CHAPTER 48

Blood Components from Pluripotent Stem Cells

Shi-Jiang Lu, Erin A. Kimbrel, Qiang Feng, Feng Li and Robert Lanza
Advanced Cell Technology, Inc., Marlborough, Massachusetts

INTRODUCTION

For decades, supplies of transfusable blood components have failed to keep up with increasing demand. This continual shortfall has prompted efforts to develop safe and effective blood substitutes which can be produced from inexhaustible and non-immunoreactive sources and in limitless quantities. This chapter summarizes recent efforts to develop alternative sources for red blood cells, platelets, and various subtypes of white blood cells.

Given their potential to differentiate into any cell type in the body, human embryonic stem cells (hESCs) have been touted as the future of regenerative medicine. Unlike adult stem cells, hESCs are capable of expanding indefinitely in culture without losing their pluripotency, and this makes them an attractive cell source to be used for the large-scale production of a variety of therapeutic cell types [1]. Adding another dimension to the field of regenerative medicine, the advent of human induced pluripotent stem cells (iPSCs) may allow patient-specific therapies to be produced [2,3], thus circumventing potential issues with Human Leukocyte Antigen (HLA) mismatching and immuno-incompatibility. While each has its own advantages and disadvantages, hESCs and iPSCs represent two pluripotent stem cell sources with far-reaching clinical potential in treating neurologic disorders, repairing or replacing damaged tissues, and as detailed here, producing transfusable blood components.

Hematopoietic stem cells (HSCs) located within the bone marrow normally give rise to and are responsible for replenishing all mature cells within the adult blood system. Arising from HSCs, common myeloid progenitor (CMPs) are capable of differentiating into erythrocytes, megakaryocytes/platelets, monocytes, and granulocytes while common lymphoid progenitors (CLPs) eventually produce natural killer, T, and B cells (Fig. 48.1). By differentiating hESCs/iPSCs down particular hematopoietic lineages, researchers have already been able to obtain highly enriched populations of *in vitro* generated blood components. Each of the mature cell types within the blood system can be used for distinct clinical purposes and this chapter will focus on the ability of hESCs/iPSCs to serve as substitutes for primary cells in these endeavors.

RED BLOOD CELLS

Erythrocytes or red blood cells (RBC), the oxygen-carrying component of the blood, are the most plentiful cell type in the peripheral blood and comprise approximately 40–45% of total blood volume with a concentration of 5×10^{12} cells/liter (Fig. 48.1). Despite the body's

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00048-3

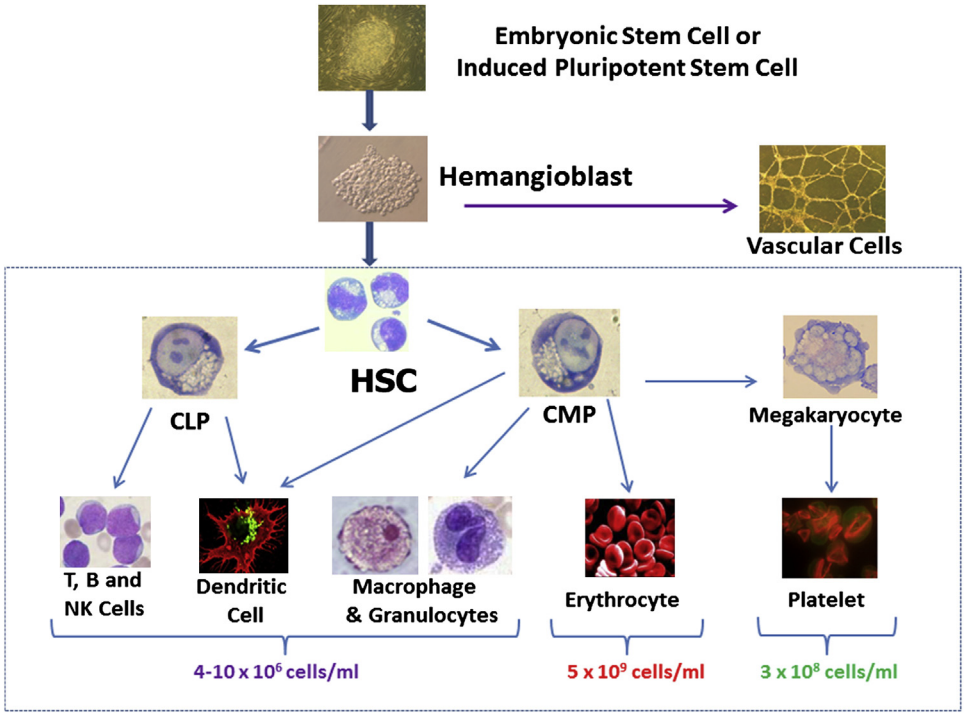

FIGURE 48.1
Simplified schematic of hematopoietic differentiation from human pluripotent stem cells. Human embryonic stem cells and induced pluripotent stem cells are able to recapitulate hematopoietic differentiation *in vitro* after initial differentiation to hemangioblasts, bipotential progenitors for both vascular and hematopoietic lineages. The boxed region shows hematopoietic differentiation as it is thought to occur *in vivo*. Hematopoietic stem cells (HSC) undergo successive stages of differentiation to give rise to progenitor cells in both the myeloid lineage and lymphoid lineage. These progenitors will undergo further differentiation to eventually give rise to mature cells within the peripheral blood. Numbers under each type of cellular blood components are normal cell numbers per milliliter of human peripheral blood.

seemingly abundant capacity to produce RBCs, they are transfused in over half of all anemic patients admitted to intensive care units in the United States [4–6] and it is estimated that nearly 5 million patients receive approximately 16 million units of RBCs per year in the United States alone [7]. Limitations in the supply of RBCs can have potentially life-threatening consequences for patients, specifically for those who have rare or unusual blood types with massive blood loss due to trauma or other emergency situations. Unfortunately, the supply of transfusable RBCs, especially 'universal' donor type (O)Rh$^-$, is often insufficient, particularly in the battlefield environment and/or major natural disasters due to the lack of blood type information and the limited time required for life saving transfusion. Moreover, the low prevalence of (O)Rh$^-$ blood type in the general population (<8% in Western countries and <0.3% in Asia) further intensifies the consequences of blood shortages for emergency situations where blood typing may not be possible. The derivation of (O)Rh$^-$ RBCs from hESCs/iPSCs clearly offers an attractive option for alleviating the constant shortage in donated RBCs.

Erythropoiesis

Erythropoiesis is a highly regulated, multistep process by which the body generates mature RBCs. During mammalian development, erythropoiesis consists of two major waves:

1) Primitive erythropoiesis, which is initiated in the yolk sac with the generation of large *nucleated* erythroblasts, and
2) Definitive erythropoiesis, which arises from the fetal liver with the development of smaller *enucleated* erythrocytes [8].

Definitive erythropoiesis in fetal liver features the production of enucleated RBCs that quickly become dominant in embryonic circulation. The switch of hemoglobin from embryonic ($\zeta_2\varepsilon_2$ and $\alpha_2\varepsilon_2$) to fetal types ($\alpha_2\gamma_2$) also occurs at the initiation of definitive erythropoiesis [9–11]. In the adult bone marrow (BM), definitive erythropoiesis begins when an HSC-derived CMP commits to the erythroid lineage. The appearance of the

pronormoblast (also called proerythroblast or rubriblast) marks the first stage of differentiation and is subsequently followed by early, intermediate, and late normoblast (erythroblast) stages, at which time the nucleus is expelled and the cell becomes a reticulocyte. Upon exiting the BM, reticulocytes enter the circulation to become fully mature RBCs, expressing adult forms of hemoglobin ($\alpha_2\beta_2$) and delivering oxygen to tissues of the body. They circulate for about 120 days before they are engulfed by macrophages and recycled [12].

RBCs from adult stem cells

RBCs can be derived from a variety of primary stem cell sources including umbilical cord blood (CB), peripheral blood (PB) and BM. $CD34^+$ cells from CB, PB and BM have been isolated and differentiated into erythrocytes with high purity after weeks of culture with a combination of cytokines including erythropoietin (EPO), stem cell factor (SCF), and interleukin-3 (IL-3) [13–15]. Co-culturing with mouse MS-5 stromal cells or human mesenchymal stem cells facilitates enucleation, which is the hallmark of mature RBCs, and is likely to impart flexibility and improve the ability to traverse through capillaries that are half the size of erythrocytes. The stem cell-derived erythrocytes have similar properties to normal RBCs, including membrane deformation capacity, intrinsic enzymatic activity, and balanced adult/fetal forms of hemoglobin that can bind and release oxygen. Additionally, these erythrocytes have been found to survive *in vivo* in NOD/SCID mice, being detectable three days after transplantation. Recently, Douay and his colleagues showed that autologous RBCs generated under good manufacturing practice (GMP) conditions from PB $CD34^+$ cells behaved the same as their natural counterparts do when re-infused into the autologous recipient [16]. This first preclinical study provided proof of principle for transfusion of *in vitro* generated RBCs and the necessary safety data that could support an investigational new drug application. Despite their potential utility and substantial *in vitro* expansion using bioreactors [17], however, these primary cells still represent donor-limited sources of blood substitutes.

RBCs from embryonic stem cells

Human embryonic stem cells (ESCs) represent an alternative stem cell source for generating blood components, one whose capacity for expansion far exceeds that of BM, PB, or even CB. Two different *in vitro* differentiation methods have been widely used to generate RBCs from hESCs:

1) Embryoid body (EB) formation whereby hESCs are initially allowed to cluster and form three-dimensional spheres prior to creating single cell suspensions; or
2) Co-culturing hESCs on top of animal stromal feeder cell layers.

While somewhat different in approach, both systems have encountered the same obstacles in generating fully mature adult RBCs. For example, Chang et al. generated erythroid cells from hESCs by isolating and expanding non-adherent cells of day-14 EBs for an additional 15 to 56 days [18]. The resulting cells co-expressed high levels of embryonic ε- and fetal γ-globins but little or no adult β-globin. In addition, the cells had not enucleated. In other studies, Olivier et al. [19] and Qiu et al. [20] used sequential stroma co-culture steps with FHB-hTERT human fetal liver stromal cells and mouse MS5 cells from 2 to 5 weeks to produce hESC-derived erythrocytes. Despite their careful multistep approach and relatively large yields (0.5 to 5×10^7 cells), the resulting cells had similar problems to those generated by the EB method; they mainly expressed embryonic (ε) and fetal (γ) globin isoforms, with only a limited amount of adult β-globin being detectable [19,20]. Despite these reports, other studies suggests that specific types of stroma can, in fact, facilitate the expression of adult β-globin in developing erythrocytes. Using immunostaining with globin chain specific monoclonal antibodies, Ma et al. showed that almost 100% of hESC-derived erythrocytes expressed the adult β-globin chain after co-culture with murine fetal liver derived stromal cells (mFLC) [21], however the β-globin content and identity was not verified by an accurate

physical method such as HPLC or mass spectrum. Yet, the majority of the cells still had not enucleated, a problem that does not seem to have an easily explainable mechanism or simple solution.

Not only must *in vitro* generated RBC substitutes be fully matured and enucleated to use in the clinic, but they must also be capable of large-scale production. Related to this issue, we recently developed a strategy that efficiently and reproducibly generates functional hemangioblasts (the common precursor cell to all hematopoietic and endothelial cell lineages) using a serum-free culture system and have been able to do so with high purity (>95%) and in a relatively large scale [22,23]. Using the hemangioblast system, we have generated functional RBCs (blood types A, B, O, and both RhD^+ and RhD^-) on a large scale from multiple hESC lines (Fig. 48.2), approximately 10^{10} to 10^{11} erythroid cells were generated from a single six-well plate of hESCs [24], which is over a thousand-fold more efficient than previously reported methods [19,20]. Oxygen equilibrium curves of hESC-derived erythroid cells were comparable to normal transfusible RBCs and responded to changes in pH and 2,3-diphosphoglyerate (Fig. 48.2). During the course of our studies, we found that extended *in vitro* culture facilitated further maturation of these erythroid cells, including a progressive decrease in size, increased expression of the erythrocyte cell surface marker, glycophorin A (CD235a), as well as chromatin and nuclear condensation. When the extended culture was performed on OP9 stromal cells, it resulted in the extrusion of the pycnotic nucleus in up to 65% of cells and the generation of enucleated erythrocytes with a diameter of approximately 6–8 μm, similar to their natural counterpart. At this stage, the erythrocyte population is nearly 100% positive for glycophorin A, has a very high content of hemoglobin, and expresses ABO antigen. Although the cells were found to express fetal and embryonic globin chains, globin chain specific-PCR and immunofluorescent analyses showed that after extended culture, expression of adult β-globin increased from 0% to 15%. Overall, these results show that it is feasible to differentiate and mature hESCs into functional oxygen-carrying erythrocytes on a large scale. The identification of a hESC line with a $(O)RhD^-$ genotype would permit the production of ABO and RhD compatible (and pathogen-free) 'universal donor' RBCs [24]. While considerable effort is still needed to bring hESC-derived RBCs to clinical trials, these efforts certainly provide a promising lead.

RBCs from induced pluripotent stem cells

The successful reprogramming of somatic cells into a pluripotent state has been achieved by ectopic expression of various combinations of transcription factors such as Oct4, Sox2, Klf4, c-Myc, LIN28 and Nanog cells [2,3]. The derivation of these iPSCs is less controversial than that of hESCs and thus, they open up an exciting new route to obtain pluripotent stem cells. Moreover, the fact that iPSCs can be produced in a patient-specific manner will eliminate the issue of immuno-rejection in cell, tissue, or organ replacement therapies in the future. A number of groups including our own have published methods for generating RBCs from iPSCs [25–34]. These erythrocytes possess classic morphology, express glycophorin A, and have abundant hemoglobin content. As observed in the hESC differentiation systems, regardless of their origin, iPSCs generate RBCs expressing mostly fetal hemoglobin (hemoglobin F). RBCs expressing hemoglobin F are slightly less efficient than those expressing adult hemoglobin for oxygen delivery. However, patients who retain expression of hemoglobin F in adult life are not anemic. Thus, the fetal phenotype of RBCs derived from iPSCs derived from patients with hemoglobinopathies is not necessarily a barrier for autologous transfusion. The majority of the cells derived from iPSCs consisted of ortho-chromatic erythroblasts, enucleated RBCs accounted for less than 10% of the culture. Thus, there is a long way to go in terms of achieving 100% enucleation *in vitro*.

However, our study revealed some intrinsic molecular and cellular abnormalities in the iPSC derivatives, such as increased apoptosis, limited CFU capability and limited expansion [34].

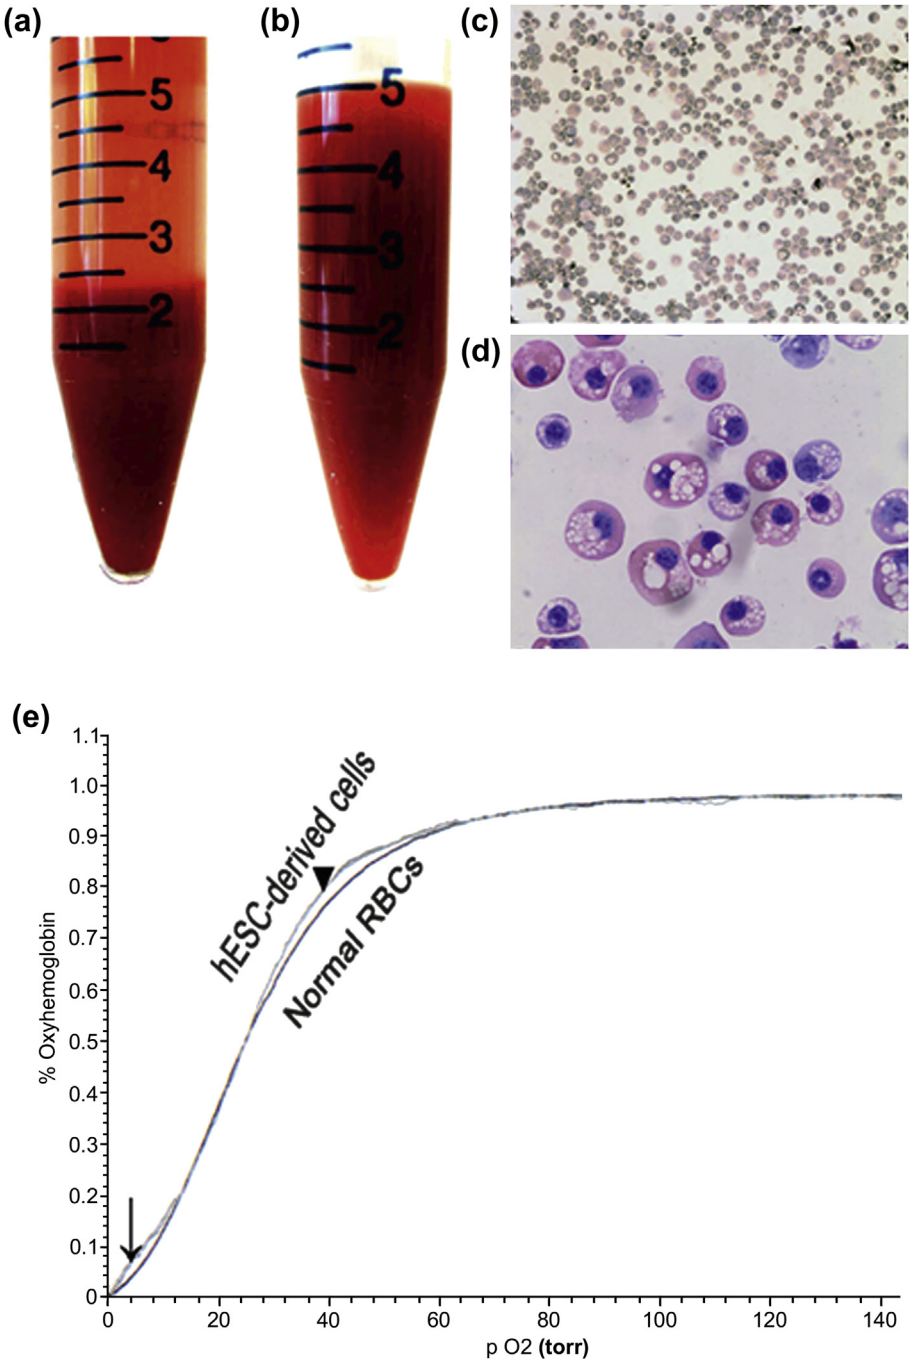

FIGURE 48.2
Large-scale production of erythroid cells from hESCs. (a) Erythroid cells (pellet) derived from 2×10^6 hESCs; (b) Erythroid cells from panel a were resuspended in equivalent hematocrit of human whole blood; (c,d) Morphology of erythroid cells derived from human ESCs (c, ×200; d, ×1000); (e) Functional characterization of hESC-derived erythroid cells. Oxygen equilibrium curves of normal human erythrocytes and human ESC-derived erythroid cells. The two curves are virtually indistinguishable at their midpoints, whereas the curve of human ESC-derived erythroid cells is leftward shifted at low (→) and high (▼) oxygen saturation percentages. *(This research was originally published in Blood. Lu et al. Biologic properties and enucleation of red blood cells from human embryonic stem cells, Blood 2008; 112:4475—4484. © the American Society of Hematology.)*

The exact cause(s) of these abnormalities is unclear at this time but may be due to alterations caused by the modified genome of virally reprogrammed cells. In spite of transgene silencing after reprogramming, Dias et al. [28] reported a background of transgene expression in differentiated cells obtained from transgenic hiPSCs and showed that it can affect their properties. However, these authors observed no difference in erythroid differentiation between transgene-free and transgenic hiPSC lines. Our recent data showed that viral-free hiPSCs have much improved hemangioblast and erythroid lineage capability than hiPSCs carrying viral DNA. The hemangioblast colonies derived from viral-free iPSCs displayed healthy morphology, large colony size comparable to hESC-derived hemangioblasts, and solid further expansion capability. Upon further erythroid differentiation, a relative large quantity of RBCs

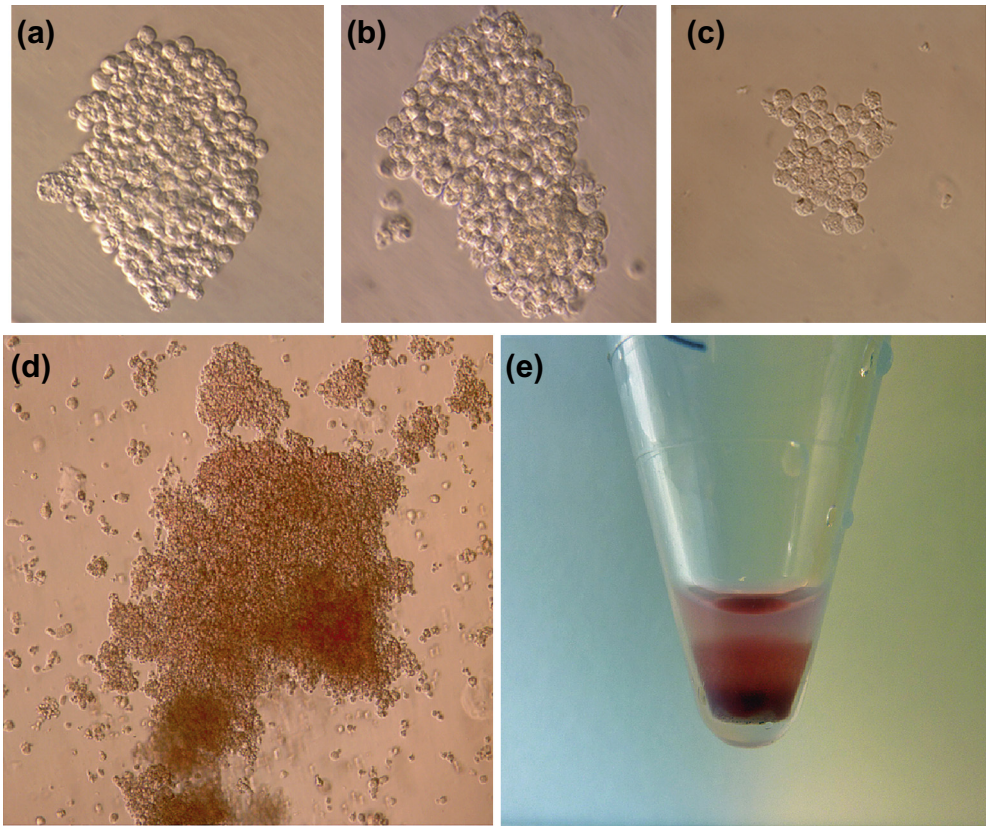

FIGURE 48.3

Transgene-free iPSCs show comparable hematopoietic differentiation capability as hESCs. (a) Hemangioblast colony derived from hESCs (×400); (b) hemangioblast colony derived from transgene-free iPSCs (×400); (c) hemangioblast colony derived from transgenic (viral-integrated) iPSCs (×400); (d) CFU-E from transgene-free iPSCs; (e). Erythrocytes from transgene-free iPSCs.

was obtained from these viral-free iPSCs (Fig. 48.3). More research will be needed to figure out the mechanism underlying the disparate observations.

Another new approach for RBC generation involves the direct differentiation of human fibroblasts to multipotent hematopoietic progenitors, thus bypassing the need for pluripotent stem cells like hESCs or iPSCs altogether [35]. In this study, Szabo et al. used ectopic Oct4 to transdifferentiate fibroblasts directly to $CD45^{+}$ hematopoietic progenitors, and by exposing them to EPO, were able to produce erythroid lineage cells that expressed high levels of adult β-globin, low levels of fetal γ-globin, and were capable of enucleation [35]. Further investigation will be required to determine which starting cell source, hESCs, iPSCs, or Oct4-transduced fibroblasts, will be the most useful for the development of *in vitro* generated RBC substitutes.

The manufacture of safe and effective red blood cell substitutes will help alleviate many of the risks, complications, and hardships associated with donor dependent RBC sources. As summarized here, significant progress has been made towards this end by manipulating the differentiation potential of hESCs and iPSCs and driving them towards erythrocyte development. *In vitro* differentiation systems that can be scaled-up for mass production of RBC substitutes have already been developed and the hemangioblast methodology described in this chapter represents one such possibility. Despite many exciting advances with *in vitro* culture systems, problems associated with the final stages of erythrocyte maturation, namely enucleation and globin switching will still need to be fully resolved before hESC/iPSC-derived RBCs can be produced in a stroma-free manner, scaled-up for mass production,

and brought to the clinic. Another obstacle for application of these methods is that they require very high cost to produce sufficient number of RBCs that are applicable in the clinic.

MEGAKARYOCYTES AND PLATELETS

Platelets (thrombocytes), anucleate discoid-shaped cell fragments, are generated from large (50 to 100 μm in diameter) multinucleated (up to 128 N) megakaryocytes (MK). Given their central role in hemostasis (the stoppage of blood loss at sites of vascular injury) and vascular repair, it is no surprise that platelets are incredibly abundant in the peripheral blood. With a concentration of $\sim 3 \times 10^{11}$/liter, their levels are second only to those of RBCs (Fig. 48.1). However, compared to RBCs, platelets have a rather short life span, lasting only 7–9 days in the circulation. Given their high rate of turnover, a serious condition called thrombocytopenia (platelet counts are $<50 \times 10^3$/μl) can occur if platelet production is somehow defective as in patients with liver failure or leukemia, or if platelets are being destroyed, as in patients undergoing chemotherapy. Platelet transfusions can be given to those suffering from life-threatening thrombocytopenia but, due to high demand and limited shelf life, transfusable platelets are often in short supply [36]. Furthermore, refractoriness occurs in approximately one out of every three patients who require repeated platelet transfusions [37,38] and while both immunological and non-immunological complications may be to blame, HLA alloimmunization is the primary cause of refractoriness [7,38]. Over the past few decades, a steady increase in demand for platelets in combination with their limited shelf life has presented a constant challenge for blood centers and donor dependent programmes. Scientists and clinicians have become increasingly interested in developing alternative sources, like pluripotent stem cells, for functional transfusable platelets.

Megakaryopoiesis and thrombopoiesis

Megakaryocytes, the precursor of platelets, provide a constant source of platelets to the blood system and are themselves produced through a process called megakaryopoiesis. As with RBCs, MKs are generated through the initial differentiation of HSCs into CMPs. Progressive commitment of CMPs to the megakaryocyte lineage is principally regulated by thrombopoietin (TPO). The maturation of megakaryocyte involves an increase in expression of the cell surface markers, GPIIb/IIIa (also known as CD41 or αIIb/βIII integrin receptor) and GPIb/GPIX/GPV receptors and a substantial increase in cell mass (50 to 100μm in diameter), which results in cytosolic accumulation of α granules, dense bodies, and platelet-associated proteins like von Willebrand factor (vWF) and platelet factor-4 [39,40]. Several rounds of endomitosis lead nuclear polyploidization and cells with up to 128N in DNA content [41,42]. Once polyploid MKs are produced, cellular processes on the MK body called 'proplatelets' begin to appear, with their eventual fragmentation and release resulting in the generation of platelets. On a molecular level, thrombopoiesis is a highly coordinate process, with sophisticated reorganization of membrane and microtubules and precise distributions of granules and organelles [43]. Despite the mechanism of platelet generation from MKs is not completely understood, it appears to be extremely efficient *in vivo*, with 2,000–10,000 platelets being produced per MK [44,45].

Megakaryocytes/platelets from adult stem cells

In theory, megakaryopoiesis and thrombopoiesis can be performed *in vitro*, the first evidence of which was reported in 1995 using CD34+ HSCs [46]. Matsunaga et al. [47] used an *in vitro* culture system to demonstrate the feasibility of producing functional platelets for clinical use. A 3D culture system described by Sullenbarger et al. [48] provides additional evidence that it is possible to produce platelets in scalable quantities. Platelets generated from these studies demonstrated aggregation capacity when stimulated with either ADP or thrombin, the physiological agonists for normal blood platelets. Subsequent studies have shown that

HSCs from PB, BM, and CB are also capable of producing megakaryocytes and functional platelets [49–51]. Yet, the limited *in vitro* expansion capabilities of primary $CD34^+$ cells make these cells unable to replace donation as a source of platelets. For this reason, hESCs may be a better starting cell population for large-scale *in vitro* production.

Megakaryocytes/platelets from embryonic and induced stem cells

The first study to report the *in vitro* production of MKs from hESCs was published in 2006 using an OP9 co-culture method [52], yet the MKs rarely generated any proplatelet-like structures. Since then, one group has reported the successful generation of both MKs and functional platelets from hESCs and, more recently, from iPSCs [53,54]. In these studies, Takayama et al. co-cultured hESCs or iPSCs on C3H10T1/2 stromal cells for 14–15 days, then handpicked sac-like structures containing hematopoietic progenitors and replated single cell suspensions onto fresh stroma in medium containing TPO, stem cell factor (SCF), and heparin for 9–23 days. During this time, polyploid, CD41a/CD42b double positive MKs emerged and produced platelets containing characteristic morphology, as assessed by electron micrography [53]. A variety of *in vitro* tests confirmed platelet functionality, while in their most recent study, a laser-induced vascular injury model was used to show that their iPSC-derived platelets readily incorporate into newly developing thrombi *in vivo* [54].

The use of both serum and animal feeder layers throughout the above mentioned studies hinders the ability of these methods to be adapted for clinical use. Additionally, as hand-picking of sac-like structures is both time- and labor-intensive, alternative methods will likely have to be developed for large-scale production. Towards this end, we have been able to use the hemangioblast system described above for RBC, as an alternative, serum- and feeder-free method for the generation of MKs [55]. Yet, similar to Takayama's studies, we also found that efficient platelet generation from MKs still requires conventional stroma co-culture. Differential-interference contrast and electron microscopy analyses showed ultrastructural and morphological features of hESC-derived platelets were indistinguishable from those of normal blood platelets. In functional assays, hESC-derived platelets adhered to and spread on fibrinogen, vWF, and type I collagen-coated surfaces in respond to thrombin stimulation, formed micro-aggregates, and facilitated clot formation/retraction when stimulated with physiological agonists. Live cell microscopy demonstrated that hESC-platelets formed lamellipodia and filopodia in response to thrombin activation, and tethered to each other as observed in normal blood. Importantly, fluorescence intravital microscopy studies demonstrated that hESC-derived platelets incorporated into developing mouse platelet thrombi at sites of laser-induced arteriolar wall injury in a manner and degree similar to that observed for normal human blood platelets, providing the first evidence for *in vivo* functionality of hESC-derived platelets [55] (Fig. 48.4).

