TSP-4 branch of the thrombospondins. COMP is a secretory product of chondrocytes and is localized in their territorial matrix in cartilage. Beyond the fact that COMP interacts with collagens II and IX, little is known about its normal function in cartilage. Mice lacking COMP develop a normal skeleton and have no significant abnormalities. However, mutations in COMP cause pseudoachondroplasia and multiple epiphyseal dysplasia in humans [85,86]. At birth, affected individuals have normal weight and length but show reduced growth of long limb bones and striking defects in growth plate regions. These defects are caused by retention of mutant protein in the RER of chondrocytes, causing premature cell death. Mutations in COMP appear therefore to generate a mutant phenotype by a mechanism involving RER stress in chondrocytes.

The members of the vertebrate tenascin family (C, R, W and X) are large, multimeric proteins with subunits composed of multiple protein modules [82]. The modules include heptad repeats, fibronectin type 3 repeats, EGF-like domains, and a carboxyl domain with homology to the carboxyl-terminal domains of β-and γ-fibrinogen chains. These modules form rod-like structures that interact with their amino-terminal domains to form oligomers. Alternative splicing of tenascin-C generates multiple isoforms. The tenascins are differentially expressed in different tissues and at different times during development and growth [82]. For example, tenascin-R is only expressed in the central nervous system, in contrast to tenascin-C, which is found both in the central nervous system as well as in peripheral nerves. Tenascin-C expression is high during development and inflammation and around tumors, but is otherwise relatively low in postnatal tissues, with some interesting exceptions. In tissue regions of high mechanical stress, the levels of tenascin expression are high, suggesting a role for tenascin-C in the mechanisms used by cells to cope with mechanical stress. In fact, tenascin-C was first identified as a 'myotendinous antigen' because of the high level expression at tendon-muscle junctions [87]. It is also expressed by other cells that are exposed to mechanical stress, including osteoblasts, perichondrial cells around cartilage, smooth muscle cells and fibroblasts in healing wounds. This association between mechanical stress and expression is also seen for other tenascins. Thus, tenascin-W is expressed by both osteoblasts and smooth muscle cells and tenascin-X is expressed at high level in the connective tissue 'wraps' in skeletal muscle. Consistent with a 'mechanical' role in connective tissues is also the finding that a form of Ehlers-Danlos syndrome, with hypermobile joints and hyperelastic skin, is caused by a deficiency in tenascin-X [88].

The finding that collagen XII (see above) interacts with tenascin-X, combined with data showing that tenascin-X can bind to collagen I fibrils, possibly via interaction with the small proteoglycans decorin, suggests that a complex of collagen XII and tenascin-X are important interfibrillar bridges in skin [89]. This complex may also mediate attachment of collagen fibrils to cells, since tenascin can bind to integrin receptors. That a similar complex between collagen XII and tenascin-C may be present at myotendinous junctions is suggested by the high level expression of both collagen XII and tenascin-C at such junctions [90].

The interactions between tenascins and cells are relatively weak compared to other proteins such as fibronectin and thrombospondin. In certain experimental conditions tenascin-C can be an adhesive molecule for cells; it can also, however, have anti-adhesive effects [82]. The adhesive activity can be mediated by either cell surface proteoglycans or integrins, depending on cell type. Tenascin-C can bind heparin and this may be responsible for interactions with cell surface proteoglycans such as glypican. Tenascin-C can also block adhesion by covering up adhesive sites in other matrix molecules such as fibronectin and sterically block their interactions with cells. Tenascin-C has therefore been characterized as a cell adhesion-modulating

protein. Likewise, Tenascin-R can both promote neuronal cell adhesion and act as a repellant for neurites.

PROTEOGLYCANS — MULTIFUNCTIONAL MOLECULES IN THE EXTRACELLULAR MATRIX AND ON CELL SURFACES

A variety of proteoglycans play important roles in cellular growth and differentiation and in matrix structure. They range from the large hydrophilic space filling complexes of aggrecan and versican with hyaluronan, to the cell surface syndecan receptors. In basement membranes the major heparan sulfate proteoglycan is perlecan [91]. With three heparan sulfate side chains attached to the amino-terminal region, its core protein is multimodular in structure, having borrowed structural motifs from a variety of other genes. These include an LDL receptor-like module, regions with extensive homology to laminin chains, a long stretch of N-CAM-like IgG repeats, and a carboxyl-terminal region with three globular and four EGF-like repeats similar to a region of laminin. Alternative splicing can generate molecules of different lengths. Perlecan is present in a number of basement membranes, but is also found in the pericellular matrix of fibroblasts and in cartilage ECM. In fact, fibroblasts, rather than epithelial cells, appear to be major producers of perlecan (for example, in skin). In liver, perlecan is expressed by sinusoidal endothelial cells, and is localized in the perisinusoidal space. Mutations in the *unc-52* gene in *C. elegans*, encoding a short version of perlecan, cause disruptions of skeletal muscle [92]. This indicates that the molecule, as a component of skeletal muscle basement membranes, is important for assembly of myofilaments and their attachment to cell membranes. Binding of growth factors and cytokines to the heparan sulfate side chains also enables perlecan to serve as a storage vehicle for biologically active molecules such as bFGF. The critical role of perlecan is further highlighted by the dramatic effects of knocking out the perlecan gene in mice [93]. Most of the mutant embryos die halfway through pregnancy and the few embryos that survive to birth have severe defects in the brain and the skeleton. The skeletal defects include severe shortening of axial and limb bones and disruption of normal growth plate structure.

Several small leucine-rich repeat proteins and proteoglycans with homologous core proteins are found in a variety of tissues where they interact with other matrix macromolecules and regulate their functions [94]. They include decorin, biglycan, lumican, and fibromodulin. Decorin binds along collagen fibrils and plays a role in regulating fibril assembly and mechanical properties [95,96]. It also modulates the binding of cells to matrix constituents such as collagen, fibronectin and tenascin [97]. Through binding of TGF-β isoforms the small proteoglycans help sequester growth factors within the ECM and thus regulate their activities [98].

A variety of proteoglycans also have important functions at cell surfaces. These include members of the syndecan family, transmembrane molecules with highly conserved cytoplasmic domains, and glypican-related molecules that are linked to the cell surface via glycosyl phosphatidylinositol. Through their heparan sulfate side chains these molecules can bind growth factors, protease inhibitors, enzymes, and matrix macromolecules. They are therefore important modulators of cell signaling pathways and cell-matrix contacts [99,100].

Hyaluronan is an important component of most extracellular matrices [101]. It serves as a ligand for several proteins, including cartilage link protein and aggrecan and versican core proteins. In cartilage, based on such interactions, it is the backbone for the large chondroitin sulfate-containing aggrecan proteoglycan complexes responsible for the compressive properties of cartilage [102] (Fig. 10.10). It also is a ligand for cell surface receptors and regulates cell proliferation and migration [103,104]. One receptor for hyaluronan is the transmembrane molecule CD44. By alternative splicing and variations in post-translational modifications, a family of CD44 proteins is generated [105]. These show cell and

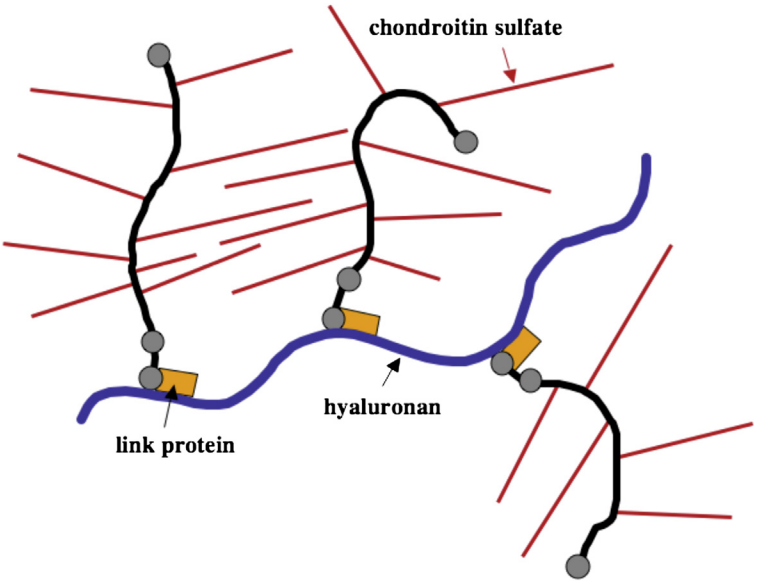

FIGURE 10.10
Diagram of a portion of a large proteoglycan complex from cartilage. Monomers of aggrecan, composed of core proteins with glycosaminoglycan side chains (mostly chondroitin sulfate) are bound to hyaluronan. The binding is stabilized by link proteins. For clarity, only some of the glycosaminoglycan side chains are shown in the monomers.

tissue-specific expression patterns and are thought to have distinct functional roles. Hyaluronan-mediated cell motility is based on the interaction of hyaluronan with a cell surface associated protein called RHAMM (receptor for hyaluronate-mediated motility) [106]. As a space filling molecule and through its interaction with cell surface receptors hyaluronan is important for several morphogenetic processes during development. It creates cell free spaces through which cells (for example neural crest cells) can migrate, and its degradation by hyaluronidase is important for processes of cellular condensation. Since hyaluronan is not immunogenic, is readily available and can be easily manipulated and chemically modified, it is receiving considerable attention as a tissue-engineering biopolymer [107].

CONCLUSION

Research efforts during the past 40 years have led to significant insights into the composition of extracellular matrices and the structure and function of the major components. We now realize that the evolution of vertebrates and mammals was associated with an expansion of several families of matrix molecules, providing cells with an increasing repertoire of isoforms and homologs to build different tissues. It is also evident that the increasing number of different families of genes encoding matrix molecules during evolution of more complex organisms involved shuffling and recombination of genes encoding a relatively small number of structural and functional modules. Finally, the data suggest that cells are building matrices by adding layer upon layer of components that can interact with various affinities (but mostly on the low side) and in multiple ways with their neighbors. The result is an extracellular matrix that readily can be fine-tuned to meet the demands of the moment but one that is relatively resistant to the effects of mutations that may cause dysfunction of specific components. As we learn to use these insights to identify the most critical matrix properties from a cellular point of view, exciting and rapid advances in tissue engineering should follow.

CHAPTER 11

Morphogenesis and Tissue Engineering

A.H. Reddi
Department of Orthopedic Surgery, School of Medicine, University of California, Davis, Sacramento, California

INTRODUCTION

Morphogenesis is the developmental cascade of pattern formation, the establishment of the body plan and architecture of mirror-image bilateral symmetry of musculoskeletal structures, culminating in the adult form. Tissue engineering is the emerging discipline of fabricating spare parts for the human body, including the skeleton, for the functional restoration and aging of lost parts due to cancer, disease or trauma. It is based on rational principles of molecular developmental biology and morphogenesis and is further governed by bioengineering. The three key ingredients for both morphogenesis and tissue engineering are inductive morphogenetic signals, responding stem cells, and extracellular matrix scaffolding [1] (Fig. 11.1). Recent advances in the molecular cell biology of morphogenesis will aid in the design principles and architecture for tissue engineering and regeneration.

The long-term goal of tissue engineering is to produce functional tissues *in vitro* for implantation *in vivo* to repair, enhance, and replace damaged tissue, and to preserve physiological function. Tissue engineering is based on the principles of developmental biology, evolution and self-assembly of supramolecular assemblies and higher hierarchal tissues and even whole embryos and organisms (Figs. 11.2 and 11.3). Regeneration recapitulates embryonic development and morphogenesis. Among the many tissues in the human body, bone has considerable powers for regeneration and therefore is a prototype model for tissue engineering. On the other hand, articular cartilage, a tissue adjacent to bone, is recalcitrant to repair and regeneration. Implantation of demineralized bone matrix into subcutaneous sites results in local bone induction. The sequential cascade of bone morphogenesis mimics sequential skeletal morphogenesis in limbs and permits the isolation of bone morphogens. Although it is traditional to study morphogenetic signals in embryos, bone morphogenetic proteins (BMPs), the primordial inductive signals for bone were isolated from demineralized bone matrix from adults. BMPs initiate, promote, and maintain chondrogenesis and osteogenesis and have actions beyond bone. The recently identified cartilage-derived morphogenetic proteins (CDMPs) are critical for cartilage and joint morphogenesis.

The symbiosis of bone's inductive and conductive strategies is critical for tissue engineering and is in turn governed by the context and biomechanics. The context is the microenvironment, consisting of extracellular matrix scaffolding, which can be duplicated by biomimetic biomaterials, such as collagens, hydroxyapatite, proteoglycans, and cell adhesion proteins, including fibronectins and laminins. The rules of architecture for tissue engineering are

an imitation and adoption of the laws and signals of developmental biology and morphogenesis, and thus they may be universal for all tissues, including bones and joints and associated musculoskeletal tissues in the limbs.

The traditional approach for identification and isolation of morphogens is first to identify genes in fly and frog embryos by means of genetic approaches, differential displays, substractive hybridization, and expression cloning. This information is subsequently extended to mice and men. An alternative approach is to isolate morphogens from bone, the premier tissue with the highest regenerative potential. Morphogenesis is the developmental cascade of pattern formation, the establishment of the body plan and architecture of mirror-image bilateral symmetry of musculoskeletal structures in the appendicular skeleton, culminating in the adult form. Our expanding knowledge of bone and cartilage morphogenesis is a prototypical paradigm for all of tissue engineering. The principles gleaned from bone

morphogenesis and BMPs can be extended to tissue engineering of bone and cartilage and other tissues.

BONE MORPHOGENETIC PROTEINS (BMPS)

Bone grafts have been used by orthopedic surgeons for nearly a century to aid and abet recalcitrant bone repair. Decalcified bone implants have been used to treat patients with osteomyelitis [2]. It was hypothesized that bone might contain a substance, osteogenin, that initiates bone growth [3]. Urist [77] made the key discovery that demineralized, lyophilized segments of rabbit bone, when implanted intramuscularly, induced new bone formation. The diaphysis (shafts) of long bones of rats were cleaned of marrow, pulverized and sieved. The demineralization of matrix was accomplished by 0.5 M HCl (Fig. 11.4). Bone induction, a sequential multistep cascade, is depicted in Fig. 11.5 [4–6]. The key steps in this cascade are chemotaxis, mitosis, and differentiation. Chemotaxis is the directed migration of cells in response to a chemical gradient of signals released from the insoluble demineralized bone matrix.

The demineralized bone matrix is composed predominantly of type I insoluble collagen, and it binds plasma fibronectin [7]. Fibronectin has domains for binding to collagen, fibrin, and heparin. The responding mesenchymal cells attached to the collagenous matrix and proliferated as indicated by [3H]thymidine autoradiography and incorporation into acid-precipitable DNA on day 3 [8]. Chondroblast differentiation was evident on day 5, chondrocytes on days 7–8, and cartilage hypertrophy on day 9 (Fig. 11.5). Vascular invasion was concomitant on day 9 with osteoblast differentiation. On days 10–12 alkaline phosphatase was maximal. Osteocalcin, bone γ-carboxyglutamic acid containing gla protein (BGP), increased on day 28. Hematopoietic marrow differentiated in the ossicle and was maximal by day 21. This entire sequential bone development cascade is reminiscent of bone and cartilage morphogenesis in

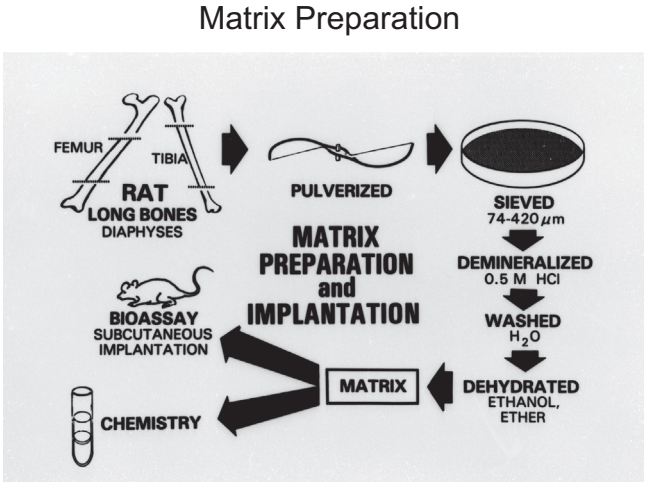

FIGURE 11.4
Preparation of the demineralized bone matrix (DBM). The diaphysis (shafts) of femur and tibia are cleansed of marrow and dried prior to pulverization. The pulverized bone matrix is sieved to a particle size of 74–420 μm and demineralized by 0.5 M HCl, dehydrated in ethanol and diethyl ether. The resulting matrix is a potent inducer of cartilage and bone, and we isolate, by means of chemical techniques, the active osteoinductive agent BMP.

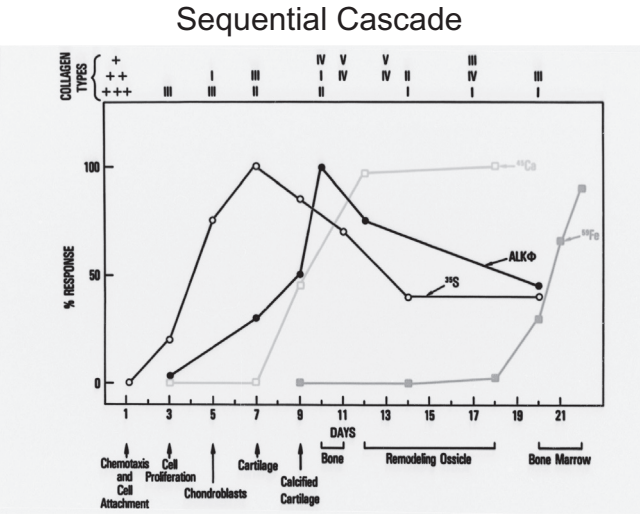

FIGURE 11.5

Developmental sequence of extracellular matrix-induced cartilage, bone, and marrow formation. Changes in 35SO4 incorporation into proteoglycans and 45Ca incorporation into the mineral phase indicate peaks of cartilage and bone formation, respectively. The 59Fe incorporation into heme is an index of erythropoiesis, as plotted from the data of Reddi and Anderson (1976) [5]. The values for alkaline phosphatase indicate early stages of bone formation [4]. The transitions in collagen types I to IV, summarized on top of the figure, are based on immunofluorescent localization = polymorphonuclear leukocytes. (Source: Ref. [6], with permission.)

the limb bud [6,9]. Hence, it has immense implications for isolation of inductive signals initiating cartilage and bone morphogenesis. In fact, a systematic investigation of the chemical components responsible for bone induction was undertaken.

The foregoing account of the demineralized bone matrix-induced bone morphogenesis in extra-skeletal sites demonstrated the potential role of morphogens tightly associated with the extracellular matrix. Next, we embarked on a systematic study of the isolation of putative morphogenetic proteins. A prerequisite for any quest for novel morphogens is the establishment of a battery of bioassays for new bone formation. A panel of *in vitro* assays was established for chemotaxis, mitogenesis, and chondrogenesis, and an *in vivo* bioassay was established for bone formation. Although the *in vitro* assays are expedient, we monitored routinely a labor-intensive *in vivo* bioassay, for it was the only bona fide bone induction assay.

A major stumbling block in the approach was that the demineralized bone matrix is insoluble and exists in the solid state. In view of this, dissociative extractants such as 4 M guanidine HCl or 8 M urea as 1% sodium dodecyl sulfate (SDS) at pH 7.4 were used [10] to solubilize the proteins. Approximately 3% of the proteins were solubilized from demineralized bone matrix, and the remaining residue was mainly insoluble type I bone collagen. The extract alone or the residue alone was incapable of new bone induction. However, addition of the extract to the residue (insoluble collagen) and then implantation in a subcutaneous site resulted in bone induction (Fig. 11.6). Thus, it would appear that in optimal osteogenic activity collaboration takes place between the soluble signal in the extract and insoluble substratum or scaffolding [10]. Thus, an operational concept of tissue engineering was established, in which soluble signals bound to extracellular matrix scaffold act on responding stem/progenitor cells to induce tissue digestion. This bioassay was a useful advance in the final purification of bone morphogenetic proteins and led to the determination of limited tryptic peptide sequences leading to the eventual cloning of BMPs [11–13].

In order to scale up the procedure, a switch was made to bovine bone. Demineralized bovine bone was not osteoinductive in rats, and the results were variable. However, when the guanidine extracts of demineralized bovine bone were fractionated on an S-200 molecular

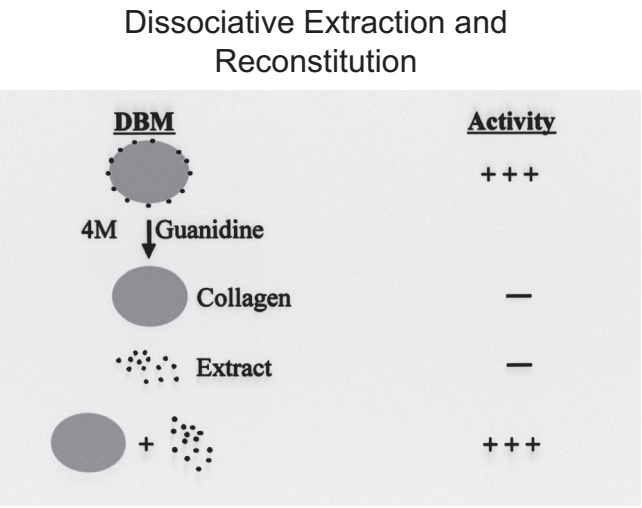

FIGURE 11.6
Dissociative extraction by chaotropic reagents such as 4M guanidine and reconstitution of osteoinductive activity with insoluble collagenous matrix. The results demonstrate a collaboration between a soluble signal and insoluble extracellular matrix. This experiment further established the basic tenets of tissue engineering in 1981 as signals, scaffolds, and responding stem cells.

sieve column, fractions less than 50 kD were consistently osteogenic when bioassayed after reconstitution with allogeneic insoluble [14,78]. Thus, protein fractions inducing bone were not species specific, and appeared to be homologous in several mammals. It is likely that larger molecular mass fractions and/or the insoluble xenogeneic (bovine and human) collagens were inhibitory or immunogenic. Initial estimates revealed 1 μg of active osteogenic fraction in a kilogram of bone. Hence, over a ton of bovine bone was processed to yield optimal amounts for amino acid sequence determination. The amino acid sequences revealed homology to TGF-β1 [14]. The important work of Wozney and colleagues [11] involved cloning BMP-2, BMP-2B (now called BMP-4), and BMP-3 (also called osteogenin). Osteogenic protein-1 and -2 (OP-1 and OP-2) were cloned by Ozkaynak and colleagues [13]. There are nearly 10 members of the BMP family (Table 11.1). The other members of the extended TGF-β/BMP superfamily include inhibins and activins (implicated in follicle-stimulating hormone release from pituitary), Müllerian duct inhibitory substance (MIS), growth/differentiation factors (GDFs), nodal, and lefty, a gene implicated in establishing right/left asymmetry [15,16]. BMPs are also involved in embryonic induction [15,17–19].

BMPs are dimeric molecules, and their conformation is critical for biological action. Reduction of the single interchain disulfide bond resulted in the loss of biological activity. The mature monomer molecule consists of about 120 amino acids, with seven canonical cysteine residues. There are three intrachain disulfides per monomer and one interchain disulfide bond in

TABLE 11.1 Bone morphogenetic proteins

BMP	Other names	Function
BMP-2	BMP-2A	Bone and cartilage morphogenesis

BMP-15		?

the dimer. In the critical core of the BMP monomer is the cysteine knot. The crystal structure of BMP-7 has been determined [20]. It is highly possible that in the near future the crystal structure of BMP receptor and receptor contact domains will be determined [20].

CARTILAGE-DERIVED MORPHOGENETIC PROTEINS (CDMPS)

Morphogenesis of the cartilage is the key rate-limiting step in the dynamics of bone development. Cartilage is the initial model for the architecture of bones. Bone can form either directly from mesenchyme, as in intramembranous bone formation, or with an intervening cartilage stage, as in endochondral bone development [6]. All BMPs first induce the cascade of chondrogenesis, and therefore in this sense they are cartilage morphogenetic proteins. The hypertrophic chondrocytes in the epiphyseal growth plate mineralize and serve as a template for appositional bone morphogenesis. Cartilage morphogenesis is critical for both bone and joint morphogenesis. The two lineages of cartilage are clear-cut. The first, at the ends of bone, forms articulating articular cartilage. The second is the growth plate chondrocytes, which, through hypertrophy, synthesize cartilage matrix destined to calcify prior to replacement by bone, and are the 'organizer' centers of longitudinal and circumferental growth of cartilage, setting into motion the orderly program of endochondral bone formation. The phenotypic stability of the articular (permanent) cartilage is at the crux of the osteoarthritis problem. The maintenance factors for articular chondrocytes include TGF-β isoforms and the BMP isoforms [21].

An *in vivo* chondrogenic bioassay with soluble purified proteins and insoluble collagen scored for chondrogenesis. A concurrent reverse transcription–polymerase chain reaction (RT-PCR) approach was taken with degenerate oligonucleotide primers. Two novel genes for CDMPs 1 and 2 were identified and cloned [22]. CDMPs 1 and 2 are also called GDF-5 and GDF-6 [23]. CDMPs are related to BMPs (Table 11.2). CDMPs are critical for cartilage and joint morphogenesis [24]. CDMPs stimulate proteoglycan synthesis in cartilage. CDMP 3 (also known as GDF-7) initiates tendon and ligament morphogenesis.

PLEIOTROPY AND THRESHOLDS

Morphogenesis is a sequential multistep cascade. BMPs regulate each of the key steps: chemotaxis, mitosis, and differentiation of cartilage and bone (Fig. 11.7). BMPs initiate chondrogenesis in the limb [25,26]. The apical ectodermal ridge is the source of BMPs in the developing limb bud. The intricate dynamic, reciprocal interactions between the ectodermally derived epithelium and mesodermally derived mesenchyme sets into motion the train of events culminating in the pattern of phalanges, radius, ulna, and the humerus.

The chemotaxis of human monocytes is optimal at femtomolar concentrations [27]. The apparent affinity was 100–200 pM. The mitogenic response was optimal at the 100 pM range. The initiation of differentiation was in the nanomolar range in solution. However, caution should be exercised, because BMPs may be sequestered by extracellular matrix components, and the local concentration may be higher when BMPs are bound on the extracellular matrix. A single recombinant BMP human 4 can govern chemotaxis and mitosis differentiation of cartilage and bone, maintain phenotype, stimulate extracellular matrix, and promote

TABLE 11.2 Cartilage-derived morphogenetic proteins

CDMP	Other names	Function
CDMP 1	GDF-5	Cartilage condensation
CDMP 2	GDF-6	Cartilage formation, hypertrophy

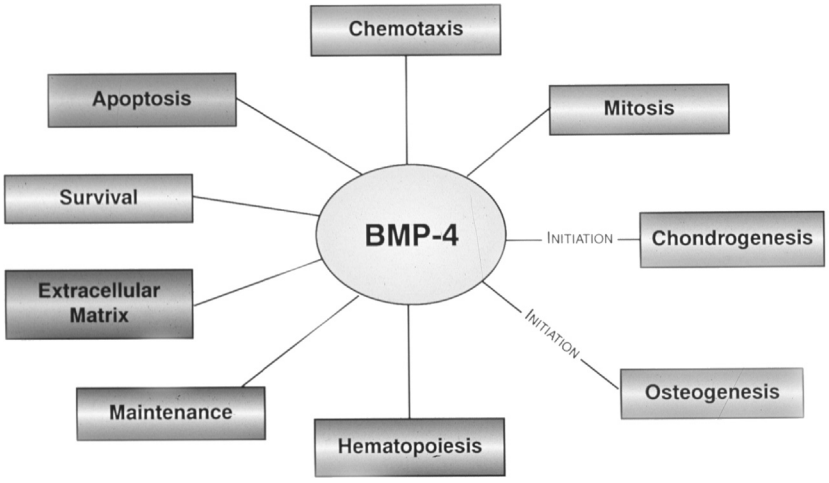

FIGURE 11.7
BMPs are pleiotropic molecules. Pleiotropy is the property of a single gene or protein to act on a multiplicity of cellular phenomena and targets.

survival of some cells but cause the death of others (Fig. 11.7). Thus BMPs are pleiotropic regulators that act in concentration-dependent thresholds.

BMPS BIND TO EXTRACELLULAR MATRIX

It is well known that extracellular matrix components play a critical role in morphogenesis. These structural macromolecules and their supramolecular assembly in the matrix do not explain their role in epithelial–mesenchymal interaction and morphogenesis. This riddle can now be explained by the binding of BMPs to heparan sulfate heparin and type IV collagen [28–30] of the basement membranes. In fact, this binding might explain in part the necessity for angiogenesis prior to osteogenesis during development. In addition, the actions of activin in development of the frog, in terms of dorsal mesoderm induction, are modified to neuralization by follistatin [31]. Similarly, Chordin and Noggin from the Spemann organizer induce neuralization via binding and inactivation of BMP-4 (Fig. 11.2). Thus neural induction is likely to be a default pathway when BMP-4 is non-functional [32,33]. Thus, an emerging principle in development and morphogenesis is that binding proteins can terminate a dominant morphogen's action and initiate a default pathway. Finally, the binding of a soluble morphogen to extracellular matrix converts it into an insoluble matrix-bound morphogen to act locally in the solid state [28].

Although BMPs were isolated and cloned from bone, work with gene knockouts has revealed a plethora of actions beyond bone. Targeted disruption of BMP-2 in mice caused embryonic lethality. The development of the heart is abnormal, indicating a need for BMP-2 in heart development [34]. BMP-4 knockouts exhibit no mesoderm induction, and gastrulation is impaired [35]. Transgenic overexpression of BMPs under the control of keratin 10 promoter leads to psoriasis. The targeted deletion of BMP-7 revealed the critical role of this molecule in kidney and eye development [36,37]. Thus the BMPs really are true morphogens for such disparate tissues as skin, heart, kidney and eye. In view of this, BMPs may also be called body morphogenetic proteins [38].

BMP RECEPTORS

Recombinant human BMP-4 and BMP-7 bind to BMP receptor IA (BMPR-IA) and BMP receptor IB (BMPR-IB) [39]. CDMP-1 also binds to both type I BMP receptors. There is collaboration between type I and type II BMP receptors [75]. The type I receptor serine/threonine kinase phosphorylates a signal-transducing protein substrate called Smad 1 or 5^{25}. Smad is a term derived from the fusion of the *Drosophila* Mad gene and the *Caenorhabtitis elegans* (nematode) Sma gene. Smads 1 and 5 signal in partnership with a common co-Smad, Smad 4 (Fig. 11.8). The

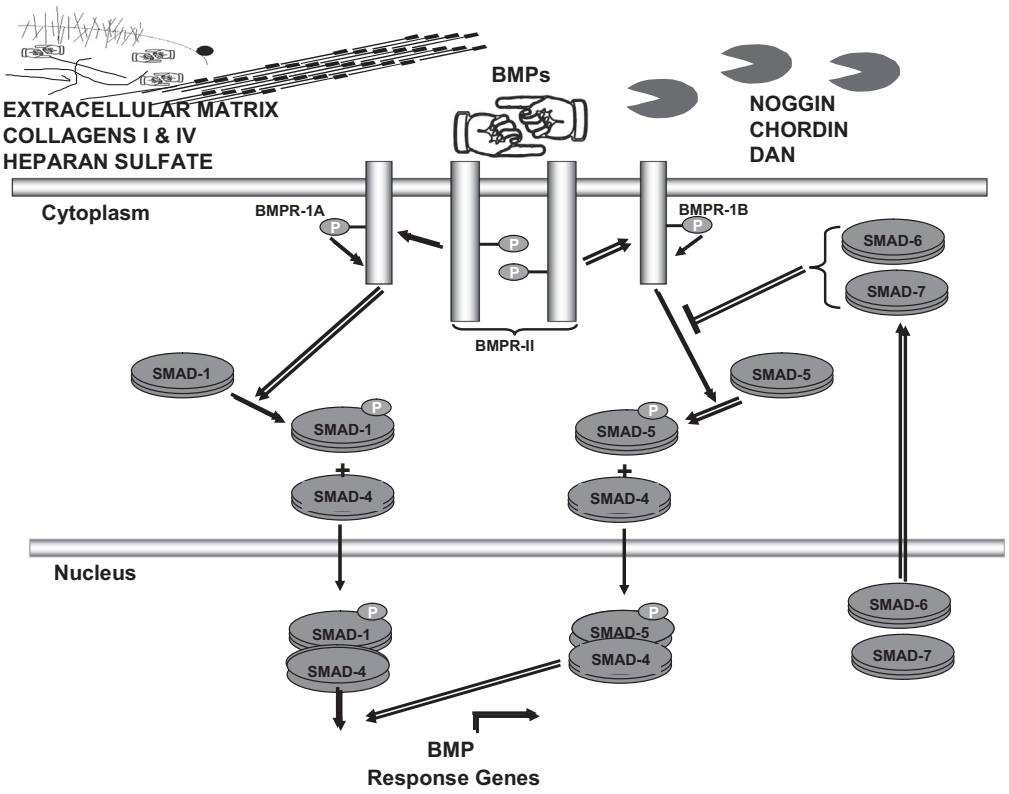

FIGURE 11.8

BMP receptors and signaling cascades. BMPs are dimeric ligands with cysteine knot in each monomer fold. Each monomer has two β-sheets, represented as two pointed fingers. In the functional dimer, the fingers are oriented in opposite directions. BMPs interact with both type I and II BMP receptors. The exact stoichiometry of the receptor complex is currently being elucidated. BMPR-II phosphorylates the GS domain of BMPR-I. The collaboration between type I and II receptors forms the signal-transducing complex. BMP type I receptor kinase complex phosphorylates the trimeric signaling substrates Smad 1 and Smad 5. This phosphorylation is inhibited and modulated by inhibitory interacts with Smad 4 (functional partner) and enters the nucleus to activate the transcriptional machinery for early BMP-response genes. A novel Smad-interacting protein (SIP) may interact and modulate the binding of heteromeric Smad 1/Smad 4 complexes to the DNA.

transcription of BMP-response genes are initiated by Smad 1/Smad 4 heterodimers. Smads are trimeric molecules, as discovered by X-ray crystallography. The phosphorylation of Smads 1 and 5 by type I BMP receptor kinase is inhibited by inhibitory Smads 6 and 7 [40]. Smad-interacting protein (SIP) may interact with Smad 1 and modulate BMP-response gene expression [15,41,42]. The downstream targets of BMP signaling are likely to be homeobox genes, the cardinal genes for morphogenesis and transcription. BMPs in turn may be regulated by members of the hedgehog family of genes, such as Sonic and Indian hedgehog [43], including receptors patched and smoothened and transcription factors such as Gli 1, 2, and 3. The actions of BMPs can be terminated by specific binding proteins, such as noggin [33].

RESPONDING STEM CELLS

It is well known that the embryonic mesoderm-derived mesenchymal cells are progenitors for bone, cartilage, tendons, ligaments, and muscle. However, certain stem cells in adult bone marrow, muscle and fascia can form bone and cartilage. The identification of stem cells readily sourced from bone marrow may lead to banks of stem cells for cell therapy and perhaps gene therapy with appropriate 'homing' characteristics to bone marrow and hence to the skeleton. The pioneering work of Friedenstein et al. [44] and Owen and Friedenstein [45] identified bone marrow stromal stem cells. These stromal cells are distinct from the hematopoietic stem cell lineage. The bone marrow stromal stem cells consist of inducible and

determined osteoprogenitors committed to osteogenesis. Determined osteogenic precursor cells have the propensity to form bone cells, without any external cues or signals. On the other hand, inducible osteogenic precursors require an inductive signal, such as BMP or demineralized bone matrix. It is noteworthy that operational distinctions between stromal stem cells and hematopoietic stem cells are getting more and more blurry! The stromal stem cells of Friedenstein and Owen are also called mesenchymal stem cells [46], with potential to form bone, cartilage, adipocytes, and myoblasts in response to cues from the environment and/or intrinsic factors. There is considerable hope and anticipation that these bone marrow stromal cells may be excellent vehicles for cell and gene therapy [47].

From a practical standpoint, these stromal stem cells can be obtained by bone marrow biopsies and expanded rapidly for use in cell therapy after pretreatment with BMPs. The potential uses in both cell and gene therapy is very promising. There are continuous improvements in the viral vectors and efficiency of gene therapy [48,79]. For example, it is possible to use BMP genes transfected in stromal stem cells to target the bone marrow.

MORPHOGENS AND GENE THERAPY

The recent advances in morphogens are ripe for techniques of regional gene therapy for orthopedic tissue engineering. The availability of cloned genes for BMPs and CDMPs and the requisite platform technology of gene therapy may have immediate applications. Whereas protein therapy provides an immediate bolus of morphogen, gene therapy achieves a sustained, prolonged secretion of gene products. Furthermore, recent improvements in regulated gene expression allow the turning on and off of gene expression. The progress in vectors for delivering genes also bodes well. The use of adenoviruses, adeno-associated viruses, and tetroviruses is poised for applications in bone and joint repair [48–51]. Although gene therapy has some advantages for orthopedic tissue engineering, an optimal delivery system for protein and gene therapy is needed, especially in the replacement of large segmented defects and in fibrous non-unions and mal-unions.

BIOMIMETIC BIOMATERIALS

Our earlier discussions of inductive signals (BMPs) and responding stem cells (stromal cells) lead us to the scaffolding (the microenvironment/extracellular matrix) for optimal tissue engineering. The natural biomaterials in the composite tissue of bones and joints are collagens, proteoglycans, and glycoproteins of cell adhesion, such as fibronectin and the mineral phase. The mineral phase in bone is predominantly hydroxyapatite. In its native state, the associated citrate, fluoride, carbonate, and trace elements constitute the physiological hydroxyapatite. Its high protein-binding capacity makes hydroxyapatite a natural delivery system. Comparison of insoluble collagen, hydroxyapatite, tricalcium phosphate, glass beads, and polymethylmethacrylate as carriers revealed collagen to be an optimal delivery system for BMPs [52]. It is well known that collagen is an ideal delivery system for growth factors in soft and hard tissue wound repair [53]. Hydrogels may be of great utility in cartilage tissue engineering [74].

During the course of systematic work on hydroxyapatite of two pore sizes (200 or 500 μm) in two geometrical forms (beads or disks), an unexpected observation was made. The geometry of the delivery system is critical for optimal bone induction. The disks were consistently osteoinductive with BMPs in rats, but the beads were inactive [54]. The chemical compositions of the two hydroxyapatite configurations were identical. In certain species, the hydroxyapatite alone appears to be 'osteoinductive' [55]. In subhuman primates, hydroxyapatite induces bone, albeit at a much slower rate. One interpretation is that osteoinductive endogenous BMPs in circulation progressively bind to an implanted disk of hydroxyapatite. When an optimal threshold concentration of native BMPs is achieved, the hydroxyapatite becomes

osteoinductive. Strictly speaking, most hydroxyapatite substrata are ideal osteoconductive materials. This example in certain species also serves to illustrate how an osteoconductive biomimetic biomaterial can progressively function as an osteoinductive substance by binding to endogenous BMPs. Thus, there is a physiological-physicochemical continuum between the hydroxyapatite alone and progressive composites with endogenous BMPs. Recognition of this experimental nuance will save unnecessary arguments among biomaterials scientists about the osteoinductive action of a conductive substratum such as hydroxyapatite.

Complete regeneration of baboon craniotomy defect was accomplished via recombinant human osteogenic protein (rhOP-1; human BMP-7) [76]. Recombinant BMP-2 was delivered by a poly(-hydroxy acid) carrier for calvarial regeneration [56].

Copolymers of polylactic acid and polyglycolic acid with recombinant BMP-2 were used in a non-union model in rabbit ulna, and complete unions were achieved in the bone [57].

An important problem in the clinical application of biomimetic biomaterials with BMPs and/or other morphogens is its sterilization. Although gas (ethylene oxide) can be used, one should always be concerned about reactive free radicals. Using allogeneic demineralized bone matrix with endogenous native BMPs, as long as a low temperature (4°C or less) is maintained, the samples tolerated up to 5—7 M rads of irradiation [58,59]. The standard dose acceptable to the Food and Drug Administration is 2.5 M rads. This information would be useful to the biotechnology companies preparing to market recombinant BMP-based osteogenic devices. Perhaps, the tissue-banking industry, with its interest in bone grafts [60], could also use this critical information. The various freeze-dried and demineralized allogeneic bone may be used in the interim as satisfactory carriers for BMPs. The moral of this experiment is it is not the irradiation dose but the ambient sample temperature during irradiation that is absolutely critical.

TISSUE ENGINEERING OF BONES AND JOINTS

Unlike bone, with its considerable prowess for repair and even regeneration, cartilage is recalcitrant. But why? In part this may be due to the relative avascularity of hyaline cartilage and the high concentration of protease inhibitors and perhaps even of growth inhibitors. The wound debridement phase is not optimal for preparing the cartilage wound bed for the optimal *milieu interieur* for repair. Although cartilage has been successfully engineered to predetermined shapes [61], true repair of the tissue continues to be a real challenge, in part due to hierarchical organization and geometry [62]. However, considerable excitement in the field has been generated by a group of Swedish workers in Gothenburg, using autologous culture-expanded human chondrocytes [63]. A continuous challenge in chondrocyte cell therapy is progressive dedifferentiation and loss of characteristic cartilage phenotype. The redifferentiation and maintenance of the chondrocytes for cell therapy can be aided by BMPs, CDMPs, TGF-β isoforms, and IGFs. It is also possible to repair cartilage using muscle-derived mesenchymal stem cells [64]. The possibility of problems posed by cartilage proteoglycans in preventing cell immigration for repair was investigated by means of chondroitinase ABC and trypsin pretreatment in partial thickness defects [65], with and without TGF. Pretreatment with chondroitinase ABC followed by TGF revealed a contiguous layer of cells from the synovial membrane, hinting at the potential source of repair cells from synovium. Multiple avenues of cartilage morphogens, cell therapy with chondrocytes and stem cells from marrow and muscle, and a biomaterial scaffolding may lead to an optimal tissue-engineered articular cartilage.

Recombinant human and BMP-2 and BMP-7 were approved in 2002 by the Food and Drug Administration (FDA) for tibial non-unions and single-level spine fusion. BMPs have been used in healing segmental defects (Fig. 11.9). The proof of the principle of tissue engineering based on BMPs as signals, molding via a scaffold, and responding cells can be demonstrated (Fig. 11.10).

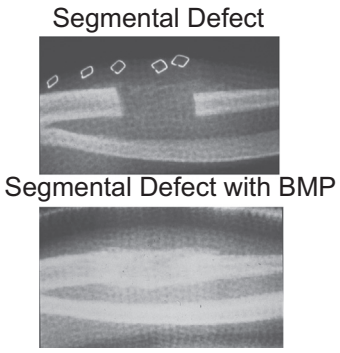

FIGURE 11.9
Repair of segmental defects in a primate bone by means of recombinant human BMP-7 and collagenous matrix scaffold. *(Photographs provided by Dr. T. K. Sampath.)*

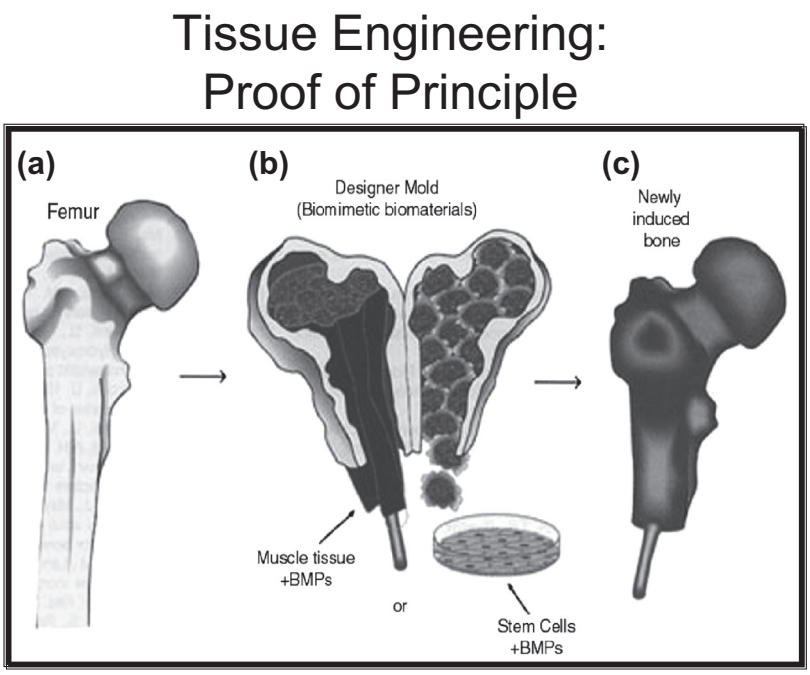

FIGURE 11.10
Proof of the principles of tissue engineering was established *in vivo* by Khouri et al. (1991) [73]. A mold was used to contain the vascularized muscle flap and treated with purified BMPs and collagen scaffold. The newly formed bone faithfully reproduced the shape of the mold. In the future, one can use stem cells directed by recombinant BMPs to induce bone.

FUTURE CHALLENGES

It is inevitable that as humans age that they will be confronted by impaired locomotion due to wear and tear in bones and joints. Therefore, the repair and possibly complete regeneration of the musculoskeletal system and other vital organs, such as skin, liver, and kidney, may potentially need optimal repair or a spare part for replacement. Can we create spare parts for the human body? There is much reason to be optimistic that tissue engineering can help patients. We are living in an extraordinary time with regard to biology, medicine, surgery, bioengineering, computer modeling of predictive tissue engineering and technology. The confluence of advances in molecular developmental biology and attendant advances in inductive signals for morphogenesis, stem cells, biomimetic biomaterials, and extracellular matrix biology augers well for imminent breakthroughs.

The symbiosis of biotechnology and biomaterials has set the stage for systematic advances in tissue engineering [14,66,67]. The recent advances in enabling platform technology include molecular imprinting [68]. In principle, specific recognition and catalytic sites are imprinted

using templates. The applications include biosensors, catalytic applications to antibodies and receptor recognition sites. For example, the cell-binding RGD site in fibronectin [69] or the YIGSR domain in laminin can be imprinted in complementary sites [70].

The rapidly advancing frontiers in morphogenesis with BMPs, hedgehogs, homeobox genes, and a veritable cornucopia of general and specific transcription factors, coactivators, and repressors will lead to co-crystallization of ligand–receptor complexes, protein–DNA complexes, and other macromolecular interactions. This will lead to peptidomimetic agonists for large proteins, as exemplified by erythroprotein [71]. To such advances one can add new developments in the self-assembly of millimeter scale structures floating at the interface of perfluorodecalin and water and interacting by means of capillary forces controlled by the pattern of wettablity [72]. The final self-assembly is due to minimization of free energy in the interface. These are truly incredible advances that will lead to man-made materials that mimic extracellular matrix in tissues. Superimpose on such chemical progress a biological platform in a bone and joint mold. Let us imagine a head of the femur and a mold fabricated via computer assisted design and manufacture. It faithfully reproduces the structural features and may be imprinted with morphogens, inductive signals, and cell adhesion sites. This assembly can be loaded with stem cells and BMPs and other inductive signals, with a nutrient medium optimized for the number of cell cycles, and then it predictably exits into the differentiation phase to reproduce a totally new bone femoral head. In fact, such a biological approach with vascularized muscle flap and BMPs yielded new bone with a defined shape and has demonstrated proof of the principle for further development and validation [73]. We indeed are entering a brave new world of prefabricated biological spare parts for the human body, based on sound architectural rules of inductive signals for morphogenesis, responding stem cells with lineage control, and with growth factors immobilized on a template of biomimetic biomaterial based on extracellular matrix. Like life itself, such technologies evolve with continuous refinements to benefit humankind by reducing the agony of human pain and suffering. In conclusion, based on principles of evolution, development, and self-assembly, the fields of tissue engineering and regenerative medicine are poised to make explosive advances with immense applications in the clinic.

CHAPTER 12

Gene Expression, Cell Determination, and Differentiation

Frank E. Stockdale
School of Medicine, Stanford University, Stanford, California

INTRODUCTION

Studies of skeletal muscle development were the first to provide the principles for understanding the genetic and molecular bases of determination and differentiation. Molecular signals from adjacent embryonic structures activate specific genetic pathways within target cells. Important families of transcriptional regulators are expressed in response to these cues to initiate important developmental processes in skeletal muscle as well as in other tissues and organs. Both activators and repressors are essential to control the time and location at which development occurs, and self-regulating, positive feedback loops ensure that, once begun, development can proceed normally. An understanding of the mechanistic basis of the embryonic commitment to a unique developmental pathway, and the subsequent realization of the adult phenotype, are essential for understanding stem cell behavior and how this might be manipulated for therapeutic goals.

This chapter focuses on determination and differentiation, classical embryological concepts that emerged from descriptive embryology. It has been through the study of muscle development that the genetic basis of these processes was first revealed, laying out a mechanistic basis for understanding determination and differentiation. Following success in studies of skeletal muscle (reviewed in references [1] and [2]), genetic pathways involved in the determination of other systems, some of which are detailed in other chapters in this book, have also been uncovered, largely because of the underlying conservation of structure among the various effector molecules and mechanisms.

DETERMINATION AND DIFFERENTIATION

Determination describes the process whereby a cell becomes committed to a unique developmental pathway, which, under conditions of normal development, appears to be a stable state. In many cases, cells become committed early in development yet remain highly proliferative, expanding exponentially for long periods of time before differentiation occurs. Until recently, determination could only be defined post hoc. Prior to the discovery of transcriptional regulators there were few markers to indicate whether or not a cell was committed to a unique phenotype. Thus, determination was operationally defined as that state that existed immediately prior to differentiation, that is, before expression of a cell-type-specific

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00012-4

phenotype. The identification of transcription factors that control the differential expression of large families of genes changed this concept.

Determination and differentiation are processes that are coupled during embryogenesis, where a small number of pluripotent cells (stem cells), expand and enter pathways through which they form the diverse cell types of the adult. The process of differentiation describes the acquisition of the phenotype of a cell, most often identified by the expression of specific proteins achieved as a result of differential gene expression. The differentiated state is easily determined by simple observation in most instances, because most differentiated cells display a unique phenotype as a result of the expression of specific structural proteins. Skeletal muscle cells are an extreme example of this, having a cytoplasmic matrix filled with highly ordered myosin, actin, and other contractile proteins within sarcomeres — the functional units of contraction — giving the fibers their cross-striated pattern. As development proceeds, there is a gradual narrowing of the possible final cell phenotypes that individual cells can adopt, with the final cell fate (set of genes expressed) determined by factors both extrinsic and intrinsic to the cell (Fig. 12.1).

Changes in gene expression responsible for directing cells to differentiate along particular developmental pathways result from the response to stimuli received from surrounding cells and the specific cellular phenotype of the cell itself at the time of interaction. For example, cells of recently formed somites have the potential to form either skeletal muscle or cartilage in response to adjacent tissues, and the fate adopted is a result of their location with respect to adjacent structures — the notochord, neural tube, and overlying ectoderm — that produce signaling molecules that determine phenotype [3]. In addition to the activation of muscle-specific structural and enzyme-encoding genes, the differentiated state is maintained by the continued expression of specific regulatory transcription factors, which can now be identified

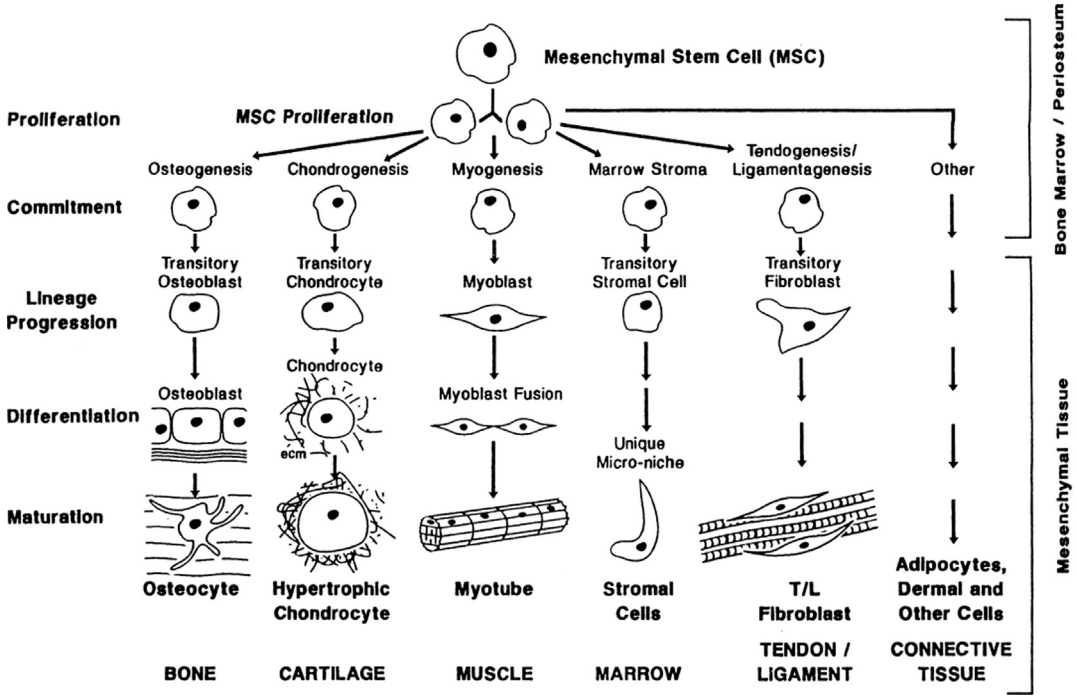

FIGURE 12.1

The process of commitment and differentiation. Cells arise during gastrulation in the vertebrate embryo that subsequently produce all the different cell type of the body. Cells that can be designated as mesenchymal stem cells (MSC) proliferate and, in response to cues from the cellular environment, enter lineages that undergo differentiation and subsequent maturation into the mature cell types.

using modern tools of cellular and molecular biology, including monoclonal antibodies, antisense nucleic acid probes, and gene chip analyses.

Commitment and differentiation to a skeletal muscle fate begins in the somites of the early vertebrate embryo. Within the embryonic somites, two distinct anatomical regions contain muscle progenitors. Specified by signals from the adjacent structures, the dorsal portion of each somite forms an epithelial structure, the dermomyotome, which contains the precursor cells of all skeletal muscles that will form in the vertebrate body (with the exception of those found in the head). The medial portion of dermomyotome contains cells that form the axial musculature surrounding the vertebral column, while cells of the ventral-lateral portion of the dermomyotome undergo a process of delamination and migrate into the forming appendages to produce the appendicular musculature of the limbs and body wall [4]. While the muscle fibers that form from the different regions of the somite are nearly indistinguishable, myogenesis in the axial and appendicular muscles is regulated by different effectors, demonstrating the complexity of determination and differentiation in the early embryo.

MyoD AND THE bHLH FAMILY OF DEVELOPMENTAL REGULATORY FACTORS

It was not until late in the twentieth century that experiments first demonstrated that cellular commitment to specific developmental fates could be determined by the expression of a single gene or a very small number of genes [5–9]. With the improvements in tissue culture methods and rapid advances in molecular biology that permitted the introduction of foreign genes into mammalian cells, the first factor capable of specifying a cell to a particular cellular phenotype, MyoD, was isolated and characterized in the laboratory of Dr. Harold Weintraub [10,11]. MyoD expression is specific to skeletal muscle, and introduction of MyoD cDNA into fibroblasts of the 10T1/2 cell line converts them at a high frequency into stable myoblasts, which in turn express skeletal muscle proteins. MyoD was only the first of a family of myogenic regulatory factors (MRFs) to be discovered; others include myf-5 [12], myogenin [13], and MRF4 [14]; reviewed by Berkes and Tapscott [1]. The importance of MyoD and myf-5 to the determination of skeletal muscle was demonstrated when double knockout of these two genes in transgenic mice resulted in a nearly complete absence of skeletal muscle [15].

MRF members share a common structure, a stretch of basic amino acids followed by a stretch of amino acids that form two amphipathic helices separated by an intervening loop (the helix-loop-helix [HLH] motif), and they are nuclear-located DNA-binding proteins that act as transcriptional regulators [1]. Experiments have demonstrated that the basic amino acids are required for DNA binding and are essential for the myogenic conversion of fibroblasts to muscle, while the HLH motif plays an essential role in the formation of heterodimers with other ubiquitously expressed HLH proteins (products of the E2a gene) as well as in DNA binding [16,17,18].

Nature being conservative, it is not surprising that the bHLH motif was found in transcriptional factors regulating the determination of cell types other than muscle. Based on homology with MyoD, the transcription factor NeuroD was isolated by the Weintraub laboratory and shown to act as a neuronal determination factor [19]. Expression of NeuroD in presumptive epidermal cells of Xenopus embryos converted many into fully differentiated neurons. Interestingly, NeuroD also plays an important role in the differentiation of pancreatic endocrine cells and the retina [20,21,22]. While NeuroD is involved primarily in neuronal differentiation and survival, neurogenin, whose expression precedes that of NeuroD in the embryo, functions more like a determination factor [23]. Overexpression of Xenopus neurogenin induces ectopic neurogenesis as well as ectopic expression of NeuroD. Additional bHLH family members, including HES, Math-5, and Mash-1, have been isolated and participate in the determination of neural cells as well.

Differences in the expression of various members of the neurogenic bHLH family help to explain the diversity of neuronal cell types. For example, genetic deletion of the Mash-1 gene eliminates sympathetic and parasympathetic neurons and enteric neurons of the foregut [54], while knockout of NeuroD leads to a loss of pancreatic endocrine cells as well as cells of the central and peripheral nervous system [20]. In addition to the various bHLH activators, other homeodomain-containing transcription factors are required for specification of neuronal subtypes.

Because cardiac muscle has so much in common with skeletal muscle, including a large number of contractile proteins, an exhaustive search was made for MyoD family members in the heart. Surprisingly, MyoD family members were not found in the developing heart, and thus they play no part in the differentiation of cardiac muscle cells. However, a different family of bHLH-containing factors, including dHAND and eHAND, were found in the developing heart, autonomic nervous system, neural crest, and deciduum. In the heart these factors are important for cardiac morphogenesis and the specification of cardiac chambers [25,26]. Unlike their MyoD family cousins, neither of the HAND proteins plays a role in the differentiation of cardiac muscle cells.

Acting as dominant negative regulators of the bHLH family of transcriptional regulators is a ubiquitously expressed family of proteins that contain the helix-loop-helix structure but lack the upstream run of basic amino acids essential for specific DNA binding by MyoD family members. Termed inhibitors of differentiation (Id), these proteins can associate specifically with MyoD or products of the E2A gene, and attenuate their ability to bind DNA by forming non-functional heterodimeric complexes [27]. In proliferating myoblasts, Id inhibit the terminal differentiation program by complexing with the E12/E47 protein until the cell receives an appropriate stimulus. Id levels decrease on terminal differentiation.

Neuronal development is also regulated in part by repressors of the neurogenic family of bHLH activators. The HES family of HLH-containing proteins is expressed in neural stem cells, where they maintain proliferation of neuronal precursors and prevent premature differentiation in cells expressing NeuroD and neurogenin. The interaction of unique sets of positively acting bHLH activators and negatively acting members of the HES family helps explain how different subsets of neurons undergo differentiation at different times during development, so that the complex structure of the brain can be produced [29,30].

MEFS AND microRNAs — COREGULATORS OF DEVELOPMENT

MEF2 proteins are transcriptional activators that bind to A+T-rich DNA sequences found in many muscle-specific genes, including those encoding contractile proteins, muscle fiber enzymes, and the muscle differentiation factor myogenin. While some members of this family of MADS-box regulatory factors show a nearly ubiquitous distribution among tissue types, a few show expression that is more restricted to striated muscle [31]. Because they do not act alone, MEF2 family members must physically interact with MyoD family members at their DNA-binding domains to positively regulate transcription of downstream muscle-specific differentiation genes [32]. Additionally, the transcriptional activation of muscle-specific genes requires that either the MyoD or MEF2 protein provide a transcriptional activation domain. Interestingly, although the wide tissue distribution of some MEF2 family members suggested that they may act in combination with bHLH family members found in other cell types (such as neurogenin in neural precursors) to activate downstream genes (Molkentin and Olson, 1996), no evidence has been found to that effect [33,34].

A common method of regulation in most differentiating cells which results in specification, maintenance, and regulation of all complex regulatory circuits, are non-coding RNAs which includes microRNAs [35]. Differentiation requires not only the acquisition of new functions through gene activation and transcription, but also the suppression of gene transcription at

the expression level [29]. MicroRNAs (miRNAs), which regulate gene expression at the transcriptional and post-transcriptional levels, play key roles in differentiation [35]. They can suppress gene expression by binding to mRNAs through complementarity in sequence between the two and altered expression by alternative splicing [36]. In particular, they have been shown to play key roles in the post-transcription regulation in skeletal muscle cell differentiation. Specific microRNAs interact with MyoD and other bHLH transcription factors, such as Twist, in cooperation with MEF2 by binding of MyoD and myogenin [37]. Some of the key functions of MEF2 that are central to muscle cell gene transcription are controlled by microRNAs. Particular miRNAs are absent from undifferentiated myoblasts and are strongly upregulated upon differentiation [36]. Experiments suggest that miRNAs also act as modulators of myogenic differentiation, affecting expression of genes not involving Mef2. An example is that an increase of miR1 expression in muscle cell culture accelerates myoblast differentiation by downregulating histone deacetylase 4 (HDAC4), a repressor of muscle differentiation [38]. The interplay between transcription factors and microRNAs provides the fine tuned modulation of protein expression characteristic of differentiating cells.

Pax IN DEVELOPMENT

Much of what has been learned about the role of MyoD and myf-5 in the determination of skeletal muscle has come from studies on transgenic mice in which various genetic loci have been deleted [15,39–43]. This work suggested that MyoD and myf-5 acted as redundant activators of myogenesis, albeit with some slight distinctions. Subsequently, Pax3, a DNA-binding protein with both a paired box and a paired-type homeodomain, was identified as a key regulator of myogenesis [44,45]. Double knockout of Pax3 and myf-5 leads to a complete absence of skeletal muscle and places Pax3 genetically upstream of MyoD [46]. Using knock-in experiments where the lacZ marker gene replaced Pax3, Buckingham's group demonstrated that Pax3 and myf-5 are activated independently of one another. The implication is that axial muscle (myf-5-dependent) and appendicular muscle (MyoD-dependent) are specified separately in the embryonic somites by two different pathways [47,48], and that a Pax gene (or more than one) is required for this specification (determination).

A second member of the paired box transcription factor family, Pax7, has also been implicated in myogenesis. Pax7 was isolated from satellite cells, a population of muscle-committed stem cells found in intimate association with mature muscle fibers and involved in muscle growth and repair in the adult. Pax7 is specifically expressed in proliferative myogenic precursors, both embryonic myoblasts as well as satellite cells, and is down regulated at differentiation [49]. Transgenic mice lacking the Pax7 gene have normal musculature, albeit with reduced muscle mass, but a complete absence or markedly reduced numbers of satellite cells [49,50]. These investigators found that in these Pax7 mutants, satellite cells, which are cells responsible for postnatal growth of skeletal muscle, are progressively lost by cell death. These results suggest that specification of skeletal muscle satellite cells requires Pax7 expression, or that Pax7 expression is responsible for survival of satellite cells. The interplay of the many factors that control the initiation and maintenance of myogenesis are shown in Fig. 12.2.

SATELLITE AND STEM CELLS IN SKELETAL MUSCLE DIFFERENTIATION AND REPAIR

The reason that a discussion of skeletal muscle differentiation is so central to a basic understanding of cell differentiation is that this tissue unites concepts of tissue formation and tissue repair. The unifying concept is the stem cell. Among the first to be considered as stem cells were the satellite cells of skeletal muscle (reviewed by Wang and Rudnicki [51]). These cells lie just beneath the basal lamina that surrounds each muscle fiber within an anatomic muscle. These cells meet the definition of stem cells [46] because they are self-renewing. They are cells set aside in early muscle development, during which they contribute to fiber lengthening as

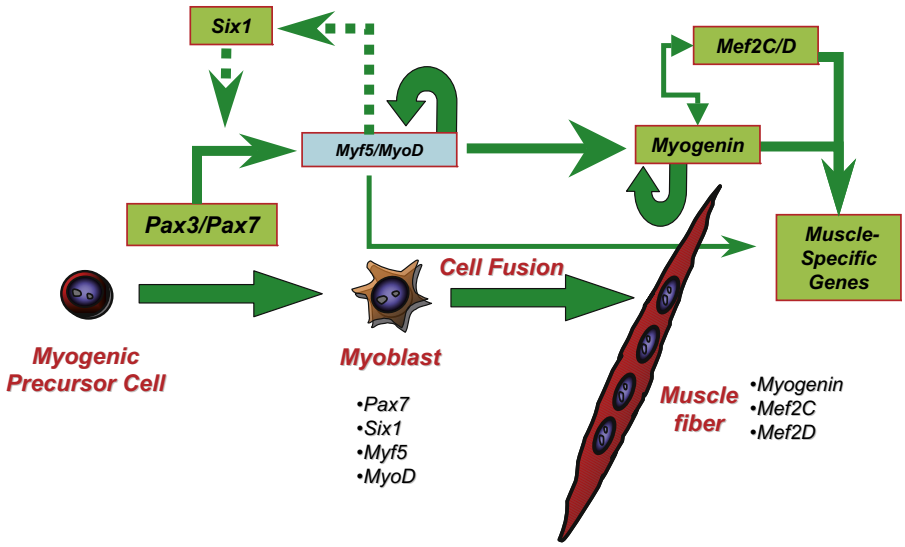

FIGURE 12.2
A regulatory network controls muscle cell differentiation. *(Provided by Dr. Michael Rudnicki and modified.)*

muscles grow, as well as to the formation of additional fibers as the neonate matures. On the other hand, muscle hypertrophy, as in weight lifters, is primarily produced by expansion is size of the fibers rather than fiber number. However, because of injury of small numbers of fibers, satellite cells can fuse with existing fibers during this process. They are located within special niches formed by the basal lamina. These niches keep satellite cells in a quiescent state until there is injury to the fibers of a muscle on which they lie. Injury results in the release of cytokines that initiate the proliferation and migration of the satellite cells on the surface of the injured fibers. The cell divisions of satellite cells are asymmetric – one daughter forms another satellite cell (stem cell) and is retained in the niche and the other goes forward as a myogenic cell, which most often fuses with an injured fiber to reconstitute its multinuclear state, or occasionally, depending on the nature of the injury, to form a new fiber [52]. Thus, while muscle regeneration in higher vertebrates is very limited, new fibers can form and old fibers can be repaired while still retaining a supply of stem cells for future tissue repair. The challenge to investigators of tissue engineering is to develop strategies to facilitate extensive muscle stem cell proliferation, cell survival, and efficient cell differentiation of transplanted cells. Equally challenging is gaining an understanding of the cells that form the connective tissue scaffolding of an anatomic muscle, if such satellite cells or stem cells are to successfully be used to treat neuromuscular disease or to reconstitute muscles following trauma [53].

Among the most promising new approaches to repair of skeletal muscles damaged by disease or trauma are embryonic stem cells (ES cells) and induced pluripotent stems (iPS cells). In recent times there has been a flurry of experimental activity in model systems for regenerating and primary muscular diseases, which exploit these two types of cells [54–56]. ES cells are derived from the inner cell mass of pre-implantation human and other vertebrate embryos. These cells can differentiate into a variety of cell types, including skeletal and cardiac muscle, under the influence of factors added to culture media in which they are grown. On the other hand iPS cells can be derived from many adult human cell types obviating, in the case of humans, the need for human embryos. iPS cells can be obtained through direct reprogramming of different human somatic cells to a pluripotent state by a limited number of genes, or by transfection with retroviruses, lentiviruses or plasmids [54]. There is also a variety of other cells types that have been specifically linked to skeletal muscle differentiation [57], including bone marrow-derived side-population cells [58], mesenchymal stem cells [59], pericytes [60], CD133+ progenitor cells [61] , and mesoangioblasts [62] because they show a high myogenic propensity *in vitro* and *in vivo*. But only ES and iPS cells overcome the disadvantage of the latter cell types because they can be produced in sufficient quantities for study and transplantation.

The use of ES cells from humans is complicated by ethical considerations, whereas iPS cells are not, because they do not require human embryos. iPS cells also have the advantage that each individual could have their own cells (autologous patient-specific stem cells) used to form iPS cells, thus obviating the immunological rejection that accompanies the use of ES cells. The hurdles to overcome in tissue engineering of muscle are the size of muscles in humans (human anatomic muscles are relatively large), which require large numbers of cells for adequate repair. This means that transplanted cells must proliferate and endure *in vivo*, and that they become co-opted into the satellite cell lineage for subsequent hypertrophy of the muscle or its repair. In any situation where cells for transplantation are encouraged to proliferate and differentiate *in vitro* following viral transfection, an important challenge is the formation of teratomas [63] or insertional mutagenesis.

The advantage of iPS cells for skeletal muscle transplantation has been exploited in murine model systems. Darabi and colleagues [64,65] and Mizuno and colleagues [66] have used iPS cells from the mouse transfected with a gene (Pax 7) fostering myogenic differentiation showing that these engineered cells are effective in engraftment, improving muscle function in disease models. The studies demonstrate in principle that the use of stem cell transplantation can be effective.

However, for human transplantation it will be important that human iPS cells be directed into the myogenic lineage without the use of transfection or other approaches that alter the structure of the genome [67]. The use of non-transfection strategies is desirable, as the integration of transfected genes can be problematic for the functioning of the cells. Recently, the hurdle of making human iPS cells initially obtained from retrovirally transformed cells that can undergo myogenesis *in vivo* may have been overcome when tested in an immunoincompetent model mouse systems [68]. Under specific culture conditions, myogenic iPS cells were obtained which formed human muscle when transplanted, supplying satellite cells for subsequent regeneration in response to injury, and reportedly do not form tumors. While these approaches with human iPS cells are exciting and hold great promise, additional work is needed before induced pluripotent stem cell transplantation can be applied in humans.

CONCLUSIONS

Determination and differentiation are in large part controlled by the expression of transcriptional regulators. The processes begin early in development and involve the formation of stem cells that become committed to specific pathways of regulated gene expression. The regulators responsible were first characterized in studies examining commitment to, and differentiation of, skeletal muscle, and muscle development serves as a model for the mechanisms involved. Some other developing organs, such as the central and peripheral nervous systems and the pancreas, employ very similar mechanisms and closely related members of the bHLH family of proteins to drive development. However, for reasons that are not clear, other organs, such as the heart, in which cardiac cells express many of the same contractile protein genes as their skeletal muscle cousins, use other mechanisms. As our understanding of the mechanisms and effectors of determination and differentiation during embryonic development increase, we will be better able to conceive and apply strategies to engineer stem cells, embryonic or adult-derived, to address medical problems through transplantation.

INTRODUCTION

Clinical disorders typically associated with musculoskeletal and cardiovascular tissues (i.e., osteoarthritis and myocardial infarction, respectively) often result in the loss of native tissue structural organization and mechanical function [1,2]. Tissue engineering is a rapidly growing field that seeks to restore the structure and function of tissues damaged due to injury, aging or disease through the use of cells, biomaterials, and biologically active molecules (Fig. 13.1). Despite many early successes, there are few engineered tissue products available for clinical use, and significant challenges remain with regard to translating tissue-engineering technologies to the clinic for successful long-term repair of dysfunctional tissues. The precise reasons for graft failure are not fully understood, but they include a combination of factors that lead to the breakdown of repair tissues under conditions of physiologic loading.

Two critical aspects of tissue-function in many tissue and organ systems are the transmission or generation of mechanical forces and the maintenance of blood circulation. In particular, articular cartilage and myocardium have highly specialized tissue composition and structure to allow for the specific mechanical and transport properties of these tissues. Although different in many respects, cartilage and cardiac tissues both perform critical biomechanical functions *in vivo* and lack intrinsic capacity for self repair. Therefore, cartilage and cardiac tissues are ideal targets for functional tissue engineering.

At the time of implantation, tissue-engineered constructs rarely possess mechanical properties that can withstand the high magnitudes of mechanical stresses experienced *in vivo*. For many native tissues, however, the potential range of *in vivo* stresses and strains are not well characterized, thus making it difficult to incorporate a true 'safety factor' into the design criteria for engineered tissues. In addition, matching a single mechanical parameter, such as modulus or strength, is rarely sufficient, as most tissues possess complex viscoelastic, non-linear, and anisotropic mechanical properties that may vary with age, site, and other factors [3].

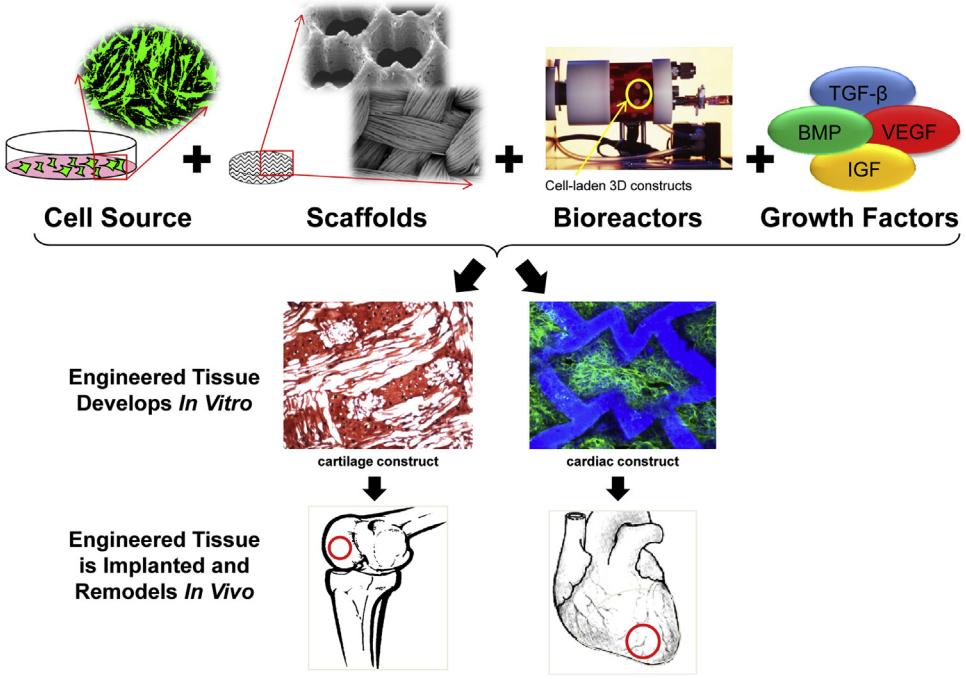

FIGURE 13.1

Strategy for engineering functional tissues *in vitro*. Cells, scaffolds, bioreactors, and growth factors are used as tools to create functional engineered tissues. This chapter focuses on the *in vitro* culture of engineered cartilage and cardiac constructs that can be utilized for basic research and, potentially, for repair of damaged articular cartilage and myocardium. *Top Panel: scaffold images adapted from Engelmayr, Jr., G.C. et al., Nature Materials 7:1003, 2008 [67] (top) and Moutos and Guilak, Tissue Eng Part A 16:1291, 2010 [42] (bottom). Middle Panel: engineered cartilage image adapted from Valonen, P.K., et al., Biomaterials, 31(8):2193, 2010 [93]; engineered cardiac image adapted from Engelmayr, Jr., G. C. et al., Nature Materials 7:1003, 2008 [67].*

A number of complex interactions must also be considered, as the graft and surrounding host tissues are expected to integrate and remodel in response to their changing environments post-implantation [4]. For example, convective transport of oxygen, nutrients, and waste products may become a limiting factor. Currently, most tissue-engineered constructs do not contain a functioning vasculature at the time of implantation, instead relying on either anastomosis of implanted capillary networks to the host vasculature or *de novo* angiogenesis to provide transport capability. Because oxygen has low solubility in aqueous media and diffuses over distances of only 100 to 200 μm, oxygen transport is often a limitation in cell survival within large, anatomically relevant grafts [5–7].

An evolving discipline referred to as 'functional tissue-engineering' has sought to address the aforementioned challenges by developing guidelines for rationally investigating the role of biological and mechanical factors in tissue engineering. A series of formal goals and principles for functional tissue engineering have been proposed in a generalized format [3,8,9]. In brief, these guidelines include development of:

1) Improved definitions of functional success for tissue-engineering applications;
2) Improved understanding of the *in vivo* mechanical requirements and intrinsic properties of native tissues;
3) Improved understanding of the biophysical environment of cells within engineered constructs;
4) Scaffold design criteria that aim to enhance cell survival, differentiation, and tissue mechanical function;
5) Bioreactor design criteria that aim to enhance cell survival and the regeneration of functional tissue-engineered constructs;

6) Construct design criteria that aim to meet the metabolic and mechanical demands of specific tissue-engineering applications; and
7) Improved understanding of biological and mechanical responses of an engineered tissue construct following implantation.

Since these guidelines were proposed, significant progress has been made toward developing *in vitro* culture systems and techniques to enhance graft mechanical properties and engineer functional tissues.

One of the key challenges in functional tissue engineering is optimizing the *in vitro* culture environment in order to produce three-dimensional (3D) implants that can meet the requirements of the *in vivo* milieu. In particular, the ability to precisely define and control *in vitro* culture conditions can be exploited to improve and ultimately control the structure, composition and mechanical properties of engineered tissues. This chapter focuses on how advanced *in vitro* culture strategies, including the use of scaffold systems, bioreactors, growth factors and mechanical conditioning, can influence the development and performance of engineered tissues (Fig. 13.1). Although the discussion addresses cartilage and cardiac tissues specifically, the concepts are also of relevance to other tissues and organs that serve some mechanical function (e.g., muscle, tendon, ligament, bone, blood vessels, heart valves, bladder) and are the targets of tissue-engineering research efforts. The following sections of this chapter will consider key concepts, the importance of *in vitro* studies, and the influence of selected *in vitro* culture parameters on the development and performance of engineered tissues. Illustrative examples and alternative approaches for engineering cartilage and cardiac tissues are provided.

KEY CONCEPTS FOR ENGINEERING FUNCTIONAL TISSUES

Fundamental parameters for engineering functional tissues

Many tissue-engineering approaches involve the *in vitro* culture of cells on biomaterial scaffolds to generate functional engineered constructs. The working hypothesis is that *in vitro* culture conditions have a significant influence on the structural and mechanical properties of engineered tissues, and therefore can be exploited to manipulate the growth and functionality of engineered tissues. ***In vitro culture conditions*** will refer to tissue-engineering scaffold systems, bioreactors, growth factors, and mechanical conditioning regimens that mediate cell behavior and functional tissue assembly [10,11]. ***Scaffolds*** will be defined as 3D material structures designed to perform some or all of the following functions:

1) Promote cell-biomaterial interactions, cell adhesion, and extracellular matrix (ECM) deposition;
2) Permit sufficient transport of gases, nutrients and regulatory factors to allow cell survival, proliferation and differentiation;
3) Biodegrade at a controllable rate that approximates the rate of tissue regeneration under the culture conditions of interest; and
4) Provoke a minimal degree of inflammation or toxicity *in vivo* [7,12].

Bioreactors will be defined as laboratory devices designed to perform some or all of the following functions:

1) Provide control over the initial cell distribution on 3D scaffolds;
2) Provide efficient mass transfer of gases, nutrients, and growth factors to tissue-engineered constructs during their *in vitro* cultivation; and
3) Expose the developing constructs to convective mixing, perfusion, and/or mechanical, electrical, or other biophysical factors in a controlled manner [5,6,13–17].

Mechanical conditioning will be defined as the *in vitro* application of dynamic mechanical loads (i.e., compression, tension, pressure, and/or shear) to cells, tissues, and/or three-dimensional

(3D) engineered tissue using custom designed systems. These fundamental *in vitro* culture parameters can be controlled independently or in combination to strategically meet the requirements of the specific tissue to be engineered.

Fundamental criteria for engineering functional tissues

The biological and mechanical requirements of an engineered tissue depend on the specific application. For example, engineered cartilage should provide a low-friction, articulating surface and be able to withstand and transmit load in compression, tension, and shear; whereas engineered cardiac tissue should propagate electrical signals, contract in a coordinated manner, and withstand dynamic changes in pressure, tension, and shear. In addition to tissue-specific requirements that serve as design principles for functional tissue engineering, there are fundamental criteria that all engineered tissues should meet:

1) At the time of implantation, an engineered tissue should possess sufficient size and mechanical integrity to allow for handling and permit survival under physiological conditions;
2) Immediately following implantation, an engineered tissue should provide some minimal level of biomechanical function that should improve progressively until normal tissue function has been restored; and
3) After implantation, an engineered tissue should mature and integrate with surrounding host tissues.

IMPORTANCE OF *IN VITRO* STUDIES FOR ENGINEERING FUNCTIONAL TISSUES

Cells cultured *in vitro* tend to retain their differentiated phenotype and function under conditions that resemble their natural *in vivo* environment; these conditions may be generated using a combination of scaffolds, bioreactors, growth factors, and mechanical conditioning [3,8–11]. *In vitro*-grown tissue-engineered constructs can potentially be transplanted *in vivo* for tissue engineering and regenerative medicine applications or utilized as platforms for *in vitro* testing of cell and tissue-level responses to molecular, mechanical, or genetic manipulations.

In vitro studies relevant to tissue engineering and regenerative medicine

In vivo models are essential for clinical translation of engineered tissues as they provide insight into the functional performance of engineered tissues. However, these models are complicated by high variability and biological and mechanical environments that differ from those existing in the human condition. To overcome these limitations, *in vitro* studies can be designed to understand the performance of the engineered tissue *in vivo* by: (i) addressing the challenges of *in vivo* complexity in more controllable *in vitro* systems, and (ii) exploring how an *in vitro*-grown construct may behave when implanted *in vivo*. For example, tissue-engineered cartilage constructs pose a significant challenge with regard to variable and incomplete integration upon implantation *in vivo* [18]. To address the challenge of tissue integration, researchers have taken the approach of evaluating the integration of engineered tissues with native tissues using not only *in vivo* models [19], but also *in vitro* models (Fig. 13.2). In one study, cells were combined with three types of scaffolds [fibrin, agarose, and poly(glycolic acid) (PGA)], incorporated with explants of native articular cartilage, and cultured as composites for 20 or 40 days [20]. The presence of native cartilage significantly altered cell proliferation and matrix accumulation in the composites. Additionally, although engineered constructs based on all three scaffold materials adhered to the native cartilage, there were significant differences in the adhesive strength between the groups, suggesting that the type of scaffold may influence construct integration *in vivo*.

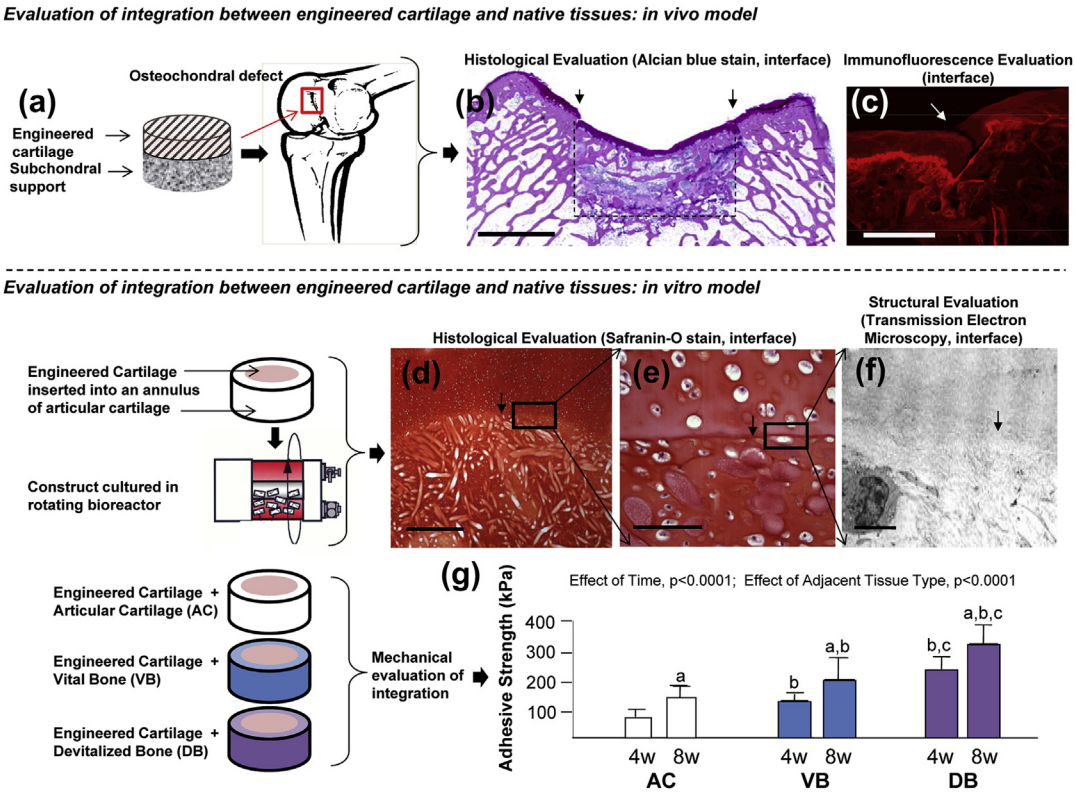

FIGURE 13.2

Studies of the clinically relevant problem of engineered cartilage integration. Top Panel: a) Osteochondral implant integration was studied using adult rabbits with surgically created osteochondral defects. b, c) Histological appearances of explants harvested after 6 months. b) Alcian blue stain, scale bar: 2.5 mm, dashed line shows borders of original defect; c) Immunofluorescence stain, scale bar: 400 μm. Arrows indicate areas of incomplete integration between engineered and host cartilages. Bottom Panel: Engineered cartilage integration was studied using rotating bioreactors to culture engineered cartilage construct disks within rings of articular cartilage (AC), vital bone (VB), and devitalized bone (DB). d, e) Histology of the construct-AC interface (Safranin-O stain, scale bars: 500 μm and 50 μm for D and E, respectively). f) Transmission electron micrograph of the construct-AC interface (scale bar: 5 μm). Arrows at interfaces point toward the construct and arrowheads indicate the scaffold. g) Adhesive strength for construct disks cultured in rings of AC (*white*), VB *(blue)* or DB *(purple)* for 4 or 8 weeks *(4w, 8w)*. Data represented are mean ± SD. [a]Significant difference due to time; [b]Significantly different from the corresponding AC composite; [c]Significantly different from the corresponding VB composite. *Top panel: adapted from Schaefer et al., Arthritis & Rheumatism, 46(9):2524, 2002 [19]. Middle and Bottom panels: adapted from Tognana et al., Osteoarthritis Cartilage 13(2):129, 2005 [21].*

In another *in vitro* study, cells were combined with hyaluronan benzyl ester scaffolds, incorporated with three types of explants (native articular cartilage, vital bone, or devitalized bone), and cultured in rotating bioreactors for 4 or 8 weeks (Fig. 13.2) [21]. Engineered cartilage constructs interfaced with the solid matrix of adjacent cartilage without any gaps or intervening capsules. Additionally, focal intermingling between construct collagen fibers and native cartilage collagen fibers provided evidence of structural integration (Figs. 13.2d–f). Interestingly, adhesive strength was higher for constructs cultured adjacent to bone than cartilage and highest for constructs cultured adjacent to devitalized bone (Fig. 13.2g). These findings could be explained by the differences in adjacent tissue architecture (histological features) and transport properties (diffusivity) [21]. Perfused bioreactors consistently yielded significantly higher amounts of glycosaminoglycans (GAG) and total collagen in engineered cartilage co-cultured adjacent to engineered bone than either engineered cartilage, native cartilage, or native bone [22]. These results suggest that the type of native tissue with which the engineered tissue is combined may influence construct integration *in vivo*. Collectively, information can be gleaned from *in vitro* studies with respect to the integration potential of a tissue-engineered construct prior to *in vivo* implantation.

In vitro platforms relevant for high throughput screening of drugs and other agents

In vitro models can also be utilized to generate physiologically responsive tissue for screening pharmaceutical and therapeutic drugs (reviewed in Vandenburgh et al. [23]). This type of model can be designed for high throughput screening, thereby reducing the need for human tissue and organ harvest. Moreover, if based on human rather than animal cells (e.g., Schaaf et al. [24]), *in vitro* models can provide a more relevant system than *in vivo* animal models, which may differ significantly from the human case in their physiologic responses.

For example, a tissue-engineered drug screening platform referred to as 'engineered heart tissue' was developed by combining neonatal rat heart cells with ECM components such as Matrigel™ and fibrin [25]. The cell-ECM-fibrin mixture was cast between two flexible posts such that maturation of the neonatal cells and condensation of the maturing tissue between the flexible posts yielded strips of cardiac-like tissue which contracted regularly. Pharmaceutical agents with known cardiac effects induced the expected changes within the engineered heart tissue in a repeatable fashion, suggesting that engineered tissues of this type could be used for relatively high throughput drug screening. Moreover, human embryonic stem cells (ESCs) were recently cultured to form engineered heart tissue that was successfully used to screen a panel of drugs with known pro-arrhythmic effects [24]. Engineered heart tissue may also be used as a surrogate cardiac tissue to explore *in vitro* the integration into native heart tissue of various cell populations, such as murine cardiomyocytes, cardiac fibroblasts, and murine ESC-derived cardiac cells [26,27]. These studies together suggest that engineered heart tissue can provide a valuable platform for screening cardiac pharmaceutical and cell therapeutics.

In vitro experiments, such as those described above, are designed to elucidate cell- and tissue-level responses to molecular and mechanical stimuli, and thus improve the understanding of complex *in vivo* phenomena and promote clinical translation of tissue-engineering technologies. In this context, the *in vitro* culture environment plays a key role by allowing for controlled and reproducible test conditions that limit the variability associated with the *in vivo* environment.

INFLUENCE OF SELECTED *IN VITRO* CULTURE PARAMETERS ON THE DEVELOPMENT AND PERFORMANCE OF ENGINEERED TISSUES

It is well-understood that traditional two-dimensional (2D) *in vitro* culture techniques cannot sufficiently recapitulate the microenvironment experienced by cells and tissues *in vivo*. Furthermore, physical forces are critical for the development of tissues and organs during embryogenesis and post-natal growth and remodeling. Therefore, functional tissue-engineering strategies aim to recreate a 3D microenvironment *in vitro* that mimics the *in vivo* milieu through the use of scaffold systems, bioreactors, growth factors, and mechanical conditioning [3,8,9,11,14,28].

Culture duration

CARTILAGE TISSUE ENGINEERING

With increasing *in vitro* culture duration, chondrocytes assemble a mechanically functional ECM (e.g., Buschmann et al. [29]), and cardiomyocytes develop contractile responsiveness to electrical impulses (e.g., Radisic et al. [30]). For example, over a 40 day period of *in vitro* culture, constructs based on bovine calf chondrocytes and PGA scaffolds contained increasing amounts of GAG and type II collagen, and decreasing amounts of the PGA scaffold (Fig. 13.3a) [31]. In this system, the relatively high rates of ECM synthesis and deposition by the calf chondrocytes approximately matched the relatively high degradation rate of the PGA scaffold, a finding that did not hold true when the same scaffold was studied with other cell types

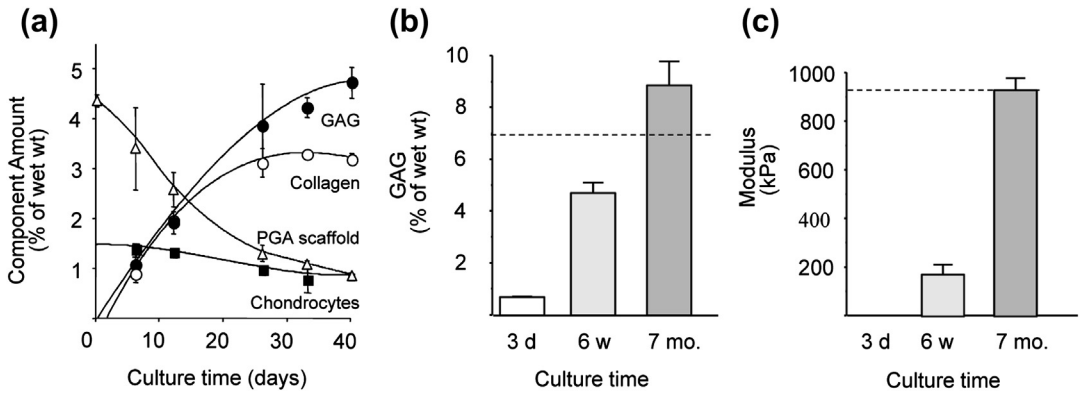

FIGURE 13.3

Effects of culture duration on the composition and function of engineered cartilage. a, b) Bovine calf chondrocytes were cultured on non-woven PGA scaffolds in rotating bioreactors for up to 7 months. a) Short-term changes in the construct amounts of GAG *(closed circles)*, total collagen *(open circles)*, cells *(squares)*, and PGA scaffold *(triangles)*. b, c) Long-term changes in construct amounts of GAG and Aggregate modulus (H_A), measured at 3 days, 6 weeks, and 7 months *(3d, 6w, and 7mo)*. Data are represented as mean ± SD. Dashed lines indicate average values obtained for native bovine calf cartilage. *a): adapted from Freed et al., Experimental Cell Research, 240:58, 1998 [31]; b) and c): adapted from Freed et al., Proc Natl Acad Sci USA, 94:13885, 1997 [32].*

(e.g., bone-marrow-derived mesenchymal stem cells [MSCs]) [11]. The structural and functional properties of engineered cartilage constructs can be improved to some degree by further extending the culture duration. For example, 7 month long cultures carried out in rotating bioreactors operated on Earth yielded engineered cartilage constructs with very high GAG fractions (~8% of wet weight) and compressive moduli (~0.9 MPa) that were comparable to normal articular cartilage (Fig. 13.3b, c), although the collagen fraction and dynamic stiffness of the 7 month constructs remained sub-normal [32].

Optimal maturation of tissue-engineered cartilage *in vitro* may improve cartilage repair with respect to ECM quality and integration after implantation *in vivo* [33]. A recent study correlated engineered cartilage maturity with *in vivo* repair [34]. Engineered cartilage was prepared by culturing chondrocytes on ECM scaffolds for 2 days, 2 weeks, or 4 weeks. Constructs were then implanted into full thickness cartilage defects in rabbit knee joints. In this study, the use of more mature engineered cartilage improved osteochondral defect repair; however, another study showed that prolonged *in vitro* culture of engineered constructs prior to *in vivo* implantation may lead to ECM degradation, resulting in sub-optimal performance *in vivo* [35]. Collectively, these findings suggest that while *in vitro* tissue maturation may enhance the *in vivo* performance of the engineered tissue, the optimal tissue maturation conditions are likely to be cell type-, scaffold-, culture condition-, and/or animal model-dependent.