The studies described above provide an important proof of principle for the *in vitro* manufacturing of functional platelets from hESCs/iPSCs, yet the efficiency of platelet production will need to be significantly improved in order to achieve clinically relevant yields. Using animal stromal cells for *in vitro* platelet generation from hESCs/iPSCs is another major obstacle for clinical translation. Our recent studies demonstrated that MKs generated from hESCs or iPSCs can efficiently produce functional platelets without animal stromal cells, which should be beneficial for future applications. Considering the optimal *in vivo* capacity of megakaryocyte development from HSCs and platelet production from megakaryocytes, both the initial hematopoietic amplification stage and downstream platelet biogenesis could stand to be optimized. Strategies to increase the efficiency of megakaryocyte/platelet production include the development of novel culture systems that mimic the *in vivo* BM microenvironment as well as the optimization of media formulations and concentrations of cytokines, small molecule mimetics, and nutrients. For instance, TPO receptor agonists such as YM477, AMG531 have been found to enhance megakaryopoiesis and thrombopoiesis [56,57].

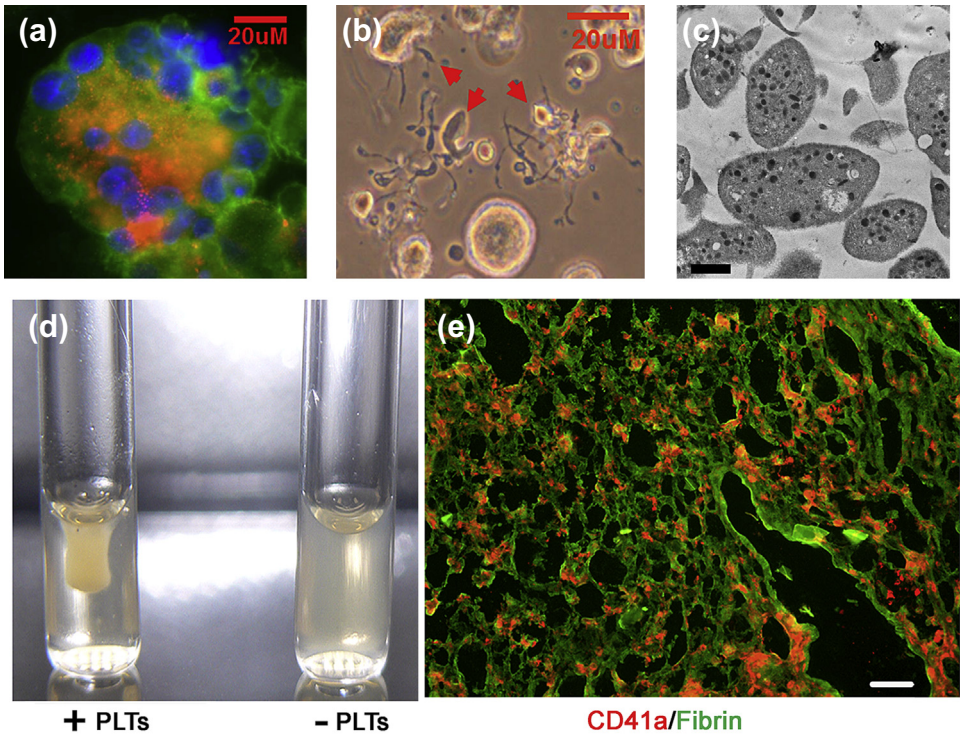

FIGURE 48.4

Generation and characterization of megakaryocytes (MKs) and platelets derived from hESCs. (a) Immunofluorescence of von Willebrand factor (vWF, red) and CD41 (green) proteins in MKs derived from hESCs. vWF is localized in the cytoplasm in a punctate pattern, which is typical for MKs. CD41 is expressed on the surface. DAPI (blue) stain shows polynuclei (polyploidy); (b) Phase contrast image of proplatelet forming MKs derived from hESCs; (c) Thin-section transmission electron microscopy of platelets generated from hESCs, Bar = 1 μm; (d) *In vitro* functional characterization of platelets generated from hESCs. Platelet-depleted human plasma was added with (+PLTs) or without (−PLTs) hESC-platelets (1.5×10^7/ml), and thrombin (2 U/ml) and $CaCl_2$ (10 mM) were then added to the suspensions to induce clot formation/retraction. No clot formation/retraction was observed without addition of hESC-platelets (−PLTs); (e), Clot cryo-sections were stained with anti-human CD41 (red) and anti-human fibrin (green) antibodies. Images were taken under a fluorescence microscope. Bar = 50 μm. *(This research was originally published in Cell Research. Lu et al, Platelets generated from human embryonic stem cells are functional* in vitro *and in the microcirculation of living mice, Cell Res. 21:530–545, 2011. © IBCB, SIBS, CAS.)*

In addition, physiological parameters such as pH, media viscosity, and oxygen levels may all be optimized for increased platelet biogenesis. Lastly, *in vivo* observations which helped formulate the proplatelet model of platelet biogenesis suggest that shear force could play an important role in platelet release [43,58]. Adaptation of such mechanical force in culture systems may also significantly promote proplatelet growth and platelet release.

WHITE BLOOD CELLS

Dendritic cells

Even though white blood cells (WBCs or leukocytes) only represent about 1% of the cells within the peripheral blood (Fig. 48.1), they play extremely important roles in protecting the body against viruses, bacteria, and the outgrowth of cancer cells. Straddling the interface between innate and adaptive immunity, dendritic cells (DCs) are one of the body's three main types of professional antigen-presenting cells (APCs). Clinically, DCs may be used in the development of vaccine-based therapies in order to stimulate specific T cell responses against a variety of disease-associated antigens [59,60]. Originating from HSCs, human DCs can develop through both myeloid and lymphoid lineage differentiation pathways. Myeloid (m) DCs arise from monocytes, secrete IL12 in response to activating stimuli, and express toll-like

receptors TLR2 and TLR4 (Fig. 48.1). Lymphoid lineage-derived DCs (plasmacytoid (p) DCs) have similar functional characteristics to mDCs, but secrete IFNα, and express TLR7 and 9 [61]. Once in contact with a suitable antigen, immature DCs become activated and undergo the process of maturation, which involves proteolyzing an antigen and presenting its fragments on the DC surface using MHC class I or II molecules for $CD8^+$ or $CD4^+$ T cells to recognize, respectively.

Innovative work performed in the late 1990s provided the proof of concept for clinical use of DCs as studies showed that *ex vivo* generated DCs (from allogeneic or autologous BM or PB sources) could be loaded with melanoma-specific antigens and stimulate anti-tumor immune responses once injected into patients [62,63]. Since then, other studies have shown that DCs exposed to whole killed tumor cells can also elicit specific cytotoxic CD8+ T cell responses [64]. Currently, over 200 clinical trials are underway to explore the safety and efficacy of DC-based vaccines for diseases such as melanoma, multiple myeloma, type I diabetes, HIV, and hepatits C viral infections (www.clinicaltrials.gov). In April 2010, Provenge (Silpuleucil T, developed by Dendreon) became the first DC-based vaccine therapy to gain full Food and Drug Administration (FDA) approval and is a treatment option for patients with metastatic castration-resistant prostate cancer [65]. Given the high cost of tailor-made autologous or allogeneic DC-based vaccines like Provenge, hESCs may serve as a cost-effective alternative cell source for the derivation and large-scale manufacture of antigen-primed DCs.

By applying methods established in the mouse ESC system, Slukvin et al. [66] were the first group to produce functional DCs from hESCs. They used a three-step differentiation method involving an initial OP9 stroma co-culture followed by two successive liquid culture steps and a purification procedure. A few other studies have since reported the generation of hESC-derived myeloid-lineage DCs using EB formation and have done so in a serum-free or serum- and feeder-free manner [67–69]. These hESC-derived DCs had characteristic large eccentric nuclei, spiny dendritic processes, and expressed DC surface markers CD11c, CD40, CD45, CD86, HLA class I, and HLA class II to varying degrees. Reported yields ranged from 2 DCs per hESC in one study [67] to 3–5 DCs per hESCs in a more recent study [68]. Our laboratory has similarly been able to produce both hESC-and iPSC-derived DCs with characteristic morphological features (Fig. 48.5). Despite subtle differences compared to monocyte-derived DCs, hESC-derived DCs produced in these studies and in our own lab appear to be functional upon maturation in assays measuring IL12p70 secretion, chemotaxis, antigen-uptake and proteolysis, induction of T cell proliferation, and stimulation of antigen-specific cytotoxic CD8+ T cell responses [67,68] (and unpublished data). Importantly, rigorous preclinical animal studies will still be needed before hESC-DCs can be further developed for clinical use.

Natural killer cells

Arising from HSC-derived CLPs, human natural killer (NK) cells comprise approximately 1−2% of peripheral blood lymphocytes, or 0.01−0.02% of all cells in the PB and circulate for about 2−4 weeks [70]. Belonging to the innate immune system, they provide rapid, non-specific responses against various microbial infections and contribute to tumor cell detection and elimination [70]. NK cells mount a protective response if they encounter a cell with insufficient MHC I expression, yet, to prevent inappropriate cell killing, the process for surveying MHC I expression is rather complex. In brief, if a cell lacks sufficient self MHC I molecules, interplay between various activating and inhibitory signals help NK cells mount an appropriate protective response, being either cytokine release, natural cytotoxicity, or antibody-dependent cellular cytotoxicity (ADCC). $CD56^{bright}$, $CD16^{low}$, KIR^{low}, CD94- immature NK cells are the principal cytokine secretors while $CD56^{dim}$, $CD16^{high}$, KIR^{high}, $CD94^{+}$ mature NK cells are largely responsible for cytotoxicity responses [71].

Groundbreaking work in the 1980s by Rosenberg and colleagues stimulated considerable interest in and a variety of approaches for harnessing the cytotoxic capabilities of NK cells [72,73]. While the details of these studies are reviewed elsewhere [74], *ex vivo* stimulation and infusion of autologous or allogenic NK cells have now been used in experimental therapies for many different types of cancers with variable efficiency. With many improvements being made to clinical protocols over the years, over 200 clinical trials are currently being performed to evaluate the safety and efficacy of NK cell-based immunotherapy for leukemia, lymphoma, melanoma, glioma, renal cell carcinoma, and cancers of the breast, pancreas, lungs, head and neck (www.clinicaltrials.gov). The biggest hindrance to these adoptive transfer approaches thus far appears to be the difficulty in obtaining sufficient numbers of NK cells from peripheral blood mononuclear or lymphokine activated killer cell collections.

The use of hESCs for *in vitro* generation of NK cells may provide larger pools of suitable effector cells and thus may be able to overcome this hurdle. However, only one group, led by Dan Kaufman at the University of Minnesota has been able to successfully and reproducibly derive functional NK cells from hESCs [75,76]. Their optimized two-step differentiation procedure begins by co-culturing undifferentiated hESCs on M210-B4 stroma for 17−20 days, at which time, CD34+/CD45+ double positive cells, which represent <5% of all cells, are isolated from the culture and transferred onto AFT024 stroma in medium containing SCF, FL, IL7, and IL15. After 30−35 days total, a highly enriched homogenous population of $CD45^{+}CD56^{+}CD94^{+}$ NK cells emerge. *In vitro* assays showed they are capable of secreting IFNγ in response to IL12/IL18 stimulation, and also display potent natural cytotoxicity against K562 erythroleukemia cells and ADCC against Raji cells [75]. These hESC-NK cells were subsequently shown to harbor natural cytotoxicity against other types of cancer cells and displayed *in vivo* anti-tumor activity in a xenograft mouse model [76]. More recently, this same group has been able to successfully produce functional NK cells from iPSCs and shown that they harbor anti-HIV activity [77]. Despite these exciting findings, the requirement for two different types of stroma co-culture as well as the need to isolate rare CD34/CD45 double positive cells limits the utility of this approach for large-scale, cost-effective, clinical grade production of hESC/iPSC-generated NK cells. Further optimization will need to be performed before such hESC/iPSC-derived NK therapies can move into clinical trials.

T cells

As part of the adaptive immune system, T cells develop in the thymus and can be stimulated to mount antigen-specific immune responses against a variety of pathogens and cancer cells. They are present at a concentration of $\sim 1 \times 10^{9}$ cells/liter of peripheral blood, thus representing ~10% of WBCs or 0.1% of all circulating cells (Fig. 48.1). While a detailed background on T cell biology is beyond the scope of this article, T cells can generally be divided into six main subtypes based on function and cell surface marker expression: helper $CD4^{+}$ T

cells; cytotoxic $CD8^+$ T cells; long-lived $CD4^+$ or $CD8^+$ memory T cells; immunosuppressive regulatory T cells (Tregs); skin, gut, or lung-resident γδ T cells; and rare, CD1d-restricted NK T cells.

Clinical interest in T cells as therapeutic agents largely revolves around the isolation and *ex vivo* expansion of specific antigen-responsive helper and/or cytotoxic T cell subsets in order to generate a highly-specific immune response once infused into a patient. $CD4^+$ helper T cells will secrete particular cytokines in response to MHC II-presented antigens while $CD8^+$ cytotoxic T cells will respond to MHC I-presented antigens and unload cytotoxic enzymes to induce apoptosis in antigen-expressing target cells. Adoptive T cell therapy (ACT) was first described in 1988 as a treatment option for melanoma [78] and since then, many improvements have been and are still being made to increase the utility, safety, and efficacy of ACT protocols [79–81]. The risks and complexities involved in exploiting the adaptive immune system make T cell-based therapies incredibly expensive and still largely experimental. However, the power of ACT is large enough to warrant efforts that might be able to streamline or make the therapy more cost-effective. Towards this end, several groups have devised protocols to differentiate T cells from pluripotent human cell sources.

In 2006, the first report that hESCs could be differentiated into T cells was published [82]. In it, Galic et al. [82] cultured H1 hESCs on regular OP9 cells for 7–14 days whereupon, CD34+ cells were isolated and injected into a Thy/Liv implant within SCID or $RAG2^{-/-}$ mice. Within the thymus-like environment of the implant, the hESC-derived cells were found to differentiate into T cells [82]. Three years later, Galic et al. [83] switched to an EB-based method and noted improvements in the Thy/Liv generated hESC-derived T cells. By four weeks, CD4/CD8 double positive cells began to appear and by eight weeks, CD4 single positive and CD8 single positive cells that had undergone TCR rearrangements also emerged [83]. Another study published in 2009 was able to achieve mature T cells using a completely *in vitro* culture system [84]. Timmermans et al. [84] began their T cell differentiation protocol by co-culturing H1 hESCs on OP9 cells in αMEM plus 20% fetal calf serum. Similar in nature to the ES sacs described for megakaryocyte generation, they described the appearance of 'hematopoietic zones' in the cultures. After 12 days, they isolated $CD34^{hi}CD43^{lo}$ cells and replated them onto delta 1 (DL1)-expressing OP9 cells for five to seven weeks in the presence of FL, SCF, and IL7. After 14 days, they observed the emergence of CD4/CD8 double positive cells within a larger $CD3e^+$ $CD5^+$ population and after 30 days, noted the presence of $CD3^+$ T cells that had undergone TCR rearrangements. These hESC-derived T cells were found to be functional in assays examining their PHA-induced proliferation and IFNγ production [84]. In total, these hESC-based differentiation protocols for T cell generation show great potential to be further developed for use with iPSCs and one day, will hopefully be applicable to ACT protocols for human immunotherapy.

Granulocytes

Other leukocyte populations, including granulocytes (neutrophils, eosinophils, basophils) may have utility as hESC-based therapies, however interest in and/or development of these cell populations has not been as great as for other cell types. For granulocytes, the expense and/or difficulty in bringing hESC-based therapies to the clinic may not be warranted. For example, neutrophils are chemotactic phagocytes that migrate to sites of infection and provide protection against bacteria. Neutropenia (neutrophil counts less than 5×10^8 cells/liter) can cause an afflicted individual to be at higher risk for developing infections. While allogeneic neutrophil transfusions were shown to alleviate the risk of infections over thirty years ago, the use of antibiotic, antiviral, and/or antifungal therapies have largely replaced them in the clinic.

Nonetheless, hESCs can be induced to differentiate into neutrophils, as shown by two studies published in 2009 [85,86]. Both studies used KhES-C hESCs in an EB-based method to

generate $CD11b^+$ neutrophils that expressed varying levels of other neutrophil cell surface markers. While hESC-derived neutrophils were noted to be slightly larger than those in the peripheral blood [86], they were found to be functional in three *in vitro* assays assessing chemotaxis, phagocytosis, and production of reactive oxygen species [85,86]. One study also showed *in vivo* chemotaxis of hESC-derived neutrophils in response to IL1β expressed in an air-pouch inflammatory mouse model [85]. It remains to be determined whether hESC-neutrophils (or other types of granulocytes) will ever be developed for use as transfusion reagents, but *in vitro* differentiation systems for their generation may be useful for delineating cytokine requirements for hematopoietic differentiation, drug screening efforts, or elucidating molecular details of certain inherited diseases.

PERSPECTIVES

As reviewed here, peripheral blood components have many different therapeutic applications and hESCs/iPSCs have garnered a lot of interest as a renewable cell source that can be used for their generation. From RBCs and platelets being used in transfusions to treat cytopenias to DCs, NK cells, and T cells being used in immunotherapies to treat cancer and HIV, hESCs/iPSCs may be useful for generating these mature cell types in abundant supplies and in cost-effective ways. Although CB, BM, and PB have been investigated as sources of progenitors for the generation of large-scale transfusable RBCs and platelets [13–15,47,48], it is clear that even after expansion and differentiation, these progenitors represent donor-limited sources. Pluripotent stem cells, especially transgene-free human iPSCs [87–90], represent a new source of stem cells that can be propagated and expanded *in vitro* indefinitely, providing a potentially inexhaustible and donorless source of blood components for therapy. For hESCs, the ability to create banks of cell lines with matched or reduced incompatibility could potentially decrease or eliminate the need for immunosuppressive drugs and/or immunomodulatory protocols (e.g., $(O)RhD^-$ lines for the generation of universal RBCs). Inasmuch as iPSCs could potentially be produced from a patient's own cells, they carry enormous potential as another alternative source of pluripotent stem cells for treating human diseases related to many different organ systems, and could eliminate tissue incompatibility issues altogether.

While the field of regenerative medicine is still in its infancy, some hESC-based therapies are starting to be tested in clinical trials. In early 2012, researchers from Advanced Cell Technology and UCLA reported their preliminary results on treatment of patients with Stargardt's macular dystrophy and dry age-related macular degeneration using retinal pigment epithelium (RPE) cells derived from hESCs [91]. They have not noted any abnormal proliferation, teratoma formation, graft rejection, or other untoward pathological reactions or safety signals. Functional visual improvements were observed in both patients [91]. This is the first clinical trial of using hESCs or iPSCs therapeutically in human beings, and the safety and efficacy of it will likely have a significant impact on the development of other types of hESC/iPSCs-based therapies as well as the policies of the FDA towards the use of any hESC/iPSCs-derivatives to treat human diseases.

CHAPTER 49

Red Blood Cell Substitutes

Thomas Ming Swi Chang
Artificial Cells & Organs Research Center, Departments of Physiology, Medicine and Biomedical Engineering, McGill University, Montreal, Quebec, Canada

INTRODUCTION

In 1957, the author initiated the first research on artificial cells including modified hemoglobin [1,2]. Artificial cells (Fig. 49.1) retain biologically active materials like hemoglobin, enzymes, cells, adsorbent and other materials [2–5]. Their dimensions can vary in the macro, micro, nano and molecular ranges (Fig. 49.2). The membrane of artificial cells retains larger molecules and suspensions, but allows permeable molecules like oxygen and substrates to enter and products, peptides and other material to leave. In this way the enclosed materials are protected from immunological rejection and other materials from the external environments. Until 1989, most of the research concentrated on artificial cells containing enzymes, cells, microorganisms, adsorbent, peptides and others.

Concentrated research and development on modified hemoglobin only started after 1987 because of public concerns about HIV in donor blood. After extraction from red blood cells and before modification, hemoglobin can be sterilized by pasteurization, ultrafiltration and chemical means. These procedures can remove microorganisms including those responsible for AIDS, hepatitis and others. However, as described below, hemoglobin has to be modified before it can be used. There are many situations where modified hemoglobin can potentially be used to substitute for red blood cells [4–12]. These include trauma surgery, cardiopulmonary bypass surgery, cancer surgery, other elective surgery, and cardioplegia. Another area is in dealing with severe traumatic injuries like traffic accidents and other accidents that result in

severe bleeding and hemorrhagic shock. The number of traumatic injuries requiring blood substitutes in civilian use is small when compared to the requirements in major disasters or wars. Modified hemoglobin is especially useful in emergency situations such as these. Since modified hemoglobin does not contain red blood cell membrane and therefore no blood group antigens, it can be used without the need for cross-matching or typing. This would save much time and facilities and would permit on-the-spot transfusion as required, similar to giving intravenous solution. This is further facilitated by the fact that modified hemoglobins can be stored as a solution at room temperature for more than two years. They can also be lyophilized and stored as a stable, dried powder, which can be reconstituted with the appropriate salt solution just before use. Another area of use is where the patients' religious belief do not allow them to use donor blood for transfusion.

MODIFIED HEMOGLOBIN

Why do we have to modify hemoglobin?

Hemoglobin in the red blood cell is responsible for carrying oxygen from the lung and delivering it to the tissues. It is a tetramer of four subunits: two alpha subunits and two beta subunits [13] (Fig. 49.3). Hemoglobin is in the 'oxy', relaxed, or 'R' state when it is carrying oxygen. To release oxygen, the hemoglobin molecule undergoes conformational change with a 15° rotation. The molecule is then in the 'deoxy', tensed, or 'T' state. A red blood cell contains a cofactor, 2,3-DPG, which facilitates this conformational change. Thus, hemoglobin inside red blood cells has a high P_{50} which allows it to readily release oxygen to the tissue at physiological oxygen tensions.

Hemoglobin can be extracted from red blood cells by removing the cell membranes to form stroma-free hemoglobin. Attempts in clinical trials in patients to use stroma-free hemoglobin as blood substitute have not been successful, because of renal toxicity and other adverse effects [14]. When infused into the circulation, each four subunit hemoglobin molecule (tetramer) is rapidly broken down into two subunits (dimers). These toxic dimers are the major causes of the adverse effects.

Modified hemoglobin

Biotechnological approaches can be used to either crosslink or encapsulate the hemoglobin molecules to prevent it from dissociating into dimers, and also to allow it to have an acceptable P_{50} [1–3,15,16]. Many groups have since contributed to progress in this area, especially since 1989 [1–79].

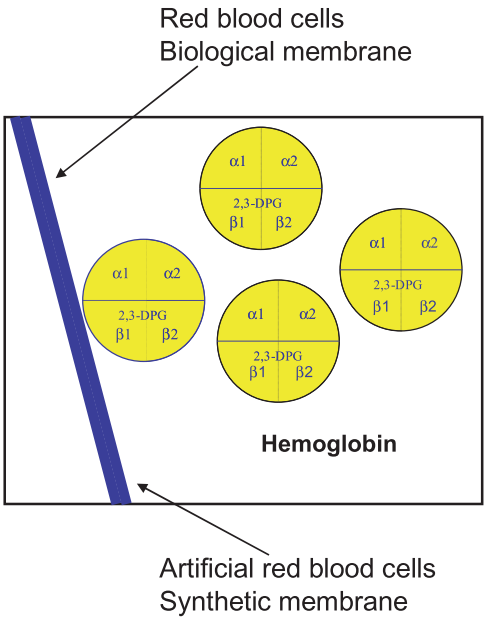

FIGURE 49.3

Inside the red blood cell, each hemoglobin molecule stays as a tetramer of four subunits: two alpha subunits and two beta subunits. Cofactors, 2,3-DPG, retained in the red blood cell facilitate the hemoglobin to release oxygen as required by the tissues. Artificial red blood cell has the same content as red blood cells but the membrane is made of synthetic material. *(Modified From Chang, Biomaterials, Artificial Cells and Immobilization Biotechnology, an International Journal, 20:154-174, 1992 with permission of Marcel Dekker Publisher)*

Microencapsulation of hemoglobin to prepare a complete artificial red blood cell [1,2] is a rather ambitious concept (Fig. 49.3). Although this attempt to mimic red blood cells has resulted in a complete red blood cell substitute, it is rather complicated. Further research is needed and this approach is now considered as a third generation modified hemoglobin and will be discussed later. Simpler crosslinked modified hemoglobin has been developed as first generation modified hemoglobin for more immediate clinical applications, as is discussed below.

FIRST GENERATION MODIFIED HEMOGLOBIN

Polyhemoglobin based on nanobiotechnology

Hemoglobin contains many amino groups, many of which are on the surface of the hemoglobin molecule. This author first reported the use of nanobiotechnology using a bifunctional agent (diacid) to crosslink and assemble hemoglobin molecules into polyhemoglobin [2,3] (Fig. 49.4). This was first used to form ultrathin polyhemoglobin membranes for artificial red blood cells. It was also found that with decreasing size of artificial cells all the hemoglobin molecules are crosslinked into polyhemoglobin. Crosslinking prevents the breakdown of hemoglobin tetramers into dimers. The reaction is as follows:

$$\underset{\text{Diacid}}{\text{Cl}-\text{CO}-(\text{CH}_2)_8-\text{CO}-\text{Cl}} + \underset{\text{Hemoglobin}}{\text{HB}-\text{NH}_2} = \underset{\text{Polyhemoglobin}}{\text{HB}-\text{NH} = \text{CO}-(\text{CH}_2)_8-\text{CO}-\text{NH}-\text{HB}}$$

Glutaraldehyde is another bifunctional agent first used by this author in a similar nanobiotechnological approach to prepare soluble nanodimension polyhemoglobin [15]:

$$\underset{\text{Glutaraldehyde}}{\text{H}-\text{CO}-(\text{CH}_2)_3-\text{CO}-\text{H}} + \underset{\text{Hemoglobin}}{\text{HB}-\text{NH}_2} = \underset{\text{Polyhemoglobin}}{\text{HB}-\text{NH}-\text{CO}-(\text{CH}_2)_3-\text{CO}-\text{NH}-\text{HB}}$$

Since then, a number of other groups have independently carried out extensive studies using this principle of glutaraldehyde crosslinked polyhemoglobin. The two most successful ones are glutaraldehyde crosslinked human polyhemoglobin [17–19] and glutaraldehyde crosslinked bovine polyhemoglobin [20–22,42].

Other sources of hemoglobin for forming glutaraldehyde crosslinked polyhemoglobin include hemoglobin from procine red blood cells [25] and hemoglobin from red blood cells of placentas discarded after birth [26]. Other cross-linkers have also been developed.

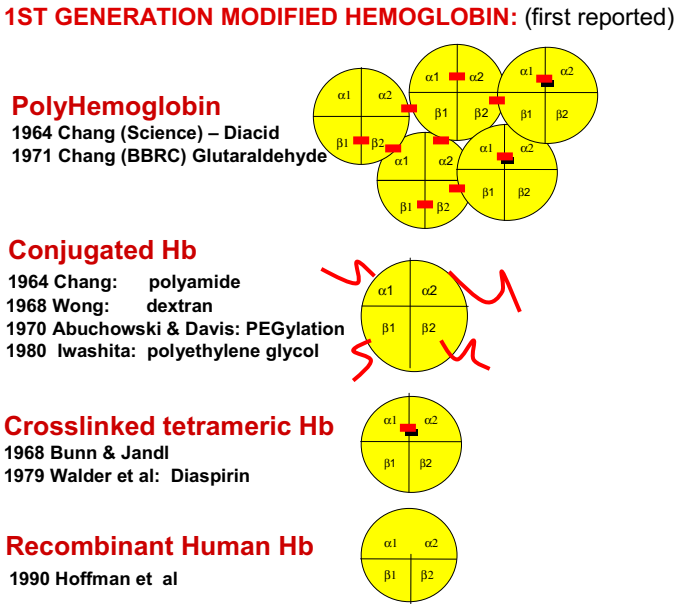

FIGURE 49.4
Molecular dimension red blood cell substitutes in the form of polyhemoglobin, conjugated hemoglobin, intramolecularly crosslink hemoglobin and recombinant hemoglobin. *(Modified from: Chang, Art Cell Blood Sub Biot, 2004. With copyright permission from Marcel Dekker Publisher)*

Intramolecularly crosslinked hemoglobin

Studies have been carried out to specifically crosslink hemoglobin molecules intramolecularly to form crosslinked tetrameric hemoglobin (Fig. 49.4). For example, a bifunctional agent, 2-Nor-2-formylpyridoxal 5-phosphate which is also a 2,3-DPG analogue can intramolecularly crosslink the two beta subunits of the hemoglobin molecules [16]. Another 2,3-DPG pocket modifier, bis(3,5-dibromosalicyl) fumarate (DBBF) intramolecularly cross-links the two alpha subunits of the hemoglobin molecule [27–29].

Conjugated Hemoglobin

Conjugated hemoglobin is the crosslinking of hemoglobin into polymers [2,3]. The use of soluble polymers resulted in soluble conjugated hemoglobin with good circulation time [30,31]. Two new nano dimension conjugated hemoglobin based the use of polyethylene glycol are being tested in ongoing clinical trials [12,32–34].

Sources of hemoglobin

Where do we obtain all the hemoglobin needed for preparing modified hemoglobin? Red blood cells from outdated donor blood are one major source of human hemoglobin. Another source is human hemoglobin from red blood cells of discarded placentas after the delivery of babies [26]. In addition to hemoglobin from human sources another source is bovine hemoglobin [20] and hemoglobin from porcine red blood cells [25]. Another promising source is human hemoglobin produced by recombinant technology in microorganisms [35–37]. Another potential source that has been developed is synthetic heme that is linked to recombinant human albumin [10,38].

Efficacy and safety of modified hemoglobin blood substitutes

Modified hemoglobin no longer has problems related to the breakdown of hemoglobin into toxic dimers. However, how safe is modified hemoglobin when injected into animals and humans? Animal studies using properly prepared modified hemoglobin have not shown adverse effects on coagulation factors, leucocytes, platelets or complement activation [4–6,39,40], [8–12]. Very stringent, sensitive immunological studies have been carried out for polyhemoglobin, conjugated hemoglobin and microencapsulated hemoglobin [6,41]. Results show that modified homologous polyhemoglobins (e.g., rat polyhemoglobin injected into

rats) are not immunogenic even with repeated injection. Heterologous polyhemoglobin (e.g., non-rat hemoglobin injected into rats) is not immunogenic initially but is immunogenic after repeated injections with Freud's adjuvant. Conjugation and microencapsulation markedly decreased the antigenicity of heterologous polyhemoglobin. Other studies show that without the use of Freund's adjuvant, repeated subcutaneous and intravenous injections of heterologous cross linked hemoglobin are much less immunogenic [28]. Clinical trials using a bovine polyhemoglobin did not show adverse immunological effects [23,24,42]. Another important area of safety study is the distribution of modified hemoglobin after infusion and also its effect on the reticuloendothelial system. Another factor is that safety response in animals is not necessarily the same as in humans, especially in the case of immunological and hypersensitivity reactions. We have worked out a simple *in vitro* screening test [6] which consists of adding 0.1 ml of modified hemoglobin to a test tube containing 0.4 ml of human plasma or blood, and then analyzing for complement activation. This have been used to detect trace contamination of blood group antigens, antibody-antigen complexes, endotoxins, trace fragments of microorganisms, impurities in polymers, some emulsifiers and others. Detailed animal studies show that modified hemoglobins are effective in short-term applications like hemorrhagic shock, exchange transfusion, hemodilution in surgery and some other conditions. However, despite all the detailed *in vitro* and *in vivo* safety and efficacy studies and screening tests described above, extensive clinical trials in the last 20 years show that some of the blood substitutes have problems related to increased vasoconstriction as discussed below.

Vasoactivity and nitric oxide

Not all modified hemoglobins have been successful in clinical trials, since vasopressor effects have been observed in some of the first generation modified hemoglobin blood substitutes. For example, intramolecularly crosslinked hemoglobin and first generation recombinant human hemoglobin blood substitutes contain 100% of molecular dimension modified hemoglobin. Infusion causes vasopressor effects and also increased smooth muscle contractions. With another type of polyhemoglobin that contained more than 30% molecular dimension modified hemoglobin, significant vasoactivity and increased smooth muscle contractions were also observed when using larger volumes. On the other hand, the use of nanodimension polyhemoglobin with $<1\%$ molecular dimension modified hemoglobin did not show vasopressor effects even when large volumes, of up to 10 liters, were infused. This has led to the proposal that the intercellular junctions of the endothelial lining of vascular wall allow molecular dimension hemoglobin to enter into the interstitial space [6] (Fig. 49.5). There, hemoglobin acts as a sink for binding and removing the nitric oxide needed for maintaining the normal tone of smooth muscles [6,43]. This results in the constriction of blood vessels and other smooth muscles, especially those of the esophagus and the GI tract. On the other hand, nano dimension polyhemoglobin would not cross the intercellular junction and therefore does not result in vasoconstriction (Fig. 49.5). Others argue that one cannot compare the different types of modified hemoglobin since there are major differences in the chemistry involved and in the oxygen affinity. We have therefore prepared laboratory versions of nano dimension polyhemoglobin, each containing different percentages of molecular dimension hemoglobin using the same glutaraldehyde crosslinking, and characterized them to ensure that they all have the same oxygen affinity [5,44]. The results show that samples with a very low percentage of molecular dimension modified hemoglobin do not cause vasoconstriction or changes in electrocardiograms. With increasing percentage of molecular dimensions modified hemoglobin, there was increasing degree of vasoconstriction and elevation of the ST segment of the electrocardiogram. ST elevation could be due to vasoconstriction, resulting in a decreased supply of oxygen to the heart, and this may explain the observation of small myocardial lesions in some primates and swine after they were infused with one type of molecular dimension modified hemoglobin [45]. This theory is further supported by the lack of vasoconstriction using non-extravasating hemoglobin polymer [46]. Furthermore, a second

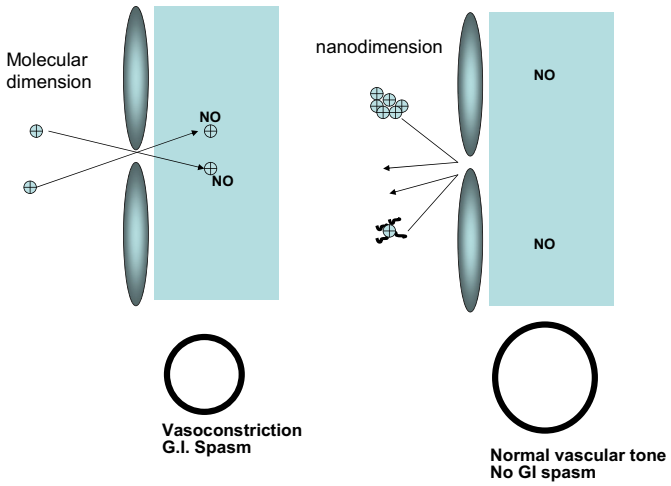

FIGURE 49.5

Molecular dimension modified hemoglobin can transverse the intercellular junction of the endothelial cells of the vascular wall. It will then bind with nitric oxide thus removing it resulting in increase vasoactivity since removal of nitric oxide results in contraction of smooth muscles of the vascular wall and other smooth muscles. Nanodimension modified hemoglobin that do not contain any significant free molecular dimension modified hemoglobin. They cannot transverse the intercellular junction and therefore do not cause vasoconstriction. *(From Blood Substitutes. 1997 monograph by TMS Chang with permission of copy right holder.)*

generation molecular dimension recombinant human hemoglobin that did not bind nitric oxide, did not cause vasoconstriction [43]. Since recombinant hemoglobins crosses the intercellular junction and are removed quickly, their circulation time can be increased by crosslinking to form nanodimension polyhemoglobin [35]. Another approach in ongoing clinical trial is to prepare polyethylene glycol (PEG) conjugated hemoglobin that with its water of hydration would result in a nano dimension modified hemoglobin, and this does not result in vasopressor effects [12]. A more recent observation in mice with endothelial dysfunction showed that unlike normal mice, polyhemoglobin with <1% tetratmer can still result in vasoconstriction and this can be prevented by nitrite oxide inhalation [47]. A number of other approaches are being investigated to solve this problem for instance Kluger's group [62] and Hsia's group [49].

Present clinical status of first generation modified hemoglobin

Two of the most successful ones are based on glutaraldehyde crosslinked polyhemoglobin. These have been developed independently by two groups based on Chang's basic principle of glutaraldehyde crosslinked polyhemoglobin [15]. One is pyridoxalated glutaraldehyde human polyhemoglobin [17,18]. They show in Phase III clinical trial that this can successfully replace extensive blood loss in trauma surgery by maintaining the hemoglobin level with no reported side effects [18]. They have infused up to 10 liters into individual trauma surgery patients. In 2009 this group reported their clinical trial results in trauma hemorrhagic shock ambulance patients [19]. The control group was given the standard saline solution in the ambulance. Since polyhemoglobin does not have blood group antigens, it can be given in the ambulance before reaching the hospital. The control group needs red blood cell transfusion on arrival at the hospital. On the other hand, when given up to a total of six units, the patients did not need red blood cell transfusion for an average of 12 hours. Although repeated infusion can be given to prolong this time, this was not part of the clinical trial protocol. Side effects observed were non-fatal myocardial infarctions (0.6% in the control group and 3% in the polyhemoglobin group). Another one is glutaraldehyde crosslinked bovine polyhemoglobin that has been extensively tested in

	DONOR RBC	BLOOD SUBSTITUTES (PolyHemoglobin)
INFECTION	POSSIBLE	STERILIZED
SOURCE	LIMITED	"UNLIMITED ?"
BLOOD GROUPS	YES	NONE
USAGE	Xmatch, typing	Immediately
STORAGE	42 DAYS	>1YEAR
FUNCTIONS	RBC	OXYGEN CARRIER

FIGURE 49.6

Comparison of polyhemoglobin with donor red blood cells. Polyhemoglobin has many advantages over red blood cells and is useful for use during surgery. However, it cannot be used in a number of other clinical conditions. This is because unlike red blood cells (RBC), polyhemoglobin is only an oxygen carrier. It does not have RBC enzymes needed for many functions including the removal of oxygen radicals. Furthermore, its circulation time is much shorter than that of RBC. *(Modified from: Chang, Art Cell Blood Sub Biot, 2004. With copyright permission from Marcel Dekker Publisher)*

clinical trials for surgical patients [20,22,42]. This bovine polyhemoglobin has been approved for routine patient use in South Africa and more recently in Russia [50]. The above two polyhemoglobins have been approved for compassionate uses in humans in North America. Conjugated hemoglobin of sufficient nanodimension is in earlier stages of clinical trials [12,33].

Nanodimension polyhemoglobin and conjugated hemoglobin have a number of advantages when compared to donor red blood cells (Fig. 49.6). Unlike red blood cells, there is no blood group and thus they can be given immediately, on the spot, without the need for time-consuming typing and cross-matching. They can be sterilized and are free from infectious agents. Donor blood has to be stored at 4°C, and is only good for 42 days. Polyhemoglobin can be stored at room temperature for more than one year. Thus, they have important roles in a number of clinical conditions. In some other conditions related to severe and sustained ischemia we may have to add antioxidant enzymes to oxygen carriers in order to avoid the potential for ischemia reperfusion injury and other potential problems [51,52,76] (Fig. 49.7).

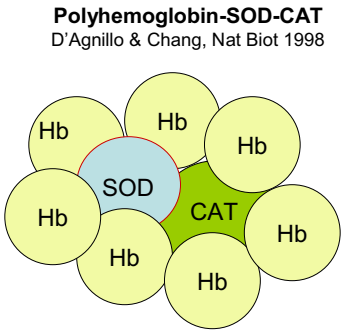

FIGURE 49.7

Crosslinking of hemoglobin with two RBC enzymes to form polyhemoglobin-catalase-superoxide dismutase (PolyHb-CAT-SOD). Unlike polyhemoglobin, this has RBC enzymes that can remove oxygen radicals. *(Modified from: Chang, Art Cell Blood Sub Biot, 2004. With copyright permission from Marcel Dekker Publisher)*

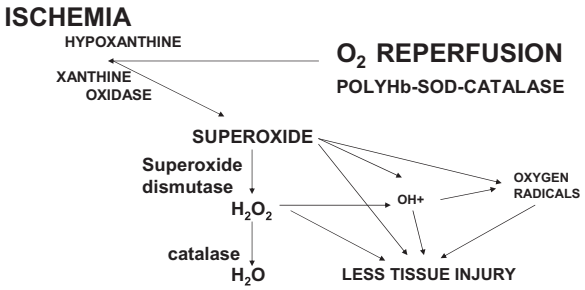

FIGURE 49.8
In conditions like severe sustained hemorrhagic shock, stroke, myocardial infarction and organ transplantation, reperfusion with polyhemoglobin can sometimes result in oxygen radicals that causes tissue injury. PolyHb-CAT-SOD can supply oxygen and at the same time significantly lower any oxygen radicals formed. *(From: Chang, Monograph on Blood Substitutes, 1997. With copyright permission from copyright holder TMSC)*

NEW GENERATIONS OF MODIFIED HEMOGLOBIN

Polyhemoglobin crosslinked with RBC antioxidant enzymes

In sustained severe hemorrhagic shock or other ischemic conditions, oxygen carriers alone may result in ischemia reperfusion injuries due to the production of oxygen radicals [51,52] (Fig. 49.8). We are studying the use of a crosslinked polyhemoglobin-superoxide dismutase-catalase (PolyHb-SOD-CAT) (Fig. 49.7) [52,53]. The intestine is one of the organs that is most likely to be injured in this type of ischemia reperfusion injury. We found that unlike PolyHb, PolyHb-SOD-CAT did not cause a significant increase in oxygen radicals when it is used to reperfuse ischemic rat intestine [6]. Polyhemoglobin exists in solution, and is therefore more likely to be able to perfuse partially obstructed vessels in stroke, myocardial infarction and other conditions than red blood cells. In a rat stroke model (Fig. 49.9), we found that after 60 minutes of ischemia, reperfusion with polyHb resulted in significant increase in the breakdown of blood-brain barrier and increase in brain edema [54]. On the other hand, polyHb-SOD-CAT did not result in these adverse changes [54]. Supported by another group in Korean kidney liver transplant [40]. These results have been supported by research using this approach in kidney and liver transplantation [40].

Polyhemoglobin crosslinked with RBC antioxidant enzymes and carbonic anhydrase

Even though erythrocytes transport both oxygen and carbon dioxide, research on blood substitutes has concentrated only on the transport of oxygen and its vasoactivity and oxidative effects. Recent study in a hemorrhagic shock animal model shows that the degree of tissue

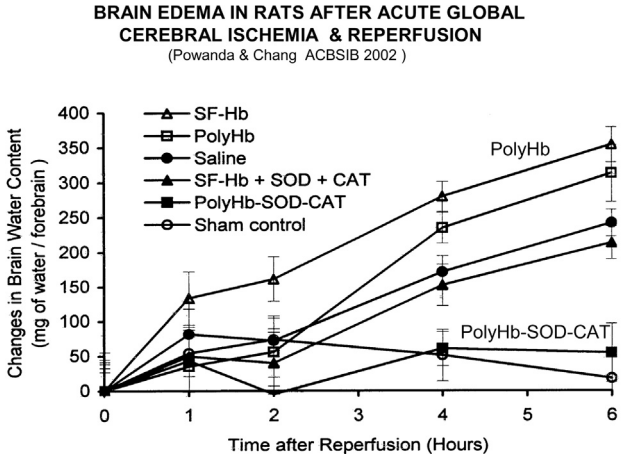

FIGURE 49.9
This is a rat model of acute global cerebral ischemia followed by reperfusion with different oxygen carrying solutions. Unlike polyhemoglobin, polyHb-CAT-SOD does not cause brain edema when used in this situation. *(From: Powanda and Chang, Art Cell Blood Sub Biot, 2002. With copyright permission from Marcel Dekker Publisher)*

PCO_2 elevation is directly related to mortality rates [55]. Therefore we have designed a novel nanobiotechnological preparation with antioxidant properties that can transport both O_2 and CO_2 [56]. This is in the form of polyhemoglobin-catalase-superoxide dismutase-carbonic anhydrase. We have studied its effect on elevated tissue PCO_2 in a hemorrhagic shock rat model and found that it is more efficient than red blood cells in lowering elevated tissue PCO_2 levels [57].

Polyhemoglobin-fibrinogen: an oxygen carrier with platelet properties

Polyhemoglobin, like red blood cells, does not contain clotting factors or platelets to aid in coagulation when needed. Thus with extensive replacement of whole blood with polyhemoglobin or red blood cells, there is a need to replace clotting factors and platelets. We have prepared a novel blood substitute that is an oxygen carrier with platelet-like activity [75]. It is formed by crosslinking fibrinogen to hemoglobin to form polyhemoglobin-fibrinogen (polyHb-Fg). This was studied and compared to polyHb for its effect on coagulation both *in vitro* and *in vivo*. In the *in vitro* experiments, PolyHb-Fg showed similar clotting times to whole blood whereas polyHb showed significantly higher clotting times. This result was confirmed in *in vivo* experiments using an exchange transfusion rat model. Using PolyHb, exchange transfusion of 80% or more increased the normal clotting time (1−2 mins) to >10 mins. Partial clots formed with PolyHb did not adhere to the tubing wall. With PolyHb-Fg, a normal clotting time is maintained even with 98% exchange transfusion.

Polyhemoglobin crosslinked with tyrosinase

Tumors are not well perfused with blood, but radiation therapy and chemotherapy works better with better tissue oxygenation. Since polyhemoglobin is in solution, it can perfuse tumors more effectively than red blood cells, and thus has been shown to increase the sensitivity of tumors to radiation therapy and chemotherapy [20,34,58]. We have recently crosslinked tyrosinase with hemoglobin to form a soluble polyhemoglobin-tyrosinase complex [59]. This has the potential dual function of supplying the needed oxygen for radiation therapy and also lowers the systemic tyrosine needed for the growth of melanoma. This preparation inhibits the growth of murine B16F10 melanoma culture. In mice, it significantly delays the growth of B16F10 melanoma compared to the control group, without causing adverse effects or changes in the growth of the treated animals [59]. We are now investigating the nanoencapsulation of polyhemoglobin-tyrosinase in polyethyleneglycol-polylactide (PEG-PLA) or polylactide (PLA) nanocapsules [60,77].

Artificial red blood cells

The first artificial red blood cells (Figs. 49.1, 49.3) have oxygen dissociation curves similar to red blood cells, since 2-3-DPG is retained inside [1]. Hemoglobin also stays inside as a tetramer, and red blood cell enzymes like carbonic anhydrase and catalase retain their activities [2,3]. These artificial red blood cells do not have blood group antigens on the membrane and therefore do not aggregate in the presence of blood group antibodies [3]. However, the single major problem is the rapid removal of these artificial cells from the circulation. Much of the studies since the initial research aim to improve survival in the circulation by decreasing their uptake by the reticuloendothelial system. Since removal of sialic acid from biological red blood cells results in their rapid removal from the circulation, we started by modifying the surface properties of the artificial red blood cells [3]. This included the use of synthetic polymers, negatively charge polymers, crosslinked protein, lipid-protein, lipid-polymers and others. Since that time many researchers around the world have started to carry out research on artificial red blood cells [5].

One major step forward is the preparation of submicron lipid membrane artificial red blood cells, resulting in very significant improvements in circulation time [61]. Due to the addition

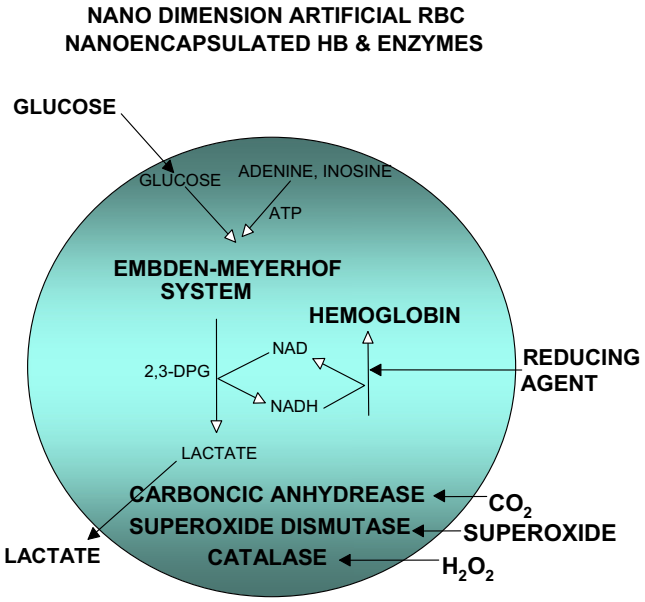

FIGURE 49.10
Nanodimension artificial red blood cells with polyethylene-glyco-polylactide membrane. In addition to hemoglobin, this contains the same enzymes that are normally present in red blood cells. Thus, it has the complete function of the red blood cells. *(From: Chang et al, Art Cell Blood Sub Biot, 2003. With copyright permission from Marcel Dekker Publisher)*

of polyethylene glycol to the lipid membrane, the circulation time has been increased to a half time of about 36 hours in rats [9,10,79]. These advances make it now possible to scale-up for detailed preclinical studies towards a clinical trial [10,11]. The uptake is mainly by the reticuloendothelial system. It is possible to replace 90% of the red blood cells in rats with these artificial red blood cells. The animals with this percentage of exchange transfusion still remain viable. Studies also reported effectiveness in hemorrhagic shock. There are no changes in the histology of the brain, heart, kidneys and lungs of rats treated in this way.

Using a modification of this author's earlier method of micron dimension biodegradable polymeric membrane artificial cells [63] we have recently prepared nano dimension artificial red blood cells [6,39,64,65]. These nano artificial RBC, sized 80 to 150 nanometers, contain all the red blood cell enzymes and can convert methemoglobin to hemoglobin [5,39] (Fig. 49.10). Our studies show that using a polyethylene-glycol-polylactide copolymer membrane we are able to increase the circulation time of these nano artificial red blood cells to double that of polyhemoglobin (Fig. 49.11) [39]. Further studies show that one infusion with a volume of one third of the total blood volume did not result in long-term adverse effects on the biochemistry and histology of the kidney [64] or liver [48]. Our most recent study was carried out using PEG-PLA membrane nano artificial cells containing polyhemoglobin-catalase-superoxide dismutase-carbonic anhydrase in a hemorrhagic shock rat model with two thirds of the blood removed, resulting in a mean arterial blood pressure of 30mm Hg. After one hour of hemorrhagic shock at 30mmHg, infusion of this preparation effectively resuscitated the animal and lowered the elevated tissue PCO_2 [78].

A CHEMICAL APPROACH BASED ON PERFLUOROCHEMICALS

There is another type of blood substitute based on a chemical approach that was first demonstrated by Clark and then Geyer using perfluorochemicals (PFCs) [66]. This approach was developed by a number of investigators including Chen, Clark, Geyer, Faithful, Keipert, Lowe, Mitsuno, Naito, Nose, Ohyanagi, Reiss, Sloviter, Yokoyama and many others [67,68]. Perfluorochemicals are synthetic fluids in which oxygen can dissolve and that can be made into fine emulsions for use as oxygen carriers. Their greatest advantage is that they can be produced in large amounts. Furthermore, their purity can be more easily controlled. However, PFCs have a lower capacity for carrying oxygen than Hb. Improved perfluorochemicals have allowed a higher concentration of PFC to be used and a blood substitute based on perfluoro-octyl

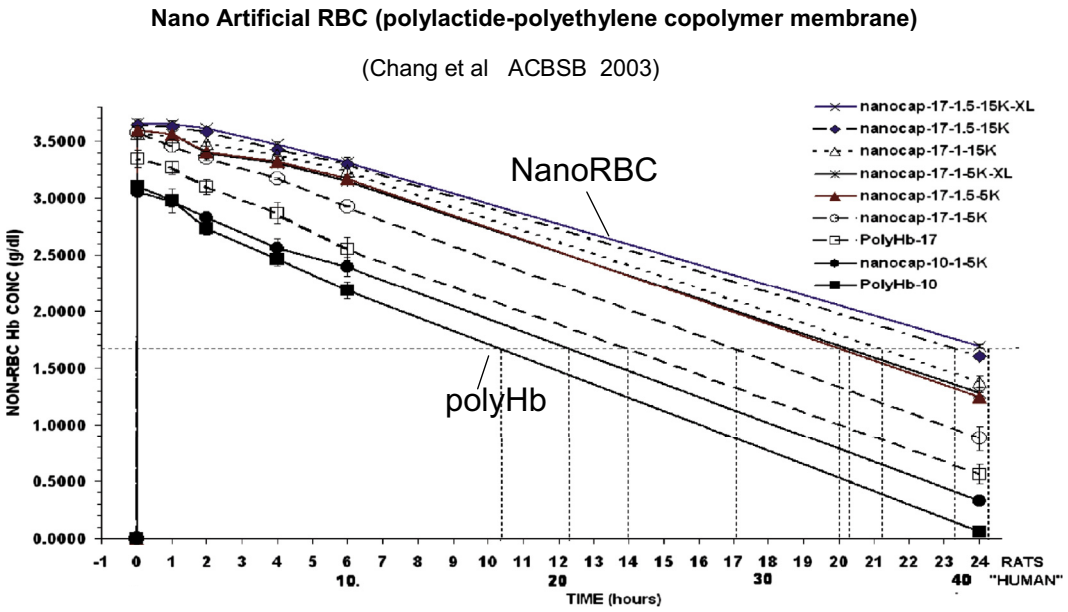

FIGURE 49.11

Nanodimension artificial red blood cells with polyethylene-glyco-polylactide membrane. The circulation time is double that of polyhemoglobin. The circulation half time of polyhemoglobin in human is about 24 hours. This means that the nanodimension artificial RBC may have a circulation time of about 48 hours in human. *(From: Chang et al, Art Cell Blood Sub Biot, 2003. With copyright permission from Marcel Dekker Publisher)*

bromide ($C_8F_{17}Br$) with egg-yolk lecithin as the surfactant has been tested in clinical trials. The results are being carefully analyzed.

CONCLUSIONS

Blood substitutes have encountered two major barriers. First, it was mistakenly thought that a blood substitute would be simple to produce, would not need much basic research and hence could be easily developed for clinical applications when needed. Thus, the crisis of HIV contaminated donor blood was followed by catch up and short cut efforts to quickly produce some type of blood substitute. The urgency of the HIV crisis resulted in a rush into clinical trials resulting in a number of blood substitutes with rather severe adverse side effects. Eventually, two types of polyhemoglobin were manufactured and tested clinically with promising results [19,42]. Unfortunately, Natanson et al. [76] carried out a meta-analysis that included all the results of all hemoglobin based blood substitutes, including those that had failed earlier. This has led to a second barrier with the mistaken conclusion that all blood substitutes are toxic and not effective. South Africa and Russia have analyzed the risk/benefit according to their own needs and have approved the routine clinical use of one type of polyhemoglobin [50].

We now know that a blood substitute is a very complicated material that cannot be produced for clinical use without the required basic knowledge. We have to approach a blood substitute as a highly interdisciplinary type of basic and applied research and development, involving polymer chemistry, cell physiology, molecular biology, biotechnology, clinical medicine and other areas. The belated but ongoing emphasis on this interdisciplinary approach will accelerate the clinical realization of blood substitutes. This brief overview cannot include the numerous ongoing studies and research in this area. More details are available in many detailed publications, books and symposium volumes in this area [4–6,8–12,18,33,42,68–74].

CHAPTER 50

Lymphoid Cells

Una Chen
International Senior Professional Institute (ISPI e.V.), Giessen, Germany

INTRODUCTION

For researchers interested in cell-based therapy, it is a great challenge to learn how to expand lymphoid cells and their precursor cells *ex vivo* under defined conditions. Lymphocytes are defined by their cell surface receptor — BCR (B Cell Receptor, or immunoglobulin, Ig) for B cells and TCR (T Cell Receptor) for T cells. Precursor B cells bear a pre-B receptor, which contains lambda 5 in mice ('physi' in humans), and precursor T cells bear a pre-TCR-alpha. No biochemically and genetically defined surface receptors for the progenitors of lymphoid precursors have been reported. It is not entirely clear how committed stem cells differentiate into lymphoid cells, which then mature into effector cells. Many theories have been postulated. Differentiation and maturation involve both antigen-independent and antigen-dependent processes. For the first process, I will explore the sequential commitment model proposed in references [1,2]. For my treatment of the second process, I am indebted to many colleagues who helped me to summarize current views.

Ligand-receptor interactions must play an important role in causing lymphoid cells to proliferate and differentiate. The term ligand means all external signals, including those provided by stroma cells and cytokines during the antigen-independent stage and those provided by Ag (antigens) and APCs (antigen-presenting cells), or accessory cells during the antigen-dependent stage. The process of turning on and turning off transcription factors at each stage of differentiation as a consequence of ligand-receptor interaction is one of the key elements controlling both the phenotype and the function of cells. Transcription factors known to be important at various stages of lymphopoiesis, due to the notion that the growth of lymphoid (precursor) cells can be manipulated at will by using genetic tools, have been discussed in the last three editions. There are examples of expansion of normal lymphoid (precursor) cells in culture. All are based on the support of stroma cell lines and cytokines. On removal of these elements, cells either differentiate toward terminal effector cells or die. Recently, the post transcriptional regulations of various pathways are shown to be conducted by the miRNAs (micro RNAs), which are the regulators of networks.

I have arbitrarily defined seven stages of lymphopoiesis to discuss in detail. For each one, I discuss the available cellular and molecular markers, the current understanding of cellular phenotype, the potential of these cells to expand *ex vivo*, and if possible, what could be done in the future.

Both somatic and genetic manipulations are possible in animal models. By combining modern cellular and molecular technologies and available mutant mice, one should be able to grow normal lymphoid (precursor) cells at every stage of lymphopoiesis.

Despite the efforts of many, human stroma cell lines that can reproducibly support the growth of different stages of lymphoid (precursor) cells are still under development. The inducible

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00050-1

regulation of stage-specific and lymphoid-specific transcription and post-transcriptional factors in controlling the growth of normal lymphoid cells seems to be the key element.

The aim of this chapter is to help the reader to understand lymphocytes and their precursors. The intention of research is to learn how these cells might be manipulated to make them useful in cell-based, somatic gene/molecular therapy. I attempt to address the possibility of growing normal lymphoid cells and their stem cells – of mouse and human origin – in a controllable manner. That is, cells should proliferate *ex vivo* without becoming malignantly transformed and with little or no differentiation.

Three main types of stem cells can be distinguished: totipotent, pluripotent, and multipotent. Totipotent and pluripotent stem cells usually divide symmetrically to give rise to two daughter stem cells, with the same properties and identical phenotype to their parent. Under appropriate conditions, totipotent and pluripotent stem cells can differentiate into any other form of stem cell. The known stem cell lines that seem to be close to totipotent are ESCs (embryonic stem cells) and, more recently, iPCs (induced pluripotent cells). Multipotent stem cells, which exist for the lifetime of an organism, undergo primarily asymmetric divisions. One daughter cell is another stem cell like its parent, whereas the other daughter cell is a more highly differentiated cell that performs a tissue-specific function. Due to this unique property, multipotent stem cells are ideal vehicles for cell-based, somatic, gene/molecular therapy. They will carry the transgene for the lifetime of the organism, and they will maintain expression of the transgene in the differentiated cells that they spawn.