CARDIAC TISSUE ENGINEERING

Engineered cardiac tissue slowly forms contractile units over time in culture, beginning with spontaneous beating of single cells or groups of cells. As neonatal rat heart cells mature, elongate, and form networks, coordinated, coherent contractions develop throughout the construct [36,37]. For example, engineered cardiac tissue cultured for up to 8 days exhibited a temporal increase in contractile amplitude [30]. In another study, engineered heart tissue exhibited coherent contraction at 7–9 days in culture, increased in force of contraction between 9 and 15 days in culture, and then stabilized [25]. Cells within these constructs showed an elongated phenotype consistent with more mature cardiomyocytes. For cardiac tissue engineering, however, increasing culture duration alone is not sufficient to produce functional tissue for implantation. At present the maximal contractile force generation reported for an engineered cardiac construct (~4 mN/mm^2) remains more than an order of magnitude below that of normal heart muscle [28].

Scaffold systems

CARTILAGE TISSUE-ENGINEERING SCAFFOLDS

Novel 3D scaffold designs have attempted to mimic aspects of native ECM using composite scaffold structures. As biomimetic physical and mechanical properties are difficult to achieve with a single, homogeneous material, several approaches for tissue engineering have employed composite scaffold systems, which are often designed with fiber reinforcement and layered structures [7].

Fiber-reinforced constructs for cartilage repair

This type of design typically utilizes a fibrous phase comprised of a non-woven, knitted, or 3D woven fabric within a cell-supporting phase comprised of a hydrogel or sponge-like material. The cell-supporting phase generally provides a favorable environment for proliferation, differentiation, and ECM synthesis, while the fiber phase functions as a mechanical reinforcement and stabilizer for the construct.

For example, hydrogels known to support chondrogenesis (e.g., agarose, alginate, and fibrin) have been combined with degradable non-woven or woven 3D scaffolds to engineer functional cartilage. To test the influence of a hydrogel cell-carrier system for chondrogenesis, non-woven poly(lactic-co-glycolic acid) (PLGA) meshes were seeded with either dissociated bovine chondrocytes or with chondrocytes suspended in alginate [38] and then implanted subcutaneously in nude mice. The alginate cell-carrier increased seeding efficiency by assisting in the retention and uniform distribution of cells throughout the pores of the non-woven mesh. The fiber-reinforced hydrogel also yielded a physically robust construct that maintained its initial geometry over time, without a negative effect on ECM synthesis. Similar studies showed success when non-woven PGA was either combined with a chondrocyte-laden fibrin gel [39] or with MSCs in a type I collagen and alginate gel [40].

Woven 3D fabrics embedded with hydrogels have also been utilized and replicate the complex biomechanical behavior of native articular cartilage [41]. A microscale 3D weaving technique was employed to fabricate multiple layers of continuous fibers in three orthogonal directions (Fig. 13.4a–d). Composite scaffolds comprised of 3D woven fiber bundles of PGA [41] or poly(ϵ-caprolactone) (PCL) [42] were used in combination with fibrin gel to mimic the physical properties of native articular cartilage, specifically, its inhomogeneous, anisotropic, non-linear, and viscoelastic mechanical properties. Construct compressive mechanical properties and equilibrium coefficient of friction were found to be similar to those of native articular cartilage throughout the defined culture period (Fig. 13.4e–g). Further, constructs seeded with human adipose-derived stem cells (ASCs) supported the elaboration of ECM which stained positive for the presence of chondroitin 4-sulfate and type II collagen (Fig. 13.4h, i). In other studies, the infiltration of this 3D woven PCL scaffold with a slurry of cartilage-derived ECM enhanced the chondrogenesis of ASCs, while providing a mechanically functional construct that resisted cell-mediated contraction [43]. A unique advantage of this composite structure is that scaffolds can be designed and fabricated with predetermined control of site-dependent variations in mechanical properties and porosity within a biocompatible matrix.

Fiber reinforcement can also improve the mechanical properties of sponge-like scaffolds that otherwise have insufficient mechanical properties to support mechanical loading. For example, a scaffold comprising a web-like collagen micro-sponge and knitted PLGA fabric was fabricated for engineering cartilage tissue [44]. The knitted fabric provided the mechanical integrity lacking in the collagen micro-sponge, and the collagen micro-sponge filled in the large pores of the fabric to facilitate uniform cell distribution and cartilage-like tissue formation. Similarly, reinforced PLGA foam scaffolds were produced by embedding short PGA fibers into the bulk polymer prior to foaming [45]. The mechanical properties of these scaffolds

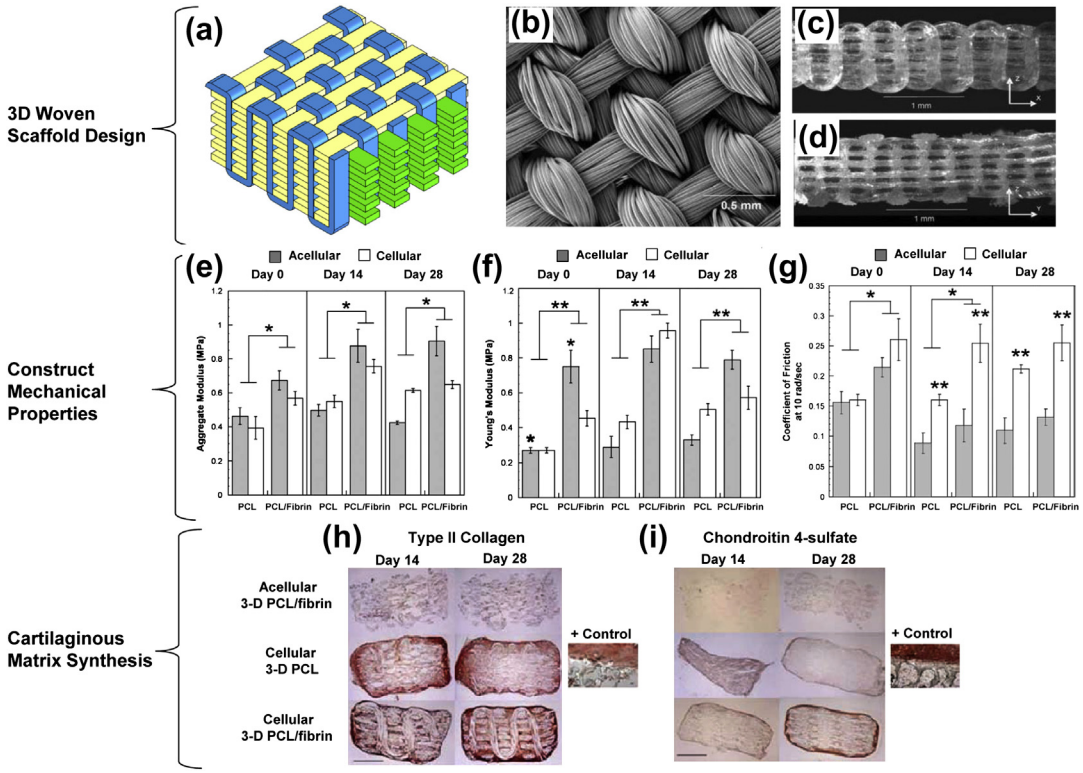

FIGURE 13.4

Structural and mechanical properties of a representative cartilage tissue-engineering scaffold. Top Panel: Fiber architecture of 3D orthogonally woven PCL scaffold. a) Schematic and b, c, d) scaffold weave and fiber morphology as shown with scanning electron microscopy (a — surface view, scale bar: 0.5 mm; b, c — Cross-sectional view through the X-Z plane b), and Y-Z plane c), scale bar: 1 mm). Middle Panel: Compressive biomechanical properties of scaffolds without and with cultured cells at days 0, 14, and 28. e) Aggregate modulus (H_A) and f) Young's modulus as determined by confined and unconfined compression, respectively. The addition of fibrin to 3D PCL scaffolds significantly increased H_A and E for both acellular and cellular groups (ANOVA, *$p<0.05$, **$p<0.0001$). g) Equilibrium coefficient of friction measured under steady frictional shear. Cellular constructs displayed significantly higher coefficients of friction against a rotating stainless steel platen than did acellular scaffolds (ANOVA, *$p<0.05$, **$p<0.001$). Data represented as mean ± SEM. Human adipose-derived stem cells used as cell source. Bottom Panel: Immunohistochemistry of acellular 3D PCL—fibrin composite scaffolds, cellular 3D PCL constructs, and cellular 3D PCL-fibrin composite constructs at days 14 and 28. h) Type II collagen and h) Chondroitin 4-sulfate (scale bar: 1 mm). Human adipose-derived stem cells used as cell source. *Adapted from Moutos and Guilak, Tissue Eng Part A 16: 1291, 2010 [42].*

could be tailored for potential use in articular cartilage repair by adjusting the material composition [46]. Collectively, this work demonstrates that fiber reinforcement is a controllable design variable that can be manipulated in order to engineer scaffolds to suit the load-bearing requirements of an engineered tissue.

Stratified constructs for cartilage repair

In an attempt to recapitulate the structural, compositional and mechanical inhomogeneity of articular cartilage, which varies with depth from the tissue surface, several groups have designed stratified constructs (reviewed in Klein et al. [47]). In one study, a two-layered stratified structure based on agarose was developed in an effort to mimic the depth-dependent mechanical properties of articular cartilage [48]. Constructs with a top layer composed of 2% agarose and a bottom layer composed of 3% agarose exhibited zonal differences in the compressive elastic modulus immediately after fabrication. Another study reported on the use of a photopolymerizing poly(ethylene glycol) diacrylate (PEGDA) hydrogel system that supported chondrocyte-mediated matrix synthesis which histologically resembled the depth-dependent composition of native articular cartilage [49]. Furthermore, in a recent study the layered organization of PEG-based hydrogels comprised of chondroitin sulfate (CS), matrix

metalloproteinase-sensitive peptides (MMP-pep), and/or hyaluronic acid (HA), promoted the differentiation of bone-marrow derived MSCs into chondrogenic phenotypes that resembled those found in the zones of articular cartilage [50,51]. The three-layered, PEG-based construct incorporated CS and MMP-pep into the top layer (superficial zone), CS into the middle layer (transitional zone) and HA into the bottom layer (deep zone), thus resulting in a construct with spatially-varying mechanical and biochemical properties. Overall, these stratified structures resulted in depth-dependent variations in construct properties, thereby mimicking some of the inhomogeneous aspects of native articular cartilage.

Osteochondral constructs

Since bone-to-bone interfaces are known to integrate more effectively than cartilage-to-bone interfaces, osteochondral constructs are considered a promising technique for repairing full thickness articular cartilage defects. Progress in the development of osteochondral constructs using multi-material strategies has been reviewed by several groups [52–54]. In one study, an anatomically-shaped osteochondral construct was developed by casting a layer of chondrocyte-seeded agarose gel on top of devitalized trabecular bone [55]. Other approaches have included: engineered cartilage grown on non-woven PGA sutured to a subchondral support made of Collagraft™ [19], a hyaluronan benzyl ester sponge for cartilage regeneration attached with fibrin glue to a calcium phosphate ceramic sponge for bone regeneration [56], differentially applied chondrogenic and osteogenic growth factors on MSCs seeded in stacked silk scaffolds [57], a 3D printed scaffold of mixed PLGA/PLA for the upper cartilage region with a PLGA/tricalcium phosphate mix for the lower bone region [58], a collagen gel for chondrogenesis cultured upon a bone-inducing hydroxyapatite base [59], a cartilaginous tissue layer overlying a porous biodegradable calcium polyphosphate substrate [60] and chondrocyte-laden agarose hydrogels layered on constructs composed of mineral-containing microspheres [61] or directly containing a mineral phase [62].

CARDIAC TISSUE-ENGINEERING SCAFFOLDS

Scaffolds designed for cardiac tissue engineering must meet very different requirements to those developed for cartilage tissue engineering. Cardiac tissue-engineering scaffolds should provide the necessary microvascular and mechanical properties to meet the demands of a continuously contracting tissue, considering the cellular, geometric, mass transport, and oxygen supply concerns of native cardiac tissue. Scaffold approaches for cardiac tissue engineering have been reviewed by several groups [7,17,28] and are discussed briefly here.

Many natural and synthetic materials have been examined for use in cardiac tissue engineering. As described previously, Matrigel™, combined with fibrin and/or thrombin [25,63,64] or with collagen sponges [30,65] has been used to generate contractile engineered cardiac tissue *in vitro*. However, when considering clinical translation of these scaffolds, material limitations become apparent. Specifically considering the mechanical requirements of cardiac tissue, collagen gels and sponges may lack the mechanical strength required to withstand suturing and/or repeated cycles of stretch and relaxation. On the other hand, synthetic polymers popular in other tissue-engineering applications (e.g., PCL, PLGA) may be too stiff to form engineered cardiac tissue that possesses appropriate contractile properties. Therefore, development of other scaffolds that more closely mimic the native structural, mechanical, and transport properties of cardiac tissue is an area of active research.

In pioneering work, Ott et al. developed a biomimetic scaffold for cardiac tissue engineering through de-cellularization of adult rat hearts [66]. These de-cellularized hearts were repopulated by intramural injection and coronary artery perfusion with neonatal heart cells and aortic endothelial cells and cultured with pulsatile flow and electrical stimulation to regenerate the nascent pump function of the heart. Although this system for cardiac tissue engineering has proven successful in many respects, the efficiency of re-cellularization remains

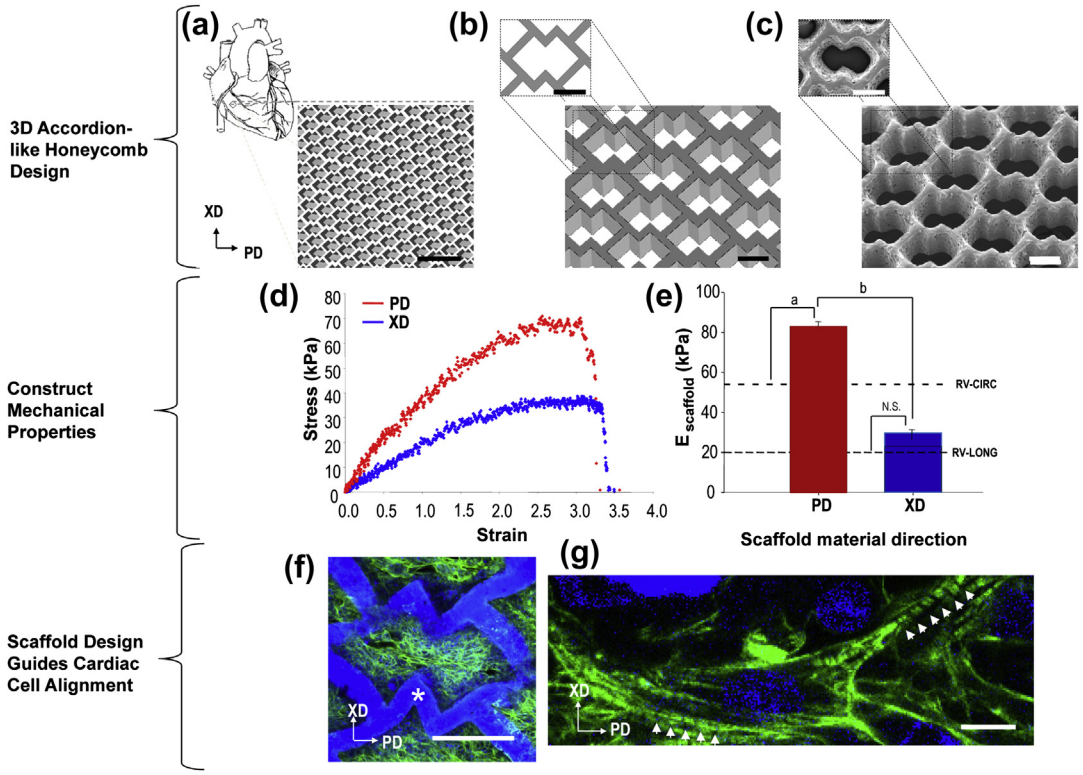

FIGURE 13.5

Scaffold design for engineering cardiac tissue. Top Panel: a, b) Schematics of accordion-like honeycomb scaffold design (a — scale bar: 1 mm, b — scale bar: 200 μm). c) Scanning electron micrograph of the scaffold architecture fabricated by laser microablation of a biodegradable elastomer, poly(glycerol sebacate) (PGS) (scale bar: 200 μm). Preferred direction (PD) and orthogonal cross-preferred direction (XD) material directions are indicated. Middle Panel: d) Representative uniaxial stress strain plot of PGS scaffold with cultured neonatal rat heart cells (scaffolds were fabricated from PGS membranes cured for 7.5h at 160°C; cells were cultured for 1 week). e) Scaffold anisotropic effective stiffnesses (E_{PD} and E_{XD}) are compared to specimens of native adult rat right ventricular (RV) myocardium harvested in two orthogonal directions (RV_{CIRC} and RV_{LONG}, respectively). Data are represented as mean ± SD. [a]Significant difference between scaffold and RV; [b]Significant difference due to scaffold test direction; N.S. indicates not significant. Bottom Panel: f, g) Confocal micrographs of neonatal rat heart cells cultured on accordion-like honeycomb scaffolds for 1 week. (Stain: filamentous F-actin (green), counterstain: DAPI (blue), scale bars: 200 μm and 10 μm, for f and g, respectively). Scaffold indicated by white asterisks; cross-striations indicated by white arrows. *Adapted from Engelmayr, Jr., G. C. et al., Nature Materials 7: 1003, 2008 [67].*

low and the mechanical stiffness of the de-cellularized and re-cellularized tissues remains considerably higher than that of native myocardium.

In order to design a scaffold to address some of the specific structural and mechanical requirements of cardiac tissue, an elastomeric scaffold with accordion-like honeycomb pores was microfabricated from poly(glycerol sebacate) (PGS) (Fig. 13.5) [67]. The accordion-like honeycomb pores were chosen as a first step toward mimicking the native structure of collagen within the myocardial ECM (Fig. 13.5a–c). These scaffolds, when combined with neonatal rat heart cells, yielded constructs with anisotropic mechanical properties that closely matched to the right ventricular myocardium, coordinated contractions in response to electrical stimulation, and allowed for some degree of elongation and alignment of the neonatal heart cells (Fig. 13.5d–g). In addition, PGS scaffolds designed based on finite element simulations provided a platform for cell delivery while simultaneously recapitulating the mechanical properties of the left ventricular myocardium [68].

Many other scaffold designs have also utilized PGS as an elastomer for cardiac tissue engineering. One study used salt leaching to produce a porous scaffold, combined with laser cutting to produce microvascular channels for transport and oxygen diffusion [69], and

another utilized semi-automated layer-by-layer assembly of planar polymer sheets with through-pores to create 3D structural patterns that directed the orientation of meso-scale cardiac muscle-like fibers [70]. Scaffold modifications that sought to provide greater oxygen, nutrient, and waste transport (i.e., microvascular channels), or to condition the construct with mechanical stresses (i.e., cyclic stretch), can potentially increase the viability of the cells within the scaffold over time.

Bioreactors and growth factors

Bioreactors, which are capable of initiating, maintaining, and directing cell growth and tissue development in a well-defined and tightly controlled culture environment, have proven to be crucial tools for 3D tissue culture. Tissue culture bioreactors represent a controllable model system for:

1) Studying the effects of biophysical stimuli and therapeutic agents on cells and developing tissues;
2) Simulating responses of an *in vitro*-grown construct to *in vivo* implantation and thereby helping to define its potential for survival and functional integration; and
3) Developing and testing physical therapy regimens for patients who have received engineered tissue implants.

As described in the studies highlighted below, bioreactors have been utilized to:

1) Improve cell infiltration and distribution by dynamically seed cells within 3D scaffolds;
2) Overcome the limitations associated with oxygen and nutrient transport that are often observed in tissues cultured in static environments; and
3) Enhance matrix synthesis and mechanical properties by biophysical stimulation of the developing constructs [13–15,17,71,72].

CELL SEEDING

Applying an appropriate cell type to a biomaterial scaffold is the first step in the tissue-engineering process, and the seeding technique may have a critical role in directing subsequent tissue formation [73,74]. Scaffold cell seeding has traditionally been done statically and performed manually using pipettes, but these static seeding techniques often lead to inefficient and spatially non-uniform cell distribution within the scaffold [75], which may result in disparate ECM deposition throughout the construct [73,76]. In order to overcome the challenges associated with static seeding, bioreactor-based dynamic cell seeding techniques have been developed. Numerous types of bioreactors have been explored, including spinner flasks [77], wavy-walled reactors [78], and perfused vessels [79].

For some combinations of cells and scaffolds, dynamic cell seeding resulted in scaffolds with high and spatially uniform initial cell densities, which increased ECM deposition and compressive modulus in the resulting engineered cartilage [31,77,80]. For other combinations, perfusion of a cell suspension directly through a scaffold enabled spatially uniform seeding and enhanced tissue regeneration [75,79,81]. Engineered cartilage seeded in perfused bioreactors with alternating medium flow reportedly exhibited higher cell viability and uniformity than controls seeded statically and in spinner flasks [75]. Likewise, engineered cardiac tissue seeded in perfused bioreactors with alternating medium flow exhibited higher cell viability and spatial uniformity than controls seeded in mixed petri dishes [79].

CONSTRUCT CULTIVATION

Cellular apoptosis and the formation of necrotic regions within 3D engineered constructs cultured under static conditions suggest that diffusion alone does not provide sufficient mass transport of oxygen, nutrients, and wastes for cell survival within a construct. Bioreactors help

to mitigate these mass transfer limitations and provide a controlled microenvironment for 3D construct development. Several groups have demonstrated that mass transport limitations could be minimized, cell viability, differentiation, and function enhanced, and matrix synthesis improved within engineered constructs with the use of bioreactors that induce convective mixing (spinner flasks [77,80] and rotating bioreactors [31,77,82]), and perfusion [14,15,65,79,83–86].

Convective mixing, flow, and mass transport are required to supply the oxygen, nutrients, and regulatory factors that are in turn required for the *in vitro* cultivation of large tissue constructs [5,6,87]. Oxygen is the factor that generally limits cell survival and tissue growth, due to its relatively low solubility, slow diffusion rate and high consumption rate [6,88]. Different tissue types have different oxygen requirements, depending on cell type(s), concentrations and metabolic activities. For example, articular cartilage, an avascular tissue, has a lower requirement for oxygen than myocardium, a highly vascularized tissue. Experimental and modeling studies have correlated oxygen gradients within engineered tissues with morphology and composition [6,89,90].

CARTILAGE TISSUE-ENGINEERING BIOREACTORS

A variety of bioreactors have been used to engineer cartilage constructs. Rotating bioreactors supported the growth of engineered cartilage constructs 5 to 8 mm thick based on bovine calf chondrocytes and PGS scaffolds [31,32,76,77]. More recently, human chondrocytes were expanded in 2D and then cultured on hyaluronan benzyl ester scaffolds in rotating bioreactors for up to 4 weeks [91]. While constructs cultured statically and in bioreactors contained similar amounts of GAG and collagen, the bioreactor-grown constructs exhibited a bi-zonal structure, consisting of a collagenous surface capsule deficient in GAG and an inner region that stained more positively for GAG. As compared to bovine calf chondrocytes, expanded human chondrocytes deposited relatively lower amounts of matrix. In another study, a wavy-walled bioreactor was used to culture bovine calf chondrocytes on PGA scaffolds, and increased construct growth, defined by weight, cell proliferation, and ECM deposition, was observed in bioreactors as compared to spinner flasks [92].

In an effort to explore the influences of bioreactors and exogenous growth factors, an oscillatory perfused bioreactor providing slow, bi-directional perfusion was used to study cartilage constructs made by culturing adult human MSCs on 3D woven PCL scaffolds for 3 weeks (Fig. 13.6) [93]. Constructs cultured in bioreactors had higher aggregate moduli, higher total collagen contents, and similar GAG contents compared to constructs cultured statically (Fig. 13.6a, b). Constructs cultured statically in medium containing chondrogenic growth factors but not serum exhibited better chondrogenesis and more homogeneously positive matrix staining for GAG and collagen type II than otherwise identical medium containing serum (Fig. 13.6c–e). Constructs cultured in medium without chondrogenic growth factors and with serum did not exhibit chondrogenic differentiation (Fig. 13.6f). Together, these studies show that bioreactors and growth factors can influence cell morphology, proliferation, and ECM deposition in engineered cartilage.

CARDIAC TISSUE-ENGINEERING BIOREACTORS

In the case of engineered cardiac tissue, convective mixing in rotating bioreactors and spinner flasks supported the growth of a tissue-like surface layer ~100 to 200 μm thick [36,37,88]. Moreover, perfusion of culture medium directly through an engineered cardiac construct can significantly improve construct thickness and spatial homogeneity [65,79,83,88]. Specific design of perfusion bioreactors for cardiac tissue engineering is described in [14], and bioreactors designed specifically for electrical stimulation of cardiac constructs are described in [16]. In one example, perfused bioreactors enhanced the survival of heart cells cultured on porous collagen sponges by increasing the transport of oxygen and insulin-like growth factor-I

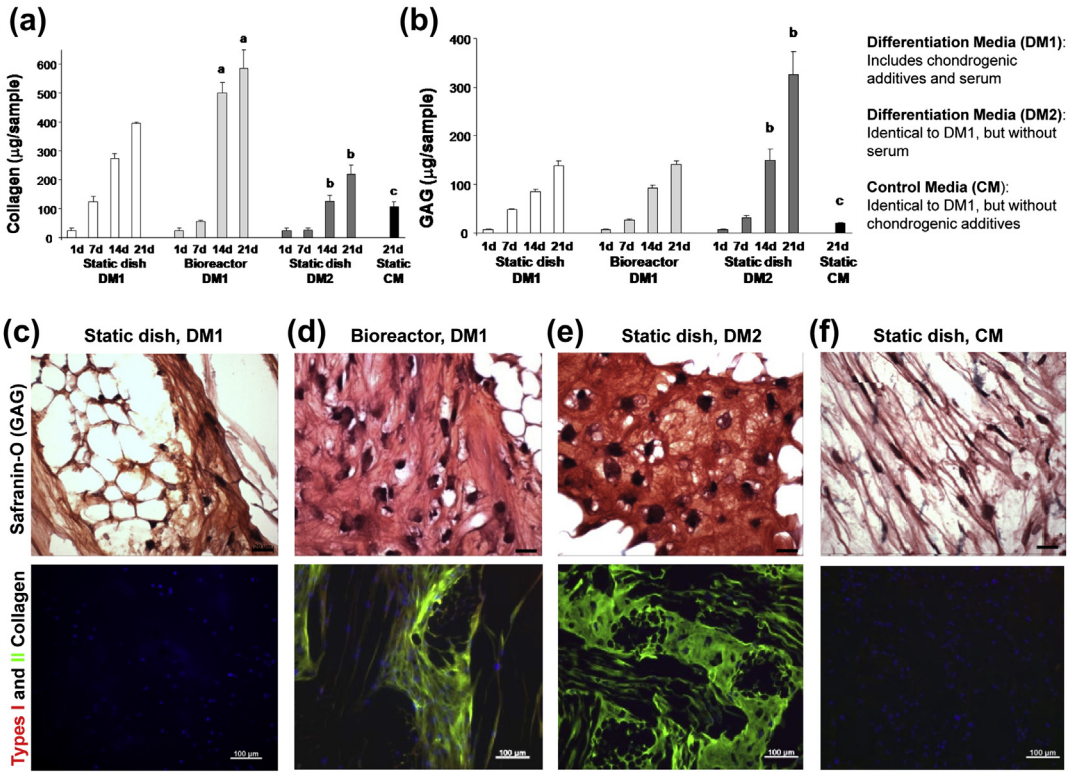

FIGURE 13.6

Bioreactors and growth factors influence the structure and composition of engineered cartilage. Human MSCs were cultured on 3D woven PCL scaffolds in static dishes or bioreactors and in three different culture media (differentiation medium 1 (DM1), differentiation medium 2 (DM2), and control medium (CM)) for up to 21 days. Top Panel: Time evolutions of construct amounts of a) total collagen and b) GAG. Data are represented as mean ± SEM. [a]Significant difference due to type of culture vessel, [b]Significant difference due to presence of serum, [c]Significant difference due to chondrogenic additives, which included TGF-β-3, insulin-transferrin-selenium (ITS), dexamethasone, and ascorbic acid. Bottom Panel: Histological sections of 21-day constructs cultured c) statically in DM1, d) in bioreactors in DM1, e) statically in DM2, and f) statically in CM and stained with safranin-O for GAG (top, scale bars: 20 μm) or immunostained for collagen type II (green) and type I (red, not seen) with DAPI (blue) counterstain (bottom, scale bars:100 μm). *Adapted from Valonen, P.K., et al., Biomaterials, 31(8): p. 2193, 2010 [93].*

(IGF-I) (Fig. 13.7) [86]. Neonatal rat heart cells were seeded on scaffolds at high density by hydrogel-entrapment, and then slow, bi-directional perfusion culture was carried out in an oscillatory perfused bioreactor for 8 days. Bioreactor-grown constructs grown exhibited improvements over static controls with respect to several benchmarks, including reduced apoptosis, increased contractile amplitude, and increased expression of the contractile protein cardiac troponin-I (Fig. 13.7a–c). In the static control group (Fig. 13.7d), heart cells remained rounded and did not exhibit cross-striations, whereas in the bioreactor group (Fig. 13.7e), some cells were elongated and striated, albeit to a lesser degree than native adult rat ventricular myocardium (Fig. 13.7f). Moreover, perfusion of medium supplemented with IGF-I yielded further improvements in construct properties, presumably due to enhanced transport of growth factor to the heart cells within the 3D construct.

In another study done in the oscillating perfused bioreactor, heart cells cultured on two-layered, 500 μm thick PGS scaffolds with fully interconnected accordion-like honeycomb pores exhibited increases in the gap junctional protein connexin-43 and MMP-2, an enzyme associated with tissue remodeling [94]. In other studies, sustained release and delivery of IGF [95] or sequential delivery of IGF-I and hepatocyte growth factor (HGF) [96] enhanced survival and maturation of heart cells in a 3D model and protected against oxidative stress. Together, these studies suggest that bioreactors and growth factors may work in tandem to enhance heart cell viability, contractility and differentiation in 3D myocardial grafts.

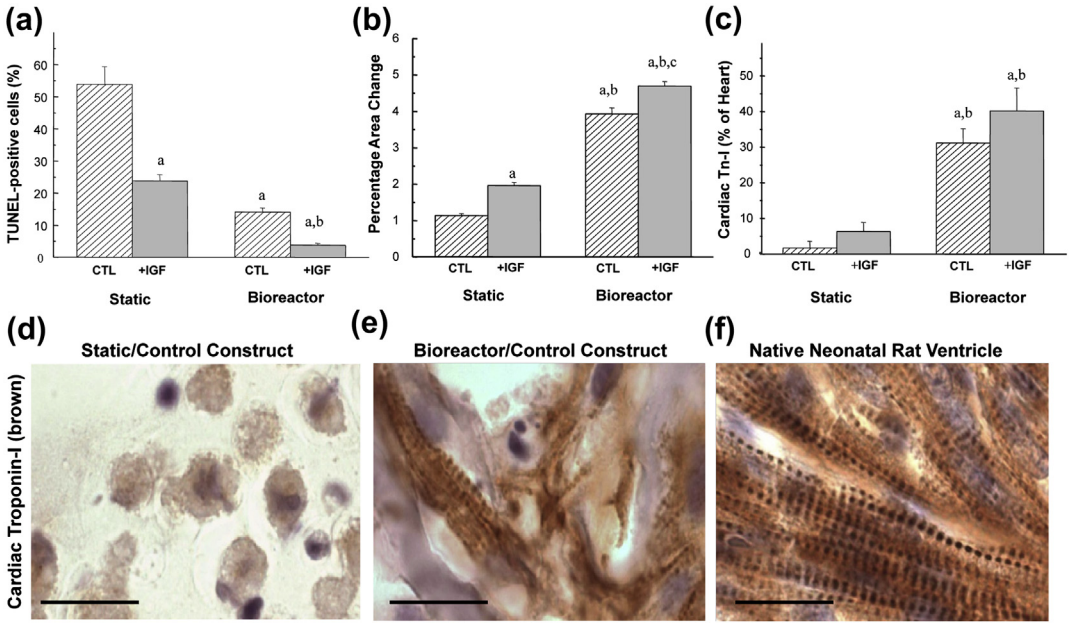

FIGURE 13.7

Bioreactors and growth factors influence the structure and composition of engineered cardiac tissue. Neonatal rat heart cells were seeded in hydrogel and cultured on collagen sponge scaffolds either statically or in bioreactors in two different media (control, CTL, or with supplemental growth factor, IGF-I). Top Panel: a) Apoptosis (TUNEL-positive cells, % of total cells), b) Contractile amplitude (% area change), c) Cardiac troponin-I (Western blot, % of native neonatal rat heart). Data are represented as mean ± SEM. [a]Significantly different from Static/CTL; [b]Significantly different from Static/IGF; [c]Significantly different from Bioreactor/CTL. Bottom Panel: Histological appearances of d) static control construct, e) bioreactor control construct, and f) native neonatal rat ventricular myocardium immunostained for cardiac troponin-I (brown). Scale bars: 20 μm. *Adapted from Cheng, M., et al., Tissue Eng Part A, 15(3): 645, 2009 [86].*

Bioreactors and mechanical forces

Bioreactors can be utilized to apply biomechanical signals (shear, compression, tension, pressure, or a combination thereof) to growing tissues [97,98]. Chondrocytes are quite responsive to mechanical signals and remodel the matrix according to the loads applied; thus the choice of loading regime can directly influence the development of the structure, composition, and mechanical properties of cartilaginous constructs (reviewed in Grad et al. [99]). Likewise, skeletal [100], smooth [101], and cardiac [28,63,64] muscle cells are quite responsive to mechanical signals.

EFFECTS OF HYDRODYNAMIC FORCES

Hydrodynamic forces associated with convective mixing can have a significant effect on the composition, structure, and properties of engineered tissues. For example, engineered cartilage cultured in rotating bioreactors had thinner surface capsules and higher fractional amounts of GAG than constructs grown in spinner flasks [77,82,102,103]. The flow field in the spinner flask was unsteady, turbulent (Reynolds number of 1758), and characterized by large spatial variations in the velocity field and maximum shear stresses [104]. In contrast, the flow field in the rotating bioreactor (slow turning lateral vessel, STLV) was predominately laminar with shear stresses of ~1 dyn/cm^{2}and a well-mixed interior due to secondary flow patterns induced by the freely-settling constructs [102]. A model of tissue growth in the rotating bioreactor that accounted for the intensity of convection over 6 weeks of *in vitro* culture was used to predict the morphological evolution of an engineered cartilage construct [105]. In particular, the model predicted that high shear and mass transfer at the lower corners of a settling, discoid construct would preferentially induce tissue growth in these regions, and that temporal changes in construct size and shape would further enhance local variations in the flow field in a manner that accentuated localized tissue growth. The computed velocity fields and shear

stress data corresponded well with the morphological evolution of engineered cartilage, as shown by superimposing a calculated flow field on a histological cross-section of an actual construct. The above examples suggest that combining experimental studies and computational modeling of hydrodynamic shear stresses and concentration gradients in bioreactors may help to explain underlying mechanisms that control the growth of engineered tissue constructs.

EFFECTS OF MECHANICAL TENSION, COMPRESSION, AND SHEAR LOADING

It is well known that mechanical forces are critical for determining the architecture of native tissues such as bone [106], and there is growing evidence that mechanical factors are important factors in determining stem cell fate [107]. In particular, the role of *in vitro* mechanical stress in maintaining and promoting the chondrogenic phenotype has been the topic of several investigations, but the specific influences of different physical stimuli and their interactions with the biochemical environment are not fully understood. For example, dynamic compression caused a ~2-fold increase in cartilage nodule density and a 2.5-fold increase in GAG synthesis in stage 23/24 chick limb-bud cells cultured in agarose gel [108]. Likewise, cyclic hydrostatic pressure significantly increased the amounts of proteoglycan and collagen in aggregates of human bone-marrow-derived MSCs [109]. In another study, compression enhanced chondrogenic differentiation in mouse embryonic E10 stage cells embedded in collagen type I compared to unloaded controls, as shown by upregulation of SOX-9 and downregulation of IL-1β expression [110].

A variety of devices have been custom designed and built to study the effects of mechanical conditioning (i.e., compression, tension, pressure or shear) on cells and tissues *in vitro* (reviewed in Brown et al. [111], Darling et al. [112], and Waldman et al. [113]). For engineering cartilage, devices typically apply dynamic compression (e.g., Buschman et al. [29], Mauck et al. [114]), hydrostatic pressure (e.g., Mizuno et al. [115], Toyoda et al. [116]) or mechanical shear (e.g., Waldman et al. [117]). For engineering skeletal, smooth, and cardiac muscle tissues, devices typically apply dynamic tensile strain [63,64,97,100,101,118–121] or pulsatile hydrostatic pressure [122–125].

MECHANICAL EFFECTS ON ENGINEERED CARTILAGE TISSUE

In the case of engineered cartilage, a number of studies have shown that mechanical conditioning can enhance chondrogenesis. Dynamic loading has been shown to increase GAG accumulation and ECM assembly, and therefore, the mechanical properties of constructs based on bovine calf articular chondrocytes and a variety of 3D scaffolds including agarose gel [29,114], PGA non-woven mesh [126], and self-assembling peptide gel [127]. Similar results were also observed for adult canine chondrocytes in an agrose gel under dynamic loading conditions [128]. Application of dynamic loading was also investigated in a layered agarose construct, with encapsulated bovine articular chondrocytes, with varying mechanical properties (2% agarose vs. 3% agarose) [129]. These results indicated preferential matrix formation in the 2% agarose layer and an increased elastic modulus in only the initially softer, more permeable layer (2% agarose) [129]. Although the aforementioned studies focused on cells encapsulated in hydrogels, similar results (i.e., increased ECM production and compressive modulus of construct) were found when dynamic loading was applied to calf chondrocytes cultured within a porous calcium polyphosphate scaffold. Overall, the response of chondrocytes to dynamic loading depended on the amount and composition of ECM in the developing construct [130], and in some studies loading increased both synthesis of new GAG and its loss into the culture media [127,131].

The influence of dynamic loading on engineering cartilage has also been investigated in MSC-laden hydrogel systems. In a hyaluronic acid-based hydrogel seeded with human MSCs, dynamic compressive loading enhanced cartilage-specific matrix synthesis and more uniform distribution, increased construct mechanical properties, and suppressed the expression of

hypertrophic markers [132]. In another study [133], mechanical loading of MSC-laden agarose constructs prior to chondrogenesis decreased functional maturation and increased chondrogenic gene expression. In contrast, loading initiated after chondrogenesis and matrix elaboration further improved the mechanical properties of engineered constructs, but only when TGF-β3 levels were maintained and under specific loading parameters. Overall, these results demonstrated that the combination of dynamic compressive loading initiated after chondrogenesis and sustained TGF-β exposure may enhance the mechanical properties and matrix distribution of engineered cartilage constructs.

The effects of mechanical stimuli on engineered cartilage may vary among different scaffold systems. In one study, fibrin hydrogels seeded with chondrocytes were cultured under unconfined compression (static and oscillatory) [134]. Compared to the free-swelling control condition, static loading had minimal influence on matrix synthesis or construct stiffness. When comparing the constructs exposed to static versus oscillatory loading, the constructs cultured under dynamic conditions were found to be softer with less matrix accumulation [134]. Although dynamic compressive loading often results in favorable outcomes in terms of engineering functional cartilage tissue, the scaffold material in which the cells are cultured may influence the effects of mechanical conditioning.

In the aforementioned studies, the cell-laden constructs were loaded in dynamic compression; however, the influence of shear, hydrostatic pressure, and tensile forces has also been explored for cartilage regeneration. For example, the application of shear stress yielded constructs with higher amounts of ECM and higher compressive moduli than those exposed to compressive stress [117]. Likewise, application of dynamic hydrostatic pressure affected chondrogenesis in 3D cultures of bovine [115] and human [116] chondrocytes. In another study, the influence of intermittent loading induced with hydrostatic pressure was investigated during cartilage formation [135]. The application of hydrostatic pressure increased the GAG content of the engineered cartilage construct. Finally, the influence of oscillatory tensile loading on chondrocytes derived from distinct tissue zones of articular cartilage (superficial, middle, and deep) was investigated [136]. Tensile loading stimulated proteoglycan synthesis only in superficial zone chondrocyte populations. The results of these studies collectively suggest that loading conditions other than compression may enhance the properties of engineered cartilage constructs, and a combination of loading regimens may be necessary to engineer the different zones of articular cartilage (reviewed in Klein et al. [47]).

MECHANICAL EFFECTS ON ENGINEERED MUSCLE TISSUE

In the case of engineered muscle, dynamic tensile and pulsatile loading can affect construct composition, contractility, and pharmacological responsiveness [23,63,64,97,100,101,118–120,122–124]. Cyclic stretch affects not only the structure (e.g., orientation of cells and collagen) [119] but also the mechanical function (i.e., contractility) [28,63,64,118] of engineered cardiac tissue. Recently, scaffolds have been specifically designed for mechanical stimulation in cardiac tissue engineering [121]. In this study, chitosan-collagen scaffolds with an array of parallel channels were seeded with rat neonatal heart cells and subjected to dynamic tensile stretch for 6 days using a custom designed bioreactor. Mechanical conditioning promoted cardiomyocyte alignment and elongation, and increased cell-to-cell connections as evidenced by increased connexin-43 expression, although these results were dependent on high local stress conditions and were not achieved in areas of the scaffold with lower stress.

Instead of utilizing cyclic stretch to provide mechanical stimulation, some studies utilize pulsatile hydrostatic pressure. One such example used a bioreactor designed to provide physiologically relevant shear stresses and flow rates via pulsatile perfusion [125]. Culture under these pulsatile perfusion conditions enhanced the contractility of the constructs by increasing the contractile amplitude and lowering the excitation threshold.

Together, these mechanical conditioning studies demonstrate that specific loading protocols may be exploited to stimulate specific responses in engineered tissue constructs, and emphasize the potential utility of bioreactors which provide mechanical conditioning in the form of stretch or pulsatile flow in studying and promoting *in vitro* construct formation.

CONCLUSIONS

As the field of functional tissue engineering progresses, the development of engineered tissue replacements may require additional exogenous influences to achieve many of the important requirements for long-term success. Scaffolds can provide structural, biochemical and mechanical cues, and in combination with bioreactors, growth factors, and mechanical conditioning, may enhance *in vitro* generation of functional tissue-engineered constructs. *In vitro* models can be used to assess construct physiologic and pharmacologic responses, including responses to environments mimicking those into which the constructs will eventually be implanted *in vivo*. Nonetheless, it is important to note that other rapidly evolving technologies also may have a significant impact on tissue engineering, and it is important to consider *in vitro* culture parameters in light of the role of novel molecular and gene therapies, and other changing technologies.

CHAPTER 14

Principles of Bioreactor Design for Tissue Engineering

Sarindr Bhumiratana, Jonathan Bernhard, Elisa Cimetta and Gordana Vunjak-Novakovic
Columbia University, New York, New York

INTRODUCTION

The fascinating development of human tissues and organs entails tightly regulated mechanisms, which synchronize biological cues such as cell-secreted cytokines with external stimuli such as physical signals and structural framework. By mimicking the native milieu of tissue development and regeneration, bioreactors can coax the cells to form viable and functional tissues *in vitro*.

In this chapter, we discuss the design of tissue engineering bioreactors with physiologic-like environments and their application in regenerative medicine as well as in the studies of development and disease. We first review representative bioreactor designs, then focus on three different areas of application for advanced bioreactors:

1) Regenerative medicine,
2) Biological research,
3) High-throughput drug screening.

PRINCIPLES OF BIOREACTOR DESIGN

Cell/tissue culture techniques arose from the historical concept that, in an appropriate environment, cells and tissues can survive and remain viable outside the body. To date, traditional cell culture provides a tool for controllable proliferation of the cells and induction of specific differentiated phenotypes. However, the conventional cell culture materials — well plates and culture flasks — lack the ability to generate native-like functional tissues.

In nature, cells are the key architects of the tissues and organs. Under suitable conditions, they can remodel their immediate microenvironment and form functional tissue units. The 'biomimetic' approach to tissue engineering combines these biological principles with engineering design, directing metabolically active cells into three-dimensional (3D) spatial arrangements that, in response to genetic and environmental signals, gradually form tissue structures. In both *in vivo* (development/regeneration) and *in vitro* (tissue engineering) settings, the environmental cues are the principal determinants of the cell phenotype. Therefore, advances in bioreactor design have focused on mimicking the native environments

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00014-8

in vitro. In general, a bioreactor must support 3D tissue development, maintain cell viability and function within the tissue, and provide appropriate molecular and physical cues. This section describes how tissue engineers perceive the physiology of the human body, and also reviews the key engineering concepts and approaches to mimic the native environment.

An engineering perspective of physiological systems

The approaches to mimicking the native environment are based on the knowledge gleaned from developmental biology, cell biology and normal and pathological tissue function. Progress in cell and developmental biology has advanced our understanding of genetic expression and regulatory pathways that affect cellular function and tissue development. For example, a blastocyst develops into three distinguished germ layers via spatial and temporal regulation of specific signaling pathways: SMAD (portmanteau between small body size and mothers against decapentaplegic) and Mix paired-like homeobox (Mixl1) for endoderm; Fibroblast growth factor (FGF), Wingless-related integration site (WNT) and Bone morphogenetic protein (BMP) for mesoderm; and BMP and downregulation of WNT for ectoderm [1]. Tissue engineers can apply such knowledge to study biological systems, optimize biological responses and generate functional tissues. In order to mimic the native tissue environment, the engineering perspective is implemented both microscopically (at the molecular and cellular levels) and macroscopically (at the tissue and organ levels) (Fig. 14.1).

At the microscopic level, cellular mechanisms are regulated by spatial and temporal presentation of molecular factors. Molecular transport is dominated by diffusion (an exception being transport through motor protein such as kinesin and dynein), while cell behavior is influenced by cell-cell and cell-matrix interactions. Fundamental biochemistry has demonstrated that the activation and deactivation of cell signaling pathways relies on the presence of promoters and inhibitors and their affinities for the receptors.

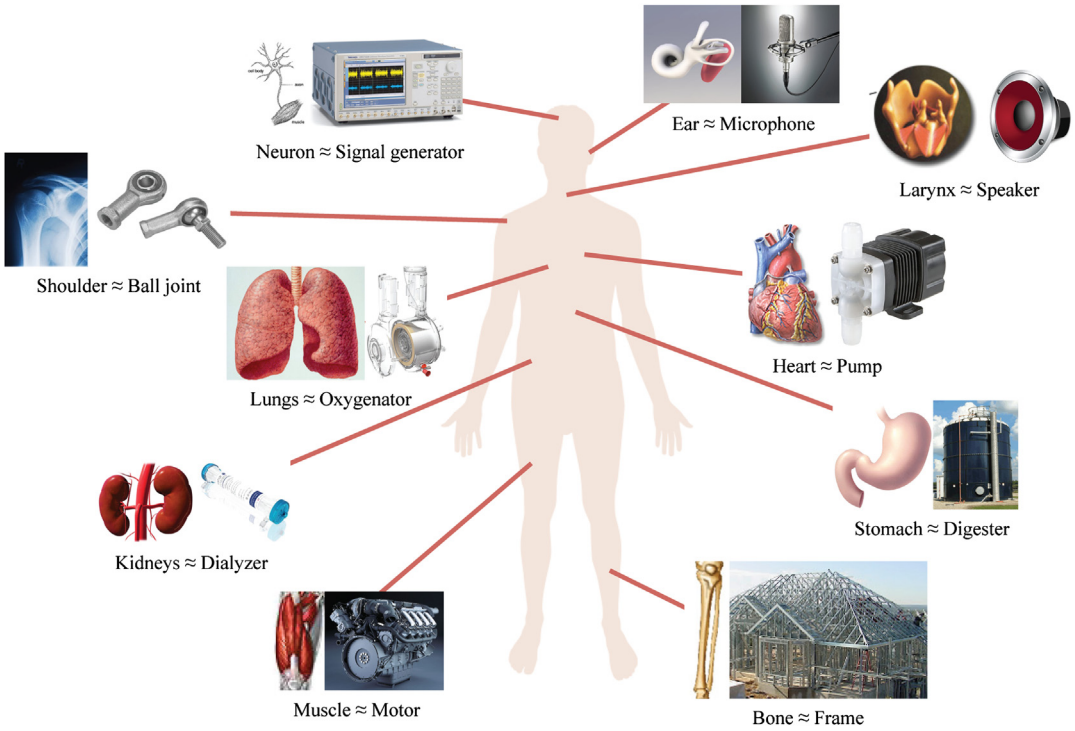

FIGURE 14.1

Engineering perception of human organs and tissues. The understanding of tissue environment and physiological function provides a basis for the design of various types of bioreactors.

For many individual pathways, the essential molecules and factors regulating the desired processes have been identified. However, tissue engineering requires control over a combination of multiple factors that alter cell behavior through multiple regulatory pathways. Such ability would result in the optimization of cellular responses and diverse solutions for enhancement of tissue formation that cannot be achieved either *in vivo* (due to the complexity of the systemic environment that limits control over regulatory factors) or using conventional tissue culture systems (due to the batch-wise operation that prevents control of cellular environment in space and time, and the lack of physical factors). Innovative bioreactor designs offer solutions for quantitative studies of cellular mechanisms in response to changes in molecular transport, mechanotransduction, and the presence of other cells or extracellular matrix.

At the macroscopic level, the cell populations and extracellular matrix (ECM) interact to provide 'engineering' functions (Fig. 14.1). For example, the heart chamber is comparable to a pump moving fluid (blood) through pipes (blood vessels), the lungs work like a gas exchanger and the kidney combines filtration, osmosis, passive and active mechanisms to transport large amounts of molecules and water. Capillary networks provide a supply of oxygen and nutrients to the tissue by combining the convective and diffusive schemes. Cartilage and meniscus absorb impact forces and lubricate joints. Signaling in nerve cells is analogous to electrical signals. Despite the 'engineering' components and functions of our tissues, the biological systems are much more complex, versatile and adaptive than anything we have ever built. For example, blood vessels contract or expand to modulate the flow resistance in response to blood pressure or to a change in blood flow rate, and non-critical bone fractures heal perfectly over time. Viewing physiological systems from an engineering perspective provides guidance for the design of bioreactors, and is critical for defining their operating regimes.

Key engineering concepts for mimicking native environment

Today, bioreactors are developed based on our increasing understanding of physiological systems and their function, in conjunction with multi-disciplinary approaches to enhance and optimize cellular responses. The key concepts and approaches to mimic physiological phenomena in the human body are summarized in Table 14.1.

MASS TRANSPORT

To promote cell viability and well-being, bioreactors must provide adequate mass transport of nutrients, biochemical factors, and most importantly oxygen to the cells [2,53]. In addition, the system must allow rapid removal of metabolic products from the cellular environment. In physiological settings, these functions are provided by the vasculature, which readily adapts to the changes in metabolic demands of the cells.

To generate and maintain viable and functional tissues, tissue engineering needs to effectively build a vascular supply, or at least replicate the convective-diffusive transport normally provided by the vasculature. Static cell culture techniques rely on diffusional transport mechanisms that are efficient only within the thin superficial layer in contact with culture medium (in most cases only $\sim$100–200 μm thick), and fail to support three-dimensional tissues [3]. As the cell density increases, so does the nutrient demand. As a result, nutrients are depleted over short distances, and the cells positioned further from the source of nutrients and oxygen (i.e., those in the tissue interior) cannot remain viable [2,3,53,54].

Several different bioreactor technologies have been developed to increase transport rates between the cells and culture medium. Wave-wall bioreactors create an undulating motion of the culture medium to limit the size of the stagnant cell layer present at the surfaces of tissue constructs [2]. Spinner flasks achieve mixing of the external environment through the use of stirring components. A drawback of both of these simple systems is that they generate hydrodynamic shear stresses that can cause cell dedifferentiation [3]. If too high, shear stress can result in the formation of a fibrous capsule surrounding the tissue construct.

TABLE 14.1 Bioreactor designs and important parameters to mimic physiological phenomena

Physiological phenomena	Physical/ biological cues	Bioreactor design	Important parameters	References
Blood supply through capillary network	Adequate supply of oxygen, growth factors, and nutrition through convective transport	–Spinner flask –Rotating wall vessel –Wave –Perfusion	–Movement speed –Flow rate	[2–4]
Weight bearing joints during locomotion	Mechanical compression resulting in tissue pressurization	–Compressing platen –Pressurized chamber	–Static/dynamic compression –Length –Frequency –Strain	[5–10]
Stretching muscles and tendons	Tensile force pulling tissue and cells	–uni-/bi-stretching motion –Radial stretching motion	–Strain –Tensile force –Tensile stress –Frequency	[11–17]
Fluid flow over cells	Hydro static/dynamic shear force	–Perfusion in thin wall –3D Perfusion	–Shear stress –Fluid flow rate –Complex flow based on simulation	[18–21]
Joint movement	Shear force from tissue sliding	–Sliding surfaces	–Translational speed –Friction	[22–24]
Development, wound healing, cell firing	Electrical current and potential difference	–Electrical stimulator –Electromagnetic Current	–Voltage –Current –Frequency (AC and DC pulsed)	[25–28]
Muscle contraction	Electrical signal depolarizes cells	–Electrical stimulator	–Voltage –Current –Frequency	[29–31]
Cell adhesion to tissue matrix	Cell-substrate attachment through antigens and protein binding	–Micropatterning substrate	–Substrate chemistry, spatial distribution, and stiffness	[32–35]
Cell-cell communication	Local cellular contact	–Microcontact printing –Micromolding contact area	–Cell types –Cell density –Cell surface area in contact	[36–39]
Cellular response to biological signals	Biochemical concentration	–Microfluidic multi-well system	–Biochemical concentration –Temporal Presentation	[40, 41]
Chemotaxis	Concentration gradient	–Microfluidic gradient chamber	–Chemicals and factors –Gradient strength –Gradient Profile	[42–47]
In vivo response by multiple cell types, factors, and properties	Tissue *in vivo* response Cell type and stimulating factors	–*In vivo* implantation	–Complex tissue development, formation and function (ex. Angiogenesis, or bone/ cartilage tissue)	[48–52]

Rotating wall bioreactors were created to provide mixing while limiting the shear stress applied to the cells. The bioreactor rotation creates a dynamic flow environment by balancing the rotational, gravitational, and drag forces, so that the tissue constructs are suspended in culture medium in a state of free fall [2,3]. These conditions were termed 'simulated microgravity',

since they effectively randomize the gravity vector without having effect on gravity force. The dynamic nature of the settling of the tissue constructs in the rotating flow, which is associated with fluctuations in the amplitudes and directions of flow velocity and shear vectors, prevented the formation of fibrous capsules and significantly improved the cultivation of some tissues, cartilage in particular. Still, the size and viability of the tissue constructs depended on the internal diffusion of nutrients.

In tissue engineering, the most common practice to increase transport is to augment diffusion with convection, by mechanisms governing blood-tissue exchange of nutrients, oxygen and metabolites, using perfusion bioreactors [2]. In a perfusion bioreactor, medium is pumped through the scaffold, providing transport of nutrients inside the porous material. Perfusion bioreactors have been shown to be superior over both static culture [20] and spinner flask bioreactors [55] in terms of the resulting homogeneity of cell distribution.

MECHANICAL CUES

Physical forces play important roles in regulating all phases of tissue formation. As the cells proliferate and produce extracellular matrix, the volume of the tissue changes and exerts forces to the adjacent cells. For example, during mandibular development, shear forces exerted along the longitudinal growth of the mandible induce bone formation, while compression at the tip of the mandibular body induces cartilage formation. Interestingly, the type of cartilage strongly depends on the acting mechanical forces. Hyaline cartilage in the knee joint is thick and can withstand high compressive forces, while fibrocartilage on the mandibular condyle is very thin, consistent with its role in lubrication rather than in absorbing compressive forces. As a result, various types of bioreactors were designed to utilize various physical stimulation regimes.

Bioreactors applying mechanical compression were first developed for cartilage tissue engineering. These bioreactors generally comprise of a platen, which compresses tissue constructs statically or dynamically at a defined displacement or load. Different compressive regimes have been investigated and demonstrated to enhance deposition and functionality of cartilage matrix [5–7]. Hydrostatic pressure, a simpler set up than platen compression, has also been employed to show similar effects [8]. This is not surprising, as cartilage is a dense viscoelastic tissue containing large amounts of water. When the tissue is compressed, the low hydraulic conductivity prevents water from flowing out, leading to an increase in hydrostatic pressure, which stimulates the chondrocytes.

Bioreactors that apply mechanical tension have been developed to study the formation of tissues such as ligament, muscle, or blood vessels. These tissues are stretched and exert tensile forces during their physiologic function. A tensile stress can be applied unilaterally, bilaterally or radially with either displacement or force control. Axial stress was shown to stretch the cells attached to the scaffold and induce a number of cellular responses, including cell elongation, alignment, differentiation and coupling [11–15]. Radial stress was shown to regulate smooth muscle cell organization and differentiation in vascular grafts [16].

Bioreactors applying shear force have utilized two different mechanisms: by the flow of fluid or by sliding a rigid material over the cell or tissue surface. The same mechanisms are associated with the physiological flow of fluid over osteocytes during bone compression and sliding of cartilage over meniscus during joint movement. By varying shear stress through changes in fluid viscosity and flow rate, primary osteoblast and mesenchymal stem cells showed increased osteogenic expression and produced more bone proteins and minerals [18,20,21]. Likewise, surface motion over cartilage enhanced chondrogenic responses [56].

ELECTRICAL SIGNALS

Electrical signals are inherent to most tissues. Depending on the specific state of the tissue (development, damage, or homeostasis) the electrical signals change with the specific tissue

activities [25]. Electrical currents have been measured in tissue development, wound healing and preconditioning of engineered tissues [25]. These studies have shown the importance of electrical currents in the differentiation, maturation and assembly of electrically excitable cells.

The presence of large electrical currents within the embryo shows that electrical signals are important for stem cell differentiation and early development. Studies of animal embryos show the presence of an electrical field during first cell divisions. Notably, the reversal of the direction of this electrical field caused developmental defects [25]. Equipping bioreactors with electrical fields has enabled the use of electrical signals to modulate stem cell differentiation. By applying an alternating current with a 1 Hz frequency, neural stem cells were induced to differentiate into astrocytes [26]. Similarly, a 15 Hz frequency of a pulsed electromagnetic field was able to increase osteogenic differentiation of human mesenchymal stem cells [27].

In wounds, an electrical field is generated across the damaged tissue. Its strength depends on the tissue type, but in general, a stronger field is recorded at the edges of a wound in comparison to its center [25]. The upregulation of sarcoma and inositol-phospholipid signaling pathways establish the directionality of the electrical field, which mediates cell migration into the wound [28]. Similar electrical fields also promoted directed cell migration [28].

The incorporation of electrical stimuli in the bioreactor design for electrically active tissues, such as muscle and nerves, allows for better tissue development and augmented functionality of engineered tissues. For example, the application of pulsed electrical signals 2 ms duration at a frequency of 1 Hz resulted in significant structural organization of the myocardial grafts [29]. Electrical stimulation resulted in improved cardiac cell alignment and significant improvements of the amplitude and synchronicity of myocyte contractions [29].

CELLULAR MICROENVIRONMENT

Ideally, biological studies should be performed under conditions that recapitulate specific aspects of the complex native environment. The capability to modulate regulatory factors and measure cellular responses can lead to the recreation of native-like environments and quantitative studies of cell behavior. Of key interest are cell responses to other cells, matrix, and biophysical factors.

Microscale technologies enable fast and accurate control of the cell microenvironment and exploration of the underlying mechanisms through which the local microenvironment regulates cell behavior. The structure and organization of cellular assemblies can be precisely controlled by patterning techniques [35], through which cells can be guided to adhere onto specific locations with specific physical properties. Commonly used techniques include:

1) Microcontact printing of alkanethiols and proteins on gold-coated glass or other substrates;
2) Replica molding for fabrication of micro and nanostructures in polyurethane or epoxy;
3) Solvent-assisted micromolding of nanostructures in poly-methyl-methacrylate.

Patterns of adhesive and non-fouling proteins determine the spatial distribution of cells and the formation of focal adhesions. Pioneering studies [32] have proved that cell shape, regardless of the type of ECM printed on the substrate to mediate cell adhesion, plays a major role in determining cell fate and function. Micro- and nano-scale geometric cues can induce different functional outputs on cultured cells (for example growth or apoptosis) as a result of exogenously controlled microenvironmental stimuli. Combination of specific mechanical and biochemical properties of the cell culture substrate enabled the study of a plethora of previously unexplored biological phenomena.

Lineage specification in stem cells could be directed by substrate stiffness. By mimicking *in vivo*-like matrix elasticity using variably compliant polyacrylamide gels, and directing cell attachment by coating the surfaces with collagen I or other adhesion proteins, evidence was presented that soft matrices that mimic brain are neurogenic, stiffer matrices that mimic muscle are myogenic, and more rigid matrices that mimic bone prove osteogenic [33,34].

Another important component of the *in vivo* microenvironment is the tightly controlled spatial and temporal pattern of soluble factors. Spatial gradients of morphogens and other chemical cues play a fundamental role in determining cellular response *in vivo*. Since the advent of microscale technologies, researchers have invested heavily into the development of highly controllable platforms for delivering complex physiological signals.

One of the earliest, still widely used and re-adapted, microfluidic devices was developed by Jeon's group to generate dynamic spatial-temporal gradients of morphogen concentrations [45]. Their simple device combined a modular mixer with a gradient-maker network, capable of controlling multiple gradient shapes. Different concentration profiles could be generated depending on the configuration and number of fluidic inputs, the design of the microchannels network and the flow rates of the incoming streams. Splitters and mergers induced the mixing (primarily by diffusion) of fluid streams with different compositions, thus allowing sequential generation of a variety of concentration gradient profiles such as linear, saw-tooth, and bimodal.

Microfluidic technologies have enabled the investigation of many previously unexplored biological questions. Among them, one study demonstrated the effect of the concentration gradient of growth factors on human neural stem cells [42]. After seven days in culture under continuous flow with concentration gradients, cells proliferated and differentiated into astrocytes in a graded fashion, in proportion to the growth factor concentration. Similarly, neural progenitors cells were studied under conditions mimicking the *in vivo*-like presentation of morphogens known to act via the formation of concentration gradients during embryo development [46]. Neural progenitor cells derived from human embryonic stem cells were cultured for up to eight days under concentration gradients of cytokine cocktails (sonic hedgehog, fibroblast growth factor 8, bone morphogenetic protein 4). Differentiation of progenitor cells was successfully guided in a manner directly proportional to the concentration gradient, with complex neural networks formed inside the culture channel.

Cellular migration

Chemotaxis and chemokinesis regulate cancer metastasis, embryogenesis, inflammation, wound healing and many other biological processes. Evidence has been found for the role of fast-switching spatial and temporal regulation patterns *in vivo*. However, effective study of these complex biological events has long been hindered by a lack of necessary technologies. Recent technological advances, such as microstructured membranes and valves in microfluidic devices, allow increased control over the local concentrations. As a result, integration of these components enables fast and accurate switching between different concentration gradients and stimulation patterns.

Microscale physiological stimulation is essential for studying biological phenomena such as directed cell migration [43]. For example, neutrophils, the fundamental component of the physiologic defense machinery, have been among the most widely studied cell phenotypes with regards to cell migration. Neutrophils' movements are regulated by complex phenomena involving continuously changing chemical signals. With the aid of advanced microfluidic systems, it has become possible to study their complex behavior [44]. By controlling the type and the temporal presentation of signaling molecules, the migratory patterns of neutrophils can be predicted. Additional stimulations (other than spatial and temporal gradients alone)

are necessary in a higher hierarchical fashion to fully encompass the complex behavioral responses of neutrophils *in vivo*.

COMPLEX SIGNALING OF *IN VIVO* BIOREACTORS

The bioreactors developed thus far have demonstrated capability to partially mimic native environment for *in vitro* culture. However, tissue generation is a complex process involving numerous interconnected pathways, cell types, and interactions needed for proper development [52,57]; thus, these complex physiological processes make it difficult to generate complete physiological mimics *in vitro*. One particular challenge is the generation of vasculature within engineered tissues. To this end, significant research has been directed to the development of *in vivo* bioreactors [51]. Most *in vivo* bioreactors are placed into highly vascularized, minimally functioning locations within the body [51,52,57]. Adequate nutrient supply, and the availability of angiogenic factors and different cell types, can facilitate the development of vasculature to support tissue-engineered constructs [48].

Despite the successes in creating complex tissues that are highly vascularized, shortcomings have prevented this technology from being broadly adopted. Firstly, only a limited number of locations in the body meet the conditions necessary for proper construct development [57]. Secondly, due to the high variability of processes *in vivo*, significant control of variables is lost and additional stimulation, such as mechanical or electrical, is difficult to incorporate [57]. However, continued work is ongoing to solve these problems while maintaining the extraordinary benefits of the *in vivo* bioreactors.

ADVANCED BIOREACTORS IN TISSUE ENGINEERING

In order to study the complex biological responses and generate native-like tissues *in vitro*, bioreactor designs have advanced with greater complexity. Despite these improvements, the bioreactors are maintaining user-friendly operation to provide effective experimental tools and reduce user errors. This section introduces advanced bioreactor systems that have been successfully used to progress their application of regenerative medicine, biological research and high-throughput screening.

Regenerative medicine

Generating functional tissue grafts of clinically relevant sizes *in vitro*, by using autologous or immunologically matching stem cells would change the way we currently treat tissue loss. Engineered grafts would overcome the combined limitations of autografts (lengthy surgical procedures, donor site morbidity), allografts (immune rejection, disease transfer, limited supply), and xenografts (immune rejection and disease transfer). However, the engineering of functional grafts matching the needs of the patient and the specific clinical condition remains a challenge to bioreactor design [58]. We discuss here two studies that have employed innovative bioreactor techniques in attempts to engineer functional tissues.

DECELLULARIZING AND RECELLULARIZING LIVER FOR TRANSPLANTATION

The most commonly used technique in liver transplantation is orthotopic transplantation, in which the native liver is removed and replaced by the donor organ in the same anatomic location as the original liver. Tissue engineering offers a promising substitute to allograft transplantation which would overcome the problem of donor liver shortage and the complications caused by donor mismatch. Notably, the difficulties in providing sufficient transport rates of oxygen and nutrients to metabolically active cells in large pieces of engineered liver tissue have limited the development of liver grafts.

Uygun et al. demonstrated a novel approach to generating transplantable liver grafts using a custom-designed perfusion bioreactor [59]. The bioreactor consisted of a simple perfusion chamber in which a whole rat liver was submerged in fluid and connected to the perfusion

loop by portal vein cannulation, with the inferior vena cava and superior vena cava left open for the fluid outlet. The bioreactor was connected via tubing to a pump and a reservoir. The liver was first decellularized by perfusion with Sodium Dodecyl Sulfate (SDS), an anionic detergent that lyses cells and solubilizes cytoplasmic components, Triton X and Phosphate Buffered Saline (PBS). This decellularization process generated a translucent acellular scaffold, which retained the gross anatomical shape of the liver (Fig. 14.2a–c). While cellular content was mostly removed, the technique retained 100% of the fibrillar collagen and ~50% of the glycosaminoglycans of native liver. Importantly, the structural components of the vascular network, consisting of the portal and venous circulation system all the way down to the microcirculatory branches, were largely preserved (Fig. 14.2d).

The same bioreactor was used to seed the decellularized livers with adult rat hepatocytes via portal vein perfusion-recirculation with high engraftment efficiency (> 95%) and viability (> 90%). After seeding, recellularized liver grafts were transferred into a new perfusion chamber (Fig. 14.2e), configured into a pouch between two hermetically sealed silicon sheets filled with culture medium, and cultured for five days. An important aspect of this approach is that the preserved vascular structure enabled connection of the recellularized liver to the host vasculature at the time of transplantation. The blood supply that was established immediately maintained viability of transplanted cells for 8 hours *in vivo*. This study demonstrates the utility of perfusion bioreactors for generating liver grafts by decellularizing and recellularizing whole rat livers, and for maintaining perfusion *in vivo* by preserving the vascular network and connecting it to the host vasculature.

BIOREACTOR FOR ENGINEERING FULLY CELLULARIZED, ANATOMICALLY SHAPED BONE GRAFTS

The use of bone autografts, allografts, and engineered bone substitutes all require pre-implantation shaping in order to match the anatomical features of the specific defect. The ability to generate functional bone grafts with precisely defined geometries would significantly reduce the time of surgery, improve grafting outcomes and eliminate a number of complications associated with the use of other grafts. Maintaining viability and function of the cells in clinically sized, anatomically shaped tissue constructs requires a well-controlled supply of nutrients and oxygen throughout the tissue constructs.

Recently, a custom-designed perfusion bioreactor was developed to support cultivation of clinically sized, anatomically shaped human bone grafts by bioreactor cultivation of bone marrow mesenchymal stem cells on scaffolds made of decellularized bone [4]. Human temporomandibular joint (TMJ) condyles were engineered by using two different bioreactor systems: mixing chambers for seeding scaffolds with cells, and perfusion chambers, anatomically shaped, to differentiate stem cells and assemble bone matrix. The seeding bioreactor was adapted from the spinner flask cultivating system, and contained three scaffolds fixed in place and submerged in cell suspension. Magnetic stirrers created a convective flow that propelled cell suspension deep into the scaffold pores permitting cell adhesion.

The cultivation bioreactor consisted of a specially designed bioreactor chamber connected via a perfusion loop to a medium reservoir and a peristaltic pump to recirculate medium and perfuse it through the scaffold within the chamber. The chamber consisted of a soft Polydimethylsiloxane (PDMS) block created as a negative mold that fully entrapped the scaffold, and an outside casing chamber that contained the inlet and outlet ports for culture medium perfusion (Fig. 14.2f–h). Both the scaffold and the bioreactor chamber were fabricated using a three-dimensional file created from clinical images of a human TMJ. By employing computer software to analyze fluid flow patterns, the locations for the medium inlet and outlets were optimized to ensure perfusion of all regions of the seeded scaffold (Fig. 14.2i). After five weeks of cultivation, tissue growth was evident by the formation of confluent layers of lamellar

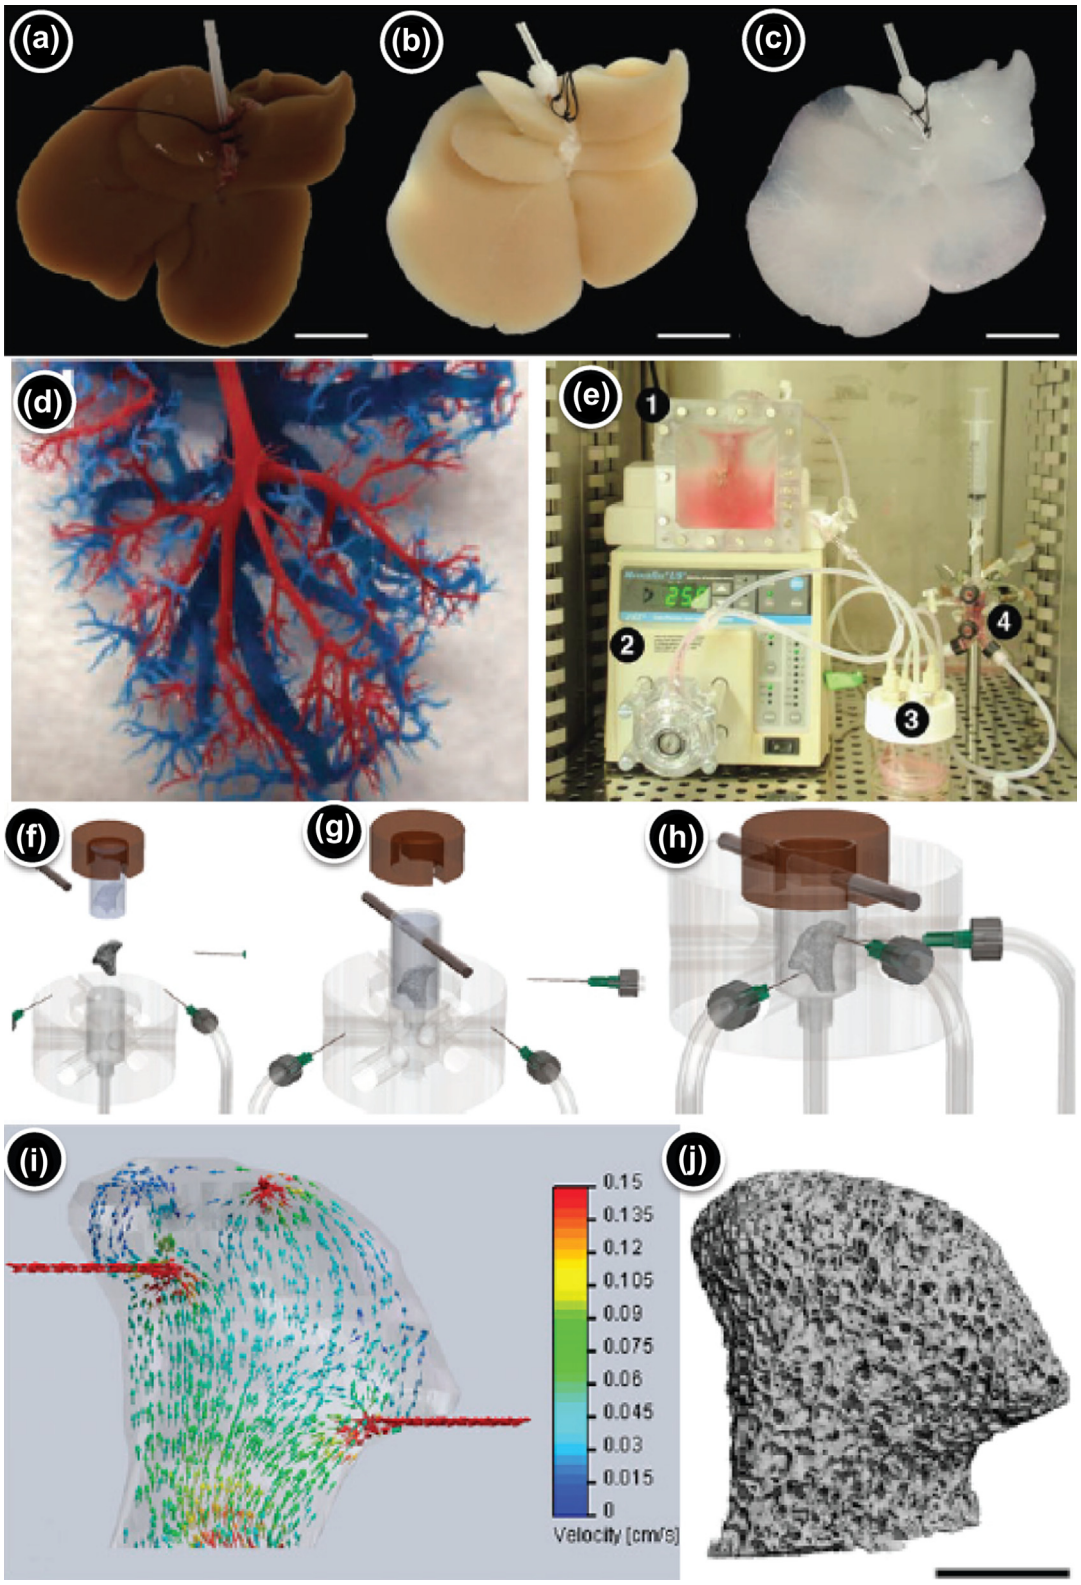

FIGURE 14.2

(j) Architecture of the mineralized bone matrix after 5 weeks of cultivation in the perfusion bioreactor [4].

bone (by scanning electron microscopy), markedly increased volume of mineralized matrix (by microcomputerized tomography; Fig. 14.2j), and the formation of osteoids (histologically). The cells were present at a physiologic density and were fully viable, likely an important factor for graft function and successful integration with the host tissues.

These studies of two distinctly different and rather complex tissues — liver and bone — demonstrate that custom-designed bioreactors can be used in conjunction with biological scaffolds and cells to grow viable and functional tissues *in vitro* in clinically relevant sizes and shapes. It is expected that further advancements in bioreactor designs, such as incorporating additional regulatory signals (molecular, cellular, hydrodynamic, mechanical), will continue to drive tissue-engineering approaches towards clinical translation.

Biological research

During development and regeneration, tissues are formed from coordinated sequences of stem cell renewal, specialization and assembly that are orchestrated by cascades of regulatory factors. Standard *in vitro* techniques typically fail to replicate the complexities of the *in vivo* milieu, often resulting in unrealistic biological readouts that fall short of being physiologically predictive of the actual *in vivo* situation. In this context, there is a clear need for bioengineered environments that combine tissue-specific transport and cell signaling with multiple cell types, and 3D spatial-temporal control of molecular and physical signals, in ways resembling the contexts encountered *in vivo*. There is a growing recognition of how important microenvironmental control is in studying development, regeneration and disease in settings predictive of human situations.

CELL COMMUNICATION

Cell co-cultures are typically performed by either seeding different cell types one after another (into the same or different regions of the scaffold), or by direct seeding of mixed cell populations [37–39]. The spatial and temporal control of cell-cell interactions is as challenging as it is important for proper tissue development and function. One of the most elegant approaches developed thus far has demonstrated that dynamic regulation of cell-cell interactions can be achieved by direct manipulation of adherent cells and the resulting tissue organization with micrometer-scale precision (Fig. 14.3a) [36]. The device is composed of two interlocking comb fingers and an integrated snap-lock mechanism, which was fabricated using electromechanical microfabrication methods (Fig. 14.3a-*a*).

The silicon fingers are pre-coated with polystyrene, the tissue culture plastic material, and can be seeded individually with different cell types and re-assembled in the desired configuration (Fig. 14.3a-*b,c*). The parameters for cell-cell contact and communication between cell populations can be controlled separately and cultured simultaneously (Fig. 14.3a-*d*). For example, by setting a μm-scale separation between the plates, cell contacts can be eliminated while soluble signaling is maintained, in a way dependent on the separation distance. In addition, plates are interchangeable, enabling dynamic regulation of diverse signaling phenomena (cell contact-mediated and soluble signaling) without the need of interrupting culture or setting up multiple experimental runs.

This device enabled the investigators to deconstruct the dynamics of intercellular communication between hepatocytes and supporting stromal cells in co-culture. The preservation of hepatocyte viability and liver-specific functions depended on the complex dynamics of spatial and temporal signal sequences, resulting in the identification of key signals. The adaptability of this microbioreactor system is suitable for studying a broad spectrum of biological processes. The integration of microfluidic components for fluid delivery would enable recreation of the dynamically changing microenvironment of the *in vivo* niche, while preserving the cell-mediated signaling originating from the multiple cell types.

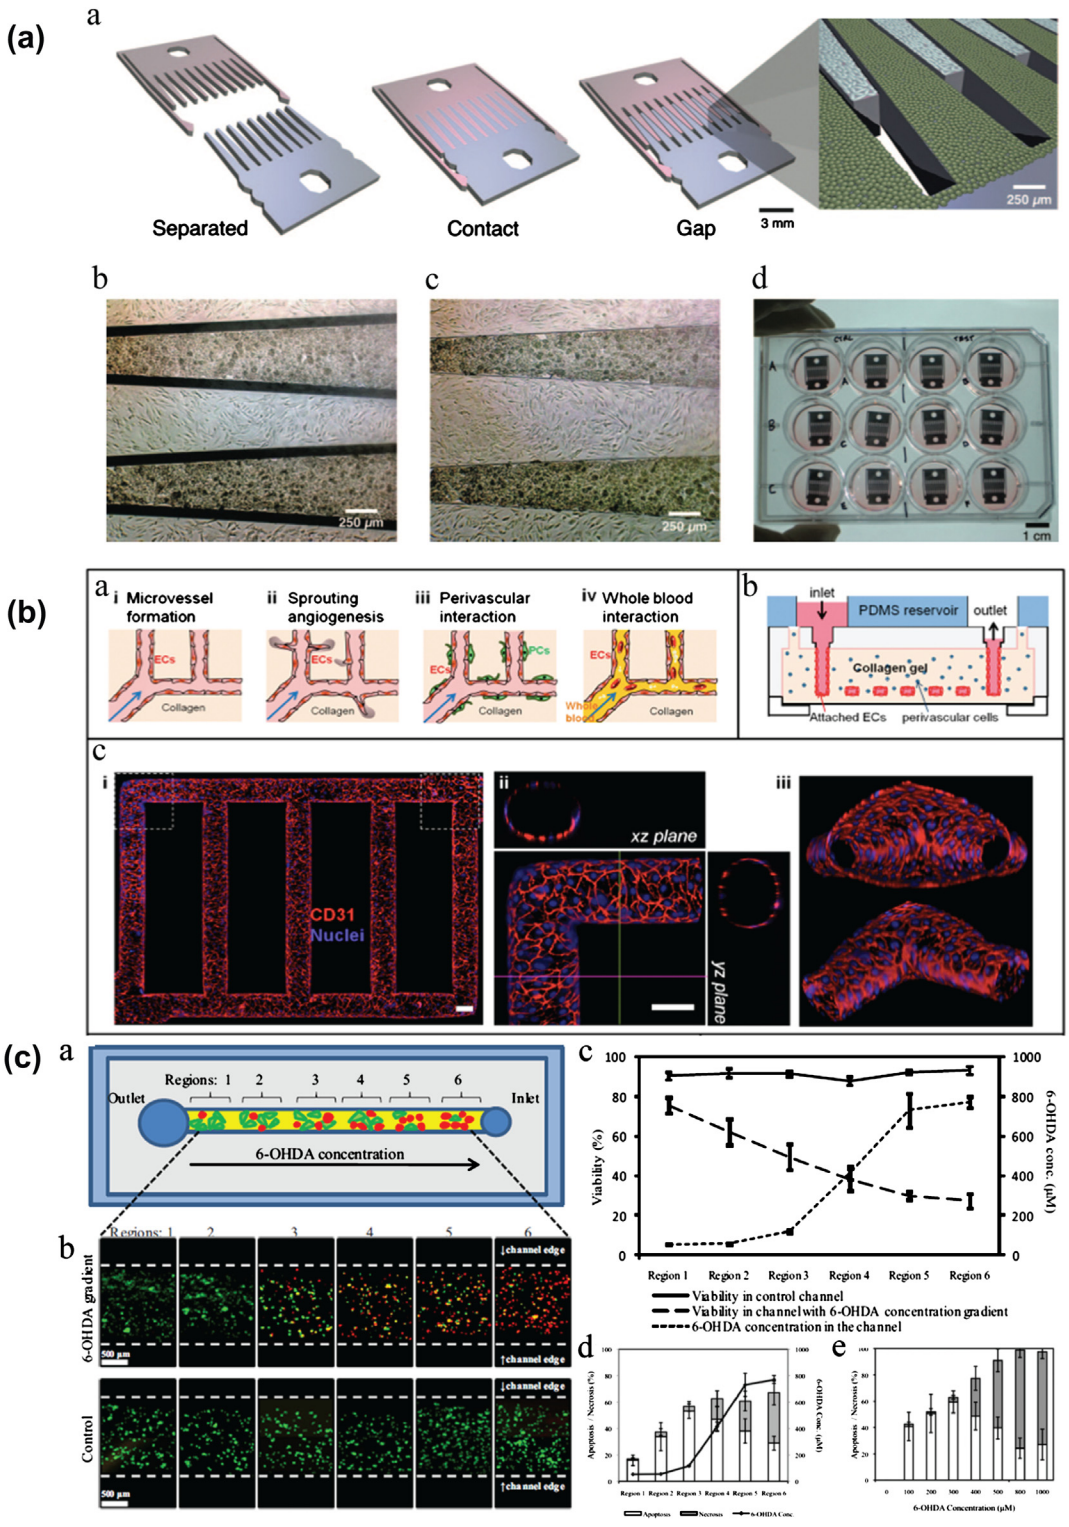

FIGURE 14.3

Appropriate actuation can provide an interlocked configuration (center), or micron-scale gap separation (right). (b and c) Co-culture of hepatocytes (darker cells) and 3T3 fibroblasts demonstrating the different spatial configurations, gap (b) and interlocked (c). (d) Mechanism dimensions were designed to conform to a standard 12 well plate to allow simple cell culture and reproducibility [36]. **(b) Generation of complex microvessel networks.** (a) Schematic of the theoretical development of the microfluidic vessel networks achieved through sequential seeding of endothelium and subsequent development. (b) Schematic of the microfluidic bioreactor system, with arrows demonstrating fluid flow.

In summary, technologies capable of recreating and dissecting the complexity of cell communication might prove very useful in the studies of cell development, disease onset and progression, therapy development and cell niche investigation.

TISSUE DEVELOPMENT

Native tissues develop under tight spatial and temporal control of multiple factors, with synergistic and competing effects. Averaged tissue properties are important for determining the utility of engineered tissue grafts but are less instructive for defining the cell-scale phenomena. Therefore, more precise microscale systems are needed for appropriate cell-scale observations of relevant phenomena. A recent advance resulted in a network of endothelialized microfluidic vessels generated within collagen matrix that were fabricated via standard lithography and micromolding (Fig. 14.3b) [60]. Custom-designed microstructured PDMS constructs were used as templates to mold the microvessel structures, with sealed plexiglass frames used to define the thickness, size and shape. Collagen gel provided adequate mechanical stiffness and structural stability of the vessel microstructures while also enabling remodeling through cellular degradation and deposition of extracellular matrix (Fig. 14.3).

One important design characteristic of the bioreactor was the ability for sequential seeding, allowing different cell types to seed either the vessel channels or the extravascular collagen gel. Gravity-driven perfusion of culture medium was maintained for up to two weeks to form endothelium, which exerted a barrier-function to the transfer of solutes from the lumen into the surrounding matrix (Fig. 14.3).

Specific behaviors were identified depending on the different stimulations of the microvessel networks. For example, stimulation with a proangiogenic environment found in the vicinity of ischemic tissue or solid tumors resulted in less organized structures with loose cell-cell contacts, cell sprouting from the endothelium into the bulk collagen matrix and increased leaking into the surrounding areas. Remarkably, the *in vitro*-produced vascular endothelium was non-thrombogenic, and could be induced by inflammatory factors into a prothrombotic state. Following perfusion with whole human blood, 'healthy' vessels showed little or no platelet adhesion, while large aggregates of platelets formed immediately in an induced inflammatory environment. This bioreactor technology enabled investigation of the endothelial interactions with other cell types, for complex phenomena such as angiogenesis and thrombosis. This system holds great potential for modeling of tumor progression, inflammation, thrombosis, and many other pathological states.

DISEASE MODELS

Primary human cell cultures or animal cell lines are often used as *in vitro* models for disease and screening studies. However, these models often fail to represent the highly specialized characteristics of human tissues. The possibility of reconstructing *in vivo*-like niches resembling the natural architecture, biomechanics, soluble environment, spatial and temporal delivery of factors opens exciting prospects for studying disease physiology in organ-specific contexts.

In a recent study [47], microfluidic technologies were applied to an *in vitro* model of Parkinson's disease. A simple microfluidic channel was fabricated by soft lithography, seeded with cells, and used to generate concentration gradients of neurotoxins for 24 hours

(c) Confocal images of the precisely controlled development of the microfluidic vascular networks. i. the entire network, ii. varying projections of the corner regions, including luminal views, iii. varying projections of the branching segments [60]. **(c) Microfluidic device for disease modeling.** (a) Schematic of the microfluidic device that enables the study of the concentration related effect of the 6-OHDA neurotoxin on neuronal cells. Representative image of the live/ dead staining of PC12 cells is included in the schematic. (b) The upper row demonstrates the live/ dead images with a channel toxin concentration of 1000 μM. The lower demonstrates the live/ dead images with no added toxin. (c) Quantification of PC12 cell viability within the channel based on the region segmentation marked in part B. (d) Quantification of PC12 apoptosis/ necrosis of the experimental treatment along the channel following the region segmentation marked in part B. (e) Quantification of the apoptosis/ necrosis of PC12 cells exposed to varying concentrations of 6-OHDA performed in static culture [47].

(Fig. 14.3c). The viability, apoptosis and necrosis of cells in the channels were determined. Cell viability was inversely proportional to the concentration of neurotoxin. Interestingly, low drug concentrations mainly induced death by apoptosis, while higher concentrations resulted in cell necrosis. Such *in vitro* mimics of *in vivo* events will be crucial for developing novel therapeutic targets.

The integration of similar bioengineered environments with novel stem cell sources can open new perspectives in understanding the fundamental biology of disease, investigating the mechanisms of disease, and developing new treatment modalities. Recent advances have proven the feasibility of deriving patient-specific pluripotent stem cells (iPS cells) to be used for a multiplicity of purposes, including disease modeling studies. A series of diseases have already been investigated *in vitro* using iPS cells differentiated into disease-relevant cells. These advances represent a fundamental tool for developing high-throughput screens for candidate drugs and performing mechanistic studies of disease pathogenesis [61].

High-throughput screening

High-throughput screening methods are beginning to incorporate robotics, microspotting, data processing control software, liquid handling devices, and sensitive detectors. The integration of such components into miniaturized biological experimental systems allows researchers to more readily conduct vast chemical screenings. High-throughput screenings can dramatically improve the identification of active compounds, antibodies or genes which modulate biomolecular pathways and can help studying cell behavior in a combinatorial, efficient manner.

OPTIMIZING TISSUE CULTIVATION TECHNIQUES

Robotic fluid handling and microspotting facilitate high-throughput studies of different immobilized factors in microarrays, but require time-dependent stimulation to be applied simultaneously. Microfluidic platforms, which facilitate studies of diffusible growth factors with spatial and temporal control, have historically been difficult to scale-up into larger, individually manipulated culture chambers.

Versatile, fully automated microfluidic cell culture systems that create arbitrary media formulations in independent cell culture chambers can help address these requirements [40]. A classical example of this approach is an automated microfluidic platform with 96 individually addressable culture chambers, with a volume of 60nL each, that was capable of maintaining cell viability for weeks and was designed to screen for the effects of multiple conditions on cell behavior (Fig. 14.4a). Culture conditions could be customized in terms of cell seeding density, composition of culture medium, and feeding schedule, and each culture chamber could be imaged with time-lapse microscopy. Multiplexers and mixers (controlled by actuators and valves) allowed generation of broad ranges of medium compositions and accurately controlled the temporal feeding/washing patterns.

The automation was also extended to post-processing procedures such as fixing and staining of the cell samples, achieving improved accuracy and saving reagents. hMSCs were selectively stimulated to either proliferate or differentiate into the osteogenic or adipogenic lineages. This microfluidic platform, also designed to precisely study the effects of culture medium exchange rates, allowed exploration of different types of temporal gradients in the environmental conditions. As a case study, the authors tested eight different durations of osteogenic stimulation on the differentiation and motility of hMSCs. Bioreactor design incorporating automated and multiplexed devices demonstrated the ability to quantitatively and systematically determine the optimal cell and, thus, tissue cultivation method.

DRUG SCREENING

The integration of relevant stem cell sources with advanced technologies will also likely become a significant resource for preliminary drug screening, eliminating or greatly reducing the need for costly (and at times poorly predictive of the actual human physiology) animal experiments. A particularly important need for *in vitro* modeling of multi-organ systems is the prediction of toxicity. A novel 'organ-on-chip' concept [41] involves advanced engineered systems in which cells are cultured within microfluidic devices designed to recapitulate specific microenvironment of living organs. Such *in vivo*-like niches, which resemble the natural architecture, biomechanics, soluble environment, spatial and temporal delivery of factors, open exciting opportunities for studying disease physiology in organ-specific contexts. The additional capability of organ-to-organ communication would bring the study of toxicology and pharmacology to an unprecedented level, and could shorten time to market for novel therapies.

Human cardiomyocytes, derived from embryonic stem cells, were used as a renewable and scalable source for cardiac pharmacology assays. Patch clamp analyses and multichannel electrode arrays (MEA) allowed generation of field potential duration (FPD) values of the cardiomyocytes following exposure to different drugs [62]. The use of MEA allowed a dramatic increase in the throughput, obtaining large amounts of data using limited number of cells and reagents (Fig. 14.4). One of the most widely used criteria for cardiac drug toxicity is the prolongation of the QT interval (the time between the start of the Q wave and the end of the T wave in the heart's electrical cycle. It's the portion of an ECG representing the time from the beginning of ventricular depolarization to the end of ventricular repolarization), which can signal ventricular arrhythmias. After having established a working model for cardiotoxicity, the authors demonstrated improved performance of their model in detecting QT prolongation/shortening and arrhythmia caused by various drugs. This method, measuring drug toxicity responses on *in vitro* models of human cardiac cells, proved to be reliable for preclinical

evaluation of new drugs. This success suggests it can be used in replacement of the current assays, which typically rely on tedious, operator dependent, single cell-based measurements (i.e., patch clamp). Patient-specific studies would also enable developing ad hoc, personalized therapies.

SUMMARY

The development of bioreactors for tissue culture applies engineering concepts to mimic native tissue environments and physiological functions. Previous studies have extensively demonstrated various types of natively mimicking bioreactor systems on tissue engineering and in the study of cellular responses. To date, the bioreactor designs have been increasingly progressed to the point which allows scientists and tissue engineers to generate fully cellularized functional tissue grafts, study complex biological responses *in vitro*, and improve tissue culture methods and pathological treatments. Engineers and scientists are continuously advancing bioreactor system in tissue engineering toward (i) developing complete tissue cultivation systems for generation of functional tissue grafts for clinical appplication, (ii) providing tools to study sophisticated biological responses which will open up novel direction for tissue regeneration and tissue engineering, and (iii) optimizing cellular cultivation techniques, especially in the field of stem cell research, which is the most clinically relevant cell source for regenerative medicine.