Both lymphoid and lymphoid precursor cells are the progeny of HSCs (hematopoietic stem cells). One of the main tasks here is to review whether lymphoid cells and their progenitors possess stem cell-like properties. Are they self-renewing? And with available culture conditions and technology, can they expand *ex vivo* under controllable growth conditions? Unlimited growth of lymphoid cells and their progenitors is well documented. Lymphoid leukemia cells develop either spontaneously or after infection with viruses. These cell lines are useful for studying lymphoid cells but not for cell-based therapy, because they develop tumors when reintroduced into the organism. Thus, this chapter is devoted to exploring the possibility of growing normal lymphoid cells that can be engineered in culture and re-implanted into syngeneic or autologous hosts for therapeutic purposes. Other mouse normal cell types, expandable at will using genetic approaches, are available: tet-on (tetracycline-inducible) glial stem cells, mesenchymal stem cells, tet-off (tetracycline-regulated) ectodermal progenitor cells, lung stem cells, as well as tet-on and tet-off pancreatic beta islet cells, summarized in Chen [3].

PROPERTIES OF LYMPHOCYTES

Lymphoid precursor cells are bipotential progenitors of pre-T and pre-B cells. The development of lymphoid precursor cells is independent of the presence of Ag (Antigen). It is controversial whether lymphoid precursor cells divide asymmetrically with self-renewal. Lymphocytes and their precursors are similar to cells of other lineages, in that they proliferate, differentiate, migrate, communicate with other cells, age, and die. However, lymphocytes also possess the following unique properties that distinguish them from other cells:

1) Formation of receptor genes by VDJ recombination,
2) Requirement for a thymus-like environment to generate mature CD4+/8+ T cells,
3) Requirement for somatic education and selection by Ag,
4) Somatic hypermutation to generate more diversity in B cells,
5) Immunologic memory,
6) Ig heavy-chain CSR (Class Switch Recombination) in B cells,
7) Kappa light-chain editing somatically to generate new specificities of B cell receptor,

8) Secretion of various cytokines by CD4+T helper cells, Treg (T regulatory) cells, in communicating and regulating other lymphoid cell populations [4].

Development of techniques to expand *ex vivo*, to manipulate genetically, and to re-implant lymphocytes and their precursors into host animals requires lymphocyte engineers.

LYMPHOCYTE ENGINEERING: REALITY AND POTENTIAL

Two models describe the sequence of cell commitment during lymphopoiesis: stochastic and inductive. In this section, I use an inductive model in an attempt to explain lymphocyte commitment during development of the organism and in the adult.

Inductive model of sequential cell commitment of hematopoiesis

This model is divided into two parts. The first part deals with the Ag-independent stage, starting with the differentiation from the null cells (fertilized egg to ESCs, or iPS cells) to mesoderm and then to lymphoid precursor cells. A significant portion of the first part of this model was expanded from Bailey's hypothesis of developmental progress [4a] and modified according to Brown et al. [1,2].

ANTIGEN-INDEPENDENT STAGE OF LYMPHOPOIESIS — PART 1

Because multipotent stem cells are committed to differentiate, it is hypothesized that the differentiation sequence is genetically determined. Cells within the sequence are pre-committed in how they are determined. Cells within the sequence are pre-committed in their ability to respond to various inducers of differentiation; and on encountering appropriate factors or a suitable microenvironment, they proliferate and mature along a particular pathway. It is proposed that multipotent stem cells that do not receive a signal to differentiate into mature end cells progress to the next stage in the sequence of development. Alternatively, cells that do not receive a signal die. Only cells that receive proper signals will differentiate further toward mature end cells. Because commitment is gradual, there is a continuous spectrum of multipotent stem cells. Thus, some of them may be able to respond to inducers of one sort or another. In terms of self-renewal, multipotent stem cell populations continually occupy each potential for proliferation at any given time and therefore respond to the requirement for each cell type. Some daughter cells will differentiate into the next stage. The continual development of stem cells may not be diverted entirely toward one cell type, even in the presence of differentiation factors for that type. Because stem cells divide as they respond, some cells are still able to progress to the next stage of commitment.

ANTIGEN-DEPENDENT STAGE OF LYMPHOPOIESIS — PART 2

The second part of this model deals with the Ag-dependent stage, after receptors are expressed on the surface of lymphocytes. There are two main lineages of lymphocytes: T cells and B cells. T cells can mature into CD8+ cytotoxic T cells and CD4+ helper/regulatory T cells. Based on their function and the spectrum of cytokines produced, CD4+ helper T cells can be divided into Th1, Th2 and more recently, Th17 subpopulations. Treg cells are defined by the expression of Foxp3 and CD25 markers, and the regulatory function. The main functions of CD4+ T cells are to recognize cell-bound antigens, and to communicate with and help cytotoxic T and B cells to perform their duties as effector cells. Both lineages generate memory cells. How and when lymphoid cells become committed to differentiate into effector cells or into memory cells remains a mystery.

Diagrams to explain this model

Fig. 50.1 is a simple diagram to explain this model. HSCs are multipotent stem cells derived from the mesoderm. Originally they are descended from common stem cells (null, or 0, cells),

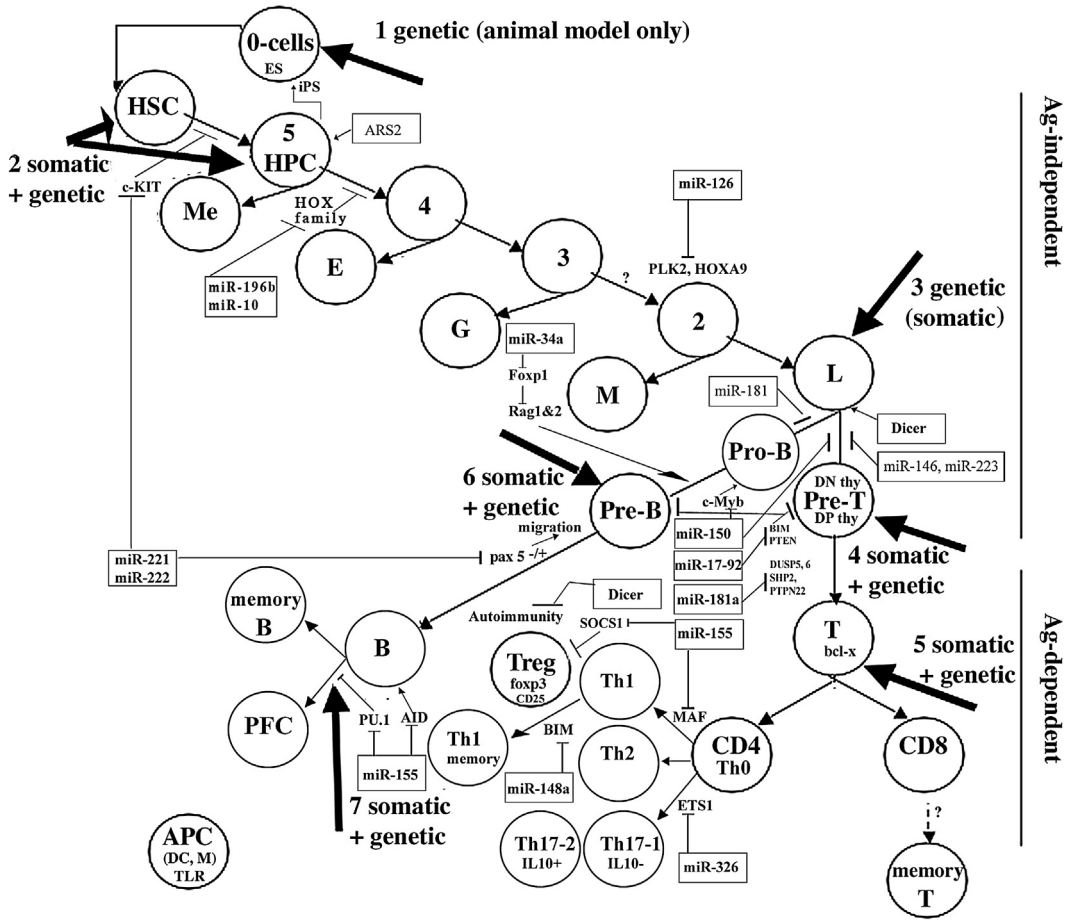

FIGURE 50.1

Proposed sequence of cell commitment during lymphopoiesis and stages of hematopoiesis and lymphopoiesis at which somatic and/or genetic engineering of lymphocytes and their precursor cells might be feasible. Solid block arrows point to the cell stages that might be targeted. The first part of the theory is the sequential commitment model of hematopoiesis of Brown et al. [1,2], modified to include the pattern of expression of transcription factors. The cells depicted diagonally to the right represent HSCs (hematopoietic stem cells) committed to multipotent precursor cells or HPCs (hematopoietic progenitor cells), which gradually lose pluripotency, as expressed by the numbers 5, 4, 3, and 2 inside the stem cells. Number 5, for example, means that the HPCs at this stage have the potential to differentiate into five different types of precursor cells. The committed monopotent precursor cells can then differentiate toward mature end cells, such as Me (megakaryocytes), E (erythrocytes), G (neutrophils/granulocytes), M (monocytes), and finally L (lymphocytes). HSCs are derived from very primitive stem cells (null cells, or 0 cells), such as fertilized eggs and/or ESCs, ES (embryonic stem cells), and/or iPSCs, iPS (induced pluripotent stem cells). In the second part of the theory, lymphoid precursor cells differentiate into mono-potential precursor B-cells (B) and monopotent precursor T cells (T). After the expression of cell surface receptors and on encountering Ag (antigen), B cells can differentiate to PFCs (plaque-forming cells) or memory B cells. T cells can become CD8+ or CD4+ cells after education and maturation in the thymus. CD8+ memory T cells can be generated at a certain stage of differentiation. CD4+Th1+memory T cells are also described. Foxp3+ (Forkhead box P3), CD25+ Treg (T regulatory)-cells are rediscovered and APCs (antigen processing cells), including dendritic cells and macrophage, seem to play a role in directing peptide-antigen recognition and activation of Th1, vs Th2, vs Th17+ cells. Th17+ cells can be further distinguished into two populations: IL10-, Th17−1 cells and IL10+, Th17−2 cells. Lipid antigen is directed to TCR via the CD1 molecule pathway. The transcription factors are expressed and are known to affect differentiation. The data come mostly from phenotypic expression in loss/gain of function approaches. The known transcription factors are cited in Chen 2007 and not repeated here. The microRNA (miRNA) pathway, which involves ARS2 (arsenate resistance protein 2), affects engraftment or reconstitution potential of HSC. Individual miRNA's, which shown to repress the expression of HSC relevant genes and to affect the differentiation of lymphoid cells and other lineages from stem cells, are indicated: miR-221 / miR-222 regulate c-KIT expression, which is thought to influence stem cell homeostasis. MiR-221 / miR-222 are also suggested to repress pax5−/+ expression, implied in the migration destination of PreB-cells/B-cells to peripheral lymphoid tissues (Melchers, personal communication, unpublished). MiR-196b is expressed in HPC and regulates mRNAs encoding the homeobox (HOX) family, possibly in cooperation with another, not yet well defined,

such as fertilized eggs, and from ESCs or iPS. The cells diagonally to the right (Fig. 50.1) represent cells committed to hematopoietic lineages, which gradually lose their multipotentiality during embryogenesis. This concept is expressed with numbers (5, 4, 3, and 2) inside the progenitor cells on the diagonal. For example, HSCs (non-cycling) enter the proliferating stage to become the hematopoietic progenitor cells (HPCs, cycling). The number 5 on a cell, for instance, means that the HPCs at this stage have the potential to differentiate into five different types of precursor cells.

The committed, monopotent precursor cells then differentiate toward mature end cells, such as Me (megakaryocytes), E (erythrocytes), G (neutrophils/granulocytes), M (monocytes), or L (lymphocytes). Lymphoid precursor cells then differentiate into monopotential precursors for B and T cells. After expression of Ag receptors on the cell surface and on encountering Ag, B cells differentiate into plasma cells, i.e., PFCs (plaque-forming cells), or memory B cells. T cells become CD8+ or CD4+ after thymic education, maturation, and negative and positive selection. Memory T cells are generated later during differentiation. Fig. 50.2 shows the markers and events that occur during the development of pre-T cells – the process of maturation, education, and apoptosis of mature CD4+ or CD8+ T cells from CD4+8+ T cells. Genes encoding transcription factors and other important genes known to be expressed specifically in lymphopoiesis and that affect function, i.e., loss of function (knockout, knock-down) or gain-of-function (ectrophic expression by transducing with retroviral vectors containing transgene of interests) are cited in the chapter of Chen [4]. Recently post-transcriptional events, especially the miRNA pathways, have been shown to play important roles in targeting the mRNAs encoding for genes relevant to the differentiation and function of the precursor/mature cells of the immune system. Some are described in the Fig. 50.1.

Some comments on this model

Very little is known about how totipotent and pluripotent stem cells differentiate into ectoderm, mesoderm, and endoderm or how mesoderm differentiates into hematopoietic lineages. These are the central issues of embryogenesis, and this part of the model is intentionally very sketchy. Why and when multipotent, lineage-specific stem cells divide asymmetrically or progress to the next stage of commitment are unknown. The underlying rules may be stochastic or inductive. But the progression of the stage of commitment is more likely due to the turning on and off of genes encoding transcription factors, and the post-

miR-10 family members. MiR-126 represses the mRNAs encoding polo-like kinase 2 (PLK2) and HOXA9, promotes the expansion of lymphoid-myeloid committed progenitor cells [16]. The production of miRNAs by Dicer is required for efficient T cell, as well as B cell development. miR-146, and miR-223 target the developmental stage from lymphoid committed stage to T cell development, and miR-181 repress the development from lymphoid committed stage to pro-B stage [58]. During the T cell development in the thymus, the miR-17–92 cluster is shown to target mRNAs encoding for PTEN (phosphatase and TENsin homologue) and BIM (BCL-2-Interacting Mediator of cell death). The repression of mRNAs coding for BIM by miR-17–92 cluster also affects the differentiation of pre-B to B cells. MiR-181a is shown to target mRNAs encoding for phosphatases such as DUSP5 (DUal-specificity protein phosphatase 5), DUSP6, SHP2 (SH2-domain-containing protein tyrosine phosphatase 2) and PTPN22 (protein tyrosine phosphatase, non-receptor type 22). In the periphery, T cell differentiation is modulated by several miRNAs: miR-155 is shown to have dual roles in T cells: to repress mRNAs of MAF (Macrophage-Activating Factor) which leads to in favor of the differentiation of CD4+Th0 cells towards Th1 cells; to repress mRNAs of SOCS1 (suppressor of cytokine signaling 1) which is implicated in the survival of Treg cells. MiR-148a is shown to repress mRNAs encoding for BIM, affecting the commitment of Th1 memory (Haftmann and Radbruch, personal communication, unpublished). MiR-326 is shown to target mRNAs encoding ETS1 and resulting in promoting the differentiation of CD4+Th0 cells toward Th17 cells. miRNAs are implied to maintain immune tolerance of Treg cells to self- tissues, thereby preventing autoimmunity. During the B cell development, besides the role of miR-17–92 cluster on BIM (above), miR-150 is shown to repress mRNAs encoding for MYB, affecting the development of ProB cells. In the periphery B cell development, Beside affecting two steps of T cells development (above), miR-155 targets mRNAs encoding for AID (activation-induced cytidine deaminase) and PU.1 which promotes class switch and antibody production [16].

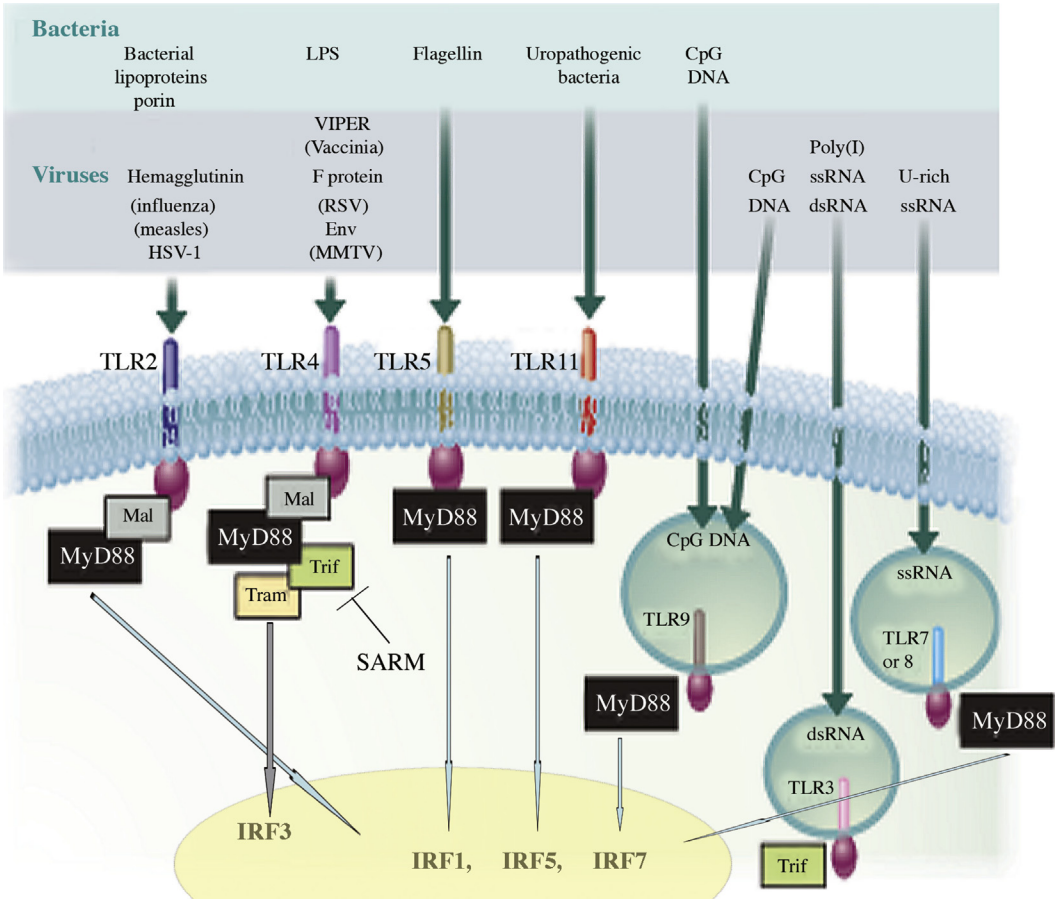

FIGURE 50.2

Going down the Toll mine. Toll-like receptors (TLRs) provide a repertoire for sensing pathogen-derived molecules during the innate immune response. TLRs in endosomal membranes detect bacterial and viral nucleic acids. The relative contribution of each TLR to the innate immune response is not yet known because pathogens contain multiple ligands specific for several different TLRs. The signaling pathways associated with each TLR are different, although they share common components. Specific signals may emanate from the adapter proteins recruited by each TLR (MyD88, Mal, Trif, and Tram). One important question concerns how the immune response is tailored to each pathogen according to the activation of specific signaling pathways triggered by different pathogen products (O'Neill et al., 2003). Besides dsRNA, TLR3 was shown to be able to sense ssRNA such as poly(I) (polyinosinic adid) [105]. HSV-1, herpes simplex virus 1; LPS, lipopolysaccharide; VIPER (Viral inhibitor peptide of TLR4) from A46 protein of vaccinia virus [104], RSV, respiratory syncytial virus (corrected following the erratum, Science, postdate 4 June 2004); MMTV, mouse mammary tumor virus; Porin (bacterium, not influenza). *(From O'Neill [62] with permission. The figure has been modified following the erratum in Science, postdate 4 June 2004), i.e., Porin is a bacterial component and not viral and is shifted from the grey region upward to the green region. I have also included the IRF family transcriptional factors as targets for TLR 5 members signaling [64]).*

transcriptional events regulating the epigenesis, and expression, degradation of mRNAs and the translation machinery.

Brown and coworkers originally formulated their model based on data from the differentiation pattern of several myeloid cell lines. Their scheme of the development of lymphoid lineages was purely hypothetical in the original model, and the development of mature lymphoid cells (in Part 2, Ag-dependent step) was not included. It was proposed that precursor B cells become committed before precursor T cells. I have modified this step to the pre-commitment to lymphoid precursor cells. Also, I have changed the commitment of lymphoid precursor cells to occur after the myeloid precursor cells. However, the committed lymphoid precursor cells should still be viewed as hypothetical, because there are many examples supporting the common lineage development of B cells and myeloid cells and not of precursor T cells. Committed lymphoid precursor cells are not clearly identified and isolated (details in Stage 3, later).

There is ambiguity in the original model; for example, the issue of the timing of each point of decision was not addressed. The original hypothesis implied that stem cells that do not receive the appropriate signals would proceed 'spontaneously' to the next stage in the differentiation sequence. Based on published data and on observations on the abortive development of lymphoid cells from blood islands derived from EBs (embryoid bodies) [4,5] and on the essential requirement of cytokines to maintain and to propagate stem cells derived from transgenic fetal liver, I tend not to be in favor of spontaneous progression; appropriate inductive signals for the transcriptional activation of lineage-committed genes are stringently required. Moreover, because programmed cell death plays an important role in the fate of cells during embryogenesis, I have included apoptosis as another important factor. This model has gained support from the phenotypes of mice in which genes encoding transcription factors have been deleted by knockout, knock-down, the so-called loss-of-function approach, and from the phenotype of cells in which transgenes are transduced using retroviral vectors, the so-called gain-of-function approach. Transcription factors controlling the sequential commitment of HSCs have been summarized [4]. In this chapter, I shall include the individual/clusters of miRNAs, which are reported to play critical roles in regulating the differentiation pathways and some functions of lymphoid (precursor) cells.

CRITERIA FOR ENGINEERING DEVELOPMENTAL STAGES OF LYMPHOPOIESIS

I attempt to explore the feasibility of engineering lymphoid cells and their stem cells at several defined stages of differentiation. The criteria for deciding on feasibility are:

1) Intrinsic self-renewal of HSCs, HPCs, and more differentiated cells,
2) The availability of cell surface markers for identification and purification,
3) The supply of recombinant growth factors and appropriate stroma cells,
4) The existence of favorable cell culture conditions that promote growth instead of differentiation,
5) The possibility of educating lymphocytes to become antigen-specific memory cells,
6) The possibility of introducing, either genetically or somatically, genes of interest along with inducible promoter and regulatory sequences,
7) The possibility to introduce siRNAs / miRNAs of interests into the cells in culture or by genetic manipulation of mice to show the phenotype of targeting the mRNAs encoding the gene products.

Technical advances make the engineering of HSCs, HPCs, and lymphoid cells attractive for further manipulation, such as introducing new genes or reprogramming cells to iPS or manipulating the gene products and function post-transcriptionally via miRNAs.

STAGES OF LYMPHOPOIESIS FOR ENGINEERING

Fig. 50.1 shows a schematic diagram of the stages at which lymphoid cells and lymphoid precursor cells might be engineered. These stages are now discussed individually.

Stage 1: 0 cells

Null (0) cells include the fertilized eggs, which are totipotent, the blastocyst-derived Embryonic Stem Cell (ESC) lines, and somatic cells reprogrammed into induced Pluripotent Stem Cells (iPS), both of which are pluripotent. Mouse ES cell lines of different strain origin have been available for a long time, and they possess the property of differentiating into different somatic lineages *in vitro* and *in vivo*, homologous recombination, and germline transmitted through the crossing and breeding of progeny. ES cells from many other animal species are also available. Establishment of human ES-like cell lines has been reported since 1998, and many

In Vitro Fertilization (IVF) units can derive such cell lines. Cellular reprogramming of mouse somatic cells to ES-like, or iPS was reported, when embryonic fibroblasts were infected with retroviral vectors containing four transcription factors: Oct4, Sox2, Klf4 and c-Myc (mOSKM) [6,7]. Using similar strategy, human iPS cells (h-iPS) were derived using human OSKM transcription factors [8] or when Klf4 and c-Myc were replaced with transcriptional factors, Nanog and Lin28 [9].

Other technologies and delivery methods have been rapidly applied to this field; integrating viral vector system in combination with Dox-inducible expression, transient or excisable methods have been reported. More encouraging approaches include non-integrated RNA viral vectors (such as the Sendai virus [10], or more recently temperature-sensitive Sendai virus (Yamada, et al., personal communication, unpublished)), recombinant proteins incorporating cell-penetrating peptide moieties [11,12], improved episomal plasmid vectors [13], modified synthetic mRNAs of hOSKM [14,14a], are shown to be able to reprogram human skin fibroblasts and other cell types to become h-iPS cells. Some strategies are labor intense, but have reasonable efficiency and no genomic alternation which allow potential clinical application. More strategies to derive iPSs are developing.

Through differentiation *in vitro*, several lineage-committed cells, such as those from bone and cartilage, have been shown to be obtainable from hES cells and h-iPS. There are conflicting reports about the differentiation potential of hES/h-iPS cells into lymphoid lineages *in vitro* (see later).

Due to its potential to be an unlimited source for 'personalized' transplantation or autotransplantation for treating blood diseases, many groups are investigating whether iPSs could differentiate into lymphoid lineages *in vitro*. Some investigators suggested that iPSs might retain epigenetic memory; i.e., they are prone to differentiate preferentially into the original somatic cell types from which they are derived. This might distinguish iPSs from ES cells.

Strictly speaking, the only way to prove that an hES/iPS cell line is truly pluripotent is to demonstrate germline transmission in human beings − a task that should not even be considered. Similarly, genetic and cellular engineering at this level should be limited to studies *in vitro*. ES/iPS cells are stem cell lines that divide symmetrically. Unlike lineage-committed stem cells, which are rare, ES/iPS cells are almost an exception, being readily available in abundance. mES cells can proliferate without differentiation if feeder cells and/or cytokines such as LIF (leukemia inhibitory factor) are provided, whereas the hES/h-iPS cell lines established so far are feeder-cell-dependent, and LIF has no supportive effect. They can be induced to differentiate by removing the feeder cells (and cytokines). A few surface molecules are available for characterizing ES/iPS cells. Antibodies against various components that have been used to characterize such cells, such as those against stage- specific embryonic antigen-l (SSEA-l), enable one to distinguish undifferentiated from differentiated mES cells. mES/m iPS cells are SSEA1+, SSEA3−, SSEA4−, TRA-1−60−, TRA-1−81−, Oct4−, Oct6+, AP+ (alkaline phosphatase), telomerase+; hES/h-iPS cells are SSEA1−, SSEA3+, SSEA4+, TRA1−60+, TRA1−81+, Oct4+, AP+, telomerase+.

Stem cell genomics, or the systems biology approach to stem cells, is being used. It considers the complex nature of cells and aims at a comprehensive understanding of stem cell mechanisms. The gene expression profiles of different stem cell types are being determined using DNA microarrays. These molecular signatures are stored and available in the stem cell database and allow a comparison of different stem cell types. On the basis of the obtained molecular signature, candidate genes, such as transcription factors, are subjected to the loss-of-function approach by knocked-out, knocked-in, or knocked-down by RNAi/siRNA, and the effects on the expression of downstream genes are determined with DNA microarrays. In this way, gene regulatory networks can be rapidly identified. More miRNAs pathways identified to regulate networks are characterized.

This approach has been used to identify gene regulatory networks implicated in the self-renewal and differentiation of mES cells. Based on a microarray time course study of retinoic acid-induced ES cell differentiation, 169 genes that are downregulated in the course of differentiation were found, and 40 of them were investigated further. ES cell cultures infected with lentiviral vectors containing the EGFP gene in addition to one of these 40 genes (RNAi/siRNA knock-down or overexpression) were investigated in a competition assay, where respective infected cells were mixed with not infected cells. In this way, higher or lower proliferation rates of the infected cells could be determined based on measured EGFP fluorescence. Changes in ES cell number could be due to a function of the respective gene in cell cycle progression, cell survival, or prevention of lineage-specific differentiation. Downstream effects of changes of gene expression were determined with DNA microarrays. Such an approach also applies to the study of other cells, such as hES cells, hEC cells, h-iPS cells, HSCs, pre-B cells of mouse and, human origins, as well as mouse pre-T cells [15], and Treg cells (ref. cited in [4]).

In addition to microarray studies for stem cells, the extent of post-transcriptional modifications within the stem cell transcription has been reported. Thousands of genes expressed in HSCs and ES cells undergo alternative splicing. Using combined computational and experimental analyses, the frequency of alternative splicing has been found to be especially high in tissue-specific genes, as compared to ubiquitous genes. Negative regulation of constitutively active splicing sites can be a prevalent mode for generation of splicing variants, and alternative splicing is generally not conserved between orthologous genes in human and mouse (ref. cited in [4]).

The study of miRNAs has become a major subject in recent years. miRNAs are highly conserved, small, single-stranded non-coding RNAs, encoded by genomic DNA and are most commonly transcribed by RNA polymerase II. They function by directly binding to the 3′ untranslated regions (UTRs) of specific target mRNAs, leading to the repression of protein expression and the promotion of target mRNA degradation. The initial discovery was made in plants and worms, and later they were found in mammals. At least 700 different miRNAs have been identified in the human genome, and $>$ 100 different miRNAs are expressed by immune cells. miRNAs have the potential to influence the molecular pathways that control the development and function of the immune system. The pathways of miRNAs are shown to be the regulators of networks. In addition, several post-transcriptional regulatory mechanisms that affect miRNA processing have been identified. The processes of miRNA biogenesis, target mRNA repression and function have been reviewed [16–18] and are beyond scope of this chapter.

Many genes encoding lymphoid-specific functions have been knocked out, miRNA/siRNA knock-down technology has been applied, and more studies are under way to develop specific deletions or replacements of genes. Vectors with inducible promoters are being used to introduce genes in a controllable, tissue-specific manner. Fig. 50.1 includes various individual or clusters of miRNAs, which have been shown to target the mRNAs encoded by genes critical for the regulation of differentiation to lymphoid lineages from HSCs.