CHAPTER 15

Regulation of Cell Behavior by Extracellular Proteins

Amy D. Bradshaw
Dept. of Medicine, Medical University of South Carolina, Charleston and the Ralph H. Johnson Department of Veteran's Affair Medical Center, Charleston, South Carolina

INTRODUCTION

The extracellular milieu is critical for the control of the behavior of every cell in all tissues. Many factors can contribute to the environment of a cell, for example, cell-cell contact, growth factors, extracellular matrix (ECM) proteins, and matricellular proteins. All of these components act together to regulate cell surface protein activity, intracellular signal transduction, and subsequent gene expression which leads to proliferation, migration, differentiation, and ultimately the formation of complex tissues. This chapter will focus on matricellular proteins as modulators of extracellular signals. The matricellular proteins are characterized as secreted, modular proteins that are associated with the extracellular matrix but do not act as structural constituents [1]. Presumably, the function of matricellular proteins is to provide a link between the extracellular matrix and cell surface receptors, or cytokines and proteases localized in the extracellular environment whose activity might be affected by this interaction [1]. Thrombospondin 1 and 2, tenascin-C, osteopontin, and SPARC are representatives of this class of proteins. A growing body of evidence points to these proteins as important mediators of growth factor, ECM, and cell signaling pathways (Table 15.1). Consequently, *in vitro* systems designed to mimic tissue conditions should consider the influence of matricellular proteins.

THROMBOSPONDIN-1

Thrombospondin-1 is a 450,000 dalton glycoprotein with seven modular domains [2]. To date, five different paralogs of thrombspondin have been identified, termed thrombospondin-1–5. This chapter will review the two more characterized forms, thrombospondin-1 and thrombospondin-2. At least five different ECM-associated proteins are able to bind to thrombospondin-1: collagens I and V, fibronectin, laminin, fibrinogen and SPARC [2]. Likewise, cell surface receptors for thrombospondin are numerous, and include the integrin family of extracellular matrix receptors [3]. Given the significant number and variety of thrombospondin-1-binding proteins, it is of little surprise that a wide variety of functions have been attributed to this protein, some of which appear to be contradictory. Many of these disparities may, however, actually reflect the dynamic interaction of thrombospondin-1 with

other extracellular factors which can influence cells in different ways to give rise to distinct cellular outcomes – a common theme in matricellular protein biology.

Several studies have established an anti-angiogenic function of thrombospondin-1 [3]. *In vitro*, aortic endothelial cells transfected with anti-sense thrombospondin-1 cDNA generate twice as many capillary-like structures on a gelled basement membrane in comparison to control cells that produce higher levels of thrombospondin-1 [4]. *In vivo*, increased expression of thrombospondin-1 by tumor cells results in decreased vascularization and an accompanied reduction in tumor progression by a number of different types of tumor-derived cells [5].

One mechanism by which thrombospondin-1 might influence angiogenesis is by promoting cell death in microvascular endothelial cells [6]. CD-36, a thrombospondin-1 cell surface receptor, has been shown to be required for caspase-3 mediated induction of apoptosis by thrombospondin-1. Anti-migratory effects elicited by CD-36 interaction with thrombospondin-1 in endothelial cells have also been demonstrated. Recently, CD36 complex formation with β1 integrins has suggested these cell surface receptors collaborate in thrombospondin-1 (and -2) cell signaling [7]. Another thrombospondin receptor, CD47, has been implicated in cardiovascular function as a potent regulator of nitric oxide (NO) [8]. Engagement of CD47 by thrombospondin-1 inhibits NO production. As NO is known to be significantly decreased in cardiovascular tissues in aging, the age-dependent increase in thrombospondin-1 has been implicated as mechanism that might account for deficient NO signaling in chronic diseases of aging. As the first natural inhibitor of angiogenesis, characterization of the mechanisms by which thrombospondin-1 functions has provided valuable insight into strategies to control blood vessel formation.

Thrombospondin-1, like many of the matricellular proteins, influences cytokine activity. For example, thrombospondin-1 has been shown to interact specifically with transforming growth factor (TGF) β [9]. This interaction leads to activation of the latent form of TGFβ, presumably

through a conformational change in the cytokine which allows interaction with cell surface receptors [9]. Consequently, the presence of thrombospondin-1 in the extracellular milieu might affect the activity of this potent, multi-functional cytokine. Generation of a thrombospondin-1 null mouse lends support to the importance of thrombospondin-1-mediated activation of TGFβ *in vivo*. The phenotype manifest in the absence of thrombospondin-1 expression mimics to some degree the phenotype of the TGFβ-null mouse [10]. Specifically, similar pathologies of the lung and pancreas are observed in both mice and, importantly, thrombospondin-1-null mice treated with thrombospondin-1 peptides show a partial restoration of active TGFβ levels and a reversion of the lung and pancreatic abnormalities toward tissues of wild-type mice. Importantly, thrombospondin-1 is a potent chemoattractant for inflammatory cells. Therefore, a reduction in active TGF-β levels in thrombospondin-1 null mice might be influenced by inflammatory cell recruitment.

The function of thrombospondin-1 in the activation of TGF-β appears to be of greater significance in some tissues in response to injury in adulthood rather than in development. For example, in the heart, thrombospondin-1 null mice have an altered response to both pressure overload (PO) induced hypertrophy and to myocardial infarction in comparison to the response in wild-type animals although uninjured adult hearts appear grossly normal. In hearts with PO, an increase in the number of myofibroblasts is found in thrombopsondin-1 null versus wild-type hearts in the absence of increases in fibrillar collagen [11]. As myofibroblasts are frequently associated with sites of robust collagen production, the lack of increased collagen suggests myofibroblast differentiation is impaired in the absence of thrombopsondin-1. In fact, thrombopsondin-1-null myofibroblasts from PO hearts are smaller and produce less collagen type I than those from wild-type counterparts. TGF-β is known to induce myofibroblast differentiation, hence the authors of this study conclude that inefficient TGF-β activity in the absence of thrombopsondin-1 likely influences myofibroblast phenotype in PO hearts.

Thrombospondin-1 influences cell adhesion and cell shape. For example, it will diminish the number of focal adhesions of bovine aortic endothelial cells and thus will promote a migratory phenotype [12]. Thrombospondin-1, therefore, is proposed to modulate cell:matrix interaction to allow for cell migration when necessary. An intermediate-stage of adhesion describes cell responses to counter-adhesive matricellular proteins and, as such, is predicted to promote cell motility [12]. Accordingly, thrombospondin-1 expression is observed during events such as dermal wound repair, when cell movement is required. Thrombospondin-1 is also expressed by many tumor cells and might facilitate metastatic migration [7].

THROMBOSPONDIN-2

Similar to thrombospondin-1, thrombospondin-2 inhibits angiogenesis *in vivo*. Recombinant thrombospondin-2 contained in pellets implanted in the rat cornea inhibited basic-fibroblast growth factor (bFGF)-induced vessel invasion to nearly the same degree as thrombospondin-1 [13]. Thus, the observation that the thrombospondin-2 null mouse appears to have a greater degree of vascularization in the skin is in accordance with the hypothesis that thrombospondin-2 might serve as an endogenous regulator of angiogenesis in mice [14]. In fact, the expression pattern of thrombospondin-2 is more consistent with the importance of this protein in vascular formation, as the mRNA for thrombospondin-2 is more closely associated with the vasculature in developing tissues, in comparison to that of thrombospondin-1 [15].

How might thrombospondin-2 mediate the inhibition of angiogenesis? Abrogation of thrombospondin-2 expression results in increased amounts of matrix metalloproteinase (MMP)-2 activity [16]. Thrombospondin-2 binds to MMP-2 and facilitates uptake by scavenger receptors on cell surfaces. Hence without thrombospondin-2, MMP-2 levels accumulate

in the extracellular milieu and result in significant decreases in cell adhesion. The increase in MMP-2 levels is correlated with decreased amounts of tissue transglutaminase on thrombospondin-2-null cell surfaces [17]. As transglutaminase is known to enhance integrin-mediated cell attachment and serve as a substrate of MMP-2, the increase in MMP-2 activity is proposed to elicit decreased cell adhesion in the absence of thrombospondin-2 by diminishing amounts of transglutaminase on cell surfaces. Hence, blood vessel formation appears to be sensitive to levels of MMP-2 in tissues. Likewise, tissue transglutaminase on cell surfaces might also contribute to angiogenic events.

Another observation from the thrombospondin-2 null mouse is that of altered collagen fibrillogenesis in the skin, relative to that seen in wild-type mice. The collagen fibrils in the null mice are larger in diameter, have aberrant contours, and are disordered [14]. Presumably this effect on collagen fibril formation contributes to lower tensile strength of the skin in thrombospondin-2-null mice compared to their wild-type counterparts. An intriguing relationship between aberrant collagen fibril morphology and decreased transglutaminase activity is suggested by the thrombospondin-2 null phenotype. Recent evidence also suggests that thrombospondin-2 is a pro-fibrotic molecule. In the absence of thrombospondin-2, less collagen deposition is found in a murine cardiac graft model [18], whereas increased thrombospondin-2 levels in scleroderma fibroblasts contribute to increased collagen production through upregulation of miR 7 [19].

Thrombospondins-1 and -2 can act as negative regulators of cell growth. In particular, endothelial cells are susceptible to an inhibition of proliferation by both proteins, resulting in their classification as inhibitors of angiogenesis. However, the variety of cell surface receptors for thrombospondins allows for diverse signaling events in different cell types; consequently, there might be situations when thrombospondin appears to support angiogenesis as well [20]. Thrombospondin-1 has been shown to modulate the activity of at least two cytokines, TGF-β and hepatocyte growth factor (HGF): diminished activity, in the case of HGF, or enhanced activity, as seen for TGF-β. Finally, thrombospondin-1 can alter cell shape to promote a migratory phenotype but can also inhibit migration. Such conflicting conclusions illustrate the importance of contextual presentation of matricellular proteins in various assays. Further characterization of the thrombospondins, including closer examination of the remaining family members (thrombospondins-3–5), will no doubt yield fascinating insight into this multi-functional gene family.

TENASCIN-C

Tenascin-C is a matricellular protein with a widespread pattern of developmental expression, in comparison to a restricted pattern in adult tissues. In addition to tenascin-C, three other, less-characterized forms of tenascin have been identified: tenascin-R, tenascin-X, and tenascin W [21]. This review will focus on tenascin-C, as the best characterized of the tenascin gene family. Tenascin-C consists of six subunits (or arms) linked by disulfide bonds to form a 2,000 kDa molecule that can associate with fibronectin in the ECM [22]. Like thrombospondin-1, a number of different functions have been attributed to tenascin-C and, accordingly, a number of cell surface receptors appear to mediate distinct properties of this matricellular protein. Cell surface receptors for tenascin-C include annexin II and at least five different integrins receptors, of which $\alpha_9\beta_1$ demonstrates the highest affinity for tenascin-C [23]. Whereas the integrins appear to support cell adhesion to tenascin-C, annexin II is thought to mediate the counter-adhesive function attributed to this protein. Hence, tenascin-C can act as either an adhesive or as a counter-adhesive substrate for different cell types, dependent upon the profile of receptors expressed on the cell surface.

Tenascin-C has also been shown to modulate the activity of growth factors: specifically, it promotes epidermal growth factor (EGF)-dependent and bFGF-dependent cell growth [24,25]. In fact, Jones et al. (1997) have shown that smooth muscle cells plated in a collagen gel secrete

MMPs that degrade the collagen to expose integrin receptor binding sites. Engagement of these receptors induces tenascin-C expression; tenascin-C is subsequently deposited into the extracellular matrix and can itself serve as an integrin ligand. The deposition of tenascin-C leads to cell shape changes initiated by a redistribution of focal adhesion complexes concomitant with a clustering of EGF receptors on the cell surface. Presumably, clustering of the EGF receptors facilitates EGF signaling and thereby enhances the mitogenic effect of EGF. Conversely, when MMP activity is inhibited, tenascin-C expression is decreased and the cells become apoptotic [25]. Thus, tenascin-C is able to modulate EGF activity such that the presence of this matricellular protein supports cell growth and its absence induces programmed cell death.

Similarly, tenascin-C supports tumor metastatic colonization by breast cancer cells through suppression of cell apoptosis [26]. Tenascin-C expression by stromal cells as well as by metastasis-initiating breast cancer cells appears to protect tumor-derived cells from apoptotic stresses and thereby faciliates establishment of metastatic colonization in some tissues [27,28]. A function of tenascin-C in hematopoiesis following myeloablation in adult mice is also reported. Tenascin-C expression in the bone marrow niche microenvironment is required for regeneration of hematopoiesis after ablation but is not required to maintain steady-state conditions [29].

Given the widespread expression of tenascin-C in the developing embryo, the lack of an overt phenotype in the tenascin-C-null mouse is surprising [30]. In particular, the high level of tenascin-C expression in the central and peripheral nervous system had indicated that the absence of this protein might lead to neuronal abnormalities. Although no histological differences could be detected in the brains of adult tenascin-C-null mice, they displayed behavioral aberrations including reduced anxiety and enhanced novelty-induced activity [31,32]. In addition, altered numbers of embryonic central nervous system stem cells are noted in the absence of tenascin-C expression, an observation confirming that the composition of the extracellular matrix is an important factor in cell differentiation [33].

The genetic background of the tenascin-C-null mouse is likely to be a major factor in the identification of tissues in which tenascin-C might be functionally important. For example, Nakao et al. (1998) use three different congenic mouse lines to study the effect of Habu-snake venom-induced glomerulonephritis in a tenascin-C-null background. Although the disease is worse in all tenascin-C-null mice in comparison to wild-type controls, each line exhibits a different level of severity. Induction of the disease in one strain, GRS/A, results in death from irreversible renal failure [34]. Moreover, mesangial cells cultured from tenascin-C-null animals do not respond to cytokines such as platelet-derived growth factor (PDGF) unless exogenous tenascin-C is included in the culture medium. Hence, tenascin-C can also modulate the activity of this growth factor as observed previously for EGF. Tenascin-C provides another example of a matricellular protein able to affect growth factor efficacy.

Although tenascin-C shows a limited pattern of expression in the adult, an induction of tenascin-C is seen in many tissues undergoing wound repair or neoplasia [35]. Thus tenascin-C, like the other matricellular proteins, is ideally suited to act as a modulator of cell shape, migration, and growth. One mechanism by which tenascin-C influences cell behavior is through the modulation of fibronectin interaction with cells. Tenascin-C decreases cell adhesion to fibronectin through competition with a heparan sulfate proteoglycan, syndecan 4 [36]. Syndecan 4 is required for efficient cell attachment to fibronectin and for tenascin-C inhibition of adhesion to fibronectin. Hence, a scenario in which tenascin-C competes for syndecan 4 binding to fibronectin is consistent with these results. Certain proteolytic fragments of tenascin-C interfere with fibronectin assembly although full-length tenascin-C does not demonstrate inhibition of fibronectin fibrillogenesis [37]. Given the high levels of proteolytic activity in wounds, for example, cleavage of tenascin-C might be one mechanism by which regulation of fibronectin assembly is achieved.

The paucity of developmental abnormalities manifested in the tenascin-C-null mouse points to the greater importance of tenascin-C in remodeling events which take place in response to injury or transformation. For example, tenascin-C has been shown to regulate cardiac neovascularization by bone-marrow-derived endothelial progenitor cells in response to angiogenic stimuli in adult mice [38]. In addition, as mentioned, high levels of tenascin-C expression are frequently associated with several types of malignancies including tumors of the brain and breast [21].

OSTEOPONTIN

As the name implies, osteopontin was originally classified as a bone protein. A more thorough examination, however, reveals a widespread expression pattern for this protein with multiple potential functions [39]. Osteopontin associates with the extracellular matrix, as it binds to fibronectin and to collagens I, II, III, IV, and V. Osteopontin also affects cellular signaling pathways by virtue of its capacity to act as a ligand for multiple integrin receptors as well as Cluster Designation (CD)-44 [39]. Thus osteopontin, like most of the matricellular proteins, is able to act as a bridge between the extracellular matrix and the cell surface. Since matricellular proteins might be synthesized, secreted, and incorporated into the extracellular matrix with greater ease than more complex secreted proteins that must be incorporated into fibrils and assembled into a network, a bridging function might be useful during remodeling events in the organism when rapid conversion of the cellular substrata is required for cell movement.

In support of this concept, Weintraub et al. (1996) report that transfection of vascular smooth muscle cells with anti-osteopontin cDNA reduces adhesion, spreading, and invasion of three-dimensional collagen matrices. Addition of osteopontin to the collagen gel restores the capacity of these cells to invade the gel [40]. Osteopontin also appears to be susceptible to modification by extracellular proteases which have revealed cryptic integrin binding sites within the sequence. The protease thrombin cleaves osteopontin at the N-terminal domain and exposes binding sites for integrin $\alpha 9\beta 1$ and $\alpha 4\beta 1$ [41]. In addition, Senger et al. (1996) report that endothelial cells treated with vascular endothelial growth factor (VEGF) increase their expression of the integrin $\alpha v\beta 3$, another osteopontin cell surface receptor, concomitantly with an increase in osteopontin. These investigators also show an increase in the amount of thrombin-processed osteopontin in tissues injected with VEGF and radiolabeled osteopontin. The significance of this result lies in the enhanced support of endothelial cell migration *in vitro* by thrombin-cleaved versus full-length protein. Since the migratory activity of the endothelial cells is blocked partially by an anti-$\alpha v\beta 3$ antibody, the remainder of the activity might be attributed to $\beta 1$-integrins or to other cell surface receptors [42].

In pulmonary hypertension, adventitial fibroblasts from pulmonary arteries demonstrate an activated phenotype characterized by high rates of proliferation and migratory potential. High levels of osteopontin expression are correlated with this activated phenotype [43]. Furthermore, silencing of osteopontin expression significantly reduces proliferation and migration in hypertensive fibroblasts whereas increased osteopontin activity stimulated proliferation and invasion by normal fibroblasts [43]. Thus osteopontin is predicted to be a primary determinant of the activated phenotype characteristic of adventitial fibroblasts in hypertensive lungs. Increased levels of osteopontin secreted by senescent fibroblasts also promote migration of mammary epithelial cells, a process linked to neoplastic progression and tumor development in aging tissues [44].

The capacity of osteopontin to influence cell migration might be linked to matrix metalloproteinase activity. Osteopontin is a member of the recently classified SIBLING (Small Integrin Binding LIgand N-linked Glycoprotein) family of proteins that have been shown to bind to and regulate the activity of MMPs [45]. Osteopontin binds to recombinant proMMP-3

and active MMP-3. In addition, a decrease in MMP-9 activity has been reported in osteopontin-null myofibroblasts and vascular smooth muscle cells [46].

The promotion of cell survival is another property ascribed to osteopontin. Denhardt and Noda (1998) have reported that human umbilical vein endothelial cells plated in the absence of growth factors will undergo apoptosis. If these cells are plated on an osteopontin substrate, however, apoptosis is inhibited [47]. Furthermore, rat aortic endothelial cells subjected to serum withdrawal undergo programmed cell death, a response inhibited by an osteopontin substratum. In fact, it is the ligation of integrin αvβ3 by osteopontin at the cell surface that induces nuclear factor-kappa B (NF-κB) a transcription factor that controls a variety of genes through direct binding to their promoters. Thus osteopontin and other αvβ3 ligands can protect cells from apoptosis [48].

Osteopontin is involved in inflammatory responses. Expression of osteopontin is found to increase during intradermal macrophage infiltration, and purified osteopontin injected into the rat dermis leads to an increase in the number of macrophages at the site of administration. Importantly, anti-osteopontin antibodies inhibit macrophage accumulation in a rat intradermal model after a potent macrophage chemotactic peptide is used to induce an inflammatory response [49]. Osteopontin expression is required for development of an effective T_H1 immune response [50]. Interestingly, a recently described intracellular form of osteopontin has been implicated as the mediator of interferon-α production in plasmacytoid dendritic cells [51].

The phenotype of the osteopontin-null mouse supports the hypothesis that osteopontin affects macrophage activity. Although the number of macrophages does not appear to differ significantly in incisional wounds of wild-type and osteopontin-null mice, the amount of cell debris was higher in wounds of the latter animals. Because macrophages are thought to be primary mediators of wound debridement, osteopontin could be important in the regulation of macrophage function [52]. Collagen fibril formation in the deeper dermal layers of the wounded osteopontin-null mice also appear to be affected. Osteopontin-null mice have smaller collagen fibrils compared to wild-type controls. Similar to thrombospondin-2, osteopontin might affect collagen fibrillogenesis especially at wound sites, as no differences are seen in the size of collagen fibrils in unwounded skin [52].

The pro-inflammatory and profibrotic properties of osteopontin suggest that osteopontin might contribute to human diseases in which inflammation and fibrosis contribute to pathological processes such as in systemic sclerosis (SSc). In fact, high levels of circulating osteopontin are present in patients with SSc. Osteopontin-null mice, when challenged with bleomycin to induce dermal fibrosis, exhibit significantly reduced levels of collagenous extracellular matrix and fewer macrophages [53]. Similarly, in a renal model of fibrosis, significantly less interstitial fibrosis and inflammatory infiltration occur in osteopontin-null mice in comparison with wild-type animals [54].

An additional function of osteopontin as a negative regulator of calcification is supported by a number of different studies [55]. Osteopontin inhibits apatite crystal formation *in vitro* and facilitates resorption of cellular minerals. As shown in an *in vivo* model of ectopic calcification, the capacity of osteopontin to abrogate calicification is dependent upon phosphorylation of osteopontin and the presence of the integrin-binding RGD sequence in osteopontin [56].

Osteopontin and its repertoire of cell surface receptors represent components of a pathway used by cells in need of rapid movement or migration. In addition, the ligation of osteopontin by certain cell surface receptors supports cell survival and thus provides a mechanism for a given tissue to protect a subset of cells, expressing the appropriate receptor, from apoptosis. Hence, osteopontin is a useful protein in events which require cell movement and cell survival, such as wound healing and angiogenesis, and has the potential to contribute to cancer progression.

SPARC

SPARC (secreted protein acidic and rich in cysteine; BM-40; osteonectin) was first identified as a primary component of bone but has since been shown to have a wider distribution [57]. Increased expression of SPARC is observed in many tissues undergoing different types of remodeling. For example, SPARC is found in the gut epithelium, which normally exhibits rapid turnover, and in healing wounds. An increase in SPARC is observed during glomerulonephritis, liver fibrosis, and in association with many different tumors. Like the other matricellular proteins, SPARC interacts with the extracellular matrix by binding to collagens I, III, IV, and V [57].

SPARC has also been shown to bind to a variety of growth factors present in the extracellular space [58]. For example, SPARC binds to PDGF-AB and BB and prevents their interaction with PDGF cell surface receptors. PDGF-stimulated mitogenesis is inhibited by the addition of SPARC [59]. SPARC can also prevent VEGF-induced endothelial cell growth, as it binds directly to the growth factor and thereby prevents VEGF receptor stimulation of the mitogen-activated protein kinases, Erk-1 and Erk-2 [60]. *In vivo*, regulation of VEGF activity by SPARC via VEGF receptor 1 occurs during choroidal neovascularization after injury [61].

Interestingly, a variety of mitogenic stimulators are inhibited by SPARC in culture, some of which do not necessarily associate physically with this protein. For example, SPARC is thought not to bind to bFGF, but SPARC inhibits bFGF-stimulated endothelial cell cycle progression [58]. Apparently, the effect of SPARC on cell proliferation is complex and could occur through; i) a direct prevention of receptor activation, and/or; ii) a pathway mediated by a cell surface receptor recognizing SPARC. To date, cell surface receptors for SPARC include stabilin-1 on macrophages and VCAM-1 on endothelial cells [62,63]. SPARC also affects integrin engagement on a number of different cell types. Furthermore, SPARC interaction with integrin heterodimers appears to be cell-type dependent [58].

Another significant effect of SPARC on cells in culture is its capacity to elicit changes in cell shape. Many cell types plated on various substrata retract their filopodia and lamellopodia and assume a rounded phenotype after exposure to SPARC. Bovine aortic endothelial cells, for example, are prevented from spreading in the presence of SPARC [58]. Clearly cell rounding could contribute to the inhibition of cell cycle mentioned previously; however, these two effects of SPARC appear to be independent. Motamed and Sage (1998) have shown that inhibition of tyrosine kinases reverses the counter-adhesive function of SPARC but has no effect on cell cycle inhibition [64]. Thus, at least in endothelial cells, SPARC appears to mediate two aspects of cell behavior through different mechanisms.

The targeted inactivation of the SPARC gene in mice has provided insight into SPARC activity in tissues. In support of SPARC as a regulator of cell proliferation, primary mesenchymal cells isolated from SPARC-null mice proliferate faster than their wild-type counterparts [65]. The majority of SPARC-null phenotypic abnormalities, however, are seen as aberrant extracellular matrix assembly. Early onset cataractogenesis reported in two independently-generated SPARC-null mice appears to be caused by inappropriate basement membrane synthesis by lens epithelial cells [66]. In the absence of SPARC, collagen IV, a SPARC ligand, is not localized to the outer border of the lens capsule, in contrast to its distribution in wild-type capsules [67]. In skin, collagen fibrils are small and uniform in diameter in comparison to those of wild-type dermis. In fact, fibrosis in SPARC-null mice in response to a variety of stimuli is decreased in several tissues including, lung, kidney, and skin [66]. Hence a growing body of evidence supports a function of SPARC in assembly and stability of fibrillar collagen and basement membranes.

Two studies have examined SPARC interaction with collagen I to define the SPARC-binding site(s) on fibrillar collagen heterotrimers [68,69]. Interestingly, SPARC shares the identical fibrillar collagen-binding site with that of Discoidin domain receptor (DDR) 2 and von

Willebrand factor. Down-stream signaling pathways activated by DDR2 engagement of collagen include increased cell proliferation and enhanced cell migration. Thus, engagement of collagen I by SPARC is predicted to prevent collagen engagement by DDR2 (and by von Willebrand factor) and perhaps diminish DDR2-dependent cell activities, such as cell proliferation, in certain cells and tissues.

In addition to its effect on cell cycle, recent evidence shows that SPARC influences TGF-β-dependent pathways in some cell types. Mesangial cells isolated from SPARC-null mice show a decrease in collagen I expression accompanied by a decrease in the levels of the cytokine TGFβ-1, in comparison to wild-type cells [70]. TGFβ is a known positive regulator of extracellular matrix synthesis. Addition of recombinant SPARC to SPARC-null mesangial cultures restores the levels of collagen I and TGFβ nearly to those of wild-type cells [70]. SPARC also promotes the TGFβ signal transduction pathway in epithelial cells [71]. In pericytes, the absence of SPARC increased TGF-β-mediated inhibition of migration, an effect dependent upon the TGF-β receptor endoglin and integrin α_v [72]. Thus it appears that SPARC can act as a regulator of TGF-β activity and, perhaps by extension, influences collagen I production.

Once again, we see SPARC as an example of a multi-functional protein able to regulate cell shape and modulate growth factor activity. In addition, SPARC appears to be a key factor in extracellular matrix assembly in both basal lamina and interstitium. Consistent with these functions, a homolog of SPARC termed SPARC-like protein 1 (hevin) was recently shown to be counter-adhesive and modulatory of extracellular matrix structure [57].

CONCLUSIONS

In addition to the proteins described here, others are also potential candidates for inclusion in the family of matricellular proteins. These include small proteoglycans such as the matrix-associated protein, decorin, which has been shown to be an endogenous regulator of TGFβ activity, as well as certain members of the recently classified CCN gene family [73]. The CCN proteins are secreted, modular, and exhibit functions based, at least in part, on integrin-mediated mechanisms. Whereas CCN1 (CYR 61) enhances apoptosis in fibroblasts, endothelial cell adhesion to CCN1 promotes cell survival [73]. Periostin and other SPARC family members are also recognized as matricellular proteins [57,74]. Further analysis of these proteins and their actions will expand our comprehension of matricellular proteins and the functions they serve in regulating cell interaction with components of their immediate environment.

In any cellular environment, numerous extracellular signals are in place to control cell behavior. In adult tissues, injury and disease both lead to a wide-scale release of multiple factors, either secreted from cells or sequestered in the extracellular matrix, that are capable of eliciting potent cellular responses. Appropriately, an increase in the expression of many matricellular proteins is associated with pathological events. Hence, the matricellular proteins appear to be ideally suited to act as modulators of these extracellular signals. They are able to serve as bridges between the extracellular matrix and cell surface receptors, such that cell shape changes or cell movements can be initiated prior to matrix breakdown or synthesis. At least three matricellular proteins, thrombospondin-2, osteopontin, and SPARC, appear to participate in matrix synthesis, either through the promotion of collagen fibrillogenesis or the enhancement of collagen production. Matricellular proteins can either inhibit or potentiate specific growth factor signal transduction pathways. Thus, different growth factor effects may be amplified or subdued by the presence or absence of these proteins. The fact that multiple receptors exist for most of the matricellular proteins allows for diverse functional consequences for different cell types in a complex tissue in response to a matricellular ligand. A given repertoire of cell surface receptors can stimulate (or inhibit) a particular pathway in a cell-type dependent manner. Apparently, evolution has fine-tuned these proteins to serve as specialized mediators of extracellular signals that provide a coordinated, efficient resolution of tissue injury.

INTRODUCTION

Tissue remodeling is an essential process in the maintenance and survival of all organisms throughout life. Tissue remodeling occurs throughout the entire span of injury, repair and wound healing. Early studies clarified the sequence and time course of appearance of different cell types and their changing phenotypes in healing wounds [1–3]. However, the mechanisms that regulate the tissue remodeling that constitutes the wound healing process remain incompletely understood. An essential component of the regulatory processes that drive tissue remodeling includes the different growth factors and the cytokines that dictate cell type and tissue specificity of responses that drive tissue remodeling. The regulation of their gene expression is the critical component that establishes the timing and sequence of appearance of the tissue remodeling that leads to the healed wound. Coordination of these properties effectively defines the wound healing process.

A major step forward came from experiments in which different growth factors/cytokines were applied directly to experimental wounds. These experiments defined in greater detail the process of tissue remodeling *in vivo*. They established that specific factors not only accelerated wound healing, but appeared to faithfully recapitulate the normal wound healing process [2–22].

These studies later proved valuable to better understand the tissue-remodeling characteristic of different malignancies. The different growth factors/cytokines proved to be oncogenes when inappropriately expressed in different cell types. Constitutively expressed growth factors/cytokines were found to be pathogenic in different models of malignant neoplasms both *in vivo* and *in vitro*. In these models, the phenotypes of the experimental tumors were profoundly influenced by the constitutively expressed growth factor/cytokine that functioned to transform the cells used in these different cancer models. These factors also are likely to be major contributors in the remodeling characteristic of atherosclerosis and other inflammatory states. In all these instances, the deregulation of growth factors and other cytokines may have serious consequences for the host; tight regulation of their activities is needed for normal function.

WOUND HEALING

Normal wound healing proceeds in a clear sequence through different overlapping stages, ending with the healed wound. Common features of all wounds are clumps of activated platelets that are seen at sites of injury where they release granule products. Also products of the coagulation process are deposited locally. The sequential migration of neutrophils begins immediately, and later in time, monocytes, and fibroblasts follow. Wound macrophages (derived from circulating monocytes) and fibroblasts in turn become activated, initiating a

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00016-1

cascade of new gene expression leading to the *de novo* synthesis of growth factors and other cytokines, synthesis of extracellular matrix proteins (including collagens and elastin), and proliferation of fibroblasts. Later, tissue remodeling results in active collagen turnover and cross-linking that lasts from two weeks to one year post-wounding.

Factors that arise locally were thought to account for the cell migration and activation of fibroblasts in wounds [23–25]. However, circulating platelets are invariably associated with wounds and are now known to release factors into wounds originally stored within intracellular compartments such as the platelet granules. These factors attract neutrophils, monocytes, fibroblasts, and other (tissue-specific) cells, such as the smooth muscle cells. Platelets thus are important mediators in the initiation processes of inflammation and subsequent tissue remodeling leading to repair. Platelet release is initiated by products of coagulation, such as thrombin, and by platelet exposure to foreign surfaces, such as collagen. Platelet release occurs within seconds of platelet activation. Synthesis of other potent molecules, such as the prostaglandins and leukotrienes, also influence intracellular responses and extracellular activities which contribute significantly to early events within wounds. These factors also initiate the transcriptional activation of genes that encode proteins with other signaling roles, serving to attract inflammatory cells locally. Because inflammatory cells are in close proximity to platelets in a number of models of inflammation (immune complex disease and atherosclerosis), it is likely that platelets are important in the earliest stages of different inflammatory states. Platelets and inflammatory cells appear to 'talk' to each other in essential ways, by releasing cytokines and growth factors to attract additional inflammatory cells, and to stimulate the transcription of factors that regulate or encode additional mediators of inflammation and wound repair. Studies with platelet-derived growth factor (PDGF) in the *in vivo* contexts noted above support these functional roles for PDGF and other platelet secretary proteins released at the time of platelet activation.

Platelet-derived growth factor (PDGF)

PDGF was initially described as a potent mitogen and many of its critically important properties have been identified [26–35]. However, PDGF directs cell migration, activates diverse cell types, and upregulates expression of genes unique to different cell types that otherwise are quiescent and not normally expressed at significant levels. Gene induction in response to PDGF establishes gene activation pathways that provide the temporal sequence of expression of genes in diverse pathways of central importance in tissue remodeling and repair. Experiments alluded to above, in which PDGF was directly applied to wounds, demonstrated that PDGF accelerates the normal healing process; it does not distort it, indicating PDGF together with its downstream signaling molecules upregulates the genetic programmes needed for wound healing in a precise order. However, there was little if any information to establish the relative contributions of PDGF and the different growth factors to the healing of normal wounds, and thus experimental strategies continue to focus on *in vitro* properties of growth factors. Additional models and reagents are needed to directly test these results *in vivo*.

PDGF was originally identified as a potent mitogen in serum for fibroblasts [26,27]. Purified human PDGF is a heterodimeric molecule consisting of two separate but highly related polypeptide chains (A and B chains) [12]. The B chain of PDGF is ~92% identical with the protein product of the v-sis gene, the oncogene of simian sarcoma virus, an acute transforming retrovirus, and thus it is a proto-oncogene [32,33]. The study that showed the relationship of the v-sis gene and the B-chin of PDGF was the first to demonstrate the function of a proto-oncogene. It also was the first 'Eureka' discovery that came from comparative sequence coning.

Both BB and AA homodimers of PDGF also have been isolated from natural sources. They are expressed in many cell types of diverse origins, including macrophages, endothelial cells, both smooth and skeletal muscle cells, fibroblasts, glial cells and neurons. These cells secrete molecules with PDGF-like activity. The detection of these molecules has been associated with

the expression of the mRNAs for A and B chains that can be specifically associated with chain isoforms of PDGF. However, identification of the specific isoform(s) at the level of the protein has been difficult because reagents to detect each isoform specifically were not available in early studies. Multiple PDGF-AA transcripts have been detected in cells that are alternative splice variants of the single seven-exon gene [36,37]. Three splice variants result in short and long processed proteins, 110 and 125 amino acids [36–38] in length. These different length PTGF A chain products are important but have not yet been fully worked out. There is differential regulation of the transcripts. They bind with different affinities to the extracellular matrix [17,39]. The transcripts for both proteins are widely expressed in multiple cell types.

Each of the three isoforms (BB, AB, and AA) binds to the PDGF-α receptor, whereas only the BB isoform binds with significant affinity to the type of PDGF receptor-β [40–42]. Both receptor types are highly homologous trans-membrane tyrosine kinases and are expressed in a cell type-specific manner, not only governing cell target specificity of the PDGF response [43], but also adding both complexity and thus diversity to the potential roles of PDGF in inflammation and wound healing. The functions of PDGF *in vivo* thus are regulated by the need for specific ligand-receptor interactions to transduce the signals required for various functions of PDGF and the upregulation of other genes that propagate the cascade of events initiated by PDGF.

Growth factors and cytokines as early mediators of the inflammatory process

To better understand the roles of growth factors and other cytokine mediators of inflammation, tissue remodeling, and wound healing, experimental strategies were designed to first isolate and characterize these factors and to analyze their properties *in vitro*. Other studies determined the sites and levels of expression of these factors *in vivo*. Reagents were then developed to test the properties of these factors in different experimental models to analyze normal functions of growth factors and other cytokines in the intact animal.

Early work focused on the roles of PDGF as a mitogen. However, in addition to the striking potency of PDGF as a mitogen, PDGF also is strongly chemotactic for human monocytes and neutrophils, a property of PDGF that may be more important in early phases of inflammation. Optimal concentrations of PDGF that are required for maximum chemotactic and mitogenic activity are 20 and 1 ng/ml, respectively [44], concentrations of PDGF that are well below those measured in human serum (~50 ng/ml) [44]. Because platelets invariably aggregate and release platelet granule products at wound sites, the concentrations of PDGF at these sites may be substantially higher than those in serum. PDGF also is a chemoattractant for fibroblasts and smooth muscle cells but requires a somewhat higher concentration [45,46], suggesting PDGF also functions in later phases of wound healing through its influence on fibroblast and smooth muscle cell movement [46].

In contrast to the PDGF AB isoform, the chemotactic potential of PDGF AA has been controversial. This controversy was important to resolve because the A chain homodimers of PDGF (PDGF AA) are widely expressed in normal and transformed cells. However, PDGF AA has been independently established as a strong chemoattractant for human monocytes, granulocytes, and fetal bovine ligament fibroblasts. Relevant to the roles of monocytes/tissue macrophages in the wound healing process, it was shown that highly purified (>98%) monocytes require the addition of lymphocytes or interleukin 1 (IL-l) for chemotactic responsiveness to PDGF AA, but not for the chemotactic activity of formyl-methionyl-leucyl-phenylalanine (fMLP) or C5a. This apparent specificity of monocytes for activation before becoming responsive to PDGF as a chemoattractant indicates the striking complexity of the different cellular responses to cytokines. It also indicates that regulation of the chemotactic response of the monocyte to PDGF AA by the lymphocyte or cytokines may be another regulatory level of importance in the ultimate pathway to tissue remodeling and wound healing *in vivo* [47].

Other platelet secretary products than PDGF also are active in the process of tissue remodeling during wound healing for example, Platelet factor 4 is a potent chemoattractant [48–51].

β-thromboglobulin (TG-β) is a highly active chemotactic factor for fibroblasts [46]. Apart from platelet secretary proteins released immediately at injured sites, different lymphokines, a peptide derived from the fifth component of complement, collagen-derived peptides, fibronectin, tropoelastin, and elastin-derived peptides are wound-associated factors that also are potent chemo attractants. These different chemo attractants are functional with different cell types and thus exhibit different cell type specificity [52–55].

In addition to its roles as a mitogen and in cell migration, PDGF also activates the polymorphonuclear leukocyte [56] and is capable of inducing monocyte activation responses, as evaluated by generation of superoxide anion (O_2) from the membrane-associated oxidase system, release of granule enzymes, and enhanced cell adherence and cell aggregation. Superoxide anion release in monocytes is observed at 10 ng/ml and the levels of PDGF-dependent release are comparable to release induced by 10^{-7} ml/liter fMLP. The potency of PDGF to induce this response in monocytes is of the same magnitude as that observed in polymorphonuclear leukocytes (PMNs). Similarly, lysozyme release and monocyte adherence are increased in a dose-dependent manner in response to PDGF and achieve maximal responses at 40 ng/ml PDGF. The PDGF concentrations required to achieve maximal monocyte aggregation was twofold (60 ng/ml) that found for PMNs and, at this concentration of PDGF, it is likely to occur only in the immediate vicinity of platelet aggregates. PDGF thus induces the full sequence of cell activation events in human monocytes, similar to that in human PMNs. These properties may well be of major significance resulting in the release of enzymes and other factors required to begin the process of tissue breakdown required for remodeling.

Other early cellular effects important to inflammation and repair also may be initiated by the release of PDGF from platelets and cells within the wound. For example, collagenase expression was studied in normal human skin fibroblasts that were cultured for 24 hr in the presence of PDGF. Collagenase release is required for the breakdown of collagen necessary for the later remodeling of collagen and for tissue repair [10,57]. A dose-dependent, saturable increase in collagenase activity in culture media was observed with paralleled increases in immunoreactive collagenase protein, suggesting that the enhanced synthesis of an immunologically unaltered enzyme. The specificity of this effect was demonstrated by collagenase stimulatory effect with that on total protein synthesis and DNA synthesis. Under *in vitro* conditions that produced a 2.5-fold increase in collagenase synthesis, there was a ~20% increase in total protein synthesis and no detectable change in DNA synthesis. In addition, as a second control, platelet factor 4, another platelet-derived protein, caused a <20% increase in collagenase expression. In time course studies, stimulation of collagenase synthesis was first observed 8–10 hr after exposure to the growth factor. Furthermore, when cells were exposed to PDGF for ~24 hr, an increase in the rate of collagenase synthesis were seen for ~6 hr after PDGF was removed, after which the rate reverted to control levels. Growth factors-regulated expression of collagenase may be of unique importance to tissue remodeling, because it occurs somewhat later than the most immediate responses to PDGF at the time collogen degradation may be essential for progression of remodeling and tissue repair [57].

Patients with Werner's syndrome, an autosomal recessive disorder, undergo an accelerated aging process and premature death. Fibroblasts from such patients typically grow poorly in culture but have a markedly attenuated mitogenic response to platelet-derived growth factor and fibroblast growth factor (FGF). In contrast, these cells have a full mitogenic response to fetal bovine serum. The Werner's syndrome cells express high constitutive levels of collagenase *in vitro*. However, induction of collagenase was not seen to occur in the Werner's syndrome fibroblasts in response to PDGF. The failure of one or more PDGF-mediated pathways in Werner's syndrome cells coupled with the phenotype of this disorder provides important support for roles of PDGF and other cytokines in tissue remodeling [58].

Inflammatory response mediators activate transcription of quiescent genes

Another potentially highly important role of PDGF and other growth factors and cytokines in wound healing is the upregulation of early-intermediate response genes in cells activated by PDGF. In response to PDGF and other cytokines, fibroblasts and other cells initiate transcription and expression of genes that are dormant in the absence of stimulation. The products of some of these genes are important in the intracellular propagation of the mitogenic signal but others are important since they propagate intercellular communication, direct cell migration, and activation of cells of different types. The products of these genes [10,58–60] thus serve to coordinate diverse responses designated to combat wound infection and to initiate and propagate the healing process.

The PDGF early/early-intermediate response genes *JE* and *KC* were first isolated by differential colony hybridization [58]. Only later were they identified as cytokines belonging to a newly described superfamily of small inducible genes (SIGs) [61] (now known as the chemokine family). This family includes platelet granule proteins, including the platelet basic protein and platelet factor 4. These PDGF-induced cytokines regulate pathways of gene activation that account in part for cell type specificity and the temporal responses of wound healing. The *JE* gene encodes a basic (PI = 10.4) 148-amino acid polypeptide [60, 61] that shows 82% amino acid identity with the murine *JE* gene [62]. Both rat and murine *JE* gene products contain N-terminal hydrophobic leader sequences, virtually identical alternating hydrophobic and hydrophilic domains, a single N-linked glycosylation site at position 126 that is conserved in both the murine and rat *JE* genes, and identical intron-exon splice junctions.

The importance of the *JE* gene product was suggested when the human homolog of the rodent *JE* gene was identified as monocyte chemotactic protein-l (MCP-1) [63]. MCP-l is identical with monocyte chemotactic and activating factor (MCAF) [64,65], HC11 [66], and with the smooth muscle cell chemotactic factor (SMC-CF) [67]. Both the MCP-l and rodent *JE* genes are induced in fibroblasts by PDGF [also serum, phorbol myristate acetate (PMA), double-stranded RNA, and interleukin-l] and each cross-hybridizes to the same bands on Southern blots [68]. Antibodies raised to the murine *JE* cross-react with MCP-l. MCP-l is a potent factor chemotactic for monocytes but not for neutrophils [69], a specificity of cell type recognition that is not seen with many of the other chemotactic factors that have been characterized [70], suggesting it has a unique role in the inflammatory process. Other cytokines with sharply defined functional activity also have been identified in the chemokine family. MCP-l/SMC-CF or related molecules appear to be the major chemotactic factor(s) released by a number of tumor cell lines as well [67]. This relationship calls to attention the surprising parallels that have been found between tumor cells and cells which are activated such as the fibroblast.

The genes of this family are normally not expressed at detectable levels but can be induced in the presence of the appropriate stimuli. Remarkably, each of the inducers has an important role in cell growth, inflammation, or immune responses, thus, linking downstream effectors as common endpoints of multiple different stimuli. Increasing knowledge of this family of genes and their products has suggested an enlarging role for PDGF and other cytokines in the sequential and cell type-specific development of inflammation and the evolution of the wound healing process [71].

BIOLOGICAL PROPERTIES OF THE SIG (CHEMOKINE) FAMILY MEMBERS

Neutrophil activation protein/IL-8 (NAP-l/IL-8) is a highly cell type-specific activator and chemotactic factor for neutrophils but not for monocytes [73]. NAP-l/IL-8 was identified in conditioned medium of lipopolysaccharide-stimulated monocytes [72,73] and its gene (*3–10C*) was cloned independently as a staphylococcal enterotoxin A-induced gene from

peripheral blood leukocytes [74]. NAP-l is also chemotactic for T lymphocytes and basophils [75,76] and is the N-terminal processed form of endothelial-derived leukocyte adhesion inhibitor (LAI), an inhibitor of neutrophil adhesion that protects endothelial cells from neutrophil-mediated damage [77,71].

MCP-l is chemotactic for monocytes. It was purified from the culture media of human glioma cell line U-105MG [69], THP-l cells [78], phytohemagglutinin-stimulated mononuclear cells [79], and double-stranded RNA [poly(rI).poly(rC)]-stimulated fibroblasts [71,80].

Macrophage inflammatory protein-l (MIP-l) was purified in two forms (MIP-l, MIP-2) from lipopolysaccharide-stimulated RAW264.7 cells. It is chemotactic for polymorphonuclear cells [81]. MIP-l induces an oxidative burst and degranulation in neutrophils and promotes inflammatory reactions. MIP-l is also a prostaglandin-independent pyrogen [82]. MIP-2 is a potent chemotactic factor for neutrophils and causes neutrophil degranulation, but does not induce an oxidative burst [71].

Platelet factor 4 (PF4) is a platelet granule protein that is chemotactic for both neutrophils and monocytes [83]. It has immunoregulatory activity [84] and can inhibit angiogenesis [85]. Platelet basic protein, connective tissue-activating peptide III (CTAP-III), β-thromboglobulin, and neutrophil-activating peptide-2 (NAP-2) are N-terminal proteolytic processed forms of a single gene product. CTAP-III is mitogenic for human dermal fibroblasts [86]. NAP-2 is induced in monocytes when they are exposed to lipopolysaccharides and can stimulate the release of elastase from human neutrophils [71,72].

Melanoma growth stimulatory activity (MGSA) is a mitogen for cultured melanoma and pigmented (nevus) cells [87]. Primary melanoma cells secrete MGSA and, for this reason, it has been suggested to be an autocrine regulator of growth. The protein product of MGSA is identical to the *gro-α* gene isolated by subtractive hybridization of mRNA from transformed hamster CHEF/16 cells. The rat analog, cytokine-induced neutrophil chemoattractant (CINC), is chemotactic for neutrophils [88]. The murine analog (*KC*) is a PDGF-inducible gene [58,71].

Regulation of *JE* gene expression by glucocortocoids

The role of PDGF and other cytokines in the induction of otherwise unexpressed genes has resulted in additional insights into the wound healing process. The addition of dexamethasone and other steroid drugs to PDGF- and serum-stimulated BALB/c 3T3 fibroblasts prevents the PDGF and serum-dependent induction of the *JE* gene in a dose-dependent manner. Furthermore, induction follows the rank order of potency expected for glucocorticoid receptor-mediated anti-inflammatory activity. The inhibition appears to be highly specific for inflammatory mediators, suggesting that the role of PDGF in the induction of selective SIG family members may be a highly important step at which glucocorticoids negatively influence both inflammation and repair [71].

GROWTH FACTORS AND ACCELERATED HEALING

Much new information about the roles of growth factors and other cytokines has resulted from the direct application of PDGF to experimental wounds in animals. Morphometric methods and histologic analysis were used to compare wounds treated with supra-physiological concentrations of growth factors to untreated wounds. This approach, coupled with the *in vitro* approaches cited above, has greatly clarified roles of PDGF-enhanced tissue repair and remodeling. It has stimulated similar experiments with other cytokines as well.

In one set of experiments, exogenous PDGF was applied locally, and once only, to incisional wounds in rats and rabbits. PDGF accelerated tissue repair in a dose-dependent manner [7,16]. A single application of PDGF to rat incisions enhanced the strength required to 'break' the healing wound by 150 to 170% over a 3-week time course [7]. PDGF accelerated healing by

4–6 days over the first 2 weeks and by 5–10 days between 2 and 7 weeks post-wounding [9]. At 89 days post-wounding, both PDGF-treated and control wounds had achieved similar wound strength (90% of unwounded dermis). The PDGF doses therefore induced a long-lasting enhancement in the rate of healing, supporting the view that PDGF and other growth factors initiate events required for normal healing of wounds and also enhance the normal rate of wound healing and tissue remodeling.

In these wounds, PDGF significantly increased the rate of increase of cellularity and granulation tissue formation. The early appearance of wounds treated with PDGF is that of a highly exaggerated inflammatory response. An increased neutrophil influx was seen at 12 hrs, and shortly thereafter a marked increase in influx of macrophages followed. Fibroblast infiltration was found from day 2 onwards, persisting through 21 days post-wounding [7]. Furthermore, enhanced cellular function of fibroblasts could be established in treated wounds. Increased numbers of procollagen-containing fibroblasts were strikingly apparent as early as 2 days post-wounding. At 28 days, it was not possible to distinguish activated from non-activated fibroblasts in treated and untreated wounds. These results indicate that PDGF accelerates the healing response.

Furthermore, within limits of detection, PDGF-stimulated wounds also result in a healed wound that cannot be distinguished from its untreated counterpart [9]. PDGF stimulation of wounds thus is multifunctional in diverse ways, perhaps through the recruitment and activation of macrophages and fibroblasts and through upregulation of expression at different cytokine genes whose functions and cell type specificity provide additional diversity to the normal healing process.

Another polypeptide growth factor that is stored in the granules of platelets, transforming growth factor β (TGF-β), appears also to be very important in tissue repair [89]. Both PDGF and TGF-β increase collagen formation, DNA content, and protein levels in wound chambers implanted in rats [4,90]. TGF-β enhances the reversible formation of granulation tissue when injected subcutaneously into newborn mice [91]. A single application of human TGF-β at the time of wounding advanced by 2–3 days the breaking strength required to rupture the incision margins after when assayed at 1 week. The marked augmentation of wound healing using both human PDGF (hPDGF) and recombinant *c-sis* homodimers (rPDGF-B) revealed a unique pattern of response when compared with the results obtained with TGF-β [7,92].

Circular excision wounds also were placed through the dermis of the rabbit ear to the level of underlying cartilage, a model that is important since it does not allow contraction from the wound margins [16]. In-growth of extracellular matrix and granulation tissue was measured by histo-morphometric techniques [16]. In that model, a single application of PDGF increased granulation tissue by ~200% at 7 days, in association with a predominance of fibroblasts and collagen-containing extracellular matrix [16]. The healed wound again was indistinguishable from the control, non-PDGF-treated, healed wound. Interestingly, PDGF also nearly doubled the rate at which re-epithelialization occurred and neo-vascularization was prominent in granulation tissue. These unexpected findings in view of the known cell type specificity of PDGF suggested upregulation either of PDGF receptors or of other cytokine genes stimulating cell type-specific epithelial and/or endothelial cell functions. Whereas again the mechanisms of the PDGF effect are not established, the influence of a single application of a growth factor remarkably accelerated the inflammatory response and the subsequent tissue remodeling to result in a healed wound of normal appearance.

In this model also, PDGF accelerated deposition of matrix largely composed of glycosaminoglycans and later of collagen [93]. The normal sequence in repair and the acceleration of wound healing are, to all appearances, identical to those in an untreated wound, supporting the view that the role of PDGF is to accelerate normal wound healing in human wounds. It has been demonstrated in human wounds that PDGF AA expression is increased

within healing pressure ulcers. The accumulation of PDGF AA is accompanied by activated fibroblasts, extracellular matrix deposition, and active neovessel formation. However, far less PDGF AA is present in chronic non-healing wounds. Thus, upregulation of PDGF AA may be important in the normal repair process as well [94–96].

PDGF BB, bFGF, and epidermal growth factor (EGF), applied locally at the time of wounding, cause a twofold increase in complete re-epithelialization of treated wounds, whereas TGF-β significantly inhibits re-epithelializarion. Both PDGF BB and TGF-β increased the depth and area of new granulation tissue, the influx of fibroblasts, and the deposition of new matrix into wounds. Explants from treated wounds remained metabolically more active than controls, incorporating 473% more [[3]H]-thymidine into DNA and significantly more [^{3}H]-leucine and [^{3}H]-proline into collagenase-sensitive protein [16]. The different response to growth factors underscores the importance of tissue and cell type specificity of the growth factors to tissue repair, and perhaps also the need for exquisite timing of induction of different factors in the orderly progression of the healing process.

The use of these wound healing models provided the basis to suggest at least one mechanism whereby PDGF may function *in vivo* [10,97]. Wounds in animals that were pretreated with glucocorticoids or total body irradiation to reduce circulating monocytes to non-detectable levels had a sharply reduced influx of wound macrophages. PDGF was tested in these animals. It was shown that the PDGF-induced acceleration of incision repair was abrogated in glucocorticoid-treated animals [10]. However, PDGF attracted a significant influx of fibroblasts into the compromised wounds of animals. The fibroblasts lacked procollagen type I, suggesting the requirement of the wound macrophage to support stimulation of fibroblast procollagen type I synthesis. PDGF alone does not stimulate procollagen type I synthesis when added directly to fibroblasts *in vitro* [98,99]. However, PDGF-activated macrophages synthesize TGF-β [10], a potent activator of the fibroblast procollagen type I gene [165,99]. It is suggested that TGF-β may be a second signal messenger to induce collagen formation in PDGF-treated wounds. This suggestion is supported directly in experiments in which macrophages and fibroblasts in PDGF-treated incision wounds were shown to contain increased levels of intracellular TGF-β [10].

The results with wound healing models and PDGF have illustrated much about inflammation, tissue remodeling, and the process of wound healing. Other *in vivo* models of PDGF-treated wounds also indicate that PDGF stimulates normal and reverses deficient dermal repair [4,6,100], and have suggested roles for this growth factor in inflammation [101], uterine smooth muscle hypertrophy [102], lens growth and transparency [163] and the central nervous system [103]. What may be the most important conclusions are that PDGF has the potential to initiate and accelerate the process, and to sustain it to an end point that is effectively identical to untreated wounds. The most important mechanisms of its activity may be the consequences of its potent chemotactic activity and its ability to induce multiple autocrine loops that lead to an endogenous cascade of new gene activation and cell-specific cytokine synthesis within the healing wound. Clinical trials have now established the efficacy of PDGF in advancing the healing of diabetic ulcers. PDGF is now 'in the clinic'.

ROLE OF BASIC FIBROBLAST GROWTH FACTOR AND ANGIOGENESIS

Normal wound healing can be divided into three phases: inflammation, fibroplasia, and maturation provoked by liberated angiogenic factors. Vessel-dense granulation tissue is central to the process of tissue repair. The formation of new blood vessels provides a route for oxygen and nutrient delivery, as well as a conduit for components of the inflammatory response. Endogenous bFGF, like PDGF, is also found in the wound site and is presumed to be a necessary part of natural wound healing. Mechanically damaged endothelial cells and burned wound

tissue release significant amounts of bFGF into the wound area, suggesting that damaged endothelial cells at the cut edges of blood vessels, as well as other damaged cells at the site of a wound, may provide an early source of bFGF [104–106]. A slightly later and more sustained supply of bFGF at the wound site is delivered by the invading activated macrophages [107–109]. Moreover, recombinant bFGF has been shown to enhance healing, if added exogenously to a wound site [110]. It is now clear that bFGF can act as an angiogenic factor *in vitro* [111] and *in vivo* [112], directing endothelial cell migration and proliferation, and that bFGF is a mitogen to endothelial cells. It also upregulates expression of plasminogen activator and the αvβ3 integrin that promotes both migration of endothelial cells and luminal formation [18,113]. The effects of stimulating endothelial cell growth, capillary differentiation, and connective tissue cell growth by bFGF contribute to wound healing and tissue regeneration [106,166].

Wound healing involves the interactions of many cell types, and is controlled in part by growth factors. Intercellular communication mediated by gap junctions is considered to play an important role in the coordination of cellular metabolism during the growth and development of tissues and organs. Basic FGF, known to be important in wound healing, has been found to increase gap junctional protein annexin 43 expression and intercellular communication in endothelial cells and cardiac [114]. It has been proposed that an increased coupling is necessary for the coordination of these cells in wound healing and angiogenesis, and that one of the actions of bFGF is to modulate intercellular communication. In a variety of animal models, exogenous bFGF has been shown to accelerate wound healing by speeding granulation tissue formation and increasing fibroblast proliferation and collagen accumulation at the site of a subcutaneously implanted sponge in rats [115–116]. Fresh wound tensile strength has also been increased [117]. However, the greatest benefit from the application of exogenous bFGF can probably be obtained in cases in which wound healing is impaired. Research on skin flaps indicates that bFGF has the potential to increase viability by accelerating flap revascularization when administered in a sustained release manner [164]. This may have applications to open or nonunion fractures with impaired wound healing. Despite encouraging experimental results to date coming from studies showing that treatment of genetically diabetic mice with recombinant bFGF not only increased fibroblast and capillary density in the wound, but also accelerated wound closure, clinical application of recombinant human bFGF has fallen short of expectations. In a randomized double blind placebo-controlled study, direct application of bFGF to non-healing ulcers of diabetic patients did not accelerate wound healing [118]. In a subsequent randomized placebo-controlled trial to study the effect of recombinant bovine bFGF in the healing of burned tissues, all patients treated with bFGF had faster granulation tissue formation and epidermal regeneration, compared with those in the placebo group. Superficial and deep second-degree burns treated with bFGF healed in a mean of 9.9 days (SD 2.5) and 17.0 days (SD 4.6), respectively, compared with 12.4 (2.7) and 21.2 (4.9) days. No adverse effects were seen locally or systematically with bFGF. It is indicated that bFGF effectively decreased healing time and improved healing quality. Clinical benefits for use of bFGF in burn wounds would be shorter hospital stays and the patients' skin quickly becoming available for harvesting and grafting [119].

PLEIOTROPHIN REMODELS TUMOR MICROENVIRONMENT AND STIMULATES ANGIOGENESIS

Pleiotrophin (PTN) is a PDGF-inducible, heparin-binding cytokine that functions as a downstream effecter of PDGF. Pleiotrophin was first purified as an 18 kD, heparin-binding, mitogenic polypeptide from bovine uterus [120] and as neurite outgrowth promoting activity from neonatal rat brain [124]. The *Ptn* cDNA encodes a lysine-rich, highly basic protein of 168 amino acids with a 32 amino acid signal peptide that is nearly 50% identical in amino acid sequence with the protein product of *Mk* [121], a gene expressed in early stages of retinoic-acid-induced differentiation in mouse embryonal carcinoma cells [122].

Pleiotrophin and MK are the only known members of this family. Pleiotrophin lacks homology with members of the heparin-binding growth factor (HBGF) family of structurally related polypeptides [123].

The *Ptn* gene is expressed during neuroectodermal and mesodermal development but not in endoderm, ectoderm, or trophoblasts [125]. Expression levels of *Ptn* peak in late embryonic development and the immediate postnatal period and correlate with peaks of growth and differentiation in both neoectoderm and mesoderm [121,124]. In adults, PTN expression is limited to selected cell populations and is constitutive; however, *Ptn* gene expression is upregulated after injury and during repair. In cultured cells, its expression is modulated by growth factors, including PDGF and steroid hormones [126–128].

Pleiotrophin normally signals a diversity of responses that suggest its potential importance in deregulated growth and tumor angiogenesis when it is inappropriately expressed in the cancer cell. PTN has mitogenic activity for fibroblasts [120], for brain capillary endothelial cells [129], and for SW-13 (adrenal carcinoma) cells in soft-agar culture [130]. Pleiotrophin also stimulates angiogenesis *in vivo* and *in vitro* [129]. Furthermore, the *Ptn* gene is a proto-oncogene; *Ptn* transformed NIH 3T3 cells develop into rapidly growing and highly vascular tumors in flanks of nude mice [131,132]. Importantly, it is highly expressed in many human breast cancers [130,133]. Introduction of the exogenous *Ptn* gene into 'premalignant' SW13 (adrenal carcinoma) cells or MCF-7 (human premalignant breast carcinoma) stimulates highly malignant subcutaneous tumor growth at sites of implantation in flanks of nude mice [134] Chang and Deuel Submitted Zuka and Deuel Submitted). The highly malignant phenotype of human malignant breast cancer cells and other cells with constitutive activation of the *Ptn* gene is reversed when a dominant negative inhibitor of PTN signaling or a *Ptn* gene targeted ribozyme is introduced [134–136] (Chang and Deuel), thus establishing that a single gene mutation that stimulates activation of the *Ptn* gene alone is fully sufficient to 'switch' the premalignant phenotype to a highly malignant phenotype. These findings may be highly significant, since many different human malignancies of different origins express *Ptn* at readily detectable levels [135,137–141]. Importantly, in those cell lines studied, expression of the endogenous *Ptn* gene is constitutive and PTN signaling in those instances which have been studied PTN has been found to be a major contributor to be a major contributor to the highly malignant phenotype [135,137–140].

The pleiotrophin receptor is the transmembrane receptor protein tyrosine phosphatase (RPTP) β/ζ [142]. RPTPβ/ζ was the first transmembrane tyrosine phosphatase receptor for which a ligand was discovered. Pleiotrophin inactivates the tyrosine phosphatase activity of RPTPβ/ζ leaving unchecked the persistent activity of a tyrosine kinase(s) that phosphorylate the tyrosine otherwise dephosphorylated by RPTPβ/ζ [142]. Through inactivation of RPTPβ/ζ, the tyrosine phosphorylation levels of the substrates of RPTPβ/ζ are sharply increased. As noted above, pleiotrophin is the first natural ligand to be discovered for any of the RPTPs [142]. Anaplastic Lymphoma Kinase (ALK) also has been proposed as a receptor for PTN [143], but, subsequent studies effectively ruled out ALK as a PTN receptor. Syndecan 3 also has been suggested to function as the PTN receptor. The downstream targets of PTN/RPTPβ/ζ signaling pathway are β-catenin [142], β-adducin [144] and Fyn [145]. β-catenin, β-adducin, and Fyn also are substrates of RPTPβ/ζ; the steady state levels of tyrosine phosphorylation of each of these proteins is sharply increased in PTN-stimulated cells. However, each of these proteins is phosphorylated in non-PTN-stimulated cells as well, suggesting their steady state levels of tyrosine phosphorylation are maintained by the endogenous PTN/RPTPβ/ζ signaling pathway. Each of the downstream targets of PTN signaling are important regulators of cytoskeletal structure [142,144] and destabilization of cytoskeleton and loss of cell-cell adhesion is the immediate response of cells stimulated by PTN [142], suggesting that a major target of exogenous PTN is de-stabilization of cytoskeletal elements and cell-cell adhesion through the coordinated increase in tyrosine phosphorylation of these substrates of RPTPβ/ζ. This finding

is substantiated since pleiotrophin also has been found to induce an epithelial-mesenchymal transition.

Collagens and elastin are the major fibrillar elements in the cardiovascular system and thus are major determinants of vascular tone, distendability, and other properties of aorta and other vessels. Midkine (MK, *Mk*) is a growth factor which shows ~50% amino acid identity to PTN [145]. Analysis of the aorta of *Ptn*−/− and *Mk*−/− mice uncovered the previously unknown but remarkable findings that PTN and MK are major regulators of the transcripts of the catecholamine biosynthesis pathway [146,147] and the transcripts of the renin-angiotensin pathway [146,148] in mouse. Since procollagen and elastin synthesis is known to be regulated through both the catecholamine and the angiotensin II signaling pathways, the striking downregulation of the elastin precursor gene in aorta of *Ptn* −/− and *Mk* −/− mice define PTN and MK as critical regulators of elastin expression. Furthermore, tumors of MMTV-*PyMT* transgenic mice in which expressed very high levels of the MMTV-*Ptn* transgene have strikingly increased synthesis of collagen and elastin interspersed with activated stroma, which is also seen in wound healing process [149]. These data, collectively, suggested that pleiotrophin plays an important role in remodeling the microenvironment of cells both in normal and disordered conditions.

OTHER ROLES OF GROWTH FACTORS AND CYTOKINES

A growing appreciation for roles of growth factors in many normal and abnormal processes is emerging from numerous other investigations of a diverse nature. For example, TGF-α and TGF-β are expressed with high specificity in developing mouse embryo [150,151], PDGF may mediate normal gliogenesis [87]; maternally encoded FGF, TGF-β, and PDGF have been implicated as important in the developing Xenopus embryo [152–154]; and bFGF is a potential neurotrophin during development [155]. PDGF also has been identified within plaques and is a potent vasoconstrictor and thus has been implicated in the genesis of atherosclerosis [156,157]. Furthermore, PDGF is secreted from endothelial cells and arterial smooth muscle cells [37,158–162] and activated monocytes/macrophages [160]. Elevated levels of PDGF receptors are found in synovial cells in patients with rheumatoid arthritis [162]. In each instance, however, when the *in vitro* studies are considered in the context of roles of the growth factors in inflammation and tissue repair, it seems likely that common roles of growth factors are associated with normal development and the abnormal remodeling is associated with disease states, indicating the importance of attention to mechanisms that regulate cell type and temporal levels of expression of the growth factors and their cognate receptors.

CONCLUSIONS

Much needs to be learned concerning the roles of growth factors and cytokines if we are to establish fully how they function in both normal and de-regulated tissue remodeling. Remarkable progress over the past several years has resulted from the identification, isolation, cloning, and characterization of the properties of these molecules and their use in wound healing models. The most important lesson learned from their use appears to be that the growth factors and cytokines are important to initiate and accelerate the normal processes involved from injury to repair. The growth factors are the 'trigger' that opens sequential activation of downstream pathways of critical importance to the progressive tissue remodeling that leads to the healed wound.

Questions for future avenues of investigation should address mechanisms by which these factors initiate and propagate the processes and the regulatory signals that govern cell type specificity, differentiation responses in cells migrating into and dividing within wounds, and the temporal sequences needed for orderly progression to a healed and ultimately functional tissue. Answers to these questions also will do much to advance the phenotype of malignant cancers, atherosclerosis, and other proliferative diseases.

CHAPTER 17

Mechanobiology, Tissue Development and Organ Engineering

Donald E. Ingber
Wyss Institute for Biologically Inspired Engineering at Harvard University, Harvard Medical School & Vascular Biology Program, Boston Children's Hospital and Harvard School of Engineering and Applied Sciences, Boston and Cambridge, Massachusetts

INTRODUCTION

Tissue engineering has as its main goal the fabrication of artificial tissues for use as replacements for damaged organs and complex body structures. Great advances have been made in terms of developing prosthetic devices that can repair structural defects (e.g., vascular grafts) and even replace complex mechanical behaviors (e.g., artificial joints). However, the challenge for the future is to develop tissue substitutes that restore the normal biochemical functions of living tissues and organs, in addition to their structural features. To accomplish this feat, we must first establish precise design criteria for tissue engineering and develop new fabrication approaches to create complex organomimetics that reconstitute the tissue-tissue interfaces and physical microenvironments of living organs. These design features should be based on a thorough understanding of the molecular, cellular and biophysical basis of tissue regulation. In particular, they must take into account the important role that insoluble extracellular matrix (ECM) scaffolds and mechanical stresses play in control of cell phenotypes or 'fates' (e.g., growth, differentiation, motility, apoptosis, different stem cell lineages) during tissue formation, maintenance, and repair. This latter point is critical, since the spatial organization of cells and the mechanical constraints imposed on them as they grow actively regulate tissue development [1], as well as tissue and organ function throughout adult life [2].

The goal of this brief chapter is not to provide an extensive review of literature in the field of ECM biology or tissue development. Rather, it will summarize the known functions of ECM and describe some insights we have made relating to how ECM regulates cell growth and function as well as tissue morphogenesis. Our analysis of this regulatory mechanism should be of particular interest to the tissue engineer, because it has led to the identification of critical chemical and mechanical features of ECM that are responsible for control of cell fate switching in developing tissues. In addition, the reader will be introduced to some unanswered puzzles in developmental biology which, if deciphered, could provide powerful new approaches to tissue regeneration and repair. Finally, recent advances will be described in terms of micro-engineering human 'organs-on-chips' that recapitulate complex structures and functions of living human organs, which have opened new avenues of investigation for drug screening as well as modeling complex disease processes *in vitro*.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00017-3

EXTRACELLULAR MATRIX STRUCTURE AND FUNCTION

Composition and organization

One of the most critical elements of tissue engineering is the ability to mimic the ECM scaffolds that normally serve to organize cells into tissues. ECMs are composed of different collagen types, large glycoproteins (e.g., fibronectin, laminin, entactin, osteopontin), and proteoglycans that contain large glycosaminoglycan side chains (e.g, heparan sulfate, chondroitin sulfate, dermatan suflate, keratan sulfate, hyaluronic acid) [see chapter 10 by Olsen for more details]. While all ECMs share these components, the organization, form, and mechanical properties of ECMs can vary widely in different tissues depending on the chemical composition and three-dimensional (3D) organization of the specific ECM components that are present. For example, interstitial collagens (e.g., types I, III) self assemble into 3D lattices which, in turn, bind fibronectin and proteoglycans. This type of native ECM hydrogel forms the backbone of loose connective tissues, such as dermis. In contrast, basement membrane collagens (types IV, V) assemble into planar arrays; when these collagenous sheets interact with fibronectin, laminin, and heparan sulfate proteoglycan, a planar ECM results (i.e., the 'basement membrane'). The ability of tendons to resist tension and of cartilage and bone to resist compression, similarly result from local differences in the organization and composition of the ECM.

In vivo foundation for cell anchorage

The first and foremost function of ECM in tissue development is its role as a physiological substratum for cell attachment. This feature is easily visualized by treating whole tissues with ECM-degrading enzymes (collagenase, proteases); cell detachment and loss of cell and tissue morphology rapidly result. Cells that are dissociated in this manner can reattach to an artificial culture substrate (e.g., plastic, glass). However, adhesion is again mediated by cell binding to ECM components that are either experimentally immobilized on the culture surface, deposited *de novo* by the adhering cells, or spontaneously adsorbed from serum (e.g., fibronectin, vitronectin) [3–9]. In fact, standard tissue culture plates are actually bacteriological (non-adhesive) plastic dishes that have been chemically treated using proprietary methods to enhance adsorption of serum- and cell-derived ECM proteins. To summarize, cells do not attach directly to the culture substrate (i.e., plastic or glass), rather they bind to intervening ECM components that are adsorbed (or derivatized) to these substrates. For this reason, cell adhesion can be prevented by coating normally adhesive culture surfaces with polymers that prevent protein adsorption, such as poly(hydroxyethylmethacrylate) [9,10].

Spatial organizer of polarized epithelium

Living cells exhibit polarized form as well as function (e.g., basal nuclei, supranuclear Golgi complex, apical secretory granules in secretory epithelia). Dissociated cells fail to orient in a consistent manner when cultured on standard tissue culture substrata or on interstitial connective tissue. In the case of epithelial cells, the normal polarized form is often restored if the cells synthesize and accumulate their own ECM, or if they are cultured on exogenous basement membrane (i.e., the specialized epithelial ECM) [11–14]. These types of studies suggest that basement membrane normally serves to integrate and maintain individual cells within a polarized epithelium. Clearly, there are many intracellular and intercellular determinants of polarized cell form and function (e.g., cytoskeletal organization, organelle movement, junctional complex formation). However, anchorage to ECM appears to provide an initial point of orientation and stability on which additional steps in the epithelial organization cascade can build. ECM may regulate the orientation of other cell types (e.g., chondrocytes, osteoclasts) as well.

Scaffolding for orderly tissue renewal

All tissues are dynamic structures that exhibit continual turnover of all molecular and cellular components. Thus, it is the maintenance of tissue pattern integrity that is most critical to the survival of the organism, and regeneration of normal tissue architecture is one of the main goals of tissue engineering. Maintenance of specialized tissue form requires that cells that are lost due to injury or aging must be replaced in an organized fashion. Importantly, orderly tissue renewal depends on the continued presence of insoluble ECM scaffoldings which act as templates that maintain the original architectural form and assure for accurate regeneration of pre-existing structures [15]. For example, when cells within a tissue are killed by freezing or treatment with toxic chemicals, all of the cellular components die and are removed; however, the basement membranes often remain intact. These residual ECM scaffoldings assure the correct repositioning of cells (e.g., cell polarity) and restore different cell types to their correct locations (e.g., muscle cells within muscle basement membrane, nerve cells in nerve sheaths, endothelium within vessels, etc.), in addition to promoting the cell migration and growth which are required for the repair of all the component tissues. Conversely, loss of ECM integrity during wound healing results in disorganization of tissue pattern, and thus, scar formation. Uncoupling between basement membrane extension and cell doubling also leads to disorganization of tissue morphology during neoplastic transformation [16].

Establishment of tissue microenvironments

ECMs often establish a physical boundary between neighboring tissues. For example, the basement membrane normally restricts mixing between the epithelium and underlying connective tissue, and compromise of basement membrane integrity is indicative of the onset of malignant invasion when seen in the context of tumor formation [16]. The ECM boundary also may regulate macromolecular transport between adjacent tissues given that the basement membrane forms the semi-permeable filtration barrier in the kidney glomerulus [17]. However, little is known about this potential function of the ECM in other local tissue microenvironments.

Sequestration, storage, and presentation of soluble regulatory molecules

ECMs may modulate tissue growth and morphogenesis through their ability to bind, store, and eventually release soluble regulators of morphogenesis. For example, the soluble mitogen, basic fibroblast growth factor (FGF) exists in an immobilized form in ECMs deposited by cells cultured *in vitro* [18], as well as in normal tissues (e.g. corneal basement membranes) *in vivo* [19]. In fact, many cytokines (e.g., FGF, VEGF, HGF, insulin-like growth factor, hematopoietic growth factors, etc.) are normally stored bound to heparin, heparan sulfate or other specific binding proteins within natural ECMs [20,21]. The low growth rate observed in most normal tissues may result from sequestration of mitogens by ECM, whereas release of these stored factors ('stormones') due to injury or hormonally-induced changes in ECM turnover may help to switch growth on locally. Binding of other types of regulatory molecules to the endothelial basement membrane (e.g., plasminogen activator inhibitor [22]) also may play a role in tissue physiology (e.g., blood coagulation, cell migration).

Regulator of cell growth, differentiation, and apoptosis

Most normal (non-transformed) cells only grow when attached and spread on a solid substrate [10]. Cells attach and spread *in vitro* either by depositing new ECM components or by binding to exogenous ECM [3–9]. In fact, cell spreading and growth can be suppressed by inhibiting ECM deposition *in vitro* using drugs [4–6]. Cell growth stimulated by soluble mitogens has also been shown to vary depending on the type of ECM component used for cell

attachment (e.g., collagen versus fibronectin [3,8,23]) as well as on the mechanical properties of the ECM (e.g., malleable gel versus rigid ECM-coated dish) [24–28].

Interestingly, ECM substrates that promote growth tend to suppress differentiation and vice versa. For examples, many cells proliferate and lose differentiated features when cultured on attached type I collagen gels that can resist cell tension and promote cell spreading. In contrast, the same cells cease growing and increase expression of tissue-specific functions (e.g. albumin secretion in hepatocytes, milk secretion and acinus formation by mammary cells, capillary tube formation by endothelial cells) if cultured on the same gels that are made flexible by floating them free in medium or on attached ECM gels that exhibit high malleability (e.g., basement membrane gels, such as Matrigel). Under these conditions, the cells exert tension across their adhesions, resulting in contraction of the ECM gel and cell rounding which, in turn, shuts off growth and turns on differentiation-specific gene functions. The differentiation-inducing effects of these malleable ECM substrates can also be suppressed by making the gels rigid through chemical fixation [24,27], thus confirming the critical role of cell-generated mechanical forces in this response.

While local changes in ECM turnover may promote tissue remodeling, large-scale breakdown of the ECM may force the same growing tissues to undergo involution. Many cultured cells rapidly lose viability and undergo programmed cell death (i.e., apoptosis) when detached from ECM and maintained in a round form [29,30]. Loss of basement membrane integrity is also observed in regions of tissues that are actively regressing [31,14] and growing tissues (e.g., capillaries, mammary gland) can be induced to involute using pharmacological agents (e.g., proline analogues) that inhibit ECM deposition and lead to basement membrane dissolution *in vivo* [14,32,33]. Recent transgenic mice studies confirm that growing tissues can be made to involute by shifting the endogenous proteolytic balance such that total ECM breakdown results [34]. These findings suggest that local changes in ECM composition and flexibility may regulate cell sensitivity to soluble mitogens, and thereby control cell growth, viability, and function in the local tissue microenvironment.

PATTERN FORMATION THROUGH ECM REMODELING

Mesenchymal control of epithelial pattern

Probably the greatest insight into the role of ECM in tissue development comes from analysis of embryogenesis. In the embryo, genesis of a tissue's characteristic form (e.g., tubular versus acinar) and deposition of ECM are both controlled by complex interactions between adjacent epithelial and mesenchymal cell societies. The epithelial cell is genetically programmed to express tissue-specific (differentiated) functions and to deposit the insoluble basement membrane which functions as a common attachment foundation that both separates adjacent tissues and stabilizes tissue form [35,36]. However, while production of tissue-specific cell products (cytodifferentiation) is determined by the epithelium, tissue pattern (histodifferentiation) is usually directed by the surrounding mesenchyme. For example, when embryonic mammary epithelium is isolated and combined with salivary mesenchyme, the mammary epithelial cells take on the form of the salivary gland although they still produce milk proteins [37]. However, the specificity of these epithelial-mesenchymal interactions can vary widely from organ to organ. For instance, embryonic salivary epithelia specifically require salivary mesenchyme for successful development, while pancreatic epithelia will undergo normal cytodifferentiation and histodifferentiation in response to mesenchyme isolated from a variety of embryonic tissues [38].

Tissue patterning through localized ECM remodeling

The complex tissue patterns that are generated through epithelial-mesenchymal interactions result from the establishment of local differentials in tissue growth and expansion in a

microenvironment that is likely saturated with soluble mitogens. The classic work on salivary gland development by Bernfield and coworkers revealed that the epithelium imposes morphological stability through production of its basement membrane, whereas the mesenchyme produces local changes in tissue form, specifically by degrading basement membrane at selective sites [35,39–42]. An increased rate of cell division is observed in the tips of growing lobules where the highest rate of ECM breakdown and re-synthesis (i.e., highest turnover rate) is also observed. At the same time, the mesenchyme slows basement membrane turnover and suppresses epithelial cell growth in the clefts of the glands. This is accomplished by secretion of fibrillar collagens which slow ECM degradation locally, and thereby promote basement membrane accumulation in these regions. Similar local coupling between ECM turnover, cell growth rates and tissue expansion is observed in many other developing tissues, including growing capillary blood vessels [43].

It is important to note that increased ECM turnover involves enhanced rates of matrix synthesis as well as degradation. In fact, net basement membrane accumulation (i.e., increased area available for cell attachment) must result for epithelial tissues to grow and expand laterally, and thus the local rate of ECM synthesis must be greater than that of degradation in these high turnover regions. If the rate of ECM degradation is significantly greater than synthesis, then net basement membrane dissolution along with cell retraction and rounding results. As described above, this would lead to cell death and tissue regression rather than expansion.

Role of mechanical stresses

Before ending discussion of the role of ECM in pattern formation, it is critical to emphasize that while chemical regulators mediate tissue morphogenesis, the signals that are actually responsible for dictating tissue pattern are often mechanical in nature [2]. The pattern-generating effects of compression on bone, shear on blood vessels, and tension on muscle are just a few examples. Mechanical stresses are also important for embryological development; however, internal cell-generated forces appear to play a more critical role [1]. For example, mechanical tension that is generated via actomyosin filament sliding within the cytoskeleton of the cells that compose the embryo plays a key role during gastrulation [44] as well as during tissue morphogenesis [45]. In fact, the pattern of development can be experimentally altered by applying external stresses to the embryo using micropipettes [46], or by altering the level of cytoskeletal tension [47]. Mechanical compression of mesenchyme associated with the 'condensation' of mesenchyme that commonly precedes formation of new organ rudiments has been recently shown to be sufficient to induce whole tooth organ formation during embryogenesis [48]. The pattern-generating capabilities of mesenchyme isolated from different developing tissues also correlates with differences in their ability to exert mechanical tension on external substrates (e.g., reference [49]). Local changes in ECM turnover may drive morphogenetic patterning of tissues, in part, by altering the mechanical compliance of the ECM and thereby, changing cell shape or cytoskeletal tension [49a,50], as will be described below.

MECHANOCHEMICAL SWITCHING BETWEEN CELL FATES

Given the pivotal role that ECM plays in tissue development, many studies have been carried out to analyze how changes in cell-ECM interactions act locally to regulate cell sensitivity to soluble mitogens, and thereby establish the differentials of growth, differentiation, apoptosis and motility that are required for tissue morphogenesis. To accomplish this, simplified *in vitro* model systems have been developed which retain the minimal determinants necessary for maintenance of the physiological functions of interest (i.e., cell growth and differentiation) [9,51,52]. For example, to determine the effects of varying cell-ECM contacts directly, we pre-coated bacteriological petri dishes that were otherwise non-adhesive with different densities of purified ECM molecules, such as fibronectin, laminin, or different collagen types. Quiescent,

serum-deprived cells were plated on these dishes in a chemically-defined medium that contained a constant and saturating amount of soluble growth factor.

When capillary endothelial cells were studied, DNA synthesis and cell doubling rates increased in an exponential fashion as the density of immobilized ECM ligand was raised and cell spreading was promoted [9]. When higher cell plating numbers were used to promote cell-cell interactions as well as cell-ECM contact formation, the capillary cells could be switched between growth and differentiation (capillary tube formation) in the presence of saturating amounts of soluble mitogen (FGF) simply by varying the ECM coating density [51]. Specifically, when plated on a high ECM density (e.g., >500 ng/cm^2 fibronectin), the cells attached, spread extensively, formed many cell-cell contacts, and organized into a planar cell monolayer. When the same cells were plated on a low ECM density (<100 ng/cm^2, the cells attached but they could not spread, and thus only cell clumps or aggregates were observed. When the same capillary cells were plated on a moderate density, cells first attached, spread, and formed cell-cell contacts as they did on the higher ECM densities. However, the tensile forces generated by the cells appeared to overcome the resistance provided by their relatively weak ECM adhesions and thus, the cell aggregates began to retract over a period of hours until a mechanical equilibrium was attained. Under these conditions, formation of an extensive network comprised of interconnected capillary tubes resulted. Many of these capillary tubes became elevated above the culture surface, although the network remained adherent to the culture dish at discrete points through interconnected multicellular aggregates. The importance of mechanical forces for this switching between growth and differentiation was confirmed by demonstrating that similar capillary tube formation could be induced on the high ECM density that normally promoted spreading and growth, simply by increasing the cell plating numbers and thereby amplifying the level of cell tension.

The same system was used to demonstrate similar shape (stretch)-dependent switching between growth and differentiation in other cell types. For example, the growth and differentiation of primary rat hepatocytes could be controlled independently of cell-cell contact formation by varying cell-ECM contacts and cell spreading using the method described above [52]. Additional studies confirmed that ECM exerts its regulatory effects at the level of gene expression [54,53] and that these effects are mediated at least in part through modulation of the cytoskeleton [55]. These results are consistent with those from other laboratories, which demonstrate that malleable ECM gels (e.g., Matrigel, native collagen gels) that promote cell rounding also induce differentiation and suppress growth — whereas the opposite effects are produced when these gels are fixed and made rigid [24–27].

Altering cell-ECM contacts by varying ECM coating densities influences cell function via two distinct but integrated mechanisms. First, increasing the local density of immobilized ECM ligand promotes clustering of transmembrane ECM receptors on the cell surface which are known as 'integrins' [56]. Integrin clustering, in turn, activates a number of different chemical signaling pathways (e.g., tyrosine phosphorylation, inositol lipid turnover, Na+/H+ exchange, MAP kinase) that are also utilized by growth factor receptors to alter cellular biochemistry and gene expression [57–61]. Activation of these signaling pathways likely plays an important role in control of cell differentiation and survival; however, integrin-dependent chemical signaling alone is not sufficient to explain how cells are induced to enter S phase and proliferate [9,30,53,62,63]. A second mechanism that involves tension-dependent changes in cell shape and cytoskeletal organization, or changes in the level prestress (isometric tension) within the cell and linked ECM, also comes into play.

The importance of tension-dependent changes of cell shape and cytoskeletal organization was demonstrated directly by developing a model system in which cell distortion was varied independently of the local density of immobilized ECM molecule by controlling the spatial distribution of ECM anchors that can resist cell-generated traction forces. This was made possible by adapting a technique for forming spontaneously assembled monolayers (SAMs) of

alkanethiols [64] to create micropatterned surfaces containing adhesive ECM islands with defined surface chemistry, shape and position on the cell (micrometer) scale, separated by non-adhesive regions [30,65]. The method involves the fabrication of a flexible elastomeric stamp that exhibits the particular surface features of interest using photolithographic techniques. The topographic high points on the stamp (e.g., 40 x 40 μm square plateaus raised above recessed intervening regions) are coated with an alkanethiol ink and the stamp is then apposed to a gold-coated surface. The alkanethiol forms SAMs covering only the regions where the stamp contacts the surface (i.e., 40 x 40 μm squares). Then the surrounding uncoated regions are filled with a SAM composed of similar alkanethiols that are conjugated to poly(ethylene glycol) (PEG) that prevents protein adsorption. The result is a chemically-defined culture surface that is completely covered with a continuous SAM of alkanethiols, however, the local adhesive islands of defined geometry support protein adsorption, whereas the surrounding boundary regions coated with PEG do not. Thus, when these substrates are coated with a high density of purified ECM protein, such as laminin or fibronectin, adhesive islands of defined shape and position, coated with a saturating density of matrix molecule result. Using this technique, cell position and shape can be precisely controlled because the cells only attach to the ECM-coated adhesive islands. In fact, even square and rectangular shaped cells exhibiting 90° corners can be engineered using this approach [30,65].

This micropatterning method was first used to ask the question: if cells are restricted to a small size similar to that produced on a low ECM coating concentration, but the local density of immobilized integrin ligand is increased 1000-fold, which is the critical determinant of cell function — the ECM density or cell shape? The answer was that it was cell shape. Primary hepatocytes remained quiescent on small adhesive islands coated with a high ECM density, even though the cells were stimulated with high concentrations of soluble growth factors, and cell growth (DNA synthesis) increased in parallel as the size of the adhesive island was increased [65]. Similar results also were obtained with capillary endothelial cells [30]. Moreover, inhibition of hepatocyte growth on the small islands also was accompanied by a concomitant increase in albumin secretion. In the case of endothelial cells, the cells were similarly induced to differentiate into capillary tubes when cultured on linear patterns that supported cell-cell contact as well as a moderate degree of cell distension whereas the cells were induced to undergo apoptosis (cellular suicide) when cultured on the smallest islands that fully prevented cell extension [30,66]. Thus, cells shape and function can be engineered simply by altering the geometry of the cell's adhesive substrate.

Intracellular signals elicited by integrin receptor clustering due to ECM binding have been shown to be critical for control of cell growth and function [56–58,61]. Thus, one could argue that cell shape and mechanical distortion of the cytoskeleton (CSK) are not important. Instead, it might be the increase in the total area of cell-ECM contacts and the associated enhancement of integrin binding that dictates whether cells will grow, differentiate or die on large versus small adhesive islands. To explore this further, substrates were designed in which a single small adhesive island (which would not support spreading or growth) was effectively broken up into many smaller islands (3–5 μm in diameter) that were separated by non-adhesive barrier regions [30]. When capillary cells were plated on these substrates, their processes stretched from island to island and the cells exhibited an overall extended form similar to cells on large islands. However, the total area of cell-ECM contact was almost identical to that exhibited by non-growing cells on the smaller islands. These studies revealed that in the presence of optimal growth factors and high ECM binding, DNA synthesis was high in the cells that spread over multiple small islands whereas apoptosis was completely shut off [30], thus confirming that cell shape distortion is the critical governor of this response.

Importantly, cell distortion also impacts cell migration as well as stem cell lineage switching. For instance, when cells on square islands are stimulated with motility factors, the cells preferentially extend new motile processes (e.g., lamellipodia, filopodia, microspikes) from

their corners, whereas they extend in all directions along the edge of round cells on circular islands [67]. Cells on polygonal ECM islands also prefer to form new lamellipodia from corners with acute angles rather than obtuse ones [83]. In contrast, when mesenchymal stem cells are cultured on different sized ECM islands, those on small islands switch on the fat cell lineage, whereas the spread cells on larger ECM islands become bone cells [68]. Thus, taken together, these results suggest that microfabrication methods might lead to new approaches to tissue engineering using microfabricated substrates. With this approach, it may be possible to direct cell migration, growth and differentiation of stem cells in specific locations by modifying the surface chemistry and topography of artificial materials, instead of creating gradients of soluble chemokines.

The effects of shape distortion on cell fate switching may, in part, be mediated by changes in the level of isometric tension or 'prestress' within the cytoskeleton. For example, both flexible and poorly adhesive culture dishes that inhibit growth and induce differentiation dissipate prestress, whereas substrates that stimulate cell spreading and growth (e.g., rigid dishes) support high levels of cytoskeletal tension. Small ECM islands that inhibit cell spreading also prevent pulmonary vascular smooth muscle cells from responding to vasconstrictors, such as endothelin-1 (as measured by increases of myosin light chain phosphorylation), and similar effects are produced by culturing cells on flexible ECM substrates that dissipate tensional prestress in the ECM and in the interconnect cytoskeleton (i.e., linked through transmembrane integrins) [68a,69]. In addition, cells preferentially differentiate on ECM substrates that are compliance-matched with their cytoskeleton and that have a mechanical stiffness similar to that of their natural tissues [70–72]. Cells also migrate up gradients of ECM stiffness, a process known as durotaxis [73]. These observations suggest that tissue formation may be controlled by changing the physical properties of either the ECM or of the cell, or by altering tension generation in the cytoskeleton.

Regional variations of cell shape distortion or of cytoskeletal prestress similarly drive tissue patterning in the embryo. For example, during tissue morphogenesis, only a subset of cells must respond to soluble growth factors by proliferating locally and sprouting or budding outward relative to neighboring non-growing cells. This process is repeated along the sides of the newly formed sprouts and buds, and the whole process reiterates over time; this is how the fractal-like patterns of tissues develop. This process is mediated by regional changes in ECM structure: the ECM thins in regions where new buds or sprouts will form due to local enzymatic degradation [39]. Because tissues are prestressed (due to the action of cytoskeletal contractile forces), a local region of the tensed ECM may thin more than the rest like a 'run' in a woman's stocking. Cells anchored to this region will also stretch or spread, whereas the shape of neighboring cells on intact ECM would remain unchanged. If cell spreading promotes growth, then local cell growth differentials would result.

This possibility that tissue morphogenesis may be controlled through changes in the mechanical force balance between the cytoskeleton and the ECM is supported by recent experimental studies in embryonic and adult systems. Analysis of the effects of cell shape on cell cycle progression *in vitro* have revealed that these effects are mediated by altering signal transduction through the small GTPase Rho and its downstream target, Rho-associated kinase (ROCK) that controls cytoskeletal tension generation [62,63]. Importantly, when cytoskeletal contractility was suppressed in whole embryonic lung rudiments by inhibiting Rho or ROCK, both epithelial branching morphogenesis and angiogenesis were inhibited, and this was accompanied by decreased basement thinning (as if there was no tension in the stocking) [47]. In contrast, stimulating the Rho pathway had the opposite effect (i.e., it increased morphogenetic branching) at moderate levels of activation and caused complete organ contraction and inhibition of tissue growth at very high levels of stimulation [47]. Altering the cellular force balance by modulating ECM rigidity also can alter expression of the angiogenic factor receptor VEGFR2 (via control of nuclear transport of opposing transcription factors) and

thereby, regulate angiogenesis both *in vitro* and *in vivo* [74]. Thus, local changes in ECM structure and cell shape caused by altering cytoskeletal prestress may govern how individual cells respond to chemical signals in their microenvironment *in vivo*, just as experimental studies using microfabricated ECM islands have demonstrated *in vitro*. This mechanism for establishing local growth differentials may play a critical role in morphogenesis in all developing systems [50,74a].

MECHANOBIOLOGY SUMMARY

In summary, our work has shown that the development of functional tissues, such as branching capillary networks, requires both soluble growth factors and insoluble ECM molecules. The ECM appears to be the dominant regulator, however, since it dictates whether individual cells will proliferate, differentiate, undergo directional motility or die locally in response to soluble stimuli. This local control mechanism is likely critical for the establishment of the local differentials in cell growth, motility, differentiation, apoptosis and stem cell commitment that mediate pattern formation in all developing tissues.

Analysis of the molecular basis of these effects has revealed that ECM molecules alter cell growth via both biochemical and biomechanical signaling mechanisms. ECM molecules cluster specific integrin receptors on the cell surface and thereby activate intracellular chemical signaling pathways [57–60], stimulate expression of early growth response genes (e.g., c-fos, jun-B) [53], and induce quiescent cells to pass through the G_0/G_1 transition. However, in addition, the immobilized ECM components must physically resist cell tension and promote changes of cell shape [9,30,33,52,65] and cytoskeletal tension [55,62,63,75] in order to promote full progression through G_1 and entry into S phase. In fact, studies with living and membrane-permeabilized cells confirm that changes in cell shape result from the action of mechanical tension which is generated within microfilaments and balanced by resistance sites within the underlying ECM [69,76]. Local changes in ECM structure or mechanics will therefore alter the ECM's ability to resist cell tractional forces exerted on integrins, and thereby produce changes in cytoskeletal organization. This will, in turn, alter the level of isometric tension (prestress) in the cytoskeleton, as well as modulate the activity of various signal transduction pathways signal inside the cell [2]. Taken together, this work suggests that the pattern-regulating information that the ECM conveys to cells is both chemical and mechanical in nature. Thus, design of future artificial ECMs for tissue and organ engineering applications must take into account the critical role that mechanical forces and these mechanotransduction mechanisms play in biology.

THE FUTURE

Early tissue-engineering efforts by reconstructive surgeons and material scientists started with knowledge of the clinical need and of the mechanical behavior of connective tissues on the macroscopic scale, and worked backwards. The long-term goal for the field is to design and fabricate tissue and organ substitutes starting from first principles. This includes incorporating biologically inspired mechanical and architectural principles, as well as an in depth understanding of the molecular and biophysical basis of tissue regulation. Clearly, given the potent and varied functions of the ECM, fabrication of artificial ECMs will play a central role in all of these future efforts. We and others have already begun to explore the utility of synthetic bioerodible polymers as cell attachment substrates [77,78] and the potential usefulness of immobilized synthetic ECM peptides for controlling cell growth and function [53,52,79]. These materials offer a major advantage in terms of biocompatibility since the artificial substrates completely disappear over time, and thus the implanted donor cells become fully incorporated into the host. They also provide great chemical versatility, as well as the potential for large-scale production at relatively low cost. In addition, use of synthetic chemistry reduces the likelihood of batch to batch variation during large-scale production, a problem which can

potentially complicate use of purified ECM components. For these reasons, polymer chemistry and novel fabrication techniques will likely lead to development of more effective tissue substitutes.

However, if we understood the fundamental principles that guide ECM remodeling and pattern formation in tissues, perhaps tissue engineering might take a different approach in the future. For example, one could envision entirely new methods of clinical intervention if we understood how tissue-specific mesenchyme generates tissue pattern; how ECM turnover is controlled locally; how cell-generated contractile forces contribute to tissue repair and remodeling; or how compressing or pulling tissues alter their growth and form. This knowledge could lead to methods for identifying and isolating relevant 'pattern-generating' cells; for developing pharmacological modifiers of ECM remodeling that may be incorporated in local regions of implants to promote or suppress tissue expansion locally; and for fabricating 'biomimetic' scaffolds that mimic the mechanical and architectural features of natural ECMs necessary to switch on or off the function of interest (e.g., growth vs. differentiation or apoptosis) at a particular time or place. These are the just a few of the challenges for the future.

Finally, one glimpse of the future comes from our recent work that focuses on the development of human 'organs-on-chips' in which microscale-engineering technologies are used to create microfluidic devices lined by cultured living human cells that recapitulate the physiological microenvironments of whole living organs. The goal is to develop organomimetic microdevices that enable study of complex human physiology in an organ-specific context. Our first success in this area was the development of a human breathing 'lung-on-a-chip' that reproduces key structural, functional, and mechanical properties of the fundamental functional unit of the living human lung — the alveolar-capillary interface. We did this by microfabricating a microfluidic system containing two closely apposed microchannels separated by a thin (10 μm) porous flexible membrane made of poly(dimethylsiloxane) (PDMS), which was coated with ECM. Human alveolar epithelial cells were cultured on one side of the membrane with air flowing above their apical survace, and human pulmonary microvascular endothelial cells were cultured on the other with flowing medium containing human white blood cells to mimic blood flow. Breathing movements were reproduced in this engineered microsystem by applying cyclic suction to neighboring hollow microchambers; this rhythmically deforms the central porous membrane and attached cell layers much as occurs at the living alveolar-capillary interfaces during breathing.

The lung-on-a-chip was shown to replicate the complex organ-level responses of living human lung, including the inflammatory response triggered by bacteria or cytokines introduced into the air space [80]. The endothelial cells rapidly become activated in response to these cues, and increase their expression of ICAM-1, which induces adhesion of primary human neutrophils flowing in the capillary channel; this is followed by their transmigration across the capillary-alveolar interface and into the alveolar space where the white blood cells engulf the bacteria. Because the PDMS has high optical clarity, the entire human inflammatory response can be visualized in real-time within this biochip.

Importantly, we found that the breathing motions and rhythmic distortion of the cells are absolutely critical for them to mimic organ-level physiology and pathophysiology. For example, we found that physiological breathing movements greatly accentuate toxic and inflammatory responses of the lung to silica nanoparticles (12 nm) that were introduced into the air channel to mimic airborne particulates [80]. Mechanical strain also enhanced epithelial and endothelial uptake of nanoparticulates and stimulated their transport into the underlying microvascular channel. Importantly, similar effects of physiological breathing on nanoparticle absorption are observed in whole mouse lung. Moreover, we have recently extended this work by developing a microengineered human disease model of pulmonary edema [81], which closely mimics this life-threatening side effect that is induced by the cancer chemotherapic interleukin-2 (IL-2) in human patients, and is characterized by fluid

accumulation and fibrin deposition in the alveolar airspace. Again, we found that physiological breathing motions are responsible for the majority of the effects of IL-2 on pulmonary vascular leakage, and we confirmed this in an animal model. Finally, when we adapted the same microengineering approach to produce a human 'gut-on-a-chip' lined by human intestinal epithelial cells, we also found that by mimicking peristaltic-like mechanical motions and the trickling fluid flows of the living gut, we obtained levels of differentiation and functionality never seen before *in vitro* [82]. These included spontaneous formation of intestinal villi, restoration of epithelial barriers, and gaining the ability to co-culture intestinal bacterial (microbiome) on the human epithelium without compromising tissue viability or function.

Human organ-on-chips models could provide a potential new approach to enhance our fundamental understanding of complex disease processes and to enable more rapid, accurate, cost-effective and clinically relevant testing of drugs, as well as cosmetics, chemicals and environmental toxins. On-chip human disease models also could help to facilitate the translation of basic discoveries into effective new treatment strategies.

But most importantly, these results demonstrate the power of combining insights into mechanobiology with advanced engineering approaches as we seek to confront future challenges in tissue and organ engineering.

Acknowledgments

I would like to acknowledge that the success of many of the studies summarized would not have been possible without the assistance of my major collaborators, including Drs. Judah Folkman, Robert Langer, Martin Schwartz, Jay Vacanti, and George Whitesides, and the multiple students and postdoctoral fellows who executed these experiments in our laboratories, particularly Dan Huh and Hyun-Jung Kim who led the organ on-chip efforts. This work was supported by grants from NIH, NASA, DoD, DARPA, ARO, NSF and the Wyss Institute for Biologically Inspired Engineering at Harvard University.

INTRODUCTION

The goal of achieving *in vivo* induced regeneration for a variety of tissue and organs following severe injury remains at the forefront of current tissue-engineering investigations. Typically, an analog of the extracellular matrix is utilized as a template that, when properly formulated, induces regeneration of lost or damaged tissue. Currently, successful regeneration has been induced in the skin and peripheral nerves [1], while progress has been made in developing appropriate extracellular matrix analogs to alter the typical organismic response to injury in a variety of tissues, including kidney, cartilage, bone, central nervous system, and brain dura. These investigations, active for the previous three decades, have primarily focused on identifying the optimal extracellular matrix analog components to block organized wound contraction and scar tissue formation, while inducing regeneration of physiological tissue [1]. Although many tissue engineering investigations currently focus on developing techniques appropriate for synthesis of tissues and organs *in vitro*, such products must eventually be implanted in the appropriate anatomical site of the host. Since implantation of an organ construct is almost always preceded by a surgical procedure that generates a severe wound, it is essential to master the evolving methodology of *in vivo* wound healing in order to synthesize appropriate neo-organ constructs *in vitro* for eventual implantation. The goal of this chapter is to inform the reader about the salient features of the organismic response to injury, the historical underpinnings of current studies of induced tissue regeneration, induced tissue regeneration as a technique to treat severe injuries to a variety of tissue and organs, and the future directions of research in this field.

MAMMALIAN RESPONSE TO INJURY

Defect scale

Treatment options for organ injury depend significantly on the scale of the defect. Microscopic defects can be treated using a wide variety of soluble factors (i.e., herbs, potions, pharmaceuticals, vitamins, hormones and antibiotics). However, organ-scale defects present a significantly larger wound site, require considerably different treatment practices, and constitute the focus of this article. These defects, primarily created by disease or by an acute or chronic insult that result in millimeter or centimeter scale wounds, cannot be treated with drugs because the problem is the failure of a mass of tissue including cells, soluble proteins

and cytokines, and insoluble extracellular matrix (ECM). Significant loss of function in the affected tissue or organ, termed the 'missing organ', leads to consequences such as lack of social acceptance in cases of severe burns and facial scars, loss of mobility and sensory function in the case of neuroma, and life-threatening symptoms in cases such as cirrhotic liver, large-scale severe burns, and ischemic heart muscle.

REGENERATION VERSUS REPAIR

Certain organisms have the ability to regenerate significant portions of damaged tissue. An example is the amphibian newt, which regenerates functional limbs following amputation. The mammalian fetus has displayed the ability to regenerate damaged organs and tissue spontaneously up to the third trimester of gestation; however, adult mammals do not typically exhibit spontaneous regeneration following severe organ injuries [1,2]. Instead, the adult mammal response to severe injury is closure of the wound by contraction and scar tissue formation, a process termed repair. Cell-mediated contraction of the wound site is observed in many different species in varying degrees, at many organ sites [1]. Distinct from repair, regeneration is characterized by synthesis of physiological (normal, functional) replacement tissue in the wound site that is structurally and functionally similar to the original tissue. Based on these observations, for the remainder of this text the term 'early fetal' refers to the fetal response to injury that leads to regeneration, while 'adult' refers to all mammals (adult as well as late fetal) that respond to injury via repair.

The contractile fibroblast phenotype, termed the myofibroblast, plays a critical role in determining the nature (repair or regeneration) of mammalian wound healing. During adult repair, myofibroblast-mediated organized wound contraction and scar tissue synthesis is observed [1]. During early fetal healing, differentiation of myofibroblasts has not yet occurred and regeneration of damaged tissue and organs occurs in the absence of contraction. The data suggest that induced organ regeneration in the adult may be encouraged by developing techniques to stimulate partial reversion to early fetal healing. Additionally, the transforming growth factor-β (TGF-β) family of molecules has been implicated in this ontogenetic transition between fetal regeneration and adult repair response to injury. TGF-βs are multifunctional cytokines with widespread effects on cell growth and differentiation, embryogenesis, immune regulation, inflammation, and wound healing [3]. In terms of their relationship with repair processes, TGF-β1 and TGF-β2 are known to promote scarring, while TGF-β3 may reduce scarring [4,5]. As such, deficient levels of TGF-β1 and β2 and increased levels of TGF-β3 are observed in early gestational ('fetal' regenerative healing response) compared to late gestational ('adult' repair healing response) mice. These results implicate increased TGF-β1, β2, and decreased TGF-β3 expression along with myofibroblast activity in late gestation and post-partum fetal scar formation [6]. The available evidence suggests future experiments utilizing procedures for control of TGF-β in conjunction with other tissue-engineering constructs that modify myofibroblast behavior, such as bioactive scaffolds, to induce regeneration of tissues that are known to be non-regenerative.

Tissue triad

There are three distinct tissue types, termed the tissue triad, which together define the structure of most organs: the epithelial layer, the basement membrane layer, and the stroma (Fig. 18.1) [1,7]. Developmental and functional similarities between this triad in a variety of tissues and organs such as skin and peripheral nerves have been observed, suggesting that it can be used as an illustrative device to understand injury response in other organs as well [1]. A layer of epithelial cells (the epithelial layer) covers all surfaces, tubes, and cavities of the body; this layer is cell-continuous and avascular; unlike the basement membrane and stroma, the epithelial layer does not comprise a significant amount of ECM. The basement membrane is an acellular, avascular, continuous layer of ECM components separating the epithelial layer and

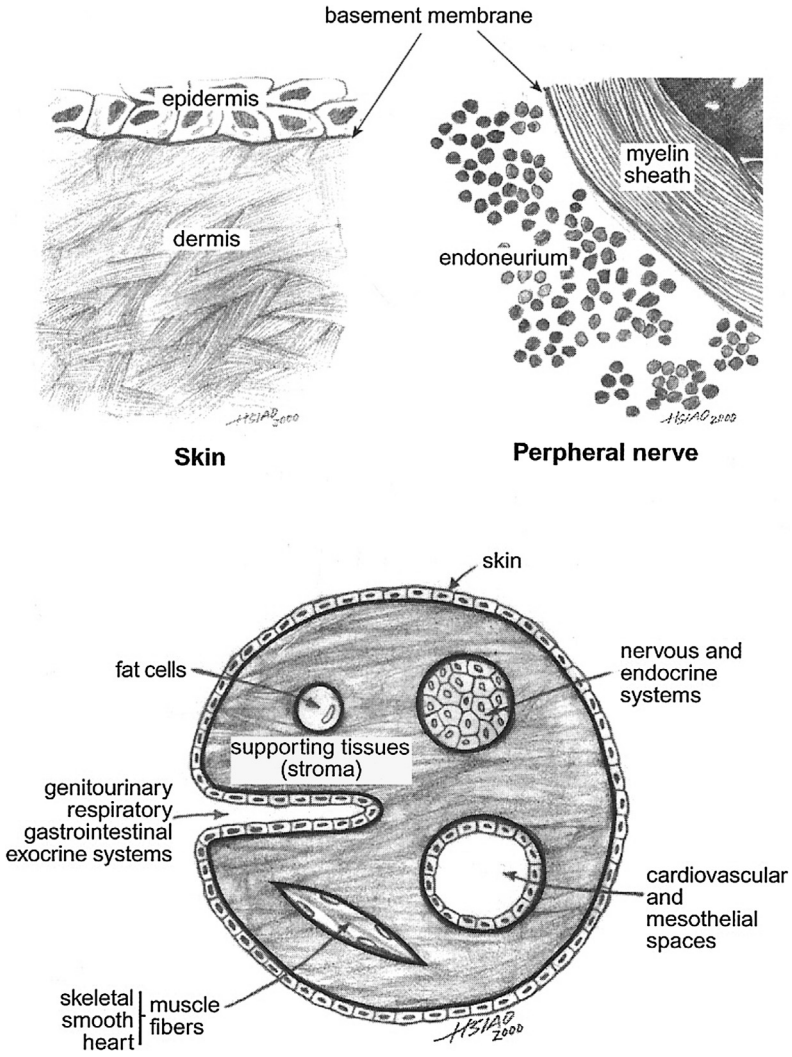

FIGURE 18.1

Schematics of the tissue triad structure observed in mammalian tissue. *Top*: Tissue triad of skin and peripheral nerves. The basement membrane is a thin extracellular matrix tissue located between the cellular and non-vascular epithelia (epidermis, myelin sheath) and the cellular, vascularized stroma (dermis, endoneurium). *Bottom*: Diagram of the distribution of epithelial, basement membrane, and stromal tissues in the mammalian system. Examples of stromal tissues are bone, cartilage, and their associated cell types as well as elastin and collagen. Examples of epithelial tissues are those covering the surface of the genitourinary, respiratory, and gastrointestinal tracts as well as surfaces of the mesothelial cells in body cavities, muscle fibers, fat cells, and endothelial cells in the cardiovascular system [1].

the stroma. The stroma is cellular, contains ECM and connective tissue components, is heavily vascularized, and provides a reservoir for nutrient uptake to and waste removal from the basement membrane and epithelia.

Following injury to a variety of tissues, such as the skin, peripheral nerves, blood vessels, lung, kidney, and pancreas, the epithelial and basement membrane layers regenerate spontaneously when the stroma remains intact, while the damaged stoma heals through repair-mediated contraction and scar formation processes [1,8–18]. Understanding the injury response of the tissue triad has suggested a paradigm for inducing regeneration in non-regenerative tissues: the repair mechanisms appear to be activated by disruption of the stromal architecture, and proper replacement of the stromal layer is critical for any regeneration to occur. As such, development of materials to act as analogs of the ECM to replace the lost stromal architecture has been a primary focus of studies of regenerative medicine over the past two decades.

METHODS TO TREAT LOSS OF ORGAN FUNCTION

Six approaches have been used to restore some level of functionality to a damaged tissue or organ: transplantation, autografting, implantation of a permanent prosthetic device, use of stem cells, *in vitro* synthesis of organs, and induced regeneration. The last three techniques are often collectively referred to as 'tissue engineering' [19]. *In vivo* induced regeneration is the only methodology to date which has modified the adult mammalian wound healing response to induce regeneration. All six techniques will be briefly discussed in the following sections; a more detailed description has been previously published [1].

Transplantation

Transplantation is widely used to replace complex tissues and organs, but is limited by two significant factors. While transplantation of a select few tissues such as the eye and testis occur without rejection, a significant challenge facing transplantation is the immunological barrier between the donor and host. After transplantation, the donor organ is attacked and rejected by the host's immune system. The primary clinical method for preventing such rejection is the use of immunosuppressive drugs for the remainder of the host's life to suppress their immune system. However, immunosuppression also makes the host vulnerable to infections [20]. A second major obstacle is the difficulty in finding immunocompatible donors and the shortness of supply of suitable organs [21].

Autografting

With autografting, the donor and the recipient are the same individual; a fraction of the tissue or organ is harvested from an uninjured site and grafted at the non-functional site [22]. Autografting removes issues related to immune response, but necessitates the creation of a second wound site (donor site), subjecting the patient to a second severe trauma and additional loss of functionality. Therefore, autografting is utilized only when sufficient autograft tissue is available and when the loss of functionality or morbidity at the primary wound site outweighs that at the harvest site, giving it limited applicability. Typical applications of autografting follow severe burns and peripheral nerve injuries in the hand.

Permanent prosthetic device

Permanent, prosthetic devices are typically fabricated from biologically inert materials such as metals, ceramics, and synthetic polymers that do not provoke the immune response problems inherent to many transplanted tissues. Even though these devices are fabricated from bio-inert materials, interactions between the prosthesis and the surrounding biological environment still lead to a number of unfavorable physical and biological manifestations. Specific examples are the formation of a thick, fibrous scar tissue capsule around the implant [23], stress-shielding of the surrounding tissue [24], platelet aggregation to implanted surfaces [25], and accumulation of wear particles both at the site of implantation and in the lymphatic system [26]. The spontaneous remodeling process of the tissues surrounding the implant can also be significantly altered, leading to further tissue degradation [27]. These often-serious side effects illustrate the difficulty of replacing bioactive tissues with bio-inert implants fabricated from materials possessing drastically different material and mechanical properties.

Stem cells

The pluripotent nature of stem cells offers a multitude of therapeutic possibilities [28,29]. Current efforts in stem cell research have focused on understanding stem cell plasticity, aging, and ways of controlling differentiation [30–33]. Mesenchymal [34], epithelial [35], and neural stem cells [36] have been grown *in vitro* and studied. More recently, experimental investigations of stem cells have also focused on utilizing hematopoietic and embryonic stem cells. In particular, techniques for harvesting and identifying them [37,38], expanding and

differentiating them in culture [30,39–45], and re-implanting them at an injury site [42,46] have been at the forefront of stem cell research. Importantly, many of these studies have made the transition to exploring biomaterial-mediated effects on basic cell bioactivity [47,48] and regenerative potential [49–54]. An improved understanding of stem cell behavior and the development of stem cell-based technologies also raise a number of important ethical questions [55], consideration of which will play a significant role in the development of stem cell-based tissue-engineering solutions.

In vitro synthesis

In vitro synthesis requires the growth of a functional volume of tissue *in vitro*. It allows total control over the culture environment, including soluble regulator content (i.e., growth factors, cytokines), insoluble regulator content (i.e., ECM proteins), and a variety of cell culture media and loading conditions. In order to develop large (critical dimension >1 cm), bioactive scaffolds, it is important to metabolically support the cells within these constructs. There are two mechanisms available for the transport of metabolites to and waste products from cells in a scaffold: diffusion, and with *in vivo* applications, transport through capillary networks formed in the scaffold via angiogenesis. While angiogenesis becomes the limiting factor *in vivo*, significant angiogenesis is not observed for the first few days after implantation, and is not present at all *in vitro*. As a result, current tissue engineering constructs are size limited (<1 cm) due to diffusion constraints. Improving metabolite influx is critical for larger, more complex scaffolds. Additionally, the complexity of biological systems, specifically cytokine, growth factor, and intercellular signaling needs throughout the volume of developing tissue have to date precluded, with a few exceptions such as *in vitro* culture of replacement heart valves [56] and epithelial sheets for severe burn patients [57], the formation of complex tissues *in vitro*.

Induced *in vivo* organ synthesis (induced regeneration)

Induced organ synthesis *in vivo* relies on the processes inherently active in the wound site to regenerate lost or damaged tissue. A highly porous analog of the ECM, also termed a scaffold, is utilized to induce regeneration at a wound site where the organism would normally respond via repair processes. Induced organ synthesis was made possible by the development of fabrication techniques to produce ECM analogs with well-defined pore microstructure, specific surface area, chemical composition, and degradation rate [1,13]. Its first application was the use of a collagen-glycosaminoglycan (CG) scaffold (termed dermal regeneration template – DRT) that induced skin regeneration following severe injury. The DRT displayed high biological activity when implanted into a full-thickness skin wound and was capable of inducing regeneration of the underlying dermal layer of skin as well as the epidermal and basement membrane layers [13,58]. Efforts using decellularized matrices have presented a new avenue for generating material platforms for tissue regeneration such as in the area of urogenital and intestinal repair [59–63].

For the remainder of this review, we will focus on studies on the structure and function of ECM analogs used in tissue-engineering applications as well as an in-depth discussion of the tissue-engineering approaches utilized to induce regeneration of a number of tissues, namely skin, peripheral nerves, and orthopedic tissues.

ACTIVE EXTRACELLULAR MATRIX ANALOGS

Fundamental design principles for tissue regeneration scaffolds

Porous, three-dimensional scaffolds have been used extensively as biomaterials in the field of tissue engineering for *in vitro* study of cell-scaffold interactions and tissue synthesis and *in vivo* induced tissue regeneration studies. These scaffolds, analogs of the ECM, act as a physical support and, more importantly, as an insoluble regulator of biological activity that affects cell processes such as migration, contraction, and division. For the remainder of this review, the

term active or bioactive ECM analog will refer to scaffolds that induce regeneration of normally non-regenerative tissues following severe injury. It has been hypothesized that these active ECM analogs induce regeneration by establishing an environment that selectively inhibits wound contraction by preventing the organized contractile response and blocking scar synthesis, the two processes normally responsible for closing a wound following severe injury [1]. Recent efforts suggest that porous collagen scaffolds enhance regeneration both in injured adult skin and peripheral nerves by disrupting the formation of a contractile cell capsule at the edges of the wound. Notably, capsules or clusters of contractile cells were hypothesized to impose a universal mechanical barrier during wound healing which, if disrupted appropriately, enhances the quality of induced regeneration in a wider range of organs [64].

Four physical and structural properties must be controlled to critical levels for the fabrication of an active ECM analog: the degradation rate which defines the template residence time, the chemical composition, the pore microstructure (mean pore size, shape, and orientation), and the scale of the scaffold that is defined by the critical cell path length [1]. These characteristics and any governing models that help to describe cell behavior in active ECM analogs will be discussed briefly in the following section.

Template residence time

The length of time that the scaffold remains insoluble in the wound site (residence time) is critical in defining its bioactivity. For physiologic tissue to be synthesized at a wound site, the scaffold must initially support cell migration, proliferation, and organization, but the scaffold must then degrade in such a manner that it does not interfere with the native tissue synthesis and remodeling processes. These considerations require a scaffold residence time with an upper and lower bound, a concept that has been formalized as the isomorphous tissue replacement model: the scaffold residence time must be approximately equal to the time required to synthesize a mature tissue via regeneration at the specific tissue site under study [65]. In the case of a full-thickness skin wound, for example, this healing time is approximately 25 days, and the degradation kinetics of the active ECM analog that induces skin regeneration was optimized for that time period [13]. Alternatively, the healing time of a peripheral nerve injury is dependent on the gap length: peripheral nerve trunks grow unidirectionally, from the proximal toward the distal stump, at a rate of approximately 1 mm/day [66]. Accordingly, during induced regeneration of peripheral nerves across a gap, a scaffold in contact with the nerve stumps (either the tube into which the stumps are inserted or the scaffold structure in the tube lumen) must remain in an insoluble state over a period approximately equal to the time, of order 10−20 days, during which axon elongation proceeds from the proximal to the distal stump.

An intact scaffold cannot diffuse away from the wound bed; therefore the simplest method for achieving isomorphous tissue replacement requires the insoluble scaffold structure to be degraded by enzymes in the wound bed into low molecular weight fragments. The lifetime of the scaffold is defined by the degradation time constant (t_d) and can be compared to the normal healing process time constant for a wound at the anatomic site of interest (t_h) [67]. When the scaffold remained in the wound bed as a non-degradable implant ($t_d/t_h > 1$), dense fibrous tissue similar to scar was synthesized underneath the scaffold [1,13,68]. When the scaffold degraded rapidly ($t_d/t_h < 1$), wound healing was marked by wounds contraction and scar synthesis similar to the reparative healing process observed in an ungrafted wound and no regeneration was observed [67]. Because different wound sites and even the same wound site in different species may have different time constants for healing (t_h), it is necessary to adjust the degradation rate of the ECM analog for each wound site and species in order to satisfy the isomorphous tissue replacement requirement and induce regeneration.

Scaffold resistance to degradation can be increased by increasing the relative density (solid content) of the scaffold. However, a more elegant option that does not involve changing the

structural characteristics of the scaffold is also available: scaffold degradation resistance increases with increasing crosslink density between the fibers that make up the scaffold structure [13,69–71]. In the case of collagen-based scaffolds, degradation in the wound bed is accomplished primarily by native collagenases. Decreased degradation rates for collagen-based scaffolds has been achieved by introducing glycosaminoglycans (GAGs) into the collagen mixture, which results in the formation of additional crosslinks, and by further crosslinking the resultant scaffold using a multitude of physical and chemical crosslinking processes. Dehydrothermal (DHT) crosslinking is a physical technique where the scaffold is exposed to a high temperature under vacuum, leading to the removal of water from the scaffold. Drastic dehydration (<1% water content) of the scaffold leads to the formation of inter-chain amide bonds through condensation [72]. DHT crosslinking is adjustable; exposure to higher temperatures or longer lengths of time produces a higher crosslink density and slower degradation rate [70,73]. UV treatment is a second physical crosslinking technique that can create crosslinks between collagen fibers due to the effects of radiation [74]. Chemical crosslinking treatments, such as glutaraldehyde [73] or carbodiimide [75] exposure can also be utilized to induce covalent bonds between collagen fibers. These crosslinking techniques are considerably more powerful, resulting in significantly higher crosslink densities and slower degradation rates. However, chemically crosslinked scaffolds must be extensively washed to remove all traces of the typically cytotoxic chemicals. Additionally, some chemical crosslinkers integrate a portion of the chemical compound into the crosslink; degradation of these scaffolds releases cytotoxic agents into the wound site so these techniques must be used with care [76,77]. While described in detail for collagen-based scaffolds, these crosslinking tools and techniques can be applied to a multitude of scaffolds, fabricated from both natural and synthetic materials.

Chemical composition

The chemical composition defines the ligands displayed on the scaffold surface. Cell behaviors such as attachment, migration, proliferation, and contraction are all mediated by interactions between the focal adhesions and integrins expressed on the cell surface and the ligands available on the scaffold surface. An active ECM analog must be fabricated in a manner, and from specific materials, that leads to expression of a chemical environment conducive to cell-scaffold interactions that prevent organized wound contraction and scar synthesis and that instead induce regeneration.

A multitude of different materials have been used to fabricate scaffolds for many tissue-engineering applications including studies of induced *in vivo* regeneration. Several synthetic, non-degradable polymers such as (poly)dimethyl siloxane have been occasionally utilized; these polymers, which parenthetically violate the principle of isomorphous tissue replacement, do not express ligands on their surface and have not induced regeneration. Degradable synthetic polymers such as poly(L-lactide) and poly(lactide-co-glycolide) variants have been fabricated to satisfy isomorphous tissue replacement and with surfaces that have been modified chemically to display appropriate ligands; however, these materials have not been observed to prevent contraction and scar formation nor to induce regeneration of stromal tissue. A chemical composition that has been used successfully to induce regeneration is a graft copolymer of type I collagen and a sulfated glycosaminoglycan (GAG) [1,13]. Collagen is a significant constituent of the natural ECM, and collagen-based scaffolds have been used in a variety of applications due to many useful properties: low antigenic response and a high density of ligands that interact specifically with integrin receptors in fibroblasts (the cell type predominantly responsible for cell-mediated contractions processes during repair). Particular collagen scaffolds have been observed to promote cell and tissue attachment and growth as well as to induce regeneration of tissue following injury [1,13,78–81]. However, in order to induce regeneration, the periodic banding (~64 nm) of the collagen fiber structure must be selectively abolished to prevent platelet aggregation that leads to repair [1]. A number of other natural protein-based scaffolds (i.e., hyaluronate-based, fibrin-based, and chitosan-based

scaffolds) have also shown great promise in the field of tissue engineering. These natural polymers are also capable of facilitating cell binding similar to that observed with collagen scaffolds in part due to their expression of natural ligand binding sites, but these materials have not been developed to the point of inducing regeneration at this point.

Template pore microstructure

The biological activity of any ECM analog also depends significantly on its three-dimensional pore microstructure. Having migrated into the scaffold, the cell interacts with the surrounding scaffold environment, making use of its cell surface receptors to bind to specific ligands on the scaffold surface. The first critical component of ECM analog microstructure to consider is the open- or closed-cell nature of the scaffold. An open-cell pore microstructure exhibits pore interconnectivity which a closed-cell microstructure exhibits membrane-like faces between adjacent pores, effectively sealing the environment of one pore from its neighbors. Pore interconnectivity is critical for scaffold bioactivity because cells to be able to migrate through the construct and to interact with other cells in a manner similar to that observed *in vivo*. A second critical structural feature is the relative density (R_d) or porosity of the ECM analog. The relative density of the scaffold is calculated as the ratio of the scaffold density to the density of the solid from which the scaffold is made. Porosity, a measure of how porous the scaffold is, is the pore volume fraction of the scaffold. Additionally, the relative density and porosity are inversely related: scaffold porosity can also be defined as $(1 - R_d)$. These variables both define the amount of solid material in the scaffold; when the pores are closed, too small, or when the relative density is too large, cells are not able to migrate through the scaffold, a significant impediment for a tissue-engineering scaffold. An active ECM analog must possess an open-cell pore structure with a relative density below a critical value that is characteristic of each application, but is typically significantly $<10\%$ (bioactive porosity typically $>90\%$). This structural criteria, determined from the results of a number of experiments studying cell-scaffold interactions, suggest that a critical number of cells are required within a bioactive scaffold [1].

The mean pore size of the ECM analog significantly influences its bioactivity; hence the effect of mean pore size will now be discussed in conjunction with the application of cellular solids modeling and a discussion of scaffold specific surface area. To describe even a simple cell-scaffold interaction, a highly detailed model describing the number of receptors utilized per bound cell and the nature of the binding and receptor sites needs to be developed. However, a more generic explanation can be used to describe the complexity of the cell-scaffold interaction and the significant influence the pore size has on its bioactivity. At first pass, it is apparent that there is a minimum pore size requirement for a bioactive ECM analog: the pores must be large enough to allow cells to fit through the pore structure and populate the analog. There is also an observed upper bound to pore size [1,13]; it has been hypothesized that this upper bound in mean pore size if due to the effects of scaffold specific surface area. To further test this hypothesis, cellular solids modeling techniques have been integrated to better describe scaffold microstructure using a quantitative framework. The complex geometry of foams (and of scaffolds) is difficult to model exactly; instead, dimensional arguments that rely on modeling the mechanisms of deformation and failure in the foam, but not the exact cell geometry, will be used [82]. Scaffold relative density (R_d) and mean pore size (d) together define the scaffold specific surface area (SA/V), the total surface area of pore walls available for cell attachment. A cellular solids model has been developed and experimentally validated to accurately predict SA/V of collagen-based scaffolds [83]:

$$\frac{SA}{V} = \frac{10.17}{d}(R_d)^{1/2} \tag{1}$$

Increasing mean pore size in a series of constructs and keeping R_d constant decreases the overall SA/V, while increasing R_d and keeping the mean pore size constant increases SA/V. The

primary feature of this structural analysis to consider is that a change in the construct SA/V indicates a change in the available area to which cells bind. This calculation and experimental result suggests the significance of the scaffold SA/V in defining its bioactivity. If the SA/V is too small (i.e., due to a relatively large mean pore size), an insufficient number of cells will be able to bind to the scaffold and the cells that remain free will contribute to the spontaneous repair mechanism. As previously discussed, there is also a minimum mean pore size, defined by the characteristic dimension of the cell: approximately 10−50 μm for most cells. When the scaffold pore size is smaller than this critical dimension, cells will be unable to migrate through the scaffold whereas when the pore size is too large an insufficient specific surface area will be available. These upper and lower bounds of the scaffold mean pore size, mediated by cell size and specific surface requirements, have been determined experimentally for each cell type for tissues where regenerative templates have been used [1].

The shape of the pores that make up the porous scaffold must also be considered. Cells have been observed to be exquisitely sensitive to the mechanical properties of the underlying substrate [84], and slight changes in the mean shape of the pores can result in significant variations in the extracellular mechanical properties [82,85] and overall construct bioactivity [86]. Changes in mean pore shape may also play a role in defining the areas of the scaffold available or unavailable for binding and the predominant direction of cell migration as well as in the geometrical organization of cells within the scaffold.

Critical cell path length

Successful migration of cells into an active ECM analog and their initial survival is critically important for successful regeneration. While the effect of the structural characteristics (i.e., pore size, shape, relative density) on the bioactivity of an ECM analog has been discussed, there is another important characteristic to consider: an adequate source of metabolites (i.e., oxygen, nutrients). There are two mechanisms available for transport of metabolites to and waste products from the cells: diffusion to and from the surrounding wound bed or transport along capillaries that have sprouted into the scaffold as a result of angiogenesis. While angiogenesis becomes the limiting factor for long-term cell survival and growth, significant angiogenesis is not observed for the first few days after implantation. Therefore, early cell survival inside the scaffold is defined solely by diffusion. The critical scaffold thickness, the maximum scaffold thickness than can be supported by metabolite diffusion, has been observed empirically in to be on the order of a few millimeters [1].

A quantitative model of cell metabolic requirements and nutrient diffusion characteristics that defines the critical cell path length for cell migration into a scaffold has been developed to describe the salient features of this process [1,87,88]. Here, the complexity of the nutritional requirements of the cell is simplified by generically considering a critical nutrient that is required for normal cell function; such a nutrient is assumed to be metabolized by the cell at a rate R in moles/mm^3/sec. The nutrient is pictured being transported from the wound bed, where the concentration of nutrient is assumed to be a constant, C_o, over a distance L via the exudate until it reaches the cell within the scaffold. Immediately following implantation of the scaffold, nutrient transport is performed exclusively via diffusion that can be modeled using the scaffold diffusivity D in mm^2/sec. Dimensional analysis readily yields the cell lifeline number (S):

$$S = RL^2/DC_o \tag{2}$$

The cell lifeline number characterizes the relative ratio of the rate of nutrient supply to nutrient consumption by the cell. If the rate of consumption of the critical nutrient exceeds greatly the rate of supply, $S >> 1$, the cell will soon die. At steady state ($S = 1$) the rate of consumption of nutrient by the cell equals the rate of transport via diffusion over a distance L; at steady state, the value of L is the critical cell path length, L_c, the longest distance away from the wound bed that the cell can migrate without requiring nutrient in excess of that supplied by diffusion. For

many cell nutrients of low molecular weight, L_c is of order a few hundred micrometers to a few millimeters, a distance short enough to suggest the need for very close proximity between wound bed and implant and to indicate that *in vivo* regeneration of large tissue or organs requires incorporation of special promoters to angiogenesis [1,67].

As a result, recent experimental work has focused on understanding the relationship between scaffold pore microstructure and permeability; scaffold permeability controls diffusion-based metabolite and waste transport to and from the scaffold and influences the final hydrostatic pressure distribution in the scaffold. Both of these parameters can significantly influence cell behavior and overall scaffold bioactivity. Cellular solid modeling tools that quantitatively describe scaffold permeability in terms of salient microstructural features have been utilized in this analysis. Both scaffold pore size and compressive strain can vary significantly with different applications, making them the primary features to characterize in terms of scaffold permeability. An open-cell foam, cellular solids model has been developed to accurately model scaffold permeability (K) in terms of scaffold mean pore size (d), percent compression (ε), a system constant (A), and scaffold relative density (ρ^*/ρ_s) was developed [89]:

$$K = A \cdot d^2 \cdot (1-\varepsilon)^2 \cdot \left(1 - \frac{\rho^*}{\rho_s}\right)^{3/2} \tag{3}$$

The cellular solids model (Eq. 3) of scaffold permeability suggests that scaffold permeability increases with increasing pore size and decreases with increasing compressive strain, a result that has also been observed experimentally for a series of collage-based scaffolds. The excellent comparison between experimentally measured permeability and that which is predicted from the cellular solids model suggests that such predictive modeling tools can be used to describe scaffold permeability for many different scaffold architectures under a variety of physiological loading conditions.

Active collagen-glycosaminoglycan scaffolds

Collagen-glycosaminoglycan scaffolds have been observed to have a high degree of bioactivity and be able to induce regeneration of non-regenerative tissues at a variety of anatomical sites. Three specific wounds and the appropriate ECM analogs have been studied in our laboratory: skin regenerated via the DRT [1,13,90], peripheral nerves regenerated by the nerve regeneration template (NRT) [71,86,91,92], and the conjunctiva regenerated by a modified DRT [93]. As predicted, the bioactivity of the DRT and NRT has been found to be closely related to specific physical parameters of the scaffold. Scaffold mean pore size (Fig. 18.2) [13], degradation rate (Figs. 18.3, 18.4) [13,71], chemical composition [13], pore orientation [86], and the pore volume fraction have all been shown to have a significant effect on the quality of regeneration and it appears that only a narrow range of structural features satisfies the criteria for bioactivity [1].

BASIC PARAMETERS FOR *IN VIVO* REGENERATION STUDIES: REPRODUCIBLE, NON-REGENERATIVE WOUNDS

In vivo regeneration of injured or excised tissue can be modeled as a process taking place within a bioreactor that is surrounded by a reservoir with constant properties; the bioreactor symbolizes the entire organism with its complex homeostatic mechanisms. From an engineering standpoint, the bioreactor must have a defined and consistent anatomical and physicochemical environment for quantitative study of any biological process. In order to study induced *in vivo* regeneration, it is therefore critical to standardize the wound site where studies are performed. Without a standardized, reproducible wound site, it is impossible to accurately and statistically assess differences between ECM analogs within a single laboratory or to compare results from different, independent laboratories. Billingham and Medawar [94] introduced the concept of an anatomically constant wound for the study of massive skin

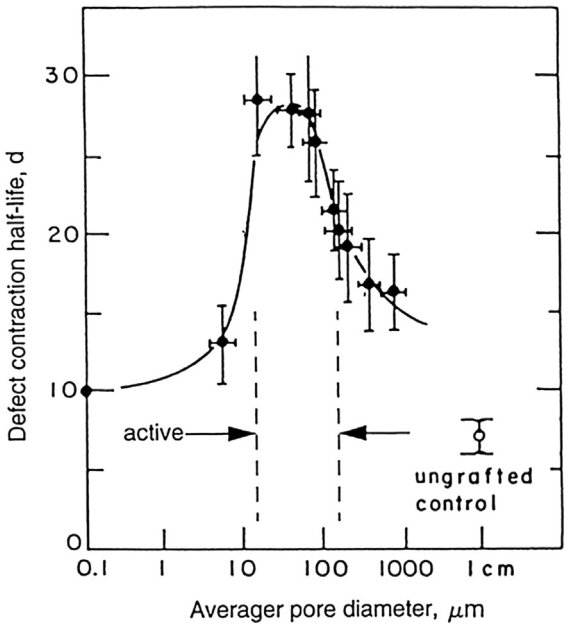

FIGURE 18.2
Bioactivity of ECM analog variants for skin regeneration versus scaffold mean pore diameter [13].

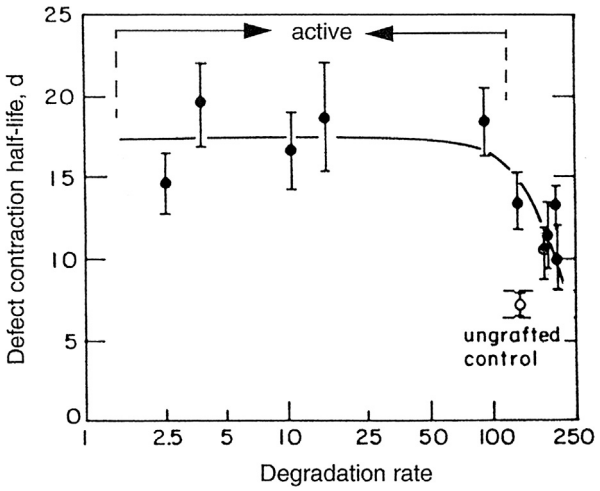

FIGURE 18.3
Bioactivity of ECM analog variants for skin regeneration versus scaffold degradation rate [13].

injuries. This concept has been amplified and standardized; it is referred to as the anatomically well-defined wound [1] and has been applied to the study of injuries in skin, peripheral nerves and a variety of other wound sites. The anatomically well-defined wound for studies of skin regeneration is the full-thickness skin wound where all tissue (epithelia, basement membrane, stoma) is removed down to the underlying fascia [1]. For peripheral nerve regeneration studies, the standardized wound is complete transection (total or full axotomy) of the nerve trunk, typically at the midpoint of the sciatic nerve [1]. For studies of cartilage repair following injury, the standardized wound model is complete removal of the cartilage down to the underlying subchondral bone [95]. These models standardize the experimental wound environment, making it possible to obtain statistically significant results that can be compared meaningfully. However, in clinical cases, the nature of the wounds typically varies on a case-by-case basis, and it is important to understand the applicability of each treatment methodology to the range of injuries that are encountered. For example, while a tubular scaffold can be used to study peripheral nerve regeneration using the full axotomy model, a tubular implant would be difficult to implement clinically in the case of severe crush injuries that do not result in complete nerve trunk transection.

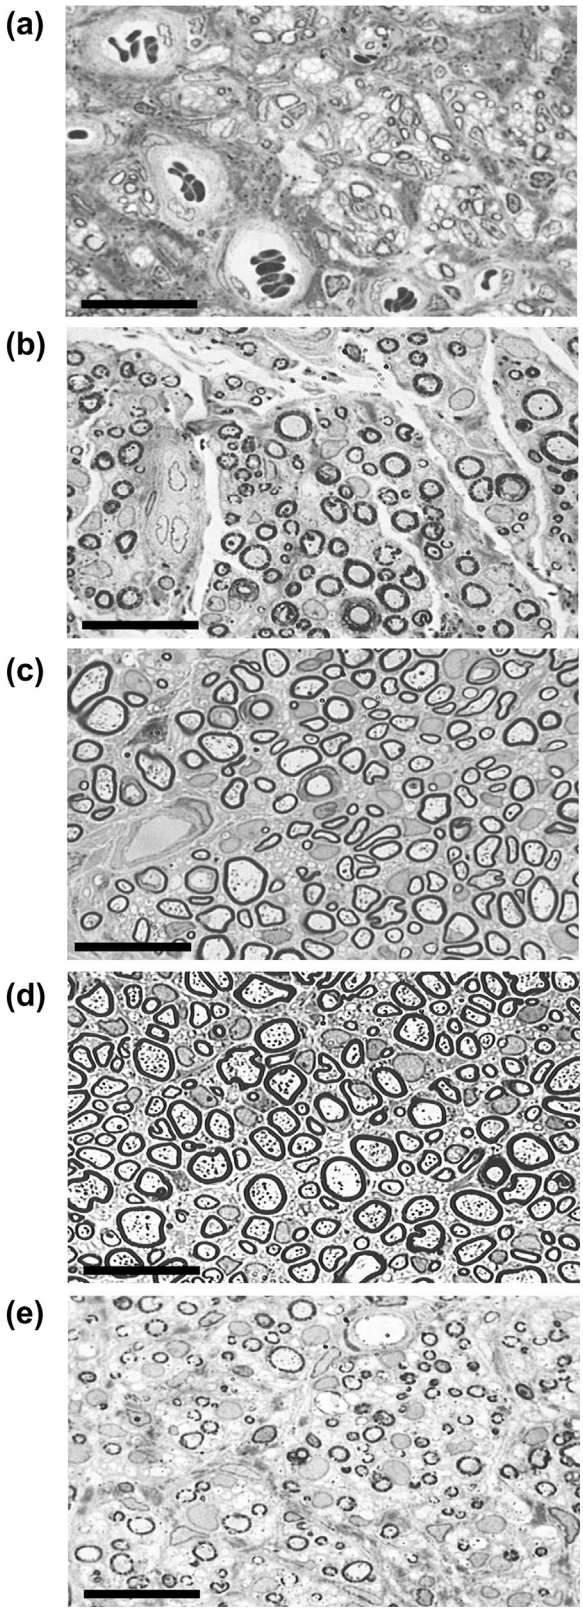

FIGURE 18.4
Histomorphometic, cross-sectional images of the regenerated nerve trunk from the five collagen tubes with distinct degradation rates, devices a to e. The devices are arranged in order of lowest to highest crosslink density, or most rapid to slowest degradation rate from a to e. Nerves trunks regenerated in devices c and d, characterized by intermediate levels of the crosslink density and degradation rate (device half-life: 2—3 weeks), showed superior morphology, with significantly larger axons, a more well-defined myelin sheath, and a significantly larger N-ratio. Light micrograph images of toluidine blue stained cross-sections of regenerated axons taken from the midpoint of the 15 mm gap. Scale bar = 25 μm [71].

EXAMPLES OF *IN VIVO* ORGAN REGENERATION

Skin regeneration

Patients exhibiting skin wounds with loss of a substantial fraction of total body surface area (TBSA) face an immediate threat to their survival, originating primarily from the loss of their epidermis. One result of this loss is an increase by an order of magnitude of the moisture evaporation rate, which if left uncorrected, leads to excessive dehydration and shock. Another result is a sharp increase in risk of massive bacterial infection, which if allowed to progress, frequently resists treatment and leads to sepsis. Even when patients manage to survive these immediate threats, there is a residual serious problem of quality of life, originating from the occurrence of crippling contractures and disfiguring scars due to the physiological repair process. Conventional treatment is based on use of autografting, which yields excellent results at the treatment site but which is burdened by the trauma caused at the donor site as well as by the unavailability of donor sites when the TBSA exceeds about 40–50%.

Of the three major tissue types that together comprise skin, the epidermis and basement membrane layers regenerate spontaneously following injury provided there is a dermal substrate (stromal layer) underneath. Complete regeneration of the damaged epithelia and basement membrane is typically observed following first and second degree burns, small cuts and scrapes, and blisters. However, complete skin regeneration is not observed in the case where substantial damage to the underlying stroma occurs; such cases include third-degree burns, deep cuts, and scrapes. In these cases, similar to the full-thickness, anatomically well-defined wounds created for studies of skin regeneration, organized wound contraction and scar synthesis is observed. A more in-depth description of the skin tissue triad, salient anatomical features, and its regenerative capacity has been previously published [1].

In addition to the clinical success of the collagen-based DRT, there are four other technologies developed to induce skin regeneration that have achieved variable levels of success that will be briefly discussed here to motivate further thought about scaffold-based options for treating severe injuries. Since its launch, this device (Integra Dermis Regeneration TemplateR) has been used with over 200,000 patients suffering skin loss around the world (Trasca T., Integra LifeSciences, Plainsboro, NJ). In the following section, the DRT, Cultured Epithelial Autograft (CEA), Living Dermal Replacement (LDR), Living Skin Equivalent (LSE), and the Naturally Derived Collagen Matrix (NDCM, Alloderm) will be discussed.

The DRT is a collagen-glycosaminoglycan scaffold whose microstructural and materials properties have been optimized to produce a bioactive ECM analog that, when implanted, induces sequential regeneration of the underlying dermis and resultant regeneration of the basement membrane and epithelial layers. The effectiveness of the DRT has been demonstrated clinically with a population of massively burned patients [1,58] and in animal experiments utilizing a full-thickness (anatomically well-defined) skin wound [1,13,68].

The DRT is typically used as an acellular implant that induces regeneration of the dermis, thereby providing the essential substrate for spontaneous regeneration of the epidermis and basement membrane layers. Following dermal regeneration by the unseeded DRT, epidermal cells from the wound edges migrate into the center of the wound and form a mature epidermis and basement membrane in a process termed sequential regeneration [58,96–99]. The resultant regeneration of appropriate tissue layers (tissue triad) along with associated structures (i.e., rete ridges) has indicated that the DRT is capable of inducing regeneration of mature skin in a full-thickness skin wound model (Fig. 18.5) [100].

Clinically, the DRT is used as an acellular, bilayer device consisting of an inner layer of the active ECM analog and an outer layer of elastomeric poly(dimethyl siloxane). The layer of silicone is removed about two weeks after grafting the device, having served the important

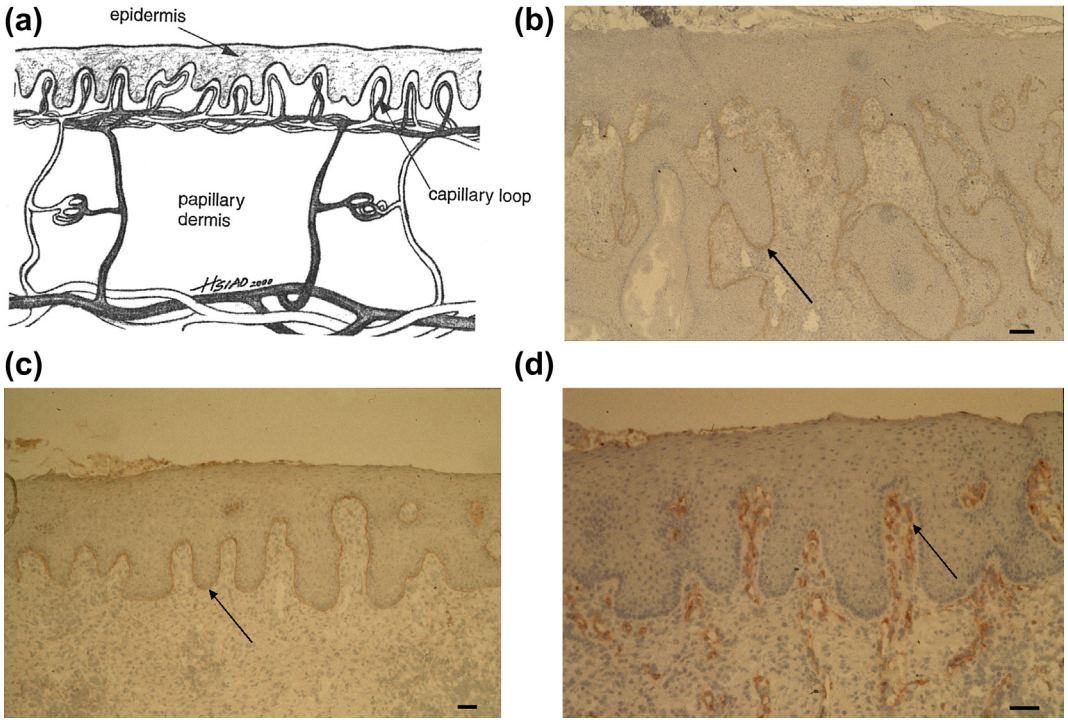

FIGURE 18.5
Diagram of normal skin showing the characteristic rete ridges at the dermo-epidermal junction and the vascular network (capillary loops) that populates the subepidermal region (a) [1]. As early as 12 days after grafting a full-thickness skin wound with a keratinocyte-seeded DRT, anchoring fibrils were observed in the regenerating basement membrane (arrow). The basal surface epithelium and the periphery of the epithelial cords are labeled with type VII collagen immunostaining, identifying the anchorage structures at the dermo-epidermal interface. Bar: 150 μm (b). As early as 35 days after grafting a full-thickness skin wound with a keratinocyte-seeded DRT, a confluent hemidesmosomal staining pattern is observed at the dermo-epidermal junction (arrow) by immunostaining for the $\alpha_6\beta_4$ integrin. The pattern observed in the regenerating skin is identical to that observed in physiologic skin. Bar: 100 μm (c). A full-thickness skin wound grafted with a keratinocyte-seeded DRT was observed to regenerate many of the structure observed in normal skin. Immunostaining for Factor VIII 35 days after grafting revealed that capillary loops had formed in the rete ridges of the regenerated dermis (arrow) similar to those observed in physiologic skin. Bar: 75 μm. (d) [100].

temporary role of controlling moisture flux and bacterial invasion at the site of organ synthesis. The DRT is fabricated from collagen-glycosaminoglycan copolymer with a 98:2 ratio of microfibrillar, type I collagen to chondroitin 6-sulfate. The microstructure of the DRT has been optimized with both a lower and upper pore size bound of 20 ± 4 μm and 125 ± 35 μm, respectively. Additionally, the biodegradation rate of the DRT has been optimized with lower and upper bounds of residence time in the wound bed of 5 and 15 days, respectively [1,13]. Clinical use of the DRT has emphasized the treatment of patients with massive burns, as well as those who require resurfacing of large or small scars from burns. The DRT is responsible for regenerating the underlying dermal architecture, providing the appropriate stromal layer upon which native regenerative processes of the basement membrane and epithelial layer can take place. For wounds of relatively small characteristic dimension, e.g., 1 cm, epithelial cells migrating at speeds of order 0.5 mm/day from the wound edges can provide a confluent epidermis within 10 days. In such cases, the unseeded DRT fulfills all the design specifications set for successful *in vivo* skin regeneration. However, the wounds incurred by a massively burned patient are typically of characteristic dimension of several centimeters, often more than 20–30 cm. These wounds are large enough to preclude formation of a new epidermis by cell migration alone within a clinically acceptable time frame. Current clinical protocol favors harvesting and use of a very thin autoepidermal graft from another part of the patient's body, thin enough not to leave behind a scarred donor site, to cover the neodermis [58,101,102], or

application of a CEA (described below) on top of the DRT following removal of the poly(dimethyl siloxane) membrane.

A keratinocyte-seeded DRT has been used in guinea pig and swine animal models; the keratinocyte-seeded DRT induces simultaneous formation of a dermis as well as the epidermal and basement membrane layers and removes the requirement for epithelial cell-mediated migration from the wound edges for successful skin regeneration. Although the keratinocyte-seeded DRT induces simultaneous regeneration of skin in the guinea pig model, an animal model characterized by extensive organized wound contraction that is significantly more severe than that observed with humans, the sum total of the results of studies using the DRT suggest that *in vivo* synthesis of skin in the clinical setting does not require anything more than the DRT [1].

CEAs are an epidermal graft formed from a sheet of keratinocytes grown *in vitro* and then implanted into the wound site [103–105]. A small epidermal sample is removed from the patient, dissociated, and the resultant cells are then cultured *in vitro* until they form an epithelial membrane. However, in the case of full-thickness skin wounds where there is no underlying dermis to support the epidermal sheet, rapid CEA degradation is typically observed and long-term clinical applicability has not been observed; in particular, one persistent problem is the formation of blisters under large areas of the graft (avulsion). However, in the case of partial-thickness wounds where a significant portion of the stroma remains, the 'take' of the CEA graft has been very good. As such, the CEA has been used to cover significant areas, as large as 50% of the TBSA, for both partial-thickness and as a temporary solution for full-thickness wounds to prevent immediate wound dehydration and infection. Additionally, regardless of whether the graft was placed on a partial- or full-thickness skin wound, the resulting CEA graft exhibited mechanical fragility due to a lack of the 7-S domain of type IV collagen, anchoring fibrils, and rete ridges [57]. These structures, required for the formation of a physiological dermo-epidermal junction, as well as the formation of a physiological collagen and elastin fiber architecture observed in the normal, adult dermis are not formed after grafting of the wound site with the CEA. Without these structures, the CEA cannot be used as a permanent skin replacement; instead, the CEA is often used as a temporary coverage as part of a more substantial treatment regimen such as autografting or DRT implantation.

The LDR is a polyglactin-910 nylon surgical mesh scaffold fabricated from a copolymer of 90 wt% glycolic acid and 10 wt% lactic acid termed PGL that was developed to be an analog of the ECM and induce skin regeneration following injury. The PGL fibers, approximately 100 μm in thickness, were knitted into a mesh that exhibits a pore microstructure with a characteristic dimension of 280–400 μm. This mesh structure presented a large-weave structure, relative to the characteristic cell dimension of approximately 10 μm that allowed rapid cell incorporation and ample nutrient diffusion. Prior to implantation, the acellular PGL mesh was cultured *in vitro* with fibroblasts until the cells were observed to synthesize several important ECM components such as collagen and elastin *in vitro*. Immediately prior to implantation, the upper surface of the PGL scaffold was seeded with keratinocytes to produce a bilayer graft. Once the keratinocytes reached confluence on the surface of the PGL mesh, the entire structure was grafted into the wound site [106]. A thin, fragile epidermal layer typically developed by 10 days post-grafting and became cornified as early as 20 days post-grafting. Additionally, by 20 days post-grafting the LDR scaffold had degraded completely with minimal inflammatory response. While the interface between the graft and the wound bed stained positive for laminin, consistent with the synthesis of a lamina lucida layer, no other component of the basement membrane was synthesized. In addition, rete ridges were not synthesized and a thick layer of fibrotic tissue with a large fibroblast population and vascular in-growth, characteristic of scar tissue formation, was observed below the newly synthesized epidermal layer. In summary, while the LDR showed the ability to induce regeneration of a neo-epidermis, it did not exhibit the ability to induce regeneration of a complete basement membrane or dermal layer [106].

The LSE was formed by populating a collagen lattice with dermal fibroblasts that *in vitro* contracted the lattice and synthesized additional ECM proteins, forming a neo-dermal layer [107]. Similar to the LDR, after the initial culture period, the upper surface of the neo-dermal layer was seeded with a suspension of keratinocytes. Once seeded, the keratinocytes attached to the collagen construct, proliferated, and differentiated to form a multilayered, epidermal structure within one to two weeks, all *in vitro*. Although short segments of the lamina densa were observed along the dermo-epidermal convergence *in vitro*, the cultured LSE did not exhibit a complete basement membrane layer, Rete ridges, or any other skin appendages at the end of the *in vitro* culture period [108]. At this point, the construct was then implanted into the wound site. Continued structural and biological changes were observed in the LSE following grafting, indicating that remodeling was taking place. A functional, fully differentiated epidermis was observed as early as seven days following grafting, and by fourteen days a vascularized subepidermal layer with many of the structural characteristics of normal dermis, such as a 'basketweave' collagen fiber pattern, was present. However, continued maturation into a formalized dermal region was not observed. Experimental results across multiple animal models and experimental trials were consistent in indicating that the LSE was able to induce regeneration of a mature epidermis and basement membrane, but a mature dermal layer was not observed and the dermo-epidermal junction remained flat.

Instead of relying on technologies to fabricate a three-dimensional scaffold structure from either synthetic or natural materials (i.e., LSE, LDR, DRT), the NDCM technology uses decellularized dermal tissue as a scaffold to induce skin regeneration. Decellularized matrices were explored as platforms that possess favorable mechanical properties for surgical handling, and which contained a surface chemistry in many ways similar to that of the native ECM [109]. The main advantage of the NDCM over a homograft (cellularized dermal tissue from a human donor) and xenograft (cellularized dermal tissue from an animal donor) is that owing to decellularization, the antigenicity of the scaffold is significantly reduced, thereby eliminating the incidence of rejection. The NDCM has been used primarily to treat full-thickness burns and burns to areas of the skin where contraction and scar formation would inhibit functionality (i.e., feet and hands). The NDCM is typically implanted into full-thickness skin wounds and is often covered by a thin autograft of the patient's own epidermis to speed the healing process. This treatment, similar to that observed with the use of the DRT, results in a high percentage of graft take; additionally, the thin autograft of epidermal tissue significantly decreases the time for complete graft re-epithelialization. Patients showed normal range of motion, grip strength, motor control, and functionality along with formation of appropriate anatomical structures (i.e., rete ridges) following treatment [110,111], demonstrating the utility of a naturally derived material in tissue-engineering applications.

Peripheral nerve regeneration

The mammalian peripheral nervous system also consists of a distinct tissue triad. Thousands of axons make up a nerve trunk where each axon is surrounded sequentially by an epithelial, basement membrane, and stromal layer. Schwann cells wrap around the individual axon, forming the myelin sheath that constitutes the cell-continuous, epithelia [112]. Surrounding the epithelia is the acellular ECM layer (basement membrane) connecting the myelin sheath and the stromal layer (Fig. 18.1). The endoneurium is the stromal layer of cells, blood vessels, and ECM that surrounds, insulates, and protects all nerve fibers [1]. Similar to that observed with skin, the myelin sheath (epithelia) and basement membrane regenerate spontaneously following injury (Fig. 18.6) while the endoneurium (stromal layer) does not [1,91].

GENERAL FINDINGS

While there have been a large number of studies investigating many different device designs, few have been shown to perform as well as the peripheral nerve autograft (typically the sural

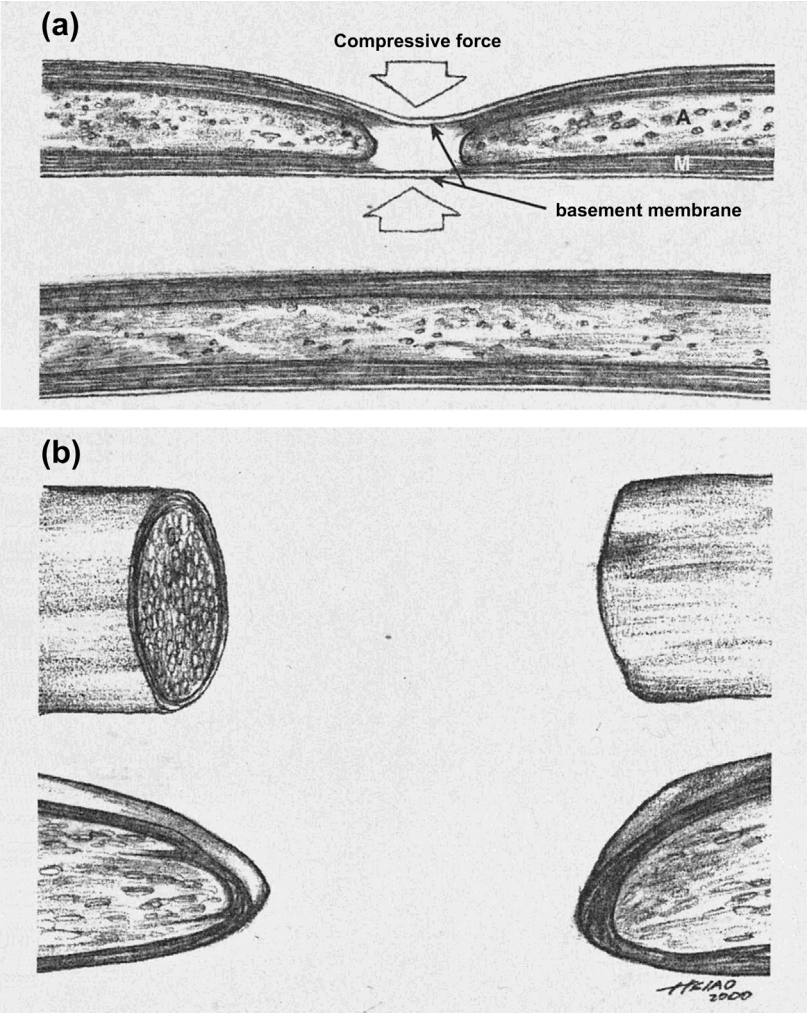

FIGURE 18.6
Axons and myelin sheath inside a nerve fiber are regenerative. Following mild crush injuries, the axoplasm (A) and myelin sheath (M) degenerates along the length of the crushed nerve fiber, but the basement membrane remains intact throughout. Spontaneous regeneration of the nerve fiber occurs within a few weeks of injury (a). Most of the supporting tissues (stroma) surrounding nerve fibers are not regenerative. Although axons are regenerative following transection, the remainder of the nerve trunk is not. Following transection, each stump is closed via cell-mediated contraction and neuroma synthesis (b) [1].

nerve from the leg), and none appear to have been able to improve over the autograft for gaps larger than 10 mm [113]. For studies of peripheral nerve regeneration, complete axotomy (total severance of the nerve trunk) was utilized as the standardized wound model. However, the large number of assays and experimental arrangements employed by independent investigators has made it difficult to effectively compare experimental outcomes. A new methodology has recently been formalized to standardize this comparison, allowing for effective assessment of the quality of peripheral nerve regeneration [114]. This technique compares the frequency of reinnervation (%N) across the experimental gap. The frequency of reinnervation across a gap is reported as percent of nerve trunks fitted with an experimental chamber where axons are observed to bridge the gap between the transected stumps; %N has been used by a large number of investigators as a dimensionless measure of nerve regeneration and, when not reported directly, can often be calculated from data presented by individual investigators.

The investigator reported %N can be normalized to correct for the effect of changes in gap length, animal species, and experimental chamber; the normalization process calculates the critical axon elongation length (L_c) [114], and is based on analysis of data from an early study which showed that a relatively small increase in the gap length bridged by a silicone tube is followed by a sharp drop in %N 115. Data from this and several other reports have been used to construct a sigmoidal curve, termed a 'characteristic curve', for %N versus gap length (L) for the silicone tube configuration. The critical length (L_c) is a single quantitative

parameter that describes the effectiveness of a given nerve repair device in promoting nerve regeneration, and is calculated as the length where the particular device results in 50% reinnervation (and 50% formation of neuroma). Reinnervation at the midpoint is used in this calculation rather than reinnervation at the distal stump because elongating axons reach the gap midpoint faster than the distal stump so midpoint data reach a time-independent state earlier than distal stump data. Given the widespread use of the unfilled silicone tube in studies of rat sciatic nerve defects, its characteristic curve ($L_c = 9.7 \pm 1.8$ mm) is often used to define a laboratory standard for all comparisons, allowing comparison of other experimental devices to the silicone standard by comparing their respective characteristic curves and L_c. Using the silicone tube or any other well-defined construct as a control, it is possible to estimate the length shift, $\triangle L$, the difference between values of L_c for the experimental chamber and that of the control. $\triangle L$ can be used as a simple measurement of relative regenerative activity exhibited by any device. Data obtained from different animal models can also be compared by normalizing each species result to the silicone tube standard tested in most animal models [114].

EFFECT OF TUBULATION

Peripheral nerve regeneration is not observed in the absence of a tubular device connecting the two ends of a transected nerve stump if the gap between the two transected stumps is greater than a few millimeters [1]. It has also been observed that insertion of the distal stump into the tube is required for successful regeneration [1,113]; this result indicates that even though axon elongation takes place from the proximal to the distal stump, the distal stump appears to provide a critical cytokine field responsible for guiding axon elongation (neurotrophic effect). However, while it has been observed that a tube is all that is required to induce regeneration across a gap of modest length following complete transection, the physical parameters of the tube and any material in the tube lumen significantly affect the kinetics and quality of regeneration; these effects will be discussed in the remaining sections of this review.

EFFECT OF TUBE CHEMICAL COMPOSITION

A variety of natural and synthetic polymers have been used in peripheral nerve regeneration conduits, and the choice of tube (conduit) composition has been found to significantly affect the quality of regeneration; for a complete review of the literature, please consult previous publications by the authors [1,116]. Early conduits were produced from naturally occurring materials that were easily harvested and implanted such as bone, dura, perineurium, and blood vessels [1]. More recent devices have utilized non-degradable, synthetic materials such as stainless steel, rayon, and silicone as well as degradable, synthetic polymers such as polyester, polyglactin, and polylactate, and natural polymers such as collagen, laminin, and fibronectin [1,117].

Non-degradable tubes have typically resulted in a poor quality of regeneration marked by significant formation of a neural scar (neuroma) [1,118]. Conversely, conduits fabricated from ECM components, specifically collagen, fibronectin, and laminin, have been generally shown to enhance the quality of peripheral nerve regeneration [1,86,91,119–123]. Collagen tubes in particular have been observed to induce the highest quality of regeneration, as measured by both morphological and electrophysiological methods [1,91,124]. It has been hypothesized that this optimal chemical composition was observed because collagen tubes contain inherently bioactive binding sites (ligands) for attachment and migration of various cell types, and can be manufactured in such a way that the tube wall pore structure can display a range of cell and protein permeabilities. Additionally, the degradation rate of the collagen tubes can be tailored to degrade with half-lives that vary over a very wide range to meet the requirements of the isomorphous tissue replacement model [71,86].

EFFECT OF TUBE PERMEABILITY

Conduit permeability significantly affects the mechanism and quality of peripheral nerve regeneration. Tube permeability can be defined by its initial structural features (i.e., scaffold porosity, pore size) or its degradation characteristics (i.e., rapid degradation quickly permeabilizes the tube). Additionally, the conduits may be protein permeable but cell impermeable or cell and protein permeable. No appreciable increase in the quality of peripheral nerve regeneration was observed for the protein permeable and cell impermeable conduit compared to the impermeable conduit [125–127]. However, cell (and therefore protein) permeable tubes exhibited significantly superior regenerative capacity compared to impermeable as well as protein permeable and cell impermeable conduits [1,127–132]. Device permeability also significantly influences the contractile response following peripheral nerve injury; permeable collagen tubes display a significantly thinner contractile capsule surrounding the regenerating nerve trunk than biodurable silicone tubes [118]. It is hypothesized that device permeability reduces myofibroblast-mediated contraction of the wound site by permitting migration of the contractile cells away from the wound site through the tube wall [1] and by allowing connective tissue cells from the surrounding environment access to the tube lumen [125].

EFFECT OF TUBE DEGRADATION RATE

A biodurable conduit, such as a silicone tube, initially induces partial reinnervation between proximal and distal stumps following implantation [118]. However, as the initially regenerated nerve trunk remodels and matures, the silicone tube constricts this process, resulting in pain and eventual degeneration of the regenerated nerve; prevention of the ultimate degeneration of the initially regenerated nerve trunk requires a difficult second surgical procedure that can further harm the nerve trunk. For this reason, one of the historical goals in studies of peripheral nerve regeneration studies is identification of a suitable degradable conduit. Superior performance of biodegradable tubes compared to tubes made from materials that were either biodurable or which had a very low degradation rate has since been reported in studies by several investigators [1,71,130,133–137]. Examples include comparison of tubes made of two biodurable polymers, silicone and poly(tetrafluorethylene), and two degradable polymers, a copolymer of poly(lactic acid) and ε-caprolactone (PLA/PCL) as well as collagen [137]. This study indicated that the degradable tubes induced a higher quality of regeneration compared to the biodurable tubes over a 6 mm gap in the mouse sciatic nerve. Additionally, a number of degradable collagen tubes have been shown to perform as well as the autograft, considered to be clearly superior to regeneration via a silicone tube and commonly thought to fall short functionally only of physiological (pre-injury) nerve [91,124,138–141].

While the regenerative advantage of a degradable tube versus a biodurable tube is supported by the evidence, there have not been many extensive studies on the effect of the magnitude of the degradation rate and whether an optimal degradation rate exists as has been found in the study of ECM analogs (the DRT) to induce skin regeneration [13]. Recently, one of the first comprehensive studies of the effect of the degradation rate of collagen tubes on the quality of peripheral nerve regeneration has been published by these authors; this study utilized a 15 mm gap in the rat sciatic nerve and evaluated the regenerative capacity of a homologous series of porous, collagen tubes, showing a significant effect of degradation rate on the quality of peripheral nerve regeneration [71]. The chemical composition, pore structure, and permeability of the conduits in this study were kept constant while the crosslink density was steadily increased to create a series of five devices with *in vivo* degradation half-lives varying between <1 week to >100 weeks, The quality of peripheral nerve regeneration was observed to vary significantly with tube degradation rate; the highest quality of peripheral nerve regeneration was observed for tubes with a degradation half-life of two to three weeks (Fig. 18.4) [71]. This data suggests that the positive effects of tubulation in treating peripheral nerve injuries are due to the presence of the tube immediately following injury; tubulation appears to significantly affect the early mechanisms of peripheral nerve regeneration. A speculative view

of the maximum regenerative activity observed in the present study can be based on the putative existence of a lower and higher limit in tube degradation rate similar to that observed for the DRT [13]. When the degradation rate of the collagen tubes is excessively slow, the tubes behave as if they were biodurable, remaining intact long enough to interfere with tissue remodeling. In contrast, tubes that degrade very rapidly fail to maintain a protected environment for regeneration that is the basis for the use of tubulation to promote nerve regeneration.

EFFECT OF TUBE FILLING

A wide variety of solutions, ECM analogs, and cell suspensions have been introduced into the tube lumen in an effort to improve the quality of peripheral nerve regeneration. Use of ECM macromolecules, such as collagen, laminin and fibronectin, in both solution and gel form, has been observed to have no significant effect on peripheral nerve regeneration; furthermore, when gel concentrations exceeded certain critical levels, a negative effect on the quality of regeneration is observed [121]. However, a laminin-coated collagen-based scaffold has been observed to improve the quality of regeneration, implying the requirement of an insoluble structure within the tube lumen in addition to any soluble regulators to improve the quality of regeneration [123].

Several insoluble substrates, ECM analogs inserted into the empty lumen of the tube prior to implantation, have shown significant regenerative activity. Examples include highly oriented fibrin fibers and axially oriented polyamide filaments that significantly improved the quality of regeneration [142–144]. Specific ECM analogs have been observed to significantly increase the maximal gap length that can be bridged by axonal tissue [1,120,145], the speed of axonal bridging [119,123], and the quality of regeneration [1,86,91].

The ECM analog that has been found to induce the highest quality of regeneration is a collagen-based scaffold termed the NRT [1,146]. The NRT has induced regeneration of a functional peripheral nerve across gaps varying from 10 to 15 mm in the rat sciatic nerve [1,91]. Like the DRT, the microstructural and material properties of the NRT have been optimized. The highly bioactive NRT is characterized by axially (extending between the proximal and distal stumps) elongated pore tracks defined by axially oriented ellipsoidal pores with a mean pore size of approximately 35 μm [86,147]. This pore structure is hypothesized to improve the quality of peripheral nerve regeneration by providing directional guidance to the formation of linear Schwann cell columns which act as tracks for axon elongation (microtube hypothesis) [1,148]. The positive effect of an axially oriented fiber structure has also been observed using a fibrin fiber-based ECM analog in the tube lumen [142]. The degradation rate of the NRT has also been found to significantly affect the quality of regeneration, with an *in vivo* degradation half-life on the order of six weeks found to be optimal; NRT variants that degraded too rapidly or too slowly led to significantly poorer functional recovery [1,146]. The long-term morphological structure and electrophysiological function of nerves regenerated using the NRT has been observed to be at the level of an autografted nerve, the current gold-standard for peripheral nerve injury treatment [91,149].

Soluble regulators and cell suspensions have also been introduced into the tube lumen in an effort to improve the quality of regeneration. Suspensions of Schwann cells showed very significant regenerative activity [150], further supporting the microtube hypothesis which describes nerve regeneration as dependent on early formation of linear columns of Schwann cells extending from the proximal towards the distal nerve trunk. In addition to the use of a cell suspension, solutions of acidic (aFGF) and basic fibroblast growth factor (bFGF) were also observed to improve the quality of regeneration [151,152]. However, the use of nerve growth factor (NGF) was not found to improve the quality of regeneration [153].

A variety of conclusions have been drawn about the relative efficacy of the various biomaterials and devices employed in the study of peripheral nerve regeneration. Nerve chamber configurations that had the highest regenerative activity were those in which the tube wall comprised certain synthetic biodegradable polymers such as collagen, was cell-permeable rather than protein permeable or impermeable, and had an *in vivo* degradative half-life on the order of 2 to 3 weeks. Introduction of an insoluble regulator (ECM analog in the form of a scaffold) into the tube lumen, but not of ECM components in a gel or solution form, also significantly improves the quality of regeneration. The optimal ECM structures were found to be highly porous with controlled degradation rates and an axially aligned microstructure. In addition, suspensions of Schwann cells as well as solutions of either acidic or basic fibroblast growth factor placed within the tube lumen with or without an insoluble ECM analog have been shown to improve the quality of regeneration.

Cartilage and fibrocartilage disk tissue-engineering applications

Articular cartilage contains an avascular, non-neural ECM composed primarily of type II collagen and glycosaminoglycans. Compared to other tissues, cartilage possesses a very low cell density and a very high ECM density; the chondrocytes populating the cartilaginous ECM display low proliferative activity and, due to the high ECM protein density, are unable to migrate through the tissue. Due to the low proliferative activity, avascularity, and high ECM protein density, injuries to cartilage display an injury response distinct from traditional injury responses characterized by inflammatory processes, cell-mediated contraction, and scar synthesis. No repair or regeneration processes are observed *in vivo* following cartilage injuries; instead, the scope of injury increases as the wound edges become increasingly degraded, eventually compromising the joint [95]. Severe cartilage injuries are extremely prevalent in today's active society, resulting in pain, decreased patient activity, and eventually disability, profoundly impacting quality of life. The current methods for treating such focal cartilage defects include microfracture, autologous chondrocyte implantation, and osteochondral autografting [95]. In the case of microfracture and autologous chondrocyte implantation, a flap of periosteum is sewn over the cartilage defect area and is sealed with fibrin glue. With microfracture, immediately prior to application of the periosteal flap, microfractures in the subchondral bone are created to allow bone marrow cells access to the then-sealed cartilage defect in an attempt to utilize the stem cell population in the bone marrow to regenerate the damaged cartilage. With autologous chondrocytes implantation, a biopsy of cartilage tissue is removed from the patient prior to surgery and cultured *in vitro* to obtain a large chondrocyte population that is then injected back into the periosteal flap sealed cartilage defect. In the case of osteochondral autografting, a series of osteochondral plugs consisting of cartilage, the underlying subchondral bone, and the tidemark region separating them are removed from a non-loading region at the edge of the damage joint. These plugs are then implanted into the primary cartilage defect using an approach termed mosaicplasty, named after the mosaic pattern of the implanted osteochondral plugs [95]. These procedures, however, exhibit limited long-term success in treating the cartilage injury. Preclinical studies implementing tissue-engineering approaches have yielded results that represent improvements over the currently employed cartilage repair procedures.

Various synthetic and natural materials have been employed to fabricate porous, bioresorbable scaffolds for articular cartilage tissue engineering. Among the list of bioresorbable or partially resorbable materials used for cartilage repair are collagen, hyaluronan, fibrin, polylactic acid (PLA) and polyglycolic acid (PGA), and chitosan scaffolds and gels, devitalized cartilage, hydroxyapatite, demineralized bone matrix, and bioactive glass [95]. Natural polymers such as collagen provide a more native surface to cells, and have been the primary focus of tissue-engineering studies due to previous successes in peripheral nerve and skin regeneration. Studies have confirmed that the addition of cells seeded within these 3D scaffolds enhance matrix synthesis and increase type II collagen production *in vivo* and *in vitro*

[95,154,155]. There are various cell types that may be used to enhance cartilage synthesis when seeded into matrices, including articular chondrocytes and chondroprogenitor cells derived from bone marrow, periosteum, or perichondrium [95,154].

Preliminary investigations have been focused on the bioactivity of chondrocytes in a series of ECM analogs. Promising results have been observed for adult articular chondrocytes cultured *in vitro* in type II CG scaffolds, where the chondrocytes have retained high biosynthetic capacity for producing type II collagen, the predominant ECM component of cartilage [156]. Type II CG scaffolds seeded with autologous, articular chondrocytes have also been evaluated for their *in vivo* regenerative capacity in a full-thickness cartilage injury model; the full-thickness cartilage injury, with cartilage removed down to the subchondral bone, is the standardized, anatomically well-defined wound utilized for *in vivo* studies of cartilage regeneration. The greatest total amount of reparative tissue was found in the cell-seeded type II CG scaffolds as opposed to unseeded type II CG scaffolds and seeded or unseeded type I CG scaffolds. Moreover, examination of the reparative tissue formed in the subchondral region of defects treated with the chondrocyte-seeded type II collagen scaffolds indicated that the majority of the tissue was positive for type II collagen and that good integration was observed between the implant and the surrounding cartilage. These results indicate an influence of the exogenous chondrocytes on the process of chondrogenesis [157]. Such studies of the healing of chondral defects in animal models have revealed that there is some potential for regeneration of this connective tissue. The introduction of certain biomaterial scaffolds along with selected surgical procedures and cell therapies has been demonstrated in animal studies to facilitate the cartilage reparative process and now offers the promise of extending the longevity of clinical treatments of cartilage defects [154,155,158]. Recently, CG scaffolds populated with TGF-β1 transfected meniscus cells were used to successfully fill avascular zone meniscus lesions with repair tissue [159]. Other work has compared type I and type II CG scaffolds for intervertebral disk tissue-engineering applications, finding that type II CG scaffolds were preferential to type I on the basis of cell number as well as protein and GAG synthesis [160].

In a separate series of studies, the regenerative potential of chondrocytes encapsulated in photopolymerized poly(ethylene oxide) hydrogels and self-assembling peptide hydrogels gels have been tested using an *in vitro* culture model followed by *in vivo* implantation. Preliminary results suggest that photocrosslinked [161] and self-assembling hydrogels [162,163] are promising scaffolds for tissue-engineering cartilage as cell viability was maintained, uniform cell seeding was achieved, the biochemical content of the ECM proteins synthesized within the construct were similar to those found in native cartilage [161,162]. Additionally, the importance of the biomechanical environment during *in vitro* culture of chondrocytes within a three-dimensional construct has been observed; improved biosynthesis of ECM components, notably native proteoglycans, is observed when a cyclic loading environment is applied to *in vitro* chondrocytes cultures within a series of hydrogel and scaffold constructs [164]. Collectively these findings provide the basis for the rational development of approaches for the more complete regeneration of articular cartilage, and demonstrate that meaningful clinical outcomes can be achieved even if complete regeneration is not achieved [154,155,158].

Bone, osteochondral regeneration applications

In addition to solidification-induced structural modifications, the CG construct can be chemically modified to create collagen composites. Mineralized CG scaffolds are of particular interest for orthopedic applications due to their potential to mimic the native biochemistry of bone: interpenetrating collagenous matrix (organic) and CaP (mineral) content [165,166]. The addition of a mineral phase to the classic CG scaffold archetype allows for the development of materials with the requisite biochemical and biomechanical properties for bone and osteochondral tissue engineering. Mineralized CG scaffolds have been created via two distinct mechanisms: coating a fully formed CG scaffold, or synthesizing mineralized CG chemistries

prior to scaffold fabrication. Mineralized collagen-GAG have been fabricated via a surface coating process [167]. Here, CG scaffolds were initially synthesized using conventional freeze-drying and then sequentially soaked in phosphate ($NaNH_4HPO_4$) and calcium ($CaCl_2$) solutions. This treatment improved construct compressive modulus nearly 70-fold, from 0.3 kPa to 31 kPa, while maintaining high porosity (95%) [167]. Alternatively, CGCaP scaffolds have been fabricated from a triple co-precipitate suspension of collagen, GAG, and calcium phosphate (CaP) [168,169].

The CGCaP scaffold technology has been used as the basis for creating multiphase collagen scaffolds for the repair of interfacial tissues, notably osteochondral defects. The multi-compartment scaffold was designed to be a single biomaterial construct containing multiple regions ('compartments'), each with distinct microstructural, chemical, and mechanical properties that are connected via a continuous interface between regions. The initial multi-phase scaffold developed via this approach contains an osseous compartment for subchondral bone regeneration (type I collagen, chondroitin 6-sulfate, and CaP) and a cartilagenous compartment for cartilage regeneration (type II collagen and chondroitin 6-sulfate). The continuous interface can be created by layering the cartilaginous compartment and the osseous compartment suspensions in a conventional freeze-drying mold, but then incorporating a processing step to enable partial diffusive mixing between the two suspensions near their interface. After forming an interdiffusion zone, freeze-drying was used to form the final multicompartment scaffold microstructure (Fig. 18.7) [170]. This approach can reduce some complications observed in layered scaffolds with abrupt interfaces including delamination, foreign body contamination (from glue or other adhesive), and inefficient cellular transport between scaffold phases [170]. The differential chemistry, microstructure, and mechanics of the osseous and cartilaginous compartments enable these layered scaffolds to exhibit compressive deformation behavior that mimics behavior observed in natural articular joints [170]. These layered scaffolds are currently the subject of numerous *in vitro* and *in vivo* experiments for various orthopedic tissue-engineering applications. This scaffold system has shown improved healing of osteochondral defects in a caprine model [171] and is currently undergoing Phase I clinical trials for primary and secondary (backfill of traditional mosaicplasty harvest sites) osteochondral defects in the knee. The developed technologies and techniques may hold promise for the regeneration of not only osteochondral defects, but also other orthopedic interfaces such as the osteotendinous insertion.

CONCLUSIONS

Following severe injury, the typical physiological response is characterized by a complex inflammatory response, cell-mediated wound contraction, and scar tissue synthesis characterized as repair. However, introduction of a suitable analog of the extracellular matrix into the wound site has been observed to block cell-mediated contraction of the wound site and induce regeneration of physiological tissue. Although several ECM analogs have been studied, only those with a narrowly defined structure have been shown to be capable of regeneration. The microstructural, chemical compositional, and biodegradation rate specificity of these templates appears to be related to the requirement for inhibition of wound contraction prior to the incidence of regeneration. A number of appropriate materials have been developed and tested for use in particular *in vivo* wound sites, notably the skin, peripheral nerve, conjunctiva, and cartilage. The results of *in vitro* and *in vivo* investigations of many biomaterial constructs suggest that the properties of an ECM analog must be tailored to the specific wound site and species, requiring further development of appropriate *in vivo* and *in vitro* models to further understand the complexity of cell-scaffold interactions and the process of induced regeneration.

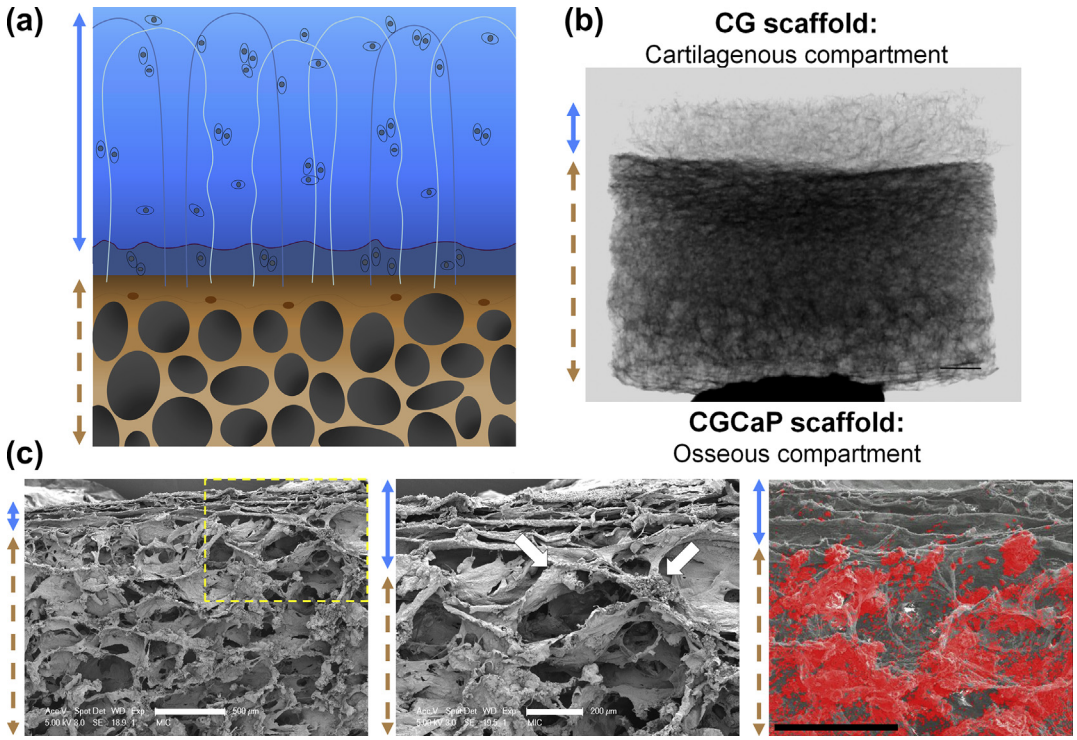

FIGURE 18.7

a) Structure of the natural articular joint showing articular cartilage and subchondral bone joined by a continuous interfacial region. b) X-ray μCT image of the layered osteochondral scaffold showing distinct cartilaginous and osseous compartments (scale bar 1 mm). c) Scanning electron microscope (SEM) images of the osteochondral scaffold showing the complete scaffold microstructure (left; scale bar 500 μm), and the interfacial region (middle; scale bar 200 μm) showing continuity between the osseous (tan dashed arrow) and cartilaginous (blue solid arrow) compartments including collagen struts extending across the transition (white arrows). No regional areas of delamination or debonding are observed between the compartments. Distribution of Ca mineral (P similar but not shown) content (red shading) superimposed over an SEM image of the osteochondral scaffold showed distinct mineralized (high CaP content, tan dashed arrow) and non-mineralized (low/zero CaP content, blue solid arrow) layers (right; black scale bar 400 μm). *Reprinted with permission from [170].*

INTRODUCTION

Control of the cellular environment is crucial for understanding the behavior of cells and for engineering cellular function [1–3]. This chapter describes the use of a set of tools in microfabrication called 'soft lithography' for patterning the substrate to which cells attach, the location and shape of the areas to which cells are confined, and the fluid environment surrounding the cells, all with micrometer precision. We summarize examples where these tools have helped to control the microenvironment of cells, and have been useful in solving problems in fundamental cell biology. The methods described here are experimentally simple, inexpensive, and well suited for patterning biological materials.

How do tissues assemble *in vivo*? How do cells interact with each other in tissues? How do cells respond to stimuli? How do abnormal stimuli give rise to pathological conditions? Answering these fundamental biological questions, and using the information thus obtained for medical applications, requires understanding the behavior of cells in well-controlled micro-environments. Many of the challenges in trying to control the environment experienced by individual cells lie in the relevant scales of size, as well as the character of the stimuli. These scales of size range from angstroms (for molecular detail), through micrometers (for an individual cell), to millimeters and centimeters (for groups of cells); the types of stimuli that must be addressed include the molecular composition of the liquid in which the cell is immersed, the topographical and chemical composition of the surface to which the cells attach, the nature of neighboring cells, and the temperature.

Researchers have used a number of techniques to pattern cells and their environment [4]. Before the 1990s, the most commonly used technique was photolithography, used in biological studies with varying degrees of success [4–6]. Examples include topographical

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00019-7

features that confine the growth of snail neurons to silicon chips, as first demonstrations of interfacing natural computation with artificial ones [7,8]. However, photolithography is not a technique best suited for biological studies. It is an expensive and time-consuming technology; it is poorly suited for patterning non-planar surfaces; it provides too little control over surface chemistry to pattern sufficiently diverse types of biomolecules on surfaces; it is poorly suited for patterning materials such as hydrogels; the equipment required to use it is rarely routinely accessible to biologists; and it is directly applicable to patterning only a limited set of photosensitive materials (e.g., photoresists).

Microfabrication and micropatterning using stamps or molds fabricated from elastomeric polymers ('soft lithography') provide versatile methods for generating patterns of proteins and ligands on surfaces, micro-scale chambers for culturing cells, and laminar flows of media in capillaries, all in the 0.1–100 micrometer size range [1–3,9]. Soft lithographic methods are relatively simple and inexpensive. The elastomeric polymer most often used in these procedures – polydimethylsiloxane (PDMS) – has several characteristics (optical transparency, ease in manipulation, and low cost) that make it attractive for biological applications [10]. As a new technology, soft lithography is being increasingly used in cell biology, due to its biocompatibility, simplicity, and adaptability to biological and biochemical problems. This chapter gives an overview of the application of soft lithography to the patterning of cells and their fluidic environment, using micro-scale features and laminar flows.

SOFT LITHOGRAPHY

Soft lithography solves many of the problems that required the application of microfabrication to biological problems [1,2,11]. Soft lithographic techniques are inexpensive, are relatively procedurally simple, are applicable to the complex and delicate molecules often dealt with in biochemistry and biology, can be used to pattern a variety of different materials, are applicable to both planar and curved substrates [12], and do not require stringent control (such as a clean room environment) over the environment in which they are fabricated beyond that required for routine experiments with cultured cells [2,3]. Access to photolithographic technology is required only to create a master for casting elastomeric stamps or membranes, and even then, the requirement for chrome masks – the preparation of which is one of the slowest and most expensive steps in conventional photolithography – can often be bypassed in favor of high-resolution printing [13,14]. Soft lithography offers special advantages for biological applications, in that the elastomer most often used (PDMS) is compatible with most types of optical microscopy commonly used in cell biology, is permeable to gases such as O_2 and CO_2, is mechanically flexible, seals conformally to a variety of surfaces (including most types of Petri dishes), is generally biocompatible [15], and can be implantable *in vivo*. The soft lithographic techniques that we will discuss include self-assembled monolayers (SAMs), microcontact printing (μCP), microfluidic patterning (μFP), laminar flow patterning (LFP), patterning with micro-topographies, we also introduce application of these tools in dynamic control of surfaces and three-dimensional (3D) patterning.

SELF-ASSEMBLED MONOLAYERS (SAMS)

Introduction to SAMs

Since many of the studies involving the patterning of proteins and cells using soft lithography have been carried out on SAMs of alkanethiolates on gold, we give a brief introduction to SAMs here [16–20]. SAMs are organized organic monolayer films normally formed by exposing a surface of a gold film to a solution containing an alkanethiol (RSH). SAMs allow control at the molecular level by chemical synthesis of derivatized alkanethiol(s); this molecular control, in turn, gives control over the properties of the interface. The properties of surfaces covered with SAMs are often largely or entirely determined by the nature of the terminal groups of these alkanethiols. The ease of formation of SAMs, and their ability to present a range of

chemical functionality at their interface with aqueous solution, make them particularly useful as model surfaces in studies involving biological components. Furthermore, SAMs can be easily patterned by simple methods such as microcontact printing (μCP) with features down to 100 nanometers in size [21,3]. These features of SAMs make them structurally the best-defined substrates for use in patterning proteins and cells. SAMs on gold are used for many experiments requiring the patterning of proteins and cells, because they are biocompatible, easily handled, and chemically stable. SAMs on silver, although better defined structurally than those on gold, cannot be used in most experiments with cultured cells, due to the toxicity of silver [22]. SAMs on palladium and platinum are just starting to be explored [23,24].

The substrates for SAMs are easy to prepare; once formed, SAMs are stable for weeks under conditions typical for culturing cells. Gold substrates are prepared on glass cover slips or silicon wafers by evaporating a thin layer of titanium or chromium (1−5 nm) to promote the adhesion of gold to the support, followed by a thin layer of gold (10−200 nm) [25]. SAMs formed on these gold substrates are stable to the conditions used for cell culture, but care should be taken to avoid strong light and temperatures above ~70°C since both can result in degradation of the SAM [26,21].