Growth requirement for differentiation of ES/iPS cells to lymphoid cells

Under appropriate conditions, ES/iPS cells can differentiate *in vitro*. Many different culture systems are available for studying the development of lineage commitment. Because ES/iPS cells are pluripotent, optimal culture conditions would enable the formation of mature cells and tissues and even of organs in well-organized three-dimensional structures *in vitro*. That is, one should be able to generate an artificial fetus in culture without any external cells or other factors. In fact, organogenesis from ES/iPS cell culture is still in its infancy. Nevertheless, with the culture conditions and system that we have developed, mature and embryonic cells in

some form of tissue-like organization, though never become the functional and true organs, of certain orderly structures (gut-like, epidermal-like, and thymus-like structures), can be observed.

Many genes have been identified that play important roles in the differentiation of ES/iPS cell to mesoderm and then to derivatives such as HSCs (see figure legends [4]).

Many researchers have attempted but failed to study the differentiation of lymphopoietic precursor cells obtained from mES cells. Many have observed the development of yolk sac blood islands in culture; these presumably contain HSCs. But only myeloid cells could be produced in the culture systems reported. Only a few systems allow the generation of lymphoid precursor cells, and these were mostly B cells, but also T and B cells, in a quantity sufficient for further manipulation [4,5].

The reasons for these variations are unclear. It is partially due to the origin and pluri-potentiality, hence the fragility and variability, of ES cells but partially due to experimental manipulations, different culture conditions [5,18a], and the transient expression of genes relevant to the developmental stage of hemato-lymphopoiesis from mesoderm equivalent at the yolk sac stage. Homeodomain transcription factors, HoxB4 (see later) is an example of such genes. Even in the hands of a single researcher, the potential of lymphopoiesis from the same ES cell lines varies greatly among different experiments, and why this is so remains a mystery. The culture conditions vary, depending on which lineages are chosen for study. For example, methylcellulose culture is preferred for myeloid lineages but is inferior for lymphoid lineages. Several culture conditions that favor the differentiation of ES / iPS cells to lymphoid lineages are available.

Through the work of many groups, it has become clear that lymphoid precursor cells can be obtained from mouse ESCs in culture. However, the development of mature B plasma cells and mature T cells requires a two-step procedure — a two-step culture procedure for plasma cells, and culture and animal implantation for mature B and T cells. When chimeric bone marrow cells from embryoid body-implanted nude mice, which contain cells of ESC origin, were injected into the host mice, the bone marrow cells were shown to repopulate the primary and secondary lymphoid organs, i.e., bone marrow, spleen, and lymph nodes. The data indicate that HSCs and HPCs derived from ESC can be transferred. However, when injected into the host animal, such as lethally irradiated adult mice instead of un-irradiated nude mice, dissociated cells from blood island of the EB, instead of the whole EB, killed the mice when intravenial injection was performed, and failed to repopulate the host immune system or to achieve a stable engraftment when intra-peritoneal injection was performed [5].

The work on the expression of (transcriptional) molecules such as HoxB4, Cdx4, and especially, the transduction of transgenic expression under the inducible tet-promoter using retroviral vector, has been shown to understand the mechanism and pathway. HoxB4 is a homeodomain-containing transcription factor with diverse roles in embryonic development and the regulation of adult stem cells. This gene has a double life and can act in opposite ways when expressed by different cells, promoting the proliferation of stem cells while activating the apoptotic pathway in some embryonic structures. It is implicated in the self-renewal of definitive HSCs, being transiently expressed in blood developmental stages somewhere between the yolk sac stage and the fetal body stage and also being expressed in human cervical carcinoma. Persistent overexpression of HoxB4, however, inhibits the development of blood lineage.

It was examined to show its effect on hemopoiesis using a variety of tools, including retroviral transgenic expression. Expression of Homeodomain transcription factors, HoxB4 in primitive progenitors, and when combined with culture on stromal cells, induces a switch to the definitive HSC phenotype. These progenitors engraft lethally irradiated adult mice and contribute to hematopoiesis in primary and secondary hosts. Thus, HoxB4 expression

promotes the transition from primitive cells to become HSCs. Overexpression a high level of expression, of HoxB4 is shown to perturb the differentiation and to predispose the manipulated cells to leukemogenesis. HoxB4 may affect cell growth in a dose-dependent manner and may disturb the differentiation into lymphopoiesis.

The manipulation of essential genes has partially overcome the problems of variability in the development of hematopoietic cells from mesoderm-derived cells, such as yolk sac cells and EBs, and increased engraftment into irradiated adult mice. Combining HoxB4 gain-of-function and caudal gene family, Cdx4 gain-of-function has been shown to increase the multilineage haematopoietic, including lymphoid, engraftment of lethally irradiated adult mice.

Others that have been tried are: mMix, Stat 5, a signal transducer under similar inducible conditions to express in mES-derived HSC and to grow similarly on OP9 stroma cells, shown to increase the induction of preferable myeloid, rather than lymphoid, differentiation. BCR/ABL, a chronic myeloid leukemia-associated oncoprotein, is shown to transform a subset of HSC between erythryo- and lymphoid-myeloid lineages (ref. cited in reference [4]).

The combined *in vitro* and *in vivo* culture system described earlier using nude mice as the hosts can also be employed to study thymic stroma as well as well-organized, highly differentiated cells of many other lineages, including gut epithelia, skin with hair follicles, bone, muscle, neurons, and glia. One essential requirement for successfully applying this combined system is that the cells should first differentiate in culture, until the EB developed before the subcutaneous implantation. Otherwise, tumors may grow, due to the expression of the acylated dimeric iLRP (immature 32—44 kDa Laminin Receptor Protein) and other, still-to-be-identified OFA (OncoFetal antigen) positive in early to mid-gestation [19]. The development of endogenic thymic epithelial cells as well as stroma cells inside the ES-embryonic bodies also explain partially the findings of an efficient development of T cells in the absence of exogenous stroma cells.

Stroma cell line RP.0.10 is able to support both T- and B-lymphoid precursor cells derived from ESCs in some labs. Stroma cell lines OP9 and S17 were originally reported to support B precursor cells and myeloid but not T precursor cells derived from ESCs. Many other stroma cell lines do not support the differentiation of ESCs to lymphoid precursor cells. The S17 stroma cell line was compared to many stroma cell lines for the production of cytokines and stroma function, i.e., the stem cell support function (ref. cited in reference [4]) (see also later, Stage 2; there were no correlations in the assays. Thus a yet-to-be-identified extracellular matrix molecule of S17 cell lineage may play a role in supporting the function of HPCs.

With the insertion of genes involved in Notch-Delta signaling pathways, it was shown that the OP9-derived cell line, OP9-DL1 (Delta-like 1), increases efficient T cells, which appeared from sources such as fetal liver [20], human cord blood [21], ES cells [22] and recently ES / iPS (see later). The study using switch cultures shows that while necessary to induce and sustain T cell development, Notch/Delta signaling is not sufficient for T-lineage specification and commitment but, instead, can be permissive for the maintenance and proliferation of uncommitted progenitors that are omitted in binary-choice models. Moreover, it was demonstrated that a three-dimensional structure to allow the interaction of precursor-supporting cells plays an essential role for it to function well (see also Stage 4).

Other candidate molecules and cells that may support the lymphopoiesis include the following: dlk, an epidermal growth factor-like molecule of 66 kDa in stroma cell lines was reported to influence the requirement for IL (interleukin)-7 in supporting mouse pre-B lymphopoiesis, and dlk is suggested to play an important role in the bone marrow HPC microenvironment. Another high-molecular-weight CD166 (HCA/ALCAM) glycoprotein was shown to express in human HPCs as well as stroma cells. This molecule is involved in adhesive interaction between HPCs and stroma cells in the most primary blood-forming organs.

Rethinking the seemingly conflicting results and the inconsistent report of differentiation of ES/iPS cells to lymphocytes, I wonder if culturing ES/iPS-derived lymphoid progenitor cells on stroma cell lines derived from the most primitive stroma environment from the fetus (such as paraaortic cells) may be a better choice for obtaining consistent results, rather than using the existing stroma cell lines. Indeed, stroma cell lines from such a source have been derived.

The field of hESC/iPS (human ESCs/induced pluripotent) cells represents a theoretically inexhaustible source of precursor cells that could be differentiated into any cell type to treat degenerative, malignant, or genetic diseases or injury due to inflammation, infection, and trauma. This pluripotent, endlessly dividing cell has been hailed as a possible means of treating various diseases. hESCs/iPSs are also an invaluable research tool to study development, both normal and abnormal, and can serve as a platform to develop and test new therapies.

They are also a potential source of HSCs for therapeutic transplantation and can provide a model for human hematopoiesis. The first stable hES cell line was reported in 1998 [23]. Now many centers can establish hES cell lines, and clinical trials for treating spinal injury and Macular Dystrophy are proceeding in the US and Europe. The first human iPS cell line was reported in 2007 [8], and many other labs could derive such somatic reprogrammed stem cell lines using better strategies. The current goal is to establish clinical grade hES/iPS cell lines for potential therapeutic purposes. Many clinical grade hES cell lines are available. However, so-called clinical grade, personalized, stem cell lines — the human iPS cell lines — still need to be derived in the clean air condition. Hopefully in due time, the limiting steps such as the sources for establishing Good Manufacturing Practices (GMP) grade non-integrating vectors/synthetic RNAs, other essential technical tools, raw materials required for culturing of transfected or transduced somatic cells, and the isolators instead of GMP facility, will become widely available and affordable.

More attempts to differentiate hESCs to HSCs *in vitro* have been reported recently [24–29b]. From such studies, hES cells have been shown to differentiate into HSCs, using various protocols and different supportive stroma cell lines, with or without cytokines. It seems that the differentiation into mesoderm-derived lineages and then to MHE (mesodermal-hematoendothelial) lineage can occur, resembling human yolk sac development. The cellular and molecular kinetics of the stepwise differentiation of hESCs to primitive and definitive erythromyelopoiesis from hEBs in serum-free clonogenic assays have been demonstrated [27]. Hematopoiesis initiates from CD45+ hEB cells, with the emergence of MHE colonies. A first wave of hematopoiesis follows MHE colony emergence and is predominated by primitive erythropoiesis. A second wave of a definitive type of colonies of erythroid, Granulocyte-Macrophage (GM), and multi- lineage Colony Forming Cells (CFCs) follows. These stages of hematopoiesis proceed spontaneously from hEB-derived cells without requirement for supplemental growth factors during hEB differentiation. Gene expression analysis revealed that initiation of hematopoiesis correlated with increased levels of SCL/TAL1, GATA1, GATA2, CD34, CD31, and Cdx4. These data indicate that the earliest events of embryonic and definitive hematopoiesis can be differentiated from hESCs *in vitro*.

However, differentiating hEBs further into HSCs, and lymphohematopoietic lineages is variable and unpredictable.

Vodyanik et al. [25] reported that hES cells could differentiate to CD34+ cells using mouse stroma OP9 (better than S17 and MS-5) co-culture system. However, when cultured on stroma MS-5 (but not OP9, S17) in the presence of stem cell factor, Flt3-L, IL7, and IL3, such CD34+ cells could differentiate into natural killer cells and pre-B-lymphoid cells which expressed mRNAs for VpreB and Ig-alpha (CD79a or mb-1) components of pre-B cell receptor complex, as well as myeloid lineages, but not T lymphoid cells. In another report, the hES-derived CD34+ cells were implanted into fetal sheep intraperitoneally and differentiated in primary

and secondary hosts, the cells could differentiate into many cell types but no lymphoid cells could be detected [29a]. Martin et al. [109] claimed that natural killer (NK) cells could be derived, but not T or B lymphoid cells under the culture condition and protocol used.

The expression of transcription factor HoxB4 appears to play a role in causing cells to become lymphoid cells in the mouse system and would explain the occasional determination of precursor cells to commit to lymphoid lineages. It implies right away that can apply to study the lymphohemopoiesis in the human system. Indeed, Bowles et al., (2006) have reported such an attempt. Culture of hES cells on mouse feeder cells or in cell-free culture conditions result in low levels of differentiated HPCs. Transgenic stable HoxB4-hESC clones were generated by the lipofectamin transfection method. *In vitro* differentiation of hESCs, as EBs, in serum-containing media without cytokines led to the sequential expansion of erythroid, myeloid, and monocytic progenitors from day 10 of culture. These cells retained the capacity to develop into blood elements during culture. Overexpression of HoxB4 considerably augments the development of three myeloid lineages of hESCs; however, no lymphoid progeny were reported.

Theoretically, lentiviral vector introducing HoxB4 under a tet-on system should be a comparable approach for further study. However, another report does not support this notion to show a functional role of HoxB4 in HSCs in their combined *in vitro* and *in vivo* system, using Server Combined ImmunoDeficiency (SCID) mice [26]. It is interesting that hES-derived HSCs failed to reconstitute i.v. transplanted host because of cellular aggregation causing fatal emboli formation, which is similar to our attempt using mEB-derived cells. Direct femoral injection allowed host survival and resulted in multilineage hematopoietic repopulation. However, hES-derived HSCs had limited proliferative and migratory capacity compared with somatic HSCs, which correlated with a distinct gene expression pattern of hESC-derived HSCs that included HoxA and HoxB gene clusters. Transduction of HoxB4 had no effect on the repopulating capacity of hES-derived cells. A yet-to-be-identified molecular program is postulated to contribute to the atypical behavior of hES-derived cells *in vivo*.

The following more recent reports contribute to the positive aspects of the debate. Using sequential *in vitro* co-culture of EGFP-expression hESC on stroma OP9 for 10 days, and engraftment into the kidney capsule of SCID mice, or RAG2−/− mice, containing fragments of human thymic- and fetal liver tissues, the so-called SCID-hu(Thy/Liv) / RAG2-hu(Thy/Liv) mice, Galic et al. [28] demonstrated that T lymphoid lineage with the phenotype of EGFP-expressing cells could be found in various stages of thymocyte maturation, including immature CD4+CD8+, and mature CD4+CD8−, and CD8+CD4− cells. When such thymocytes were harvested and cultured with plate-bound anti-CD3 plus soluble anti-CD28 stimulating conditions, the cells were shown to be responsive to the stimulation by increasing CD25 expression. The reporter EGFP transgene continued to express at high frequency in the hosts throughout thymopoiesis in 3−5 weeks of experimental time.

Timmermans et al. (2009) used four steps of differentiation protocols by co-culturing hESC with stroma OP9, and OP9-DL1. After 7−9 weeks of differentiation, they could find T lymphoid cells, with the phenotype of CD4+CD8beta+ and TCRgamma-delta+ cells. CD3+ T cells was stimulated with PHA, and shown to be able to proliferate and to produce IFNγ.

Thus, conflicting reports continue to surface, giving the impression that the differentiation into lymphohemopoiesis seems to be, if not more rare, as rare as variable as the *in vitro* differentiation system using mES cells. The question of the variability among different hES cell lines and clones, similar to the observation using mES cells, are also reported. Derived, somatic, tissue-committed, stem, precursor cells remain rare. The study of individual gene expression using hES cells and its relationship with the group of genes and the final outcome of the cell fate is a challenge and will require more research in the future. Combining multiple genes, such as mMix, Cdx4, and HoxB4, with a gain-of-function approach might be a possible way of increasing the lymphohematopoiesis derived from hES cells.

In addition to hES cells, many groups are investigating whether iPSs could differentiate into lymphoid lineages *in vitro*, using the iPSs derived from blood cells as well as fibroblasts.

Below are some selected examples of potentially promising experiments. Wada et al. [110] used a three step system for m-iPS differentiation *in vitro*: EB formed after 5 days differentiation: in suspension culture, single cells were harvested and co-cultured with Flt3L (Flt3 Ligand) and stroma OP9 for eight days, then harvested every six days and co-cultured with Flt3L, IL7, and stroma OP9 for B cells, or stroma OP9-DL1 for T cells. The results showed that mouse B cells and embryonic fibroblast derived iPS could differentiate into T cells by showing TCRVbeta rearranged, CD4−CD8+ were generated, Treg could be detected upon TGFbeta stimulation, but no B cells could be detected. The data challenged the suggestion that iPS tend to retain epigenetic memory.

Carpenter et al. [111] reported differentiation into pre-B cells by co-culturing human dermal fibroblast derived iPS cells with stroma OP9 for 10 days. CD34+ cells were harvested, then co-cultured with stroma MS-5 for a further 21 days. The differentiated cells had the phenotype of CD45+ CD19+ CD10+; and expressed mRNAs encoding for Pax5, IL7R-like, and VpreB receptor; exhibited partial genomic D fragment-J fragment of Heavy chain (D-JH) rearrangements, but no full Variable region of Heavy chain -J fragment of Heavy chain (VHJH) rearrangement. Such cells were negative for surface IgM and CD5 expression.

For the purpose of treating patients infected with HIV, Ye et al. (personal communication, unpublished) developed HIV resistant h-iPS by preparing iPS cells from patients CD34+ cells and peripheral blood mononuclear monocytes using Sendai viral vector. iPS cells were knocked out both wild-type CCR5 alleles or replaced them with the CCR5δ32 mutation using BAC based homologous recombination and differentiate them into HSC by the spin Embryoid Body (EB) method without any stroma cells in the culture. The HSCs are ∼50% CD34+ and ∼25% CD34+/CD43+ HSC, HIV resistant, and could be used for further characterization, differentiation into mature blood cells including monocytes and lymphocytes, and for autologous transplantation.

In order to completely remove the residual Sendai viral vector containing the MOSK which was shown to interfere with the differentiation potential of iPS *in vitro*, Yamada et al. (personal communication, unpublished) derived h-iPS cells from blood T cells or fibroblasts, which were reprogramd using temperature sensitive (ts)-Sendai viral vector containing tsA58 (SV40Tag)MOSK. Such iPS could differentiate in culture to HSC by co-culturing with stroma OP9, and further cultured at the presence of stroma OP9-DL1 plus SCF, IL7, Flt3L, T lymphoid lineages could be detected. Tumor antigen-specific CD3+, CD4+ or CD8+ lymphocytes from precursor T cells could be generated and expanded. Antigen-specific T cells derived from iPS were also obtained by Nishimura et al. (personal communication).

Vizcardo et al. (personal communication) could establish Mart1-T-iPS cells from Mart1 (Melanoma antigen recognized by T cells 1)-specific CTL cells. These iPS cells were differentiated *in vitro* into CD4+CD8+Mart-1+ precursor T cells. In the mouse system they could expand proT cells with solid phase DL-1 and IL7. The h-Mart1-T-iPS was shown to differentiate to proT-cell stage *in vitro* and to expand using a set of human cytokines. They are trying to induce mature T cells by transplantation into NSG (NOD-SCID common gamma−/−) mice and *in vitro*.

Stage 2: HSCs and HPCs

The terms hematopoietic stem cells, progenitor cells, and precursor cells are used loosely in the literature. Hematopoietic stem cells and HPCs are defined as two populations of stem cells sharing similar surface markers. HSCs are rather quiescent, non-cycling stem cells, whereas HPCs are cycling cells. In mice, c-kit+, thy-1low, lin−, and scal+ bone marrow cells are defined as HSCs or HPCs. HSCs and HPCs in bone marrow are heterogeneous in size and in self-renewal capacity. Moreover, they have finite life spans. In human bone marrow,

CD34+HLA-lin-thy-1low rhodamine123low stem cells are generally defined as HSCs and HPCs. However, CD34 is also expressed in other lineages, such as vascular endothelial cells and muscle precursor cells. It is well established that mouse HSCs and HPCs can be isolated, cultured, and transduced by retroviruses and used to repopulate animal hosts. In addition to bone marrow, they can be isolated from fetal liver, cord blood, fetal blood, yolk sac, and para-aortic spanchnopleura.

DO HSCS AND HPCS SELF-RENEW?

The self-renewal of HSCs and HPCs was carefully examined (ref. cited in reference [4]). By transferring bone marrow stem cells from one host to the other, it was found that the pool of donor bone marrow stem cells was smaller on transfer, and it was concluded that self-renewal is limited for somatic bone marrow stem cells. However, the results could be due to a dilution effect of the donor stem cells, if a certain absolute number of stem cells were required for the successful implantation of donor stem cells in the bone marrow. Using fluorescence *in situ* hybridization (FISH) and telomerase assays, it was shown that telomere DNA length predicts the age and replication capacity of human fibroblasts. DNA telomere length has been correlated with the replication potential of HSCs and HPCs. In human CD34+, CD71low, and CD45RAlow bone marrow stem cells, the length of telomeric DNA in HSCs and HPCs is correlated with the age of the donor. Stem cells in adults have shorter telomeres than those found in fetal cells, but both have the same telomerase activity. When the HPCs were expanded with cytokines without the support of stroma cells, there was a loss of telomeric DNA in culture. The loss of telomeric DNA in HSCs and HPCs from older people and cultured stem cells was interpreted as meaning that their replication potential is finite. An alternative interpretation would be that the culture conditions that allow stem cells to grow in the presence of cytokines may not favor the maintenance of telomerase activity and hence not the self-renewal of HSCs and HPCs.

Work on global miRNA expression profiling of human CD34+ HSC / HPC from Bone Marrow (BM), mobilized Peripheral Blood Cells (PBC) harvests, and umbilical cord blood have helped to identify several miRNAs expressed by the stem cell population. Genetic manipulation of the mice also helped to identify the miRNAs pathway related factors. Arsenate-resistance protein 2 (ARS2) is one of the factors identified to be involved in post-transcriptional regulatory mechanisms that affect miRNA processing. ARS2 expressed by HPC and is a component of the RNA cap-binding complex that promotes processing of pri-miRNA transcripts [30]. Mice deficient in ARS2 have bone marrow failure, possibly owing to defective HSC function, such the engraftment or reconstitution potential of HSC. Individual miRNAs, which shown to repress the expression of HSC relevant genes and to affect the differentiation of lymphoid cells and other lineages from stem cells are indicated in Fig. 50.1: miR-221 and miR-222 were shown to inhibit c-Kit expression in HSC and HPC, leading to impaired cell proliferation and engraftment potential of human CD34+ cells in NOD-SCID mice [31]. miR-221 and miR-222 are also suggested to play a role influencing cell migration at the Pre-B cell stage.

miR-196 and miR-10 were found to be located in the HOX loci; directly repress HOX family expression, thus regulating HSC homeostasis. Particularly, miR-196b was found to express in mouse HPC, regulated by transcription factor Mll (Mixed lineage leukemia), and to modulate HSC homeostasis and lineage commitment by repressing HOX family [32]. miR-126 is thought to act on suppressor PlK2 (polo-like kinase 2), shown to increase colony formation of bone marrow M-L progeny *in vitro* [33]. More work is needed to study the role of miRNAs in the long-term engraftment potential of HSC *in vivo*.

Many culture systems for studying the biology of mouse HSCs and HPCs are available. Many mouse stroma cell lines support the growth of HPCs. Studies on human stem cells use mouse stroma cell lines, such as S17 and AFTO24 among many others, or mixed primary stroma populations, called MSCs (mesenchymal stem cells), isolated from human bone marrow or

other sources, to support purified HSCs and HPCs or unseparated bone marrow cells. The establishment of heterogeneous human stroma cell lines with the help of a plasmid-containing SV40 T antigen under the control of an inducible metallothionein promoter has been reported, but their ability to support lymphopoiesis could not be demonstrated. Mixed human stroma cells, or MSCs, and cell lines that support human long-term culture-initiating cells also exist. However, these human stroma cell lines could not be shown to support the development of human lymphocytes from bone marrow stem cells.

MSCs have become a promising field, and many clinical trials are under way. The expansion of human MSCs in culture presents a challenge. They proliferate poorly in media supplemented with human serum, and they require the presence of selective lots of Fetal Calf Serum (FCS). Human MSCs are not immunogenic in an allogenic system *in vitro*, nor are they rejected *in vivo*. This makes them candidates for allogenic cellular therapy. MSCs have immunomodulatory effects: they inhibit T cell proliferation in mixed lymphocyte cultures, prolong skin allografts survival in baboons and decrease graft versus host disease (GvHD) when co-transplanted with hematopoietic cells. MSC induce their immunosuppressive effect, at least in part via a soluble factor and in part due to the activation of CD4+CD25hFoxp3+ Treg cells with suppressor activity through production of prostaglandin E2, transforming growth factor beta 1 and by direct cell contact [34]. Interestingly, MSCs have been shown to express Foxp3 [35]. A report indicated that prolonging the culture of MSCs runs the risk of them becoming tumor cells [36]. However, others have claimed that over several years of study in treating GvHD [37], no tumor has been observed (Le Blanc, personal communication, unpublished). Clinical trials which use MSCs to treat familial hemophagocytic lymphohistiocytosis [38], autoimmune disease such as scleroderma, multiple sclerosis, Crohn's disease and other diseases are ongoing [39].

Major problems in growing HSCs and HPCs are the variability of culture conditions, the efficiency of differentiation of the cultured cells to lymphoid lineages, and the poor reproducibility in the hands of different investigators. Also contributing to problems is the failure to report specific reagents and ingredients used as well as undescribed procedures, stroma cell conditions, batches of serum, and growth factors required in each system. Of course, the intrinsic multipotentiality of HSCs and HPCs also contributes significantly to variability. Many have claimed that a cocktail of cytokines alone could promote the differentiation of myeloid lineages from HSCs and HPCs in mouse and human systems (ref. cited in reference [4]).

A few have claimed the development of B cells at various stages of maturation, but no mature T cells could be found in such culture conditions, however, they are not reproducible in other's laboratories. The maintenance of long term cultures of self-renewing stem cells with potency for lymphopoiesis, especially T lymphopoiesis, requires stroma cells, additional cytokines, a three-dimensional structure to support the precursor cell-stroma cell interaction (also see Stage 3), and other culture conditions yet to be defined. Recently, several groups reported that solid phase-Delta-L-1, either fixed on tissue culture dish surface, or integrated into mouse stroma OP9 can mimic the thymic stroma requirement for growing human and mouse T cells from early progenitor cells including iPS derived HSC (see stage 1, above). Several culture systems seem to be promising for expansion *ex vivo* and potential differentiation of human and mouse HSCs. Human-based supporting cell lines, such as an endothelial-like cell line, ECV304/T24, were used to generate split-function amphotropic packaging cell lines. This manipulated cell line, APEX, was used for transduction and for support of the growth of HSPs [40]. The development of supporting human cell lines for lymphopoiesis is essential for the production of large quantities of cultured cells for manipulation and re-implantation.

Ruedl et al. [41] reported that transduction of mouse HPS with retroviral vector containing gene coding for NUP (NUcleoPorin) 98 and HOXB4 fusion can expand bone marrow derived HPCs for several weeks in culture, with the expansion of cells of ca.1016 fold. The expanded cells can differentiate into all lineages including T and B cells, mimic the self-renewal property

of primary HSC-HPS. An additional important finding is that such immortalized cells do not produce tumor in transplanted mice. This study opens interesting questions, such as whether this viral vector containing NUP98-HOXB4 fusion protein can immortalize the HSCs of embryoid bodies differentiated from mES cells in culture, and show similar potential to differentiate into all lympho-hemapoietic lineages. Another question is whether this viral vector can immortalize human HSCs-HPCs, and if not, whether the counterpart of the NUP98-HOXB4 fusion protein exists and exercises similar effects in human HSCs.

SELECTED EXAMPLES OF THE CLINICAL APPLICATION OF HUMAN HSCS AND HPCS

The use of human HSCs and HPCs as the cell base for gene therapy is a complicated issue. In most clinical protocols, HPCs are transduced *ex vivo* with retroviral vectors and re-implanted into patients. One example which has undergone phase I clinical trial for decades is the treatment of ADA (Adenosine DeaminAse) deficiency. ADA deficiency exists in all cells examined. However, T cells of these patients are selectively missing, causing a SCID symptom. Despite decades of study, the mechanism by which the ADA defect causes this specific deficiency of T cells remains unknown. Possible mechanisms have been postulated, such as the apoptotic pathway of CD95 (Fas/apo-1)-induced cell death.

An ongoing, improved ADA gene therapy protocol has been described. This is a modified protocol running with more than 20 patients, using a combination of low-dose chemotherapy with busulfan/fludarabine and a single transplantation with ADA-retroviral-transduced HPC. No ADA enzyme replacement was included in this modified protocol to treat the patients. The low dose (one quarter of the full dose) chemotherapy is to condition or to make space in the bone marrow for the transplanted, gene corrected HPC. No side effect has been reported of the gene-transferred patients, they live normally, and more important, no patient died so far. This improved treatment was conducted first in Milan [42], then in several centers in UK and USA [43].

CD34+ HPCs and progeny PBL cells were collected from five ADA-SCID children before transplantation and in their myeloid and lymphoid progenies up to 47 months after transplantation and a genome-wide analysis of RISs (retroviral vector integration sites) were performed [44,45]. The data revealed similar patterns of integration into the human genome before and after transplantation, with a preference for gene-dense regions, promoters, and transcriptionally active genes. The occurrence of insertion sites proximal to proto-oncogenes or genes controlling cell growth and self- renewal, including LMO2, was not associated with clonal selection or expansion *in vivo*. Clonal analysis of cell progeny revealed highly polyclonal T cell populations and shared RISs among multiple lineages, indicating that they were derived from the engrafted HPCs.

Besides ADA-deficient SCID, several clinical trials of gene correction therapy using CD34+ stem cells have been conducted, trying to restore immune cells in patients with SCID-Xl (X-linked severe combined immune deficiency), CGD (chronic granulomatous disease), WAS (Wiskott-Aldrich Syndrome).

The study of the SCID-Xl gene therapy clinical trials has been reported in Paris, in which HPCs are the target of MLV (murine leukemia virus)-derived retroviral vectors containing IL (interleuken) receptor gamma common chains. In this trial, no chemotherapy was administered, with the expectation that the progeny lymphoid cells would have a very high selective survival in the patients, and marrow conditioning to facilitate higher engraftment of HPC would not be needed.