Preventing protein adsorption: 'inert surfaces'

Proteins play an integral part in the adhesion of cells to surfaces: cells require adsorbed proteins (or peptides that mimic parts of a protein) to adhere to the surface [27]. Control of the interaction of proteins with a surface, therefore, enables the control of the interactions of cells with that surface. Most solid surfaces − especially hydrophobic surfaces − adsorb proteins. Thus, the main challenge in controlling the interactions of proteins and cells with surfaces lies in finding surfaces that resist non-specific adsorption of proteins (surfaces that we call 'inert' for brevity). Inert surfaces provide the background necessary for spatially restricting protein adsorption or for preparing surfaces that only bind specific proteins, and are used in patterning proteins and cells, as biomaterials [28,29], and in the construction of biosensors [30].

SAMs terminated in oligo (ethylene glycol) (EG_n, $n > 2$), resist the adsorption from solution of all known proteins and their mixtures [2,19,31]. We know that EG_n groups are not unique in their ability to make inert SAMs: for example, several polar functional groups that do not contain H-bond donors often make good components of inert surfaces [32,33]. The combination of inert and adsorptive surfaces with soft lithographic techniques enables the facile patterning of proteins and cells. Patterns of hydrophobic regions (for example, SAMs terminated in methyl groups) and regions that are 'inert' provides the basis for most work using patterned cells.

A number of other substances also make the surface more or less inert. Many of them are used in connection with soft lithography, for example, bovine serum albumin (BSA) and related proteins [34], man-made polymeric materials (e.g., polyethyleneglycol, or PEG) [35], and dextran [36].

MICROCONTACT PRINTING (μCP)

Patterning ligands, proteins, and cells on SAMs

Microcontact printing (μCP) is a technique that uses topographic patterns on the surface of an elastomeric PDMS stamp to form patterns on the surfaces of various substrates (Fig. 19.1) [3]. The stamp is first 'inked' with a solution containing the patterning component, the solvent is allowed to evaporate under a stream of air, and the stamp is brought into conformal contact with the surface of the gold film for intervals ranging from a few seconds to minutes. The thiol transfers to the gold film in the regions of contact. Other components used as ink for μCP include activated silanes that react with the SiOH groups ($RSiCl_3$ or $RSi(OCH_3)_3$) present on

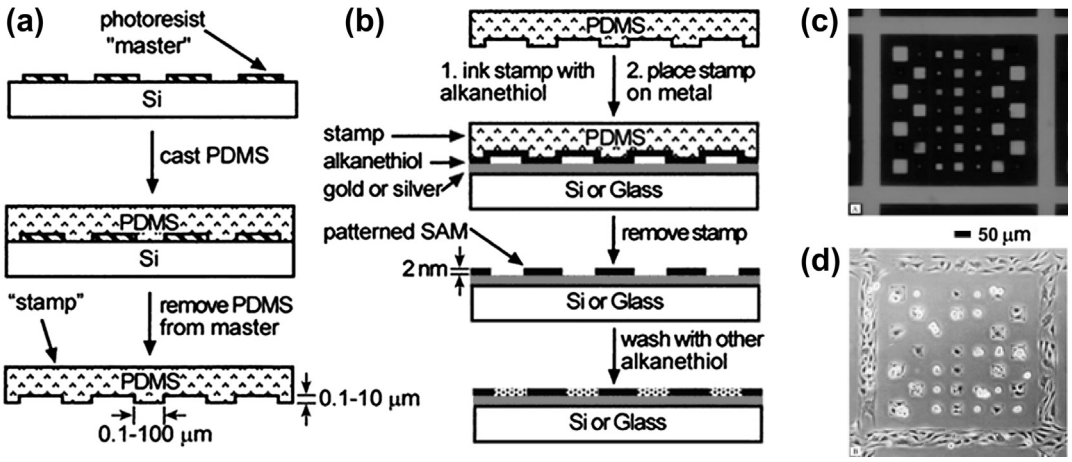

FIGURE 19.1

Molding from a master, microcontact printing (μCP), and patterning of proteins and cells. (a) A method for generating stamps (also applicable for channels and other molds) of PDMS for μCP. A PDMS stamp is prepared by pouring PDMS liquid prepolymer on a 'master' (generally generated by photolithography), followed by curing the PDMS and removing it (as an elastomeric solid) from the master. (b) A typical procedure used for μCP. A solution containing the patterning component of interest ('ink') is applied to this stamp and the solution allowed to dry. This inked stamp is placed on a substrate to allow the ink to transfer to the substrate. A substrate patterned with SAMs remains after removal of the stamp. (c) Selective adsorption of fibronectin onto a surface patterned by SAMs into areas that either promote or resist the adsorption of proteins, by μCP, visualized by immunostaining. (d) Patterned attachment and spreading of cells on the protein patterned substrate in c.

the surface of silicon (with a native film of SiO_2); and various ligands (such as amine-containing compounds) that react with activated SAMs (usually resulting in the formation of a peptide bond that tethers ligands with surfaces) [37,38].

The most general and reliable method for patterning proteins is accomplished by preparing areas of SAMs that promote the adsorption of proteins, surrounded by regions that resist adsorption of proteins (regions that we call 'inert background'), and allowing proteins to adsorb onto the adsorbing regions from solutions. For example, we used μCP to pattern gold surfaces into regions terminating in methyl groups, then filled the rest of the gold surface with an oligo (ethylene glycol)-terminated thiol to form inert regions [25]. Immersion of the patterned SAMs in solutions of proteins such as fibronectin, fibrinogen, pyruvate kinase, streptavidin, and immunoglobulins resulted in adsorption of the proteins exclusively on the methyl-terminated regions [25]. Characterization of the patterns of adsorbed proteins by electron and optical microscopy showed that the layers of adsorbed protein appeared to be homogeneous. Alternatively, proteins can be anchored to ligands patterned onto surfaces by μCP, for example, μCP of biotin onto activated SAMs allows the biospecific immobilization of avidin on the surface [37].

The ability of μCP to create patterns of ligands and proteins allows the patterning of many anchorage-dependent cells (most normal cells in multicellular organisms are anchorage-dependent) [39]; this patterning confines them to specific regions of a substrate, and allows the precise control of the size and shape of the cells (Fig. 19.1). For example, μCP allows the partition of the surface of gold into regions presenting EG_n groups and methyl groups [40]. After coating the substrates with fibronectin, bovine capillary endothelial cells attached only to the methyl-terminated, fibronectin-coated regions of the patterned SAMs. The cells remained attached in the patterns defined by the underlying SAMs for 5–7 days. We have also used SAMs on palladium for the confinement of mammalian cells [23]. EG-terminated SAMs on palladium allow the patterning of individual cells, groups of cells, as well as focal adhesions (subcellular complexes that enable cell-substrate attachment, FAs) for over four weeks; similar SAMs on gold confined cells to patterns for one to two weeks.

The application of μCP in fundamental cell biology

The ability to pattern proteins, groups of cells, single cells and their FAs has led to new studies on the effect of patterned surface environments and cell shape on cell behavior.

Our first attempt in this area was to prepare (via μCP) substrates consisting of square and rectangular islands of laminin surrounded by inert regions, and to study the behavior of rat hepatocytes on them [41]. The cells conformed to the shape of the laminin patterns; the patterning allowed the control of cell shape independently of the density of ligands in the extracellular matrix (ECM). We observed that cell size, regardless of ECM ligand density, was the major determinant of cell growth and differentiation. We then used μCP to prepare substrates that presented circular cell-adhesive islands of various diameters and inter-island spacings [42,43]. Such patterns allowed the control of the extent of cell spreading without varying the total cell-matrix contact area. We found that the extent of spreading (the projected surface area of the cell), rather than the area of the adhesive contact controlled whether the cell divided, remained in stationary phase or entered apoptosis. Dike et al. used μCP to prepare substrates with cell-adhesive lines of varying widths [43]. They found that bovine capillary endothelial cells (BCE) cultured on 10 μm wide lines underwent differentiation to capillary tube-like structures containing a central lumen. Cells cultured on wider (30 μm) lines formed cell-cell contacts, but these cells continued to proliferate and did not form tubes.

Recent progress in understanding how cell adhesion regulates cell physiology has used methods related to μCP. In several model types of cells, the strength of cell-substrate adhesion increased as the allowed area of cell adhesion increased, for small areas (typically less than 300 μm [2]); but the strength of adhesion remained constant for larger areas [44,45]. These results empirically related cell spreading to the strength of cell attachment. Within the FAs, integrin receptors need to aggregate in order to activate the appropriate biochemical pathways for the adhesion of cells [46–48]. It has not been clear, however, what maximum separation is at which integrin receptors can still perform their normal functions. Bastmeyer has used different combinations of micropatterns to determine that cells could adhere to surfaces with arrays of circles with area of 0.1 μm^2, when the spacing between these circles are less than 5 μm; but when the separation between these circles is larger than 30 μm (and when the circles are larger than 1 μm [2]), cells fail to adhere and spread on these surfaces [49]. This result gives a semi-quantitative description of the geometrical requirements for clustered integrins.

Using a combination of self-assembly of nanoparticles and micropatterns, Spatz and colleagues definitively determined the maximum distances (73 nm) between individual integrin receptors at which normal cell adhesion could occur [50]. Another report shows that when FAs mature into larger than normal sizes, they appear to exert four times as much stress on the surface as do normal FAs; this result might be important for myogenesis, the process of the formation of muscle fibers [51].

Micro-scale features enable the studies of the movement of mammalian cells. The extension of lamellipodia is an important process in the movement of cells. Bailly and coworkers used micropatterned substrates to study the regulation of lamellipodia during chemotactic responses of mammalian carcinoma cells to growth factors [52]. On stimulation with epidermal growth factor, the cells extended their lamellipodia laterally out of their patterns of confinement, over the inert part of the substrate. This result showed that the extension of lamellipodia could occur independently of any contact with the substrate. Contact formation was, however, necessary for stabilizing the protrusion. We further observed that when endothelial cells were confined to patterns with corners (such as triangles and squares), their lamellipodia tended to spread most actively from the corners of these shapes [53,54].

Most moving mammalian cells adopt asymmetric shapes. We have examined whether the asymmetry in the shape of a cell is connected to the direction of its movement [55] (Fig. 19.2).

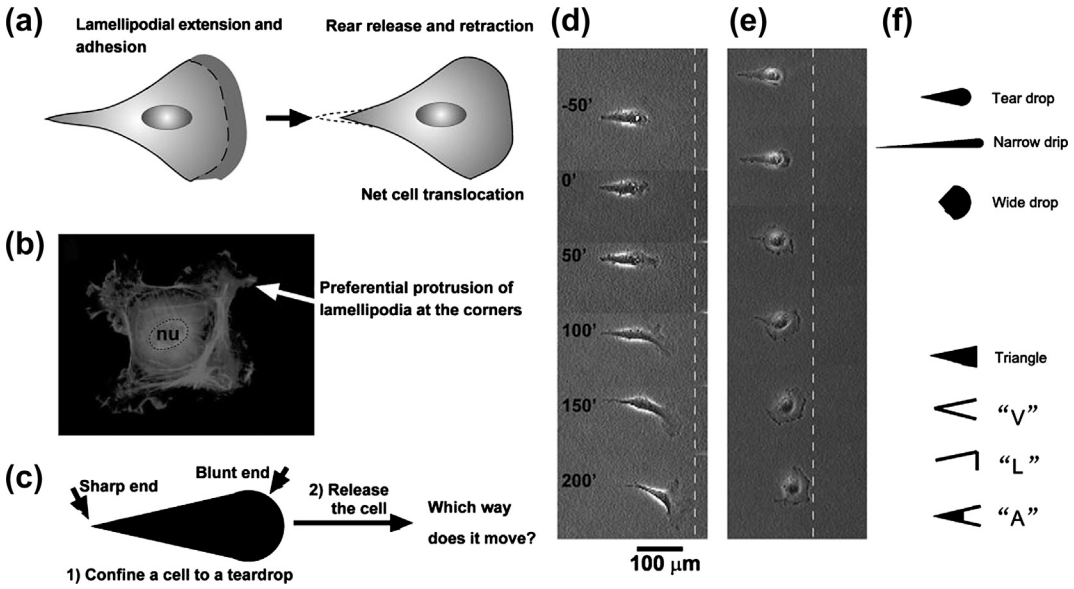

FIGURE 19.2

Understanding the relationship between cell shape and the direction of cell migration. (a) A typical migrating cell has an asymmetric, teardrop-like shape, and moves toward the blunt end. (b) When confined to shapes that have sharp corners, lamellipodia tend to extend out of the sharp corners. (c) A cell initially confined to a teardrop shape then subsequently released may choose which way it moves: toward its blunt or sharp end. (d) (e) Individual 3T3 cells and COS cells, respectively, were initially confined to teardrop shapes, and then released to move freely across the surface. The movement was predominantly toward the blunt end. Numbers indicate time past after the application of electrochemical potential (minutes). (f) Different initial patterns used to confine cells.

Since moving cells often appear to have a teardrop shape, we confined cells to teardrop-shaped patterns, and then used electrochemistry to allow free cell movement (Fig. 19.2a). It is tempting to assume that the released cells would move toward the sharp end of the teardrop pattern, considering that lamellipodia tend to extend from sharp corners (Fig. 19.2b); but when we released teardrop-shaped cells electrochemically, the pre-shaped cells appeared to prefer moving toward their blunt ends (Fig. 19.2c–e). To understand the issue in detail, we varied the initial shapes. It appeared that 'narrow drops' (regardless of details of the shape) had a similar capability to direct cell migration, while 'wide drops' failed to do so. Triangular patterns (having a similar aspect ratio to the teardrop) also direct cell migration, to the same extent as the teardrop, further confirming that the asymmetry of the initial shape alone could direct cell movement. In contrast, symmetric patterns such as rectangles, squares and circles failed to direct cell migration. To determine whether it was the shape of the spread cell or the uneven distribution of FAs underneath the cell that was responsible for directed cell motion, we started cells on 'L', 'V', and 'A'- shaped patterns (Fig. 19.2f). Because individual cells could span these patterns, the overall geometry of immobilized cells resembled each other and was similar to that of cells confined to triangular patterns. However, these patterns allowed different distributions of FAs. Triangles and 'L'-shaped cells allowed more FAs in the blunt end, 'V'-shaped patterns allowed the same amount of the FAs in the blunt end as in the sharp end, while 'A'-shaped patterned allowed more FAs in the sharp end. All these patterns appeared to direct cell migration to the same extent, thus confirming that the overall shape of cells was the determining factor in directing cell motion.

μCP offers opportunities to study not just single cells, but groups of cells. For example, Chen and coworkers devised experiments to control the size and the contact between a pair of cells, thus definitively proving that cell-cell contact, not soluble factors alone, enables cell-contact-mediated proliferation of cells in culture [56]. Toner and colleagues showed, by patterning of hepatocytes and non-parenchymal cells with precise geometrical parameters,

that the interface between the two types of cells is critical for the function of hepatocytes [57]. Ingber and his coworkers discovered, using patterned groups of two or more endothelial cells, that spontaneous ordering arises, and patterns that resemble the Chinese Yin-Yang ideograph would emerge while endothelial cells migrate on the patterns [58,59]. Studying groups of tens to hundreds of cells patterned into defined geometries, Chen and coworkers realized that the shapes of sheets of cells influence the mechanical forces that each cell within the shape experiences, and that these forces affect the physiology of individual cells differently, depending on the location of the cell in the sheet [60].

Local physical interactions between cells and extracellular matrix (ECM) influence directional cell motility, which is critical for tissue development, wound repair, and cancer metastasis. Using μCP, we tested the possibility that the precise spatial positioning of FAs governs the direction in which cells spread and move. We cultured NIH 3T3 cells on circular or linear ECM islands created by μCP. Cells could be driven proactively to spread and move in particular directions by altering either the inter-island spacing or the shape of similar-sized ECM islands. Immunofluorescence microscopy confirmed that FAs assembled preferentially above the ECM islands, with the greatest staining intensity being observed at adhesion sites along the cell periphery. Rac became activated within 2 min after peripheral membrane extensions adhered to new ECM islands, and this activation wave propagated outward in an oriented manner as the cells spread from island to island. The results suggest that physical properties of the ECM may influence directional cell movement by dictating where cells will form new FAs and activate Rac and, hence, govern where new membrane protrusions will form [61].

μCP is also a useful tool for studying dynamic development process of neurons [62]. ECM proteins and cell—cell adhesion molecules play important roles in the development and differentiation of neurons. Recently, we fabricated laminin stripes on a background of poly-L-lysine as substrates for the growth of rat hippocampal neurons, and found that a sharp change of the concentration of laminin guides the growth of neurites by leading the growth cones in a time- and space-dependent manner. The percentage of neurites that grow along the edge of laminin stripes (where there is a sharp change of concentration) decreases as a function of the concentration of laminin under a threshold value. The actin cytoskeleton plays an important role in the process of growth cone's response to the sharp change of concentration of laminin on micropatterns [63].

μCP has also been used in studies of cell division. Even though most mammalian cells become round and almost completely detach from the substrate when they divide, Bornens' group has used μCP to show that the shape of the ECM to which cells initially attach determines the direction of cell division [64].

μCP could also be used to investigate the behavior of stem cells. Micropatterns were reported to bias the differentiation of human mesenchymal stem cells: when allowed to adhere and spread, the stems cells became osteoblasts; when spreading is prohibited by small patterns of confinement, stem cells became adipocytes [65]. We reported a microarray-based approach for the high throughput screening of gene function in stem cells and demonstrated the potential of this method by growing and isolating clonal populations of both adult and embryonic neural stem cells. Clonal microarrays are constructed by seeding a population of cells at clonal density on micropatterned surfaces generated using μCP. Clones of interest can be isolated after assaying in parallel for various cellular processes and functions, including proliferation, signal transduction, and differentiation. We demonstrated the compatibility of the technique with both gain- and loss-of-function studies using cell populations infected with cDNA libraries or DNA constructs that induce RNA interference. The infection of cells with a library prior to seeding and the compact but isolated growth of clonal cell populations will facilitate the screening of large libraries in a wide variety of mammalian cells, including those that are difficult to transfect by conventional methods [66].

Other types of μCP

It is possible to pattern certain proteins (ones that can withstand drying onto the surface of the stamp, and stamping) directly onto surfaces [67–71]. Direct patterning, however, is typically applicable only to structurally stable proteins and is usually more demanding experimentally than patterning via SAMs [77]. The surface of the PDMS stamp used in this type of procedure must be rendered hydrophilic by exposure to a plasma before use [69].

Patterning cells directly with μCP was not thought to be feasible, because most cells are too delicate to be dried or stamped. We have demonstrated the stamping of proteins and cells directly with a soft hydrogel stamp (agarose) that contains large amounts of water [70,72]. The resolution of this technique (tens of micrometers) is not comparable to μCP with PDMS and SAMs, but it makes patterning cells at this large size range easier than patterning with SAMs.

Other researchers have used μCP for different types of cells on other types of surfaces. Craighead and coworkers patterned polylysine on the surfaces of electrodes to confine the growth of neurons [73]. We have synthesized oligopeptides containing a cell adhesion motif at the N-terminus connected by an oligo (alanine) linker to a cysteine residue at the C-terminus [74]. The thiol group of cysteine allowed the oligopeptides to form monolayers on gold-coated surfaces. We used a combination of μCP and these self-assembling oligopeptide monolayers to pattern gold surfaces into regions presenting cell adhesion motifs nd oligo(ethylene glycol) groups that resist protein adsorption. Wheeler et al. created patterns of covalently bound ligands and proteins on glass coverslips and used these patterns to control nerve cell growth [75]. In addition, polymers of EG and supported phospholipids have been used on a series of different substrates for pattering cells [76–79].

Recently, inspired by the composition of adhesive proteins in mussels, Lee et al. used dopamine self-polymerization to form thin, surface-adherent polydopamine films onto a wide range of inorganic and organic materials [80]. Secondary reactions can be used to create a variety of layers, including SAMs through deposition of long-chain molecular building blocks, metal films by electroless metallization, and bioinert and bioactive surfaces via grafting of macromolecules. In a recent study, we studied if polydopamine film can form on OEG SAMs in the same condition as reported for other types of surfaces. The result indicates that polydopamine can transfer onto the SAMs with high fidelity and can form flattened sheets on OEG SAMs, suggesting that polydopamine is a soft and sticky material which can be reshaped under compression. The stable adhesion of polydopamine on antifouling surfaces made it suitable for cell patterning. We confined NIH 3T3 fibroblast cells to the polydopamine patterns which were achieved by either μCP or μFP. Our studies demonstrate that polydopamine is a versatile non-specific adhesive material for cell adhesion [81].

MICROFLUIDIC PATTERNING (μFP)

The use of microfluidic channels allows patterning surfaces by restricting the flow of fluids to desired regions of a substrate. The patterning components such as ligands, proteins, and cells are deposited from the solution to create a pattern on the substrate.

Delamarche and colleagues used μFP to pattern immunogloblins with submicron resolution on a variety of substrates including gold, glass, and polystyrene [82]. Only microliters of reagent were required to cover square millimeter-sized areas. Patel and coworkers developed a method to generate micron-scale patterns of any biotinylated ligand on the surface of a biodegradable polymer [83]. These investigators prepared biotin-presenting polymer films, and patterned the films by allowing solutions of avidin to flow over them through 50 μm channels fabricated in PDMS. The avidin moieties bound to the biotin groups on the surface, and served as a bridge between the biotinylated polymer and biotinylated ligands. Patterns created with biotinylated ligands containing the RGD or IKVAV oligopeptide sequences determined the adhesion and spreading of bovine aortic endothelial cells and PC12 nerve

cells. Both our group and Toner's group used μFP to produce patterns of adsorbed proteins and adherent cells on biocompatible substrates [84–87]. We formed micropatterns of proteins deposited from fluids in separately addressable capillaries. By allowing different cell suspensions to flow through different channels, we could pattern two types of cell on surfaces with high spatial precision. After the adhesion of the two types of cells in different areas on the surface, we could remove the elastomeric stamps to allow movement of both types to be studied. By using μFP, we established an *in vitro* model on glass surfaces for patterning multiple types of cells, to simulate cell-cell interactions *in vivo*. The model employs a microfluidic system and poly(ethylene glycol)-terminated oxysilane (PEG-oxysilane) to modify glass surfaces in order to resist cell adhesion. The system allows the selective confinement of different types of cells to realize complete confinement, partial confinement, and/or no confinement of three types of cells on glass surfaces. The model was used to study intercellular interactions among human umbilical vein endothelial cells (HUVEC), PLA 801 C and PLA801 D cells [84]. By filling individual channels with different fluids, multiple components could be patterned at the same time without the need for multiple steps or the accompanying technical concerns of registration (although registration was required in the fabrication of the stamp itself). By using μFP, we patterned multiple types of cells on a same surface in one step and selectively make a 'wound' by filling low osmotic fluid into a specific channel. Without mechanical tension on adjacent normal cells, the low osmotic fluid leads to 'lysis' of the cells which would release and form gradients of soluble cytoplasmic components to initiate a collective migration of adjacent cells to perform a repair process. We observed the phenomenon of contact inhibition of locomotion, where a cell ceases to continue moving in the same direction after contacting with another cell [88].

Furthermore, by mimicking a 'wound' *in vitro*, we developed a cell-on-a-chip model that can be used to screen wound dressing candidates, thus minimizing the use of animals in the development of better methods for wound care. We simulated a cutaneous wound and screened the performances of several electrospun fibrous wound dressings in enhancing wound healing. For comparison, the performances of the wound dressings were also evaluated in a rat model. It was found that the results acquired by microchip model corroborated well with the animal experiments [89].

Adhesion on a substrate is essential for most types of cells; however, cell-cell interaction dominates certain biological processes under some situations, such as embryonic development. We developed a device consisting of two microchannels separated by a semi-porous polycarbonate membrane which had been treated to make it resistant to cell adhesion. Embryonic stem (ES) cells introduced into the upper channel self-aggregate to form uniformly-sized embryoid bodies. The size and morphology of these bodies are critical for the sequential developmental stages of naturally conceived embryos. The semi-porous membrane also allows subsequent treatment of the non-attached EBs with different reagents from the lower channel. This technique is superior to existing methods which are tedious or provide heterogeneously-sized EBs [90]. Using a similar device, we mimicked niche the microenvironment in which cancer cells reside. A 3D metastatic prostate cancer model that includes the types of surrounding cells in the bone microenvironment was established. Spheroids of metastatic prostate cancer cells (PC-3 cell line), osteoblasts and endothelial cells were formed to ensure uniform incorporation of all co-culture cell types. The model recapitulated the *in vivo* growth behavior of malignant cancer cells within the bone metastatic prostate cancer microenvironment [91]. Chemokines play a key role in the metastasis of cancer cells, however, the exact mechanism is unknown partially due to the lack of adequate research tools. We presented a microfluidic vasculature system to model interactions between circulating breast cancer cells with microvascular endothelium at potential sites of metastasis. The microfluidic vasculature produces spatially-restricted stimulation from the basal side of the endothelium that models both organ-specific localization and polarization of chemokines and many other signaling molecules under variable flow conditions. We demonstrated that

circulating breast cancer cells preferentially adhere to endothelium stimulated from the basal side with CXCL12. CXCL12 functions through CXCR4 on endothelial cells to significantly enhance adhesion of circulating breast cancer cells, independent of CXCR4 or CXCR7 on cancer cells [92]. We also investigated how cells expressing CXCR7 regulate the chemotaxis of a separate population of CXCR4 cells under physiologic conditions in which cells are exposed to gradients of CXCL12. We recapitulated a cancer-stroma microenvironment by patterning CXCR4-expressing cancer cells in microchannels at spatially defined positions relative to CXCL12-producing cells and CXCR7-expressing cells. We demonstrated that chemotaxis of CXCR4 cells depended critically on the presence and location of CXCR7 cells relative to chemokine secreting cells. This simple and robust method should be generally useful for engineering multiple microenvironments to investigate intercellular communication [93].

LAMINAR FLOW PATTERNING

Laminar flow patterning (LFP) is a characteristic method of microfluidic systems that allows two or more different solutions to flow side-by-side in a channel without convective mixing [94,95]. This technique utilizes a phenomenon that occurs in microfluidic systems as a result of their small dimensions — that is, low Reynolds number flow [96,97]. The Reynolds number (Re) is a parameter that describes the ratio of inertial to viscous forces in a particular flow configuration; it is a measure of the tendency of a flowing fluid to develop turbulence. The flow of aqueous fluids in capillaries usually has a low Re and is laminar. Laminar flow allows two or more streams of fluid to flow next to each other without any mixing other than by diffusion of their constituent molecules across the boundary between them (which is usually fairly slow). Diffusional motion of particulate components (e.g., cells) is even slower. This fluid behavior can be used to precisely control the nature and location of an interface between two miscible or non-miscible fluids, without requiring a physical divider. This means that LFP can be used to generate chemical gradients, pattern particles and cell suspensions.

In a typical set-up for LFP experiments, a network of capillaries is made by sealing a patterned PDMS slab with a glass slide or the surface of a Petri dish (Fig. 19.3a) [95]. By passing streams of fluid with different compositions from the inlets, patterns of parallel stripes of flowing fluid are created in the main channel. It is possible, therefore, to treat different parts of a single cell with different reagents if it happens to span these stripes. Fig. 19.3b and 19.3c illustrate the painting of a single cell with dyes that stained mitochondria located in different parts of the same cell [98].

Using this technique, the positions and microenvironments of cells can be controlled simultaneously in several stripes in the same channel [99,100]. Using a similar approach, we could pattern the substrate with different proteins and cells [95]. We can pattern the culture media over an individual cell by delivering chemicals selectively to cells. Since no physical barriers are required to separate the different liquid streams, different liquids can flow over different portions of a single cell.

Ismagilov and colleagues have used LFP to generate a step gradient in temperature to study the development of embryos of the fruit fly *Drosophila melanogaster* [101]. They treated the anterior (front) and posterior (back) of the embryo with media at different temperatures, and observed that the fly embryos developed normally under such a condition. They concluded that in complex biochemical systems, there exist mechanisms for compensation. They further showed that if they reverse the temperature gradient within a certain time, embryos failed to develop normally. This observation shows there is a limit in time for the compensation mechanisms.

Another type of LFP generates gradients with parallel streams of flow of increasing or decreasing concentrations. We have generated gradients of biomolecules both in solution and

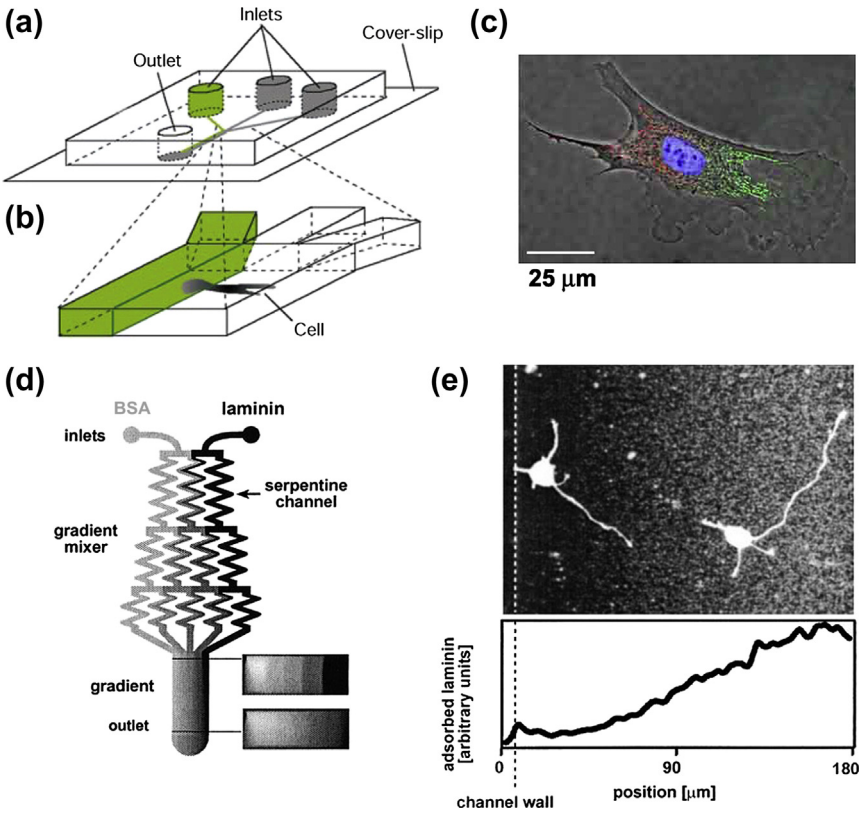

FIGURE 19.3

Manipulation of two regions of a single bovine capillary endothelial cell using multiple laminar flows. (a) Experimental set-up; (b) shows a close-up of the point at which the inlet channels combine into one main channel. (c) Fluorescence images of a single cell after treatment of its right pole with Mitotracker Green FM and its left pole with Mitotracker Red CM-H2XRos. The entire cell is treated with the DNA-binding dye Hoechst 33342. (d—e) Generation of gradients using microfluidic networks, and use of these gradients to study neuronal differentiation. (d) In appropriately designed microfluidic channels, flows generate gradients of BSA and laminin in solution. (e) The gradient in solution became a gradient on the surface when proteins adsorb, and when rat hippocampal neurons grow on the gradient, the neurons extend their longest process (the presumed axon) toward the higher concentrations of laminin in the gradient of proteins on the surface.

on surfaces (Fig. 19.3d) [102,103]. Because we can control the input concentration and the width of the microfluidic channel, it is possible to generate gradients with virtually any characteristics (e.g., the length and the slope) both in solution and on surfaces. We studied the generation of neuronal polarity — the process of the selective formation of one axon and several dendrites from a number of initially equivalent neurites projecting from a single neuron — and found that a surface gradient of laminin was sufficient to guide the orientation of this process (Fig. 19.3e) [104]. We further quantified the slope of the gradient, and determined the minimum slope required for this process to take place. We have also studied the chemotaxis of neutrophils in a solution of gradient of interleukin-8 (IL8) [105]. The neutrophils migrate directionally, toward increasing concentrations of IL8 along linear gradients. They halt abruptly when encountering a sudden drop in the chemoattractant concentration (from maximum directly to zero). When neutrophils encounter a gradual increase or decrease in chemoattractant (from a maximum gradually down to zero), however, they initially cross the crest of maximum concentration, but then they head back towards it. It would be very difficult to carry out experiments to answer questions regarding the detailed responses of cells to gradients over scales of microns without the ability to form precisely controlled gradients.

LFP has some features that make it complementary to other patterning techniques used for biological applications. It takes advantage of easily generated multiphase laminar flows to pattern fluids and to deliver components for patterning. The ability to pattern the growth medium itself is a special feature that cannot be achieved by other processes. This method can pattern even delicate structures such as portions of a mammalian cell. This type of patterning is difficult by other techniques. LFP can also give simultaneous control over surface patterns, cell positioning, and the fluid environment in the same channel. A few recent examples have combined patterned substrates with patterned flows. We have fabricated gradients of proteins on surfaces in microchannels whose floors carry patterns generated by μCP [106]. Jeon and his coworkers have combined substrates patterned in topography and

patterned flows to form a model system that conveniently isolates axons of rat hippocampal neurons from the rest of the cell for studies of their molecular biology [107]. Langer and coworkers have fabricated microchannels that have micropatterns within them to immobilize proteins and cells [108]. Folch and coworkers have used micropatterns to form myotubes from myoblasts, and then used laminar flows to deliver agrin, a proteoglycan found in the neuromuscular junction, precisely to these myotubes. In these experiments, they monitored the clustering of acetylcholine receptor (AChR), and the results corroborated the hypothesis that focalized release of agrin causes the clustering of the AChR [109].

The combination of LFP and hydrogel can accurately model *in vivo* cellular microenvironments. We have demonstrated a flexible method that allows:

1) Controlled spatial distribution (patterning) of multiple types of cells within 3D matrices of a biologically derived, thermally curable hydrogel (Matrigel); and
2) Application of gradients of soluble factors, such as cytokines, across the hydrogel.

The technique uses laminar flow to divide a microchannel into multiple subchannels separated by microslabs of hydrogel. It does not require the use of UV (ultraviolet) light or photoinitiators and is compatible with cell culture in the hydrogel. This technique makes it possible to design model systems to study cellular communication mediated by the diffusion of soluble factors within 3D matrices. This method is particularly useful for studying cells such as those of the immune system, which are often weakly adherent and difficult to position precisely with standard systems of cell culture [110].

Multiplex protein patterns could be created in a single microfluidic channel by combining LFP and μCP. Didar and his colleagues patterned (3-aminopropyl) triethoxysilane (APTES) on a glass surface by using μCP. They then introduced five primary antibodies onto the APTES patterns by LFP to form different protein microarrays in a single channel. The functionality of the microarrays was evaluated through a multiplex immunoassay using secondary antibodies specific to each patterned primary antibody (Fig. 19.4a). Their method proved to be successful for the preparation of highly resistant multiplex functional surfaces for high throughput biological assays [111].

The combination of LFP and μFP can create co-culture patterns of various geometries and compositions for manipulating cell-cell interaction dynamics. We developed a two-layered microfluidic device that sandwiches a semi-porous membrane (Fig. 19.4b). Arbitrary cellular arrangements are enabled by regulating the geometric features of the bottom channel so that as culture media drains, the flow hydrodynamically focuses cells onto the membrane only over specific regions in the bottom channel. Furthermore, when the top channel has multiple inlets, cells can be seeded in adjacent laminar streams, allowing different cell types to be patterned simultaneously in well-defined spatial arrangements. We constructed two juxtaposed non-concentric cell spheroids using mouse embryonic stem (mES) cells and hepatocytes (Fig. 19.4c). The mES cells differentiated in a spatially distinct pattern dictated by the position of the hepatocytes. This contrasts with the uniform mES differentiation observed when co-culture spheroids are formed by the conventional method of randomly mixing the two cell types. This cellular patterning method opens new possibilities for understanding and manipulating interactions between different cell types in 3D [112].

One may ask if the fluid flow required in the generation of laminar flows would cause problems for certain experiments, such as the measurement of chemotaxis, dispersion effects and driving forces. Wikswo and coworkers addressed the chemotaxis problem by measuring the motility of HL60 leukemia cells (which express CXCR2 receptors) in a gradient of CXCL8 [113]. They found that high rates of flow can affect the motility of cells. Reasonably low rates of flow, however, do not affect measurements of motile cells. Dispersion effects resulting from diffusion and convective disturbance are a big problem in LFP. This issue can be partially addressed by using oil-in-water phase systems. However, there are limitations in terms of

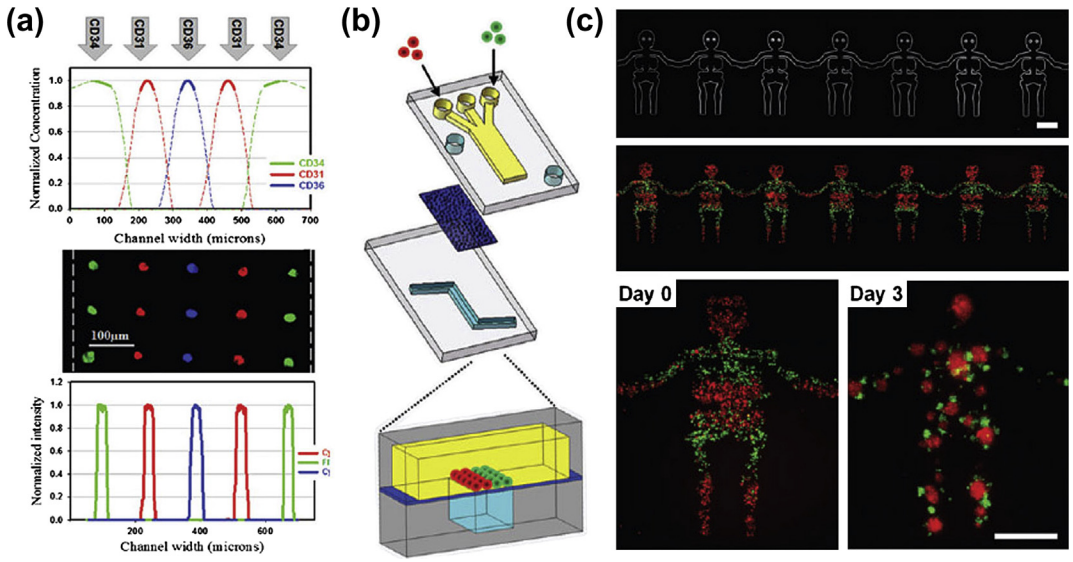

FIGURE 19.4

(a) Patterning multiplex protein microarrays with strong covalent bonds and high throughput biomarker assay. From top to bottom: Schematic representation of laminar flows containing different primary antibody solutions to create the detection interface; Simulation results for concentration distribution inside the flow streams. The areas shown with continuous solid lines correspond to the areas patterned with APTES and thus the antibodies in the flow are expected to attach to the surface at these spots; Superimposed fluorescence microscope images of the surfaces showing the multiplex immunoassay results. The white dashed lines represent the microchannel walls; Fluorescence intensities of fluorescently conjugated secondary antibodies are detected by their specific primary antibodies on the surface. (b) Schematic illustration of the compartmentalized microfluidic system for cellular patterning. Two PDMS channel layers are separated by a semi-porous polycarbonate membrane which is rendered resistant to cell adhesion. The top channel is a straight channel with a dead-end. The bottom channel consists of a straight channel with or without chambers. Cells are introduced into the top channel using multiple laminar flows. (c) Patterning co-culture of multiple cell types. An optical image of the bottom channel and fluorescent images of patterned cells. Two kinds of cells were patterned as 'human' shapes while keeping alternate five equal lines. Scale bars: 500 μm.

the biocompatibility of these systems for adherent cell culture. We presented a fully biocompatible aqueous two-phase flow system (PEG, Dextran) that can be used to pattern cells within simple microfluidic channel designs, as well as to deliver biochemical treatments to cells according to discrete boundaries. We demonstrated that these aqueous, two-phase systems are capable of precisely delivering cells as laminar patterns, or as islands by way of forced droplet formation. The system can also be used to precisely control chemical (trypsin) delivery to preformed monolayers of cells growing within channels [114]. LFP is typically implemented using syringe pumps, which is a relatively complex procedure for a biological lab. Beebe's group presented a passive microfluidic method that enables short-term LFP of multiple fluids using a single pipette and allows each sample to be loaded in any sequence, at any point in time relative to one another. The proposed method is well suited for cell-based assays, reduces the complexity of LFP to a similar level as other cell patterning methods, can be scaled to include more than two streams of fluid, and enables arrays of individually addressable devices for LFP on a single chip [115].

DYNAMIC CONTROL OF SURFACES

Electrochemical desorption of SAMs

It is possible to modulate the ability of surfaces to promote the adhesion of cells by controlling their composition. A relatively simple method to achieve this control is to desorb EG-terminated SAMs electrochemically from a substrate patterned with cells in a buffer containing proteins that promote cell attachment [116]. Electrochemical desorption converts inert areas into regions that can promote the adsorption of proteins and adhesion of cells, and thus allows initially confined cells to move out of their patterns (Fig. 19.5a). By

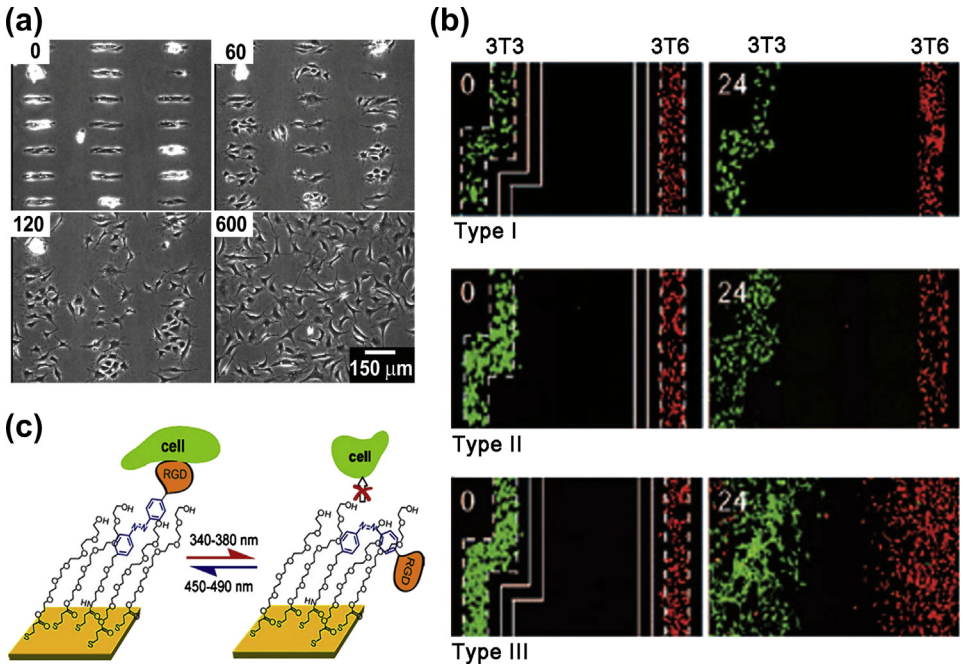

FIGURE 19.5

(a) Using electrochemical desorption of EG-terminated SAMs to release confined BCE cells and allow their free movement. Initially, bovine capillary endothelia cells are confined to a patterned array of hydrophobic regions (SAMs terminated in methyl groups) and surrounded by regions that are 'inert' (SAMs terminated in EG-terminated groups). Application of a cathodic voltage desorbs the EG-terminated SAMs to allow cells initially confined to move freely on the surface. The numbers indicate time after application of electrochemical treatment (in minutes). (b) Time-lapse phase-contrast and fluorescence micrographs for the three types of cell-cell interactions between 3T6 and NIH3T3 cells. (c) The azo moiety can be converted photochemically between the E and Z configurations to either present or mask the RGD ligand and hence modulate biospecific cell adhesion.

electrochemical desorption of SAMs in localized areas defined by a microfluidic system, we patterned multiple types of cells on the same substrate. This technique has the ability to pattern different types of cells with precisely controlled distances while allowing the free exchange of soluble molecules. It also allows these cells to move under each other's influence [117]. Based on this work, we applied selective desorption on complex patterns of cells and simulated three types of cell-cell interactions *in vivo*:

1) Those between two types of cells that are both immobilized and confined to isolated areas, such as epithelial cells and polar cells during ovarian development;
2) Those between one cell type that is immobile and another that moves freely, such as glial cells and neurons in neurodegenerative disorders; and
3) Those between two or more types of cells that are both moving freely, such as hepatocytes and fibroblasts in the liver (Fig. 19.5b).

The system is likely to make co-culturing of different types of cells dramatically more accessible to biologists [118].

Mrksich and coworkers have used the electrochemical conversion of a hydroquinone-terminated SAM into a quinone-terminated SAM to allow the attachment of a cyclopentadiene-tether peptide (which allows the immobilization of cells via the binding of integrin receptors on cell surface) to 'turn on' an otherwise inert SAM for the adhesion of cells [119]. Mrksich has used this technique for the patterning of multiple types of cells on surfaces [120]. Another technique from the same group involves desorption of an immobilized ligand (patterned in certain areas on the surface) and detachment of cells adhered to the surface via this ligand, on application of an electrical reduction, and a subsequent electrical oxidation of the substrate for immobilizing another ligand that allows the migration of

adherent cells (that were initially confined to certain areas on the surface) [121]. Some of the methods for preparing the appropriate thiols employed by Mrksich and colleagues may be too complicated for routine use in a regular cell biology laboratory, but the demonstration of such sophisticated control of the interactions between the cell and solid substrates is unprecedented. Another set of electrochemical methods can be used to activate BSA-rendered inert surfaces for cell adhesion [122,123].

There are a number of other techniques that also allow dynamic patterning of proteins and cells in time and space, such as photochemical methods, surface spatial masking, and thermoresponsive polymers.

Photoresponsive surfaces

Photochemical methods allow the inertness of a SAMs to be tuned. Mrksich and coworkers have devised a SAM that is initially inert, but has in it a nitroveratryloxycarbonyl-protected hydroquinone, which can be oxidized photochemically to generate a benzoquinone group, which, in turn allows the attachment of a ligand for immobilization of cells on surfaces [124]. Another method for photoactivation of the surface utilized a photochemical process that desorbed a ligand from SAMs on surfaces. BSA initially physically adsorbed on the surface via a photocleavable 2-nitrobenzyl group terminated SAM made this surface inert; photochemistry-mediated desorption of the 2-nitrobenzyl group, and therefore BSA, allowed cells to adhere to the surface [125]. Pearson et al. reported a method to incorporate azo group to interacting motifs. The azo capable of binding to chymotrypsin in the Z-form; rendered the system to be photoswitchable. The extent of binding of a-chymotrypsin to the azo-modified surface could be modulated by irradiation with either UV or visible light. Upon UV irradiation, the maximum binding capacity of the surface was activated, after irradiation with visible light, the binding capacity was reduced to approximately 60% of the maximum [126]. We generated a surface that allows the azo unit to reversibly present a ligand that contains RGD peptide on SAMs. The E isomer of azo can present the RGD peptide for cell adhesion, while the Z isomer of azo can mask the RGD peptide in PEG terminated SAMs to prevent cell adhesion. The interconversion between E and Z can be achieved by illuminating with two wavelengths of light (UV light, 340—380 nm, for the E to Z conversion, and visible light, 450—490 nm, for the Z to E conversion) generated by the mercury lamp of a standard fluorescence microscope (Fig. 19.5c). Because the E to Z isomerization is completely reversible, this method provides the only means we know to control cell adhesion reversibly on a molecularly well-defined surface [127].

We fabricated substrates that allow the dynamic control of FAs. We first generated a slab of PDMS with a brittle surface by oxygen plasma treatment, and then made the surface inert by physical adsorption of a polymer containing moieties of PEG [128]. By stretching the slab, we created cracks on the surface, which are not covered with the polymer containing PEG. These cracks could thus promote the formation of FAs and adhesion of cells. Releasing the stress on the slab PDMS closed these cracks, and again prevented the adhesion of cells. This stretch-and-release process could be recycled multiple times.

Thermoresponsive surfaces

Temperature is a very convenient stimulus for the manipulation of cell adhesion by controlling 'on-off' switching of thermoresponsive surfaces prepared using thermoresponsive polymers [129,130]. Thermoresponsive polymers generally exhibit a lower critical solution temperature (LCST), below which they are soluble, and above which they dehydrate and aggregate [129]. Surfaces made from these stimuli-responsive polymers switch from hydrophilic to hydrophobic states in response to changes in temperature. Because of a LCST around 32°C in water, poly (N-isopropylacrylamide) (PIPAAm) has been proven to be an excellent thermosensitive material for controlling cell adhesion [131].

PATTERNING WITH MICRO-TOPOGRAPHIES

In vivo, basement membrane, composed of ECM components, is a complex mesh of pores, fibers, ridges and other features at the nanometer scale [132,133]. Topographical cues generated by the ECM, independent of biochemistry, have direct effects on cell behaviors such as adhesion, migration, cytoskeletal arrangements, and differentiation [134–138]. Cells are inherently sensitive to local micro-scale, mesoscale, and nanoscale topographic and molecular patterns in the ECM environment, a phenomenon called contact guidance [139–141]. The development of microfluidics and micro/nanofabrication methods to control and analyze the cellular response to substrate topography has provided new insights into the interactions of cells with their microenvironments [142–145].

It is possible to confine cells to micropatterns using either elastic membranes that carry holes or microwells [146–148], or allow the initial confinement then release of groups of cells [146,147]. Chen and his coworkers fabricated stamps with multiple levels that allowed the patterning of several different types of proteins and cells at once [149]. They also used bowtie-shaped microwells of agarose gel, both to confine individual cells to particular shapes, and to allow cells to be close to each other without mutual contact [56]. Positioning cells next to each other while preventing their direct contact is difficult to achieve with μCP alone. They also fabricated arrays of micropillars (in sizes much smaller than a single cell) to probe the forces that cells apply to the substrate as they adhere to and migrate on solid surfaces [45]. Tang and coworkers succeeded in molding microstructures in hydrogels of resolution larger than 5 micrometers and used these structures to generate arrays of cells in 3D [150].

We also studied the issue of topographical contact guidance — the way that cells interact with chemically homogeneous surfaces that have topographical features. These studies provide simple methods for further studies of this interesting and complex type of interaction [94,151,152].

Apart from physical and chemical cues, cell-cell interactions also influence cell behaviors. We employed the Madin-Darby canine kidney (MDCK), a cell line with relatively strong intercellular interactions, and NIH 3T3 fibroblast cells, a cell line with relatively weak intercellular interactions, to study the interplay between contact guidance and intercellular connections. The two types of cells were patterned onto PDMS substrates with microgrooves. Although MDCK cells migrate much more slowly than 3T3 cells on flat substrates, the velocity of migration of MDCK cells parallel to the grooves is higher than that of 3T3 cells perpendicular to the grooves and contact and form cell sheet. Because MDCK cells have distinct group behavior, they contact each other very tightly, and the cell sheet acts as a barrier to prevent further migration of 3T3 cells. The 3T3 cell group could migrate only via the space between them. This experiment showed that both cell-cell and cell-substrate interactions simultaneously influence the behaviors of groups of cells [153].

Though current technologies are not developed enough to produce tissue *in vitro* that is identical to that *in vivo*, one important step is to mimic natural tissue architecture. Skeletal muscle is composed of fibrils whose organization defines their functionality. In musculoskeletal myogenesis, the alignment of myoblasts in preparation for myotube formation is a crucial step. The ability to organize myoblasts efficiently, to form aligned myotubes *in vitro* would greatly benefit efforts in muscle tissue engineering. We aligned prefused and differentiated skeletal muscle cells *in vitro* by use of continuous micropatterned wavy silicone surfaces. Alignment was found to be a function of plating density [154]. To simulate the dynamic topographies *in vivo*, by applying and releasing compressive strain, we can introduce and remove the micropatterned wavy of the silicone surfaces respectively. The reversible topography was able to align, unalign, and realign C2C12 myogenic cell line cells repeatedly on the same substrate within 24 hour intervals, and did not inhibit cell differentiation. The method provides a broadly applicable tool for investigating dynamic processes of muscle cells

[155]. Based on this, we presented a method for creating highly ordered tissue-only constructs by using rigid microtopographically patterned surfaces to first guide myoblast alignment, followed by transfer of aligned myotubes into a degradable hydrogel and self-organization of the ordered cells into a functional, 3D, free-standing construct independent of the initial template substrate. Histology revealed an intracellular organization resembling that of native muscle [156]. Furthermore, using the similar device, we developed a 3D physiological model of longitudinal smooth muscle tissue. Acetylcholine (ACh) induced a dose-dependent, rapid, and sustained force generation, vasoactive intestinal peptide and absence of extracellular calcium attenuated the magnitude and sustainability of ACh-induced force, these data were similar to force generated by longitudinal tissue [157].

THREE-DIMENSIONAL PATTERNING

Different types of cells make up tissues and organs hierarchically, and communicate within a complex, three-dimensional environment. It has become evident that 3D cell culture provides more physiological cellular environments compared to conventional 2D cell cultures. Culturing cells in hydrogel has been a widely used method, since the architecture and chemical composition of hydrogels can be easily engineered. However, previous hydrogel cultures lack precise cell positioning and reversibility, which are important characteristics in engineering cellular microenvironments. We have reported a simple reversible hydrogel patterning method for 3D cell culture. In a pre-gelled alginate solution, calcium is chelated by DM-nitrophen (DM-n) to prevent crosslinking. After sufficient UV exposure, the caged calcium is released from DM-n, causing the alginate to cross-link. By exposing a pre-gelled solution to UV selectively, we formed an alginate gel in specific regions of a microfluidic device through the light-triggered release of caged calcium (Fig. 19.6a). Since the amount of crosslinking is based on the calcium concentration, the cross-linked alginate can easily be dissolved by EDTA, thus releasing the patterned cells for further analysis [158].

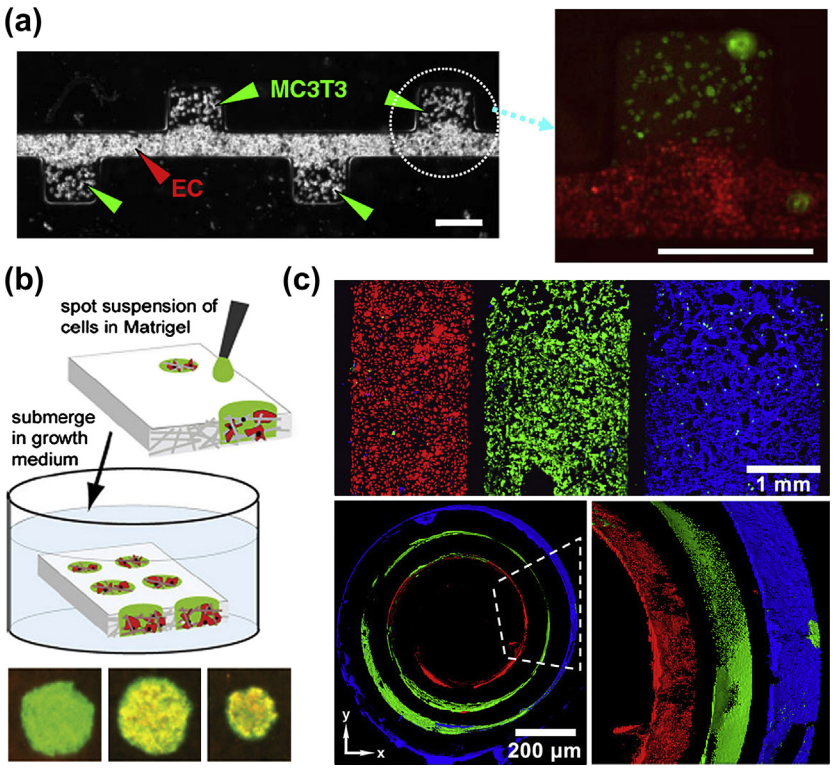

FIGURE 19.6
(a) Patterning cells in alginate hydrogels using light-directed release of caged calcium in a microfluidic device. The image shows patterned co-culture of endothelial cells and MC3T3 cells in a straight microchannel with side chambers. The endothelial cells (red fluorescence) stayed in the straight channel, while the MC3T3 cells (green fluorescence) remained in the side chamber where the alginate maintains the cells in position and in a non-spread rounded state. Scale bars shown in (a) are 200 μm. (b) Generation of 3D cultures of defined physical dimensions in the paper-supported hydrogels. (c) Three types of cells on a SIRM before and after rolling. Each color indicates a different type of cell. Red are endothelial cells; green: smooth muscle cells; blue: fibroblasts.

The density of cells in real tissues is about 10^8–10^9 cells cm^{-3} which is difficult to recapitulate in most present *in vitro* models, due to the difficulty of replicating the spatial distributions of oxygen, metabolites, and signaling molecules in tissues. To tackle this problem, we developed a device for the 3D culture of mammalian cells in microchannels by combining microfluidics and soft lithographic molding of gels containing mammalian cells. Collagen or Matrigel™ made up the matrix of each module of cell-containing gel. Each module had at least one dimension below ~300 μm. The flux of oxygen, nutrients, and metabolic products into and out of the modules was sufficient to allow cells to proliferate to densities comparable to those of native tissue. Multiple cell types with high survival ratios (99%) could be spatially organized in the microfluidic channels [159]. We also stacked and destacked layers of paper impregnated with suspensions of cells in ECM hydrogel ('cells-in-gels-in-paper' or CiGiP) to make it possible to control oxygen and nutrient gradients in 3D and to analyze molecular and genetic responses. Stacking assembles the 'tissue', whereas destacking disassembles it, and allows its analysis (Fig. 19.6b). The study offers a uniquely flexible approach to study cell responses to 3D molecular gradients and to mimic tissue- and organ-level functions [160]. *In vivo*, cells in different locations of 3D tissues are physiologically different, because they are exposed to different concentrations of oxygen, nutrients, and signaling molecules, and to other environmental factors (temperature, mechanical stress, etc). The majority of high throughput assays based on 3D cultures can only detect the average behavior of cells in the whole 3D construct. Isolation of cells from specific regions of 3D cultures is possible, but relies on low-throughput techniques such as tissue sectioning and micromanipulation. To tackle this problem, we developed a simple method for culturing arrays of thin planar sections of tissues, either alone or stacked to create more complex 3D tissue structures based on the 'cells-in-gels-in-paper' approach. The procedure starts with sheets of paper patterned with hydrophobic regions that form 96 hydrophilic zones. Serial spotting of cells suspended in ECM gel onto the patterned paper creates an array of 200 micron-thick slabs of ECM gel containing cells. Stacking the sheets with zones aligned on top of one another assembles 96 3D multilayer constructs. Destacking the layers of the 3D culture, by peeling apart the sheets of paper, 'sections' all 96 cultures at once. Because the 3D cultures are assembled from multiple layers, the number of cells plated initially in each layer determines the spatial distribution of cells in the stacked 3D cultures. This capability made it possible to compare the growth of 3D tumor models of different spatial composition, and to examine the migration of cells in these structures [161].

At the core of tissue engineering is the construction of 3D scaffolds out of biomaterials to provide mechanical support and guide cell growth into forming new tissues or organs. Recently, we reported a new fabrication strategy that results in stable tubular tissue with a high structural similarity to many biological tubular tissues. Using a stress-induced rolling membrane (SIRM) technique, we used two fabrication steps for their tubular structures. First, different types of cells were delivered and patterned on a two dimensional SIRM using microfluidic channels. Then the SIRM was released to roll up into a 3D tube. The tubes have different types of cells at specific locations, i.e., different parts of the tube wall are made up of different cells (Fig. 19.6c). Mimicking structural and functional features is a prerequisite for fabricating functional tubular tissues *in vitro*, and the realization of structural-tissue mimicry may have wide applications in simulation of many tubular tissues and enriches the toolbox for 3D micro/nanofabrication by initially patterning in 2D and transforming it into 3D [162].

CONCLUSION AND FUTURE PROSPECTS

Soft lithography brings to microfabrication low cost, simple procedures, rapid prototyping of custom-designed devices, three-dimensional capability, easy integration with existing instruments such as optical microscopy, molecular level control of surfaces, and biocompatibility [1,2]. These techniques allow patterning of cells and their environments with

convenience and flexibility at dimensions smaller than micrometers. We have described several complementary soft lithographic techniques — μCP, μFP, and LFP — which are useful in their ability to pattern the microenvironment of cultured cells.

μCP is perhaps the simplest method for patterning surfaces. It also provides the highest resolution in patterns with the greatest flexibility in the shape and size of the patterns generated. It provides the best control when one needs to pattern only two types of ligands or proteins. Microfluidic channels are well suited for patterning surfaces using delicate objects such as proteins and cells. They are also useful when multiple ligands, proteins or cells need to be patterned. LFP is similar to patterning with individual microfluidic channels except that the individual flows are kept from mixing with each other by laminar flow, not by physical walls. The ability to pattern the fluid environment is the distinguishing feature of this method, and this enables laminar flow to be used to pattern the distribution of different fluids over the surface of a single mammalian cell. This capability allows patterning of portions of a single cell, and remodeling of the cell culture environment, both in the presence of living cells. Micro-topographies can be useful for certain experiments where micropatterning alone is not sufficient. The combination of two or more of these techniques is starting to become useful for more sophisticated experiments, such as 3D pattering.

Soft lithography is still practiced by only a relatively small number of biologists, but its use is growing rapidly. There are many cell culture environments and related technologies that we have not discussed in this chapter; many of them relate to soft lithographic methods. For example, there are a number of methods of manipulation of chemistry on SAMs, and tools of micropatterns, to allow for molecular level control at the cell-substrate interface [32,163,164].

Although we are starting to have more techniques for fabrication in three dimensions, patterning of cells in three dimensions is still difficult [9,165,166]. We are making rapid progress, however, in the 'fourth dimension'; i.e., time. Since we can turn the surface 'on' and 'off' for adhesion of cells, and change the media at will in laminar flows, real-time monitoring of temporal changes in individual cells is possible [95,116,119]. The optical transparency of PDMS makes it straightforward to pattern the intensity of light in cell cultures [2]. The gas permeability of PDMS may be useful in patterning the gas surrounding cells. PDMS is electrically insulating, and molding or fabricating electrically conducting wires in it should allow patterning of electric fields around cells [95,167]. Gravitational fields can also be affected: microfluidic culture chambers with adherent cells can be turned upside down without loss of the culture media. Temperature, fluid shear, and other factors may also be accurately patterned.

The functional potential of a cell is determined by its genetics. Realization of that potential depends, *inter alia*, on whether the cell is exposed to the appropriate environment for expression of particular sets of genes. Soft lithography provides tools for patterning cells and their environment with precise spatial control. This capability aids efforts in understanding fundamental cell biology, and advances our ability to engineer cells and tissues. The ease with which electronic components or other 'non-biological' components can be fabricated with soft lithography also paves the way for the engineering of cells and tissues for use in biosensors and hybrid systems (e.g., interfaces between semiconductor-based computation and biological computation) that combine living and non-living components.

CHAPTER 20

Cell Interactions with Polymers

W. Mark Saltzman[1] and Themis R. Kyriakides[2]
[1] Department of Biomedical Engineering, Yale University, New Haven, Connecticut
[2] Department of Pathology, Yale University, New Haven, Connecticut

Scaffolds composed of synthetic and natural polymers have been essential components of tissue engineering since its inception [1]. Polymers are currently used in a wide range of biomedical applications, including applications in which the polymer remains in intimate contact with cells and tissues for prolonged periods (Table 20.1). Many of these polymer materials have been tested for tissue-engineering applications as well. To select appropriate polymers for tissue engineering, it is helpful to understand the influence of these polymeric materials on viability, growth, and function of attached or adjacent cells. In addition, it is now possible to synthesize polymers that interact in predictable ways with cells and tissues; understanding the nature of interactions between cells and polymers provides the foundation for this approach.

This chapter reviews previous work on the interactions of tissue-derived cells with polymers, particularly the types of synthetic polymers that have been employed as biomaterials. The focus of the chapter is on interactions of cells with polymers that might be used in tissue engineering; therefore, both *in vitro* and *in vivo* methods for measuring cell-polymer interactions are described. The interactions of cells in flowing blood, particularly platelets, with synthetic polymer surfaces is also an important aspect of biomaterial design, but is not considered here.

METHODS FOR CHARACTERIZING CELL INTERACTIONS WITH POLYMERS

In vitro cell culture methods

Cell interactions with polymers are often studied *in vitro*, using cell culture techniques. While *in vitro* studies do not reproduce the wide range of cellular responses observed after implantation of materials, the culture environment provides a level of control and quantification that cannot be obtained *in vivo*. Cells in culture are generally plated over a polymer surface and interaction is allowed to proceed for several hours; the extent of cell adhesion and spreading on the surface is then measured. By maintaining the culture for longer periods, perhaps for many days, the influence of the substrate on cell viability, function, and motility can also be determined. Since investigators use different techniques to assess cell interactions with polymers, and the differences between techniques are critically important for interpretation of interactions, some of the most frequently used *in vitro* methods are reviewed in this section.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00020-3

TABLE 20.1 Some of the polymers that might be useful in tissue engineering, based on past use in biomedical devices

Polymer	Medical applications
Polydimethylsiloxane, Silicone elastomers (PDMS)	Breast, penile, and testicular prostheses Catheters Drug delivery devices Heart valves Hydrocephalus shunts Membrane oxygenators
Polyurethanes (PEU)	Artificial hearts and ventricular assist devices Catheters Pacemaker leads
Poly(tetrafluoroethylene) (PTFE)	Heart valves Vascular grafts Facial prostheses Hydrocephalus shunts Membrane oxygenators Catheters and sutures
Polyethylene (PE)	Hip prostheses Catheters
Polysulphone (PSu)	Heart valves Penile prostheses
Poly(ethylene terephthalate) (PET)	Vascular grafts Surgical grafts and sutures
Poly(methyl methacrylate) (pMMA)	Fracture fixation Intraocular lenses Dentures
Poly(2-hydroxyethylmethacrylate) (pHEMA)	Contact lenses Catheters
Polyacrylonitrile (PAN)	Dialysis membranes
Polyamides	Dialysis membranes Sutures
Polypropylene (PP)	Plasmapheresis membranes Sutures
Poly(vinyl chloride) (PVC)	Plasmapheresis membranes Blood bags
Poly(ethylene-co-vinyl acetate)	Drug delivery devices
Poly(L-lactic acid), Poly(glycolic acid), and Poly(lactide-co-glycolide) (PLA, PGA, and PLGA)	Drug delivery devices Sutures
Polystyrene (PS)	Tissue culture flasks
Poly(vinyl pyrrolidone) (PVP)	Blood substitutes
Hydroxyapatite	Bone repair
Collagen	Artificial skin
Poly(*p*-dioxanone) and poly(*omega*-pentadecalactone-*co*-*p*-dioxanone) [121]	Sutures

To perform any measurement of cell interaction with a polymer substrate, the polymeric material and the cells must come into contact. Preferably, the experimenter should control (or at least understand) the nature of the contact; this is a critical, and often overlooked, aspect of all of these measurements. Some materials are easily fabricated in a format suitable for study; polystyrene films, for example, are transparent, durable, and strong. Other materials must be coated onto a rigid substrate (such as a glass coverslip) prior to study. But since cell function is sensitive to chemical, morphological, and mechanical properties of the surface,

almost every aspect of material preparation can introduce variables that are known to influence cell interactions.

ADHESION AND SPREADING

Most tissue-derived cells require attachment to a solid surface for viability and growth. For this reason, the initial events that occur when a cell approaches a surface are of fundamental interest. In tissue engineering, cell adhesion to a surface is critical because adhesion precedes other cell behaviors such as cell spreading, cell migration and, often, differentiated cell function.

A number of techniques for quantifying the extent and strength of cell adhesion have been developed: a more complete description of these techniques with early references is available (see Chapter 6 of reference [2]). In fact, so many different techniques are used that it is usually difficult to compare studies performed by different investigators. This situation is further complicated by the fact that cell adhesion depends on a large number of experimental parameters, many of which are difficult to control. The simplest methods for quantifying the extent of cell adhesion to a surface involve three steps:

1) Suspension of cells over a surface,
2) Incubation of the sedimented cells in culture medium for some period of time, and
3) Detachment of loosely adherent cells under controlled conditions.

The extent of cell adhesion, which is a function of the conditions of the experiment, is determined by quantifying either the number of cells that remain associated with the surface (the 'adherent' cells) or the number of cells that were extracted with the washes. Radiolabeled or fluorescently-labeled cells can be used to permit measurement of the number of attached cells. Alternatively, the number of attached cells can be determined by direct visualization, by measurement of concentration of an intracellular enzyme or by binding of a dye to an intracellular component such as DNA. In many cases, the 'adherent' cells are further categorized based on morphologically differences (e.g., extent of spreading, formation of actin filament bundles, presence of focal contacts). This technique is simple, rapid, and, since it requires simple equipment, common. Unfortunately, the force that is provided to dislodge the non-adherent cells is often not controlled, making it difficult to compare results obtained from different laboratories, even when they are using the same technique.

This disadvantage can be overcome by using a centrifuge or a flowing fluid to provide a controllable and reproducible detachment force. In centrifugal detachment assays, the technique described above is modified: after the incubation period, the plate is inverted and subjected to a controlled detachment force by centrifugation. In most flow chambers, the fluid is forced between two parallel plates. Prior to applying the flow field, a cell suspension is injected into the chamber, and the cells are permitted to settle onto the surface of interest and adhere. After some period of incubation, flow is initiated between the plates. These chambers can be used to measure the kinetics of cell attachment, detachment, and rolling on surfaces under conditions of flow. Usually, the overall flow rate is adjusted so that the flow is laminar, and the shear stresses at the wall approximate those found in the circulatory system; however, these chambers can be used to characterize cell detachment under a wide range of conditions.

Radial flow detachment chambers have also been used to measure forces of cell detachment. Because of the geometry of the radial flow chamber, where cells are attached uniformly to a circular plate and fluid is circulated from the center to the periphery of the chamber along radial paths, the fluid shear force experienced by the attached cells decreases with radial position from the center to the periphery. Therefore, in a single experiment, the influence of a range of forces on cell adhesion can be determined. A spinning disk apparatus can be used in a

similar fashion [3], including use with micro- or nano-patterned substrates [4]. Finally, micropipette techniques can be used to measure cell membrane deformability or forces of cell-cell or cell-surface adhesion [5].

MIGRATION

The migration of individual cells within a tissue is a critical element in the formation of the architecture of organs and organisms. Similarly, cell migration is likely to be an important phenomenon in tissue engineering, since the ability of cells to move, either in association with the surface of a material or through an ensemble of other cells, will be an essential part of new tissue formation or regeneration. Cell migration is also difficult to measure, particularly in complex environments. Fortunately, a number of useful techniques for quantifying cell migration in certain situations have been developed. As in cell adhesion, however, no technique has gained general acceptance, so it is difficult to correlate results obtained by different techniques or different investigators.

Experimental methods for characterizing cell motility can be divided into visual assays and population assays: a more complete description with early references is available in Chapter 7 of reference [2]. In visual assays, the movements of a small number (usually ~100) of cells are observed individually. Population techniques, on the other hand, allow the observation of the collective movements of larger numbers of cells: in filter chamber assays the number of cells migrating through a membrane or filter is measured, while in under-agarose assays the leading front of cell movement on a surface under a block of agarose is monitored. Both visual and population assays can be quantitatively analyzed, enabling the estimation of intrinsic cell motility parameters, such as the random motility coefficient and the persistence time: these methods are described in reference [2].

AGGREGATION

Cell aggregates are important tools in the study of tissue development, permitting correlation of cell-cell interactions with cell differentiation, viability and migration, as well as subsequent tissue formation. The aggregate morphology permits re-establishment of the cell-cell contacts normally present in tissues; therefore, cell function and survival are often enhanced in aggregate culture. Because of this, cell aggregates may also be useful in tissue engineering, enhancing the function of cell-based hybrid artificial organs or reconstituted tissue transplants [6].

Gentle rotational stirring of suspensions of dispersed cells is the most common method for making cell aggregates [7]. While this method is suitable for aggregation of many cells, serum or serum proteins must be added to promote cell aggregation in many cases, thus making it difficult to characterize the aggregation process and to control the size and composition of the aggregate. Specialized techniques can be used to produce aggregates in certain cases, principally by controlling cell detachment from a solid substratum. For example, stationary culture of hepatocytes above a non-adherent surface [8] or attached to a temperature sensitive polymer substratum [9] have been used to form aggregates. Synthetic polymers produced by linking cell binding peptides (such as RGD and YIGSR) to both ends of poly(ethylene glycol) (PEG) have been used to promote aggregation of cells in suspension [10].

The kinetics and extent of aggregation can be measured by a variety of techniques. Often, direct visualization of aggregate size is used to determine the extent of aggregation, following the pioneering work of Moscona [7]. The kinetics of aggregation can be monitored in this manner as well, by measuring aggregate size distributions over time. This procedure is facilitated by the use of computer image analysis techniques or electronic particle counters, where sometimes the disappearance of single cells (instead of the growth of aggregates) is followed. Specialized aggregometers can provide reproducible and rapid measurements of

the rate of aggregation; in one such device, small angle light scattering through rotating sample cuvettes is used to produce continuous records of aggregate growth [11].

CELL PHENOTYPE

In tissue-engineering applications, particularly those in which cell-polymer hybrid materials are prepared, one is usually interested in promotion of some cell-specific function. For example, protein secretion and detoxification are essential functions for hepatocytes used for transplantation or liver support devices; therefore, measurements of protein secretion and intracellular enzyme activity (particularly the hepatic P_{450} enzyme system) are frequently used to assess hepatocyte function. Similarly, the expression and activity of enzymes involved in neurotransmitter metabolism (such as choline acetyltransferase or tyrosine hydroxylase) are often used to assess the function of neurons. Production of extracellular matrix (ECM) proteins is important in the physiology of many tissues, particularly connective tissues and skin; collagen and glycosaminoglycan production has been used as an indicator of cell function in chondrocytes, osteoblasts, and fibroblasts. In some cases, the important cell function involves the coordinated activity of groups of cells, such as the formation of myotubules in embryonic muscle cell cultures, the contraction of the matrix surrounding the cells, or the coordinated contraction of cardiac muscle cells. In these cases, cell function is measured by observation of changes in morphology of cultured cells or cell communities.

HIGH-THROUGHPUT METHODS FOR CHARACTERIZATION OF CELL-POLYMER INTERACTIONS

Cell-polymer interactions can be analyzed using methods that allow for many parallel measurements. For example, small spots of ECM proteins can be deposited onto glass slides — or other substrates — to allow high-throughput screening of cell interactions with ECM proteins and protein combinations [12]. This microprinting method can also be applied to three-dimensional materials appropriate for tissue engineering [13]. Microarray printing of polymer and polymer blends allows for screening of interactions of cells with synthetic polymer surfaces as well [14]. Although these methods allow the parallel testing of many different cell/polymer combinations, the measurements of cell interaction are usually limited to light or fluorescence microscopy.

In vivo methods

The context of cell-polymer interactions *in vivo* is inherently complex due to the presence of blood, interstitial fluids, and the presence of multiple cell types in various activation states. Proteins from the blood and interstitial fluid adsorb to polymer surfaces in a non-specific manner and provide a substrate for cell adhesion [15]. Thus, it is believed that cells interact directly with this proteinaceous layer instead of the polymer surface, an assumption that explains the similar *in vivo* reactions elicited by a diverse array of polymers. Almost all implanted polymers induce a unique inflammatory response termed the foreign body response (FBR) [16].

The FBR can be divided in several overlapping phases that include non-specific protein adsorption, inflammatory cell recruitment — predominantly of neutrophils and macrophages, macrophage fusion to form foreign body giant cells (FBGC), and involvement of fibroblasts and endothelial cells (Fig. 20.1). The end result of the FBR is the formation of FBGCs directly on the polymer surface, and the subsequent encapsulation of the implant by a fibrous capsule that is largely avascular. To date, the molecular and cellular determinants of the FBR remain largely unknown. However, recent studies have suggested specific roles for several proteins and a key role for macrophages.

A number of implantation techniques in rodents and larger animals (typically rabbits, pigs, or sheep) have been adopted for the investigation of cell-polymer interactions. Most notably,

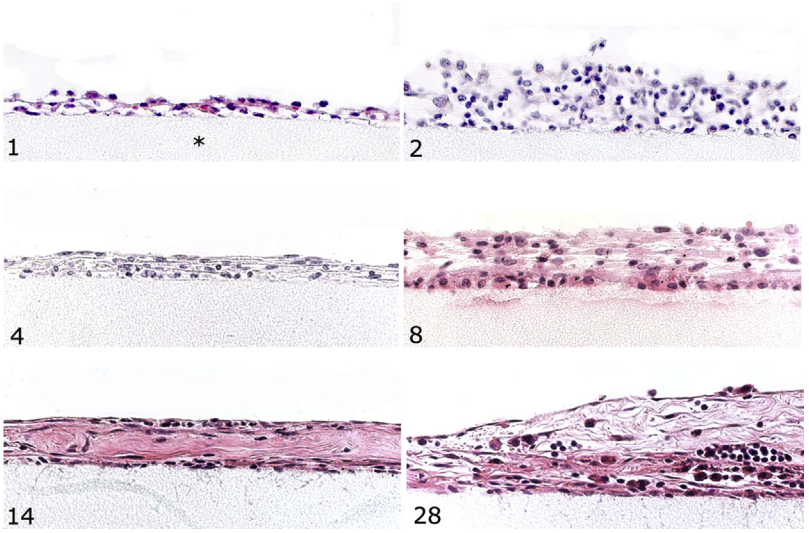

FIGURE 20.1
Development of the foreign body response. Representative images of hematoxylin and eosin-stained Millipore filter disks (mixed cellulose ester) implanted in the peritoneal cavity of wild type mice. The number on each panel indicates the number of days after implantation. In the first two days following implantation, the disks display loose and expanding layers of attached inflammatory cells. Between four and eight days, the cell layers show increased organization that appears to coincide with the deposition of collagen fibers. Continuous deposition of collagenous matrix and an overall reduction in cellular content are characteristic of the two and four week time points. * indicates the disk. Original magnification 400X.

short-term studies for the analysis of protein adsorption, inflammatory cell recruitment and adhesion, and macrophage fusion most often employ either intra-peritoneal (IP) implantation or the subcutaneous (SC) cage-implant, also known as the wound chamber model. In the IP implant model, a sterilized piece of polymer is placed in the peritoneal cavity through a surgical incision [17]. This model has been used extensively in the investigation of protein adsorption onto polymer surfaces and its impact during the early inflammatory response (0–72 hr). In general, due to the short duration, it is difficult to extrapolate the information obtained from such studies to the fate of the FBR. Implant studies of intermediate duration (days to weeks) have been executed using an SC cage-implant; in this system, a polymer is placed within a cage made of stainless steel wire mesh and then implanted through a surgical incision [18]. The SC cage-implant is useful because biologically active soluble agents can be injected through the wire mesh in the immediate vicinity of the polymer.

Both IP and SC implantations allow for the analysis of recruited, non-adherent cell populations, which are collected by lavage of the peritoneal cavity or aspiration of host-derived exudates from the cage. In addition, implant materials can be recovered and analyzed for the presence of adherent cells by various techniques, immunohistochemistry being the most reliable. Thus, both implantation models can provide information regarding the migration of cells to the implantation site and the interaction of cells (adhesion, survival, fusion) with the polymer surface. Other commonly used *in vivo* models for the analysis of cell-polymer interactions involve the implantation of test polymers directly into host tissues such as dermis (subcutaneous), muscle, bone, and brain. Generally, such studies have been carried for longer incubation periods (weeks to months). Furthermore, polymer-based constructs have been surgically implanted at sites where they are expected to perform biological functions, for example vascular grafts [19,20], heart valves [21], and cardiac patches [22]. Thus, in addition to biocompatibility and toxicity, polymers can be evaluated for their role in function of a tissue or organ. The direct implant model can be considered the most representative for most

polymer applications and can provide information regarding the FBR, such as inflammation (macrophage accumulation and polarization, FBGC formation), fibrosis (collagen content), encapsulation (capsule thickness), and angiogenesis (vascular density). Finally, in cases where the polymer is susceptible to degradation, additional analyses can be performed to evaluate the role of chemical and physical changes of the material in interactions with the tissue.

CELL INTERACTIONS WITH POLYMERS

Protein adsorption to polymers

A polymeric material that is placed in solution or implanted in the body becomes coated with proteins quickly, usually within minutes. Many of the subsequent interactions of cells with the material depend on, or derive from, the composition of the protein layer that forms on the surface. Polymers have been shown to adsorb a large number of proteins *in vitro* [23]. For example, proteomic analysis of PP, PET, and PDMS incubated with serum identified immunoglobulins, transferrin, albumin, serum amyloid P, and complement C4, among other proteins, on the polymer surface [24]. The C3 component of complement has also been shown to adsorb to medical grade PEU and adhesion of inflammatory cells to the polymer was reduced in the presence of C3-depleted serum but not fibronectin-depleted serum [25]. In contrast, *in vivo* studies employing the IP implantation method suggest that adsorption of fibrinogen is the critical determinant of the FBR [26]. Specifically, adsorption and denaturation of fibrinogen on polymer surfaces might lead to the exposure of cryptic cell adhesion motifs (integrin binding sites) which influence subsequent cellular interactions. Despite the recognized importance of adsorbed proteins, it is possible that direct contact between polymers and cells can have significant impact on cell function. Supporting evidence for such interactions was shown in study where large PMMA beads (150 μm in diameter) induced the production of a pro-inflammatory cytokine by macrophages in the absence of serum proteins [27].

Effect of polymer chemistry on cell behavior

SYNTHETIC POLYMERS

For cells attached to a solid substrate, cell behavior and function depend on the characteristics of the substrate. Consider, for example, experiments described by Folkman and Moscona, in which cells were allowed to settle onto surfaces formed by coating conventional tissue culture polystyrene (TCPS) with various dilutions of pHEMA [28]. As the amount of pHEMA added to the surface was increased, cell spreading decreased as reflected by the average cell height on the surface. The degree of spreading, or average height, correlated with the rate of cell growth (Fig. 20.2), suggesting that cell shape, which was determined by the adhesiveness

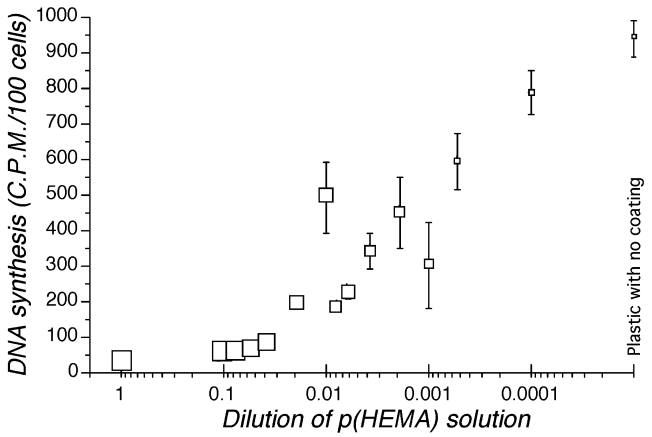

FIGURE 20.2

Cell shape and growth are modulated by properties of a polymer surface. Cell culture surfaces were produced by evaporating diluted solutions of pHEMA onto TCPS. The uptake of [^{3}H]thymidine was used as a measure of proliferation. The size of the symbol represents the relative cell height; small symbols represent cells with small heights, and therefore significant spreading, large symbols represent cells with large heights, and therefore negligible spreading. *Data replotted from Folkman and Moscona [28].*

of the surface, modulated cell proliferation. In these experiments, two well-known polymers (TCPS and pHEMA) were used to produce a series of surfaces with graded adhesivity, permitting the identification of an important aspect of cell physiology. These experiments clearly demonstrate that the nature of a polymer surface will have important consequences for cell function, an observation of considerable significance with regard to the use of polymers in tissue engineering.

Following an experimental design similar to that employed by Folkman and Moscona, a number of groups have examined the relationship between chemical or physical characteristics of the substrate and behavior or function of attached cells. For example, in a study of cell adhesion, growth, and collagen synthesis on synthetic polymers, fetal fibroblasts from rat skin were seeded onto surfaces of 13 different polymeric materials [29]. The polymer surfaces had a range of surface energies, as determined by static water contact angles, from very hydrophilic to very hydrophobic. On a few of the surfaces (PVA and cellulose), little cell adhesion and no cell growth was observed. On most of the remaining surfaces, however, a moderate fraction of the cells adhered to the surface and proliferated. The rate of proliferation was relatively insensitive to surface chemistry: the cell doubling time is ~24 hr, with slightly slower growth observed for the two very hydrophobic surfaces (PTFE and PP). Collagen biosynthesis was also correlated with contact angle, with higher rates of collagen synthesis per cell for the most hydrophobic surfaces.

Results from a number of similar studies have been summarized previously: see Table 12.1 and 12.2 in reference [2], for example. Some general conclusions emerge from this past work. For example, in a number of studies, cell adhesion appears to be maximized on surfaces with intermediate wettability (Fig. 20.3). For most surfaces, adhesion requires the presence of serum and, therefore, this optimum is likely related to the ability of proteins to adsorb to the surface. (In the absence of serum, however, adhesion is enhanced on positively charged surfaces, due to the net negative charge of most cell membranes.) Cell spreading on copolymers of HEMA (hydrophilic) and EMA (hydrophobic) was highest at an intermediate HEMA content, again corresponding to intermediate wettability [30]; in this case, spreading correlated with fibronectin adsorption [30]. The rate of fibroblast growth on polymer surfaces appears to be relatively independent of surface chemistry. Cell viability may also be related to interactions with the surface, although this is not yet predictable. The migration of surface-attached fibroblasts, endothelial cells, and corneal epithelial cells is also a function of polymer surface chemistry: see reference [2] for more details.

SURFACE MODIFICATION

Polymers can frequently be made more suitable for cell attachment and growth by surface modification. In fact, TCPS substrates used for tissue culture are obtained by surface treatment

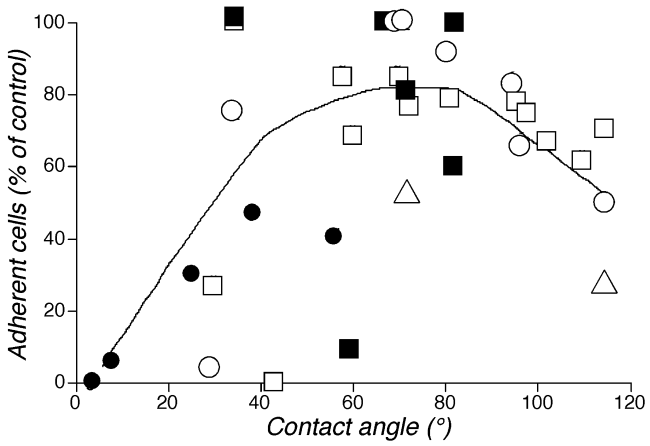

FIGURE 20.3
The relationship between cell adhesion and water-in-air contact angle. *Data replotted from Tamada and Ikada for fibroblasts (open squares) [29], Ikada for L cells (open circles) [54], Hasson et al. for endothelial cells (open triangles) [118], van Wachem et al. for endothelial cells (filled circles) [119].*

of polystyrene (PS) by glow discharge or exposure to chemicals, such as sulfuric acid, to increase the number of charged groups at the surface, which improves attachment and growth of many types of cells. Other polymers can also be modified in this manner. Treatment of pHEMA with sulfuric acid, for example, improves the adhesion of endothelial cells and permits cell proliferation on the surface [31]. Modification of PS or PET by radio frequency plasma deposition enhances attachment and spreading of fibroblasts and myoblasts [32]. The effects of these surface modifications appear to be secondary to increased adsorption of cell attachment proteins, such as fibronectin and vitronectin, to the surface. On the other hand, some reports have identified specific chemical groups at the polymer surface — such as hydroxyl (-OH) [33] or surface C-O functionalities [32] — as important factors in modulating the fate of surface-attached cells.

So far, no general principles that would allow prediction of the extent of attachment, spreading, or growth of cultured cells on different polymer surfaces have been identified. Correlations have been made with parameters such as the density of surface hydroxyl groups [33], density of surface sulfonic groups [34], surface free energy [35,36], fibronectin adsorption [32], and equilibrium water content [37] for specific cells, but exceptions to these correlations are always found. Perhaps general predictive correlations will emerge, as more complete characterization of polymer systems — including bulk properties, surface chemical properties, and nanoscale topography (as described below) — are collected. But many commonly used polymer materials are complicated mixtures, containing components that are added to enhance polymerization or to impart desired physical properties, often in trace quantities. Lot-to-lot variations in the properties of commercially available polymers can be significant.

The surface chemistry of polymers appears to influence cell interactions *in vivo*. For example, the ability of macrophages to form multinucleated giant cells at the material surface correlates with the presence of certain chemical groups at the surface of hydrogels: macrophage fusion decreases in the order $(CH_3)_2N$- > -OH = -CO-NH- > $-SO_3H$ > -COOH (-COONa) [38]. A similar hierarchy has been observed for CHO (Chinese Hamster Ovary) cell adhesion and growth on surfaces with grafted functional groups: CHO cell attachment and growth decreased in the order $-CH_2NH_2$ > $-CH_2OH$ > $-CONH_2$ > -COOH [39].

Layer-by-layer (LbL) assembly of nanofilms is a versatile approach for the control of surface properties to modulate cell attachment and function. In the most general technique, alternating layers of two polymers — one polycationic and the other polyanionic — are deposited onto a substrate to create a film of controlled thickness and chemical properties. By using a cell attachment protein, such as fibronectin, as one of the polyelectrolytes, thin films that control cell adhesion to the substrate can be created [40]. Control of conditions during LbL assembly — such as solution pH — can create films with different physical structures, which further modulate cell interactions [41]. Covalent reactions between the polymers — produced either by addition of crosslinking agents after LbL film formation or during the assembly of the film using reactive polymers — allows for the creation of more stable films [42].

BIODEGRADABLE POLYMERS

Biodegradable polymers slowly degrade and then dissolve following implantation. This feature may be important for many tissue-engineering applications, since the polymer will disappear as functional tissue regenerates. For this reason, interactions of cells with a variety of biodegradable polymers have been studied. Biodegradable polymers may provide an additional level of control over cell interactions: during polymer degradation, the surface of the polymer is constantly renewed, providing a dynamic substrate for cell attachment and growth.

Homopolymers and copolymers of lactic and glycolic acid (PLA, PGA, PLGA) have been frequently examined as cell culture substrates, since they have been used as implanted sutures

for several decades. Many types of cells will attach and grow on these materials. For example, chondrocytes proliferate and secrete glycosaminoglycans within porous meshes of PGA and foams of PLA [43]. Similarly, rat hepatocytes attach to blends of biodegradable PLGA polymers and secrete albumin when maintained in culture [44]. Neonatal rat osteoblasts also attach to PLA, PGA, and PLGA substrates and synthesize collagen in culture [45].

Cell adhesion and function has been examined on materials made from other biodegradable polymers. As an example, cells from an osteogenic cell line attach onto polyphosphazenes produced with a variety of side groups; the rate of cell growth as well as the rate of polymer degradation depends on side group chemistry [46].

Use of degradable polymers increases the complexity of analysis in the *in vivo* setting because their degradation products can cause excessive and prolonged biological responses. Depending on the material used, degradation products can be released by hydrolysis, enzymatic digestion, degradative activity of macrophages and FBGC, or combinations of these mechanisms. The effects of polymer-derived products that are released by hydrolysis or enzymatic digestion depend on the chemical properties of the polymer and are not difficult to determine. On the other hand, the effects of products released due to cellular activities are difficult to predict, because the chemical and biological mechanisms responsible for their generation and release have not been established. Furthermore, the activity of cells, and thus the rate of release, can be influenced by several parameters such as local concentrations of growth factors. It is expected that biodegradable polymers should allow for the favorable resolution of the FBR after their complete disappearance from the host tissue. The disappearance of FBGC from implantation sites after degradation of polymers to microparticles smaller than 10 μm in size has been observed (Kyriakides et al., unpublished data). Furthermore, macrophages were observed to persist until the degradation of the polymer was complete. In SC implantation sites the formation of a vascularized collagenous work as a replacement for the polymer was observed. Presumably, the physiology of the implantation site, the acuteness of the inflammatory response, and the rate of polymer degradation all influence the nature of the FBR. Favorable *in vivo* results have been obtained with biodegradable elastomeric polyesters composed of poly(diol citrates) [47]. However, the duration of the FBR was shown to exceed 12 months in implanted compressed naltrexone-poly[trans-3,6-dimethyl-1,4-dioxane-2,5-dione] (DL-lactide) loaded microspheres [48].

SYNTHETIC POLYMERS WITH ADSORBED PROTEINS

As mentioned above, cell interactions with polymer surfaces appear to be mediated by proteins, adsorbed from the local environment. Since it is difficult to study these effects *in situ* during cell culture, often the polymer surfaces are pretreated with purified protein solutions. In this way, the investigators hope that subsequent cell behavior on the surface will represent cell behavior in the presence of a stable layer of surface-bound protein. A major problem with this approach is the difficulty in determining whether surface conditions, i.e., the density of protein on the surface, change during the period of the experiment.

As described earlier, cell spreading, but not attachment, correlates with fibronectin adsorption to a variety of surfaces. Rates of cell migration on a polymer surface are usually sensitive to the concentration of pre-adsorbed adhesive proteins [49], and migration can be modified by addition of soluble inhibitors to cell adhesion [50]. It appears that the rate of migration is optimal at intermediate substrate adhesiveness, as one would expect from mathematical models of cell migration [51]. In fact, a recent study shows a clear correlation between adhesiveness and migration for CHO cells [52].

The outgrowth of corneal epithelial cells from explanted rabbit corneal tissue has been used as an indicator of cell attachment and migration on biomaterial surfaces [53]. When corneal cell outgrowth was measured on ten different materials that were pre-adsorbed with

fibronectin, outgrowth generally increased with the ability of fibronectin to adsorb to the material. Exceptions to this general trend could be found, suggesting that other factors (perhaps stability of the adsorbed protein layer) are also important.

HYBRID POLYMERS WITH IMMOBILIZED FUNCTIONAL GROUPS

Surface modification techniques have been used to produce polymers with surface properties that are more suitable for cell attachment [54]. For example, chemical groups can be added to change the wettability of the surface, which often influences cell adhesion (Fig. 20.3), as described above. Alternatively, whole proteins such as collagen can be immobilized to the surface, providing the cell with a substrate that more closely resembles the ECM found in tissues. Collagen and other ECM molecules have also been incorporated into hydrogels by either adding the protein to a reaction mixture containing monomers and initiating the radical polymerization, or mixing the protein with polymerized polymer, such as pHEMA, in appropriate solvents. To isolate certain features of ECM molecules, and to produce surfaces that are simpler and easier to characterize, smaller biologically active functional groups have been used to modify surfaces. These biologically active groups can be oligopeptides, saccharides, or glycolipids.

Certain short amino acid sequences, identified by analysis of active fragments of ECM molecules, appear to bind to receptors on cell surfaces and mediate cell adhesion. For example, the cell-binding domain of fibronectin contains the tripeptide RGD (Arg-Gly-Asp) [55].[1] Cells attach to surfaces containing adsorbed oligopeptides with the RGD sequence and soluble, synthetic peptides containing the RGD sequence reduce the cell binding activity of fibronectin, demonstrating the importance of this sequence in adhesion of cultured cells. A large number of ECM proteins (fibronectin, collagen, vitronectin, thrombospondin, tenascin, laminin, and entactin) contain the RGD sequence. The sequences YIGSR and IKVAV on the A chain of laminin also have cell binding activity, and appear to mediate adhesion in certain cells.

Because RGD appears to be critical in cell adhesion to ECM, many investigators have examined the addition of this sequence to synthetic polymer substrates. The addition of cell binding peptides to a polymer can induce cell adhesion to otherwise non-adhesive or weakly-adhesive surfaces. Cell spreading and focal contact formation are also modulated by the addition of peptide (Fig. 20.4). Since cells contain cell adhesion receptors that recognize only certain ECM molecules, use of an appropriate cell binding sequence can lead to cell-selective surfaces, where the population of the cells that adhere to the polymer is determined by the peptide [56].

The presence of serum proteins attenuates the adhesion activity of peptide-grafted PEU surfaces [57], highlighting a difficulty in using these peptide-grafted materials *in vivo*. This problem may be overcome, however, through the development of base materials that are biocompatible yet resistant to protein adsorption. One of the most successful approaches for reducing protein adsorption or cell adhesion is to produce a surface rich in PEG. A variety of techniques have been used including surface grafting of PEG, adsorption of PEG-containing copolymers, semi-interpenetrating networks, or immobilization of PEG-star polymers to increase the density of PEG chains at the surface.

As an alternate approach, matrices can be formed directly from synthetic polypeptides. For example, genes coding the β-sheet of silkworm silk have been combined with genes coding fragments of fibronectin to produce proteins that form very stable matrices with cell adhesion domains (Pronectin F®). Synthetic proteins based on peptide sequences from elastin have been used as cell culture substrates: in the presence of serum, fibroblasts and endothelial cells

adhered to the surfaces of matrices formed by γ-irradiation crosslinking of polypeptides containing repeated sequences GGAP, GGVP, GGIP, and GVGVP [58].

Surface adsorption of homopolymers of basic amino acids, such as polylysine and polyornithine, are frequently used to enhance cell adhesion and growth on polymer surfaces. Similarly, covalently bound amine groups can also influence cell attachment and growth. Polymerization of styrene with monamine- or diamine-containing monomers produced copolymers with ~8% mono- or diamine side chains, which enhanced spreading and growth: diamine-PS > monoamine-PS > PS [59].

The immobilization of saccharide units to polymers can also influence cell attachment and function. As an example, N-p-vinylbenzyl-o-β-D-galactopyranosyl-(1−4)-D-gluconamide has been polymerized to form a polymer with a polystyrene backbone and pendant lactose functionalities [60]. Rat hepatocytes adhere to surfaces formed from this polymer, via asialoglycoprotein receptors on the cell surface, and remain in a rounded morphology consistent with enhanced function in culture. In the absence of serum, rat heptaocytes will adhere to similar polymers with pendant glucose, maltose, or maltotriose. Similar results have been obtained with polymer surfaces derivatized with N-acetyl glucosamine, which is recognized by a surface lectin on chicken hepatocytes [61].

Films produced by LbL techniques can also be surface modified to modulate cell interactions. For example, for films that are assembled using covalent reactions, residual reactive groups can be used to attach small molecules that control the interaction of the film with cells. In one study, PEI films produced by covalent LbL assembly were further modified by coupling of small molecules. Coupling of hydrophobic molecules produced films that permitted cell attachment and growth, whereas covalent coupling of hydrophilic sugar groups reduced cell attachment, even in the presence of serum proteins [62].

Electrically charged or electrically conducting polymers

A few studies have examined cell growth and function on polymers that are electrically charged. Piezoelectric polymer films, which were produced by high intensity corona poling of poly(vinylidene fluoride) or poly(vinylidene fluoride-*co*-trifluoroethylene) and should generate transient surface charge in response to mechanical forces, enhanced the attachment and differentiation of mouse neuroblastoma cells (Nb2a), as determined by neurite number and mean neurite length [63]. These observations may be important *in vivo*, as well. For example, positively-poled poly(vinylidene fluoride-*co*-trifluoroethylene) nerve guidance

channels produced greater numbers of myelinated axons than either negatively-poled or unpoled channels [64]. Electrically conducting polymers might be useful for tissue-engineering applications, because their surface properties can be changed by application of an applied potential. For example, endothelial cells attached and spread on fibronectin-coated polypyrrole films in the oxidized state, but became rounded and ceased DNA synthesis when the surface was electrically reduced [65].

Influence of surface morphology on cell behavior

The microscale texture of an implanted material can have a significant effect on the behavior of cells in the region of the implant. This has long been observed *in vivo*. For example, fibrosarcomas developed with high frequency, approaching 50% in certain situations, around implanted Millipore filters; the tumor incidence increased with decreasing pore size in the range of 450 to 50 μm [66].

The behavior of cultured cells on surfaces with edges and grooves is different than behavior on smooth surfaces. In many cases, cells oriented and migrated along fibers or ridges in the surface, a phenomenon called contact guidance from early studies on neuronal cell cultures [67]. Fibroblasts orient on grooved surfaces [68], with the degree of cell orientation depending on both the depth and pitch of the grooves. Not all cells exhibit the same degree of contact guidance when cultured on identical surfaces: a comparison of cell responses to surfaces with grooves and edges, collected from early studies, is provided in Table 12.3 of reference [2]. These measurements are relevant to design of materials for tissue engineering: adhesion and initial migration of an osteoblast cell line was examined on materials with grooves ranging in pitch from 150 to 1000 nm and found to be optimal on grooves of intermediate spacing [69]. Cultured stem cells behave differently on grooved surfaces, when compared to smooth surfaces, which appears to be secondary to changes in integrin assembly, focal contact formation, and cytoskeletal organization [70].

Other textures also influence cell behavior. For example, substrates with peaks and valleys influence the function of attached cells [71]. PDMS surfaces with 2 to 5 μm texture maximized macrophage spreading. Similarly, PDMS surfaces with 4 or 25 μm^2 peaks uniformly distributed on the surface provided better fibroblast growth than 100 μm^2 peaks or 4, 25 or 100 μm^2 valleys.

The microscale structure of a surface has a significant effect on cell migration, at least for the migration of human neutrophils. In one study, microfabrication technology was used to create regular arrays of micron-size holes (2 μm × 2 μm × 210 nm) on fused quartz and photosensitive polyimide surfaces [72]. The patterned surfaces, which mimicked a structural element of 3D network (i.e., spatially separated mechanical edges), were used to study the effect of substrate microgeometry on neutrophil migration. The edge-to-edge spacing between features was systematically varied from 6 μm to 14 μm with an increment of 2 μm. The presence of evenly distributed holes at the optimal spacing of 10 μm enhanced migration by a factor of 2 on polyimide, a factor of 2.5 on collagen-coated quartz and a factor of 10 on uncoated quartz. The biphasic dependence on the mechanical edges of neutrophil migration on 2D patterned substrate was strikingly similar to that previously observed during neutrophil migration within 3D networks, suggesting that microfabricated materials provide relevant models of 3D structures with precisely defined physical characteristics. Perhaps more importantly, these results illustrate that the microgeometry of a substrate, when considered separately from adhesion, can play a significant role in cell migration.

Use of patterned surfaces to control cell behavior

A variety of techniques have been used to create patterned surfaces containing cell adhesive and non-adhesive regions. Patterned surfaces are useful for examining fundamental determinants of cell adhesion, growth, and function. For example, individual fibroblasts were

attached to adhesive micro-islands of palladium that were patterned onto a non-adhesive pHEMA substrate using microlithographic techniques [73]. By varying the size of the micro-island, the extent of spreading and hence the surface area of the cell was controlled. On small islands (~500 μm^2) cells attached, but did not spread. On larger islands (4,000 μm^2), cells spread to the same extent as in unconfined monolayer culture. Cells on large islands proliferate at the same rate as cells in conventional culture, and most cells attached to small islands proliferate at the same rate as suspended cells. For 3T3 cells, however, contact with the surface enhanced proliferation, suggesting that anchorage can stimulate cell division by simple contact with the substrate as well as by increases in spreading.

A number of other studies have employed patterned surfaces in cell culture. Micrometer-scale adhesive islands of self-assembled alkanethiols were created on gold surfaces using a simple stamping procedure [74], which served to confine cell spreading islands. When hepatocytes were attached to these surfaces, larger islands (10,000 μm^2) promoted growth, while smaller islands (1,600 μm^2) promoted albumin secretion. Stripes of a monoamine derivatized surface were produced on fluorinated ethylene propylene films by radio frequency glow discharge [75]. Since proteins adsorbed differently to the monamine-derivatized and the untreated stripes, striped patterns of cell attachment were produced. A similar approach, using photolithography to produce hydrophilic patterns on a hydrophobic surface, produced complex patterns of neuroblastoma attachment and neurite extension [76]. A variety of substrate microgeometries were created by photochemical fixation of hydrophilic polymers onto TCPS or hydrophobic polymers onto PVA through patterned photomasks: bovine endothelial cells attached and proliferated preferentially on either the TCPS surface (on TCPS/hydrophilic patterns) or the hydrophobic surface (on PVA/hydrophobic patterns) [77]. When chemically patterned substrates were produced on self-assembled monolayer films using microlithographic techniques, neuroblastoma cells attached to and remained confined within amine-rich patterns on these substrates [78].

CELL INTERACTIONS WITH POLYMERS IN SUSPENSION

Most of the studies reviewed in the preceding section concerned the growth, migration, and function of cells attached to a solid polymer surface. This is a relevant paradigm for a variety of tissue-engineering applications, where polymers will be used as substrates for the transplantation of cells or as scaffolds to guide tissue regeneration *in situ*. Polymers may be important in other aspects of tissue engineering, as well. For example, polymer microcarriers can serve as substrates for the suspension culture of anchorage dependent cells, and therefore might be valuable for the *in vitro* expansion of cells or cell transplantation [79]. In addition, immunoprotection of cells suspended within semi-permeable polymer membranes is another important approach in tissue engineering, since these encapsulated cells may secrete locally active proteins or function as small endocrine organs within the body.

The idea of using polymer microspheres as particulate carriers for the suspension culture of anchorage dependent cells was introduced by van Wezel [80]. As described above for planar polymer surfaces, the surface characteristics of microcarriers influence cell attachment, growth, and function. In the earliest studies, microspheres composed of diethylaminoethyl (DEAE)-dextran were used; these spheres have a positively charged surface and are routinely used as anion-exchange resins. DEAE-dextran microcarriers support the attachment and growth of both primary cells and cell lines, particularly when the surface charge is optimized. In addition to dextran-based microcarriers, microspheres that support cell attachment can be produced from PS, gelatin, and many of the synthetic and naturally-occurring polymers described in the preceding sections. The surface of the microcarrier can be modified chemically, or by immobilization of proteins, peptides, or carbohydrates.

Suspension culture techniques can also be used to permit cell interactions with complex three-dimensional polymer formulations. For example, cells seeding onto polymer fiber

meshes during suspension culture often results in more uniform cell distribution within the mesh than can be obtained by inoculation in static culture [81].

In cell encapsulation techniques, cells are suspended within thin-walled capsules or solid matrices of polymer. Alginate forms a gel with the addition of divalent cations under very gentle conditions and, therefore, has been frequently used for cell encapsulation. Certain synthetic polymers, such as polyphosphazenes, can also be used to encapsulate cells by cation-induced gelation. Low-melting point agarose has also been studied extensively for cell encapsulation. Methods for the microencapsulation of cells within hydrophilic or hydrophobic polyacrylates by interfacial precipitation have been described [82], although the thickness of the capsule can limit the permeation of compounds, including oxygen, through the semi-permeable membrane shell. Interfacial polymerization can be used to produce conformal membranes on cells or cell clusters [83], thereby providing immunoprotection while reducing diffusional distances.

Hollow fibers are frequently used for macroencapulsation; cells and cell aggregates are suspended within thin fibers composed of a porous, semi-permeable polymer. Chromaffin cells suspended within hollow fibers formed from copolymer of vinyl chloride and acrylonitrile, which are commonly used as ultrafiltration membranes, have been studied as potential treatments for cancer patients with pain [84], Alzheimer's disease [85], and retinitis pigmentosa [86]. Other polymer materials — such as chitosan, alginate, and agar — have been added to the interior of the hollow fibers to provide an internal matrix that enhances cell function or growth.

Polymer nanoparticles are rapidly becoming important materials for drug delivery and tissue engineering, but little is known about how particles with diameters in the range of 50 to 200 nm interact with cells. When PLGA nanoparticles (~100 nm diameter) were suspended over monolayers of airway, intestinal, or renal tubular epithelial cells, particles were internalized as soon as 30 min after first exposure, becoming widely distributed through the intracellular space over a 24 hour period [87], but the extent of nanoparticle internalization varied among the epithelial cell types. PS nanoparticle interactions with model cell membranes depend on particle size, shape, and surface chemistry, as well as membrane composition, which may be a factor in the variable interactions of particles with different cells [88]. Although multiple mechanisms of nanoparticle entry into cells have been suggested, endocytosis is important in most cells, although it is not the only mechanism. For example, PS particles (20 nm diameter) translocated — in and apical to the basolateral direction — through monolayers of cultured alveolar cells, with particles carrying a positive surface charge moving more effectively than particles with a negative surface charge, apparently by transcellular, non-endocytic mechanisms [89].

Proteins absorb readily to the surface of polymer nanoparticles, as they do to all polymer surfaces. The presence of surface-bound proteins influences the interaction of nanoparticles with cells [90]. Particle shape may also have an influence on polymer particle interactions with cells [91], although there are few studies that have examined the effect of shape, particularly for particles with diameters less than 1 μm. As in other systems, tethering of ligands to the polymer surface can influence nanoparticle interactions with cells, including enhancing association and internalization [92].

CELL INTERACTIONS WITH THREE-DIMENSIONAL POLYMER SCAFFOLDS AND GELS

Cells within tissues encounter a complex chemical and physical environment that is quite different from commonly used cell culture conditions. Three-dimensional cell culture methods are frequently used to simulate the chemical and physical environment of tissues. Often, tissue-derived cells cultured in ECM gels will reform multicellular structures that are reminiscent of tissue architecture.

Gels of agarose have also been used for three-dimensional cell culture. Chondrocytes dedifferentiate when cultured as monolayers, but re-express a differentiated phenotype when cultured in agarose gels [93]. When fetal striatal cells are suspended in three-dimensional gels of hydroxylated agarose, ~50% of the cells extended neurites in gels containing between 0.5 and 1.25% agarose, but no cells extended neurites at concentrations above 1.5%. This inhibition of neurite outgrowth correlates with an average pore radius of greater than 150 nm [94]. Neurites produced by PC12 cells within agarose gels, even under optimal conditions, are much shorter and fewer in number than neurites produced in gels composed of ECM molecules [95].

Macroporous hydrogels can also be produced from pHEMA-based materials, using either freeze-thaw or porosigen techniques. These materials, when seeded with chondrocytes, may be useful for cartilage replacement [96]. Similar structures may be produced from PVA by freeze-thaw crosslinking. Recently, a PEG-based macroporous gel was used as a scaffold for endothelial cells to form microvessel networks *in vivo* [97]. Although cells adhere poorly to pHEMA, PVA, and PEG materials, adhesion proteins or charged polymers can be added during the formation to encourage cell attachment and growth. Alternatively, water-soluble, non-adhesive polymers containing adhesive peptides, such as RGDS, can be photopolymerized to form a gel matrix around cells (see [98], for example).

Fiber meshes and foams of PLGA, PLA, and PGA have been used to create three-dimensional environments for cell proliferation and function, and to provide structural scaffolds for tissue regeneration. When cultured on three-dimensional PGA fiber meshes, chondrocytes proliferate, produce both glycosaminoglycans and collagen, and form structures that are histologically similar to cartilage [99]. The internal structure of the material, as well as the physical dimensions of the polymer fiber mesh, influence cell growth rate, with slower growth being observed in thicker meshes. Changing the fluid mechanical forces on the cells during the tissue formation also appears to influence the development of tissue structure.

In addition to fiber meshes, porosity can be introduced into polymer films by phase separation, freeze drying, salt leaching and a variety of other methods (reviewed in reference [100]). It is now possible to make porous, degradable scaffolds with controlled pore architectures and oriented pores [101,102]. Fabrication methods that provide control over the structure at different length scales may be useful in the production of three-dimensional tissue-like structures.

Most methods for producing fiber meshes are limited to producing fibers ~10 microns in diameter, which is much larger than the diameter of natural fibers that occur in the extracellular matrix, and also larger than many of the features that are known to be important in orienting or guiding cell activity. Electrospinning techniques can be used to make small diameter fibers and non-woven meshes of a variety of materials including poly(caprolactone), PLA, collagen, and elastin mimetic polymers.

CELL INTERACTIONS UNIQUE TO THE *IN VIVO* SETTING

While cell interactions with polymers *in vitro* can be described by examination of cell behaviors — such as adhesion, migration, or gene expression — or the coordinated behavior of cell groups — such as aggregation, cell interactions with polymers *in vivo* can lead to other responses, involving cells that are recruited to the implantation site and remodeling of the tissue space surrounding, or even within, the polymeric material. Inflammation, the FBR, and angiogenesis are three examples of these more global responses to an implanted material.

There is much still to learn in this area, but it is clear that both the implant material and the physiology of the implant site are important variables. A study describing a relatively simple experiment, in which ePTFE implants were placed in adipose tissue, in subcutaneous tissue, or epicardially illustrates the variability of these responses [103]. Moreover, studies

in MCP1-null mice have shown that the extent of the FBR was dependant on the implantation site [104,105]. This short section introduces these physiological responses to implanted materials.

Inflammation

The implantation of polymers through surgical incisions means that an initial component of the FBR involves a wound healing-like response and it is reasonable to assume that the early inflammatory response is mediated, at least in part, by wound-derived factors. Analysis of inflammatory cells has been pursued in several implantation models and was shown to involve predominantly neutrophils (early) and monocyte/macrophages (late). Subsequent to their recruitment, these cells are believed to utilize adhesion receptors to interact with adsorbed proteins. Studies in mice that lack specific integrins or fibrinogen have provided supporting evidence for this hypothesis [106,107]. Specifically, short-term (18 hr) IP implantation of polyethylene terephthalate (PET) disks in mice that lack fibrinogen indicated normal recruitment but reduced adhesion of macrophages and neutrophils to the polymer. In the same study, an analysis of the response in mice that lack plasminogen, indicated no changes in cell adhesion to the polymer, despite a reduction in the recruitment of both cell types in the peritoneal cavity. Thus, in addition to fibrinogen for adhesion, inflammatory cells can utilize plasminogen for migration/recruitment. Moreover, studies in mice lacking plasma fibronectin displayed altered foreign body response [108]. More recently, it was shown that polymer-macrophage interactions can lead to activation of the inflammasome leading to the secretion of the pro-inflammatory cytokine IL-1β [27]. In the same study, it was shown that mice that lack components of the inflammasome mount reduced FBR suggesting that initial interactions between cells and polymers are critical determinants of the FBR. Surprisingly, the chemokine CCL2 (also known as monocyte chemoattractant protein or MCP-1), was shown not to be important in monocyte/macrophage recruitment in long-term implants in the subcutis [104]. However, CCL2 was shown to be important for macrophage fusion leading to FBGC formation. Subsequently, it was shown that CCL2 was critical for the recruitment of inflammatory cells in the FBR when implants were placed in the peritoneal cavity of mice [105]. Consistent with the notion that macrophage responses are critical in the FBR, IP implants in CCL2-null mice displayed minimal encapsulation.

FBGC can cause damage to polymer surfaces through their degradative and phagocytic activities, and thus pose a significant obstacle to the successful application of polymer-based biomaterials and devices. *In vivo* studies have identified a critical role for interleukin (IL)-4 in the formation of FBGC [18], but the regulation of macrophage fusion is not fully understood [109]. On the other hand, several studies have focused on the role of polymer surface chemistry on macrophage function and FBGC formation. For example, analysis of macrophage adhesion, apoptosis, and fusion on hydrophobic (PET and BDEDTC-coated), hydrophilic (PAAm), anionic (PAANa), and cationic (DMAPAAmMel) surfaces implanted in the rat cage-implant model revealed that PAAm and PAANa induced more apoptosis and reduced adhesion and fusion [110].

Fibrosis and angiogenesis

Unlike wound healing, the resolution of the polymer-associated inflammatory response is characterized by the excessive deposition of a highly organized collagenous matrix and a striking paucity of blood vessels [111,112]. The collagenous capsule can vary in thickness but usually exceeds 100 μm, presumably to limit diffusion of small molecules to and from the polymer. The dense and organized nature of the collagen fibers in the capsule could play a role in limiting blood vessel formation. Implantation studies in mice that lack the angiogenesis inhibitor TSP2 indicated that an increase in vascular density in capsules surrounding PDMS disks was associated with significant loosening of the collagenous matrix [113]. However, a direct link between the arrangement of collagen fibers in the capsule and blood vessel

formation has not been established. Interestingly, the modification of the PDMS surface from a hydrophobic to a hydrophilic state altered its cell adhesive properties *in vitro* but did not cause a change in the FBR *in vivo* [113]. Such observations underscore the significance of *in vivo* evaluation of cell- and tissue-polymer interactions. Reduced encapsulation of polydimethylsiloxane (silicone rubber) disks and cellulose Millipore filters implanted SC has been reported in mice that lack SPARC (secreted protein, acidic and rich in cysteine), a matricellular glycoprotein that modulates the interactions of cells with the extracellular matrix. Interestingly, mice that lack SPARC and its close homolog, hevin, display diminished vascular density in encapsulated Millipore filters (type HA, mixed cellulose ester) [114]. Taken together, implantation studies in genetically-modified mice suggest that members of the matricellular protein group play critical roles in the FBR [112]. The process however, can also be influenced by parameters such as polymer special geometry and porosity. Comparison of the FBR elicited by expanded and condensed PTFE showed similar encapsulation but more mature fibrous capsule formation in the latter [115]. In addition, the effect of polymer porosity in the FBR was examined in SC-implanted PTFE membranes in rats where it was shown that the vascular density could be increased in capsules surrounding polymers with a pore size in the range of 5 μm [116]. However, it is unclear whether the same porosity would enhance the vascular density of capsules surrounding other polymers. Finally, an additional concern with polymer encapsulation is the presence of contractile cells, myofibroblasts, which can cause contraction of the capsule and misshape or damage polymer implants. For example, silicone-based breast implants have been shown to be susceptible to this phenomenon [117].

CHAPTER 21

Matrix Effects

Jeffrey A. Hubbell
Ecole Polytechnique Fédérale de Lausanne, Institute of Bioengineering, Lausanne, Switzerland

INTRODUCTION

The extracellular matrix serves at least three functions in its role controlling cell behavior: it provides adhesion signals, it provides growth factor binding sites, and it provides degradation sites to give way to the enzymatic activity of cells as they migrate. An understanding of these interactions is important in tissue engineering, where one may desire to mimic the biological recognition molecules that control the relationships between cells and their natural biomaterial interface, namely the extracellular matrix. The components of the extracellular matrix are on one level immobilized, but not necessarily irreversibly. Cell-derived enzymes, such as tissue transglutaminase and lysyl oxidase, serve to chemically cross-link certain components of the extracellular matrix, such as fibronectin chains to other fibronectin chains and to fibrillar collagen chains. Other components are more transiently immobilized, such as growth factors that are sequestered within the extracellular matrix proteoglycan and protein network. This network can be partially degraded, and the growth factors themselves can be proteolytically cleaved, to mobilize the growth factors under cellular control. Not all of the signals of the extracellular matrix are biochemical in nature. A biomechanical interplay between cells and their extracellular matrix also plays an important role in the functional regulation in many tissues, particular in load-bearing tissues. This chapter will consider only the biochemical aspects of biological recognition; the reader is referred elsewhere for treatments of the role of the extracellular matrix as a biomechanical regulator of cell behavior [1–5].

EXTRACELLULAR MATRIX PROTEINS AND THEIR RECEPTORS

Interactions between cells and the extracellular matrix are mediated by cell-surface glycoprotein and proteoglycan receptors interacting with proteins bound within the extracellular matrix. This section will begin with an introduction of the glycoprotein receptors on cell surfaces involved in cell adhesion. The topic will then turn to the proteins in the extracellular matrix to which those receptors bind, with a discussion of the active domains of those proteins that bind to the cell-surface receptors. Finally, the roles of cell-surface associated enzymes in the processing and remodeling of the extracellular matrix will be addressed.

There are four major classes of glycoprotein adhesion receptors that are present on cell surfaces, three of which are involved primarily in cell-cell adhesion and one of which is involved in both cell adhesion to other cells and cell adhesion to the extracellular matrix. The first three are introduced briefly, and the fourth more extensively.

The cadherins are a family of cell-surface receptors that participate in homophilic binding (i.e., the binding of a cadherin on one cell with an identical cadherin on another cell) [6–10]. These molecules allow a cell of one type (e.g., endothelial cells) to recognize other cells of same type

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00021-5

and are important in the early stages of organogenesis. These interactions depend upon the presence of extracellular Ca^{2+} and may be dissociated by calcium ion chelation. Since all cadherins are present on cell surfaces, cadherins are not involved directly in cell interactions with the extracellular matrix. They may be involved indirectly, in that they may organize cell-cell contacts in concert with another receptor system that is involved in regulation of cell-extracellular matrix binding.

A second class of receptors is the selectin family [11–14]. These membrane-bound proteins are involved in heterophilic binding between cells, such as blood cells and endothelial cells, in a manner that depends, as the cadherins, on extracellular Ca^{2+}. These proteins contain lectin-like features and recognize branched oligosaccharide structures in their ligands, namely the sialyl Lewis X and the sialyl Lewis A structures. As with the cadherins, these receptor-ligand interactions are important primarily in cell-cell interactions, and they are particularly important in the context of inflammation.

A third class of receptors represents members of the immunoglobulin superfamily, cell adhesion molecule proteins that are denoted as Ig-CAMs or simply CAMs [15]. These proteins bind their protein ligands in a manner that is independent of extracellular Ca^{2+} and they participate in both homophilic and heterophilic interactions. As for the cadherins and the selectins, they bind to other cell-surface proteins and are thus primarily involved in cell-cell interactions. One class of ligand for these receptors includes selected members of the integrin class of adhesion receptors, discussed below.

The fourth class of adhesion receptors is the integrin family [16–22]. While the other three classes of receptors described briefly above are involved primarily in cell-cell recognition, the integrins are involved in both cell-cell and cell-extracellular matrix binding. The integrins are dimeric proteins, consisting of an α and a β subunit assembled non-covalently into an active dimer. There are many known α and β subunits, with at least 18 such α subunits and eight such β subunits that are capable of assembly into at least 24 αβ combinations. Some of the αβ combinations present in the β1, β2, β3 and β4 subclasses are shown in Table 21.1; these

TABLE 21.1 Selected members of the integrin receptor class and their ligands [20]

Integrin heterodimer	Ligands
α1β1	Collagen, laminin
α2β1	Collagen, laminin
α3β1	Collagen, fibronectin, laminin, thrombospondin-1
α4β1	Fibronectin, osteopontin, vascular cell adhesion molecule-1
α5β1	RGD, fibronectin, L1
α6β1	Laminin
α7β1	Laminin
α8β1	RGD, fibronectin, tenascin
α9β1	Collagen, laminin, osteopontin, tenascin, vascular cell adhesion molecule-1
α10β1	Collagen
α11β1	Collagen
αvβ1	RGD, collagen, fibrinogen, fibronectin, vitronectin, von Willebrand factor
αXβ2	Complement protein C3bi, fibrinogen
αMβ2	Complement protein C3bi, fibrinogen, intercellular adhesion molecule-1, vascular cell adhesion molecule-1
αLβ2	Intercellular adhesion molecule-1 - intercellular adhesion molecule-5
αDβ2	Intercellular adhesion molecule-3, vascular cell adhesion molecule-1
αvβ3	RGD, bone sialoprotein, fibrinogen, fibronectin, thrombospondin, vitronectin, von Willebrand factor
αIIbβ3	Fibrinogen, fibronectin, thrombospondin, vitronectin, von Willebrand factor
α6β4	Laminin, hemidesmosomes

are the most commonly expressed integrins and are thus arguably the most generally important. The β2 integrins are involved primarily in cell-cell recognition; for example, the integrin αLβ2 binds to ICAM-1 and ICAM-2, both members of the immunoglobulin superfamily subclass of cell adhesion molecules described in the preceding paragraph. By contrast, the β1, β3 and β4 integrins are primarily involved in cell-extracellular matrix interactions.

The β1 and β3 integrins bind to numerous proteins present in the extracellular matrix, as illustrated in Table 21.1. These proteins include collagen, fibronectin, vitronectin, von Willebrand factor and laminin.

Collagen is the primary structural protein of the tissues; the reader is referred elsewhere for a focused review on this extensive topic [23,24]. Many forms of collagen exist, several of which are multimeric and fibrillar. To these collagens many other adhesion proteins bind, thus putting collagen in the role of organizing many other proteins that interact with and organize cells. Collagen also interacts directly with integrins, primarily α1β1 and α2β1.

Fibronectin is a globular protein that is present in nearly all tissues; fibronectin has been extensively reviewed elsewhere [25,26]. Fibronectin also exists in many forms, depending upon the site in the tissues and the regulatory state of the cell that synthesized the fibronectin. Almost all cells interact with fibronectin, primarily through the so-called fibronectin receptor α5β1, and to a lesser extent through the β3 integrin αvβ3 as well as other integrins as will be described farther below.

Vitronectin is a multifunctional adhesion protein found in the circulation and in many tissues [27–29]. The protein is active in promoting the adhesion of numerous cell types and binds primarily to the so-called vitronectin receptor, αvβ3, as well as αvβ1 and to the platelet receptor αIIbβ3.

Von Willebrand factor is an adhesion protein that is primarily involved in the adhesion of vascular cells; the reader is referred elsewhere for a detailed review [30–32]. It is synthesized by the megakaryocyte, the platelet-generating cells of the bone marrow, and is stored in the α-granules of circulating platelets. Activation of platelets leads to the release of the granule contents, including von Willebrand factor. Von Willebrand factor is also synthesized by and stored within the endothelial cell. A multimeric form of the protein, where tens of copies of the protein may be linked together into insoluble form, is found in the subendothelium and is involved in blood platelet adhesion to the subendothelial tissues upon vascular injury.

Laminin is a very complex adhesion protein that is generally present in the basement membrane, the proteins immediately beneath the epithelia and endothelia, as well as in many other tissues, as reviewed in detail elsewhere [33–35]. It is present as a family of forms [36]. The classic form was purified from the extracellular matrix of Engelbreth-Holm-Swarm tumor cells and consists of a disulfide crosslinked trimer of one α1 (400,000 Da), one β1 (210,000 Da) and one γ1 (200,000 Da) polypeptide chains. This form binds to the β1 integrins α1β1, α2β1, α3β1, α6β1 and α7β1, and to the β3 integrins αvβ3 and αIIbβ3, as well as to other integrins. A number of other laminin forms exist, composed of αβγ combinations of α1, α2, α3, α4 or α5, β1, β2 or β3, and γ1 or γ2 chains. The details of the differences in function of all of the various laminin forms remain only partially elucidated, but it is clear that several of them do stimulate very different behaviors in a variety of cell types. Laminin is a particularly important component of the basal lamina, i.e., the extracellular matrix beneath monolayer structures such as epithelia, mesothelia and endothelia [37]. For example, laminin contains numerous domains that bind to endothelial cells [38], and these are undoubtedly important in regulating a variety of cell-type specific functions, as discussed below.

There are several cell morphological hallmarks of integrin binding to adhesion proteins in the extracellular matrix. These include spreading of the cells, extension of cellular membrane processes called focal contacts to within approximately 20 nm of the extracellular matrix

surface [39], clustering of integrin receptors at the sites of focal contacts and assembly of intracellular accessory proteins at the site of clustered integrins to assist in the attachment of the integrin complex to the f-actin cytoskeleton [40]. These sites of clustered receptors and interaction of the transmembrane receptors with the intracellular cytoskeleton carry most of the stress between the cells and the extracellular matrix or artificial surfaces; indeed, both theoretical analysis and experimental results demonstrate that without the formation of focal contacts and without the connection of numerous transmembrane integrin αβ heterodimer complexes into much larger multi-integrin complexes by intracellular proteins such as talin, vinculin and α-actinin, cell adhesion would be very much weaker than it is in reality [40]. The focal contact serves as an important center for regulation of cell signaling, both mechanically and chemically, as discussed below.

The extracellular matrix proteins described above are very complex. They contain sites responsible for binding to collagen, for binding to glycosaminoglycans (as described below), for crosslinking to other extracellular matrix proteins via transglutaminase activity, for degradation by proteases (as described briefly below) and for binding to integrin and other adhesion receptors (as described in detail immediately below). Since the proteins must be so multifunctional, the sites that serve the singular function of binding to integrins comprise a small fraction of the protein mass. In most cases, the receptor-binding domain can be localized to an oligopeptide sequence less than ten amino acid residues in length, and this site can be mimicked by linear or cyclic oligopeptides of identical or similar sequence as that found in the protein [41]. The first such minimal sequence to be identified was the tripeptide RGD [42] (using the single letter amino acid code, shown in a footnote to Table 21.2). Synthetic RGD-containing peptide, when appropriately coupled to a surface or a carrier molecule (see below), is capable of recapitulating much of the adhesive interactions of the RGD site in the protein fibronectin, including integrin binding. At least for the case of integrin binding via αvβ3, the RGD ligand alone is capable of also inducing integrin clustering and, when the signal is presented at sufficient surface concentration, focal contact formation and cytoskeletal organization [43]. Many receptor-binding sequences other than the RGD tripeptide have been identified by a variety of methods, and a few of these sequences are shown in Table 21.2. In these receptor-binding sequences, the affinity is highly specific to the particular ordering of the amino acids in the peptide; for example, the peptide RDG, containing the same amino acids but in a different sequence, is completely inactive in binding to integrins.

TABLE 21.2 Selected cell binding domain sequences of extracellular matrix proteins (from [117], after [118])

Protein	Sequence[a]	Role
Fibronectin	RGDS	Adhesion of most cells, via α5β1
	LDV	Adhesion
	REDV	Adhesion
Vitronectin	RGDV	Adhesion of most cells, via αvβ3
Laminin A	LRGDN	Adhesion
	SIKVAV	Neurite extension
Laminin B1	YIGSR	Adhesion of many cells, via 67 kD laminin receptor
	PDSGR	Adhesion
Laminin B2	RNIAEIIKDI	Neurite extension
Collagen I	RGDT	Adhesion of most cells
	DGEA	Adhesion of platelets, other cells
Thrombospondin	RGD	Adhesion of most cells
	VTXG	Adhesion of platelets

[a]*Single letter amino acid code: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.*

One class of adhesion peptides contains the central RGD sequence. These are modified by their flanking residues, which modify the receptor specificity of the receptor-binding sequence. For example, the sequence found in fibronectin is RGDS, in vitronectin it is RGDV, in laminin it is RGDN and in collagen it is RGDT. Other adhesion peptides maintain the central D residue, such as the REDV and LDV sequences of fibronectin. The REDV and LDV sequences are relatively specific in their binding and interact with the integrin $\alpha 4\beta 1$; RGD peptides also bind to $\alpha 4\beta 1$, but the REDV and LDV sequences bind essentially only to $\alpha 4\beta 1$.

In addition to peptides that bind to the integrin adhesion receptors, there are other peptide sequences that bind to other non-integrin receptors. As an example, laminin bears several such sequences, such as the YIGSR, SIKVAV, and RNIAEIIKDI peptides. The YIGSR sequence binds to a 67 kD monomeric non-integrin laminin receptor [44]. As do the integrin receptors, this laminin receptor also interacts via its cytoplasmic domain with intracellular proteins involved with linkage to the f-actin cytoskeleton. The YIGSR sequence is involved in the adhesion and spreading of numerous cell types (see below). The SIKVAV sequence in laminin binds to neuronal cell-surface receptor and stimulates the extension of neurites [45].

In addition to the highly sequence specific binding of adhesion peptides to cell-surface receptors, most of the adhesion proteins also bind to cell-surface components by less specific mechanisms. These proteins contain a heparin-binding domain (so called because of the use of heparin affinity chromatography in purification of the protein) that binds to cell-surface proteoglycans that contain heparan sulfate or chondroitin sulfate glycosaminoglycans [46]. The peptide sequences that bind to cell-surface proteoglycans are rich in cationic residues, such as arginine (R) and lysine (K) relative to their content in the anionic residues aspartic acid (D) and glutamic acid (E), and they also contain hydrophobic amino acids, such as alanine (A), isoleucine (I), leucine (L), proline (P) and valine (V). Several of these sequences are shown in Table 21.3. For example, the heparin-binding sequence in fibronectin bears a sequence of PRRARV, having a motif of XBBXBX, which is observed in several cell adhesion proteins, X being a hydrophobic residue and B being a basic residue, either K or R. These sites within adhesion proteins such as fibronectin and laminin bind to cell-surface proteoglycan in parallel with interaction by the integrin binding sites to stabilize the adhesion complex [47]. Cell-cell adhesion molecules also employ cell-surface proteoglycan binding affinity, e.g., N-CAM bears the domain KHKGRDVILKKDVR, which binds to heparan sulfate and chondroitin sulfate proteoglycans [48]. The interactions with cell-surface proteoglycans are much less specific than those with integrins; the binding is not as sensitive to the order of the oligopeptide sequence and moreover the effect can be mimicked simply by R or K residues immobilized upon a surface, albeit certainly with a great loss in specificity [49].

The extracellular matrix is subject to dynamic remodeling under the influence of cells in contact with it. Cells seeded *in vitro* upon an extracellular matrix of one composition may adhere, spread, form focal contacts, remove the initial protein, secrete a new extracellular matrix of different protein composition and form new focal contacts. Cell-surface bound and cell-derived free enzymes play an important role in this remodeling of the extracellular matrix [50]. For example, cell-released protein disulfide isomerases are released from cells to

TABLE 21.3 Proteoglycan binding domain sequences of extracellular matrix proteins (after [117], references contained in [49])

covalently crosslink protein in the extracellular matrix by disulfide bridging. Cell-derived transglutaminases also form an amide linkage between the ε-amino group of lysine and the side group amide of glutamine to chemically cross-link proteins in the extracellular matrix. These processes are responsible, for example, for the assembly of the globular adhesion protein fibronectin into fibrils within the extracellular matrix beneath cells.

Membrane-bound and cell-released enzymes are also involved in degradation of the extracellular matrix to permit matrix remodeling and cell migration [51]. Cell-released matrix metalloproteinases such as collagenase and gelatinase, serine proteases such as urokinase plasminogen activator and plasmin, and cathepsins are each involved in both remodeling and degradation during cell migration. Accordingly, the matrix-cell interaction should be understood to be bi-directional: the cell accepting information from the matrix, and the matrix being tailored by the cell. This phenomenon has been referred to as dynamic reciprocity and has been elucidated elsewhere [52].

One of the important roles of cell-associated enzymatic degradation of the extracellular matrix is in mobilization of growth factor activity. Because growth factors are such powerful regulators of biological function, their activity must be highly spatially regulated. One means by which this occurs in nature is by high-affinity binding interactions between growth factors and the three-dimensional extracellular matrix in which they exist. Many such growth factors bind heparin, meaning that they, like adhesion proteins, bear domains that bind extracellular matrix heparan sulfate and chondroitin sulfate proteoglycans. For example, basic fibroblast growth factor binds heparin with high affinity [53]. Vascular endothelial growth factor is another example of a heparin-binding growth factor [54]. These growth factors are strongly immobilized by binding to extracellular matrix proteoglycans, and they can be mobilized under local cellular activity, e.g., by degradation of these proteoglycans, or, in the case of vascular endothelial cell growth factor, by cleavage of the main chain of the growth factor away from the heparin-binding domain by plasmin activated at the surface of a nearby cell.

Extracellular matrix proteins also play important roles in matrix interactions with growth factors. This has been best studied in the context of fibronectin [55], although other matrix molecules have also been shown to bind growth factors. In the case of fibronectin, biophysical interactions with a domain consisting of the twelfth to fouteenth type III repeats was shown to lead to binding to a host of growth factors with a dissociation constant of order 1–10 nM [55]. In this manner, just as matrix proteoglycans, matrix proteins can sequester growth factors. Matrix proteins can play a more important role though: in some matrix proteins, such as fibronectin, the integrin-binding domain is close to the growth factor-binding domain, so allowing synergistic signaling between the bound integrin and the growth factor receptor that ligates the bound growth factor [56]. In this manner, one observes that adhesion and growth factor presentation of the matrix are highly interrelated.

Fundamental studies have demonstrated that the interaction between growth factors and the extracellular matrix can dramatically alter their local behavior, where the length scale of the local response is measured in single cell diameters. Specifically, very low interstitial flows can convect cell-derived proteases directionally downstream of a cell, and these proteases can liberate matrix-bound growth factors that were previously homogeneously distributed throughout the matrix. Since the protease activity is preferentially downstream of the cell, growth factor liberation is also preferentially downstream. This can create gradients of growth factor, allowing the cell to sense the directionality of flow, even when the flows are extremely subtle [57,58].

MODEL SYSTEMS FOR STUDY OF MATRIX INTERACTIONS

Since the extracellular matrix adhesion proteins may be mimicked, at least to some degree, by small synthetic peptides, it is possible to investigate cell-substrate interactions with

well-defined systems. Foundational to them all are the interactions of cells with the surface, other than with adhesion peptides intentionally endowed upon the surface, which would produce cell adhesion. These so-called non-specific interactions are between cell-surface receptors and proteins that have adsorbed to the surface. Due to this role played by adsorbing proteins, some introduction to the protein and surface interactions leading to adsorption is warranted. The thermodynamic and kinetic aspects of protein adsorption have been reviewed and the reader is referred elsewhere for a more detailed treatment [59]. The primary driving force for protein adsorption is the hydrophobic effect: water near a hydrophobic material surface fails to hydrogen bond with that surface, and thus assumes a more highly ordered structure in which the water is more thoroughly hydrogen bonded to itself than is the case in water far away from the surface. A protein can adsorb to this surface, acting like a surfactant, and thus replace the hydrophobic material surface with a polar surface capable of hydrogen bonding with water. This releases the order in the water, with a net result of a large entropic gain. Electrostatic interactions, e.g., between charges on D, E, K or R residues on the protein with cationic or anionic functions on the material surface play a lesser but important role as well; since proteins generally bear a net negative charge, anionic surfaces typically adsorb less protein than do cationic surfaces. These observations, overly generalized in the above sentences, guide one to examine model surfaces that are hydrophilic and nonionic, as well as being derivatizable to permit coupling of the adhesion peptide under study.

The tendency for proteins to adsorb to material surfaces has been exploited as a method by which to immobilize peptides onto substrates for study. Pierschbacher et al. have described the peptide Ac-GRGDSPASSKGGGGSRLLLLLLR-NH2 (where the Ac indicates that the N-terminus is acetylated and the -NH2 indicates that the C terminus is amidated to block the terminal charges) for this purpose [60]. The LLLLLL stretch is hydrophobic and so adsorbs avidly to hydrophobic polymer surfaces, effectively immobilizing the cell-binding RGDS sequence from fibronectin. Non-adhesive proteins such as albumin have also been grafted with RGD peptide, e.g., by binding to amine groups on lysine residues on the albumin; adsorption of the albumin conjugate thus immobilizes the attached RGD peptide [61].

Surfaces coated with hydrophilic polymers have also been employed to graft adhesion peptides. One simple system that has been useful is glass modified with a silane, 3-glycidoxypropyl triethoxysilane; once the silane is grafted to the surface, the epoxide group is hydrolyzed to produce -CH2CH(OH)CH2OH groups pendant from the surface (glycophase glass). The hydroxyl groups serve as sites for covalent immobilization of adhesion peptide, e.g., via the N-terminal primary amine [62]. Titration of the surface density of grafted RGD peptides versus cell response using this system revealed quantitative information on the number density of interactions required to establish morphologically complete cell spreading [43]. A surface density of approximately 10 fmol/cm^2 of RGD was required to induce spreading, focal contact formation, integrin $\alpha_v\beta3$ clustering, α-actinin and vinculin co-localization with $\alpha_v\beta3$, and f-actin cytoskeletal assembly in human fibroblasts cultured upon this synthetic extracellular matrix. This surface density corresponds to a spacing of roughly 140 nm between immobilized RGD sites, demonstrating that far less than monolayer coverage is sufficient to promote cell responses. Silane-modified quartz has been employed as a surface to study the role of RGD sites and heparin-binding domains of adhesion proteins in osteoblast adhesion and mineralization, demonstrating a strong benefit for the involvement of both modes of adhesion [63]. The base material, glycophase glass, is only modestly resistant to protein adsorption and thus non-specific cell adhesion; accordingly, the investigation of long-term interactions, during which the adherent cells may be synthesizing and secreting their own extracellular matrix to adsorb to the synthetic one experimentally provided, are difficult to investigate. This has motivated exploration with substrates that are more resistant to protein adsorption.

An enormous amount of research has been expended into grafting material surfaces with water soluble, non-ionic polymers such as polyethylene glycol, HO(CH2CH2O)$_n$H, abbreviated

PEG. This vast body of research has been extensively reviewed elsewhere [64]. Polyethylene glycol has been immobilized upon surfaces by numerous means; three particularly effective means will be addressed in the following paragraphs.

Thiol compounds bind by chemisorption avidly to gold surfaces [65,66]. When those thiols are terminal to an alkane group, R-$(CH2)_n$-SH, the thiol adsorbs in perfect self-assembling monolayers; the thiol-gold interaction contributes about half of the energy of interaction, and the alkane-alkane van der Waals interaction contribute the other half. Accordingly, it is easy to employ alkanethiols to display, in very regular fashion, some functionality R upon a gold-coated substrate (so long as the R group is not large enough to sterically inhibit monolayer packing, in which case it can be diluted with a non-functional alkanethiol. Using this approach, Prime and Whitesides immobilized oligoethylene glycol-containing alkanethiol, HS-(CH2)11(OCH2CH2)nOH, on gold surfaces [67]. Protein adsorption was investigated upon surfaces formed with this alkanethiol and a hydrophobic co-reactant, HS-(CH2)10CH3. Degrees of polymerization (n) as low as 4 were observed to dramatically limit the adsorption of even very large proteins, such as fibronectin. When the oligoethylene glycol monolayer was incomplete, i.e., when the monolayer was mixed with the hydrophobic alkanethiol, longer oligoethylene glycol functions were able to preserve the protein repulsiveness of the surface. Since the background amount of protein adsorption on these materials is so low, one would expect them to be very useful as substrates for peptide attachment for studies with model synthetic extracellular matrices, e.g., with HS-(CH2)11(OCH2CH2)n-NH-RGDS.

Drumheller and Hubbell have developed a polymeric material that was highly resistant to cell adhesion for use in peptide grafting [68,69]. Materials that contain large amounts of polyethylene glycol generally swell extensively, rendering material properties sometimes unsuitable for cell culture or medical devices. To circumvent this, the polyethylene glycol swelling was constrained by distributing it as a network throughout a densely crosslinked network of a hydrophobic monomer, trimethylolpropane triacrylate. This yielded a material with the surface hydrophilicity of a hydrogel but with mechanical and optical properties of a glass. These materials were highly resistant to protein adsorption, even after an adsorptive challenge to the material with a very large adhesion protein, laminin, and even over multiweek durations. When the polymer network was formed with small amounts of acrylic acid as a comonomer, the polymer still remained cell non-adhesive. The carboxyl groups near the polymer surface were useful, however, as sites for derivatization with adhesion peptides such as the RGD and YIGSR sequences. Since the adsorption of proteins to those surfaces was so low, materials endowed with inactive peptides such as the RDG supported no cell adhesion.

Numerous other approaches are possible. One of particular interest, because of its ease of use, is physisorption. Block copolymers, consisting of adsorbing domains and non-adsorbing domains, can be adsorbed to material surfaces and can be used to regulate biological interactions. As an example, when the non-adsorbing domains are polyethylene glycol, surfaces can be generated which display very low levels of non-specific adhesion [70]. One convenient class of polymers are ABA block copolymers of polyethylene glycol (the A blocks) and polypropylene glycol (B), in which the hydrophilic and cell repelling polyethylene glycol domains flank the central hydrophobic and adsorbing polypropylene glycol block. The central hydrophobic block adsorbs well to hydrophobic surfaces, thus immobilizing the hydrophilic polymer and thereby resisting cell adhesion [70]. Cell adhesion peptides can be displayed at the tips of these hydrophilic chain termini, and a very effective and simple model surface can be obtained [71,72]. Similar constructions can be designed for anionic surfaces, e.g., by using a polycationic block as a binding domain, with polyethylene glycol chains attached thereto [73–75]. Adhesion-promoting peptides may be grafted to the termini of the dangling polyethylene glycol chains, to permit cell attraction to these ligands on an otherwise remarkably non-adhesive background [76].

Model systems have also been employed for ligand discovery, i.e., to determine which parts of an adhesion protein are responsible for binding to an adhesion receptor. This has been most

convincingly implemented using peptide arrays, i.e., surfaces in which peptides have been immobilized or even more powerfully synthesized in small domains upon an otherwise passive substrate [77,78]. Arrays of peptides that constitute overlapping sequences order 10 amino acids long spanning the entire length of a candidate adhesion protein can be constructed. If a receptor for the putative binding site is already known, it can be labeled, e.g., with a fluor, and the identity of peptides that bind can be determined by the location of the spots that bind the fluorescent protein. If a candidate receptor is not known, then larger spots can be synthesized (which somewhat limits the size of the peptide library that is formed), and the identity of adhesion-promoting peptides can be determined by the location of spots that promote cell adhesion and spreading, for example. Once the identity of a binding peptide is determined, the binding receptor can be determined by affinity chromatography of cell-derived proteins on columns containing bound peptide, with proteomic analysis of the protein that bind.

The above-mentioned model systems for study of cell-matrix interactions are all two-dimensional systems. Three-dimensional systems have also been developed, in an effort to mimic the spatial complexity of the natural extracellular matrix [3,79,80]. Some of these utilize natural proteins, such as cell-derived extracellular matrix, fibrin and collagen [58,81,82]. Some systems enable the identity and amounts of adhesion ligands, and potentially other ligands, to be precisely controlled. Two approaches are presented in the following paragraphs by way of example.

When fibrin forms spontaneously, non-fibrin proteins such as fibronectin, are grafted into the nascent fibrin network by the enzymatic activity of the coagulation transglutaminase factor XIIIa. This feature of coagulation has been exploited to engineer fibrin matrices, by coagulating fibrinogen in the presence of exogenous and even synthetic factor XIIIa substrates [83]. E.g., if an adhesion ligand is synthesized as a fusion with a factor XIIIa substrate peptide, the adhesion ligand will be immobilized within the fibrin network. This approach has been carried out with small synthetic adhesion peptides [84], with recombinant proteins that are fusions with a factor XIIIa substrate domain [85], and with peptides that bind glycosaminoglycans, which can in turn bind to growth factors [86]. One can incorporate other bioactive molecules such as growth factors directly within the fibrin matrices, also by expressing them as recombinant fusion proteins with factor XIIIa substrate domains [87]. Using these approaches, three-dimensional matrices for cell culture investigations of basic cellular processes can be constructed.

Synthetic three-dimensional matrices that allow precise control of cell adhesion ligand display have also been developed [79]. In one system, reactively-functionalized branched polyethylene glycol is crosslinked by a counter-reactive peptide, the peptide being designed with a sequence that is a substrate for proteases that cells use when they migrate, such as matrix metalloproteinases or plasmin [88]. To the ends of some of the polyethylene glycol arms are also grafted adhesion ligands, such as a reactive RGD peptide. Although the porosity of these hydrogels is very small compared to the length scale of the smallest of processes that cells extend when they migrate, local activation of proteases at the cell membrane surface enables the cells to proteolytically tunnel their way through the materials [89]. Another of other very clever chemical schemes have been developed for crosslinking biomimetic gels, including through chemical [90,91] and enzymatic [92,93] means. Like the fibrin materials described above, these materials are useful both as model systems for study of cell biology, as well as for therapeutic ends.

CELL PATTERN FORMATION BY SUBSTRATE PATTERNING

The ability to control material surface properties precisely enables the formation of designed architectures of multiple cells in culture and potentially *in vivo* as well. Large-scale architectures

have been formed by patterning adhesive surfaces. Four methods for patterning have been particularly powerful, photolithography, mechanical stamping, microfluidics and lift-off.

Photolithographic methods have been employed to impart patterns on cell adhesion surfaces. Alkoxysilanes have been chemisorbed to glass surfaces (using the same grafting chemistry as with the glycophase glass described above), and ultraviolet light was employed to selectively degrade the alkoxy group to yield patterns of surface hydroxyl groups [94]. These hydroxyl groups were used as sites for reaction with a second layer of an amine-containing alkoxysilane. These aminated regions supported cell adhesion and thus formed the cell-binding regions on the patterned substrate [95]. Patterned amines on polymer surfaces have also been employed to induce cell patterning via adhesive domains patterned upon a non-adhesive background [96]. These approaches have been combined with the bioactive peptide technology described above. For example, patterned amines have been used as grafting sites for the adhesive peptide YIGSR to pattern neurite extension upon material surfaces [97]. One of the goals of this work was to create neuronal networks as a simple system in which to study communication among networks of neurons. A powerful system for such work has been provided by using adhesive aminoalkylsilanes patterned upon a non-adhesive perfluoroalkylsilane background [98]. Polymers have been synthesized explicitly for the purpose of attaching adhesive peptide sequences such as RGD, and these will be very useful in future studies of cell-cell interactions in neuronal and other cell systems [99]. Such patterned surfaces have been formed to control cell shape and size, in order to gain deeper insight into the interplay between cell biomechanics and cell function [100]. It is particularly convenient in photopatterning studies to develop photochemistries on materials specifically for the purpose of immobilizing polymers and polymer-peptide adducts [101]; this has been addressed, e.g., with phenylazido-derivatized surfaces [102,103].

Alkanethiols upon gold have also been patterned using simple methods. Contact printing has been employed for this purpose [65,66]. Conventional photolithographic etching of silicon was employed to make a master printing stamp, a negative of which was then formed in silicone rubber. Structures as small as 200 nm were preserved in the silicone rubber stamp. The stamp was then wetted with a cell adhesion promoting alkanethiol HS-(CH2)15-CH3. Stamping a gold substrate resulted in creation of a pattern of the hydrophobic alkane group. The stamped gold substrate was then treated with the cell-resistant alkanethiol HS-(CH2)11(OCH2CH2)6OH. Using this system it was possible to create adhesive patches of defined size upon a very cell non-adhesive substrate [104]. Microcontact printing can also be employed with binding approaches other than alkane thiols binding to gold; e.g., adhesion proteins such as laminin have been stamped onto reactive silane-modified surfaces to produce patterns to guide neurite outgrowth in culture [105]. This very flexible and powerful system will be useful in a wide variety of cell biological and tissue-engineering applications.

A third powerful method is based on microfluidic systems, in which silicone rubber stamps are formed with silicon masters; the stamps are pressed to a surface, and the thin spaces patterned thereby are employed as capillaries to draw up fluid, containing a treatment compound, onto desired regions of the surface. The fluid can contain a soluble, adsorbing polymer with an attached adhesion peptide [71], or it can contain a peptide with some affinity linker for the surface. In the practice of the latter, it is powerful to employ the very high affinity streptavidin-biotin pair, e.g., by biotinylating the polymer at the surface and exposing, with the aid of the microfluidics channels, to peptide conjugated to streptavidin [106].

In a fourth method, also involving silicone layers on material surfaces, silicone layers can be used to pattern directly the locations in which cells adhere to surfaces, and the silicone layers can be lifted off the substrate, if desired, after such cell attachment is desired [107]. Using such approaches, it is possible to pattern 2D surfaces as well as 3D microwells atop such 2D surfaces.

CONCLUSIONS

While it is tempting to think of the matrix to which cells attach as providing primarily a mechanical support, it is clear from the text above that this is only a small part of the picture. Cell interaction with adhesive substrates is known to provide signaling information to the cells via numerous means, both biochemical and biomechanical, and this topic has been extensively reviewed [1,3,80,108–112]. The biochemical mechanisms underlying these interactions are likely numerous and have not yet been fully elucidated. One key mechanism involves the focal contact as a site for catalysis. Integrin clustering induces tyrosine phosphorylation of several proteins, many of which still have unknown function [113]. One of these proteins is a 125 kD tyrosine kinase that localizes, after it is tyrosine phosphorylated, at the sites of focal contacts; this protein has been accordingly named pp125 focal adhesion kinase, or pp125fak. Thus, although the cytoplasmic domain of integrins bears no direct catalytic activity, clustering of integrins is known to stimulate tyrosine phosphorylation and further specific kinases are know to assemble at the sites of clustered integrins. Interestingly, when cells were permitted to spread via a non-integrin mediated mechanism, specifically by interaction of cell-surface proteoglycans with surface-adsorbed polycations, phosphorylation of intracellular proteins did not occur [113]. The phosphorylation of these proteins, associated with focal contact formation, is known to be an important signal for survival of a variety of cell types [114]. Thus, the matrix plays not only a mechanical role as a support for cell adhesion and migration, but also a key signaling role in determining the details of cell behavior, ranging from survival to differentiation.

Engineered biomaterials will play an increasingly important role in deciphering the language of the interaction between cells and their extracellular matrix [79]. Indeed, this represents one of the key challenges for researchers as the field moves forward, to more faithfully represent the complexity of the natural extracellular matrix in synthetic analogs. It is clear that the complex cellular interactions that exist with the 3D milieu *in vivo* cannot be represented well by culture of cells on simple 2D substrates like cell culture flasks [80], and it falls to the tissue engineer to develop more physiologically representative models.

While one goal of biomaterials and tissue-engineering research is certainly to develop systems for the quantitative study of biological interactions, another is to develop practical novel therapeutics. Many of the concepts described above, both in terms of development of model surfaces and especially 3D matrices and with regard to manipulating cellular behavior, are directly transferable, however some cautionary comments should be made. It is not only the chemical identity of an adhesion peptide that determines its biological activity, but also its amount and distribution. This was very clearly demonstrated by Palecek et al. [115], who showed that small amounts of an adhesion molecule could enhance cell migration, whereas larger amounts could inhibit it. They further demonstrated that this effect depended on, among other features, the affinity of the receptor-ligand pair, the number of receptors, and the polarization of receptors from the leading to the trailing edge of the cell. Given that many of these features depend upon on the state of the cell and can be modulated by the cell's biological environment, e.g., by the growth factors to which the cell is exposed [116], many confounding features must be considered in translation from model to practical application [79].

CHAPTER 22

Polymer Scaffold Fabrication

Jordan E. Trachtenberg, F. Kurtis Kasper and Antonios G. Mikos
Baylor College of Medicine, Department of Bioengineering, Rice University, Houston, Texas

INTRODUCTION

The abbreviations used in this chapter are summarized in Table 22.1.

While this summary seeks to review the emerging field of bioprinting as a novel processing technique, an overview of the other main scaffold processing techniques (Table 22.2), including their benefits and limitations as compared to three-dimensional printing (3DP), will be provided. The use of 3DP as a scaffold processing technique seeks to accomplish the goal of developing more biomimetic scaffolds that incorporate the complex hierarchy of natural tissue, providing a better model for understanding tissue function and remodeling [1]. Due to the advances in the specificity and resolution of 3DP, this processing technique has the capacity to print structures with tissue-appropriate heterogeneities in terms of cell distribution and biochemical and biophysical properties [1,2]. While most processing techniques fail to produce scaffolds with microstructures that allow for cell proliferation and migration, bioprinting may be used to tailor the desired porosity and interconnectivity to create an optimal microstructure for cell growth and production of extracellular matrix (ECM) proteins [3]. Furthermore, the capacity of this method to produce scaffolds with complex porous microstructures shows promise in creating scaffolds with an internal vascular network that has not otherwise been achieved with other processing methods.

The overarching goals of printing for tissue engineering include the ability to:

1) Print cells individually or in aggregates,
2) Deposit material in a layer-by-layer approach,
3) Maintain proper structural integrity with layer fusion, and
4) Fabricate a vascular structure, all of which will be elucidated in the following sections of this chapter [4].

To address these goals, a bioprinted scaffold generally contains two important base components, which include a cell carrier material and a cell-free structural material. The cell carrier material, bioink, consists of cellularized materials embedded in hydrogels, microspheres, or as simple cellular aggregates and may include synthetic extracellular matrix (sECM) components [5]. In addition to the cell carrier material, biopaper acts as a cell-free structural material that supports the bioink and provides the foundation for the scaffold [5]. The bioprinting mechanism then uses a three-axis control system to print layer-by-layer structures of bioink and biopaper into a pre-determined three-dimensional (3D) object, such as a scaffold in the shape of a specific organ or tissue [4,6]. The hybrid bioprinting process is illustrated in

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00022-7

TABLE 22.1 List of abbreviations

Name	Abbreviation
Micro-computed tomography	μCT
Three-dimensional fiber deposition	3DF
Three-dimensional printing	3DP
Bone morphogenetic protein-2	BMP-2
Computer-aided design/computer-aided manufacturing	CAD/CAM
Charge coupled device	CCD
Computed tomography	CT
Demineralized bone matrix	DBM
Extracellular matrix	ECM
Environmental scanning electron microscopy	ESEM
Fourier transform infrared spectroscopy	FTIR
Glycosaminoglycan	GAG
High internal phase emulsion	HIPE
Hyaluronic acid	HA
Hydroxyapatite	HAp
Infrared	IR
Laser-assisted bioprinting	LAB
Laser-induced forward transfer	LIFT
Muscle-derived stem cells	MDSCs
Matrix metalloproteinases	MMP
Magnetic resonance imaging	MRI
Mesenchymal stem cells	MSCs
3-(4, 5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium	MTS
National Electrical Manufacturers Association	NEMA
Poly(ε-caprolactone)	PCL
Poly(ester amide)	PEA
Poly(ethylene glycol)	PEG
Poly(ethylene glycol)-diacrylate	PEG-DA
Positron emission tomography/computed tomography	PET/CT
Poly(hydroxymethylglycolyde-co-ε-caprolactone)	PHMGCL
Poly(lactic acid)	PLA
Poly(lactic-*co*-glycolic acid)	PLGA
Poly(N-isopropylacrylamide)	PNiPAAm
Poly(propylene fumarate)	PPF
Poly(vinyl alcohol)	PVA
Arg-Gly-Asp	RGD
Rapid prototyping	RP
Synthetic extracellular matrix	sECM
Scanning electron microscopy	SEM
Stereolithography	STL
Tricalcium phosphate	TCP
Ultraviolet	UV

Fig. 22.1 [7]. It is possible to print biopaper layers that integrate complex patterning of multiple cell types [1,3,6,8] at a high resolution. Moreover, biopaper may be printed with a layer thickness that promotes sufficient cell migration and that is conducive to stacking into a three-dimensional scaffold [9]. Depending on the complexity of the scaffold architecture, a computer-aided design (CAD) program may be used to fabricate organ-specific geometries [5,10]. Initially, the CAD model is created by a computed tomography (CT) or magnetic resonance imaging (MRI) scan from human or animal tissue. Because the scanned biological tissue may be directly implemented as the CAD model, bioprinting is advantageous because it can be tailored to a specific patient. In the case where it would be impossible to obtain CT or MRI results from the patient prior to surgery, it may also be possible to compare archived tissue scan data from patients of similar age groups and organ size [10].

TABLE 22.2 Methods of scaffold fabrication

Technique	Description	Advantages	Disadvantages
Rapid prototyping: 3DP	CAD-modeled deposition of material and/or cells; layer-by-layer stacking to create a 3D scaffold	Wide variety of materials; highly defined porosity and architecture; accurate repeatability; allows incorporation of bioactive molecules and cells	High-throughput manufacturing not available; time consuming process
Fiber bonding	Polymer fibers are heated and fused at points of intersection	Simple procedure; high surface area-to-volume ratio promotes cell attachment	High processing temperatures; limited control over porosity
Electrospinning	Voltage is applied to spin polymer fibers in a non-woven mesh	Very fine fiber thickness may be achieved	Limited control of fiber deposition and porosity; poor mechanical integrity
Solvent casting/ particulate leaching	Porogen incorporated into polymer and solidified; porogen is later dissolved/ leached	Minimal material needed for procedure; high porosity; allows incorporation of composite materials	Pore structures not interconnected; residual solvents or porogens; detrimental to bioactivity
Melt molding	Polymer and porogen heated in mold; solidification and removal from mold; porogen leached out	Control of shape with mold; flexible geometry; allows incorporation of composite materials	High processing temperatures; lack of pore interconnectivity
Membrane lamination	Thin layers of porous polymer are chemically fused	Defined contours and geometries; no visible boundary between layers	Necessary to define shape for each layer; time consuming; cytotoxic solvents
Extrusion	Polymer is heated and forced through a die; forms 3D profile of die's cross-sectional area	Ability to fabricate tubular structures	High temperatures or pressures needed
Freeze-drying	Polymer solution is emulsified; emulsion poured in mold and frozen	Some pore interconnectivity	Lower porosity than most other procedures; scaffold and pore size limitations
Phase separation	Polymer dissolved in solvent; bioactive molecules added to make homogenous mixture; cooling and freezing separates phases; solvent sublimed	Potential for drug delivery applications; bioactive molecules protected from solvents	Residual solvents; limited pore sizes
High-internal-phase emulsion	Water-in-oil emulsion following HIPE standards; monomers from organic phase used to synthesize and cross-link polymer scaffolds with pores	Injectability; good pore morphology; biodegradable polymers may be used	Limited polymer types; high processing temperatures
Gas foaming	Compressed polymer is exposed to high pressure gas; pores form with decreased pressure	Eliminates need for organic solvents; improved cell adhesion	Lack of pore interconnectivity; limited pore sizes
Peptide self-assembly	Designer peptides form into complex geometries (spheres, fibers, sheets) via hydrophobic/hydrophilic interactions	May be designed to promote various cell behaviors; compatible with *in vitro* culture	Expensive materials; design expertise required; limited scaffold size
In situ polymerization	Polymer is injected at site and polymerizes or cross-links after implantation	Immediate implantation possible; minimal processing necessary	Limited mechanical properties; limited porosity; harmful polymerization by-products; limited material choice

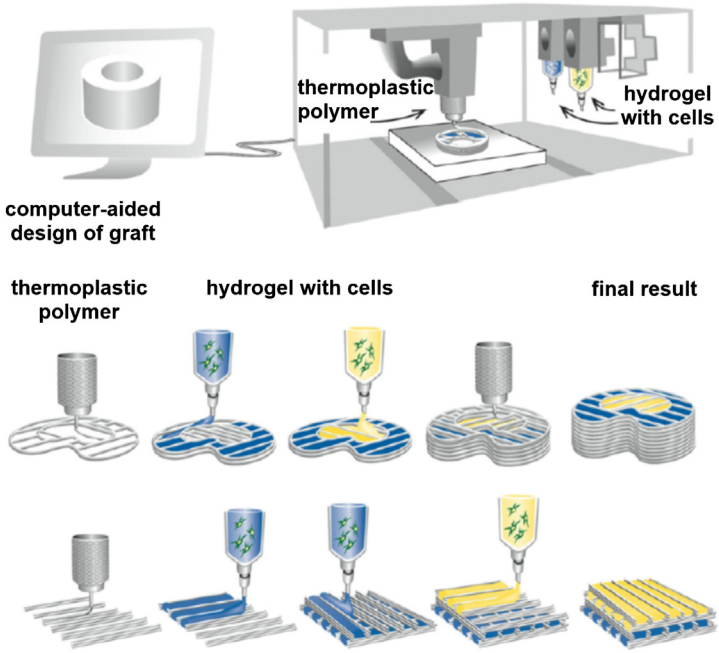

FIGURE 22.1
Step-by-step process of bioprinting, including development of computer model and printing bioink and biopaper. *Reprinted with permission from reference [7].*

After a model has been generated by CT or MRI scan, the file is converted to stereolithography (STL) format for implementation by the CAD software. The software allows further design modification based on geometric scaling, desired porosity, and resolution, to modulate structure and function of the engineered tissue. Standard software must be implemented with the printing system in order to translate the code from the CT scan into a 3D model for printing. Some commercial printers come with CAD software that is specific to the printing instrument; however, open-source printers available allow modification of user-defined software or integration with other commercial programs, such as SolidWorks® [11]. SolidWorks®, among other commercially available computer-aided design/manufacturing (CAD/CAM) software programs, provides a relatively simple interface for designing a 3DP model with parameters that may easily be modified to accommodate sample size, pore size, resolution, and geometry (Dassault Systèmes SolidWorks Corp., Waltham, MA, USA). Implementation of the CAD/CAM software may also be combined with a CT image of a tissue defect to create customized designs that are appropriate for surgical implantation [10]. Images of the tissue taken before and after the defect placement, can be combined to create the relative shape of the defect to be printed *in situ* or implanted post-printing [10]. The geometric fidelity of this shape can be later analyzed by a laser distance sensor, which detects defects in the printing uniformity and compares the resolution of the printed scaffold to that of the computer model. Once the tissue model has been developed and characterized for proper function, the final processing methods depend upon the desired method of implantation. Scaffolds may be cultured in flow perfusion conditions to allow cell-development of ECM and then implanted into the patient after the scaffold meets the structural needs of the specific tissue. On the other hand, the processing parameters of the printing system may be tuned to print *in situ* tissue replacements or repairs, which may have a promising clinical application in surgical procedures.

BIOINK: CELL PRINTING AND CHARACTERIZATION

The first goal of 3DP for tissue engineering is to develop processing methods that allow printing of cells and cellular components. Bioink, in addition to containing cells, may also incorporate bioactive components such as signaling molecules (e.g., cytokines, growth

factors), DNA, ECM molecules, and others, depending on the desired effect on the printed tissue [1]. Since cells and bioactive molecules respond to external environmental cues, it is important to determine whether processing has an effect on the biological components in the scaffold, specifically on their morphology, composition, and function [1,12]. Before printing cell-based solutions, it is important to confirm that the printing material is compatible with the processing conditions of the printer. Consequently, it is important to note that most work has investigated the encapsulation of cells in hydrogels due to their ease of use with printing conditions [5], functionality and biocompatibility [13]. Material choice will be discussed later in this section and in the following section. After testing the compatibility of the polymer solution with the printing process, it is then possible to incorporate cells and biological molecules into the material. A sterile environment for cell printing must first be prepared to minimize contamination and protect cell viability before processing. Polymer solutions must be sterile filtered, and the printer components that come in contact with cells must be sterilized with methods that take into consideration the material composition of the printer. Further cell encapsulation in a material requires consideration of many printing factors. Thus, measures must be taken to ensure proper environmental conditions to minimize the effect of printing on the material properties and biological identity of the cellular components in the scaffold.

External processing conditions that could have an impact on cell fate may include polymerization reactions, temperature, pressure, shear stress, and deposition force, some of which may not otherwise be considered in cases of cell seeding post-printing [9,14,15]. For those materials that require external environmental cues for polymerization, these factors may also threaten viability and proliferation. For instance, crosslinking may be necessary to enhance the mechanical strength of the printed polymer construct and drive cell differentiation [16]. Depending on the rate and completeness of the material's polymerization mechanism, the scaffold may be subject to ultraviolet (UV), infrared (IR), or white light after each successive layer is printed, or after the entire construct has been fabricated. In some studies, a hydrogel solution was partially crosslinked several minutes prior to printing for initial structural integrity and later fully crosslinked to fuse layers for the final structure [5,10]. Due to processing effects of shear stress from the printing nozzle, crosslinking via UV, IR, or white light, and other factors, cell viability in the printed scaffolds should be determined and compared to *in vitro* cultures.

In order to determine whether crosslinking has an effect on the mechanical integrity of the material or the fate of cells encapsulated in the material, several characterization methods may be employed. Mechanical moduli can be measured, for example, for printed scaffolds with varying crosslinking densities to optimize material parameters [5]. A comparison between the viability of printed cells to that of cells in standard culture medium would be necessary to determine if crosslinker concentrations are cytotoxic [2]. Early studies investigating the simultaneous printing of a $CaCl_2$ crosslinker with endothelial cells showed cell attachment and spreading on an alginate hydrogel after printing, offering preliminary evidence that cells can survive the printing and crosslinking process [17]. Some mechanisms have been developed to protect cells from harmful degradation or polymerization by-products until reactions have reached completion. For instance, cells encapsulated in gelatin microspheres have been successfully implemented in poly(propylene fumarate) (PPF) [18]. This temporary encapsulation technique allows cells to remain viable during crosslinking reactions induced in the polymer and will then release the cells upon completion of the crosslinked construct by dissolution of the gelatin, allowing cell migration and proliferation throughout the scaffold [19]. Furthermore, histological assays may be performed after printing to determine preferred cell differentiation pathways among crosslinked scaffolds.

In addition to influences from crosslinking, processing temperatures may restrict the materials used for cell-based printing applications. Fortunately, since 3DP can be performed at

ambient temperature, fabrication in a normal laboratory setting is more feasible [10,20,21]. Although there have been many studies investigating the incorporation of cells in hydrogels for 3DP [2,4,5,7,11,17,22,23], few investigations have been conducted on simultaneous printing of cells and scaffold for rigid polymer constructs. This may be attributed to the fact that many rigid polymers cannot be extruded in liquid form at near-ambient temperatures [24,25]. For some 3DP applications that do not employ cellular components, rigid polymers are often melted in powder form when printed [26,27], but the high melting temperatures required would have an adverse impact on cell viability, and would not be conducive to cell encapsulation. To accommodate printing of scaffolds with encapsulated cells, it is necessary for the polymer to be in its liquid form upon extrusion from the deposition tool. This is because polymers printed in solid powder form, if not melted beforehand, require the addition of solvents to dissolve and fuse into scaffold layers, but common printing deposition tools often degrade as a result of the solvent addition [28]. Moreover, there are some printing nozzles available that are resistant to solvent degradation, but printing using these tools often compromises resolution, and compatibility with powder-based polymers is limited [28]. Another group has looked at printing starch-based polymers with distilled water, but while this approach is less cytotoxic, the porogen size is limited and not amenable to high resolution applications [29]. Printing a polymer in its liquid state is also advantageous because a lower deposition pressure is required for extrusion. At high deposition pressures, shear thinning may occur, involving a sudden drop in polymer viscosity and shear stress at deposition [24]. Moreover, the polymer viscosity has a substantial impact on the injectability of the solution [25,30]. A more viscous solution requires a greater deposition force, resulting in exertion of a greater shear stress on the material and cells [10,20]. Further injectability testing may be needed to determine the optimal viscosity to promote structural integrity and cell viability when subject to shear conditions from the printer head.

While processing techniques have an impact on cell viability and behavior, the cell carrier material may need further modifications to allow proper tissue growth. In some cases, the ability to interact with cells necessitates functionalization of the material via end groups, ECM molecules, or other bioactive elements. Examples of bioactive elements may include Arg-Gly-Asp (RGD) peptides functionalized on poly(ethylene glycol) (PEG) hydrogels for cell attachment, or modification with matrix metalloproteinases (MMP)- or plasmin-sensitive crosslinkers for degradation [13,31]. A hydrophilic material, such as PEG [31–33], is relatively inert to cell interactions and requires addition of bioactive molecules to allow cell adhesion and proliferation throughout the matrix. On the contrary, a highly hydrophobic polyester such as poly(ε-caprolactone) (PCL) has been functionalized as a printable copolymer — poly(hydroxymethylglycolide-co-ε-caprolactone) (PHMGCL) — to allow cell attachment and tunable degradation [34]. There are a few other methods of manipulating cell-material interactions by printing components that allow modification post-printing. For instance, one such printing technique has been investigated using magnetized nanoparticles in alginate and in cells [20]. This technique allows direct migration of bioactive factors and spatial distribution of cells via an external magnetic field, which would modify the organization of matrix post-printing toward different paths of cell differentiation [20]. By selective printing of ECM components and other bioactive molecules throughout the scaffold, it is possible to direct cell patterning and cellular responses in the matrix, such as proliferation, migration, cell death, and differentiation [1,12,24,35].

Cells that have attached and proliferated on the scaffold also have the capacity to modify their matrix [12]. First of all, cell-secreted enzymes may have an effect on the mechanical integrity of the material. For instance, while scaffold degradation may have a negative effect on cell viability [36], the production of ECM and subsequent scaffold degradation by the cells has an effect on mechanical stability of the material [37,38]. This effect may be controlled or enhanced by external mechanical conditions; specifically, pre-loading or other means of mechanical stimulation on the scaffold prior to implantation may provide ways to modulate

cell differentiation toward hard or soft tissue lineages. Sources of mechanical stimulation may have a subsequent effect on scaffold integrity via production of different types and quantities of ECM proteins [37]. The interplay between matrix stiffness and cell migration behavior has a drastic impact on directing cell lineage, as well as the propensity for matrix degradation by proteolytic enzymes or other molecules contained in the scaffold [31]. sECM materials have been developed to allow sensitivity, via cleavage sites or other functionalities, to degradation enzymes secreted by the cells [13,31]. In addition, if the cell density comprises a significant portion of the scaffold, this may have an effect on its crosslinking ability and mechanical properties [5,20,37].

Depending on how the cells are incorporated into the scaffold, whether seeded [28] or encapsulated [13], attachment and proliferation may occur over the course of days to weeks. Immunohistochemical and colorimetric assays, fluorescent imaging, and histological staining are performed to analyze cell distribution and viability in samples after several weeks of culture. For example, a 3-(4, 5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) assay may be used to determine cell viability via quantification of mitochondrial activity [5]. Fluorescent tags may also be transfected in cells or encapsulated in cell-containing microspheres in order to visualize proliferation, viability, and distribution throughout the scaffold after printing [5,17,39,40]. Epifluorescence microscopy may be used to visualize the fluorescent molecules in the scaffold [17,40] and detect foreign-body responses *in vivo* [41]. In addition to monitoring cell viability and behavior, histological staining may be utilized to identify the presence of cell-secreted ECM molecules, such as collagen and glycosaminoglycans (GAGs). Some stains used for visualization include Safranin-O for GAG content, hematoxylin and eosin for cell morphology, masson trichrome for collagen presence, toluidine blue for proteoglycan content, and von Kossa's staining for mineralization [38,41,42]. Results from staining determine if the cell carrier material provides an appropriate microenvironment for cell proliferation and remodeling.

BIOPAPER: STRUCTURAL MATERIAL PRINTING AND CHARACTERIZATION

In order to achieve the second goal of printing with a layer-by-layer approach, cell-free structural material, or biopaper, must be printed alongside the cell carrier material to enable proper layer deposition and maintenance of resolution. When considering a structural material for printing scaffolds containing cells, it is important to minimize harmful processing procedures, such as high curing temperature and polymerization solvents, while enabling extrusion and proper layer fusion of the scaffold material. As stated previously, hydrogels make up a substantial percentage of materials used for cell-based printing applications. In order to account for both the biocompatibility and the structural needs for the scaffold, polymer hydrogels are often functionalized via crosslinking or bioactive agents to allow enhanced mechanical strength and cell attachment, respectively [5,13,24,38]. However, hydrogels often have poor mechanical strength even with the addition of functional agents, so researchers are investigating a wider variety of materials that will be amenable to printing in order to cater to the need for load-bearing tissues. For example, Boland et al. found that printed samples of alginate had significantly lower elastic modulus and ultimate tensile strength than alginate samples that were manually crosslinked [17]. This result was attributed to high porosity in the printed sample, but may have also been due to other processing factors [17]. Solving the problem of mechanical integrity would either require replacement of the hydrogel with stronger, biocompatible materials, or designing scaffolds that would allow complete cellular remodeling and degradation of the material to create naturally functioning tissue.

Within the acceptable list of materials that are both biocompatible and amenable to printing with cells, the material of choice is primarily based on the mechanical and chemical properties that most closely match the organ in question. For instance, common materials used for

chondral tissue engineering include alginate [11] and agarose [3]. Both agarose [5] and PEG [32] have been used in combination with hyaluronan as materials to print vascular structures. Manipulating the properties of alginate for its rapid gelation time and collagen for its bioactivity, Pataky et al. were able to print beads of this hydrogel blend for applications in vascular printing as well [2]. 3DP may be implemented for printing hydrogels as well as rigid polymers and ceramics. For instance, some materials employed for bone tissue engineering include PCL [26], hydroxyapatite (HAp) with PPF [43], and demineralized bone matrix (DBM) [10]. Although most major organs have not yet been successfully printed, a list of materials and cells used for printing major tissue types are summarized in Table 22.3.

Material properties are of paramount importance when considering the application and processing method for scaffold engineering, and these may have an effect on the printed resolution of the construct. As emphasized before, it is especially important to consider the viscosity and injectability of the material for a 3DP application due to limitations of the deposition mechanism. For example, the maximum deposition force for certain printer models places restrictions on highly viscous materials [10]. These material parameters have a direct influence on the final printing resolution of the material. When considering inherent injectability properties, the printed resolution should be adequate for millimeter-sized defects, which are commonly seen in most *in vivo* tissue-engineering work in small animal models [10,27,41,42,44,45]. The resolution places restrictions on not only the viscosity of the material and extrusion force, but also the syringe tip size, all of which must be carefully balanced in order to achieve uniform printing of the desired tissue-engineered scaffold [39,46]. The resolution quality may later be evaluated by imaging tools to determine accuracy to design standards.

Besides the effect of viscosity, rigidity, and degree of crosslinking on resolution, other material properties may affect cell fate, including composition, degradation and polymerization by-products, degradation rate, biocompatibility, crystallinity, porosity, and hydrophobicity. Its composition must mimic natural ECM and be amenable to cellular remodeling via production of new ECM components and work synergistically with cell signaling processes to allow proper tissue growth [1]. The degradation timescale must be appropriate to the tissue regeneration rate and the matrix must be amenable to cellular remodeling via production of ECM proteins. Because the degradation mechanics of tissue implants have variable effects on surrounding healthy tissue, including eliciting inflammatory, fibrotic, or hyperplastic responses, materials that have the potential to release cytotoxic degradation and polymerization by-products must be thoroughly investigated before use in a 3DP application to ensure

TABLE 22.3 Materials for 3DP scaffold fabrication

Tissue	Material	Cell-laden applications
Heart valve and heart tissue	PEG-DA, PEA [55]; alginate [55,68]	Human cardiac progenitor cells [68]
Skin	PCL [7], collagen [69]	Fibroblasts and keratinocytes [50,69]
Liver	Gelatin [60,70] and fibrinogen [70]; PCL, PLGA, HA, gelatin, collagen hybrid [59]	Hepatocytes [59, 60, 70], with pre-osteoblasts [59]
Peripheral nerve tissue and neural cell printing	PLA-PEG, PLA, DL-lactide [61]; collagen [71]	Neurons, astrocytes [71]
Bone	HAp and TCP [27]; brushite and monetite [44]; PCL [26,34], HAp with PPF [43], DBM [10], PHMGCL [34]; agarose, collagen, gelatin, Matrigel, PNiPAAm, fibrin, Pluronics [67]	MDSCs with BMP-2 [35]; osteoblasts, MSCs, osteogenic cells [67]
Cartilage	Alginate [11]; agarose [3]; chitosan, gelatin, collagen, PEG, PNiPAAm, PVA, fibrin [67]	Chondrocytes, MSCs [67]

biocompatibility *in vitro* and *in vivo* [25]. Moreover, the degree of crystallinity will have a direct impact on scaffold rigidity and mechanical strength, as well as indirect guidance of cell proliferation and ultimate differentiation. The material geometry, in addition to mimicking the desired tissue in function and integrity, must contain interconnected pore structures to allow fluid and mass transport of waste and nutrients, as well as allowing cell attachment, proliferation, and tissue formation. These material properties may be further characterized to determine if the scaffold appropriately models the tissue or organ.

Material properties should be characterized after printing, including surface composition, morphology, porosity, resolution, and interaction with surrounding tissue. To characterize the composition of the surface after printing, Fourier transform infrared spectroscopy (FTIR) may be utilized. The morphology — specifically, the degree of porosity control — may be visualized by gold sputtering of the printed polymer and imaging the sample using scanning electron microscopy (SEM) or environmental SEM (ESEM) for wet, uncoated samples. It is expected that the morphology and composition of the material surface will encourage cell attachment and proliferation once the cells are released from encapsulation [9]. For specific printing applications, some characterization methods may provide helpful information regarding material interaction with surrounding tissue. When characterizing printed implants for calvarial defects, *in vivo* MRI has been performed in mice to characterize the printed scaffold via T1- and T2-weighted images [42]. Clinically, T1- and T2-weighted images show tissues with different gray scales and are both helpful in determining abnormal tissue behavior or morphology in the brain. Signal intensities from these images may be measured to determine the change in microstructure and biochemical composition over time, as well as how these intensities correspond with the intensities of the healthy surrounding tissue [42]. Additionally, the MR images are helpful in measuring inflammation and the progression of wound healing [45]. Comparable imaging techniques for other parts of the body, including positron emission tomography/computed tomography (PET/CT) or X-ray scanning, may provide similar information on implant integration *in vivo*.

PRINTING MECHANISM: LAYER-BY-LAYER APPROACH

For layer-by-layer deposition to be successful, the type of printing system employed is equally as important as the choice of materials and method of cell encapsulation used to print the tissue. The printer choice will determine how the cells and materials will be deposited and organized and ultimately delegate the layered structural make-up of the scaffold. Due to the versatility of printing liquid-based materials, bioprinting has largely moved away from the traditional powder and binder process of early 3DP and more toward hydrogel and soft polymer printing [25,47]. To address further soft polymer processing applications, some of the pioneering models of 3D printers manipulated the skeleton of commercial inkjet printers, such as the HP Deskjet® [17,39,48], and filled recycled ink cartridges with cell solution to print micron-scale cell droplets [4]. This inkjet-based system allows a variety of materials and cells to be printed by simply switching out the cartridge [39]. While X- and Y-axis positioning capabilities were already available within the inherent properties of the printer, Z-axis control was implemented via a metal rod and stepper motor regulation, which is comparatively similar to the basic mechanical principle for most commercial bioprinter models today [17,42,49]. On the other hand, these preliminary models had some limitations. For instance, the scaffold dimensions in a design by Boland et al. were confined to a 50 mL conical tube filled with uncross-linked polymer solution, as pictured in Fig. 22.2 [17]. A crosslinker was deposited via the printer head on a specified area of the polymer surface, which was defined within the dimensions of a glass substrate. Crosslinking of the polymer allowed formation of the first hydrogel layer, which was then lowered by the rod to allow more uncrosslinked polymer to cover the top of the first layer and allow printing of the subsequent layer [17].

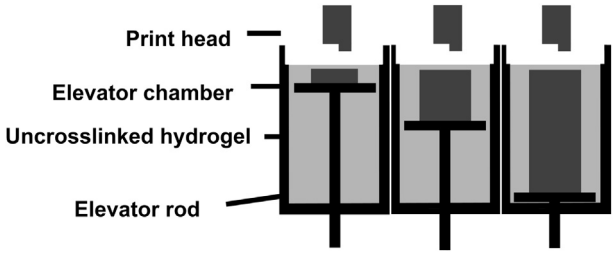

FIGURE 22.2

Since then, there have been improvements in the field with new printers in the past few years. Most bioprinting techniques under current investigation utilize 3D Plotting – also known as 3D fiber deposition (3DF) – to print layers from polymer melts instead of powders [24,25,38]. 3DF allows much easier fiber deposition and layer fusion and does not require the addition of harmful organic solvents, unlike the powder-binder method employed with previous inkjet-based models [25]. Some commercial systems (3D-Bioplotter™ Fourth Generation, Envisiontec GmbH, Germany; Fab@Home V 2.0, Cornell University, Ithaca, NY) use this method of fiber deposition. Furthermore, for inkjet-based printers, some attempts have been made to improve vascular printing [2,39]. Specifically, printing vessel-like structures that support physiological flow conditions can be achieved by modifying settings to allow printing over void space [2]. Other current models have expanded the area of the printing stage for overall structures of greater than 20 cm [49]. Additionally, improved models have eliminated the need for an elevator chamber by use of multiple deposition tools with the capacity to combine the crosslinker and uncrosslinked polymer immediately upon printing [49].

In addition to improvements in the structural integrity of the printed construct, further advances have been made in optimizing the deposition mechanism, in order to enhance material placement, tailor resolution, and reduce nozzle malfunctions. For instance, nozzle clogging is a common issue among traditional inkjet-based printers [30]. To address this issue, laser-assisted bioprinting (LAB) was developed as an efficient processing method that eliminates the need for a nozzle [15]. The LAB technique, pictured in Fig. 22.3, is based on a laser-induced forward transfer (LIFT) technique that allows highly defined printing of cellular patterns [50,51]. The LAB 'ribbon' is composed of multiple layers that must be prepared according to several parameters [15]. The collecting substrate is first coated with the material to be printed, which most often consists of droplets of polymer with encapsulated cells [14,15,23,51–53]. The top support must be adjusted to allow laser light in the UV or IR range to pass through the focusing lens and then the absorbing layer. In addition, there is a laser-absorbing interlayer between the top support and the bioink layers that is sensitive to the

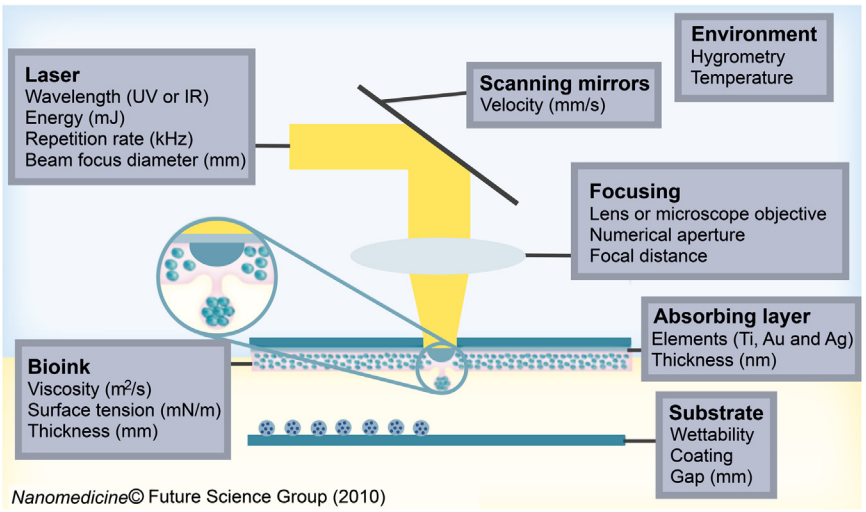

FIGURE 22.3
Laser-assisted bioprinting (LAB) parameters.

optical properties of the bioink and laser wavelength and subsequently affects light transfer [15,50,54]. The interlayer is commonly made of a thin metal film, such as gold, that protects the bioink from direct interaction with the laser beam [54] and has an impact on droplet size based on its thickness [50,52]. Laser fluence — the pulse of the laser to induce printing of the bioink droplets — and the gap distance between the ribbon and the substrate are also two important parameters to define in the set-up process and are required to set the scanning speed of the galvanic mirrors before printing [15,50]. The laser light is emitted at either a UV or IR wavelength to create nanosecond pulses of energy, allowing deposition of bioink beads on a quartz disk [15]. The volume of printed material is directly dependent upon the energy of the laser pulse, and microdroplet deposition requires the achievement of a minimum threshold energy [54]. Although this method is promising in reducing nozzle clogging, height restrictions remain a current obstacle, which makes this method more appropriate for printing cell arrays instead of tissues [9,23].

While commercial bioprinters can be costly and difficult to personalize, several open-source printers have been developed to address the demand for simple, cost-effective scaffold fabrication equipment. Printers such as the RepRap and the Fab@Home systems are based on similar principles as the early inkjet printers [17], but are modular in design and allow for much easier modification based on the needs of the user [55]. The RepRap system is unique in that it has been programmed to print daughter models from an original parent model (RepRap Original Mendel, GNU General Public License). Since most of the models contain wooden parts and exposed circuitry, it is difficult to use the RepRap in sterile cell printing applications; however, models are continuously being modified with tissue engineering in mind. The Fab@Home system has already been used in preliminary studies for tissue engineering applications [5,10,32]. The Fab@Home model uses a syringe-based deposition system that extrudes liquid polymer or injectable cement solutions at ambient temperature on a platform [49]. Updated models come with multiple syringes to allow simultaneous printing of different polymer or cellular components and incorporate more design complexity and heterogeneity (Fab@Home V 2.0 — Kit for 2 Syringe System, Cornell University, Ithaca, NY). The syringe system itself is important in determining the deposition rate, the path width, and the path height, which play key roles in the final resolution [10]. The syringe tip diameter and material choice have a substantial impact on these variables, but one of the most important considerations is the lead screw threading, or the number of threads per inch [49]. Mechanically, the threading is important in determining the speed and direction of linear motion for the moving parts of the printer. For a specified syringe size, the threading also contributes to the maximum flow rate and syringe pressure. Based on the syringe tip diameter and the extrusion force, a limited range of fiber sizes may be achieved on the millimeter scale. In addition, the Fab@Home printing set-up houses a two-syringe system, placing limitations on the ability for material variance and optimal printing speed. Ideally, this set-up would be modified to accommodate four or more deposition tools to allow simultaneous or sequential printing of different types of material and avoid complications due to switching syringes. Modular components for the Fab@Home system may be added to incorporate other functionalities in the printer, including a crosslinking unit [5,55], a laser for error analysis [10], or a removable substrate platform for *in situ* applications [10], for example. These open-source systems have revolutionized the field of bioprinting by providing inexpensive, user-friendly printing systems with the capacity to be modified and improved upon by experimentalists. For example, Fig. 22.4 depicts the Fab@Home printing system, which includes a three-axis Cartesian gantry positioning system and is designed to be easily modifiable based on modular deposition parts [49]. The deposition tool is positioned on the Y-axis, which in turn rides along the X-axis. To minimize the effect of acceleration on moving parts, the Z-axis runs independently of the X- and Y-axes by moving the working stage up and down. All axes are composed of National Electrical Manufacturers Association (NEMA) size 14 bipolar motors and rotor-mounted with lead screws [49].