Immune function has been restored in nie of 10 treated children with the transduction of gamma common gene transfer in CD34+ cells. The distribution of both TCR V beta family

usage and TCR V beta CDR3 (complementarity-determining region 3) length revealed a broadly diversified T cell repertoire. Further retroviral integration site analysis showed that insertion sites were shared by progenic T and B cells, granulocytes, monocytes, and the transduced CD34+. This finding demonstrates the initial transduction of very primitive multipotent progenitor cells with self-renewal capacity. These results provide evidence in the setting of a clinical trial that CD34+ cells maintain both lympho-myeloid potential as well as self-renewal capacity after *ex vivo* manipulation [108]. A trial in the US followed using similar techniques achieved immune restoration in another 10 patients [46].

However, due to the developed leukemia-like T lympho-proliferative disorder of a total of five of the 20 treated children in both trials, the trials were on hold [47–50]. Patients who had been clinically stable with good immune function developed a relatively abrupt onset of escalating levels of circulating T lymphocytes, with thymic mass and organomegaly. They were treated with chemotherapy and four have remained in complete remission with continued restored immunity, but one died from the leukemia. The research now focuses on the basic biology of the oncogenicity of the vector-related insertion site LMO2 of the affected T cells and of using the Lmo2-TLL transgenic mice model. The integrations are found to reside within FRA11E, a common fragile site known to correlate with chromosomal break points in tumors. The fragile sites attract a non-random number of MLV integrations. This explains the mechanism of four of the leukemia cases. The other leukemia is attributed to the transplanted IL2RG gene [48].

The reasons why this leukemic complication occurred in five of 20 XSCID gene-corrected patients, but none of more than 20 ADA-deficient SCID gene treated patients are not clear. The reasons possibly involve the role of the common gamma gene product (a trans-membrane protein capable of providing intracellular signaling), the nature of the HPCs of the XSCID patients, effects of the common gamma-deficiency on the susceptibility to transformation and the rapidity of immune reconstitution in the XSCID patients [43].

New approaches using safer integrating mouse SIN (Self INactivate) retroviral vectors, HIV-based lentiviral vector, or direct correction of the defective gene underlying the immune deficiency diseases are being developed, which might lead to safer and effective gene therapy.

Stage 3: Lymphoid precursor cells

The characterization of lymphoid lineages – committed precursor cells defined in terms of cell surface markers and functional assays of precursors and progenies – is still a challenge. One described cell type that is closest to the definition of lymphoid precursor cells is the CD4low precursor population isolated from adult thymus (ref. cited in reference [4]). Because this population of cells is restricted in its potential to differentiate into myeloid cells, it is preferentially committed to differentiate into T and B cells. These cells can also differentiate into thymic dendritic cells. The molecular markers of this population have not been well characterized. It would be interesting to see whether this population of cells can differentiate into myogenic cells, because it is possible to obtain differentiated myogenic cells from the adult thymus. The thymus contains lymphoid and MSCs, which can develop into other lineages, such as bone, cartilage and lung.

Little is known about the culture conditions for growing this population of cells. It is possible that stroma cell lines such as S17 could be used to expand the CD4low population of cells in culture, because it has been possible to use S17 and cytokines to maintain para-aortic splanchnopleural-derived precursor cells possessing T cell lineage potency in culture (in reference [4]).

A lymphoid lineage-preferable transcriptional factor, Ikaros, was thought to be an important molecular marker of lymphoid precursor cells at this specific stage of development. Ikaros was subsequently shown to have multiple effects on HSCs, lymphoid cells, T precursor cells, and others.

Using the transgenic approach, it is possible to trace lymphopoiesis between common lymphoid precursor and alpha-beta T cells. A transgenic mouse system is applied using pTalpha (pre-T cell receptor alpha) promoter to drive the human CD25 (hCD25) surface marker as a reporter. It marked intra- and extra-thymic lymphoid precursors but not myeloid cells. The extrathymic precursors were characterized as a common lymphoid precursor population (no. 1) expressing CD19-B220+Thy1+CD4+ cells using clonogenic assays. The earliest intrathymic precursors were CD4lowCD8−CD25−CD44+c-Kit+ cells and Notch-1 mRNA+.

By using the regulatory sequences from the gene encoding pre-T cell receptor alpha to drive hCD25 reporter and to produce transgenic mice, another common lymphoid precursor population (no. 2) was identified, which was B220+c-Kit−. In short term culture, population no. 2 cells could be derived from the no. 1 subset and contained cells that in clonogenic assays were characterized as bipotent T and B precursors. Mature alpha-beta T cells were produced when transgenic bone marrow cells were injected i.v.; thymocytes were cultured using a thymic organ culture system. The no. 2 subset may represent the most differentiated population with T cell potential before commitment to the B cell lineage.

The human counterpart of the mouse CD4low population is unknown. The expansion of CD34+, CD31+ human bone marrow B-progenitor cells and partial differentiation to B-precursors in serum-free culture medium in the presence of mixed primary human stroma cells and IL7 for a limited duration has been shown to be possible (ref. cited in reference [4]). A few such CD34+ precursor cells could differentiate into NK cells and T precursors when subjected to a secondary culture condition, with the thymic environment provided. The three-dimensional structure and the expression of Notch/Delta signaling of the thymic environment have been shown to play critical roles for supporting the differentiation of cells to the T cell lineages (also, in Stage 2) [51−54].

Stage 4: Precursor T cells

Mouse precursor T cells are identified to be thy-l+, CD117low, CD3−, pT+ (ref. cited in reference [4]). They can be derived from fetal and adult blood. Using markers such as the CD25, CD44, and TIS 21 (TPA-inducible sequence 21), pre-T cells can be classified into four subpopulations. They are the quiescent CD44+CD25−TIS21+ early cells and CD44−CD25+TIS21+ cells prior to TCR-beta selection. After selection, the cells are proliferating CD25+CD44+TIS-21low precursor T cells and CD25low CD44−TIS21low cells. By transgenic overexpression of TIS21 in precursor T cells and HPC, it can inhibit the expansion of thymocytes. By transgenic overexpression of TIS21 in precursor T-cells and HPC, it can inhibit the expansion of thymocytes (Konrad and Zuniga-Pflucker, 2005). Thus, somatic and genetic manipulations would become easier with cloning and identifying such "quiencenting genes" and their ability to express at stage-specific matter.

Other genes expressed which might play a role in the function of cells at this stage are the cell cycle control genes such as the D3 cycline of D type, the preTCR (pre-T Cell Receptor gene) and the BCL2A1 (antiapoptotic A1 gene). PreTCR+ cells are selected to survive and differentiate further, whereas preTCR− cells are selected to die. The induction of the BCL2A1 gene will induce pre-T cell survival by inhibiting activation of caspase-3. The knock-down of BCL2A1 expression can compromise survival, even in the presence of a functional preTCR. However, the overexpression of preTCR-induced BCL2A1 can contribute to T cell leukemia in mice and humans. Both OLIG2 and LMO1 were overexpressed in large thymic tumor masses. Gene expression profiling of thymic tumors that developed in OLIG2-LMO1 mice revealed upregulation of Notch1. Two genes considered to be downstream of Notch1 − Deltex1 (Dtx1) and preTCR-alpha − are also upregulated. The established OLIG2-LMO1 leukemic cell line was suppressed by a gamma-secretase inhibitor, suggesting that Notch1 upregulation is important for the proliferation of OLIG2-LMO1 leukemic cells. Thus Notch-Delta signaling is

critical to trigger the T cell development program. In addition, commitment to the T cell lineage is also shown to depend on BCL1b, while initiation of the T cell differentiation program begins earlier with the induction of TCF-1 (Tcf7 gene product) and GATA-3 [107].

T lymphocytes are generated in the thymus, where developing thymocytes must accept one of two fates: they either differentiate or they die. These fates are determined by signals that originate from the TCR. CD4+CD8+ thymocytes undergo one of three fates in the thymus: positive selection, negative selection (TCR-mediated apoptosis), or death by neglect. Only 5% of developing thymocytes are exported as mature T cells. Negative selection of thymocytes that express TCRs with high affinity for self-peptide-Major HistoCompatible antigen (MHC) deletes potentially self-reactive thymocytes, generating a largely self-tolerant peripheral T cell repertoire. Most negative selection is thought to occur in the thymic medulla, for this contains two types of specialized antigen-presenting cell — DCs (dendritic cells) and thymic epithelial cells (TECs). Medullary TECs transcribe genes that are normally expressed in peripheral tissues. Negative selection can occur before or after, and is thus independent of, positive selection and in thymocytes at all stages of development. Negative selection in response to high-affinity ligands might be due to increased TCR occupancy or a slower off rate (kinetic proof-reading). Although discrepancies exist between blocking experiments and genetically deficient mice, TCR signal and a second co-stimulatory signal might be required for negative selection. The kinetics of MAPK (mitogen-activated protein kinase) signaling might determine positive vs. negative selection signals. ERK (extracellular signal regulated kinase) is induced more rapidly during negative selection, which might determine the triggering of transcriptional factors, NUR77 and NF-B (ref. cited in [4]). The recent view on roles of TCR signaling required for activating T cells and for generating memory T cells has been reviewed [55].

In the thymus, two major T cell lineages — alpha-beta T cells and gamma-delta T cells developed from common lymphoid precursors. Their differentiation requires outside signaling. Development of alpha-beta T cells is driven in its early stages by signaling from the pre-TCR, most likely in a ligand-independent fashion, and later, by signals delivered by alpha-beta TCRs binding to their ligands — MHC molecules. Similarly, gamma-delta T cells require TCR signaling for their differentiation. However, most gamma-delta TCRs remain orphan receptors, and it is not clear whether ligands are required for gamma-delta TCR signaling in the development of gamma-delta T cells.

Work with transgenic and knockout mice affecting the TCR pathways suggests that TCR signaling ensures the developmental progression towards mature alpha-beta T and gamma-delta T lineages and that the strength of TCR signal instructs lineage fate; i.e., a stronger TCR signal results in gamma-delta T lineage commitment, and a weaker TCR signal results in alpha-beta T lineage commitment. This decision of alpha-beta vs. gamma-delta fate choice during thymus development is called the first TCR-controlled checkpoint.

Distinct molecular programs have been revealed to govern this lineage decision choice. ERK, Egr (early growth response), Id3 (inhibitor of differentiation 3) were identified to be potential molecular switches operating downstream of TCR which determine lineage choice. Removal of Id3 was sufficient to redirect gamma-delta TCR transgenic cells to the alpha-beta T cell lineage, even in the presence of a strong TCR signal. However, in TCR non-transgenic Id3 knockout mice, the overall number of gamma-delta T cells was increased due to an outgrowth of a Vgamma1Vdelta6.3 subset, suggesting that not all gamma-delta T cells depend on this molecular switch for lineage commitment. Thus, two or more lineages not sharing a common molecular program might exist in the gamma-delta T cell lineage. In addition to signaling through TCR, signaling from Notch and CXCR4 receptors, cooperate with the TCR in controlling the development of alpha-beta T cells and gamma-delta T cells [56].

Precursor T cells are not self-renewing. Apoptosis occurs easily, and only some cells of this compartment differentiate into double-positive mature T cells. A scale-up expansion of this

population presents a challenge. Fetal thymus organ culture systems and suspension cultures with dissociated TECs and, a cell line, OP9, which requires a very high concentration of FBS, (20%, in the culture medium) transgenic with notch-ligand such as DL1 (Delta-Like-1), for studying this particular population are available (ref. cited in reference [4]). It is possible to expand transiently para-aortic splanchnopleurally-derived precursor T cells in culture but such cells perish quickly. Variations in the physical culture environment, such as the O_2 level of the incubator where the fetal organ culture was set up, were shown to help the survival of (precursor) T cells. Free radicals promote molecules that lead to the apoptotic pathway. Thus, reducing the concentration of local O_2 and increasing the level of N_2 in the incubator, or supplying the cultured cells with a high density of stroma cells, favors the survival of (precursor) T cells.

To engineer the thymic niche *in vitro*, Shukla and Zandstra (personal communication, unpublished) have engineered an artificial thymus niche containing an immobilized ligand-hydrogel system containing Notch signaling ligands: DL4 (Delta-like 4) and Jagged-1 which are essential for T cell development. This system might allow a robust and scalable generation of mouse proT cells from HSCs and iPS (stage 2, above). It is also possible to grow mouse pre-T cells by using solid phase DL4, and cytokines such as IL7, SCF (Rolink, personal communication, unpublished).

Beaudette-Zlatanova et al. [57] described a hTEC (human thymic epithelial cell) line culture system to support T lymphopoiesis from hHSCs. The cells were immortalized by infection with an amphotropic retrovirus from a cell line containing the HPV E6E7 early genes. The parental cell line, expressing low levels of DL1 and DL4, permits HPCs to differentiate to a B cell lineage. This cell line was engineered to overexpress mouse DL1, called TEC-DL1. In co-cultures with HPCs from cord blood or BM, TEC-Dl1 cells promote the generation of CD7+CD1a+ T-lineage-committed cells, most of them being CD4+CD8+ cells. CD3+(lo) cells were detected within the Double Positive (DP) and Single Positive (SP) CD4 and CD8 populations. The CD3+(lo) SP cells expressed lower levels of IL2R and IL7R. However, this cell line is not sufficient to generate CD3+/high mature single positive T cells. OP9DL1 (and OP9) cell lines have been shown to be able to support the differentiation of T cells (and B cells), however due to its mouse origin, its clinical application for cell therapy is challenged by the regulatory authorities. Thus, this hTEC line might become a promising candidate for clinical application.

The role of miR-142, -181, and -223 in mouse hematopoiesis has been studied [58] and it was found that ectopic overexpression of miRNA-181 in mouse HSPCs resulted in an increase in B lymphopoiesis, and miRNA-142 and -223 resulted in small but significant increases in T lymphopoiesis. However, the relevant target mRNAs were not determined.

The analysis of human and mouse HSCs/HPCs showed large differences in miRNA expression. In human BM, miRNA-181 is expressed more weakly than miRNA-146, which was found to be expressed strongly in all mouse hematopoietic tissues. miRNA-142 is not expressed in human HSPs [59]. The *in silico* model indicates that miRNA-181 and miRNA-146 might block differentiation very early in human lymphopoiesis.

The production of miRNAs by Dicer is required for efficient T cell and B cell development. miR-146, miR-223, and miR-150 target the developmental stage from lymphoid committed stage to T cell development in mouse.

T cell development is controlled by complex protein signaling networks, which are subjected to regulation by miRNAs (Fig. 50.1). The expression patterns of miRNAs are found to vary between T cell subsets and stages of development. Mature miRNAs of a given miRNA species can have several variants, which can vary in length at either the 3′ or 5′ end, or can contain mutated sequences. Proliferating T cells express genes with shorter 3′UTRs than those in resting T cells, rendering these mRNAs less susceptible to regulation by miRNAs due to the

loss of miRNA binding sites. These findings suggest that miRNA-mediated regulation of mRNA targets in T cells is a dynamic process that is influenced by a broad range of factors [16].

Only a few selected individual mRNAs which play a role in early T cell development will be mentioned in this section.

Xiao et al. [60] generated mice with elevated miR-17−92 expression in lymphocytes. These mice developed lympho-proliferative disease and autoimmunity, and died prematurely. Lymphocytes from these mice showed increased proliferation and reduced activation-induced cell death. The miR-17−92 cluster was shown to target mRNAs encoding for the pro-apoptotic protein BIM (BCL-2-interacting mediator of cell death) and the tumor suppressor, PTEN (phosphatas and TENsin homologue) during DN (double negative) thymocyte stage of development by increasing T cell survival. This mechanism likely contributed the disease and death of miR-17−92 transgenic mice, and to lymphoma development in patients carrying amplifications of the miR-17−92 coding region.

The strength of TCR signaling influences whether thymocytes are positively or negatively selected during thymic development, and specific miRNAs have been implicated in this process, for example, Li et al. [103] showed that miR-181a enhanced TCR signaling strength by targeting multiple protein phosphatases, such as DUSP5 (DUal-specificity protein phosphatase 5), DUSP6, SHP2 (SH2-domain-containing protein tyrosine phosphatase 2) and PTPN22 (protein tyrosine phosphatase, non-receptor type 22), which lead to elevated steady state levels of phosphorylated intermediates and a reduction of the TCR signaling threshold. They showed that inhibiting miR-181a expression in the immature T cells reduced sensitivity and impaired both positive and negative selection. The miR-181a was also shown to increase the expression in mature T cells augmented the sensitivity to peptide antigens.

Stage 5: Mature T cells and memory T cells

Using cultures of mature T cells in the presence of APCs and recombinant cytokines, one can study the growth and differentiation of T cells from a variety of sources. Long term mouse and human T cell clones are also available. T cells can be maintained as clones in culture far longer than B cells. Human T cells (mainly NK cells) grown in the presence of cytokines in a short term culture have been re-implanted into autologous cancer patients. Most CD8+ and CD4+ T cells have a short lifespan. Memory T cells have been well studied, but in reality they do not exist in abundance and can be demonstrated *in vivo* only by repeated priming with antigen. They are very difficult to define at the cellular and molecular levels. There is no isotype 3′-end downstream of the TCR constant region for class switching to occur. Somatic hypermutation of the TCR-beta gene has never been claimed, and it is debatable whether the TCR-alpha gene is hypermutable. Memory T cells are thus defined using criteria such as accelerated cellular responses, distinct pathways of lymphocyte recirculation *in vivo*, distinct DNA motifs of TCR genes, cytokine- producing pattern and diminishing expression of surface markers (ref. cited in [4]), and functional and antigen requirements. In mice, memory CD4+ T cells are CD45RO, L-selectin (MEL-14)low. This is the equivalent of human CD45RO, keeping in mind that the CD45R family (A, B, C, and O) may not be the best marker to define naïve versus memory T cells. Because foreign antigens do not always quickly elicit unprimed T cells, memory T cells must exist, but the commitment, the mechanism of development, and the maintenance of these cells are unknown. Memory T cells are thought to be generated, either when T cells acquire specificity to kill, or to help during thymic education, or they are generated during the mature stage.

MEMORY CD8+ T CELLS

Because cell-bound antigen on APCs (see later for details) and more than one signal are required for educating T cells to perform effector functions instead of becoming tolerated,

work on the generation of CD8+ memory T cells has been mainly performed *in vivo*, using viruses. Is it possible to prevent cytotoxic T cells from performing their function by releasing granzymes. If this is the case, what happens to committed CD8+ T cells? Do they die, become anergic, or become memory cells? A study addressing the avoidance of granzyme B-induced apoptosis in target cells is interesting in this regard (ref. cited in reference [4]). Dephosphorylation of cdc2 was shown to be a critical step in granzyme B-induced apoptosis in the targets of cytotoxic T cells. A nuclear kinase encoded by the wee1 gene was transiently expressed and shown to induce phosphorylation of the tyrosine residues of cdc2 kinase, and that in turn provoked mitosis and the rescue of target cells. Because cytotoxic T cells are subject to being killed by their colleagues, the apoptosis pathway in these cytotoxic T cells could be similar to that of the target cells. The priming, clonal expansion, and differentiation into memory T cells can be achieved. The expansion of memory T cells can be demonstrated in culture. Besides viral peptide antigens, recent other examples are the use of mycobacterial glycolipids as the antigen, the antigen processed by CD1b, CD1e (ref. in [4]). Primed T cells are harvested from a human adult and stimulated *in vitro* with antigen with hIL2. The T cell clone can demonstrate the killing of cells infected with *M. (Mycobacterium) tuberculosis* (see later).

It is interesting that DNA methylation may contribute to regulation of mouse T effector cell function (ref. cited in [4]). In Dnmt1−/− (the maintenance DNA methyl-transferase), silencing of IL4, IL5, IL13, and IL10 in CD8 T cells was abolished, and expression of these Th2 cytokines increased drastically as compared with that of control CD8 T cells. Th2 cytokine expression also increased in Dnmt1−/− CD4 T cells, but the increase was less than for CD8 T cells. As a result, both Dnmt1−/− CD4 and CD8 T cells expressed high and comparable amounts of Th2 cytokines. Loss of Dnmt1 had more subtle effects on IL2 and IFN expression and did not affect the normal bias for greater IL2 expression by CD4 T cells and greater IFN expression by CD8+ T cells or the exclusive expression of perforin and granzyme B by the CD8 T cells. Dnmt1 and DNA methylation seem to be necessary to prevent cell-autonomous Th2 cytokine expression in CD8 T cells, but were not essential for maintaining proper T cell subset-specific expression of Th1 or CTL effectors. Thus, transcription factors and DNA methylation are complementary and non-redundant mechanisms by which the Th2 effector program is regulated.

MEMORY CD4+ T CELLS

Like memory CD8+ T cells, the generation of memory CD4+ T cells has been studied *in vivo*. This population of cells has been well characterized in mice. Effector memory CD4+ cells in mouse spleen against the soluble protein antigen KLH (keyhole limpet hemocyanin) and other protein antigen were found to be CD45RO, L-selectin−, CD44+ and to produce elevated levels of IL4 (ref. cited in reference [4]). Whether this population of cells can be expanded in culture remains a question. Because T cells from IL2 knockout mice survive much longer than those of conventional mice, they may be useful for studying the development of memory T cells. Moreover, molecules such as Fas and Fas ligands of the apoptotic pathways play critical roles in determining the fate of cells after activation. The Bcl-2/bcl-x family seems to function by helping the survival of cells via action on the intermediate steps of apoptosis. Genes controlling the cell death pathway may play critical roles in the development of, and the subsequent genetic manipulation of, memory T cells. It is important to improve the conditions for growing CD8+ T cells *in vitro*, because for tumor therapy, the generation of tumor-specific CD8+ T cells is a critical step. Although surface markers and the life span of a population of T cells equivalent to those of the mouse system have been documented, ethical and safety considerations have prevented a systematic study of human memory T cells *in vivo*. The possibility of producing human CD4+ T cells on a large scale has been reported. By stimulating peripheral, resting T cells with cytokines such as IL2, anti-CD28, and solid phase anti-CD3, survival and proliferation of CD4+, but not CD8+, T cells could be greatly

promoted. What remains to be shown are the specificity and function of these cells and how they are related to the regulation of the Bcl-2/bcl-x family and CD95 (Fas/apo-1) ligand and whether they are candidate memory CD4+ T cells or abortive T cells.

ROLE OF APC, TOLL-LIKE RECEPTOR, IN THE ACTIVATION OF CD4+, Th1 VS. Th2 PATHWAYS

The recognition and stimulation of antigen epitopes by T cells requires that antigen molecules first be processed to become fragmented epitope and presented properly by APCs. The APCs identified are macrophages, dendritic cells, and B cells when in the process of T–B cell cooperation. T cells will only recognize the antigenic epitope when it is embedded in MHC (major histocompatibility complexes, H2 in mouse and HLA in humans), which enables the immune system to distinguish its own cells from foreign cells.

Foreign antigens are great engineers. The nature of the antigen to be processed by the APCs decides which processed antigenic epitopes are to be presented by which kind of T cells and how to influence the reaction of the immune system. For example, when cytosol enters the host, viral proteins will be digested by proteasomes to become fragmented epitopes and be presented on the surface of APCs in complex with class I MHC. Their interaction with the CD8+ T cells will enable them to become cytotoxic T cells to perform cell-mediated immunity.

Soluble bacterial toxins (with exceptions, see next section), phagocytized into acidic vesicles in APCs, will be processed by the vesicular proteases, and the fragmented epitopes will be presented on the surface of APCs in complex with class II MHCs. In macrophages, foreign proteins within the acidic phagocytic vesicles will be digested and presented on their surface in complex with class II MHC, similar to APCs. These epitopes are recognized by the CD4+ helper T cells and will cause immune responses, such as the activation of phagocytes and antibody production by activated B cells.

Two major subsets, Th1 and Th2, were originally recognized in the population of CD4+ T cells, though more recently Treg, Th17 cells were also described. Th1 has been shown to secrete IFN-gamma and to help cell-mediated responses. Th1 stimulation results in local inflammatory responses, including the activation of macrophages, and the production of complement-fixing and -opsonizing antibodies IFN-gamma and IL12 drive the differentiation of IFN-gamma-producing Th1. Th2 is shown to secrete IL4, IL3, IL5, IL13, and IL25 and to help the generation of antibody-mediated responses. IL4 is also required for Th2 cell differentiation. Th2 activation leads to the production of IgG and IgE and to the activation of basophil and eosinophils to fight against allergens and large mucosal parasites [61].

It has been a puzzle as to how Th1 vs. Th2 cells recognize and distinguish the epitopes of foreign antigen on APCs, since both require the presence of class II MHCs. The mammalian equivalent of TLRs (Toll-like receptors) derived from Drosophila 'Toll' was discovered and helped to address this question. TLRs are found on the surface of APCs. More than 11 different receptors have been shown to bind to various cellular components of microorganisms.

The binding of most of these components to the preferred TLRs produces a differential signaling cascade that stimulates an immune response in favor of Th1 over Th2. Stimulation of TLR7, and TLR8 in humans by synthetic imidazoquinoline compounds leads to activation of the Th2 pathway; while stimulation of TLR4 by MPL (monophosphoryl lipid A) and Lipo-PolySaccharide (LPS) or viral peptides such as VIPER [104], and stimulation of TLR9 by unmethylated CpG of bacterial DNA lead to activation of the Th1 pathway. TLR11 and several other TLRs are also used for activation of Th cells, but by which specific pathways remains unknown [62,63], and other refs. cited in reference [4]. As shown in Fig. 50.2, signaling by TLRs involves five adaptor proteins: MyD88, MAL, TRIF, TRAM and SARM. Apart from NF-kappa-B activation and IFN-gamma signaling, MyD88 was shown to activate the transcription factors IRF1, IRF5 and IRF7. MAL and TRAM act as bridging adaptors, with MAL

recruiting MyD88 to TLR2 and TLR4, and TRAM recruiting TRIF to TLR4 to allow for IRF3 activation. The fifth adaptor, SARM, was shown to negatively regulate TRIF [64].

THE ROLE OF CD1 IN THE T CELL RECOGNITION OF LIPID ANTIGEN

Besides peptide-protein antigen, which stimulates the Th1, Th2 pathway via TLR on APCs, lipid antigen activates T cells by CD1 molecules, independently of TLR. Studies have shown that CD1 molecules are lipid antigen-presenting molecules that offer the lipid antigens to the TCR of T cells, resembling MHC presentation of peptides, a MHC class III molecule. They have no structural homology with TLR, though they are also present on APCs. Some lipids are recognized by the immune system as classical antigens, resembling peptides associated with MHCs, whereas other lipids trigger the TLR innate receptors. A panel of T cell clones with different lipid specificities isolated from *M. tuberculosis* was established. A novel lipid antigen belonging to the group of diacylated sulfoglycolipids, Ac2SGL(2-palmitoyl or 2-stearoyl 3-hydroxyl-phthioceranoyl-2′-sulfate-alpha-alpha′-D-trehalose) was identified. Ac2SGL is mainly presented by CD1b, after internalization in a cellular compartment with low pH.

Ac2SGL-specific T cells release IFN-gamma, efficiently recognize *M. tuberculosis*-infected cells, and kill intracellular bacteria. The presence of Ac2SGL-responsive T cells *in vivo* is strictly dependent on previous contact with *M. tuberculosis* but is independent of the development of clinically overt disease. These properties identify Ac2SGL as a promising candidate vaccine against tuberculosis.

Another molecule which has been isolated, PIM6 (hexa-mannosylated phosphatidyl-myo-inositols) is another molecule isolated, stimulates CD1b-restricted T cells after partial digestion of the oligomannose moiety by lysosomal alpha-mannosidase, and soluble CD1e, one of the CD1 family members, is required for the processing.

Recombinant CD1e was able to bind glycolipids and assist in the digestion of PIM6 into dimannosylated forms: PIM2, which was stimulatory to specific CD1b-restricted T cells.

CD1 molecules, after exiting from the endoplasmic reticulum, travel to the cell surface via the secretory pathway before being re-internalized into the endosomal compartments. CD1a molecules undergo cycles of internalization into early sorting endosomes followed by early recycling endosomes, whereas CD1c molecules travel to early recycling endosomes and, to a lesser extent, to late endosomes and lysosomes. In contrast, CD1b and human CD1d molecules recycle in late endosome, lysosome compartments where they can co-localize with CD1e. It was debatable whether CD1e participates in presentation of lipid antigens by other CD1 molecules. Recent studies showed that CD1e may positively or negatively affect lipid presentation by CD1b, CD1c, and CD1d. This effect was also shown in APCs from CD1e transgenic mice, which was caused by the capacity of CD1e to facilitate rapid formation of CD1-lipid complexes, and to accelerate their turnover. Thus CD1e helps expand the repertoire of glycolipidic T cell antigens to optimize antimicrobial immune responses through glycolipid editing. (ref. cited in [4,65,66]).

INNATE IMMUNITY, T REGULATORY CELLS, AND Th17 CELLS

Another heterogeneous population of T cells has been re-identified, the so-called Treg (Tregulatory) or suppressor cells. They can be innate or induced.

The subset of Treg cells in mouse can be identified using different surface markers and the secreted cytokines. They include:

1) Naturally occurring T cells possessing CD4+CD25+Nrp1+Foxp3+TGFbeta+, and
2) Cells induced in the periphery following antigen exposure, such as CD4+ Treg1 cells possessing CD4+CD25−/+Foxp3−/+IL10+IFNgamma+TGFbeta+IL5+; Th3 / Th17 cells

possessing CD4+CD25+Foxp3?TGFbeta+IL4+/−IL10+/− and CD8+Treg cells possessing CD8+CD25lowfoxp3-IL10+TGFbeta+/− (ref. cited in [4]).