FINAL LAYER ARCHITECTURE AND RESOLUTION

Depending on the type of printer used, different layer or droplet sizes may be achieved due to the differences in deposition mechanisms. In general, 3DP of tissue-engineered constructs produces architectures with a high level of porosity as compared to other processing techniques, and a resolution of less than 250μm may be achieved [25]. In commercial inkjet printers, nozzle sizes range from 20–30μm, which can produce droplet sizes in the range of 10–20 pL [30]. While smaller nozzle sizes can produce fiber sizes with higher resolution [30], it is important to match the extrusion area of the nozzle to the viscosity of the material to ensure proper injectability [10]. For printers that use syringe-based deposition tools, tip diameters range from about 0.8 mm for hydrogels to 1.5 mm for ceramic pastes and produce fiber sizes of less than 2 mm in width and height [10,25]. Additionally, diameters ranging from 80–140μm have been achieved for LAB-printed droplets [50]. Overall, it has been shown that bioprinting creates an appropriate resolution for proper cellular response in a printed pattern [1].

Although precise resolutions may be achieved, there is some difficulty maintaining porous structures when stacking multiple layers, specifically the fusion of layer contact points without scaffold collapse [2,6,25]. For instance, although the vertical pores may remain intact after stacking, transverse pores in hydrogel scaffolds have the propensity to collapse due to the material softness [6]. Depending on the rigidity of the material used, there are height limitations for printing 3D scaffolds that may be mitigated by additional structural support [5]. For instance, Schuurman et al. constructed a hybrid scaffold design that alternated the printing of a structural thermoplastic polymer and a cell-laden hydrogel [7]. On the other hand, biodegradable or bioinert structural inserts may be added to guide printing and be later removed upon cellular remodeling of the matrix. Consequently, the loss of pore definition and collapse of fused layers are among the main sources of resolution error for a printed scaffold. Resolution error may readily occur during the printing process due to mechanical vibrations, slight movements of the printer head, or micrometer discrepancies in distance between the printer deposition tool and the substrate [39]. Furthermore, as fibers are extruded or droplets are deposited, the act of falling from the deposition tool to the substrate may have an impact on the material morphology and create inconsistencies in the design. Additionally, some types of printed cell-based hydrogel scaffolds that have been cultured in media for several weeks,

such as collagen and pluronic-F127, have shown shrinkage or swelling, respectively, over time [11]. All of these sources of error are important to consider when printing tissues that have a low error tolerance.

To determine whether resolution and porosity have been maintained after the scaffold has been printed, adherence to design geometry may be analyzed via micro-computed tomography (μCT) scanning [25,56] or using a charge coupled device (CCD) camera [10,20,45]. While μCT is the more time-efficient process, the use of a CCD camera appears to be a more precise method of error analysis because of the ability to evaluate each layer after it is printed [10]. A CCD camera may be used to create highly defined, low noise, real-time images of the material deposition process on the work space of the 3D printer. The use of a CCD camera for real-time visualization has several advantages. This mechanism serves as a primary method— in addition to secondary analysis with a laser distance sensor — for evaluating proper spatial resolution of each layer [10] and positioning throughout the printing process [45]. It can be used to measure parameters involving Z-positioning of the nozzle over the substrate, extrusion force on the material, fusion time between printed layers, sag length of the material over time, and work life of the material before the extrusion force is no longer adequate [10,24,45]. Because this camera allows for real-time imaging of the working area at an appropriate scale, the need for troubleshooting is much more apparent between layers, and geometric fidelity may be maintained with greater ease.

To further support CCD imaging in evaluating resolution and design flaws, a laser distance sensor may be employed as a primary mode of error analysis [57]. This sensor, as a measure of geometric conformity, has the ability to raster the sample layers post-printing in order to compare the actual resolution to the desired construction based on the computer input. As it scans the workspace, it can identify X—Y and height resolution to a certain range and measure of error. Previous work achieved a range of 104 mm and a distance measurement resolution of 0.12 mm height and 0.3 mm X—Y distance [10]. In order to achieve this high level of detection, laser placement is an important aspect in order to optimize the sensing range and to most accurately depict the printing resolution. An investigation was conducted on the sensing efficacy of a laser placed between the Y-axis carriage and the printing syringe, but it is unclear how well this placement enables optimal error analysis [10]. Ideally, the sensing mechanism should be designed to properly identify areas of heterogeneous surface texture, as well as point defects of missing or excess material. Through analysis of several determined points of each layer, it is possible to convert this information into a three-dimensional solid and export the information into an error-calculation program, such as Qualify® V11 (Geomagic Inc., Research Triangle Park, NC, USA), to compare the printed solid to the intended geometric model [10].

Error analysis of each scaffold is helpful in determining the reproducibility of the printing system by comparing error among a number of scaffolds of the same geometry and sample population and correlating these results with the intended computer model [57]. To extend printed tissue applications beyond the laboratory and into the clinic, it has been suggested to compare the calculated error to standard surgical tolerances for each respective defect in an effort to improve implant technologies [10]. Cohen et al. evaluated the efficacy of *in situ* printing in meniscal defects between the tibia and femur, as well as in osteochondral defects in a calf femur [10]. A laser sensor was then used to determine points at which the scaffold showed inconsistencies with the CAD model, in which the error was calculated and found to comply with acceptable surgical standards [10]. This result shows the ability to apply 3DP technologies to surgical procedures in order to produce highly defined, customized tissue-engineered constructs. Overall, comparison of error values from the CT image and the printing process to the surgical tolerance for defect implantation allows investigators to quantify the printing accuracy and gain a greater sense of the optimal resolution. Using simple, effective technologies such as CCD imaging and laser sensing, basic printing deposition may be

transformed into a translatable technique for designing surgical-grade defect replacements tuned specifically for each patient.

PRINTING APPLICATIONS: VASCULARITY AND ORGAN FABRICATION

While the idea of printing whole organs is still in its infancy, much work is being conducted to address this new field. When first developing tissue-engineered scaffolds, one of the most important aspects of the design is to incorporate vascularity to promote oxygen, nutrient, and waste transport throughout the tissue. Several groups have investigated vascular printing using inkjet-based printers [2,48] and syringe-based printers [5,32]. Another experimental model coupled development of entire vascular networks via bioprinting and self-assembly with computer simulations of tissue fusion [40]. Further investigation has also shown promise in developing tubular structures from functionalized hyaluronan-gelatin hydrogels [5]. It has also been shown that it is possible to print vascular architectures that support physiological flow conditions present in cardiovascular microvessels [2], which is a great improvement in the field of bioprinting and tissue engineering. Once the elements of vascularity can be implemented with printing tissues, steps toward printing whole organs will be more feasible.

In addition to work on developing vascular structures, several laboratories have also developed preliminary models toward whole and partial organ printing, including heart valves [55], skin [39], bladder [58], liver [59,60], neuroregenerative tissue [61], bone [27,44,62], and osteochondral tissue [10]. Some of these studies incorporate additional rapid prototyping techniques that may be later translated to 3DP applications. Using the Fab@Home printer, educational models of a heart and aorta have been fabricated using clear silicone, and alginate has been used to print an ovine construct for meniscal repair [5]. Bioprinting has also been suggested as a method for printing tissues with zonal architecture, such as the articular cartilage model depicted in Fig. 22.5 [3]. Taking a step beyond printing scaffolds and implanting them after cell culture, some efforts have been made toward *in situ* printing for meniscal repair [10], calvarial defects [1,45], and skin replacement [39], which may provide benefits for more efficient surgical technologies. One drawback to *in situ* printing is that the scaffolds would not be primed via mechanical stimulation prior to implantation, which may result in improper cell differentiation and subsequent difficulties in tissue regeneration. However, it is

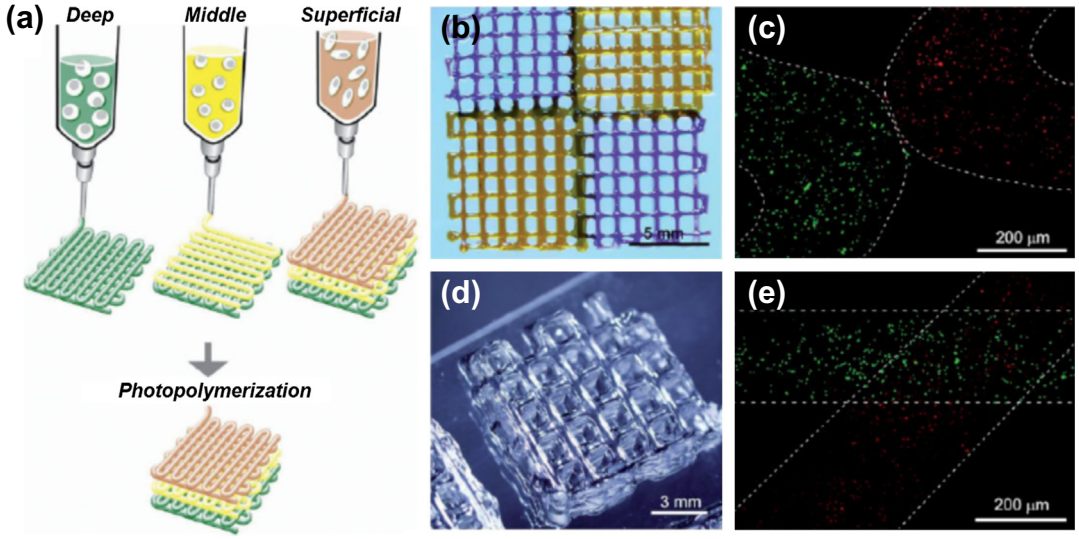

FIGURE 22.5

still unclear whether scaffold stimulation or pre-loading is necessary to promote desired tissue formation at the defect site.

To determine whether the printed tissues actually match the form and function of biological organs, it is necessary to identify or design specific characterization techniques that detect cell-cell and cell-material interactions for *in vitro* and *in vivo* conditions. As tissues and organs are printed with varying materials, growth factors, cells, and other molecules, a collective library of these 3DP scaffolds would initially allow rapid screening of optimal parameters for tissue-engineered constructs and identify factors that are crucial for cell growth and proper function [63]. Because 3DP allows the construction of scaffolds with repeatable porous architectures, processing with this method has implications for better screening of the scaffolds themselves and in flow perfusion conditions [38]. However, current methods of evaluating 3D tissue formation are time intensive and inaccurate. For instance, individual separation of cell pellets into wells may be achieved in a more rapid manner with 3DP, but these small wells do not represent the functionality and cell-material interactions found in a full-sized tissue [38]. High-throughput scaffold arrays could also be used to identify proper microenvironments for specific tissue regeneration. One dimensional assays — such as polymer blends with varying compositions — as well as 2D assays involving polymer composition and processing temperature or surface energy and hydrophobicity may be used to characterize the effect of the material on expression of cell lineage markers [12]. Furthermore, it would be desirable to develop or utilize currently available non-destructive techniques to image and characterize the scaffold prior to implantation [20]. Although progress has been made to address the biological functionality of scaffold processing via 3DP, current technologies have yet to develop methods to increase the scaffold output for 3DP. Further modification of the printing process is necessary to meet the annual clinical demand for manufacturing artificial implants.

CONCLUSIONS

Polymer processing via three-dimensional printing is an emerging technology designed to address tissue replacement needs for individual patients. Common issues in the area of 3DP include limited scaffold size and sample number. Because this technology was originally designed to create prototypes, few efforts have been made to scale-up the manufacturing process of scaffold samples. There have also been few successes in the ability to increase scaffold size due to structural instability of the materials used, which are usually natural hydrogels. Furthermore, the process of 3DP is still time intensive due to a lack of archived patient data and the ability to create a customizable scaffold library. In addition to the time needed to create a 3D computer model of the scaffold prior to printing, the actual printing process may take hours to days, depending on the size and complexity of the construct. For printing applications that require culturing each layer before stacking, fabrication time may be even more laborious. In order to overcome this obstacle, printing materials with encapsulated cells may be more beneficial than cell seeding post-printing. Additionally, although initial development of a computer-aided design is time consuming, a scaffold library created by high-throughput combinatorial methods would enable the printing process to run much more quickly in the future and allow patient-specific modifications of implants. After optimizing characterization and scaling-up the design beyond prototypes, 3DP will become a highly viable processing method for tissue-engineering applications.

CHAPTER 23

Biodegradable Polymers

Zheng Zhang, Ophir Ortiz, Ritu Goyal and Joachim Kohn
New Jersey Center for Biomaterials, Rutgers, The State University of New Jersey, Piscataway, New Jersey

INTRODUCTION

The design and development of tissue-engineered products has benefited from many years of clinical utilization of a wide range of biodegradable polymers. Newly developed biodegradable polymers and modifications of previously developed biodegradable polymers have enhanced the tools available for creating clinically important tissue-engineering applications. Insights gained from studies of cell-matrix interactions, cell-cell signaling, and organization of cellular components, are placing increased demands on medical implants to interact with the patient's tissue in a more biologically appropriate fashion. While in the twentieth century, biocompatibility was largely equated with eliciting no harmful response, the biomaterials of the twenty first century will have to elicit tissue responses that support healing or regeneration of the patient's own tissue.

This chapter surveys the universe of those biodegradable polymers that may be useful in the development of medical implants and tissue-engineered products. Here we distinguish between biologically derived polymers and synthetic polymers. The materials are described in terms of their chemical composition, breakdown products, mechanism of breakdown, mechanical properties, and clinical limitations. Also discussed are product design considerations in processing of biomaterials into a final form (e.g., gel, membrane, matrix) that will effect the desired tissue response.

In this chapter, we follow the official polymer nomenclature conventions adopted by the International Union of Pure and Applied Chemistry (IUPAC). According to these rules, the correct naming of a polymer requires the simple addition of the prefix 'poly' in front of the monomer name, *if the monomer name consists of a single word*. For example, the polymer made of ethylene is simply polyethylene. There is no space between poly and ethylene. When the monomer name consists of two or more words, it is important that the entire monomer name be enclosed in parentheses. This is needed to avoid ambiguity. For example, the polymer made of lactic acid is correctly named as poly(lactic acid). Note the absence of a space between the prefix poly and the parenthesis. Polymers made of amino acids are sometimes referred to as peptides, proteins, or poly(amino acid)s. When referring to one polymer that is made of one type of amino acid, IUPAC rules require this material to be named as a poly(amino acid). When referring to several such polymers, the plural of poly(amino acid) is poly(amino acid)s. Note the placement of the plural 's' outside of the parenthesis. When a polymer is made of several different amino acids, then that polymer would be referred to as a poly(amino acids). Note the placement of the plural 's' inside the parenthesis, indicating that this is a single polymer that contains more than one type of amino acid as monomer. Unfortunately, these rules are often violated in the contemporary literature.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00023-9

BIODEGRADABLE POLYMER SELECTION CRITERIA

The selection of biomaterials plays a key role in the design and development of medical implants and tissue-engineering products. While the classical selection criterion for a safe, stable implant dictated choosing a passive, 'inert' material, it is now understood that any artificial material placed into the body of a patient will elicit a cellular response [1,2]. This means that there are in fact no artificial materials that are totally 'inert', and some of the chemically least reactive materials, such as polyethylene or polysiloxane, can cause significant inflammatory responses. Therefore, it is now widely accepted that a biomaterial must interact with tissue in a biologically appropriate manner rather than act simply as an inert body. Consequently, a major focus of biomaterials science centers around harnessing control over cellular interactions with biomaterials. Researchers now tend to explore ways to manipulate the cellular response by including biologically active components in the design of biomaterials. Specific examples of such biologically active components include protein growth factors, anti-inflammatory drugs, and gene delivery vectors [3].

It is important for the tissue-engineering product developer to have many biomaterials options available, as each application calls for a unique environment for cell-cell interactions. Such applications include:

1) Support for new tissue growth (wherein cell-cell communication and cells' access to nutrients, growth factors, and pharmaceutically active agents must be maximized);
2) Prevention of cellular activity (where tissue growth, such as in surgically induced adhesions, is undesirable);
3) Guided tissue response (enhancing a particular cellular response while inhibiting others);
4) Enhancement of cell attachment and subsequent cellular activation (e.g., fibroblast attachment, proliferation, and production of extracellular matrix for dermis repair) [4];
5) Inhibition of cellular attachment and/or activation (e.g., platelet attachment to a vascular graft);
6) Prevention of a biological response (e.g., blocking antibodies against grafted cells used in organ replacement therapies).

Biodegradable polymers are applicable to those tissue-engineering products in which tissue repair or remodeling is the goal, but not where long-term materials stability is required. Biodegradable polymers must also possess:

1) Manufacturing feasibility, including availability of sufficient commercial quantities of the bulk polymer;
2) The capability to form the polymer into the final product design;
3) Mechanical properties that adequately address short-term function and do not interfere with long-term function;
4) Low or negligible toxicity of degradation products, in terms of both local tissue response and systemic response;
5) The capability to be formulated as a drug delivery system in applications that call for prolonged release of pharmaceutically active compounds.

BIOLOGICALLY DERIVED POLYMERS

Biologically derived polymers are materials created by living organisms, as opposed to synthetic materials which are man-made. This distinction divides the universe of medically useful, biodegradable polymers into two large subgroups. However, the delineation between these groups is not always clear-cut. For example, glycolic acid is a natural metabolite and poly(glycolic acid) is naturally produced by many organisms. However, glycolic acid can also be created synthetically from oil-derived starting materials. Currently, poly(glycolic acid) is produced commercially by both fermentation and synthetic processes. Both production pathways result in the same final product, making poly(glycolic acid) either a biologically

derived polymer or a synthetic polymer. A similar situation exists in regard to polymers derived from hydroxybutyric acid and hydroxyvaleric acid. Commonly referred to as polyhydroxyalkanoates, these polymers can be derived from bacterial fermentation, as well as purely synthetic processes. In this chapter, polyhydroxyalkanoates are included among the biologically derived polymers (since the most prevalent mode of commercial production is based on bacterial fermentation), while poly(glycolic acid) and the closely related poly(lactic acid) are introduced to the reader as synthetic polymers (since the predominant mode of commercial production is currently based on oil-derived starting materials and synthetic polymerization reactions).

The biologically derived polymers can be further classified into peptides and proteins, polysaccharides, polyhydroxyalkanoates, and polynucleotides. Each of these subgroups will be discussed separately.

Peptides and proteins

Peptides and proteins are polymers derived from naturally occurring α-L-amino acids. Peptides are usually shorter chains of dozens of amino acids linked together via amide bonds, while proteins are longer chains of hundreds of individual amino acids. The amino acids are connected via hydrolytically stable amide bonds. Therefore, these materials are usually degraded via enzymatic mechanisms. The major shortcoming of peptides and proteins as starting materials for the fabrication of any medical implant is their lack of 'processibility'. This term refers to the ability of creating a shaped device by any of the conventional polymer processing methods used in the plastics industry: compression molding, extrusion, injection molding and fiber spinning. Another important limitation of peptides and proteins as biomaterials is their inherent immunogenicity. Any peptide or protein carries the risk of being recognized as foreign by the patient's immune system. For example, for many years, the safety of using bovine collagen was a hotly debated topic because of fears that the implantation of bovine collagen could provoke an immune response and predispose the patient to autoimmune diseases.

On the other hand, peptides and proteins can have outstanding biological properties and can help the tissue engineer in designing a polymer with desirable biological activities. This fact has been the driving force behind the long-standing interest in using peptides and proteins as starting materials for medical implants or tissue-engineering products. Unfortunately, most peptides and proteins have mechanical properties that are not conducive for their use in medical implants, resulting in the utilization of only a very small number of proteins as biomaterials (Table 23.1).

COLLAGEN

Collagen is the major component of mammalian connective tissue, accounting for approximately 30% of all protein in the human body. It is found in every major tissue that requires strength and flexibility. Fourteen types of collagens have been identified, the most abundant being type I [5]. Because of its abundance and its unique physical and biological properties, type I collagen has been used extensively in the formulation of biomedical materials [6]. Type I collagen is found in high concentrations in tendon, skin, bone and fascia, which are consequently convenient and abundant sources for isolation of this natural polymer.

The structure, function, and synthesis of type I collagen has been thoroughly investigated [7]. Because of its phylogenetically well-conserved primary sequence and its helical structure, collagen is only mildly immunoreactive [8]. However, many human recipients of medical or cosmetic products containing bovine collagen have anti-bovine collagen antibodies. The clinical significance of this finding is not yet fully understood.

TABLE 23.1 Proteins used as degradable biomaterials in medical implants

Type of protein	Source	Function
Collagen	Isolated from cattle, fish, and other species	Key component of tissue architecture, provides mechanical strength, supports cell attachment and growth, provides a biocompatible matrix for cell transplantation. Used extensively as a tissue expander and bulking agent in cosmetic products
Gelatin	Partially hydrolized collagen	Used in food industry, widely explored by researchers as a matrix for three-dimensional cell culture and as a component of tissue-engineering scaffolds
Elastin	Isolated from elastic tissues of cattle and birds	Key component of tissue architecture, provides elasticity to tissues
Keratin	Isolated from skin, hair and nails of cattle and birds	Key structural component of outer skin, hair and nails. Used as a matrix for cell growth and as a component in wound dressings and skin care products
Silk	Isolated from insect larvae	Used in the textile industry because of its extraordinaty strength. Also studied as a component of tissue-engineering scaffolds and as a cell culture substrate
Proteoglycans	Various tissue extracts	Used in research of cell-matrix interactions, matrix-matrix interactions, cell proliferation, cell migration

TABLE 23.2 Widely investigated polysaccharides

Type of polysaccharide	Source	Function
Cellulose	Cell wall of green plants	Main structural component of plants which keeps the stems, stalks and trunks rigid
Starch (Amylose and amylopectin)	Present in all staple foods	Important in plant energy storage
Alginate	Found in the cell walls of bacteria	Protects bacteria from engulfment by predatory protozoa or white blood cells (phagocytes)
Glycosaaminoglycans	Widely distributed	Cell-matrix interactions, matrix-matrix interactions, cell proliferation, cell migration
Chitin/chitosan	Major component of the exoskelton of insects, shells of crustaceans, cell walls of fungi	Structural component

The individual collagen molecules will spontaneously polymerize to form strong fibers that form larger organized structures. Collagen exists in tissue in the form of collagen fibers, fibrils, and macroscopic bundles [9]. For example, tendon and ligaments are comprised mainly of oriented type I collagen fibrils, which are extensively crosslinked in the extracellular space.

In vitro, collagen crosslinking can be enhanced after isolation through a number of well-described physical or chemical techniques [10]. Increasing the intermolecular crosslinks:

1) Increases biodegradation time, by making collagen less susceptible to enzymatic degradation;
2) Decreases the capacity of collagen to absorb water;
3) Decreases its solubility; and
4) Increases the tensile strength of collagen fibers.

The free amines on lysine residues on collagen can be utilized for crosslinking, or can similarly be modified to link or sequester active agents. These simple chemical modifications provide a variety of processing possibilities and consequently the potential for a wide range of tissue-engineering applications using type I collagen.

It has long been recognized that substrate attachment sites are necessary for growth, differentiation, replication, and metabolic activity of most cell types in culture. Collagen and its integrin-binding domains (e.g., RGD sequences) assist in the maintenance of such attachment-dependent cell types in culture. For example, fibroblasts grown on collagen matrices appear to differentiate in ways that mimic *in vivo* cellular activity and to exhibit nearly identical morphology and metabolism [11]. Chondrocytes can also retain their phenotype and cellular activity when cultured on collagen [12]. Such results suggest that type I collagen can serve as tissue-regeneration scaffolds for any number of cellular constructs.

The recognition that collagen matrices could support new tissue growth was exploited to develop the original formulations of artificial extracellular matrices for dermal replacements [1,2,13–15]. Yannas and Burke were the first to show that the rational design and construction of an artificial dermis could lead to the synthesis of a dermis-like structure whose physical properties 'would resemble dermis more than they resembled scar' [15]. They created a collagen–chondroitin sulfate composite matrix with a well-described pore structure and crosslinking density that optimizes regrowth while minimizing scar formation [16]. The reported clinical evidence and its simplicity of concept make this device an important potential tool for the treatment of severely burned patients [17].

The advantageous properties of collagen for supporting tissue growth have been used in conjunction with the superior mechanical properties of synthetic biodegradable polymer systems to make hybrid tissue scaffolds for bone and cartilage [18,19]. These hybrid systems show good cell adhesion, interaction and proliferation compared to the synthetic polymer system alone. Collagen has also been used to improve cell interactions with electrospun nanofibers of poly(hydroxy acids) such as poly(lactic acid), poly(glycolic acid), poly(ε-caprolactone) and their copolymers [18–22].

In recent years, the combination of collagen scaffolds with active biological entities, such as cells, growth factors, platelet rich plasma [23] and various autologous or allogenic cell types [24] have provided significant opportunities for researchers to achieve tendon and ligament regeneration.

GELATIN

Gelatin is commonly used for pharmaceutical and medical applications because of its enzymatic biodegradability and biocompatibility in physiological environments [25–27]. Of the two types, acidic and alkaline gelatin, the former has an isoelectric point similar to collagen. The isoelectric point depends on its extraction procedure from collagen, and variations in it allow gelatin to bind with either positively or negatively charged therapeutic agents. Based on this, the acidic gelatin, with an isoelectric point of 5.0, could be used as a carrier for basic proteins *in vivo*, while basic gelatin, with an isoelectric point of 9.0, could be used for the sustained release of acidic proteins under physiological conditions. The advantage of gelatin as a carrier for controlled drug release is that the therapeutic agent can be loaded into the gelatin matrix under mild conditions. Gelatin hydrogels have been used as controlled release devices for a variety of growth factors known to enhance bone formation. Yamada et al. successfully incorporated bFGF (basic fibroblast growth factor) into acidic gelatin hydrogels, which were implanted into a rabbit skull defect to allow for the localized release over 12 weeks [28,29].

ELASTIN

Elastin is an extracellular matrix protein and is most abundant in tissues where elasticity is of major importance, such as blood vessels (50% of dry weight), elastic ligaments (70% of dry weight), lungs (30% of dry weight) and skin (2–4% of dry weight) [30,31].

The incorporation of elastin into biomaterials was a major topic of research in the 1970s and 1980s. The basic structure-function-activity correlations of various elastin sequences were discovered by Urry and his associates [32]. It is important to note that elastin is not a single, well-defined molecule. Rather, the name 'elastin' is associated with a wide range of elastic peptide and protein sequences that exist in different lengths and with different compositions. A common feature of all elastin sequences is that they are rich in glycine, proline, and lysine. In humans, elastin is synthesized early in life. By age 40 (approximately) elastin biosynthesis in humans slows down to a trickle. The appearance of skin wrinkles and other aging processes are directly related to the loss of elastin biosynthesis. This fact has been exploited as a marketing gimmick by cosmetic companies, who add elastin to a wide range of anti-aging products. However, there is overwhelming evidence that externally applied elastin is not able to pass through the skin and is not able to slow the loss of elastin from aging tissues.

When elastin was used as a component in heart valve prosthetic devices, the deposition of calcium-rich precipitates was a significant problem. This process, often referred to as 'calcification', limited the utility of elastin-containing biomaterials in cardiovascular prosthetic implants [33]. This experience illustrates that the use of natural substances is not necessarily a guarantee for clinically successful device performance.

Another important point is that not all biologically derived polymers are good cell growth substrates. While collagen is highly cell adhesive, elastin tends to discourage cell attachment and growth. This has been a concern in the biomedical community, since many potential applications of elastin (for example in blood vessel and ligament regeneration) would require a highly cell adhesive surface. This challenge can be addressed using the tools of protein engineering to incorporate cell adhesive peptide sequences within the elastin structure [32].

Overall, elastin is a highly versatile biomaterial that continues to inspire the imagination and curiosity of biomedical engineers. Recently, the ability of elastin to self-assemble into large supramolecular structures was used to fabricate sponges, scaffolds, sheets and tubes from human tropoelastin [34]. These promising studies are still ongoing.

KERATIN

Keratin is the name for a family of structural proteins which are abundant in the outer layer of human skin, in hair, and in nails. Keratin is rich in the amino acid cysteine, and it has the ability to self-assemble into bundles of fibers. Within these fiber bundles, individual strands are further crosslinked through S-S (sulfur-sulfur) bonds involving the cysteine side chains. In this way, keratin forms particularly tough, insoluble structures that are among the strongest non-mineralized tissues found in nature. The only other non-mineralized tissue that resembles the toughness of keratin is chitin (the material found in the exoskeleton of insects and the outer shell of shellfish).

Since human hair is rich in keratin, this protein is added to many hair care products. However, as in the case of the misleading marketing claims made for elastin-containing anti-aging skin products, there is no evidence that externally applied keratin can penetrate into the hair structure. While keratin was mostly studied for use in cosmetic (hair care) products, the exploration of keratin's properties also led to the development of keratin-based biomaterials for use in biomedical applications. The unusual mechanical properties and strength of keratin and its ability to self-assemble were the driving force for these biomedical studies.

The history of keratin research illustrates another major challenge when using biologically derived polymers as biomaterials. Based on the animal source used, and depending on the exact extraction procedure employed, individual keratin preparations can differ significantly from each other. The variability and irreproducibility of individual preparations is a general feature of most biologically derived polymers. Early research, mostly by Yamauchi's laboratory, focused on the preparation of protein films from keratin extracted from wool and human hair. These pure protein films were brittle and weak. The researchers could not reproduce in the laboratory the outstanding strength of keratin formed *in vivo*. Only when glycerol was added as a plasticizer, could keratin films be obtained that were relatively strong and flexible [35]. Fujii et al. also demonstrated that hair keratins were useful for preparing protein films and described a rapid casting method [36]. This research also revealed the feasibility of incorporating bioactive molecules such as alkaline phosphatase into the keratin films for controlled release applications. The films, however, had poor strength and flexibility [36]. Recently, significant progress was made by researchers at Wake Forest University, where keratin extracted from human hair was used as a matrix for the regeneration of peripheral nerves. This is currently one of the most advanced applications of keratin as a biomaterial [37].

SILK

On a weight basis, natural silk fibers can be stronger than high-grade steel. However, the strength of natural silk fibers is difficult to reproduce in the laboratory once pure silk has been extracted from the cocoons of silkworm larvae or from spider's webs. Still, the unique mechanical properties of natural silk fibers have fascinated scientists for more than a century. Recent work has demonstrated the biocompatibility of various silk protein preparations [38]. Another very interesting fact is that the degradation rate of laboratory-made silk fibers can be tailored to be from months to years after implantation *in vivo*, based on the processing procedure employed during the material's formation [39]. Finally, the thermal stability of silk biomaterials allows processing over a wide range of temperatures up to about 250°C, as evidenced by the ability to autoclave silk biomaterials without loss of functional integrity. Min and colleagues investigated the potential of electrospun silk matrices for accelerating early stages of wound healing [40]. In another study, chitin was blended with silk fibroin to fabricate composite fibrous scaffolds for skin tissue engineering. The rationale of these experiments was to combine the good mechanical properties of silk fibers with the wound healing effects of chitin [41]. The chitin/silk fibroin blends were electrospun to form nanofibrous matrices and evaluated for initial cell attachment and spreading [42]. *In vitro*, increased adhesion of keratinocytes was observed on chitin/silk blend matrices compared to pure chitin matrices, but the significance of these results for wound healing *in vivo* has not yet been established.

Overall, the exploration of silk as a biomaterial has not yet produced any commercially available medical products. While silk is a fascinating material, the studies performed so far have not discovered truly compelling reasons for the use of silk as a medical implant material.

PROTEOGLYCANS

Proteoglycans (PGs) are a major component of the extracellular matrix (ECM). They consist of one or more glycosaminoglycan (GAG) chains that are attached, via a tetrasaccharide link, to serine residues within a core protein [43,44]. GAGs are long chains of repeating disaccharide units that are variably sulfated. There are four main classes of GAGs — hyaluronan (HA), chondroitin sulfate (CS) and dermatan sulfate (DS), heparan sulfate (HS), and keratan sulfate (KS). PGs exhibit great structural diversity because each type of PG may contain different kinds of GAGs, different numbers and lengths of GAG chains, modifications in the repeating patterns of the disaccharides by a complex pattern of sulfate groups, and a different core protein structure. PGs can be present in monomeric form or can form very large aggregates. Both the core protein and the GAG chains of PGs play key roles in tissue remodeling, intracellular signaling, uptake of proteins, cell migration, and many other crucial functions in

native tissues [43,44]. The fact that PGs seem to be involved in so many crucial cell signaling pathways is the main reason for the intense interest of biomedical engineers in understanding their properties.

To replicate the biological functions of PGs in tissue scaffolds, PGs or their GAG chains have frequently been grafted to the polymers used in fabricating tissue scaffolds, or they have been grafted onto the surface of tissue-engineering scaffolds. Most notably, chondroitin sulfate GAGs have been used to create collagen–GAG hybrid materials which seem to be particularly effective in skin regeneration.

PGs are sometimes used alone or in combination with other matrix proteins such as fibrin, collagen, or chitosan to create hybrid materials [45–47]. The rationale for exploring such complex mixtures is usually an attempt to 'mix and match' biological properties with appropriate mechanical properties. For example, a mixture of PGs and extracellular matrix proteins are part of the widely used Matrigel™ scaffold. Among the various combinations, collagen–GAG scaffolds are often preferred for tissue-engineering applications, because collagen provides a very cell friendly matrix environment and the specific GAG used can affect (and regulate) cell behavior. Collagen–GAG hybrids can be readily sterilized using heat, and can be manufactured with a variety of pore structures and a wide range of degradation rates [48]. The first commercially used tissue-engineered product, an artificial skin scaffold, developed by Integra LifeSciences, a New Jersey company, is a collagen–GAG hybrid.

Biomimetic materials

Biomimetic materials are synthetic (man-made) materials that mimic natural materials or that follow a design motif derived from nature. In the previous section, a number of peptides and proteins were discussed. In general, peptides and proteins are isolated from natural sources and are therefore listed among the biologically derived polymers. However, significant research breakthroughs were made when scientists started to create mimics of natural polymers by semi-synthetic or totally synthetic means. An excellent example for this type of research approach is the work of Urry and coworkers, who used peptide synthesis methods to create artificial variants of elastin [49,50]. Using a combination of solid-phase peptide chemistry and genetically engineered bacteria, they synthesized several polymers which contained homologies of the elastin repeat sequences valine-proline-glycine-valine-glycine (VPGVG). These biomimetic polymers had better engineering properties than their natural equivalents, making it possible to create films and fibers that could then be further modified by crosslinking. The resultant films had intriguing mechanical responses, such as a reverse phase transition which results in contraction with increasing temperature [50], resembling the action of muscles. The exact transition temperature could be varied by variations in the polymer's amino acid composition [50]. Several medical applications are under consideration for this system, including musculoskeletal repair mechanisms, ophthalmic devices, and mechanical and/or electrically stimulated drug delivery.

Other investigators, notably Tirrell and Cappello, have combined techniques from molecular and fermentation biology to create novel protein-based biomaterials [51–54]. These researchers had the remarkably innovative idea of creating genetically-engineered microorganisms that would produce exactly those polymers that the researchers liked to study. In this way, completely new variations of biologically derived peptides and proteins could be prepared. These protein polymers were based on repeat oligomeric peptide units, which were controlled via the genetic information inserted into the producing bacteria. It has been shown that the mechanical properties and the biological activities of these protein polymers can be pre-programmed, suggesting a large number of potential biomedical applications [55].

Another approach to elicit an appropriate cellular response to a biomaterial is to graft active peptides to the surface of a biodegradable polymer. For example, peptides containing the RGD

sequence have been grafted to various biodegradable polymers to provide active cell-binding surfaces [56]. Similarly, Panitch et al. incorporated oligopeptides containing the REDV sequence to stimulate endothelial cell binding for vascular grafts [57].

Polysaccharides

Polysaccharides are polymers made of various sugar (saccharide) units. The most common monosaccharides are glucose and fructose. Sucrose is the chemical name of the widely used table sugar. Sucrose is a disaccharide composed of glucose and fructose. Scientists who are not experts in sugar chemistry are often unaware of the exquisite structural variability of these molecules. For example, the important human food, *starch*, and the structural polymer of all plants, *cellulose*, are both polymers of glucose. The only difference between starch and cellulose is the way in which the individual glucose units are linked together. Considering the many different isomeric variations possible for saccharides, and the different chemical bonds that can be used to link individual saccharide units together, the number of structurally different polysaccharides is extremely large. In fact, the chemistry of polysaccharides is as rich in diversity and variability as protein chemistry. It is therefore not surprising that various saccharides and polysaccharides play an important role in fine-tuning the responses of cells to their environment. As outlined above, proteoglycans (PGs) and glucosaminoglycans (GAGs) are critical in regulating key cell functions. In contrast, the industrially used polysaccharides (such as starch and cellulose) are polymers comprising exclusively various sugar (saccharide) units as monomers. These polysaccharides can be extremely large polymers containing millions of monomers, and they are mostly used in nature for cellular energy storage or as a structural material. As a general rule, most of the natural polysaccharides are not biodegradable when implanted in any mammalian species due to the lack of digestive enzymes. Therefore, without further chemical modification, most polysaccharides are not obvious material choices for use in biomedical applications.

CELLULOSE

Cellulose is the most abundant polymeric material in nature. In its most common form, it is a fibrous, tough, water-insoluble material that is mostly found in the cell walls of plants, mainly in stalks, stems or trunks. Cellulose is the major ingredient of wood. Cellulose is composed of D-glucose units that are linked together by β-(1→4) glycosidic bonds. In nature, cellulose is formed by a simple polymerization of glucose residues from a substrate such as UDP-glucose [58]. Cellulose possesses high strength in the wet state [59]. The major commercial applications of cellulose are in the paper, wood, and textile industries [60] where millions of tons of cellulose are processed annually worldwide.

The major limitation of cellulose as a biomaterial is that it is not biodegradable, due to the lack of digestive enzymes for cellulose in the human organism [61,62]. However, a number of cellulose derivatives, such as methylcellulose, hydroxypropylcellulose and carboxymethylcellulose are used as biomaterials, due to the useful material properties exhibited by these synthetically created derivatives [63].

Cellulose is not an obvious choice for biomedical applications and there is no scientific rationale to expect cellulose to have unique or useful properties as a cell growth substrate or tissue-regeneration scaffold. This, however, has not prevented a number of laboratories from exploring cellulose or cellulose derivatives as a drug delivery implant, as a barrier for the prevention of surgical adhesions, or as a scaffold in cartilage tissue engineering [64,65]. *In vivo* studies have been performed to assess the biocompatibility of a bacterial cellulose scaffold by subcutaneous implantation in rats. While there were no macroscopic or microscopic signs of inflammation around the implants, and no fibrotic capsule or giant cells were observed, the limited biodegradability of cellulose will most probably prevent the use of this material in most biomedical applications [65].

STARCH

Whereas cellulose is composed of D-glucose units that are linked together by β-(1→4) glycosidic bonds, starch is composed of D-glucose units that are linked together by α-(1→4) glycosidic bonds. This change makes starch digestible, allowing its use as a major human nutrient. The chemistry of starch is complicated by the fact that starch consists of linear and branched chains, referred to as amylose and amylopectin respectively [66]. The relative abundance of these two natural ingredients can significantly influence the material properties of starch. Consequently, literally hundreds of different starches exist, each with its own particular composition of amylose and amylopectin.

Starch can be totally water insoluble, or partially soluble at room temperature, depending on the proportions of amylose and amylopectin present. Water-soluble starches can be dispersed in water, forming clear solutions upon heating. Upon cooling, soluble starch forms a highly viscous solution at low concentrations and a stiff hydrogel at higher concentrations. This is the basis of the thickening action of soluble corn starch, which is used extensively in the food industry.

Although enzymes present in the human gut can digest starch, it is not readily biodegradable when implanted into human tissues. The cellular energy storage polymer in humans is glycogen and not starch. Consequently, starch is not an obvious choice for biomedical applications. However, some starch-based polymers are biodegradable in human tissues and biocompatible. Among many potential applications, starch-based polymers were used to prepare scaffolds for cartilage regeneration [67]. These scaffolds did not perform better than other types of scaffolds. Starch was also used for the design of implantable drug delivery systems. In spite of the research conducted by several laboratories worldwide, starch-based polymers are not likely to find major biomedical applications in the near future.

ALGINATE

Alginate is a natural anionic polysaccharide found in seaweed, which is composed of β-(1−4) linked D-mannuronic acid and α-L-guluronic acid units. Along its polymer chain, alginate has regions rich in sequential mannuronic acid units, guluronic acid units and regions in which both monomers are equally prevalent.

The most important use of alginate in biomedicine is as a cell-compatible hydrogel. Alginate can form strong hydrogels in the presence of divalent cations (such as Ca^{2+} or Ba^{2+}) that interact with the carboxylic groups present in the alginate backbone to form ionic crosslinks. In a typical experiment, a solution of alginate is added to cells suspended in physiologic buffer solution. This mixture is then dropped slowly into a solution of calcium chloride. As each drop of the cell suspension touches the calcium chloride solution, the alginate forms a hydrogel that encapsulates and captures the suspended cells. This process has been used *in vitro* to encapsulate human articular chondrocytes in the presence of recombinant human BMP-2 [68].

Alginate has a well-characterized structure, which allows for a range of comparative studies to be performed. Cells do not readily attach and grow on or within alginate hydrogels. This is a common feature of most unmodified polysaccharides. However, the carboxylic groups in its guluronic acid residues provide an easy handle for the chemical modification of alginate [69]. This feature makes it possible to attach biologically active ligands (such as the important RGD peptide) to the alginate backbone [69].

Alginate's major disadvantage is the difficulty of its isolation from contaminated seaweed, which leads to the presence of mitogenic, cytotoxic and apoptosis inducing impurities in the final processed material. Although such molecules can be removed by further purification steps, it is a time consuming and costly process [70].

GELLAN GUM

Gellan gum is another anionic polysaccharide, similar in utility profile to alginate. Gellan gum can be easily processed into transparent gels that are resistant to heat. Gellan gum is not cytotoxic [71]) and can be injected into tissues. It has been used *in vivo* in humans as an ocular drug delivery vehicle [4]. Gellan gum is still relatively unknown in the biomedical community and only a few studies have explored this material for tissue engineering [72]. Like alginate, gellan gum can be used for the encapsulation and *in vitro* culture of cells [71]. Gellan gum hydrogels were able to support the development of nasal chondrocytes, and injectable gellan gum hydrogels were efficient in the encapsulation and support of human articular chondrocytes, while also enabling active synthesis of ECM components.

GLYCOSAMINOGLYCANS

Glycosaminoglycans (GAGs), which consist of repeating disaccharide units in linear arrangement, usually include a uronic acid component (such as glucuronic acid) and a hexosamine component (such as N-acetyl-D-glucosamine). The predominant types of GAGs attached to naturally occurring core proteins of proteoglycans include chondroitin sulfate, dermatan sulfate, keratan sulfate, and heparan sulfate [73,74]. The GAGs are attached to the core protein by specific carbohydrate sequences containing three or four monosaccharides.

The largest GAG, hyaluronic acid (hyaluronan), is an anionic polysaccharide with repeating disaccharide units of N-acetylglucosamine and glucuronic acid, with many unbranched units ranging from 500 to several thousand. Hyaluronic acid can be isolated from natural sources (e.g., rooster combs) or via microbial fermentation [75]. Because of its water-binding capacity, dilute solutions of hyaluronic acid form viscous solutions.

Like collagen, hyaluronic acid can be easily chemically modified, for instance by esterification of the carboxyl moieties, which reduces its water solubility and increases its viscosity [75,76]. Hyaluronic acid can be crosslinked to form molecular weight complexes in the range 8 to 24 $\times$ 10^6 or to form an infinite molecular network (gel). In one method, hyaluronic acid is crosslinked using aldehydes and small proteins to form bonds between the C—OH groups of the polysaccharide and the amino or imino groups of the protein, thus yielding high molecular weight complexes [77]. Other crosslinking techniques include the use of vinyl sulfone, which reacts to form an infinite network through sulfonyl-bis-ethyl crosslinks [78]. The resultant infinite network gels can be formed into sheaths, membranes, tubes, sleeves, and particles of various shapes and sizes. No species variations have been found in the chemical and physical structure of hyaluronic acid. The fact that it is not antigenic, eliciting no inflammatory or foreign body reaction, makes it desirable as a biomaterial. Its main drawbacks in this respect are its residence time and the limited range of its mechanical properties.

Because of its relative ease of isolation and modification and its superior ability in forming solid structures, hyaluronic acid has become the preferred GAG in medical device development. It has been used as a viscoelastic during eye surgery since 1976, and has undergone clinical testing as a means of relieving arthritic joints [79]. In addition, gels and films made from hyaluronic acid have shown clinical utility in preventing formation of post-surgical adhesions [80—82].

The benzyl ester of hyaluronic acid, sold under the trade name HYAFF-11, has been studied for use in vascular grafts [83—88].

CHITOSAN

Chitosan is a biosynthetic polysaccharide that is the deacylated derivative of chitin. Chitin is a naturally occurring polysaccharide that can be extracted from crustacean exoskeletons or generated via fungal fermentation processes. Chitosan is a β-1,4-linked polymer of 2-amino-2-deoxy-D-glucose; thus it carries a positive charge from amine groups [89]. It is hypothesized

that the major path for chitin and chitosan breakdown *in vivo* is through lysozyme, which acts slowly to depolymerize the polysaccharide [90]. The biodegradation rate of the polymer is determined by the amount of residual acetyl content, a parameter that can easily be varied. Chemical modification of chitosan produces materials with a variety of physical and mechanical properties [91–93]. For example, chitosan films and fibers can be formed utilizing crosslinking chemistries adapted from techniques for altering other polysaccharides, such as treatment of amylose with epichlorohydrin [94]. Like hyaluronic acid, chitosan is not antigenic and is a well-tolerated implanted material [95].

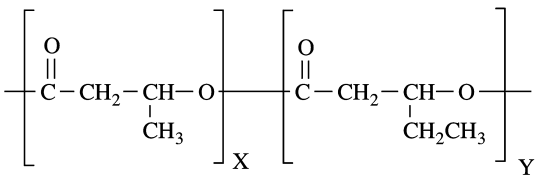
Chitosan has been formed into membranes and matrices suitable for several tissue-engineering applications [96–99] as well as conduits for guided nerve regeneration [100,101]. Chitosan matrix manipulation can be accomplished using the inherent electrostatic properties of the molecule. At low ionic strength, the chitosan chains are extended via the electrostatic interaction between amine groups, whereupon orientation occurs. As ionic strength is increased, and chain-chain spacing diminishes; the consequent increases in the junction zone and stiffness of the matrix result in increased average pore size. Chitosan gels, powders, films, and fibers have been formed and tested for such applications as encapsulation, membrane barriers, contact lens materials, cell culture, and inhibitors of blood coagulation [102].

Polyhydroxyalkanoates

Polyhydroxyalkanoates (PHA) are a group of copolymers of hydroxybutyric acid and hydroxyvaleric acid. These linear polyesters are intracellular energy storage polymers whose function is to provide a reserve of carbon and energy [103] in certain microorganisms. These polyesters are slowly biodegradable, biocompatible, thermoplastic materials [104,105]. Depending on growth conditions, bacterial strain, and carbon source, the molecular weights of these polyesters can range from tens into the hundreds of thousands. Although the structures of PHA can contain a variety of *n*-alkyl side chain substituents (see Structure 23.1), the most extensively studied PHA is the simplest: poly(3-hydroxyburtyrate) (PHB).

ICI developed a biosynthetic process for the manufacture of PHB, based on the fermentation of sugars by the bacterium *Alcaligenes eutrophus*. PHB homopolymer, like all other PHA homopolymers, is highly crystalline, extremely brittle, and relatively hydrophobic. Consequently, the PHA homopolymers have degradation times *in vivo* on the order of years [106,104]. The copolymers of PHB with hydroxyvaleric acid are less crystalline, more flexible, and more readily processable, but suffer from the same disadvantage of being too hydrolytically stable to be useful in short-term applications, in which resorption of the degradable polymer within less than one year is desirable.

PHB and its copolymers with up to 30% of 3-hydroxyvaleric acid are now commercially available under the trade name Biopol, and are mostly used as environmentally friendly polymers that degrade slowly when disposed of in a landfill. It was previously found that a PHA copolymer of 3-hydroxybutyrate and 3-hydroxyvalerate, with a 3-hydroxyvalerate content of about 11%, may have an optimum balance of strength and toughness for a wide range of possible applications. PHB has been found to have low toxicity, in part due to the fact that it degrades *in vivo* to D-3-hydroxybutyric acid, a normal constituent of human blood. Applications of these previously tested polymers, and others now under development, include



hydroxybutyric acid (HB) hydroxyvaleric acid (HV)

controlled drug release, artificial skin, and heart valves, along with industrial applications such as paramedical disposables [107–109]. Among the biomedical applications, sutures are the main product where polyhydroxyalkanonates are used, although a number of clinical trials for other applications may still be ongoing [110].

Polynucleotides

Gene delivery from the surfaces of tissue scaffolds represents a new approach to manipulating the local environment of cells [111]. Gene therapy approaches can be employed to increase the expression of tissue inductive factors or block the expression of factors that would inhibit tissue formation [112]. A biomaterial can enhance gene transfer by localized expression of the genetic material and by protecting the genetic material against degradation by nucleases and proteases. Sustained delivery of DNA from a polymer matrix may transfect large numbers of cells at a localized site and lead to the production of a therapeutic protein that could enhance tissue development. The work by Yao [113] serves as a specific example for this approach: Yao investigated the potential of chitosan/collagen scaffolds with pEGFP-TGFβ1 as a gene vector candidate in cartilage tissue engineering.

SYNTHETIC POLYMERS

The concept of a 'polymer' evolved from the study and commercial development of biologically derived macromolecules such as cellulose derivatives (celluloid, cellulose acetate) and vulcanized rubber in the nineteenth century. In 1907, the first totally synthetic polymer, Bakelite, was invented. At that time, the macromolecular structure of Bakelite and all other polymers was still not understood. It was only in 1922 that Hermann Staudinger proposed that the properties of polymers can be best explained by assuming that they consist of long chains of monomers linked together via regularly repeating bonds. The shortage of natural materials (in particular rubber) during World War II was the driving force behind the development of totally synthetic polymers. During World War II, Nylon, Teflon, various polyesters, and synthetic rubber emerged. The tremendous improvements in virtually all consumer products since 1945 would not have been possible without the development of hundreds of specialized polymers.

World War II left an additional legacy: the medical needs of millions of injured war fighters across the globe stimulated the development of new surgical procedures and innovative medical devices. Often, advances in the material sciences produced and enabled commensurate advances in medical practice. A new polymer, referred to as 'Vinyon N', was developed during World War II for use in parachutes. In 1952, vascular surgeons noticed the stretchiness and elasticity of this material and developed the first vascular graft using Vinyon N. This effort became the starting point for the development of polymer-based medical implants and devices.

The systematic development of polymers for medical implants started with a focus on inert, biostable materials to be used in implants that lasted for the lifetime of the patient. It was only in 1969 that the first biodegradable polymer, poly(glycolic acid), was used to create the first, synthetic degradable suture line – a breakthrough that ended the use of suture lines made from the intestines of animals. Due to the efforts of many research groups, a number of different polymeric structures and compositions have been explored as degradable biomaterials. However, commercial efforts to develop these new materials for specific medical applications have been limited. Thus, detailed toxicological studies *in vivo*, investigations of degradation rate and mechanism and careful evaluations of the physicomechanical properties have so far been published for only a very small fraction of those polymers. This leaves the tissue engineer with just a relatively limited number of promising polymeric compositions to choose from. The following section is focused on a review of the most commonly investigated classes of biodegradable, synthetic polymers.

Aliphatic polyesters

Aliphatic polyesters made of hydroxy acids, such as glycolic acid, lactic acid, and ε-hydroxycaproic acid, have been utilized for a variety of medical product applications. As an example, bioresorbable surgical sutures made from poly(α-hydroxy acids) have been in clinical use since 1969 [114–116]. Other implantable devices made from these versatile polymers (e.g., internal fixation devices for orthopedic repair) are now part of standard surgical protocol [56,117,118].

Although polyesters can be synthesized by polycondensation of hydroxy acids such as lactic acid [119], it is difficult to achieve high molecular weights and control the molecular weight, molecular weight distribution, and architecture of the polymer in this process. In most cases, biodegradable polyesters are synthesized in a two-step procedure: first, the hydroxy acids are transformed into intramolecular lactones (see Structure 23.2), which are then used as monomers in ring-opening polymerizations.

The ester bond of the aliphatic polyesters is cleaved by hydrolysis, which results in a decrease in the polymer molecular weight of the implant [120]. This initial degradation occurs until the molecular weight of the resulting oligomers is less than 5000 Da, at which point the oligomers become water soluble and the degrading implant starts to lose mass as well. The final degradation and resorption of the polyester implants may also involve inflammatory cells (such as macrophages, lymphocytes, and neutrophils). Although this late-stage inflammatory response can have a deleterious effect on some healing events, these polymers have been successfully employed as matrices for cell transplantation and tissue regeneration [121,122]. The useful lifetime of implants made from these polymers is determined by the initial molecular weight, exposed surface area, crystallinity, and (in the case of lactide-glycolide copolymers) by the ratio of the monomers.

Aliphatic polyesters have a modest range of thermal and mechanical properties and a correspondingly modest range of processing conditions. The polymers can generally be formed into films, tubes, and matrices using such standard processing techniques as molding, extrusion, solvent casting, and spin casting. Ordered fibers, meshes, and open-cell foams have been formed to fulfill the surface area and cellular requirements of a variety of tissue engineering constructs [56,117,123]. The aliphatic polyesters have also been combined with other components, e.g., poly(ethylene glycol), to modify the cellular response elicited by the implant and its degradation products [124].

POLY(GLYCOLIC ACID), POLY(LACTIC ACID), AND THEIR COPOLYMERS

Poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and their copolymers poly(lactic acid-co-glycolic acid) (PLGA) are the most widely used synthetic degradable polymers in medicine (see Structure 23.3). Of this family of linear aliphatic polyesters, PGA has the simplest structure and is more hydrophilic than PLA. Since PGA is highly crystalline, it has a high melting point and low solubility in organic solvents. PGA was used in the development of the first totally synthetic absorbable suture [114]. The crystallinity of PGA in surgical sutures is typically in the range 46–52% [125]. Due to the hydrophilic nature and quick water uptake, surgical sutures

made of PGA lose their mechanical strength typically over a period of 2 to 4 weeks post implantation [126].

In order to adapt the materials properties of PGA to a wider range of possible applications, researchers undertook an intensive investigation of copolymers of PGA with the more hydrophobic poly(lactic acid) (PLA) (see Structure 23.3). Alternative sutures composed of copolymers of glycolic acid and lactic acid are currently marketed under the trade names Vicryl.

Due to the presence of an extra methyl group in lactic acid, PLA is more hydrophobic than PGA. The hydrophobicity of high molecular weight PLA limits the water uptake of thin films to about 2% [125] and results in a rate of backbone hydrolysis lower than that of PGA [126]. In addition, PLA is more soluble in organic solvents than PGA.

It is noteworthy that there is no linear relationship between the ratio of glycolic acid to lactic acid and the physicomechanical properties of their copolymers. Whereas PGA is highly crystalline, crystallinity is rapidly lost in PGA-PLA copolymers. These morphological changes lead to an increase in the rates of hydration and hydrolysis. Thus, copolymers tend to degrade more rapidly than either PGA or PLA [125,126].

Since lactic acid is a chiral molecule, it exists in two stereoisomeric forms that give rise to four morphologically distinct polymers. D-PLA and L-PLA are the two stereoregular polymers, D,L-PLA is the racemic polymer obtained from a mixture of D- and L-lactic acid, and meso-PLA can be obtained from D,L-lactide. The polymers derived from the optically active d and l monomers are semi-crystalline materials, while the optically inactive D,L-PLA is always amorphous.

The differences in the crystallinity of D,L-PLA and L-PLA have important practical ramifications: Since D,L-PLA is an amorphous polymer, it is usually considered for applications such as drug delivery, where it is important to have a homogeneous dispersion of the active species within a monophasic matrix. On the other hand, the semi-crystalline L-PLA is preferred in applications where high mechanical strength and toughness are required — for example, sutures and orthopedic devices [127–129].

L-PLA (PLLA) and D-PLA (PDLA) are semi-crystalline polymers with a glass transition temperature (Tg) of approximately 60°C, and a peak melting temperature (Tm) of approximately 180°C. D,L-PLA (PDLLA) is amorphous with a Tg of approximately 55°C. Both semi-crystalline PLLA and amorphous PDLLA polymers are rigid materials. Their Young's modulus

and stress at break values are close to 3.5 GPa and 65 MPa, respectively. However, these polymers are relatively brittle with an elongation at break of less than 6% [130–132].

These polymers degrade by hydrolysis in which naturally occurring lactic acid is formed. Degradation of the polymers starts with water uptake, followed by random cleavage of the ester bonds in the polymer chain. The degradation is throughout the bulk of the material [133]. Upon degradation, the number of carboxylic end groups increases, which leads to a decrease in pH and an autocatalytic acceleration of the rate of degradation [134]. During the degradation of semi-crystalline PLLA, crystallinity of the residual material increases as hydrolysis preferentially takes place in the amorphous domains [135]. In general, the rate of degradation and erosion of amorphous PDLLA is faster than that of PLLA [136].

Ikada et al. were the first to report on the stereocomplexation of enantiomeric PLLA and PDLA polymers during co-precipitation of mixed polymer solutions in non-solvents [222]. Since then, they have shown that stereocomplexation of PLLA and PDLA can take place in dilute and concentrated solutions, during solvent evaporation and spinning, and during annealing of their mixtures prepared in the melt [137]. Other groups have also reported the formation of poly(lactic acid) stereocomplexes [138,139].

Upon stereocomplexation, the melting temperature of the poly(lactide) stereocomplexes increases to about 230°C. This is 50°C higher than the melting temperature of the enantiomeric PLLA and PDLA polymers. Stereocomplexation influences the mechanical properties of poly(lactide) films [133]. When stereocomplexes were formed from PLLA and PDLA their films were stiffer, stronger, and tougher than films prepared from the enantiomeric polymers. In addition, under hydrolytic degradation conditions, the degradation of thin films of stereocomplexes of PLLA and PDLA is slower than that of the enantiomeric PLLA and PDLA homopolymers [140]. These findings are of great interest to biomedical engineers as they provide a simple way to increase the mechanical strength of these polymers with a concomitant increase in hydrolytic stability.

Recently, PLA, PGA, and their copolymers have been combined with bioactive ceramics, such as Bioglass particles or hydroxyapatite, that stimulate bone regeneration while greatly improving the mechanical strength of the composite material [141]. It was also reported that composites of polymer and Bioglass are angiogenic (e.g., they supported the growth of blood vessels), suggesting a novel approach for providing a vascular supply to implanted devices [142].

Some controversy surrounds the use of these materials for orthopedic applications. According to one review of the clinical outcomes for over 500 patients treated with resorbable pins made from either PGA or PGA:PLA copolymer, 1.2% required reoperation due to device failure, 1.7% suffered from bacterial infection of the operative wound, and 7.9% developed a late noninfectious inflammatory response that warranted operative drainage [143]. This delayed inflammatory reaction represents the most serious complication of the use of PGA or PLA in orthopedic applications. The mean interval between device implantation and the clinical manifestation of this reaction is 12 weeks for PGA and can be as long as three years for the more slowly degrading PLA [143]. Whether avoiding reoperation to remove a metal implant outweighs an approximately 8% risk of severe inflammatory reaction is a difficult question; in any event, an increasing number of trauma centers have suspended the use of these degradable fixation devices. It has been suggested that the release of acidic degradation products (glycolic acid for PGA, lactic acid for PLA, and glyoxylic acid for polydioxanone) contributes to the observed inflammatory reaction. Thus, the late inflammatory response appears to be a direct consequence of the chemical composition of the polymer degradation products [143]. The incorporation of alkaline salts or antibodies to inflammatory mediators may diminish the risk of a late inflammatory response [144]. A more desirable solution to these problems for orthopedic (and perhaps other) applications requires the development of new polymers that do not release acidic degradation products upon hydrolysis.

Using biodegradable PGA mesh scaffolds and a biomimetic perfusion system, Niklason et al. have successfully engineered small-diameter vessel grafts using either endothelial cells (ECs) and smooth muscle cells (SMCs) obtained from vessels in various species, or mesenchymal stem cells derived from adult human bone marrow [145,146]. In this approach, *ex vivo* culture resulted in the formation of a tissue-engineered vascular structure composed of cells and ECM while the PGA degraded during the same period. Cellular material was removed with detergents to render the grafts non-immunogenic. Tested in a dog model, grafts demonstrated excellent patency and resisted dilatation, calcification, and intimal hyperplasia [147].

POLY(ε-CAPROLACTONE)

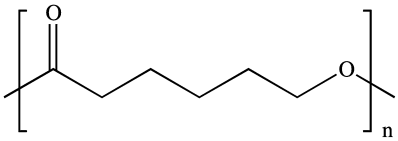
Poly(ε-caprolactone) (PCL) (Structure 23.5) is an aliphatic polyester that has been intensively investigated as a biomaterial. The discovery that PCL can be degraded by microorganisms led to evaluation of PCL as a biodegradable packaging material; later, it was discovered that PCL can also be degraded by a hydrolytic mechanism under physiological conditions [148–150]. Under certain circumstances, crosslinked PCL can be degraded enzymatically, leading to what can be called enzymatic surface erosion [148,149]. Low molecular weight fragments of PCL are reportedly taken up by macrophages and degraded intracellularly, with a tissue reaction similar to that of the other poly(hydroxy acids) [150]. Compared with PGA or PLA, the degradation of PCL is significantly slower. PCL is therefore most suitable for the design of long-term, implantable systems such as Capronor, a one-year implantable contraceptive device [151].

Poly(ε-caprolactone) exhibits several unusual properties not found among the other aliphatic polyesters. Most noteworthy are its exceptionally low glass transition temperature of about −60°C and its low melting temperature of 57°C. Another unusual property is its high thermal stability. Whereas other tested aliphatic polyesters had decomposition temperatures (Td) between 235 and 255°C, poly(ε-caprolactone) has a Td of 350°C, which is more typical of poly(ortho esters) than aliphatic polyesters [152].

A useful property of PCL is its propensity to form compatible blends with a wide range of other polymers [153]. In addition, ε-caprolactone can be copolymerized with numerous other monomers (e.g., ethylene oxide, chloroprene, THF, δ-valerolactone, 4-vinylanisole, styrene, methyl methacrylate, vinylacetate). Particularly noteworthy are copolymers of ε-caprolactone and lactic acid, which have been studied extensively [149,154]. PCL and copolymers with PLA have been electronspun to create nanofibrous tissue-engineered scaffolds that show promise for vascular applicaions [155,20–22]. The toxicology of PCL has been extensively studied as part of the evaluation of Capronor. Based on a large number of tests, the monomer ε-caprolactone, and the polymer PCL, are currently regarded as non-toxic and tissue compatible materials. Early clinical studies [156] of the Capronor system were started around the year 2000 and resulted in a commercial implant used in Europe, but not in the USA.

POLY(P-DIOXANONE)

Poly(p-dioxanone) (PDS) is prepared by the ring-opening polymerization of p-dioxanone (Structure 23.6). It is a relatively weak, rapidly biodegrading polymer that was introduced into the market in the 1980s as a new degradable suture material. When compared on a weight basis (for example per 1 gram of implant), poly(p-dioxanone) releases degradation products



STRUCTURE 23.5

that are less acidic than the degradation products released by PGA or PLA. This is a potential advantage for orthopedic applications, which led to the development of small bone pins for the fixation of fractures in non-load bearing bones. Bone pins based on poly(p-dioxanone) are marketed under the trade name Orthosorb in the USA and under the name Ethipin in Europe. Poly(p-dioxanone) is also found in suture clips.

Unfortunately, poly(p-dioxanone) is relatively weak and lacks the stiffness and strength required for most orthopedic applications. Its range of applications is therefore limited. Academic laboratories have investigated poly(p-dioxanone) mostly as a polymer for implantable drug delivery applications. Little work has been done to explore this polymer as a scaffold for tissue engineering, probably because the polymer offers no clear advantages in terms of cell attachment and tissue compatibility over the widely used poly(lactic acid) and the copolymers of lactic and glycolic acid.

POLY(ORTHO ESTERS)

Poly(ortho esters) are a family of synthetic degradable polymers that have been under development since 1970 [157,158]. Devices made of poly(ortho esters) can be formulated in such a way that the device undergoes surface erosion — that is, the polymeric device degrades at its surface only and will thus tend to become thinner over time rather than crumbling into pieces. Since surface-eroding, slab-like devices tend to release drugs embedded within the polymer at a constant rate, poly(ortho esters) appear to be particularly useful for controlled release drug delivery [159]; this interest is reflected by the many descriptions of these applications in the literature [160].

There are two major types of poly(ortho esters). Originally, poly(ortho esters) were prepared by the condensation of 2,2-diethoxytetrahydrofuran and a dialcohol [161]) and marketed under the trade names Chronomer and Alzamer. Upon hydrolysis, these polymers release acidic by-products that autocatalyze the degradation process, resulting in degradation rates that increase with time. More recently, Heller et al. [162]) synthesized a new type of poly(ortho ester) based on the reaction of 3,9-bis(ethylidene 2,4,8,10-tetraoxaspiro {5,5} undecane)

(DETOSU) with various dialcohols (Structure 23.7). These poly(ortho esters) do not release acidic by-products upon hydrolysis and thus do not exhibit autocatalytically increasing degradation rates. By selecting diols having different degrees of chain flexibility, polymers can be obtained that range from hard, brittle materials to materials that have a gel-like consistency. A drug release system for mepivacaine (a treatment for post-operative pain), was tested in Phase 2 clinical trials between 2000 and 2005 [158], and as of 2012, a fourth generation, poly(ortho ester)-based drug delivery system for prevention of chemotherapy-induced nausea and vomiting was in Phase 3 clinical trials.

Biodegradable polyurethanes

Polyurethanes, polymers in which the repeating unit contains a urethane moiety, were first produced by Bayer in 1937. These polymers are typically produced through the reaction of a

diisocyanate with a polyol. Conventional polyols are polyethers or polyesters. The resulting polymers are segmented block copolymers with the polyol segment providing a low glass transition temperature (i.e., <25°C) soft segment and the diisocyanate component, often combined with a hydrocarbon chain extender, providing the hard segment (Structure 23.8). A wide range of physical and mechanical properties have been realized with commercial polyurethanes.

Polyurethanes have been used for nearly 50 years in biomedical applications, particularly as blood-contacting material in cardiovascular devices. Intended as non-biodegradable coatings, polyurethanes fell out of favor with the failure of pacemaker leads and breast implant coatings. Subsequent studies, as reviewed by Santerre et al., have clarified much about the behavior of polyurethanes in biological systems [163]. Elucidation of the biodegradation mechanism and its dependence on the polyurethane structure and composition have led to the development of biodegradable polyurethanes for a variety of tissue-engineering applications such as meniscal reconstruction [164], myocardial repair [165] and vascular tissues [166]. Design of biodegradable polyurethanes has required alternative diisocyanate compounds. The traditional aromatic diisocyanates are putative carcinogenic compounds. Biodegradable polymers are made from biocompatible diisocyanates such as lysine-diisocyanate or hexamethylene diisocyanate that release non-toxic degradation products.

The urethane bond is essentially non-degradable under physiological conditions. Therefore, biodegradable poly(urethane)s can only be obtained when the employed soft polyol segments are degradable [163]. As an example, aliphatic poly(ester urethane)s containing random 50/50 ε-caprolactone/L-lactide copolymer segments, 1,4-butanediol and 1,4-butanediisocyanate were synthesized and used to prepare porous structures for meniscus reconstruction [167]. In these polymers, the biodegradation mechanism involves the hydrolytic cleavage of the ester bonds in the ε-caprolactone/L-lactide copolymer segments, resulting in the formation of low molecular weight blocks of the non-degradable hard segments which are ultimately excreted from the body via the liver and/or kidney.

An interesting applicaton of polyurethanes was developed by Santerre et al. where fluoroquinolone antimicrobial drugs were incorporated into the polymer as hard-segment monomers [163]. This led to the design of drug polymers (trade name: Epidel) that release the drug when degraded by enzymes generated by an inflammatory response. This is an example of a 'smart' system in that antibacterial agents are released only while inflammation is present. Once healing occurs, the enzyme level drops and the release of drug diminishes.

Polyanhydrides (Structure 23.9)

Polyanhydrides were first investigated in detail by Hill and Carothers [168] and were considered in the 1950s for possible applications as textile fibers [169]. Their low hydrolytic stability, the major limitation for their industrial applications, was later recognized as a potential advantage by Langer et al. [170], who suggested the use of polyanhydrides as degradable biomaterials. A study of the synthesis of high molecular weight polyanhydrides has been published by Domb et al. [171].

A comprehensive evaluation of the toxicity of the polyanhydrides showed that, in general, they possess excellent *in vivo* biocompatibility [172]. Their most immediate applications are in the field of drug delivery, although tissue-engineering applications are also being developed. Drug loaded devices are best prepared by compression molding or microencapsulation [173]. A wide variety of drugs and proteins, including insulin, bovine growth factors, angiogenesis inhibitors (e.g., heparin and cortisone), enzymes (e.g., alkaline phosphatase and b-galactosidase) and anesthetics have been incorporated into polyanhydride matrices, and their *in vitro* and *in vivo* release characteristics have been evaluated [174]. One of the most aggressively-investigated uses of the polyanhydrides is for the delivery of chemotherapeutic agents. An example of this application is the delivery of BCNU (bis-chloroethylnitrosourea) to

the brain for the treatment of glioblastoma multiformae, a universally fatal brain cancer [175]. For this application, polyanhydrides derived from bis-p-(carboxyphenoxy propane) and sebacic acid received Food and Drug Administration (FDA) regulatory clearance in the fall of 1996 and are currently being marketed under the name Gliadel®.

Polyphosphazenes (Structure 23.10)

Polyphosphazenes consist of an inorganic phosphorous-nitrogen backbone, in contrast to the commonly employed hydrocarbon-based polymers [176a]. Consequently, the phosphazene backbone undergoes hydrolysis to phosphate and ammonium salts, with the concomitant release of the side group. Of the numerous polyphosphazenes that have been synthesized, those that have some potential use for medical products are substituted with amines of low pKa, and those with activated alcohol moieties [177–179]. Singh and colleagues have modified the side groups to tune polyphophazine properties such as glass transition temperature, degradation rate, surface wettability, tensile strength and elastic modulus, enabling these polymers to be considered for a wider range of biomedical applications [180]. The most extensively studied polyphosphazenes are hydrophobic, having fluoroalkoxy side groups. In part, these materials are of interest because of their expected minimal tissue interaction, which is similar to Teflon.

Aryloxyphosphazenes and closely related derivatives have also been extensively studied. One such polymer can be crosslinked with dissolved cations such as calcium to form a hydrogel matrix because of its polyelectrolytic nature [181]. Using methods similar to alginate encapsulation, microspheres of aryloxyphosphazene have been used to encapsulate hybridoma cells without affecting their viability or their capacity to produce antibodies. Interaction with poly(L-lysine) produced a semi-permeable membrane. Similar materials have been synthesized that show promise in blood contacting and with novel drug delivery applications.

Poly(amino acids) and 'pseudo'-poly(amino acids)

Since proteins are composed of amino acids, many researchers have tried to develop synthetic polymers derived from amino acids to serve as models for structural, biological and immunological studies. In addition, many different types of poly(amino acids) have been investigated for use in biomedical applications [176]. Poly(amino acids) are usually prepared by the ring-opening polymerization of the corresponding *N*-carboxy anhydrides, which are in turn obtained by reaction of the amino acid with phosgene [182].

Poly(amino acids) have several potential advantages as biomaterials. A large number of polymers and copolymers can be prepared from a variety of amino acids. The side chains offer sites for the attachment of small peptides, drugs, crosslinking agents, or pendant groups that can be used to modify the physicomechanical properties of the polymer. Since these polymers release naturally occurring amino acids as the primary products of polymer backbone cleavage, their degradation products may be expected to show a low level of systemic toxicity.

Poly(amino acids) have been investigated as suture materials [178], as artificial skin substitutes [183] and as drug delivery systems [184]. Various drugs have been attached to the side chains of poly(amino acids), usually via a spacer unit that distances the drug from the backbone. Combinations of poly(amino acid)s and drugs that have been investigated include poly(L-lysine) with methotrexate and pepstatin [185], and poly(glutamic acid) with adriamycin and norethindrone [186]. Short amino acid sequences such as RGD and RGDS, strong promotors of specific cell adhesion, have been linked to the polymer backbone to promote cell growth in tissue-engineering applications [187,188].

Despite their apparent potential as biomaterials, poly(amino acids) have actually found few practical applications. *N*-carboxy anhydrides, the starting materials, are expensive to make and difficult to handle because of their high reactivity and moisture sensitivity. Most

poly(amino acids) are highly insoluble and non-processible materials. Since poly(amino acids) degrade via enzymatic hydrolysis of the amide bond, it is difficult to reproduce and control their degradation *in vivo*, because the level of relevant enzymatic activity varies from person to person. Furthermore, the antigenicity of poly(amino acids) containing three or more amino acids limits their use in biomedical applications [176]. Because of these difficulties, only a few poly(amino acids), usually derivatives of poly(glutamic acid) carrying various pendent chains at the γ-carboxylic acid group, have been identified as promising implant materials [189].

As an alternative approach, Kohn et al. have replaced the peptide bonds in the backbone of synthetic poly(amino acids) by a variety of 'nonamide' linkages such as ester, iminocarbonate, urethane, and carbonate bonds [190,191]. The term *pseudo-poly(amino acid)* is used to denote this new family of polymers in which naturally occurring amino acids are linked together by nonamide bonds (Structure 23.11).

The use of such backbone-modified pseudo-poly(amino acids) as biomaterials was first suggested in 1984 [192]. The first pseudo-poly(amino acids) investigated were a polyester from *N*-protected trans-4-hydroxy-L-proline and a poly(iminocarbonate) from tyrosine dipeptide [193,194]. Several studies indicate that the backbone modification of conventional poly(amino acids) generally improves their physicomechanical properties [190,195,196]. This approach is applicable to, among other materials, serine, hydroxyproline, threonine, tyrosine, cysteine, glutamic acid, and lysine; it is only limited by the requirement that the nonamide backbone linkages give rise to polymers with desirable material properties. Additional pseudo-poly(amino acids) can be obtained by considering dipeptides as monomeric starting materials. Hydroxyproline-derived polyesters [194,197], serine-derived polyesters [198], and tyrosine-derived polyiminocarbonates [199] and polycarbonates [200] represent specific embodiments of these synthetic concepts.

COMBINATIONS (HYBRIDS) OF SYNTHETIC AND BIOLOGICALLY DERIVED POLYMERS

Biologically derived polymers have important advantages over synthetic materials. These advantages often include reduced toxicity, since they generally originate from molecules that occur naturally in the body and biodegrade under physiological conditions [201,202], and they also exhibit improved *bioactivity*. In this context, the term bioactivity refers to the ability of a material to elicit specific cellular responses. Collagen, for example, is a bioactive material because of its ability to support cell attachment, growth and differentiation. However, the usefulness of biologically derived polymers is often limited by their poor engineering properties. Important disadvantages of biologically derived polymers are:

1) High batch-to-batch variability due to complex isolation procedures from inconsistent sources,
2) Poor solubility and processibility, preventing the use of industrial manufacturing processes,
3) Risk of contamination by pyrogens or pathogens,
4) Poor or limited materials properties such as strength, ductility, elasticity, or shelf life, and
5) Their high cost.

In overall terms, synthetic materials offer a wider range of useful engineering properties (polymer composition, architecture, mechanical properties, etc.) but they generally fail to promote cell growth and differentiation to the same degree as some of the biologically derived polymers [203]. To address these shortcomings, it is an obvious idea to combine biologically derived polymers with synthetic materials. As a general rule, the purpose of such hybrid materials is to combine the bioactivity of biologically derived polymers with the superior engineering properties of synthetic materials.

As an example, a clinically useful cornea replacement material was obtained when collagen was incorporated into a synthetic, polyacrylate-based hydrogel [204]. Another example of this approach is provided by a hybrid material derived from silk fibroin (as the hydrophobic, bioactive material) and poly(vinyl alcohol) (as the hydrophilic, synthetic component) [205]. Poly(vinyl alcohol) (PVA) can be crosslinked under mild conditions by exposure to UV (ultraviolet) radiation. This crosslinking method allows PVA and fibroin to form a highly biocompatible hydrogel with adjustable engineering properties [205].

A final example of this approach is provided by a hybrid material composed of poly(N-isopropylacrylamide) (pNIPAM) as the synthetic component and various natural polysaccharides as the biologically derived component. pNIPAM undergoes a thermally induced phase transition around 32°C that causes the soluble material to precipitate. This property allows the design of a product that is liquid and injectable at room temperature and that precipitates and forms a hydrogel at body temperature, facilitating the formation of a solid implant while eliminating the need for surgical insertion. The disadvantage of pNIPAM as a biomaterial is its inability to support cell growth and its lack of biodegradability. This can be overcome by crosslinking pNIPAM with natural polysaccharide precursors, leading to cell-permissive formulations that will biodegrade *in vivo*.

USING POLYMERS TO CREATE TISSUE-ENGINEERED PRODUCTS

The medical implant of the future will not be an artificial prosthetic device that replaces tissue lost due to trauma, disease, or aging, but a tissue scaffold that integrates with the surrounding healthy tissue and assists in the regeneration of lost or damaged tissue. As one possible implementation of this concept, the biomedical literature currently envisions such tissue scaffolds as consisting of bioactive polymers that may be shaped as porous sponge-like structures. These tissue scaffolds may either be preseeded with specific cell populations outside of the body of the patient prior to implantation into the patient, or the tissue scaffolds may be implanted into the body of the patient first, and then be colonized by the patient's own cells, leading to the regeneration of the desired tissue. In either case, one can formulate several design criteria that can guide the biomedical engineer in the process of selecting an appropriate biomaterial for the intended application.

First and foremost, one must be concerned with the bulk polymer properties. The biomaterial must have an appropriate range of physicomechanical properties, biodegradation rates, and biocompatibility appropriate for the intended application. Next, it must be possible to create the desired tissue scaffold. This requires that the desired device shape and architecture can actually be created by cost-effective fabrication methods. For example, electrospinning may be the preferred fabrication method to create an ECM-like scaffold that consists of nano-sized fibers. Since electrospinning requires that the biomaterial is soluble in non-toxic solvents, any insoluble biomaterial would not meet a key design requirement. Finally, it is important to consider the biological properties of the biomaterial. Tissue-engineering products require specific cellular responses. For example, in a bone regeneration scaffold, the ability to support the attachment and growth of osteoblasts in combination with the ability to adsorb and concentrate endogenous bone morphogenic protein on the polymer surface may be important design requirements (Figure 23.1). There is a wide range of additional requirements that impose further limitations on the selection of the biomaterial and/or the architecture of the implant. For example, whenever functional tissue has to form within the tissue-engineering scaffold, a lack of proper vascularization will impede a favorable tissue response. For encouraging angiogenesis within the scaffold, details such as pore size, pore structure and pore connectivity are often critical [206].

Once an appropriately shaped tissue scaffold has been conceptionalized, it is time to consider a wide range of secondary design criteria relating to device shelf life, ability of the device to be

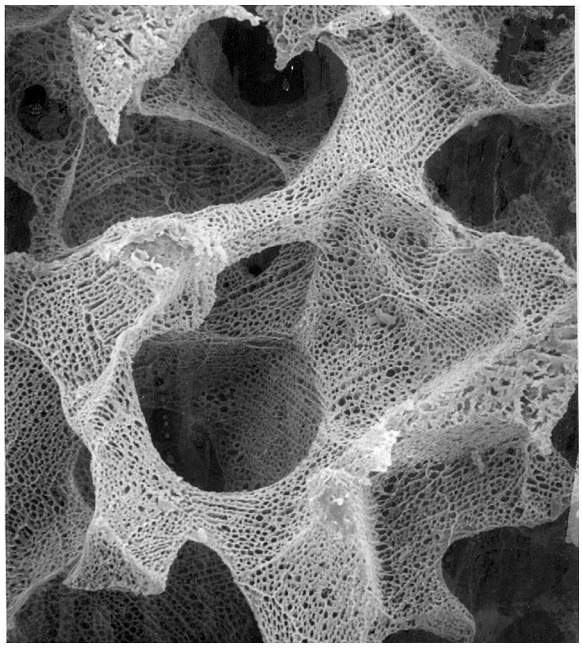

FIGURE 23.1
Bone regeneration scaffold from the New Jersey Center for Biomaterials. The scaffold has a delicate and carefully optimized pore structure consisting of large macropores (200—400 μm) and linearly aligned micropores (5—20 μm). This particular pore architecture is believed to facilitate the regeneration of bone *in vivo. (Photo: Courtesy of the Laboratory of Professor Joachim Kohn, Rutgers-the State University of New Jersey)*

sterilized and packaged for clinical use, and overall cost. Here, being able to create a terminally sterilized device is a factor often overlooked by academic researchers, who fail to consider the fact that most FDA-recognized sterilization methods cannot be applied to products that contain living cells. Thus, the requirement to ensure device sterility has been a major hurdle in translating research concepts from the laboratory to clinical practice.

Barriers: membranes and tubes

Design formats requiring cell activity on one surface of a device while precluding transverse movement of surrounding cells onto that surface calls for a barrier material. For example, peripheral nerve regeneration must allow for axonal growth, while at the same time precluding fibroblast activity that could produce neural-inhibiting connective tissue. Structures such as collagen tubes can be fabricated to yield a structure dense enough to inhibit connective tissue formation along the path of repair while allowing axonal growth through the lumen [207]. More recently, conduits composed of a silk fibroin scaffold coupled with biologics have shown improvement in performance [208]. Similarly, collagen membranes for periodontal repair provide an environment for periodontal ligament regrowth and attachment while preventing epithelial ingrowth into the healing site [209]. Anti-adhesion formulations using hyaluronic acid, which prevent ingrowth of connective tissue at a surgically repaired site, also work in this way [80].

Gels

Gels are used to provide a hydrogel scaffold, encapsulate, or provide a specialized environment for isolated cells. For example, collagen gels for tissue engineering were first used to maintain fibroblasts, which were the basis of a living skin equivalent [210]. Gels have also been used for the maintenance and immunoprotection of xenograft and homograft cells such as hepatocytes, chondrocytes, and islets of Langerhans used for transplantation [211—213]. Semipermeable gels have been created to limit cell-cell communication and interaction with surrounding tissue, and to minimize movement of peptide factors and nutrients through the implant. Injectable biodegradable gel materials that form through crosslinking *in situ* show promise for regeneration of bone and cartilage. Temenoff and Mikos review a number of injectable systems that demonstrate appropriate properties for these applications [214].

Lee and colleagues discuss the use of biodegradable polyester dendrimers (highly branched, synthetic polymers with layered architectures) to form hydrogels for tissue-engineering applications such as corneal wound sealants [215]. In general, non-degradable materials are used for cell encapsulation to maximize long-term stability of the implant. In the future, however, it may be possible to formulate novel 'smart' gels in which biodegradation is triggered by a specific cellular response instead of simple hydrolysis.

Matrices

It has been recognized since the mid-1970s that three-dimensional structures are an important component of engineered tissue development [13,14]. Yannas and his coworkers were the first to show that pore size, pore orientation, and fiber structure are important characteristics in the design of cell scaffolds. Several techniques have subsequently been developed to form well-defined matrices from synthetic and biologically derived polymers, and the physical characteristics of these matrices are routinely varied to maximize cellular and tissue responses [216–219]. Examples of engineered matrices that have led to several resorbable templates are oriented pore structures designed for regeneration of trabecular bone [220,221].

CONCLUSION

Research using currently available biomaterials and research aimed at developing novel biodegradable polymers has helped to advance the field of tissue engineering. Throughout most of the twentieth century, most research and development efforts relied on a small number of biodegradable polymers that had a history of regulatory approval, making poly(lactic acid) the most widely used biodegradable polymer. Research in the twenty first century aims to develop advanced biodegradable polymers that elicit predictable and useful cellular responses. To achieve this goal, current research efforts focus on creating bioactive materials that combine the superior engineering properties of synthetic polymers with the superior biological properties of natural materials. The extremely complex material requirements of tissue scaffolds pose significant challenges and require a continued research effort toward the development of new bioresorbable polymers.

INTRODUCTION

A key concept in tissue engineering (TE) is using material-based porous three-dimensional (3D) scaffolds to provide physical support and local environment for cells to enable and facilitate tissue development [1]. Over the past two decades, 3D scaffolds have evolved to serve complex functions to guide cellular behavior with spatial and temporal controls of the material and structural properties for different TE applications. Scaffolds can be seeded with embryonic or adult stem cells, progenitor cells, mature differentiated cells, or co-cultures of cells to induce tissue formation *in vitro* and *in vivo*; scaffolds can also be directly implanted *in vivo* with capabilities to deliver soluble/insoluble biomolecules and temporal/spatial cues to guide functional regeneration in defective tissues and organs. While the specific functions vary with tissue type and clinical need, scaffolds may potentially coordinate biological events at the molecular, cellular and tissue levels, on time and dimension scales ranging from seconds to weeks and nanometers to centimeters, respectively [2]. A central task in designing tissue engineering scaffolds is to understand the correlations between scaffold properties and biological functions.

During tissue development, morphogenetic factors are present in the extracellular environment in a dynamic way. In response, cells make decisions on how to divide, differentiate, migrate, degrade/produce extracellular matrix (ECM) and orient themselves. Based on our understanding of cell-ECM interactions in native tissues, it should theoretically be possible to design scaffolds with the capacity to modulate tissue formation via logical, systematic variations in one or more chemical and/or physical properties. Living cells and tissues, however, are not simple, linear systems. The roles that ECM structures play in orchestrating the biological events are cell-specific and kinetically complex. Moreover, the performance of any scaffold property must be evaluated, not only in the relatively controlled *in vitro* environment, but also in the context of the tissue's physiological function (e.g., under mechanical or electrical stimulation), and ultimately *in vivo*. The dynamic superposition of multiple scaffold properties with multiple environmental factors can profoundly impact the outcome of the tissue formation process. Correlations between individual scaffold properties and certain

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00024-0

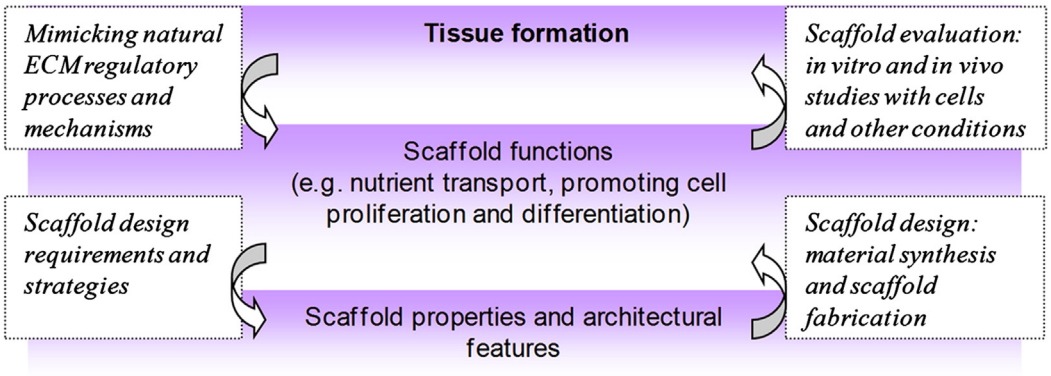

FIGURE 24.1

Scaffold synthesis consists of processes to understand the design principles and develop enabling methodologies. On one hand, scaffold design is a deductive process entailing the proposition and testing of candidate scaffold properties, and the cumulative elucidation of their independent and coupled reactions with cells and tissues. On the other hand, scaffold design is an inductive process, an exercise in recapitulating the wealth of tissue functions and cellular mechanisms observed throughout the body.

aspects of tissue formation (e.g., cellular phenotype and concomitant proliferation or ECM production) can be derived, and have even been applied to the optimization of scaffold designs [3]. From an engineering stand-point, it is desirable that scaffold properties and their regulatory functions be reproducibly integrated within a scaffold design, such that tissue formation can be induced and controlled in a stepwise manner *in vitro* and/or at the site of implantation *in vivo* [4,5] (Fig. 24.1).

Owing to the innate complexity of biological systems, reproducing natural processes and engineering tissues with the aid of scaffolds is a formidable task. Complications can arise on many fronts, such as from our incomplete understanding of native cell-ECM interactions, the difficulty of analyzing and standardizing biological systems, and even from our increasing technical capabilities of synthesizing scaffolds, which may outstrip our understanding of how to best apply them. More questions may be raised — such as to what degree of complexity a tissue-engineering scaffold should be designed, how to coordinate different types of cellular and tissue events, and how scaffolds can be designed to function robustly in response to patient-specific variations and different clinical situations. In this chapter, we summarize current scaffold design approaches and essential principles that may guide the rational multifunctional design of scaffolds for tissue engineering. Design variables are decoupled and analyzed in terms of how they have been controlled using different materials and fabrication techniques, and what implications they have in controlling the tissue formation process.

3D SCAFFOLD DESIGN AND ENGINEERING

From the perspective of material properties, mass transport, mechanics, electrical conductivity, surface chemistry and topology all mediate cell behavior at the nano, micro and macroscopic scales. These properties are often correlated with scaffold chemical compositions and structures in an interdependent way. For example, while a higher porosity may result in a beneficial increase in the mass transport capabilities of a scaffold, it may also compromise the scaffold's mechanical strength. Achieving optimal scaffold functional performance for a particular tissue-engineering application, therefore, requires balancing different factors.

An understanding of the fundamental scaffold properties and functions must form the foundation of any higher order hierarchal scaffold design involving temporal and/or spatial controls. Temporally, the scaffold properties at the onset of *in vitro* seeding (i.e., time zero) or during the acute phase of the host response following direct implantation *in vivo*, will provide an

initial set of environmental conditions for cells and tissues. These initial scaffold properties and associated functions will then evolve over time in response to passive and active interactions with the culture environment and cells, respectively. Temporal features, mainly enabled by scaffold degradation and the release of bioactive factors, are obligatory for presenting time-appropriate signals corresponding with each particular stage of tissue development. Tissues and organs are 3D structures having a characteristic organization consisting of patterns of different types of cells and ECM constituents. Spatially, anisotropic biochemical and structural properties can be incorporated into scaffolds to induce specific cell-cell interactions, cell and ECM orientations, and to guide multi-scale interactions up to the gross tissue or organ level.

Mass transport and pore architectures

The mass transport characteristics of a scaffold affect how fluid, solutes and cells move in and out of a tissue construct. As a porous 3D substrate, the mass transport in a scaffold at the initial stage is correlated with the scaffold chemical compositions and the structural parameters of its pores or voids, characterized mainly by pore size, porosity, pore interconnectivity/tortuosity, and surface area. These scaffold characteristics interdependently affect the diffusive or convective behavior of soluble nutrients, growth factors and cytokines. In addition to cell functions, the local biochemical and cellular environment can also influence the scaffold behavior [e.g., pH dependence of the hydrolysis of poly(lactic-co-glycolic acid) (PLGA) scaffolds]. In scaffolds designed to deliver bioactive soluble factors, the release profile and distribution pattern of these factors will be influenced by the mass transport characteristics of the scaffold. Compared to the vascularized tissues containing convective flows, diffusion is often the primary mass transport mechanism in engineered tissue constructs cultivated *in vitro* and prior to inosculation with the host vasculature following implantation *in vivo*. Theoretical models to simulate and predict the nutrient, protein and cell diffusion processes in scaffolds have been developed [6,7].

Once a scaffold is impregnated with cells, the solute diffusion and distribution profiles are mainly influenced by the cellular environment. In metabolically active tissues *in vivo*, most cells reside within 100 μm of a capillary. In engineered tissue constructs cultivated in static culture without medium perfusion, neo-tissue formation is generally limited to the peripheral 100–200 μm of the scaffold due to diffusion limitations [8–10]. Subsequently, the organization and density of cells in this peripheral region can further influence the distribution and availability of nutrients to cells within the scaffold interior [6]. Although certain types of cells may tolerate nutrient deficiency to some extent (such as chondrocytes under hypoxia), the induction of rapid vascularization following implantation is considered essential to establishing nutrient exchange and to the retention of a viable cell population within an engineered tissue construct. The structural characteristics of the pores and void spaces in scaffolds are the primary variables governing the initial cell distribution and organization in scaffolds.

One main parameter that affects the efficiency of initial cell impregnation is the pore size of the scaffold. The resulting geometries and spatial characteristics of individual cells or cell aggregates within the void space of scaffolds direct the subsequent cell proliferation, differentiation and tissue formation events. As observed in non-woven fibrous scaffolds made of poly(ethylene terephthalate) (PET) and seeded with human placenta trophoblast cells *in vitro*, the size of cell aggregates increased with larger pore volumes between fibers [11]. Variations in cell behavior were also observed, with attenuated differentiation and suppressed proliferation activities in larger cell aggregates compared to smaller ones [11,12]. Optimal scaffold pore sizes have been suggested for regenerating various types of tissues *in vivo*. The critical pore size was found to be above 500 μm for rapid fibro-vascularization in poly(L-lactic acid) (PLLA) scaffolds with cylindrical pores [13]. In ECM analog scaffolds (made of crosslinked collagen and glycosaminoglycans [GAG]), the average pore diameters required to induce dermis and peripheral nerve regeneration were 20–120 μm and 5–10 μm, respectively [14]. In bone engineering,

early studies by Hulbert and coworkers showed that a minimum pore size of 100 μm was required to allow bone tissue ingrowth in ceramic scaffolds [15]. Further investigations were carried out to understand the pore size requirement for bone tissue engineering. Although the optimal pore size varied with scaffold material and other parameters such as tortuosity, the general consensus is that larger pore sizes (e.g., >100 μm) may favor higher alkaline phosphatase activity and more bone formation [16,17].

Cell transport and vascularization as a result of scaffold pore size can also affect the tissue types and tissue formation process in scaffolds. When bone morphogenetic proteins were loaded into honeycomb-shaped hydroxyapatite scaffolds to induce osteogenesis, it was found that smaller diameters (90–120 μm) induced cartilage followed by bone formation, whereas those with larger diameters (350 μm) induced bone formation directly [18]. The difference was likely caused by the different onset time of vascularization and cell differentiation.

In addition to pore size, cell transport parameters such as diffusion, attachment, and migration are also affected by porosity (the fraction of pore volume), pore interconnectivity, and available surface area in scaffolds. While a high porosity is often desired, it is inversely related to the surface area available for cell attachment in 3D scaffolds. Achieving an optimal cell density in scaffolds therefore necessitates a high surface area-to-volume ratio. In order to facilitate the transport of cells and bioactive chemicals, scaffolds may also need to have pores at both macro and micro scales; features which may be difficult to obtain via traditional scaffold fabrication techniques such as particle leaching, gas foaming and phase separation. Rapid prototyping techniques such as solid free form fabrication (SFF) are emerging as important methods for generating highly controlled scaffold structures. Compared to scaffolds fabricated with traditional methods, the pore size and tortuosity in rapid-prototyped scaffolds have much narrower variations in structural distribution. Local topologies can also potentially be optimized by computational algorithms to control the permeability and mechanical properties [3]. Studies have been carried out to compare scaffolds fabricated by controlled processes with those containing irregular structures fabricated by conventional methods. In one of these studies, scaffolds with similar porosities were prepared by particle leaching or by 3D fiber deposition, and their ability to support cartilage tissue growth was compared [19] (Fig. 24.2). A significantly higher glycosaminoglycan (GAG) content was observed in the scaffolds fabricated by the controlled 3D fiber deposition process. Besides the fibrous morphology and highly accessible pores, more uniform and efficacious cell diffusion/attachment may also have contributed to the observed upregulation of GAG production and the better scaffold function. Advanced scaffolds fabricated by tightly controlled methods, with more uniform and controllable structures and properties, therefore hold promise in promoting the reproducible formation of functional engineered tissues.

Mechanics

The mechanical properties of the natural ECM are of paramount importance in dictating macroscopic tissue functions (e.g., bearing load) and regulating cellular behavior via mechanotransduction signaling. In designing tissue constructs, mechanical properties of the scaffold which resemble native tissue properties are often sought. Most importantly, in the acute phase following implantation, the scaffold must fulfill the key mechanical functions of the tissue which is being replaced. For example, the earliest TE blood vessels based on cell-contracted collagen gels were not strong enough to withstand physiologic blood pressures, and thus had to be reinforced by a tubular synthetic polymer mesh to ensure structural integrity [20]. More recent TE blood vessels based on relatively strong non-woven poly(glycolic acid) (PGA) scaffolds exhibited burst pressures exceeding physiological requirements upon implantation (>2000 mmHg) [21]. In addition to appropriately matching gross tissue mechanical properties, the scaffold must also provide an internal micromechanical environment conducive to the *de novo* synthesis and organization of ECM. For example, while non-woven PGA scaffolds have been successfully employed in blood vessel [21] and heart valve

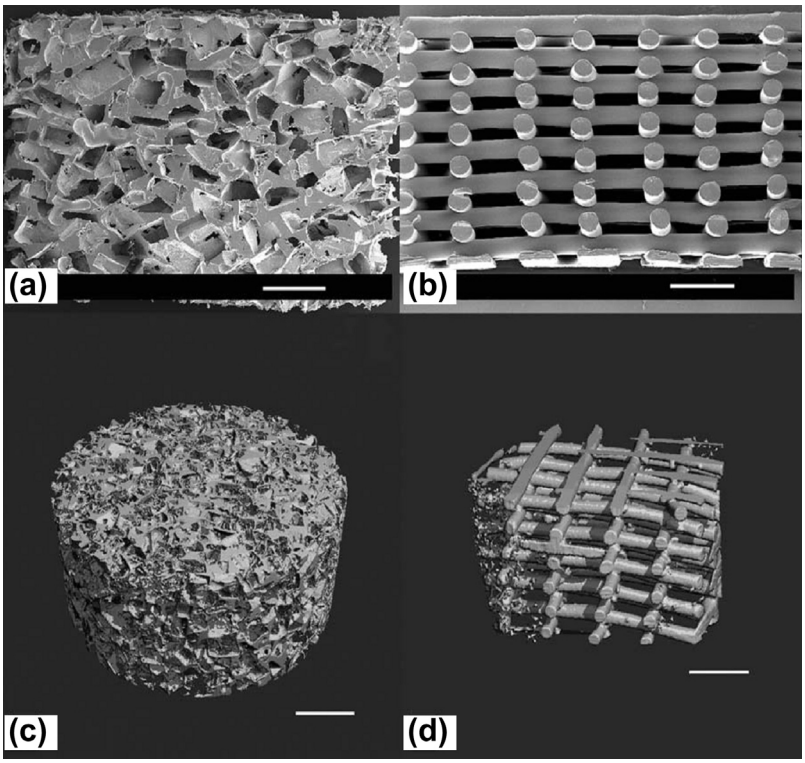

FIGURE 24.2

Designer scaffolds offer opportunities to control scaffold properties such as pore structures, surface area and mechanical strength. Electron micrographs of scaffolds fabricated by conventional method of compression-molding and particle leaching (a) and 3D fiber deposition (b); (c) and (d), 3D images of scaffolds in (a) and (b), respectively. *Reprinted from [19], with permission from Elsevier.*

TE [22], their application to myocardial tissue has been comparatively challenging [23]. In contrast to the predominant load-bearing function of vessels and valves, the primary function of myocardial tissue is cyclic contraction. While the out-of-plane compressive modulus of a typical non-woven PGA scaffold is relatively low ($\sim 6.7 \pm 0.5$ kPa [24]), the in-plane tensile and compressive moduli resisting cardiomyocyte-mediated contraction are comparable at $\sim 284 \pm 34$ kPa [25]. To understand the role of material elasticity on cell behavior, myoblasts were cultured on collagen strips attached to glass or polymer gels of varying elasticity [26]. Cells were found to differentiate into a striated, contractile phenotype only on substrates within a very narrow range of muscle-like stiffness (i.e., 8–11 kPa) (Fig. 24.3). To optimize a scaffold design for a particular application requires consideration of the gross organ and tissue level functional requirements, as well as the micromechanical requirements for appropriate tissue formation at the cell-level.

The mechanical properties of TE scaffolds are determined in part by the bulk properties of their constituent materials (e.g., modulus of elasticity, degradation rate). For example, most hydrogel materials exhibit a much lower strength and stiffness compared to hydrophobic polyester materials. As traditional PLGA-based scaffolds have a limited subset of mechanical properties, new biodegradable materials have been developed, such as poly(hydroxyalkanoates) and poly(glycerol sebacates) to improve scaffold toughness and elasticity [27,28]. Because of the high porosity and concomitant low material content, the mechanical properties of TE scaffolds are very often primarily dictated by the structural arrangement of their constituent materials (e.g., pore size, fiber diameter and orientation; Table 24.1) and associated modes of structural degeneration (e.g., fiber fragmentation, bond disruption). For example, in a recent study the effective stiffness (E) (equivalent to initial

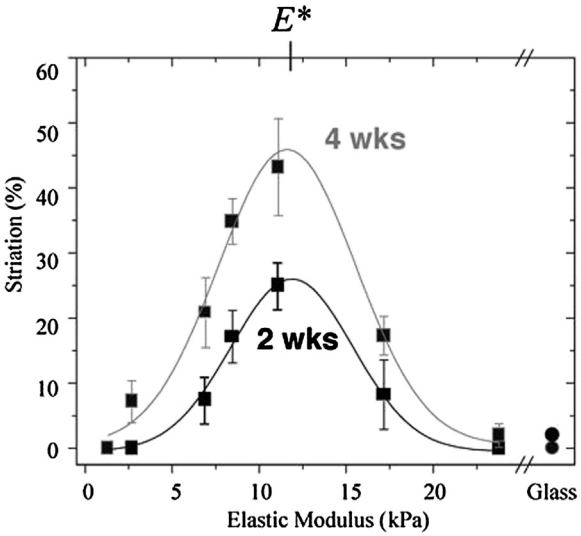

FIGURE 24.3
To understand the role of material elasticity on cell behavior, myoblasts were cultured on collagen strips attached to glass or poly(acrylamide) gels of varied elasticity. Substrate stiffness was found to have a profound influence on myocyte differentiation, with optimal differentiation (as assessed by striation) occurring within a very narrow range of muscle-like stiffness (i.e., 8–11 kPa) [26]. These results suggest that cell differentiation within 3D tissue-engineering scaffolds may exhibit a similar sensitivity to the local micromechanical properties. *Figure reproduced with permission by Rockefeller University Press.*

tensile modulus) of non-woven PGA scaffolds was predictably modulated by tuning the fiber diameter via NaOH-mediated hydrolysis [25].

In addition to the initial structure imparted during the fabrication of the TE scaffold, the modes of structural degeneration manifested by the scaffold need to be considered. For example, while 50:50 blend PGA/PLLA scaffolds do not undergo significant mechanical degeneration over a period of 3 weeks [35], scaffolds dip-coated with the biologically-derived thermoplastic poly(4-hydroxybutyrate) (P4HB) incur a rapid loss of rigidity with cyclic flexural mechanical loading as the P4HB bonds between fibers are disrupted [36]. Depending on the kinetics of scaffold hydrolysis, structural degeneration may be more pronounced and thus represent a more important consideration in scaffold design.

Because the foremost role of the scaffold following implantation is to temporarily fulfill the key mechanical functions of the replaced tissue, it is essential to consider the physiological loading state of the native tissue. While the physiological loading state may be highly complex and virtually impossible to reproduce *ex vivo*, certain mechanical testing configurations are generally more relevant than others. For example, the physiological loading state of

TABLE 24.1 Dependence of a scaffold mechanical property (initial tensile modulus) on the bulk material mechanical property and scaffold structure[a]

Material	Initial tensile modulus (MPa)		
	Fibrous scaffold	Foam scaffold	Bulk material
Poly(glycolic acid) PGA	0.284 ± 0.034 (non-woven) (29)	0.919 ± 0.067[b] (salt leach) [30]	18,780 ± 3430 (fiber) [29]

a semilunar heart valve leaflet depends on time-varying solid-fluid coupling (i.e., leaflet tissue-blood), and includes multi-axial flexural, tensile, and fluid shear stress components. In light of the strong planar anisotropy and tri-layered structures exhibited by native leaflet tissues, biaxial tensile testing [37] and flexural testing [38] have been employed to characterize their behavior.

Because engineered tissues based on synthetic polymer scaffolds inherently begin development as composite materials, their effective mechanical properties will be determined by the combined effects of the cells, ECM, scaffold, and their unique micromechanical interactions. Thus, the appropriate formulation and validation of a mathematical model to simulate and/or predict the mechanical properties of a scaffold is a critical prerequisite for developing a mathematical model to simulate and/or predict the mechanical properties of an engineered tissue. While standard phenomenological models may be useful in characterizing the gross mechanical behavior of a scaffold or engineered tissue construct (i.e., for meeting organ and tissue level functional requirements), only an appropriately formulated structural-based model can be used to design the micromechanical environment presented at the cell-level. Structurally-based models can either be computationally driven, as in the work of Hollister and colleagues [3,39], or purely analytical, as in the case of a model for non-woven scaffolds by Engelmayr and Sacks [25]. Irrespective of the solution method, the goals of structure-based modeling are both to bridge the gap between the disparate length scales of cells, tissues, and scaffolds, and in particular to accurately simulate the micromechanical environment presented at the cellular level. For example, while traditional rule of mixtures theories accounting for the volume fractions and orientations of individual composite constituents are often invoked in describing native and engineered tissues [40], higher order reinforcement effects observed via the structurally-based modeling of commercially available non-woven PGA and PLLA scaffolds preclude the use of rule of mixtures approaches. These higher order reinforcement effects, which yield proportional increases in fiber effective stiffness with increased ECM stiffness, predict a very different micromechanical environment to that predicted by a rule of mixtures, highlighting the importance of an accurate micromechanical representation of the TE scaffold.

Electrical conductivity

Electrical conduction is an important mechanism that enables cellular signaling and function in many types of tissues. The cardiac electrical conduction system is essential for maintaining the synchronous beats that pump blood in an ordered fashion. In the process of bone regeneration, naturally-occurring piezoelectric properties of the apatite crystal are hypothesized to generate electric fields involved in bone remodeling. The nervous system possesses a well-known system of electrochemical signaling. Much research has been carried out using materials to record from and influence bioelectric fields. In making tissue scaffolds, electrically conductive biomaterials have been studied to understand their abilities to interface with bioelectrical fields in cells and tissues to replicate normal electrophysiology.

A wide variety of electrically conductive polymers are available to the tissue engineer, each with differing characteristics that may direct choice for a given application. These organic compounds include poly(pyrrole), poly(vinylidene fluoride), poly(tetrafluoroethylene), poly(aniline), poly(thiophene), and poly(acetylene). Such polymers generally contain delocalized pi bonds and can be considered semiconductors, with conductivity determined by degree of doping. Polypyrrole, an aromatic heterocycle, is perhaps the most widely studied conductive biomaterial, due to both its ease of fabrication and demonstrated biocompatibility. In contrast to the static charges seen in conductive materials like poly(pyrrole), piezoelectric materials such as poly(vinylidene fluoride) display a transient charge in response to mechanical deformation. For transplantation purposes, it is often desirable to have the material biodegrade after cell delivery and incorporation into the host environment have been accomplished. Degradable conductive polymers have been synthesized using several different

approaches, including incorporation of 3-substituted hydrolysable side groups [41], degradable ester linkages connecting oligomers of pyrrole and thiophene [42] and emulsion/precipitation of poly(pyrrole) in poly(D,L-lactide) [43].

In order to tailor conductive biomaterials to a given application, scalable technologies have been developed to fabricate conductive structures of arbitrary geometry. Due to horizontal and vertical growth of polypyrrole during electropolymerization, two-dimensional photolithographically defined gold layers can be used to pattern three-dimensional structures [5,44]. Hollow polymer tubes ranging from the nano to the micro scale have been fabricated using a range of techniques, including polymerization via electrodes on opposite ends of a silicone tube [45] or via oxidation on platinum wire molds followed by reduction [46].

There are a growing number of reports demonstrating synergistic effects of conductive biomaterials and electrical stimulation. Neonatal cardiomyocytes cultured on collagen sponges and matrigel show synchronized contraction in response to applied electric fields [47,48]. Applied potentials can also be used to change the surface properties of conductive polymers, altering cell shape and function, including DNA synthesis and extension [49]. Others have shown that electrical stimulation promotes neurite outgrowth on conductive polymers beyond that seen on indium tin oxide, an inorganic conductive substrate [50]. Composite conductive polymer films have been manufactured to include substrates that direct cell function, such as hyaluronic acid to promote angiogenesis [51].

The mechanistic basis for each of these electrical-material-tissue interactions is not fully understood and will be an important area for future study. However, some leading hypotheses have emerged. This enhanced function of engineered cardiac tissues may be due to greater ultra-structural organization in response to electric fields [47]. Increased neurite outgrowth with electrical stimulation may be caused by better ECM protein adsorption [52] rather than direct effects on the cell itself although there is ample evidence of the latter. Electrophoretic redistribution of cell surface receptors likely governs the galvanotropic response of neurons to a horizontally oriented two-dimensional applied field [53]. Such mechanisms do not fully explain the alterations in cell function which occur in response to stimulation applied to the substrate or material relative to the medium or a distant ground. For such depolarization, signaling through voltage-gated calcium channels can activate ubiquitous second messengers such as cAMP and alter gene transcription affecting learning, memory, survival, and growth [54]. Such secreted gene products might be used to enhance the survival of host cells surrounding an implanted scaffold. Given that applied electric fields can so profoundly affect cell function, conductive three-dimensional scaffolds will be important tools for harnessing this interaction to create functional tissues.

Surface properties

Cells interact with scaffolds primarily through the material's surface, which can be dominated by the surface chemical and topological features. The surface chemistry here refers to the insoluble chemical environment that the scaffold surface presents to cells, which can differ from the biochemical compositions of the bulk, and/or the substances derived from surface adsorption or chemical reactions. Besides mediating cell behavior and functions inside scaffolds, controlled surface properties are of central importance in directing the inflammatory and immunological response. Controlled surface properties may be useful for ameliorating the foreign body reaction at the host-scaffold interface *in vivo* [55,56].

SURFACE CHEMISTRY

Each type of synthetic, natural, or composite scaffold gives rise to a set of distinct surface chemical characteristics governed by the material chemistry and its physical form (such as crystallinity, charge, and topology). Although numerous efforts have been made to tailor the scaffold surface, the chemical environment can exhibit extremely complicated patterns within

the biological milieu. Complex processes such as the spontaneous adsorption of a diversity of proteins from biological fluids to the scaffold surface, and the protein surface conformation are difficult to analyze, but exert profound effects on the scaffold performance. To tailor the scaffold chemical properties, the interactions of scaffolds with different environmental factors need to be considered.

Scaffolds derived from natural ECM materials such as collagen, fibrin, hylauronic acid (HA), proteoglycans, or their composites have the advantage of directly containing innate biological ligands that cells can recognize and provide natural mechanisms for tissue remodeling. ECM analogs have been created to emulate an appropriate tissue regeneration environment. For example, as an essential ECM component in natural cartilage tissue, collagen type II scaffolds may have better biochemical properties for maintaining chondrocyte phenotype and enhance the biosynthesis of glycosaminoglycans compared to collagen type I [57]. Fibrin, the native provisional matrix of blood clots, can provide ligands to initiate cell attachment and ECM remodeling [58]. HA plays a role in morphogenesis, inflammation and wound repair, and the cell-ECM interactions mediated through receptors such as CD44 and RHAMM (receptor for hyaluronan-mediated motility) can be activated in scaffolds with HA constituents [58]. The natural cell-ECM interactions, however, can also alter after purification, manufacturing and scaffold fabrication processes. For example, acid-treated type I collagen polymers contained only 5% residual crystallinity compared to native collagen. The loss of crystalline structure led to platelets binding with diminished degranulation, which in turn limited the myofibroblast numbers and the related inflammatory response at the injured site [14].

Synthetic scaffolds offer a variety of mechanisms to modulate cell behavior. Chemical reactions with biological fluids remodel the scaffold surface and affect tissue growth through both reaction dynamics and kinetics. Studies have shown that bioactive glasses (Class A bioglass composed of 45–52% SiO_2, 20–24% CaO, 20–24% Na_2O and 6% P_2O_5) have superior osteoproductive properties to either bioactive hydroxyapatite, or bioinert metals and plastics. The difference was found to be due to the surface reaction kinetics in physiological fluids. The rapid rate of the reaction that converts amorphous silicate to polycrystalline hydroxyl-carbonate apatite on the bioglass surface is the key to positively regulating the cell cycle and bone formation [59] (Fig. 24.4a). Physical processes also play active roles in

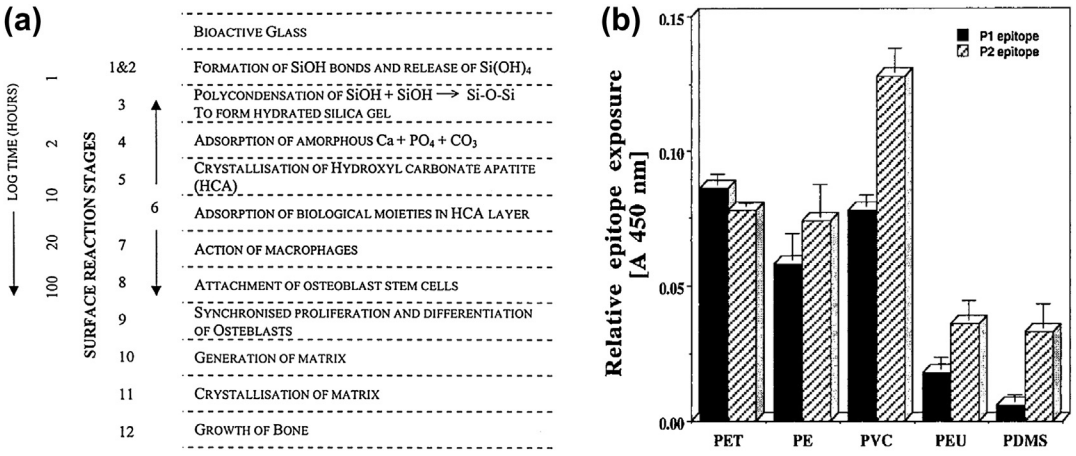

FIGURE 24.4

Understanding the molecular basis of surface interactions is essential to controlling surface functions. a) A series of surface reactions on Class A bioglass [59]. *Figure reproduced with permission from Springer.* **b)** Dynamic and kinetic mechanisms of material interactions with proteins can lead to different cell response at the scaffold surface. The example shows the exposure of two epitopes (P1 and P2) in fibrinogen on a surface varied with the substrate materials (PET, PE, PVC, PEU, and PDMS disks coated with human fibrinogen) [56]. *Figure reproduced with permission from American Society of Hematology.*

controlling the material-cell interface. Because of the adsorbed protein moieties from serum or body fluid, many polyester-based scaffolds, such as those made from poly(α-hydoxy esters), exhibit adequate adhesion to support cell attachment and tissue growth in some *in vitro* and *in vivo* applications. Methods that alter the surface hydrophobicity, e.g., by changing monomer compositions or by chemical surface treatment, can potentially improve the scaffold performance [60–62]. For example, biodegradable foams of hydrophobic polymers (e.g., PLLA and PLGA) can be efficiently wet by two-step immersion in ethanol and water. This surface treatment could overcome the hindered entry of water into air-filled pores to facilitate cell seeding [60].

Surface modifications of scaffolds have been developed to generate surface chemical specificity and recognition. The surface chemistry can be created by either incorporating bioactive moieties directly in the scaffold bulk, or by modifying the surface. These moieties bound to scaffolds trigger desired specific intracellular signaling. In particular, many synthetic and natural hydrogel materials (e.g., poly(ethylene glycol), poly(vinyl alcohol), alginate and dextran) are protein-repellent, and immobilizing biomolecules to such hydrogel scaffolds may be especially useful in tailoring the surface chemistry for cell-material interactions at the molecular level.

Cell adhesion mediated through extracellular adhesive proteins is involved in many intracellular signaling pathways which regulate most fundamental cell behaviors, including differentiation, proliferation, and migration. Enriching scaffold surfaces with specific ECM-derived adhesion proteins has been widely applied to scaffold modification. PLGA-based scaffolds have been coated with fibronectin by physical adsorption for supporting growth and differentiation of human embryonic stem cells in 3D [64]. Fibronectin was covalently attached to PVA (poly(vinyl alcohol)) hydrogels for improved cell adhesion, proliferation, and migration [65]. Fibrinogen was also denatured and fused into the backbone of a PEG (poly(ethylene glycol)) hydrogel material [66] to elicit cellular responses. Elucidating the underlying molecular mechanisms on scaffold surface however is not a trivial task. Fundamental studies have been carried out to understand how the adsorption and denaturing of proteins can lead to different cellular responses at the material surface and may provide a molecular basis to control cell-material interaction for rational design of scaffolds [56] (Fig. 24.4b).

Immobilizing peptide ligands derived from the active domains of ECM adhesion proteins to scaffolds is another major approach to generating specific surface-bound biological signals. For example, integrins, the principal adhesion receptor mediating cell-ECM attachment, comprise a family of more than 20 subtypes of heterodimeric transmembrane proteins. Each of them recognizes and interacts with certain types of ECM adhesion proteins to activate a cascade of signaling pathways which regulate essential cell activities and functions [67]. Integrins can be activated by short peptides in similar ways, e.g., Arg-Gly-Asp (RGD) from fibronectin and Tyr-Ile-Gly-Ser-Arg (YIGSR) from laminin. Provided that peptides are relatively stable and economical to use, incorporating them into scaffolds has become an important way of generating surface biomimicry and enhancing tissue regeneration [68,69]. To introduce peptide moieties, the scaffold materials need to contain appropriate functional groups, which may not be available in most hydrophobic polyesters. Methods have been developed to functionalize polyesters. For example, poly(lactic acid-co-lysine) has been synthesized, and the RGD peptide can be immobilized through the side-chain amine groups of the lysine residues [70,71].

Like the biomolecules in natural ECM, the functions of immobilized bioactive ligands in modulating membrane receptors and intracellular signaling are influenced by their spatial characteristics. For example, integrin affinity to ECM affects cell attachment and migration; as a result, 3D neurite migration demonstrated a bi-phasic dependence on RGD concentration, with intermediate adhesion site densities (between 0.2 and 1.7 mol of peptide/mol of fibrinogen) yielding maximal neurite extension compared with higher densities which

inhibited outgrowth [72]. In another study, integrin clustering, a prerequisite to many integrin-mediated signaling pathways, was recapitulated by RGD nanoclusters immobilized on a comb-polymer substrate [73].

SURFACE TOPOGRAPHY

The material-cell interactions mediated through topographical features have traditionally been studied through planar substrates. Surface modification techniques, including photolithography, contact printing and chemical treatments have been developed to generate micro- and nano-scale surface topographical features. Surface topographical features such as ridges, steps, and grooves have been found to guide cytoskeletal assembly and cell orientation. Surfaces with textures such as nodes, pores or random patterns are often associated with marked changes in cell morphology, cell activities and the production of autocrine/paracrine regulatory factors compared to smooth surfaces [74]. In general, surface roughness increases cell adhesion, migration, and the production of ECM. Cells sense and respond to topographical features in a dimensionally-dependent way. As demonstrated on titanium surfaces, microtextures increased osteoblast attachment and growth, but only the presence of nano-scale roughness led to enhanced cell differentiation in connection with elevated growth factor production [75].

Current fabrication techniques can be used to generate a wide variety of topographical features in scaffolds. Scaffolds can be randomly packed with regular or irregular geometries and shapes (e.g., particles, pellets and fibers), or condensed with amorphous structures (e.g., foam and sponge), or fabricated with specifically designed architectures. Based on the cell-material interactions, scaffolds provide different topographical properties correlated with the dimensions of scaffold geometries and shapes. When the feature size is larger or comparable in size to cells, e.g., the fiber diameter in a non-woven mesh, and pores and walls in a foam, the scaffold may provide curved surfaces for cell attachment. Pore size and surface area constitute the major topological features in an extracellular environment. As demonstrated in a study of mesenchymal stem cells seeded onto polymeric fibrous fabrics, increased fiber diameter favored cell attachment and proliferation by providing more surface area [76]. Surface treatment techniques, such as sodium hydroxide etching, have been used to generate nano-scale roughness to increase cell adhesion, growth, and ECM production [77].

The size scale of most natural ECM components, e.g., fibrous elastin and collagen, fall into the range of several to tens of nanometers. The extracellular environment is dominated by nano-scale topographical features, such as nano pores, ridges, fibers, ligand clusters and high surface area-to-volume ratios in 3D. Such native topographies can be recapitulated to a degree in scaffolds made of natural ECM polymers such as collagen and elastin. As synthetic materials have the advantage of greater control over scaffold properties, interest is growing in developing synthetic nano fibrous scaffolds. 3D PLLA-based scaffolds containing nanofibers have been produced by thermally induced phase separation processes [78,79], and selective surface adsorption of adhesion proteins was observed. In a more versatile method, electrospinning techniques have been used to fabricate a variety of synthetic and natural materials with different hydrophobicities into fibers with diameters ranging from a few to hundreds of nanometers [80]. Another important approach involves building scaffolds from the bottom up. Polypeptides made of 12–16 amino acids have been designed to form hydrogel scaffolds through β-sheet assembly [81]. Amphiphilic molecules consisting of a hydrophilic peptide head and a hydrophobic alkyl tail self-assemble into nanocylinders to form inter-woven scaffolds [82,83].

Nanofibrous scaffolds have demonstrated abilities to support cell and tissue growth. For example, when cardiomyocytes were cultured in meshes made of electrospun poly(ε-caprolactone) nanofibers, they expressed cardiac-specific markers and were contractile in 3D scaffolds [84]. In a scaffold based on self-assembled peptide amphiphilic molecules

containing the laminin epitope IKVAV, neural progenitor cells selectively differentiated into neurons [82]. The potential of designing nano-scale topographies in scaffolds remains largely unknown with regard to exactly how cell cycle, gene expression patterns, and other cell activities are regulated. Some possible mechanisms may be related to cell receptor regulation (clustering, density, and ligand-binding affinity) on nanofibers, nutrient gradients in nanoporous matrices, mechanotransduction induced by the unique matrix mechanics, and the conformation of adhered proteins for cellular recognition sites.

Temporal control

SCAFFOLD DEGRADATION

Unlike permanent or slowly degrading implants which may serve to augment or replace organ function (e.g., hip implants, artificial hearts, or craniofacial plates), tissue-engineering scaffolds serve as temporary devices to facilitate tissue healing and regeneration processes. The regeneration of a fully functional tissue ideally coincides in time with complete scaffold degradation and resorption. Controlling degradation mechanisms allows scaffolds to temporally cooperate with cell and tissue events via changes in scaffold properties and functions. Tuning the scaffold degradation rate to make it kinetically match with the evolving environment during tissue healing and regeneration is an important design criterion. Due to the multiple roles of scaffolds, the interrelations between scaffold property variables, and the different wound conditions in individual patients, it remains a challenge to design degradation properties that can be tailored to meet various clinical tissue regeneration requirements.

During scaffold degradation, some scaffold properties and functions may weaken or diminish with time. In general, there exist lower and upper limits to the optimal degradation rate, which may vary with cellular or tissue processes, scaffold chemical compositions, and scaffold functions. For example, scaffolds often need to serve mechanical functions; such as bone implants which need to support compressive loading while maintaining an environment permissive to new bone formation. If a material degrades prior to transferring mechanical load to the new tissue, the therapy would fail [85]. Alternatively, materials in bone implants that degrade too slowly may cause stress shielding, thereby impeding the regeneration process and potentially endangering surrounding tissues [86]. In skin wound models, healing can be compromised if the scaffold degradation occurs too quickly, whereas scar tissue occurs when the degradation is too slow [14]. The optimal skin synthesis and prevention of scar formation could be achieved when the template was replaced by new tissue in a synchronous way, i.e., the time constant for scaffold degradation (t_d) and the time constant for new tissue synthesis during wound healing (t_h) were approximately equal [14]. Matching tissue formation with material degradation thus requires coupling of specific temporal aspects of tissue formation processes with chemical properties of the scaffold.

Scaffold degradation can occur through mechanisms that involve physical or chemical processes, and/or biological processes that are mediated by biological agents such as enzymes in tissue remodeling. In the passive degradation mode, the degradation is often triggered by reactions that cleave the polymer backbone or crosslinks within the polymer network. Many polyester scaffolds made of lactic acid and glycolic acid, e.g., PLLA and PLGA, undergo bulk backbone degradation due to their wettability and water penetration through the surface. Hydrophilic scaffolds such as hydrogels made of natural or synthetic materials crosslinked by hydrolysable bonds (e.g., ester, carbonate, or hydrazone bonds) also convert to soluble degradation products predominantly through the bulk [87,88]. Chemical degradation can be conveniently varied through scaffold physical and chemical properties such as the backbone hydrophobicity, crystallinity, glass transition temperature, and crosslink density. Because of this flexibility, the degradation rate can principally be engineered for optimal tissue regeneration [85,89].

Scaffolds degrading through passive mechanisms exhibit limited capabilities to match with tissue growth and wound healing. In bulk degradation, the accumulation of degradation products may exert adverse effects on tissue, e.g., acidic products from PLGA degradation. In order to exert more control over the degradation properties of a scaffold and to attempt to tailor the degradation of the scaffolds, consideration of pertinent wound healing and tissue regeneration mechanisms is required. For example, it is known that orchestrated cascade of events occurs during the wound healing process and typically involves inflammation, granulation tissue formation, and remodeling of the ECM. Scaffolds should be designed to degrade *in vivo* during the formation of granulation tissue and/or during the remodeling process. Many inorganic scaffolds studied for bone tissue engineering exhibit biodegradable and bioresorbable characteristics that matches and promotes the process of new tissue formation [63,90,91].

To integrate natural biological mechanisms of ECM remodeling, a new class of hydrogels that degrade in response to proteases have been developed [92,93]. In these scaffolds, degradation occurs through cellular proteolytic activities mediated by enzymes such as collagenase and plasmin. In one of these studies, a PEG hydrogel modified with adhesion ligands was cross-linked with molecules containing matrix metalloproteinase (MMP) peptide substrates. Migration of human primary fibroblasts inside the gel was observed and found depending on the substrate sensitivity to the enzyme [94]. When used for delivering recombinant human bone morphogenetic protein-2 (rhBMP-2) into critical-sized defects in rat crania, the PEG hydrogel matrix was remodeled through the MMP mediated mechanism and supported bone regeneration within five weeks [95]. The approach demonstrated a paradigm of how scaffold degradation and intervention can be engineered to synchronize with wound healing and new tissue synthesis via natural mechanisms.

DELIVERY OF SOLUBLE BIOACTIVE FACTORS

The incorporation of delivery systems in 3D scaffolds offers an indispensable platform for enabling temporal and spatial control in tissue constructs. Compared to systemic administration, using a local controlled release system to deliver soluble inductive and therapeutic factors has the advantages of preventing rapid factor clearance, metering factors in a desired pharmacokinetic manner, and allowing therapeutic doses for an appropriate duration while limiting side effects at unwanted body locations. The release of soluble factors from scaffolds can be mediated through single or multiple mechanisms, e.g., by diffusion, dissolution, scaffold or carrier degradation, or external stimuli. In particular, delivery of growth factors has been studied for various tissues, due to their important roles in instructing cell behavior.

Built upon established particle-based delivery systems, one common method for controlling the release from a scaffold involves prefabricating biofactor-loaded particles and embedding them into a scaffold matrix [96,97]. The release of biofactors in these systems can be delayed with a minimized burst effect, compared to the particles used alone. Typical particle carriers include PLGA and hydrogel microspheres. This method takes advantage of established systems, but involves double matrices which influence the release profile. Alternatively, soluble factors may be incorporated directly into the scaffold itself without a secondary carrier/matrix. This often requires the scaffold to be fabricated under mild physiological conditions to preserve the bioactivity of proteins or other biofactors. Growth factors and proteins have been incorporated in scaffolds through surface coating [98], emulsion-freezing drying [99], gas foaming/particulate leaching [100,101] and nanofiber electrospinning [80,102]. Different delivery profiles of growth factors or DNA plasmids were achieved. Due to their hydrophilic and biocompatible nature, hydrogel scaffolds are amenable to incorporating proteins and plasmid DNA, yielding both higher loading efficiencies and bioactivity compared to PLGA-based materials. Biofactors have been immobilized in hydrogel matrices via physical interactions and/or covalent chemical bonds for prolonging retention time and controlling release via designed mechanisms [103,104].

Scaffolds that integrate controlled release methods have been used in conjunction with scaffolds for a variety of purposes, including enhancing tissue formation, stimulating angiogenesis, guiding cell differentiation and facilitating wound healing [103,105]. Delivering growth factors from scaffolds has demonstrated advantages over using the free form directly [106]. Synergistic effects on accelerating tissue regeneration have been observed when scaffolds, cells, and growth factors are combined. For example, autologous bone marrow-derived cells transplanted with scaffolds containing bone morphogenetic protein-7 resulted in the greatest bone formation compared to constructs without either growth factor or cells [107]. A major challenge in delivering biofactors involves achieving meaningful pharmacokinetic delivery. The dosage, release kinetics, and duration time should be optimized and tailored to tissue growth/healing mechanisms. For example, vascular endothelial growth factor (VEGF) acts as an initiator of angiogenesis while platelet-derived growth factor (PDGF) provides essential stimuli for blood vessel maturation. To simulate the process, PLGA-based scaffolds have been developed to deliver these two angiogenic factors with distinctive kinetics for rapid formation of a mature vascular network [108].

Instead of releasing soluble growth factors directly into the environment, they can also be initiated by cellular activities. Many growth factors are tightly sequestered in the ECM as inactive precursors, and released through their interaction with cells via specific protease mediated mechanisms. To simulate the biological process, growth factors were covalently conjugated to hydrogel matrices via proteolytically cleavable linkages. The immobilized growth factors remained active and their release was elicited by cells through plasmin activity [109,110]. In these systems, the mode of growth factor release could be varied and controlled by cellular activities to achieve precise temporal control in different clinical situations.

Spatial control

Tissues consist of hierarchically ordered structures of cells and ECM; an important tissue engineering design principle is incorporating spatial cues into 3D scaffolds to guide structural tissue formation. Such guidance involves designing anisotropic scaffold properties. By generating directional variations in cell-cell and cell-ECM communications, various cell behavior and new ECM depositions can potentially be guided.

At the macroscopic or tissue level, scaffolds are configured to have appropriate geometries that correspond to tissue/organ anatomical features. The scaffolds are seeded with cells and/or direct the ingrowth of cells from host tissues to promote spatially compartmentalized new tissue growth and wound healing. One of the first methods introduced to generate macroscopic, anatomical shapes utilized highly interconnected pore structures from laminating porous membranes of PLLA and PLGA [111]. In another example, polymeric conduits were constructed for growing blood vessels and guiding nerve tissue regeneration. Smooth muscle cells and endothelial cells have been seeded onto tubular biodegradable PGA scaffolds as an approach for engineering vascular grafts [21]. Nerve guidance channels are used for connecting damaged nerve stumps. The entubulation strategy has demonstrated abilities to guide axonal spouting, directing growth factor diffusion, and blocking undesired fibrous-tissue ingrowth. To fabricate scaffolds with more complex shapes, rapid prototyping techniques use tissue or defect images recorded by medical imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) [3,112,113]. Another approach to shape scaffold materials to fit into individual tissue defects relies on liquid-solid transformation process. *In situ* forming hydrogels solidify upon external stimuli (e.g., chemicals, light, and pH), and have been designed as injectable scaffolds for minimally invasive cell and biomolecule transplantation. For example, methacrylated PEG and HA polymers were able to photopolymerize in situ with chondrocytes and support neocartilage formation *in vivo* [114,115].

At the microscopic or cellular level, various techniques have been developed to couple cell/tissue guidance mechanisms to regenerate tissues that require directional cell growth

(e.g., nerve). Anisotropic characteristics in pore architectures, mechanics, surface properties, degradation, and delivery can potentially generate signals recapitulating haptotaxis and chemotaxis for guiding cell behavior and ECM deposition in 3D. Various scaffolds have been developed containing aligned longitudinal regions. For example, PLGA conduit devices containing physical channels have been created by low-pressure injection molding; oriented lumen surfaces facilitated and guided Schwann cell attachment for peripheral nerve regeneration [116]. Guidance can also be generated through fibrous topographical features. Aligned nanofibers made of poly(L-lactide-co-ε-caprolactone) were fabricated by an electrospinning technique and the oriented fiber structure elicited directional growth of smooth muscle cells. Fibrils in natural scaffold materials, such as collagen and fibrin, have been aligned using magnetic fields [117,118]. The resulting scaffolds increased the rate and depth of axonal elongation *in vitro* and improved sciatic nerve regeneration *in vivo* as compared to scaffolds with random fiber orientations [118].

Creating heterogeneous chemistry in scaffolds is another approach that has been explored to achieve spatial control for tissue guidance. Adhesive RGD peptides have been photo-immobilized in selected regions of agarose hydrogel matrices [119]. The patterns of adhesive and non-adhesive regions induced oriented axonal elongation and migration from dorsal root ganglion cell aggregates *in vitro*. Studies have also been carried out to incorporate chemical gradients in scaffolds. Gradients of proteins play important roles in tissue formation/remodeling during embryogenesis and wound healing. Combining fluidic systems and *in situ* forming hydrogel materials, concentration gradients of peptides and proteins have been generated in 3D matrices and exhibited abilities to modulate cell functions. For example, entrapment of nerve growth factor in a poly(2-hydroxyethyl methacrylate) hydrogel induced directional axonal growth from PC12 cells *in vitro* [120]. A microfluidic device was used to create gradients of immobilized molecules and crosslinking densities in photocrosslinked hydrogels; the gradients of immobilized RGD adhesion ligands modulated the spatial distribution of attached endothelial cells [121].

Creating spatial features involves processing of scaffolds to integrate different control mechanisms. To this end, biomaterials with improved processing may need to be combined with different fabrication techniques, so that architectural structures, biomolecules, and cells can all be combined in a desired manner. For example, to generate complex tissue patterns, it is desirable to position cells with defined microstructures. Encapsulation of cells using photopolymerizable hydrogel materials have been combined with stereolithography in rapid prototyping to create programmed cell organization in 3D [122]. In designing devices for spinal cord injury repair, as molecular, cellular, and tissue level treatments are discovered, the combinations of such treatments will be necessary to synergistically promote tissue regeneration. Multiple-channel, biodegradable scaffolds have been fabricated with capabilities to locally deliver molecular agents and control cell spatial distribution for transplantation (Moore, Friedman et al. 2006).

CONCLUSIONS

Tissue-engineering scaffolds need to be built with functions to interact with cells at different spatial and temporal scales to invoke complex, tissue-like patterns. Over the past two decades, scaffold design criteria have evolved from simply inducing tissue formation to explicitly controlling tissue formation. Tissue engineers have at their disposal an ever broadening array of techniques to fabricate scaffolds which incorporate spatially and temporally varying biochemical and physical cues. Based on our collective understanding of natural cellular and tissue processes, optimal integration of these scaffold structures and properties should in principle allow us to explicitly control the tissue formation process. The challenge, therefore, is to develop a system-level understanding of how fundamental scaffold properties (e.g., mass transport, mechanics, electrical conductivity, and surface properties)

are inter-related in affecting cell behavior, and how they can be rationally programmed – spatially and temporally – to provide the necessary signals at the right time and place to aid tissue formation/regeneration.

CHAPTER 25

The Role of the Host Immune Response in Tissue Engineering and Regenerative Medicine

Bryan N. Brown[1,2] **and Stephen F. Badylak**[1,2,3]

[3] Department of Surgery, University of Pittsburgh, Pittsburgh, Pennsylvania

INTRODUCTION

Tissue engineering and regenerative medicine-based approaches commonly employ a combination of scaffolds, cells, and bioactive molecules. Regardless of the approach used for each clinical application, the objective is the same; specifically, the restoration of structure and function. Similarly, regardless of which strategy is selected, the response of the host to the implanted construct will dictate the success or failure of the eventual outcome. The present chapter briefly reviews the default mechanisms of wound healing, the foreign body response to non-degradable permanent implants, and the host response to various strategies employed within tissue-engineered constructs. Particular emphasis is placed upon newly defined paradigms surrounding the host macrophage response.

WOUND HEALING

All materials implanted into a mammalian recipient are subject to response by the host's innate immune system. Such response occurs immediately and is dependent in part upon both the anatomical context of the implanted construct and the constituents of the implanted construct.

The default mammalian response following tissue injury is characterized by a well-documented series of events that typically result in the deposition of dense fibrous connective tissue (i.e., scar tissue) [1–3]. Only select tissues in adult mammals have the ability to regenerate following injury; among which are the bone marrow, liver, intestinal epithelium and epidermis of the skin. The default response to tissue injury has been described as occurring in four stages: hemostasis, inflammation, proliferation and remodeling [2]. Each of these stages is reviewed briefly in a general context below.

Hemostasis

Following tissue injury and associated damage to the vasculature, platelets are activated by released tissue factor, resulting in the activation of a cascade of clotting factors which causes the

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00025-2

formation of a provisional fibrin clot with entrapped erythrocytes. The provisional matrix provides a substrate for further cell migration into the site of injury and a medium for cell signaling. In addition to their role in hemostasis and provisional matrix formation, platelets also release cytokines, including platelet derived growth factor (PDGF), TGF-β, chemokine C-X-C ligand 4 (C-X-C L4), IL-1β, and the CD47 ligand thrombospondin [4–8]. These factors, among others, contribute to the initial repair process via recruitment of multiple cell types including neutrophils, macrophages, fibroblasts and other tissue-specific cells to the injury site [6].

Inflammation

Neutrophils are the first inflammatory cell type to arrive at the wound site. Neutrophils phagocytose and destroy foreign material, bacteria or cell debris that may be present, and provide additional signaling molecules that recruit macrophages to the injury site [4]. Mast cells also participate in the early stages of wound healing by releasing granules rich in enzymes, histamine, and other factors that modulate the inflammatory response [2,9]. By 48–72 hours post-injury, however, macrophages typically dominate the cell population at the site of injury [10]. These cells are of a predominantly pro-inflammatory phenotype, and they secrete cytokines and chemokines that promote the further recruitment of leukocytes to the site of injury [4,6]. Macrophages also remove apoptotic neutrophils, the phagocytosis of which may lead to a change toward a more reparative macrophage phenotype (discussed in further detail below) and the resolution of the inflammatory phase of wound healing [11–13]. The T lymphocyte population also plays an important late regulatory role in the resolution of the inflammatory process through local secretion of cytokines and chemokines, many of which are known to affect macrophage polarization [14].

Proliferative phase

The proliferative phase of wound healing involves cellular proliferation, angiogenesis, new ECM (extracellular matrix) deposition, and the formation of granulation tissue – processes that are largely mediated via the effects of the local microenvironment, including pH and oxygen tension, and the cytokine milieu secreted by macrophages, T lymphocytes and other cells within the wound site [6,15,16]. These cytokines include EGF, b-FGF, TGF-α, TGF-β, VEGF and others depending on the nature of the injured tissue [2]. Importantly, macrophage participation and phenotypic polarization during this proliferative stage or the injury response may have significant downstream remodeling effects.

Remodeling phase

Following the deposition of significant amounts of new extracellular matrix (ECM rich in collagens type I and III) during the proliferative phase, the remodeling phase of wound healing begins. This phase is characterized by matrix metalloproteinase (MMP) and tissue inhibitor of metalloproteinase (TIMP)-mediated degradation and remodeling of the newly deposited matrix components with eventual scar tissue formation/maturation [2,17]. In some cases, dysregulation of the default healing process can result in prolonged inflammation and remodeling, leading to subsequent fibrosis or hypertrophic scar formation [2,18–20].

Although these wound healing events are described as part of the default response to tissue injury, selected components of this response should also be legitimately considered as part of a constructive remodeling process. That is, the selective activation of components of the inflammatory, proliferation, and remodeling phases can result in a constructive and functional outcome as opposed to scar tissue formation. In particular, the role of macrophages in promoting a constructive remodeling outcome following implantation of tissue-engineered constructs is discussed in further detail below.

THE FOREIGN BODY RESPONSE

The foreign body reaction is a well-described tissue response in the context of classical biomaterials [21,22]; specifically, those materials which are composed of non-degradable synthetic and metallic components and intended for long-term implantation. In general, the foreign body response is considered to be an adverse occurrence, with negative implications for material longevity and local tissue structure/function relationships. While many of the materials used in the fabrication of tissue-engineered constructs are transient (degradable) or composed of biologic materials which are not necessarily subject to the foreign body response as described below, it is nonetheless important to fully understand the foreign body response. In the sections which follow, additional responses which do not fall under the category of a foreign body response and their implications for tissue engineering and regenerative medicine will be discussed.

The host response following the implantation of a non-degradable synthetic or metallic biomaterial involves a series of overlapping processes that include: blood-material interaction with deposition of a protein film on the biomaterial, provisional matrix formation, acute inflammation, chronic inflammation, granulation tissue formation, foreign body reaction, and fibrosis and capsule development [22,23]. While many of these processes are similar to those described above for the default host response to tissue injury, there are a number of key differences.

Blood-material interaction and provisional matrix formation

The surgical implantation of a biomaterial is invariably associated with tissue damage and disruption of the vasculature at the surgical site. Release of blood into the wound site results in degranulation of platelets, formation of a provisional matrix as described above for wound healing, and signaling that recruits inflammatory cells (i.e., neutrophils and macrophages) to the surgical site. Blood contact also results in adsorption of proteins to the surface of the biomaterial within seconds of implantation [24]. The proteins that adsorb to a biomaterial may include components of the coagulation system (fibrinogen and tissue factors), complement cascade (C5), and other plasma-derived proteins (albumin and IgG) [22,25]. These proteins provide a substrate with which the inflammatory cells arriving at the site of injury interact at the surface of the biomaterial. The specific proteins that attach and the behavior of the attached cells are dependent on the physical and functional nature of the biomaterial surface and on an adsorption/desorption process that is governed by the affinity of the proteins for the biomaterial surface (known as the Vroman effect) [24,25]. As described briefly below, interactions of cells with the proteins adsorbed to the surface of the biomaterial may lead to a variety of cellular responses, including adherence, activation or triggering of phagocytic pathways, among others, depending on the cell type and the proteins involved [26,27].

Acute inflammation

Acute inflammation, consisting of the emigration of neutrophils from the vasculature into the implant site, follows formation of the provisional matrix and the release of chemoattractant factors by platelets and other cells within the inflammatory site, much like the process described above for default wound healing. However, upon arrival within the wound site, neutrophils interact with the proteins adsorbed onto the biomaterial surface through integrin receptors specific for the adsorbed proteins [22]. For example, the adsorption of fibronectin and IgG plays significant roles in the Mac-1-mediated attachment of neutrophils and macrophages to biomaterial surfaces during the acute phase of inflammation [28]. Complement and serum immunoglobulin adsorption to a pathogen (termed opsonization) leads to phagocytosis by neutrophils and/or macrophages, or destruction of the pathogen via the complement pathway. In comparison, an opsonized biomaterial elicits either phagocytosis from neutrophils (and later macrophages), or will be subjected to frustrated phagocytosis,

depending on the nature of the biomaterial and its size [22,29]. The process of frustrated phagocytosis involves the extracellular release of microbicidal contents at the surface of a foreign body. This release may cause the erosion of implanted materials, and may eventually lead to failure of the material to perform as intended.

Chronic inflammation

The chronic inflammation phase associated with the implantation of a biomaterial is typically characterized by the presence of activated macrophages. This process of macrophage accumulation may occur for a period of days to months depending on the nature of the implanted material and the adsorbed proteins. A meshwork of new ECM is deposited around the biomaterial and an accompanying angiogenic process is prominent. The continued presence of macrophages at the site of biomaterial implantation is often the precursor to the formation of granulation tissue, the foreign body giant cell response, and the eventual encapsulation of the biomaterial within a dense layer of collagenous connective tissue as described below.

Granulation tissue formation, foreign body reaction, and tissue encapsulation

Chronic inflammation can progress to a granulation tissue phase, in which the deposition of new ECM and the growth of vasculature into the implantation site through the process of angiogenesis are conspicuous. The persistence of granulation tissue combined with the presence of a non-degradable biomaterial is eventually associated with the formation of foreign body giant cells. The classic histologic description of a foreign body reaction consists of macrophages and foreign body giant cells, formed through fusion of macrophages, which are typically located at or near the interface of the host tissue with the biomaterial [22,30]. There are a number of factors, including the chemical composition and surface topography, which determine protein adsorption to the biomaterial, and the subsequent degree to which a material elicits a foreign body giant cell response [31–33]. As previously stated, macrophages generally interact with protein adsorbed surfaces through cell surface integrin receptors, the ligation of which induces intracellular signaling cascades that regulate macrophage behavior. Depending on the type of signaling elicited and the immunologic microenvironment, macrophages may fuse with adjacent macrophages forming foreign body giant cells. The exact mechanisms of foreign body giant cell formation are highly complex and have yet to be fully described. An in-depth discussion of the process of foreign body giant cell formation is beyond the scope of this chapter, however, the topic of foreign body giant cell formation as it relates to biomaterials has been reviewed elsewhere [22]. In the final stage of the host response following the implantation of a biomaterial, an increasingly dense layer of collagenous connective tissue is deposited around the surface of the material, thus isolating or 'encapsulating' it from the surrounding healthy tissue.

THE HOST RESPONSE IN TISSUE ENGINEERING AND REGENERATIVE MEDICINE

The foreign body response with an outcome of tissue encapsulation is, without question, considered an undesirable outcome for tissue engineering and regenerative medicine strategies which seek to promote functional recovery. There are a number of factors which dictate the host response to engineered tissues and regenerative medicine constructs, and aspects of both the innate and acquired immune response are invariably present. Among the determinant factors are the choice of biomaterial, the types of cells included within a cell-seeded construct, and the bioactive factors or pharmaceutical interventions used as part of or in concert with the implanted construct. Each of these factors elicit some degree of response from the host, which together dictate the nature of the overall response with implications for the success or failure of the strategy of choice. While it is beyond the scope of this chapter to consider each of these

factors in depth, the reader can apply the general concepts presented below to any of the many strategies presented throughout the rest of this text.

Biomaterials

In general, tissue engineering and regenerative medicine strategies will employ degradable naturally occurring or synthetically-derived biomaterials. These materials, due to their transient nature, elicit a distinctly different response than those intended for long term implantation without degradation. The effects of these materials upon the overall host response will be profound, and the selection of material must be considered carefully. The benefits of a particular material, its structure, mechanical properties, and ability to support the growth of cells *in vitro* must be balanced against the tissue reaction it will elicit following placement. Interactions of host immune cells with the material will result in reactions which initiate a cascade of inflammatory processes, which in turn dictate the course of tissue remodeling events. Therefore, it is likely that the physical properties, such as mechanical strength or porosity, which characterize the device at the time of implantation will begin changing immediately after surgical placement *in vivo*.

There are a wide range of biomaterial-associated factors which determine the host response following its implantation, including the chemistry of the material, its hydrophobicity/hydrophilicity, ability to degrade, surface and bulk architecture, and—in the case of some naturally derived biomaterials—the processing methods for manufacturing the constructs and the presence of an endogenous ligand landscape, among a number of others. The effects of these individual properties has been described elsewhere [34,35]. A variety of strategies have been suggested for avoidance of the foreign body reaction; however, many of these are effective only in the short term and therefore have met with only modest success at best. The host response to implanted materials and constructs is both unavoidable and an essential part of a constructive remodeling response which can facilitate material integration with surrounding tissue. Examples of materials based strategies that modulate the host innate immune response to improve remodeling outcomes are discussed in the sections which follow.

Cells

In addition to biomaterials, many tissue-engineering approaches utilize cells as part of a cultured construct. The biomaterials are typically intended either as a delivery vehicle for the cells or to provide mechanical and functional support immediately upon implantation. A number of recent approaches have demonstrated that it is possible to culture and deliver scaffold free constructs consisting only of cells [36,37]. These strategies have met with varying levels of success, as is described elsewhere within this text. Of the highest importance in these applications is the source of cells. Ideally, the cells used in tissue engineering and regenerative medicine are autologous, to minimize potentially detrimental activation of the adaptive immune system. However, it is well understood that autologous sources of tissue specific cells may be limited depending upon the application. A few approaches have utilized allograft sources, and even fewer xenogeneic cell-based applications exist due to the associated immune and regulatory complications. Allograft and xenograft cells may be recognized by the host through mechanisms which have been described for organ transplantation. Recently, induced pluripotent stem cells (iPSC) have emerged as a potential source of autologous cells for tissue engineering and regenerative medicine [38,39]. While iPSC hold great promise as a source for potentially unlimited potent autologous cells, the effects of their reprogramming upon the host response to these cells following placement is currently unknown. It is logical to assume that, in all cases, recognition and resultant formation of a Th1 polarized rejection response will have negative effects upon the success of any tissue engineering or regenerative medicine strategy.

Recent evidence suggests that much of the benefit of the inclusion of cells within tissue-engineered constructs may be the ability to promote construct integration through early

paracrine mechanisms. In particular, mesenchymal stromal cells (MSCs) have become well known for their immunomodulatory properties [40]. It is highly unlikely, however, that newly formed tissues will include the initially implanted population of cells for any extended period of time. Therefore, it is also important to carefully consider the fate of the cells and the potential mechanisms of cell death. Necrotic cell death may play an important role in determining the response of immune cells to transplanted cells. In particular the specific effects of cellular debris and damage associated molecular pattern molecules released during necrotic cell death upon the immune response to implanted constructs remains largely unknown.

Bioactive factors

Bioactive factors such as growth factors, cytokines and chemokines have been shown to have wide ranging effects upon the ability of tissue-engineered constructs to support cellular growth and differentiation *in vitro*. Growth factor and cytokine delivery have been shown to have wide ranging effects upon the success of implantable constructs *in vivo*. Additional strategies may use pharmaceutical interventions in concert with the delivery of tissue-engineered constructs to improve outcomes. These strategies may be aimed at modulating and maintaining tissue specific cell phenotypes, or at modulating the local host immune response. Obviously, the inclusion of cytokines or chemokines with immunomodulatory properties will have effects upon the host response to the implanted construct and thus, effects upon the downstream course of remodeling events. Consideration of the effects of each of the potential growth factor, cytokine, chemokine, or pharmaceutical interventions which may be used is beyond the scope of this chapter. However, an example of the effects of modulation of macrophage phenotype using a cytokine loaded construct is provided in the following section.

ACQUIRED AND INNATE IMMUNITY IN TISSUE ENGINEERING AND REGENERATIVE MEDICINE

As described above, both the innate and adaptive immune responses are important in the processes of natural wound healing and in the response to implantable tissue-engineered constructs. It is well recognized that there is an important interplay between the innate and adaptive immune system which can lead to feedback and feed forward loops of inflammation — which in turn can affect outcomes. This complexity of the immune response provides an explanation, at least in part, for the failure of strategies which seek to avoid host immune cell interactions. The following sections briefly describe the role of both the acquired and innate immune responses to tissue-engineered constructs, with a focus upon newly described paradigms for the host macrophage response.

Acquired immunity in tissue engineering and regenerative medicine

The mechanisms of the host cellular and humoral response to whole organ transplantation are well known. Xenogeneic and allogeneic cellular antigens are recognized by the host, elicit immune activation and cause the production of pro-inflammatory mediators with downstream cytotoxicity and transplant tissue rejection. This Th1 type response is commonly associated with rejection. Conversely, Th2 responses are characterized by production of a different set of chemokines, and are more commonly associated with the process of transplant acceptance. The effects of the Th1 and Th2 pathways upon transplant and cell rejection are well described and readers are referred to basic immunology texts for further descriptions [41]. It is logical to assume that tissue-engineering strategies which utilize cell sources of an allogenic or xenogenic nature may elicit a destructive Th1 type response. A number of strategies have been proposed for the protection or encapsulation of cells within a construct, thereby protecting them from immune recognition [42,43]. These strategies may have utility in protecting cells which produce therapeutic molecules, such as insulin production by islet cells. However, these approaches do not promote the integration of such cells into the tissue or organ of interest and

are, therefore, often only effective in the short term. Such recognition of non-self by the host will obviously have deleterious effects upon the ability of the tissue-engineered construct to integrate within the host tissues and otherwise perform as intended.

In addition to the recognition of cellular constituents of tissue-engineered constructs, it is increasingly being demonstrated that the components of the Th1 and Th2 pathways can be activated by materials alone; especially those derived from natural sources as these may contain potentially immune-activating cellular epitopes or other biologic ligands. For example, ECM-based scaffold materials, though composed of components which are highly conserved across mammalian species, have been demonstrated to elicit a robust immune response, including not only components of the innate immune system but also activation of the acquired immune system [44,45]. These materials, though, have consistently been shown to evoke a more Th2-type T cell response, the occurrence of which is thought to play an important role in the process by which ECM scaffold materials promote constructive remodeling. Briefly, tissue cytokine analysis following ECM implantation in experiments with mice has revealed that the ECM group elicited expression of IL-4 and suppressed the expression of IFN-γ compared to groups receiving xenogeneic tissue implants. The ECM group elicited the production of an ECM-specific antibody response, however it was restricted to the IgG1 isotype. Reimplantation of the mice with another ECM scaffold led to a secondary anti-ECM antibody response that was also restricted to the IgG1 isotype and there was no evidence of the formation of a Th1 type response. Further investigation confirmed that the observed responses were in fact T cell dependent. Several synthetic biomaterials have been shown to elicit strong differential pro-inflammatory Th1 cytokine panels. For example, in a recent study, polyethylene was found to be more pro-inflammatory than a number of other synthetic scaffolds as it induced high levels of Th1 cytokines and chemokines but low levels of pro-wound healing cytokines [46].

It should be noted that both the acquired and innate immune systems are tightly coupled and that activation of the acquired immune system, its direct effects upon the tissue-engineered construct notwithstanding, will also drive an innate immune response. Together, the combined effects of the acquired and innate immune systems will dictate the eventual success or failure of a particular strategy. It is also important to note that, while the present section has focused primarily upon the T cell response to implanted constructs and materials, other responses, including hypersensitivity, immunotoxicity and allergy, may also play an important role in the host's response to implanted constructs [22,34].

The role of macrophages in the host response to tissue-engineered constructs

In general, an intense mononuclear cell reaction is seen within the site of implantation of any biomaterial or tissue-engineered construct within days of placement. This response is both a component of the normal response to the injury created during surgical placement of the construct and a component of the response to the implanted construct itself. Ideally, this response resolves quickly without detrimental effects upon the viability of the construct, its material properties, and its function. To date, prolonged macrophage interactions with biomaterial surfaces have been associated with detrimental effects and the precursor to the foreign body response as described above. Without question, the long-term presence of pro-inflammatory cells can have negative effects upon the ability of the construct to function as intended, especially if this response proceeds to a foreign body type response. However, recently a number of studies have demonstrated that the host macrophage response is an essential component of the remodeling process, which leads to constructive and functional remodeling of implanted constructs.

For example, ECM-based scaffold materials, which have now been shown to promote the formation of site-appropriate and functional host tissues when implanted in a number of preclinical and clinical applications [47–50], elicit a robust mononuclear response by

approximately 2–3 days post-implantation [51,52]. This response, which is histologically indistinguishable from the early stages of a classic chronic inflammatory response, may persist at the site of implantation for a month or more depending upon the application [51,52]; however, the response does not progress to a foreign body response. Rather, functional restoration has been observed to occur as the device degrades [47–49,53–61]. When these same materials are treated with chemical crosslinking agents which prevent their degradation, implantation results in a histologically similar acute response, but results in a markedly divergent outcome compared to the non-crosslinked material [51,62]. That is, implantation of materials which have been chemically crosslinked does not result in constructive remodeling, but rather chronic inflammation and a foreign body reaction. This dichotomous response, in which the same material altered only by the treatment with crosslinking agents results in histologically similar early outcomes but distinctly different outcomes at later time points, suggest phenotypic differences among the host innate immune cells which respond following implantation of a biomaterial.

Macrophage polarization

Initially described in the contexts of the host response to pathogen and cancer immunology, macrophages have been shown to have heterogeneous phenotypes ranging from M1 (classically activated, pro-inflammatory) to M2 (anti-inflammatory, homeostatic, wound healing) [63–68], mimicking the Th1/Th2 pathways as described above. M1 macrophages are activated by well-known pro-inflammatory signals such as IFN-γ and lipopolysaccharide (LPS), produce characteristic pro-inflammatory cytokines such as IL-1β, IL-6, IL-12, IL-23 and TNF-α, have low production of anti-inflammatory cytokines such as IL-10; produce high levels of reactive oxygen species (ROS), are efficient antigen-presenting cells, and cause the formation of inducer and effector cells in the Th1 pathway. In contrast, M2 cells are activated by molecular cues such as IL-4, IL-13, IL-10 and immune complexes; produce high levels of IL-10 and have increased expression of scavenger, mannose and galactose receptors; produce ornithine and polyamines in place of ROS; and are involved in polarized Th2 type reactions. It should be noted that the term M2 macrophage has evolved to encompass virtually all macrophages that do not fit the M1, classically activated, description [67–69]. However, this segregation into two distinct phenotypes is a marked simplification of the *in vivo* reality. Macrophage phenotype is more accurately considered as a spectrum between the M1 and M2 extreme, in which any given cell may express certain components of either phenotype.

Macrophages, unlike T cells, appear to possess remarkable plasticity once activated. M1 to M2, and M2 to M1 phenotype switching have been observed in multiple studies [70–73]. This plasticity likely represents a protective mechanism by which the host can mount an appropriate host response to a given pathogen, but also effectively resolve such a response without excessive local or systemic damage. Dysfunction of macrophage phenotype, and dysfunction of macrophage plasticity in particular, has been proposed as an underlying mechanism of a number of diseases, including cancer, atherosclerosis, insulin resistance, inflammatory bowel disease and fibrosis [18–20,65,74–80]. Macrophage phenotype has also been found to be an important modulator of the tissue remodeling process which occurs following injury in skin, skeletal muscle, cardiac tissue and the central nervous system among others [81–90]. In general, an initial M1 type response is mounted to destroy potential pathogens within the wound site and to debride the wound site of dead cells and damaged tissue. Transition to an M2 phenotype is associated with tissue remodeling resulting in either scar tissue or constructive remodeling as an outcome depending on the timing of the phenotype switch. Prolonged M1 polarization or overly exuberant transition to an M2 phenotype may lead to excessive scarring or a delay in wound healing, respectively. A description of the unique role of macrophage polarization in each of these diseases and tissue remodeling in each of these organs has been reviewed elsewhere [18,74], but it is important to note that an effective and timely switch in macrophage polarization is almost always a key component of a positive outcome.

Implications for tissue engineering and regenerative medicine

This paradigm, when applied to the host response which follows implantation of a tissue-engineered construct, has been shown to have important implications for the ability to promote constructive remodeling. For example, when applied to the host response to ECM scaffold materials, it has been shown that non-crosslinked materials elicit a more M2 type and less M1 type macrophage response than do chemically crosslinked materials [62,91–94]. A recent study which investigated the response to 15 commercially available, ECM-based, bioscaffold materials demonstrated that there were significant effects of the source tissue and methods used in the production of the material upon the ability to support a constructive remodeling outcome when implanted within the abdominal wall of rats. The phenotype of the host macrophage responses to these materials at early time points was a significant predictor of downstream tissue remodeling outcomes associated with their implantation [62].

Similar phenomena have been observed for certain synthetic materials. Recent studies have demonstrated that porous biomaterials of the same composition as those which, in their non-porous form, elicit an FBR and encapsulation heal with less encapsulation and more vascularity when implanted into either the dermis or into cardiac tissues [95–98]. To assess the importance of porosity to healing, a series of materials were made in which pores were spherical, interconnected and of uniform size. It was noted that those materials possessing pores of 30–40 μm healed with minimal fibrosis and the highest vascularity. These pores were also found to be heavily infiltrated by macrophages, but not foreign body giant cells. Further, when compared to the non-porous control, implants with 30–40 μm pores elicited a host response which was characterized by significantly higher ratios of M2/M1 macrophages [97]. Similarly, recent studies have also shown potential modulating effects of biomaterial surface topography upon macrophage polarization [95,99].

Other strategies, which seek to alter macrophage phenotype through the delivery of cytokines, have also met with increasing success in recent studies. For example, when macrophage polarization was modulated using either IFN-γ and LPS or IL-4 within polymeric nerve guidance conduits, divergent outcomes were observed [100]. Polarization of macrophages towards the M2 phenotype was shown to improve outcomes in a critically sized rat sciatic nerve gap defect model. It was further shown that the M2 phenotype is associated with increase Schwann cell chemotaxis and faster axonal outgrowth.

The studies described above are provided as an example of how a greater understanding of the host innate immune system may influence the design criteria for next generation strategies for tissue engineering and regenerative medicine. In particular, an evolving view of cellular plasticity within the innate immune system and increasing evidence which links particular macrophage phenotypes to the success of biomaterials, both for long-term implantation and/or in tissue engineering and regenerative medicine, appear to be crucial considerations in design.

CONCLUSIONS

Regardless of the composition of a tissue-engineered construct, it will undergo interactions with the host immune system which begin immediately upon implantation. These interactions will invariably include components of the host acquired and innate immune system; however, the specific components and their relative importance in determining success or failure will be construct and context dependent. Regardless of the strategy employed, it is unlikely that activation of the host innate immune system can be avoided. Therefore, designs which incorporate an in-depth understanding of the host immune response together with other requisite criteria will likely meet with improved success and downstream functionality.

CHAPTER 26

Tissue Engineering and Transplantation in the Fetus

Dario O. Fauza
Associate Professor, Department of Surgery, Harvard Medical School and Boston Children's Hospital, Boston, Massachusetts

INTRODUCTION

The fetus is, arguably, the ideal tissue-engineering subject, both as a host and as a donor. The developmental and long-term impacts of tissue implantations into a fetus, along with the many unique characteristics of fetal cells, add new dimensions which greatly expand the reach of tissue engineering, to extents unmatched by most other age groups. Indeed, perhaps not surprisingly, attempts at harnessing these prospective benefits started long before the modern eras of transplantation and regenerative medicine. The first reported transplantation of human fetal tissue took place almost a century ago, in 1922, when a fetal adrenal graft was transplanted into a patient with Addison's disease [1]. A few years later, in 1928, fetal pancreatic cells were transplanted in an effort to treat *Diabetes mellitus* [2]. In 1957, a fetal bone marrow transplantation program was first undertaken [3]. All those initial experiments involving human fetal tissue transplantation failed. It was only since the late twentieth century that fetal tissue transplantation in humans has started to yield favorable outcomes. A number of therapeutic applications of fetal tissue have already been explored, with variable results. Although the majority of studies to date have involved simply fetal cell, tissue, or organ transplantation, various engineered open systems using fetal cells have been explored in animal models and their first clinical applications are justifiably expected in the not too distant future.

Fetal tissue has also been utilized as a valuable investigational tool in biomedical science, since the 1930s. Embryologists, anatomists and physiologists have long studied fetal metabolism, feto-placental unit function, premature life support and brain activity in pre-viable fetuses [4,5]. *In vitro* applications of fetal tissue are well established and somewhat common. Cultures of different fetal cell lines, as well as commercial preparations of human fetal tissue, have been routinely used in the study of normal human development and neoplasias, in genetic diagnosis, in viral isolation and culture and to produce vaccines. Biotechnology, pharmaceutical and cosmetic companies have employed fetal cells and extra-embryonic structures such as placenta, amnion and the umbilical cord to develop new products and to screen them for toxicity, teratogenicity and carcinogenicity. Fetal tissue banks have been operating in the United States and abroad for many years as source of various fetal cell lines for research.

Considering that a large body of data has come out of research involving fetal cells or tissues, and that attempts at engineering virtually every mammalian tissue have already taken place, comparatively less has been done on the 'true' engineering of fetal tissue, through culture and

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00026-4

placement of fetal cells into matrices or membranes, or through other *in vitro* manipulations prior to implantation. Controlled human trials of open system tissue engineering have yet to be performed and a relatively small number of animal experiments have been reported thus far. Fetal cells were first used experimentally in engineered constructs by Vacanti et al. [6]. Interestingly, this investigation was part of the introductory study on selective cell transplantation using bioabsorbable, synthetic polymers as matrices. This same group performed another study involving fetal cells in 1995 [7]. Both experiments, in rodents, did not include structural replacement, or functional studies. The use of fetal constructs as a means of structural and functional replacement in large animal models was first reported experimentally only in 1997 [8,9].

This chapter offers an outlook of the infantile field of fetal tissue engineering, along with a general overview of fetal cell and tissue transplantation.

GENERAL CHARACTERISTICS OF FETAL CELLS

Immunological rejection (in non-autologous applications), growth limitations, differentiation and function restraints, incorporation barriers and cell/tissue delivery difficulties are all well known complications of tissue engineering. Many of those problems can be better managed, if not totally prevented, when fetal cells are used. Due to their properties both *in vitro* and *in vivo*, fetal cells are excellent building blocks for tissue engineering.

In vitro

Compared with cells harvested postnatally, most fetal cells multiply more rapidly and more often in culture. Depending on the cell line considered, however, this increased proliferation is more or less pronounced, or, in a few cases, not evident at all. Due, at least in part, to their proliferation and differentiation capacities, fetal cells have long been recognized as ideal targets for gene transfers.

Because they are very plastic in their differentiation potential, fetal cells respond better than mature cells to environmental cues. Data from fetal myoblasts and osteoblasts, and from amniotic mesenchymal stem cells (aMSCs) suggest that purposeful manipulations in culture or in a bioreactor can be designed to steer fetal cells to produce improved constructs. Younger mesenchymal stem cells (MSCs) from mid-gestational fetal tissues are more plastic and grow faster than adult, bone marrow-derived MSCs. MSCs have also been isolated earlier in fetal development, from first-trimester blood, liver, and bone marrow. These cells are biologically closer to embryonic stem cells and have unique markers and characteristics not found in adult bone marrow MSCs, which are potentially advantageous for cell therapy. Fetal MSCs may express Human Leukocyte Antigen (HLA) class I but not HLA class II. The presence of interferon gamma in the growth medium may initiate the intracellular synthesis and cell surface expression of HLA class II, but neither undifferentiated nor differentiated fetal MSCs tend to induce proliferation of allogenic lymphocytes in mixed cultures. Actually, fetal MSCs treated with interferon-gamma typically suppress alloreactive lymphocytes in this setting. These and other data indicate that both undifferentiated and differentiated fetal MSCs may not elicit much alloreactive lymphocyte proliferation, thus potentially rendering these cells particularly suitable for heterologous transplantation.

Fetal cells can survive at lower oxygen tensions than those tolerated by mature cells and are therefore more resistant to ischemia during *in vitro* manipulations. They also commonly lack long extensions and strong intercellular adhesions. Probably because of those characteristics, fetal cells display better survival after refrigeration and cryopreservation protocols when compared with adult cells. This enhanced endurance during cryopreservation, however, seems to be tissue specific. For instance, data from primates and humans have shown that fetal hematopoietic stem cells, as well as fetal lung, kidney, intestine, thyroid and brain tissues can

be well preserved at low temperatures, whereas non-hematopoietic liver and spleen tissues can also be cryopreserved, but not as easily.

In vivo

The expression of major histocompatibility complex (H-2) antigens in the fetus and, hence, fetal allograft survival in immunocompetent recipients is age and tissue specific. The same applies to fetal allograft growth, maturation, and function. At least in fetal mice, the precise gestational time of detection of H-2 antigen expression and the proportion of cells expressing these determinants depend on inbred strain, specific haplotype, tissue of origin and antiserum batch employed. Nevertheless, the precise factors governing the timing and tissue-specificity of H-2 antigen expression are yet to be determined in most species, including humans.

Other mechanisms, in addition to H-2 antigen expression, also seem to govern fetal immunogenicity. For example, at least in certain mammalian species, by catabolizing tryptophan the conceptus suppresses T cell activity and defends itself against rejection by the mother. In humans, fetal cells can be found in the maternal circulation in most pregnancies, and fetal progenitor cells have been found to persist in the circulation of women decades after child birth [10,11]. Interestingly, a certain population of fetal cells, the so-called pregnancy-associated progenitor cells (PAPCs), appears to differentiate in diseased/injured maternal tissue. The precise original phenotypical identity of these cells remains unknown. They are thought to be a hematopoietic stem cell, a MSC, or possibly a novel cell type. What is known is that pregnancy results in the acquisition of cells with stem-cell-like properties that may influence maternal health post-partum, by triggering disease and/or avoiding/combating it.

All these data allow us to suppose that engineered constructs made with fetal cells should be less susceptible to rejection in allologous applications. Xenograft implantations may also become viable, as studies suggest that fetal cells are also better tolerated in cross-species transplantations, including in humans [12–14].

On the other hand, while less immunogenic, some fetal cells may be too immature and functionally limited, if harvested too early. Yet, experimental models of fetal islet pancreatic cell transplantation have shown that, with time, the initially immature and functionally limited cells will grow, develop and eventually function normally. Conversely, however, certain cells, such as those from the rat's striatum, actually function better after implantation if harvested early, as opposed to late in gestation.

Fetal cells may produce high levels of angiogenic and trophic factors, which enhance their ability to grow once grafted. By the same token, those factors may also facilitate regeneration of surrounding host tissues. Interestingly, significant clinical and hematological improvement has been described following fetal liver stem cell transplantation in humans, even when there is no evidence of engraftment. These improvements have been attributed to regeneration of autologous hematopoiesis and inhibition of tumor cell growth promoted by the infused cells, through mechanisms yet to be determined. The under-differentiated state of fetal cells also optimize engraftment, by allowing them to grow, elongate, migrate and establish functional connections with other cells [13].

Applications

Because of all the general benefits derived from the use of fetal cells, along with others specific to each cell line, several types of fetal cellular transplantation have been investigated experimentally or employed in humans for decades now. Clinically, fetal cells have been (mostly anecdotally) useful in a number of different conditions, including: Parkinson's and Huntington's disease; *Diabetes mellitus*; aplastic anemia; Wiskott-Aldrich syndrome; thymic aplasia (DiGeorge syndrome) and thymic hypoplasia with abnormal immunoglobulin syndrome (Nezelof syndrome); thalassemia; Fanconi anemia; acute myelogenous and

lymphoblastic leukemia; Philadelphia chromosome-positive chronic myeloid leukemia; X-linked lymphoproliferative syndrome; neuroblastoma; severe combined immunodeficiency disease; hemophilia; osteogenesis imperfecta; skin reconstruction; acute fatty liver of pregnancy; neurosensory hypoacusis; malaria; and HIV. They have also been applied to treat inborn errors of metabolism, including Gaucher's disease, Fabry's disease, fucosidosis, Hurler's syndrome, metachromatic leucodystrophy, Hunter's syndrome, glycogenosis, Sanfilippo's syndrome, Morquio syndrome type B and Niemann-Pick disease. Experimentally, fetal cell and organ transplantation have been studied in an ever-expanding array of diseases. *In utero* hematopoietic stem cell transplantation is a promising approach for the treatment of a variety of genetic disorders. The rationale is to take advantage of prenatal hematopoietic and immunological ontogeny to facilitate allogeneic hematopoietic engraftment [15–19]. It is an entirely non-myeloablative approach to achieve mixed hematopoietic chimerism and associated donor-specific tolerance. Nonetheless, actual fetal tissue engineering as a therapeutic means has barely begun to be explored, with comparatively few studies being undertaken thus far [8,9,20–44].

FETAL TISSUE ENGINEERING

Vacanti and coworkers were the first to make use of fetal cells in engineered constructs, in the late 1980s [6]. The experiment, in rats, used fetal cells from the liver, intestine and pancreas, which were cultured, seeded on bioabsorbable matrices and later implanted. The fetal constructs were implanted in heterologous fashion and heterotopically, namely in the interscapular fat, omentum, and mesentery, with no structural replacement. They were removed for histological analysis no later than two weeks after implantation. Successful engraftment was observed in some animals that received hepatic and intestinal constructs, but in none that received pancreatic ones.

Only in 1995 was a second study performed, by the same group, involving fetal liver constructs, also implanted in heterologous and heterotopic fashion in rats [7]. Then, fetal hepatocytes were shown to proliferate to a greater extent than adult ones in culture and to yield higher cross-sectional cell area at the implant. As in the first experiment, neither structural replacement, nor functional studies were included.

Fetal constructs as a means of structural and functional replacement, in autologous fashion, in large animal models, were first reported experimentally in 1997 [8,9]. Those studies introduced a novel concept in perinatal surgery, involving the minimally invasive harvest of fetal cells, which are then used to engineer tissue *in vitro* in parallel to the remainder of gestation, so that an infant, or a fetus, with a prenatally diagnosed birth defect can benefit from having autologous, expanded tissue readily available for surgical implantation, in the neonatal period or before birth.

Congenital anomalies

Congenital anomalies are present in 3–4% of all newborns. Those diseases are responsible for nearly 20% of deaths occurring in the neonatal period and even higher morbidity rates during childhood. By definition, birth defects entail loss and/or malformation of tissues or organs. Treatment of many of those congenital anomalies is often hindered by the scarce availability of normal tissues or organs, either in autologous or allologous fashion, mainly at birth. Autologous grafting is frequently not an option in newborns due to donor site size limitations, and the well known severe donor shortage observed in practically all areas of transplantation is even more critical during the neonatal period.

Although yet to be fully explored, several studies utilizing fetal tissue engineering as a means to treat congenital anomalies have already been reported experimentally [8,9,20–44]. So far, these studies have involved different models of congenital anomalies/structural replacements,

involving the skin, bladder, trachea, diaphragm, myocardium, heart valves, blood vessels, chest wall, and craniofacial structures. However, many other anomalies are likely to benefit from this therapeutic principle. The first clinical application of fetal tissue engineering is expected in the near future, pending arguably more stringent regulatory clearances, as perhaps expected for a concept that involves both the mother and the infant, as well as unique immature cells.

Alternative sources of fetal cells

Fetal cells amenable to processing for tissue engineering can be obtained from a variety of sources besides the fetus. These include the amniotic fluid and membrane, placenta, Wharton's jelly, and umbilical cord blood. Although peripheral maternal blood can be a source of fetal cells, their consistent isolation in numbers and phenotypes compatible with tissue engineering remains to be demonstrated. So far, of all these sources, the amniotic fluid and the placenta have been the most appealing clinically, to a large extent because they are the least invasive ones for both the mother and the fetus, also because amniocentesis and chorionic villus sampling are widely accepted forms of prenatal diagnostic screening. This is particularly true for the amniotic fluid, in that a diagnostic amniocentesis is routinely offered to any mother with a fetus in whom a structural anomaly has been diagnosed by prenatal imaging (Fig. 26.1).

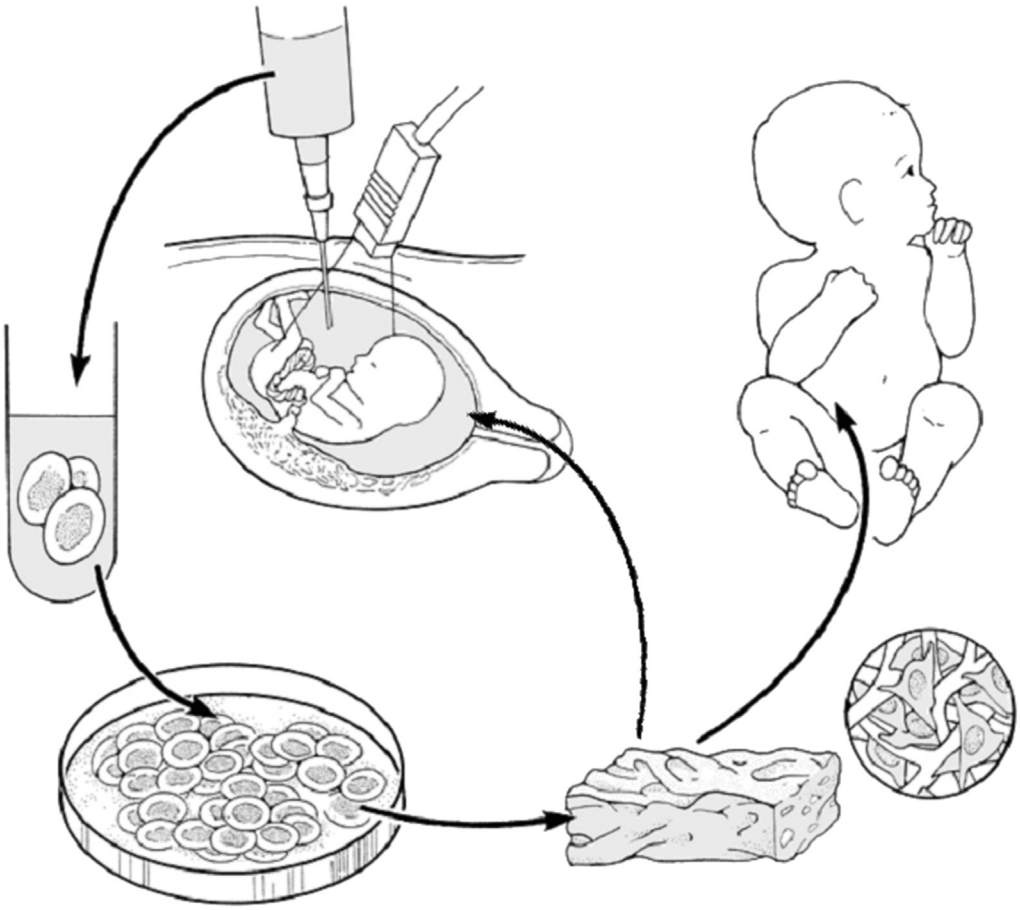

FIGURE 26.1
Diagram representing the concept of fetal tissue engineering from amniotic fluid cells for the treatment of birth defects. A small aliquot of amniotic fluid is obtained from a routine amniocentesis, typically performed when a structural anomaly is diagnosed by routine prenatal imaging screening. Fetal tissue is then engineered *in vitro* from amniotic progenitor cells while pregnancy continues, so that the newborn, or a fetus, can benefit from having autologous, expanded tissue promptly available for surgical reconstruction at birth or *in utero*.

This eliminates any additional risk to the mother and thus expands the ethically sensible range of fetal tissue engineering as a form of perinatal therapy beyond life-threatening structural anomalies.

Many amniotic and placental cells share a common origin: the inner cell mass of the morula, which gives rise to the embryo itself, the yolk sac, the mesenchymal core of the chorionic villi, the chorion, and the amnion. Most, if not all types of progenitor cells that can be isolated from the amniotic fluid and the placenta seem to share many characteristics [45]. However, a common origin of amniotic and placental progenitor cells remains to be unequivocally demonstrated. The full spectrum of cell types that can be obtained from amniotic and placental progenitor cells still has yet to be defined [38]. Moreover, certain fetal pathologic states, such as neural tube and body wall defects, among others, may lead to the availability of cells not normally found in healthy pregnancies, which could become clinically useful [46].

AMNIOTIC FLUID

Embryonic and fetal cells from all three germ layers have long been identified in the amniotic fluid [47–50]. However, the specific origins of many subsets of these cell populations still remain to be determined. The cellular profile of the amniotic fluid varies with gestational age [51]. In addition to the common origin with the mesenchymal portion of the placenta, as mentioned above, the amniotic cavity/fluid receives cells shed from the fetus and, quite possibly, from the placenta as well (although the latter is yet to be definitely confirmed).

The mechanisms responsible for the production and turnover of the amniotic fluid are thought to also determine the cell types present in the amniotic cavity. In the first half of gestation, most of the amniotic fluid derives from active sodium and chloride transport across the amniotic membrane and fetal skin, with concomitant passive movement of water. In the second half, most of the fluid comes from fetal micturition. An additional substantial source of amniotic fluid is secretion from the respiratory tract. Fetal swallowing and gastrointestinal tract excretions, while not voluminous, also play a role in the composition of the amniotic fluid. As a result of such fluid dynamics, cells present in the urinary, respiratory, and gastrointestinal tracts are shed into the amniotic cavity.

Overall, amniotic fluid composition changes predictably throughout gestation. In humans, it is isotonic with fetal plasma in early pregnancy, due to transudation of fetal plasma through the maternal deciduas, or through the fetal skin prior to keratinization, which occurs at approximately 24 weeks. Afterwards and until term, it becomes increasingly hypotonic relative to maternal or fetal plasma. All the variables that play a role in amniotic fluid composition seem to contribute to the changeable profile of its cellular component [51]. Still, much remains to be clarified about the ontogeny of many subsets of amniocytes at any gestational age [45]. This is particularly true before the 12^{th} week of gestation due, to a large extent, to the limitations of performing amniocentesis before that time.

The fact that certain progenitor cells can be found in the amniotic fluid was apparently first reported in 1993, when small, nucleated, round cells identified as hematopoietic progenitor cells were found therein (only) before the 12^{th} week of gestation, possibly coming from the yolk sac [52]. A study from 1996 was the first to suggest the possibility of mutilineage potential of non-hematopoietic cells present in the amniotic fluid, by demonstrating myogenic conversion of amniocytes [53]. That study did not specify the identity of the cells that responded to the myogenic culture conditions, in that case the supernatant of a rhabdomyosarcoma cell line. The presence of mesenchymal cells in the amniotic fluid has been proposed for decades [54,55]. However, the differentiation potential of aMSCs started to be determined only fairly recently [34,37,56–60]. Likewise, the presence of possibly more primitive, embryonic-like stem cells in the amniotic fluid was suggested only in the last few years [59,61–64].

Human amniotic epithelial cells have shown pluripotency, being able to differentiate at least into neural and glial cells, and into hepatocyte precursors. These cells have been employed therapeutically in animal models of cerebral ischemia and spinal cord injury, and as experimental transgene carriers into the liver. However, they are not yet universally considered amniotic fluid cells and will not be further discussed here. Also, given the other, more practical sources of fetal hematopoietic stem cells, other than the difficult pre-12th week amniocentesis, it is unlikely that the amniotic fluid will be a useful option for a source of these cells in clinical practice. Hence, this overview will focus on the mesenchymal and embryonic-like stem cells.

aMSCs

The amniotic fluid is rich in MSCs. We have described a very simple protocol for isolation of these aMSCs, based on mechanical separation and natural selection by the culture medium [28,30,65]. Other protocols for isolating aMSCs have also been described [55,58]. Previous data on amniotic cell culture, without description of the specific nature of the cells grown (possibly predominantly mesenchymal), show that low oxygen tension in the gas phase can be an effective means of enhancing clonal cell expansion. Although not routinely employed, if necessary, molecular HLA typing can be performed on DNA obtained from expanded MSCs, as well as from fetal and maternal blood cells, by polymerase chain reaction/sequence-specific oligonucleotide using a reverse dot blot method, in order to confirm the fetal origin of the cultured cells.

The precise origin(s) of the MSCs found in the amniotic fluid remains to be determined. At first, these cells were thought to be simply shed by the fetus at the end of their life cycle. However, they may actually come from the fetus itself, and/or the placenta, and/or the inner cell mass of the morula, staying viable within the fluid. In no way are aMSCs at the end of their life cycle. Ovine data have shown that amniotic fluid-derived MSCs (aMSCs) proliferate significantly faster in culture than immunocytochemically comparable cells derived from fetal or adult subcutaneous connective tissue, neonatal bone marrow, and umbilical cord blood [28,66]. In humans, the expansion potential of aMSCs exceeds that of bone marrow MSCs [30,57,65]. The phenotype of human aMSCs expanded *in vitro* is similar to that reported for MSCs derived from second-trimester fetal tissue and adult bone marrow [57,66–68].

Human aMSCs have shown not only mesodermal differentiation potential at least into fibroblasts, adipocytes, chondrocytes, osteocytes, and myogenic lineages, after exposure to specific culture conditions (Figs. 26.2 and 26.3) [30,34,57,68,69]. The progenitor nature of these cells imparts the possibility that they could be used to engineer constructs to correct a wide variety of defects. For example, recent large animal studies have shown that the repair of congenital diaphragmatic hernia, tracheal, chest wall and craniofacial defects can be enhanced by the respective use of tendon, cartilaginous/airway, or bone grafts engineered from aMSCs during surgical reconstruction (Figs. 26.4 and 26.5) [24,32,33,37,39,40,43,44]. Another

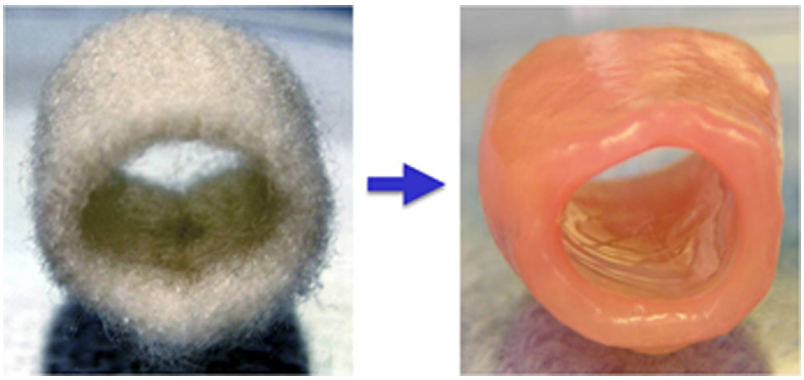

FIGURE 26.2
Representative, cross-sectional view of a 3D cartilaginous tube engineered from aMSCs (right) seeded onto a poly(lactic-co-glycolic acid) scaffold (left), previously maintained in a bioreactor under chondrogenic conditions.

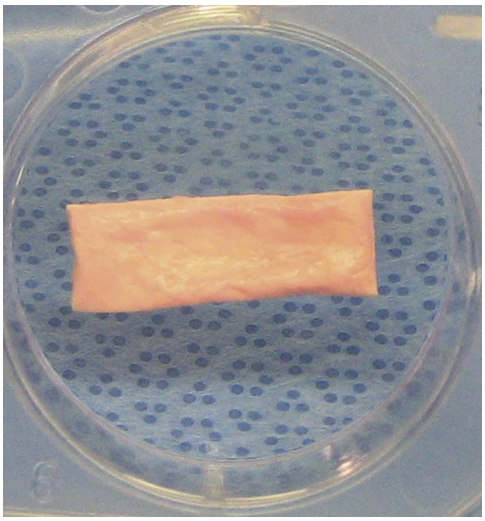

FIGURE 26.3
Representative gross view of a 3D osseous construct engineered from aMSCs seeded onto poly-L-lactic acid electrospun nanofibrous scaffolds, previously maintained in a bioreactor under osteogenic conditions.

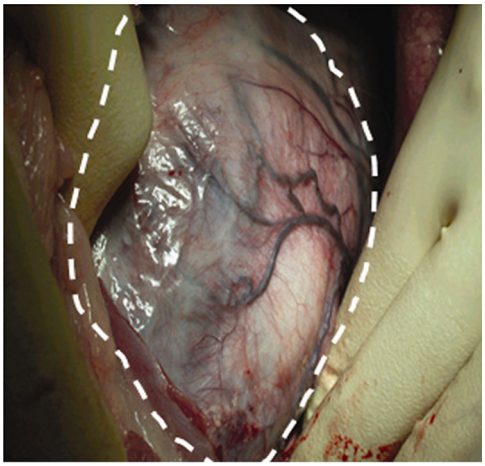

FIGURE 26.4
An intact ovine diaphragmatic tendon seen from the chest, 12 months after autologous repair with an engineered, mesenchymal amniocyte-based construct. The dotted line encircles the area of the graft. *Reproduced, with permission, from 'Kunisaki, S. M., J. R. Fuchs, A. Kaviani, J. T. Oh, D. A. LaVan, J. P. Vacanti, J. M. Wilson and D. O. Fauza (2006). 'Diaphragmatic repair through fetal tissue engineering: a comparison between mesenchymal amniocyte- and myoblast-based constructs.'* J Pediatr Surg **41***(1): 34–9; discussion 34–9'.*

proposed use of an engineered construct based on amniotic mesenchymal (and epithelial) cells is for the repair of premature rupture of membranes during pregnancy, but this has yet to be consistently achieved *in vivo* [70].