The CD4+Treg cell subsets can be further classified on the basis of their phenotype, cytokines secreted (such as newly described IL35) function, migration preference to lymphoid or to non-lymphoid tissues [61]. The cells express Foxp3 (fork-head/winged helix transcription factor), which appears to play a key role in supporting their action [67,68]. Microarray study of Treg cells isolated from different tissues of mice transgenic with Foxp3-GFP+ revealed an even more diverse heterogeneity of cell populations (later [69]). The expression of Foxp3 in Treg cells is not stable, several studies have reported the plasticity of Treg in diseases and in inflammation, shown rather complicated mechanisms exerted and influenced by (micro)-environment.

It is also important to keep in mind differences in Foxp3 expression observed in mouse vs. human T cells. In mouse, Foxp3 appears to be a reliable marker for either thymic-derived or induced Treg cells. However, nearly all human CD4+ T cells transiently express Foxp3 during activation, and this is not associated with acquisition of regulatory function. Human MSC have also been shown to express Foxp3 (in Stage 2). Thus, Foxp3 alone is not a reliable marker for human Treg cells, further complicating analyses of their function and stability [61].

In addition, not all antibodies against markers used to characterize mouse Treg work for human Treg, CD45RA marker is used in conjunction with Foxp3 to better classify human Treg phenotypes [106]. So far, three classes of human Treg have been identified based on Foxp3 and CD45RA: (1) Resting Tregs (rTreg) are CD45RA+, Foxp3low; (2) CD4+. Activated Treg (aTreg) cells are CD4+, CD45RA−, Foxp3high; and (3) cytokine-secreting non-Tregs are CD4+, CD45RA−, Foxp3lo. The way that the cytokines which are secreted fit into this classification is not clear.

When stimulated, rTreg can increase Foxp3 expression, convert to an aTreg, and proliferate *in vitro*. However, aTreg rapidly die following proliferation. Furthermore, aTreg inhibit rTreg conversion to aTreg, controlling the balance of active Treg. Naïve CD4+T cells and non-Treg CD4+ cells are also capable of converting to aTreg, but less so than rTreg. Interestingly, CD4+ non-Treg cells have higher levels of Th17 factors (RORgamma, RORalpha, IL17, later), showing a bias toward developing a Th17 phenotype.

APCs are essential in the activation of Treg cells; the immature APCs can support the differentiation of Treg cells. Targeting of antigens to immature dendritic cells has been shown to result in antigen-specific T cell tolerance *in vivo*. The mechanism of suppression could be multiple and is not entirely known. One possibility is to tolerate the APCs, and the other is via the activation of Treg. Treg cells can down-regulate Th1, and Th2 responses. Th17 cells are rather resistant to Treg suppression (later).

Suppression of CD8+T effector cells by Treg could occur to prevent the development of effector function, and could interfere with the execution during the effector phase. Direct cell contact through binding of cell surface molecules such as CTLA4 (cytotoxic T cell-associated antigen 4) on Treg cells to CD80 and CD86 molecules on T cytotoxic cells results in the suppression. The local production of suppressive cytokines such as TGFbeta, IL10, and IL35 also results in suppression. It requires the appropriate co-localization of Treg and T effector cells in different tissue, and may involve interference with the T cell receptor signaling that triggers transcription factors important in regulating effector cell function [61,70].

Treg are usually anergic (do not respond or proliferate to antigen stimulation), IL2 dependent and proliferate poorly in culture. Naïve CD4+ T cells can be converted into Treg cells expressing Foxp3 by targeting of peptide-agonist ligands to dendritic cells or by changing culture conditions, such as adding TGFbeta or reducing IL2, or at the presence of MSC [34]. Treg cell populations induced in low dose antigen conditions could subsequently be expanded by delivery of higher- or immunogenic-dose antigen [70,71].

For a better understanding of transcriptional control in Treg cells, Feuerer et al. [69] compared gene expression profiles of a broad panel of Treg from various origins or anatomical locations of mice such as spleen, peripheral lymph nodes (cervical, axillary, inguinal) of *in vivo* converted Foxp3-GFP+ cells, and lamina propria T cells from Foxp3-GFP mice [68]. The data showed that Treg generated by different means form different sub-phenotypes and could be identified by particular combinations of transcripts. None of which fully encompassed the entire Treg signature. Molecules involved in Treg effector function, chemokine receptors, and transcription factors were differentially represented in these sub-phenotypes. Treg from the gut are different to Treg converted by exposure to TGFbeta *in vitro*, however, they resembled a CD103+Klrg1+ sub-phenotype preferentially generated in response to lymphopenia.

The study of the mechanisms of human MSC-mediated allo-suppression has suggested a sequential process of Treg cell induction involving direct MSC contact with CD4+ cells followed by prostaglandin E2 and TGFbeta1 expression (Stage 2).

In vitro, Treg cells could be generated by T cell stimulation in the presence of high doses of TGFbeta [72]. However, the fast *in vitro* conversion process resulted in Treg with unstable Foxp3 expression that correlated with lack of demethylation of the Foxp3 locus. This *in vitro* conversion method was suboptimal where Treg cell activation was limited for an initial 18 hour culture period; exogenously TGF-beta must be continuously added into the culture and required the inhibition of PI3K (Phosphatidyl Inositol 3-Kinase), Akt/PKB (Protein Kinase B), or protein kinase mTOR (mammalian target of rapamycin) [73]. Thus, how to conduct large-scale production of stable Treg cells *in vitro* is still developing.

Polansky et al. [74] found that the *in vivo* priming with suboptimal antigen resulted in complete demethylation of the TSDR (Treg-specific demethylated region) within the Foxp3 locus, and stable Foxp3 expression. Daniel et al. [75] described an efficient protocol applying the combination of everolimus, a rapamycin analog, and IL2-IL2 antibody complexes to achieve highly effective antigen-driven conversion of naïve CD4+Th cells into Treg and their expansion in transgenic mice. The mechanism of the role of everolimus in enhancing Treg conversion was possibly by interfering with T cell co-stimulation, reducing cell division and thereby activation of DNA methyltransferase1; and by reducing T cell activation through the ATP-gated P2×7 receptor controlling Ca2+ influx. The resulting Treg cells exhibit increased stability of Foxp3 expression even when generated in TGFbeta-containing media in culture. This protocol constitutes an important tool to achieve immunological tolerance by Treg vaccination. Whether it can be applied to therapeutic usage remains to be investigated.

Th17 (T helper 17) cells were first described in mice [76,77] then in humans [78] and other groups) to be a CD4+ T cell subset characterized by production of IL17, which is a highly inflammatory cytokine with robust effects on stromal cells in many tissues. Studies in RA (rheumatoid arthritis) have shown that cytokines secreted by Th17 cells can be further divided: IL17A (originally described), IL17F (a total of six members), IL22, and IL21 [79].

Besides differentiate to Th1, Th2 and Treg, naïve CD4+ T helper cells can be induced to differentiate to Th17 lineage according to the local cytokine milieu. The differentiation towards Th17 and Treg phenotypes is in a mutually exclusive manner. Each phenotype is characterized by unique signaling pathways and transcription factors, such as T-bet for Th1, GATA-3 for Th2, Foxp3 for Treg and RORalpha (Receptor-related Orphan Receptor) and RORgammat for Th17 cells [80–82].

Very little is known about the pathways that control the expression of IL17 in humans. Evans et al. [78] showed that the factors that determine the expression of IL17 in human CD4+ T cells are different from mice. IL6 and IL21 were unable to induce IL17 expression in either naïve or activated T cells, and TGFbeta actually inhibited IL17 expression. The expression of IL17 was maximally induced from pre-committed precursors present in human PBL by cell-cell contact with Toll-like receptor-activated monocytes / APCs in the context of TCR ligation.

Although the pro-inflammatory activity of Th17 cells can be beneficial to the host during infection, uncontrolled or inappropriate Th17 activation has been linked to several autoimmune, including RA, multiple sclerosis, psoriasis, lupus, inflammatory bowel disease, asthma, and might also be involved in tumor and transplant rejection. In the absence of the Th1 *in vivo*, Th17 cells are capable of rejecting cardiac allografts. A report suggests that Th17 cells might be involved in the auto-inflammatory disorder AOSD (adult-onset Still's disease) [83]. Addition of inflammatory signals to a Treg inducing environment leads to Th17 development. Established Treg can be converted to Th17 cells under inflammatory conditions. These findings might explain some of the dys-regulation seen in autoimmune diseases [84,85].

T cell differentiation is modulated by several miRNAs: miR-148a is shown to repress mRNAs encoding for BIM, affecting the commitment of Th1 memory (Haftmann and Radbruch, personal communication, unpublished). miR-155 is shown to have a role in B cells (later), and dual roles in T cells:

1) To repress mRNAs of MAF (Macrophage-Activating Factor) which leads to in favor of the differentiation of CD4+Th0 cells towards Th1 cells;
2) To repress mRNAs of SOCS1 (Suppressor Of Cytokine Signaling 1) which is implicated in the survival of Treg cells.

The miR-155 maps within, and is processed from an exon of its precursor, called bic. In activated B, T cells, and APC, bic/miR-155 shows greatly increased expression. Bic/miR-155 knockout mice are immune-deficient and developed lung pathology with age. Bic/miR-155 was shown to modulate levels of transcription factor c-Maf in CD4+T cells, contributing to bias towards Th2 differentiation [86,87]. Global analysis of the network of genes regulated by Foxp3 has identified the miR-155, which is highly expressed in Tregs, as a direct target of Foxp3. The miR-155 knockout mice have reduced numbers of Treg in the thymus and periphery. However, there was no evidence for defective suppressor activity in miR-155−/− Treg cells, either *in vitro* or *in vivo*, suggesting that additional unidentified miRNAs control Treg function [88]. Lu et al. [89] have shown that miR155 deficiency in Treg cells results in increased SOCS1 expression accompanied by impaired STAT5 activation in response to limiting amounts of IL2.

Drosha and Dicer, the two RNaseIII enzymes, mediate the stepwise maturation of miRNAs. Chong et al. [90] found that miRNA biogenesis is indispensable for the function of Treg cells, mice specific deletion of either Drosha or Dicer phenocopies lack a functional Foxp3 gene or Foxp3+ cells, whereas deletion throughout the T cell compartment also results in spontaneous inflammatory disease later in life.

In order to analyze the role of miRNAs in the development and function of Treg cells, Zhou et al. [91] have crossed a Treg cell-specific, Foxp3-GFP-hCre bacterial artificial chromosome transgenic mouse to a conditional Dicer knockout mouse. The peripheral Treg cells showed altered differentiation and dysfunction. Dicer-deficient Treg cells failed to remain stable, as a subset of cells down-regulated the FoxP3, whereas the majority expressed altered levels of multiple genes and proteins including Neuropilin 1, glucocorticoid-induced TNFR, CTLA4. A significant percentage of the Treg cells possessed a memory Thelper cell phenotype including increased levels of CD127, IL4, and IFNgamma. Dicer-deficient Treg cells lost suppression activity *in vivo*. The mice rapidly developed fatal systemic autoimmune disease resembling the foxp3 knockout phenotype.

Th17 cells have been identified as important mediators of inflammatory disease. Du et al. [92] found that miR-326 promotes Th17 cell development *in vitro* and *in vivo* by targeting ETS1, a negative regulator of Th17 differentiation, resulting in promoting the differentiation of CD4+Th0 cells toward Th17 cells. The expression of miR-326 was correlated with disease severity in patients with MS (Multiple Sclerosis) and mice with EAE (Experimental

Autoimmune Encephalomyelitis). *In vivo* silencing of miR-326 resulted in fewer Th17 cells and mild EAE, its overexpression led to more Th17 cells and severe EAE.

Stage 6: Precursor B cells

Mouse and human precursor B cells have been characterized extensively. Surface markers and molecular events of precursor lymphoid to precursor B cells at intermediate stages of development have been defined (Table 50.1, Fig. 50.3) [93]. The markers for peripheral B cells at different stages are summarized in Table 50.1 [94]. More updated markers are summarized by Alinikula and Lassila [95]. For the reason of simplicity, such newly assigned markers are not included in the tables of this chapter.

TABLE 50.1 Expression of cellular and molecular markers during early stages of B cell development

	Progenitor B stage		Precursor B stage		
Human B cell	**I**	**II**	**III**		**Pre-B**
CD34	+	+	+		–

V_H–D-J_H	–	–	+	+	
V_L–J_L	–	–	–	+	

Data in this table are partially derived from Martensson et al. [102], Matthias and Rolink [94], see Chen [4].

TABLE 50.2 Expression of cellular markers during periphery stages of B cell development

	Stage periphery				
B cell marker	Immature			Mature	
	t1B cell	t2B cell	t3B cell	MZB cell	Follicular B cell
CD21	−	+	+	+	+
CD23	−	+	+	(+)	+
CD93	+	+	+	−	−
IgM	+	+	+	+	+
IgD	(+)	+	+	(+)	+

t: transitional; peripheral immature B cells can be further classified into three transitional stages. MZ: marginal zone.
This table is modified from Matthiasand Rolink [94]. More markers are described recently by Alinikula and Lassila [95].

MOUSE PRE-B CELL LINES

In the mouse system, with the help of several stroma cell lines and recombinant growth factors such as IL7 (in reference [4]), it becomes feasible to expand mouse pre-B cells without gross differentiation. On release from the stroma cells and IL7 and in the presence of the bacterial mitogen LPS, some pre-B cell lines differentiate into plasma cells. Pre-B cell clones have been established from various lymphoid organs of wild-type, transgenic, and knockout mice. Thus, both somatic and genetic manipulation of these cell lines becomes possible. Some pre-B cell lines have been used to repopulate SCID mice and RAG-2 knockout mice. Injected cells migrate to the bone marrow, lymph nodes, peritoneal cavity and spleen. Plasma cells, mature B cells, and pre-B cells were detected in the host. The percentage of cells that mature into various B compartments seems to vary from experiment to experiment.

However, several questions remain. Do these pre-B cell lines retain the capacity to expand? Are these cells self-renewing *in vivo*, as stem cells must be? The critical experiment of repeatedly transferring donor pre-B cells from one host to another, to show that the implanted cells are still precursor B cells, has not yet been done.

Pax5 signatures the commitment of lymphoid precursors to B cell lineage. Pre-B cells established from Pax5−/− mice differentiated into T cells, myeloid cells, dendritic cells and osteoclasts but not mature B cells in SCID mice. The data indicate that the microenvironment, which plays a role in keeping pre-B cells committed to the B cell lineage, may be missing in the Pax5−/− mice. BAFF (B cell activation factor, BLYS) belongs to the Tumor Necrosis Factor (TNF) family, and its receptors have a critical role in the transition from immature to mature B cells (ref. cited in references [4,94,95]).

Due to its potential to develop into mature B- lymphocytes and also into antibody-secreting plasma cells, which can be performed either *in vitro* or *in vivo*, mouse pre-B cells have been subjected to genetic modification to become a vehicle to generate and secrete human antibodies against a variety of infectious antigens in SCID mice. The genetically modified pre-B cells can be subjected to T cell-dependent stimuli, inducing somatic hypermutation in the human antibody constructs. In this way, affinity-matured antibodies can be generated, allowing the development of therapeutic antibodies with the pharmacological efficacies.

CURIOSITIES OF GROWING HUMAN PRECURSOR B CELLS

The question of whether human precursor B cells can expand *ex vivo* is still open. Several reports claim it is possible by using either primary mixed human or mouse stroma cells (ref. cited in reference [4]). When subjected to mixed stroma cells and cytokines such as IL7, most human bone marrow cells expand for a limited period and then either perish or

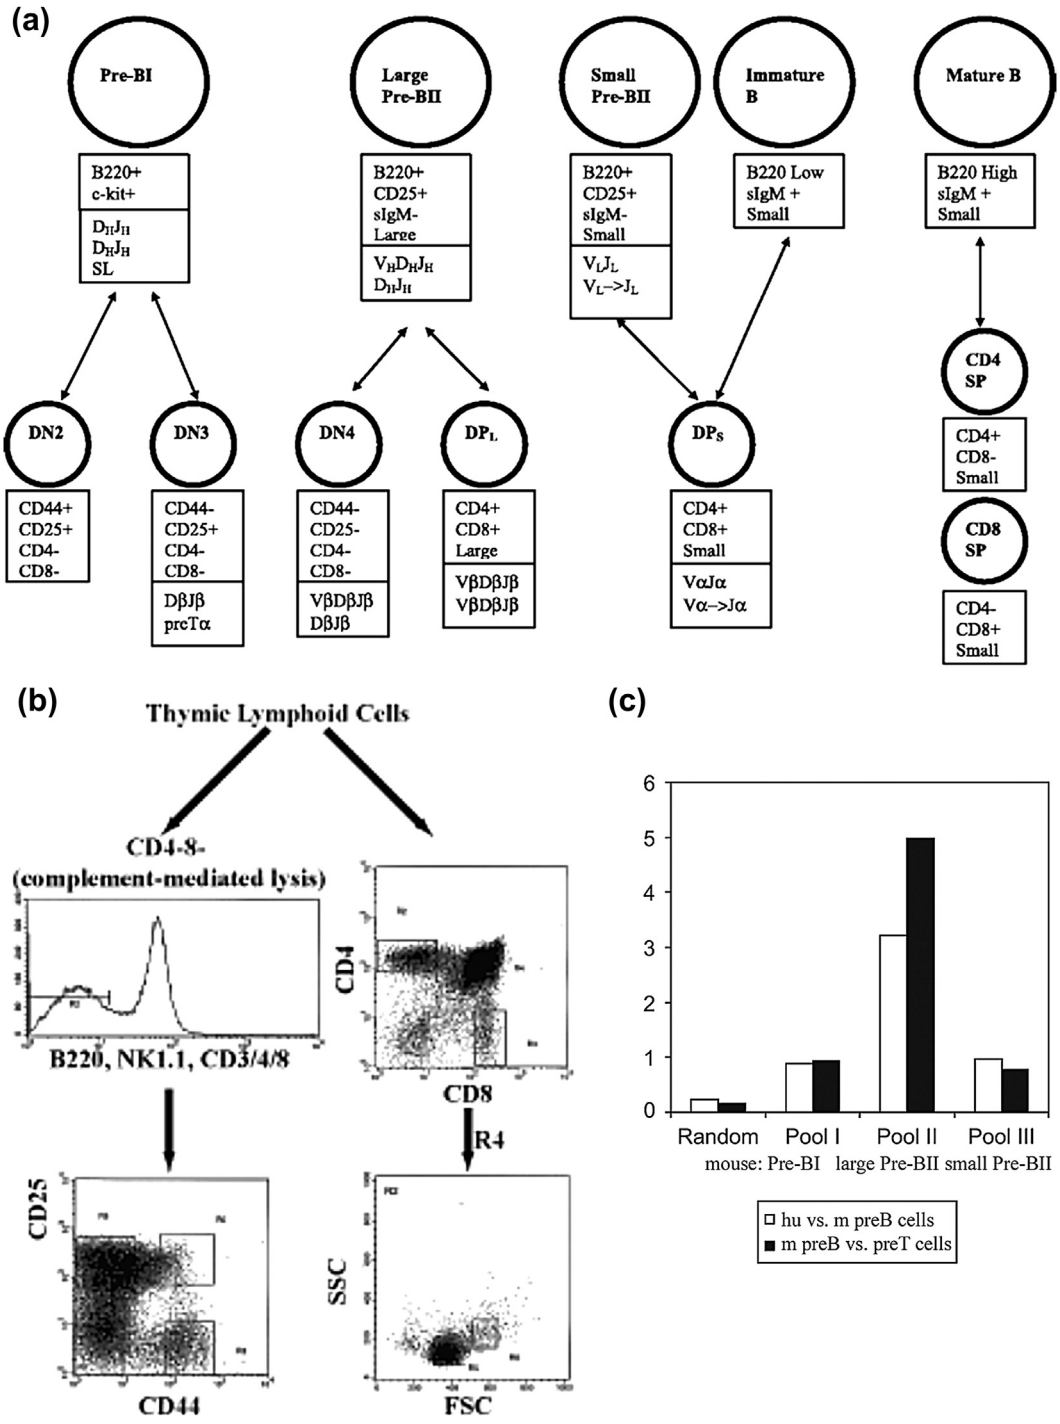

FIGURE 50.3

Surface markers and sorting strategy for isolation of thymic subsets. (a) Synopsis of cellular populations and surface markers used for isolation of lymphocyte developmental stages. Top: B cell development; bottom: T cell development. Cellular stages are depicted as circles. Markers used for separation of the stages appear in the upper boxes; Ig and TCR gene loci rearrangement status appear in the lower boxes. Arrows connect corresponding stages between B- and T cell development. SL, surrogate L chain. (b) Cell-sorting strategy for separation of T cell precursors. To obtain DN thymocytes, CD4+ and CD8+ cells were removed by complement-mediated lysis from thymus single-cell suspension. Remaining lymphocytes were stained with a panel of lineage markers (B220, NK.1.1, CD3, CD4, CD8), and negative cells (R2 gate in top left panel) were gated and analyzed for CD25 and CD44 surface expression (bottom left). For the isolation of DP and SP subsets, single-cell suspension was stained with CD4 and CD8 mAbs (top right); SP cells were sorted according to gates R2 for CD4+ and R3 for CD8+. DP thymocytes (gate R4 in top right panel) were further resolved into large (R5) and small (R6) subsets (bottom right). From Hoffmann et al. [93] with permission. (c) Similarity scores of ordered gene lists between human and mouse precursor B cells (open bars) and between corresponding stages of mouse B and T cell development (filled bars). Pool I, II and III are mouse Pre-BI, large Pre-BII, Small Pre-BII, stages shown in (a). *(Modified from Hoffmann et al. [15]. Fig. 4A.)*

differentiate. The culture conditions established seem to be appropriate only for the short term expansion of pre-B cells. However, no normal human pre-B cell lines have been established. This distinguishes mouse and human precursor B cells.

Global gene screen using microarrays on cells from stages of precursor mouse B, human B and mouse T developments has shown that gene expression patterns differ substantially between human and mouse B cell development. Among 644 genes which were differentially expressed in four early stages of human B cell development, only 48, 86, and 75 genes could be identified, which are upregulated in both human and mouse pre-BI, large pre-BII, and small pre-BII cells, respectively (see Fig. 50.3a for stage definition). A comparison of mouse B and T cell development reveals that gene expression patterns of early mouse B and T precursors are most similar, but not mouse B and human B precursors. However, in more differentiated precursors, human and mouse B precursor have a more similar gene expression profile (panel C) [93]. This finding might partially explain why the culture conditions that are optimal for growing mouse precursor B cells are not optimal for growing human precursor B cells.

The study of human pre-B cells cannot be separated completely from the study of human HSCs and HPCs, given the complexity of the cell types involved and the difficulty in establishing human stroma cell lines. The establishment of human stroma cell lines supporting the growth of human pre-B cells is critical. The failure lies partially in the inability of adherent cells derived from human bone marrow (stroma cells) to proliferate well under normal culture conditions with conventional sera. Methods for immortalizing human cells include transfecting plasmids or retroviruses containing oncogenes such as SV40 T antigen. Dando et al. [40] have done that with human fetal bone marrow, and established many stroma cell lines; a few cell lines were partially characterized for supporting the growth and expansion of cord blood stem cells. However, no further work was performed to test these cell lines using other cell types. Cell proliferation is a prerequisite for the stable integration of transgenes into chromosomes and for immortalization. A breakthrough for human HSCs and pre-B cells would be to establish stroma cell lines for B lymphopoiesis and to optimize the conditions for the growth of stroma cells, as has been done for human MSCs (ref. cited in reference [4]). MSCs have been shown to expand to large quantity when selected lots of FCS are used. The topic of expanding MSCs for clinical trials was discussed in Stage 1 (above).

THE ROLES OF miRNAs IN PRECURSOR B CELLS

The roles of miRNAs in controlling the development of ProB to PreB to B cells are thought to involve the modulation of key factors that control transcription factor networks, V(D)J recombination, selection of BCR, Ig).

Overexpression of miR-181 causes a skewing of hematopoiesis towards the development of B cells, leading to a two- to three-fold increase in the number of B cells and no increase in T cells or myeloid cells, but the target mRNA of miR-161 was not identified [58].

Mice with a conditional deletion of Dicer in early progenitor B cells had a block at the pro-B to pre-B transition [96]. The proapoptotic molecule BIM was highly upregulated. B cell development could be partially rescued by ablation of Bim or transgenic expression of the prosurvival protein Bcl-2 (B cell lymphoma 2). The V(D)J recombination program in developing B cells of Dicer-deficient mice was investigated, and intact Ig gene rearrangements in IgH and IgKappa loci were found, but increased sterile transcription and usage of D(H) elements of the DSP family in Ig Heavy chain (IgH), and increased N sequence addition in Igkappa due to deregulated transcription of the terminal deoxynucleotidyl transferase gene.

Besides affects T cell development (above), the repression of mRNAs coding for the proapoptotic factor BIM (also called BCL2-like 11) by miR-17–92 cluster also affects the differentiation of pro-B to pre-B cells. The changes observed by gene expression profiling of Dicer-

deficient B cell precursors were similar to those observed in B cells lacking the miR-17−92 family.

Constitutive expression of miR-150 causes a block at the pro-B to pre-B cell transition [112], and this inhibition depends on dys-regulation of c-Myb expression. Mice deficient in miR-150 have an accumulation of B-1 B cells in the spleen and the peritoneal cavity, with a relative decrease in the number of short life B-2 B cells. The miR-150-deficient mice have increased levels of antibody secretion both at baseline and following T cell dependent antigenic stimulation [97].

Overexpression of miR-34a causes an increase in cells at the pro-B to pre-B cell transition. miR-34a was shown to target transcription factor Foxp1, which regulates expression of the Rag1 and Rag2 (recombination-activating genes) (in [113]). Because miR-34a is a p53-induced miRNA [98], this repression might link the regulation of DNA damage responses with regulation of RAG proteins.

Besides influence stem cell homeostasis, miR-221 and mir-222 are suggested to repress Pax5−/+ expression, implied in the migration destination of Pre-B/B cells to peripheral lymphoid tissues (Melchers, personal communication, unpublished).

Stage 7: Memory B cells

B cells with surface Ig isotypes such as IgG, IgA, and IgE, which possess higher affinities for antigen, are generally defined as memory B cells. In human beings, CD38+, CD20+ germinal center B cells can be distinguished from memory CD38−, CD20+ B cells and CD38+, CD20− plasma cells. In mice, though still debating, CD38high, CD27+, IgD− memory B cells are thought to be different from long-live and short lived plasma cells, both are CD38+CD138+ [95].

The mechanisms of memory B cell generation are unknown and have been the subject of debate for decades. Memory B cells are mature B cells that have encountered antigen that have been activated but not tolerated and have switched to higher-affinity isotypes. IgM-secreting plasma cells, Syndecan-1/CD138+, are terminal cells destined to die. It is not known how memory B cells develop *in vivo*. *In vitro*, at least two systems may generate memory B cells: the germinal center-like culture system and the suspension culture system, wherein resting B cells are activated by LPS plus anti-mu. These B cells are activated, alive, proliferating, and non-abortive, but they are not plasma cells.

A SYSTEM STIMULATING GERMINAL CENTERS *IN VITRO* TO CULTURE B CELLS

In a culture environment that mimics the germinal center in lymphoid organs, B cells survive better and live longer. A germinal center-like environment is a culture system that provides cytokines and supporting cells from either purified follicular dendritic cells (FDCs) from mouse spleen (ref. cited in [4]) or stroma cells (L cells transfected with CD40 ligand called CD154, or fibroblasts). Both human and mouse B cells survive for two weeks instead of three to four days, and absolute cell numbers increase two- to three-fold.

The *in vitro* germinal center culture system developed was designed to study the differentiation of mouse B cells into plasma cells rather than to maintain long term B cells *in vitro*. Mouse FDCs are non-proliferating, terminally differentiated cells. However, other studies reported that the primary mouse FDCs could be partially replaced by fibroblast cell lines expressing CD154. The cytokines, required to maintain mature B cells in growth phase and differentiation, are controversial. For mouse B cells, combined IL2, IL4, and IL5 induce differentiation into mature cells; for further differentiation into plasma cells, IL6 seems to be essential.

For human B cells, IL2 plus ILI0, combined IL3, IL6, IL7, and combined IL2, IL6, IL10, and more recently discovered cytokines IL21 (later), have been reported to play roles in plasma cell

differentiation. Cellular interactions, including those mediated by CD40 and CD154, are critical in the generation of both memory B cells and plasma cells. If CD154 is removed in the secondary culture, human B cells differentiate into plasma cells. These memory-like cells are neither cell lines nor cell clones; rather, they are a mixed B cell type with a limited life span (up to a few weeks), and they preferentially switch to certain Ig isotypes, such as IgG and IgA. The data suggest that down-regulation of the J chain may not be essential during the development of memory B cells.

IL21, a cytokine affecting T cells, NK cells, and B cells, signaling through IL21 receptor and the common cytokine receptor gamma chain, has been shown to play a role in stimulating the differentiation of mouse (refs cited in reference [4]). In the mouse, IL21 is shown to promote differentiation of B cells into CSR (Ig class switch recombination) and plasma cells, using IL21-transgenic mice and hydro-dynamics-based gene delivery of IL21 plasmid DNA *in vivo* and *in vitro*. IL21 induces expression of Blimp-1 and Bcl-6, which play a role in the development of autoimmune disease. When human B cells were stimulated through the BCR, anti-IgM, a minimal proliferation, IgD down-modulation, and small numbers of plasma cells were shown by IL21 stimulation. In contrast, after anti-CD40 activation of human B cells, extensive proliferation, CSR (Class Switch Recombination), and plasma cell differentiation were demonstrated by IL21 stimulation. On cross linking BCR and CD40, IL21 induced the largest numbers of plasma cells. IL21 drove both CD27+ memory cells and naïve cord blood B cells to differentiate into plasma cells. In the latter, the effect of IL21 was more potent than the combination of IL2 and IL10. IL21 co-stimulation induced the expression of Blimp-1 and AICD (activation-induced cytidine deaminase), required for CSR, secreted IgG from B cells, but did not induce somatic hypermutation. IL2 enhanced the effects of IL21, whereas IL4 inhibited IL21-induced plasma cell differentiation.

A SUSPENSION CULTURE SYSTEM FOR STIMULATING B CELLS WITH LPS PLUS ANTI-MU

Systems for the short-term culture of primary splenic lymphocytes have long existed (in [4]). These systems are valuable for studying the proliferation and differentiation of B cells, T and B cell interaction, the priming of B cells by antigen, and the mechanism of memory B cell generation. If B cells could be kept alive and not tolerated but could be prevented from becoming IgM secretory plasma cells, they might become memory B cells. One example is the finding that when stimulated with a bacterial mitogen, LPS, some B cells die and some proliferate and become plasma cells (in [4]). When stimulated with anti-mu, most B cells die right away, some proliferate and exhibit growth arrest at G1 phase and then die two days later, and none become plasma cells.

When stimulated with LPS plus anti-mu, most B cells proliferate and none become plasma cells. This non-plasma-cell phenomenon has been known as an anti-differentiation effect, and it was postulated to be a way to generate memory B cells in culture. Through the efforts of many including us, the molecular mechanism of this anti-differentiation phenomenon became clear. In the presence of the two stimuli, B cells proliferate maximally, over 90% being in the cell cycle, but IgM secretion is turned off. The block has been shown to be primarily at the level of nuclear RNA processing of the mum-to-mus switch. Inducible nuclear factors binding to the pre-mRNA secretory polyA site have been reported, though the nature of these factors remains unclear.

TRANSCRIPTION FACTORS AND miRNAs ACTIVE IN THE DEVELOPMENT OF PLASMA CELLS

On activation of B cells, many transcription factors (Oct-2, OBF-1, Blimp-1, or PRDI-BF1 in human, Xbp1, IRF4, Bcl6, etc.) become engaged in the production and secretion of Ig genes. Extensive discussion on the transcriptional factors controlling the differentiation of B cells has been summarized in reference [4]. Here I will just briefly mention some key players.

Oct-2 and Blimp-l transcription factors play a role in the decision to switch from mum to mus. Blimp-l is described as a cofactor of transcription factor PU.1 and was shown to bind to multiple Ig-enhancer motifs and the J chain regulatory element. It is crucial for the transcription of mu, kappa, and J chains.

Oct2 is POU-domain-containing transcription factor, binds to the mu intron enhancer octamer motif, on which they can form a ternary complex with the coactivator OBF1, and is essential in transcriptional activation of the mu chain. It was shown that Oct2 and the J chain are highly expressed in LPS-stimulated B cells and are diminished in LPS+ anti-mu-stimulated B cells. It has been shown that Blimp-l is highly expressed in LPS-stimulated B cells and is diminished in LPS+ anti-mu-stimulated B cells. On the other hand, sterile gamma chain is highly expressed in the latter system. Transfection of Blimp-l into LPS+ anti-mu-activated B cells provoked them to become IgM-secreting plasma cells. The data indicated that transcription factors such as Oct2 and Blimp-l are tightly regulated in plasma cell development. If one postulates that LPS+ anti-mu-stimulated B cells represent some stage in memory B cell development, then the down-regulation of Oct2 and Blimp-l reflects the specific transcriptional regulation when B cells make the commitment to the memory cell pathway instead of the plasma cell pathway. The identification of such candidate transcription factors that control memory B cell commitment provided a powerful genetic tool to manipulate the turning on and off of these lineages at will.

The human Blimp-1, PRDI-BF1, is a DNA-binding protein involved in post-induction repression of INFbeta gene transcription in response to viral infection. In terminal differentiation of B cells, it has an essential function in driving differentiation and therein silences multiple genes.

Microarray experiments of the expression of Blimp-1 indicate that it regulates a large set of genes of plasma cell expression signature. Blimp-1 affects numerous aspects of plasma cell maturation, ranging from migration, adhesion, and homeostasis to antibody secretion. It regulates Ig secretion by affecting the nuclear processing of the mRNA transcript and by affecting protein trafficking by regulating genes that impact the activity of the endoplasmic reticulum. The differentiation events that Blimp-1 regulates appear to be modulated, depending on the activation state of the B cell, and hint at the complexity of Blimp-1 and the genetic program that it initiates to produce a pool of plasma cells.

There is a concerted activation-suppression of transcriptional factors during B cell differentiation. In (human) germinal center B cells, a set of genes has been shown to be involved in the differentiation: down-regulation of Bcl-6, which is implied to transform B- cells, activation of Blimp-1/PRDI-BF1, modulation of Myc, and the upregulation of the Mad1 and Mad4 transcription factors. Transcription factor E47 is required for CSR, at least in part, via expression of AICD (activation-induced cytidine deaminase). Id2 has been identified as a negative regulator of E47. Bach2 is a B cell-specific transcription repressor interacting with the small Maf proteins, whose expression is high only before the plasma cell stage. It is critical for CSR and somatic hypermutation of Ig genes. Mitf (microphthalmia-associated transcription factor) is highly expressed in naïve B cells, where it antagonizes the process of terminal differentiation through the repression of IRF-4.

Xbp1 (X-box binding protein 1) is shown to be essential for the differentiation of B cells into plasma cells. By using microarray analyses, a set of genes have been defined whose induction during mouse plasmacytic differentiation is dependent on Blimp-1 and/or Xbp1. Xbp1 increased cell size, lysosome content, mitochondrial mass and function, ribosome numbers, and total protein synthesis. Xbp1 is essential to coordinate diverse changes in cellular structure and function resulting in the characteristic phenotype of professional secretory cells.

Aiolos, a member of Ikaros family, was shown to be required for the generation of long-lived high affinity plasma cells resident in the bone marrow. Recent results on the network of transcriptional factors regulating plasma cell differentiation, have been described by Alinikula and Lassila [95].

In the periphery B cell development, miR-155, besides affecting two steps of T cells development (above), is shown to be upregulated following B cell activation in the germinal center.

B cells lacking miR-155 generated reduced extrafollicular and germinal center responses and failed to produce high affinity IgG1 antibodies [86,87]. Global gene expression profiling of activated B cells indicated that miR-155 regulates an array of genes with diverse function. Among many of the miR-155-mediated regulation of targets are PU.1 and AID (Activation-Induced cytidine Deaminase) and PU.1. PU.1. contributes to class switch and antibody production. When Pu.1 is overexpressed in B cells, fewer IgG1 cells are produced [99].

B cells perform somatic hypermutation and CSR of the Ig locus to generate antibody diversity in affinity and function. These somatic diversification processes are catalyzed by AID, a potent DNA mutator whose expression and function are highly regulated. AID also promotes chromosomal translocations. AID was regulated post-transcriptionally by miR-155. The miR-155 was upregulated in mouse B cells undergoing CSR and it targeted a conserved site in the 3′-untranslated region of the mRNA encoding AID. Disruption of this target site *in vivo* resulted in quantitative and temporal deregulation of AID expression, along with functional consequences for CSR and affinity maturation. Thus, miR-155 does so in part by directly down-modulating AID expression [100].

Mice carrying a mutation in the putative miR-155 binding site in the 3′-untranslated region of AID, designated Aicda(155) mice, were generated [101]. Aicda(155) caused an increase in steady-state Aicda mRNA and protein amounts by increasing the half-life of the mRNA, resulting in a high degree of Myc-Igh translocations. A similar but more pronounced translocation phenotype was also found in miR-155-deficient mice. Thus, miR-155 can act as a tumor suppressor by reducing potentially oncogenic translocations generated by AID.

CONCLUDING REMARKS AND PROSPECTS FOR LYMPHOCYTE ENGINEERING

I have discussed and summarized the current understanding of the expansion of lymphoid cells and their precursors ex vivo at certain stages of lymphopoiesis. I have tried to address the feasibility of expanding lymphoid cells under controlled growth conditions; that is, we need to expand untransformed, non-malignant cells. In general, in order to maintain the status of cell survival and growth without apoptosis and differentiation, cytokines and cell contact with feeder cells are required. Fundamental questions regarding the engineering of lymphoid cells and their precursors for therapeutic purposes remain and can be traced to our current understanding of the immune system. Do we ask too much for the survival in culture of cells that are programmed to die? From extensive studies in gene- manipulated mice, it is possible to generate antigen-specific memory T cells; it remains a puzzle that there is no good systematic study of human memory cells in culture, although the surface markers have been defined.

If there is a massive programmed cell death occurred during the development from HSCs to lymphoid precursors and from pre-T cell to T cell maturation, I wonder whether it is realistic to try to produce enough HPCs and precursor lymphoid cells for therapeutic purposes. In clinical protocols such as ADA trials, expansion of cells ex vivo for the purpose of reinfusion into patients is limited to as few passages as possible in order to avoid mutation and contamination in vitro. Bioreactors for large-scale production of cells in liquid suspension using cytokines are available. However, they are not designed for co-culturing of stem cells with stroma cells, additional micro-particles in culture allowing the attachment of stroma cells in such particles, are needed. With advances in culture technology and bioreactors and with increased supply of recombinant cytokines, it becomes possible to obtain a quantity sufficient for re-implantation from 10 ml of bone marrow cells. However, under these conditions, very few cells engage in lymphopoiesis. Thus, to grow the HPCs consistently and to favor

lymphopoiesis, there is a great need for a better way to grow human stem cells using human stroma cell lines. The current study using transcription factors such as HoxB4, Cdx4, and mMix; small molecules, miRNAs, to manipulate the behavior of hESCs or h-iPS in vitro may be a promising approach.

In view of the massive apoptosis at several stages of lymphopoiesis, it is amazing that mouse precursor B cells can grow normally, become lines and clones, and retain the potential to differentiate in vitro and in vivo. It is still a puzzle why the human precursor B cells cannot grow in culture yet. To grow cells from other stages of lymphopoiesis, it might be advantageous to use cells from the many available mutated or knockout mice.

The future of cell-based immune therapy lies in the ex vivo expansion of cells. Because the techniques to establish ligand-regulatable vectors are available, the derived cell lines will become available and will become valuable resources for many purposes. Other areas remain to be improved, including the search for novel markers of true HSCs and precursor lymphocytes; better sources of HSCs and HPCs, such as cord blood, fetal tissues, hES cells, h-iPS cells, improved retroviral/lentiviral vectors and large-scale culture systems for expansion of HPCs and precursor lymphoid cells.

With advances in genetic tools and mutated-mice technology, it is possible to turn on or off the transcription factors, miRNAs that control the differentiation of cells. With the discovery and understanding of Toll-like molecules on APCs to stimulate Th1 vs. Th2 vs. Treg vs. Th17, the approaches to fight against autoimmune diseases, allergy, inflammation, and transplantation rejection will become accessible. Thus, immunology will continue to be a very exciting field.

Acknowledgments

The author wishes to thank Alexander Aiuti, Betty Padovan, Hans-Martin Jack, Michael Lohoff, Ton Rolink, Claudia Haftmann, Andrea Radbruch, Raju Pareek, and all our other colleagues for providing information including unpublished observation, fruitful discussions during the revision of this chapter. The author also wishes to thank Reinhard Hoffmann, Fritz Melchers, Patrick Matthias, Ton Rolink, for giving permission to use figures and tables. CHAPTER 51

Stem Cells in Kidney Development and Regeneration

Egon Ranghini and Gregory R. Dressler
Department of Pathology, University of Michigan, Ann Arbor, Michigan

Acute renal failure (ARF) and chronic kidney disease (CKD) are significant clinical problems whose frequencies are expected to increase with the prevalence of diabetes, glomerulonephritis, obesity and hypertension. Although data regarding the incidence of CKD are still far from being conclusive, it has been estimated that this conditions affects 10% of all adult Americans [1]. Two main clinical problems may arise as consequence of CKD: first, patients present an increased risk to develop cardiovascular complication; second, CKD may ultimately lead to End Stage Renal Disease (ESRD), a condition in which kidneys are no longer functional and dialysis or kidney transplantation are required. The United States has one of the highest ESRD prevalence in the world, as more than 570,000 patients were treated in 2009. It has been forecasted that this cohort will reach approximately 800,000 patients by 2020 (United States Renal Data System; http://www.usrds.org (accessed April 2012)). This increment will be accompanied by a rise in the economic burden on society: in 2009 the average cost to treat ESRD was estimated to be about $50,000 per patient per year and about $100,000 per patient per year when co-morbidities are present [2]. Yet, the overall mortality rate five years after renal replacement therapies still remains above 50% for all patients [1], despite many advances in understanding the cell physiology of renal injury. Clearly, new approaches for the treatment of acute and CKD must be explored. Tissue engineering, cell replacement therapies, and novel growth and differentiation factors are being developed to address the limitations of current therapies. All of these approaches rely on the knowledge base obtained from basic developmental studies in the kidney, regarding the potency of renal stem cells and the genetic basis of epithelial cell differentiation and proliferation. This chapter will outline the basic elements of renal development and renal stem cell biology and discuss current and future applications of emerging technologies for renal disease.

KIDNEY DEVELOPMENT

A detailed description of early renal development and nephron formation is covered in several recent reviews [3–5]. In brief, the mammalian kidney develops from a region of mesoderm, called the intermediate mesoderm, which lies between the axial and lateral plate mesoderm along the medio-lateral axis of the embryo. The earliest morphological indication of unique derivatives arising from the intermediate mesoderm is the formation of the pronephric duct, or primary nephric duct. This single cell thick epithelial tube runs bilaterally beginning from the mid-thoracic region to a posterior cavity called the cloaca. As it grows, the nephric duct induces

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00051-3

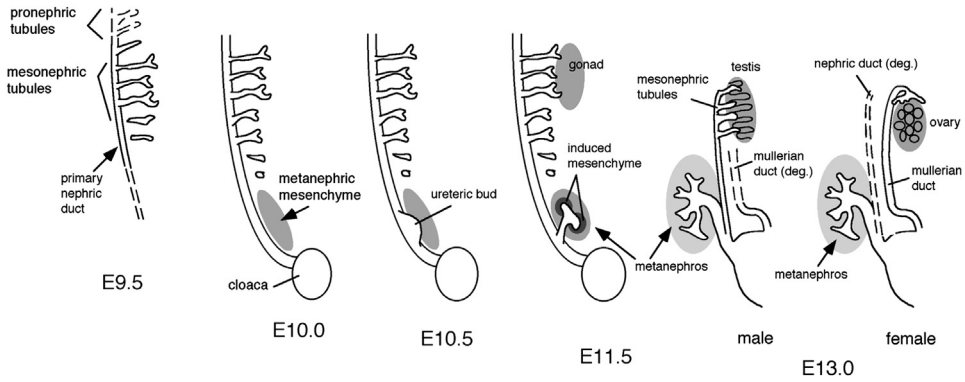

FIGURE 51.1

Urogenital derivatives of the intermediate mesoderm. A schematic of the mammalian urogenital tract during development is shown. The embryonic stages (E9.5) are shown as days post fertilization in the mouse. The primary nephric duct extends anterior to posterior, inducing mesonephric tubules along the ventral aspect. At the posterior end, the metanephric mesenchyme is induced by the ureteric bud, an outgrowth of the nephric duct. Ureteric bud derived signals induce condensation of the mesenchyme, whereas mesenchymal signals induce branching morphogenesis in the bud epithelia. By E13, male and female specific urogenital derivatives become apparent.

a linear array of epithelial tubules, which extend medio-ventrally and are thought to derive from mesenchyme surrounding this duct (Fig. 51.1). The tubules are referred to as pronephric or mesonephric, depending on their position and degree of development, and represent an evolutionarily more primitive excretory system that forms transiently in mammals until it is replaced by the adult or metanephric kidney. The adult kidney, or metanephros, is formed at the caudal end of the nephric duct when an outgrowth, called the ureteric bud or metanephric diverticulum, extends into the surrounding metanephric mesenchyme. Outgrowth or budding of the epithelia requires signals emanating from the mesenchyme. Genetic and biochemical studies indicate that outgrowth of the ureteric bud is mediated by the transmembrane tyrsoine kinase RET, which is expressed in the nephric duct, and the secreted neurotophin GDNF, which is expressed in the metanephric mesenchyme. Once the ureteric bud has invaded the metanephric mesenchyme, inductive signals emanating from the bud initiate the conversion of the metanephric mesenchyme to epithelium (Fig. 51.2). The induced, condensing mesenchymal cells aggregate around the tips of the bud and will form a primitive polarized epithelium, the renal vesicle. Through a series of cleft formations, the renal vesicle forms first a comma then an s-shaped body, whose most distal end remains in contact with the ureteric bud epithelium and fuses to form a continuous epithelial tubule. This s-shaped tubule begins to express genes specific for glomerular podocyte cells at its most proximal end, markers for more distal tubules near the fusion with the ureteric bud epithelia, and proximal tubules markers in between. Endothelial cells begin to infiltrate the most proximal cleft of the s-shaped body as the vasculature of the glomerular tuft takes shape. At this stage, the glomerular epithelium consists of a visceral and parietal component, with the visceral cells becoming podocytes and the parietal cells the epithelia surrounding the urinary space. The capillary tuft consists of capillary endothelial cells and a specialized type of smooth muscle cell, termed the mesangial cell.

While these renal vesicles are generating much of epithelia of the nephron, the ureteric bud epithelia continues to undergo branching morphogenesis in response to signals derived from the mesenchyme. Branching follows a stereotypical pattern and results in new mesenchymal aggregates induced at the tips of the branches, as new nephrons are sequentially induced. This repeated branching and induction results in the formation of nephrons along the radial axis of the kidney, with the oldest nephrons being more medullary and the younger nephrons located towards the periphery. However, not all cells of the mesenchyme become induced and convert to epithelia, some cells remain mesenchymal and migrate to the interstitium. These

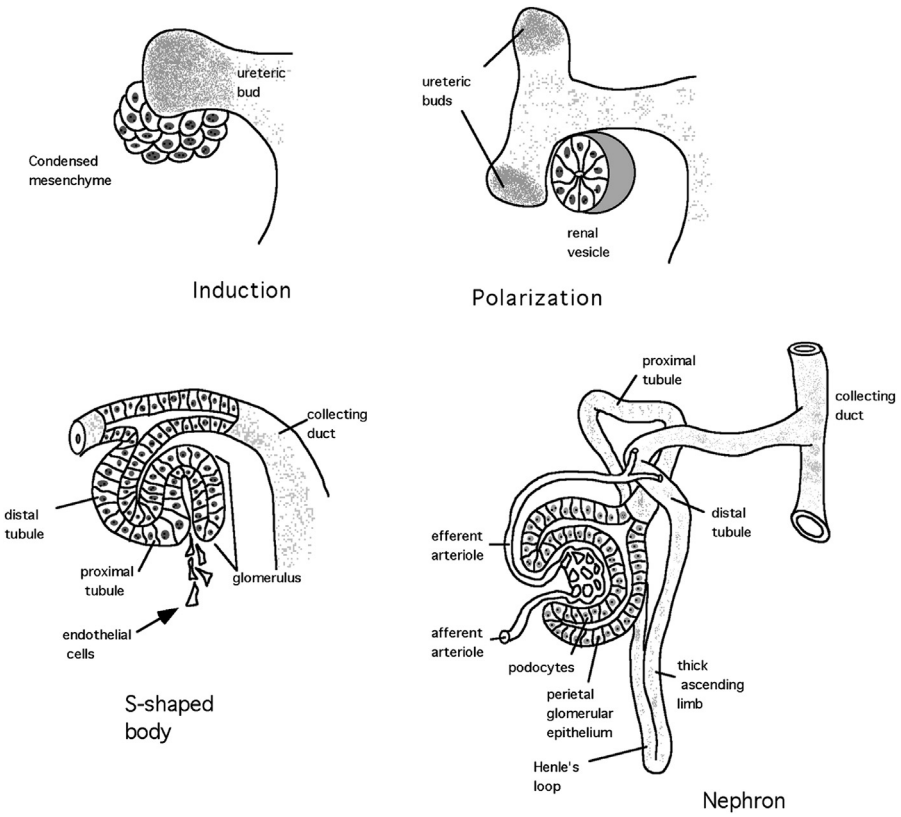

FIGURE 51.2
Sequential conversion of the metanephric mesenchyme to renal epithalia. The metanephric mesenchymal cells are induced to condense around the tips of the invading ureteric bud. These condensation undergo conversion to a primitive epithelial vesicle, the renal vesicle. The renal vesicle is in close proximity to the branching ureteric bud epithelia and fuses to form a continuous epithelial tubule. At the s-shaped body stage, the most proximal cleft becomes vascularized by infiltrating endothelial precursors. The nephron takes shape as the podocyte precursors and endothelial cells intermingle to make the glomerular tuft and the tubular components proliferate and elongate.

interstitial mesenchymal cells, or stromal cells, are essential for providing signals that maintain branching morphogenesis of the ureteric bud and survival of the mesenchyme.

The question regarding the origin of the nephron epithelial cells has been under intense debate for many years. At the time of metanephric mesenchyme induction, which occurs at the embryonic (E) day 11.5 in mouse and at the fifth week of gestation in human, there are at least two primary cell types in the developing metanephros, the mesenchyme and the ureteric bud epithelia. Though these cells are phenotypically distinguishable, they do express some common markers and share a common origin. The ureteric bud epithelium originates the collecting duct network of the nascent kidney; however, it was less clear which subpopulation of progenitor cells within the mesenchyme generates all epithelial cells of the nephron. An elegant study published by Kobayashi and colleagues [6] has answered this question: at the onset of nephrogenesis a domain of the metanephric mesenchyme adjacent to the tips of the ureteric bud, called cap mesenchyme, contains a population of renal progenitor cells that express the transcription factor *Six2*. By using a cell-fate tracking strategy whereby all descendents of the Six2-expressing progenitor cells were permanently labeled, these authors demonstrated that all epithelial cells of the main body of the nephron derive from the $Six2^{+}$ renal progenitor pool of the cap mesenchyme. The cells of the cap mesenchyme are therefore predetermined to make renal epithelia. Thus, their potential as renal stem cells has begun to be explored. To understand the origin of the metanephric mesenchyme, we begin with the patterning of the intermediate mesoderm.

GENES THAT SPECIFY EARLY KIDNEY CELL LINEAGES

The early events controlling the specification of the renal cell lineages may be common among the pro-, and mesonephric regions. Indeed, many of the same genes expressed in the pronephric and mesonephric tubules are instrumental in early metanephric development. Some

of these events that underlie regional specification have been studied in more amenable organisms, including fish and amphibians, in which pronephric development is less transient and of functional significance.

Regionalization of the mesoderm

While formation of the nephric duct is the earliest morphological evidence of renal development, the expression of intermediate mesodermal specific markers precedes nephric duct formation temporally and marks the intermediate mesoderm along much of the A-P body axis. The earliest markers specific for the intermediate mesoderm are two transcription factors of the Pax family (Fig. 51.3), *Pax2* and *Pax8*, which appear to function redundantly in nephric duct formation and extension [7]. *Pax2* is expressed both in the metanephric mesenchyme and the ureteric bud tips, where it is required for mesenchymal-to-epithelial transition (MET) of renal progenitors. At the onset of nephrogenesis *Pax2* is expressed in the comma and s-shaped body and, as the kidney develops, the expression becomes restricted to the epithelial cells of the proximal and distal tubules [5]. In the adult kidney, *Pax2* is only expressed in the collecting duct cells [8]. *Pax2* plays a crucial role for the specification of the nephric lineage: in the mouse, *Pax2* mutants begin nephric duct formation and extension but mesonephric tubules and the metanephros never develop. Besides, mutant embryos lack genital tracts [9].

The *Odd skipped related 1* (*Osr1*) gene is expressed at E7.5 in the common intermediate and lateral plate mesoderm precursors. *Osr1* mutant mouse embryos did not express several key genes important for kidney development, such as *Pax2*, *Eya1*, *Six2*, and *Gdnf* [10]. A more recent study provided evidence that *Osr1*$^{+}$ cells are the precursors of a wide spectrum of cells of

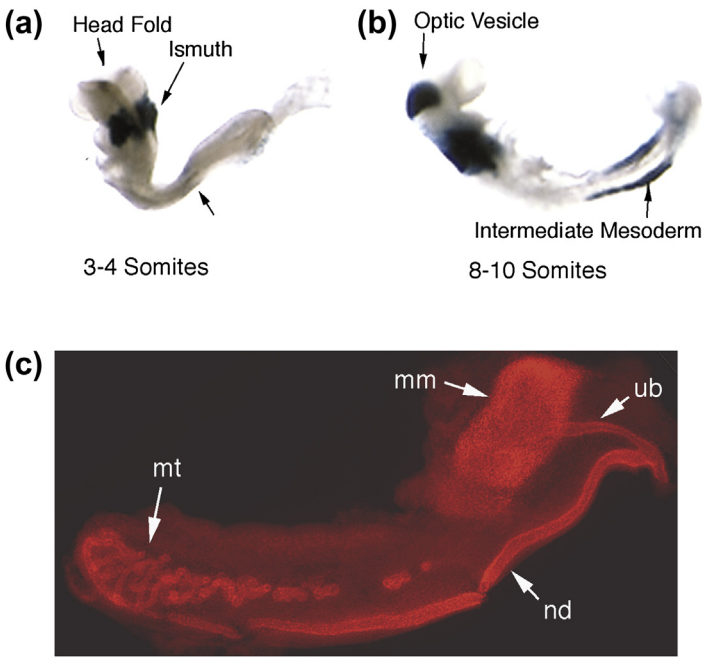

FIGURE 51.3

The activation of Pax2 expression in the intermediate mesoderm. a & b) The embryos shown carry a Pax2 promoter driving the LacZ gene and expression is visualized by staining for beta-galactosidase activity. One of the earliest markers for the nephrogenic region, Pax2 expression is activated around the 4—5 somite in the cells between the axial and lateral plate mesoderm (a). By the eight somite stage (b), Pax2 marks the growing intermediate mesoderm even before the nephric duct is formed. Pax2 is also expressed in parts of the nervous system, especially the mid-brain/hindbrain junction, known as the rhombocephalic ismuth, and in the optic placode and cup. c) By E11, staining for Pax2 protein reveals expression in all epithelial derivatives of the intermediate mesoderm including the nephric duct (nd), the mesonephric tubules (mt), the ureteric bud (ub) branching from the posterior duct, and the metanephric mesenchyme (mm).

the developing kidney. Using a temporal fate mapping strategy, Mugford and collaborators showed that cap mesenchyme, epithelial structures of the nephron, ureteric epithelium of the collecting duct, interstitial mesenchyme progenitors, pericytes, mesangium, vasculature and the kidney capsule all arise from a common *Osr1*$^{+}$ progenitor cell population that are present in the embryo between E7.5 and E11.5 [11].

The transcription factor *Six2* is also essential for kidney development. In the mouse *Six2* is expressed in the cap mesenchyme and its expression is required to maintain a population of self-renewing, multipotent nephron progenitor cells throughout kidney development [6]. Mouse kidneys lacking both copies of *Six2* alleles show ectopic mesenchyme induction, a rapid depletion of the nephron progenitors pool and impaired nephrogenesis [12]. As mentioned earlier in this chapter, *Six2*-expressing cells represent a renal progenitor cell population that generates all epithelial cells of the mature nephron [6].

The homeobox gene *Lhx1* is expressed in the intermediate mesoderm, but is initially expressed in the lateral plate mesoderm before becoming more restricted [13]. As kidney develops, the expression is present in some metanephric mesenchyme-derived structures such as pretubular aggregates, comma and s-shaped body. *Lhx1* regulates urogenital development, as rare *Lhx1* deficient mice, delivered stillborn, lack both kidneys and reproductive tract structures [14]. Indeed, null mutants in *Lhx1* also display reduced expression of Pax2, lack the nephric duct and show reduced ability to differentiate into intermediate mesoderm specific derivatives [13]. In *Pax2/Pax8* double mutants Lhx1 is not expressed and the nephric duct fails to form [7]. Since Lhx1 expression precedes Pax2 and Pax8 and is spread over a wider area in the pre- and post-gastrulation embryo and is Pax independent, it seems likely that maintenance and restriction of Lhx1 expression within the intermediate mesoderm requires activation of the *Pax2/8* genes at the 5–8 somite stage. At this stage *Osr1* expression is detectable in mesenchymal cells that surround the nephric duct, however it is not present in the Pax2 positive cells of the nephric duct.

Are Pax2/8 sufficient then to specify the renal progenitors? This question was addressed in the chick embryo by Bouchard et al. [7] using replication competent retroviruses expressing a Pax2b cDNA. Ectopic nephric ducts were generated within the general area of the intermediate mesoderm upon retrovirally driven Pax2b expression. Strikingly, the ectopic nephric ducts paralleled the endogenous ducts and were not found in more paraxial or lateral plate mesoderm. A more recent study has emphasized the role of *Lhx1* in specifying renal progenitor cells. Cirio and collaborators [15] demonstrated that the expression of a constitutive active form of *Lhx1* in *Xenopus* embryos induced an expansion of the intermediate mesoderm and pronephric anlagen, and this event was accompanied by a reduction of the paraxial mesoderm region. Conversely, the injection of a *Lhx1* antisense oligonucleotide, which suppressed *Lhx1* expression, into *Xenopus* embryos resulted in the absence of pronephric mesenchyme. These studies suggest that nephric duct formation may be induced by Pax2 in a domain of the intermediate mesoderm which is specified by the expression of Lhx1.

If Pax2/8 and Lhx1 restriction in the intermediate mesoderm are the earliest events that distinguish the nephrogenic zone from surrounding paraxial and lateral plate mesoderm, the question then remains as to how these genes are activated. In the axial mesoderm, signals derived from the ventral notochord pattern the somites along the dorsal-ventral axis. Similar notochord derived signals could also pattern mesoderm along the medio-lateral axis. However, this does not appear to be the case. In the chick embryo, the notochord is dispensable for activation of the *Pax2* gene in the intermediate mesoderm. Rather, signals derived from the somites, or paraxial mesoderm, are required for activation of *Pax2* [16]. James and Schultheiss [17] used bone morphogenetic protein 2 (Bmp2) to induce expression of intermediate mesodermal markers in a concentration specific manner. *In vitro*, high levels of Bmp2 induce a lateral plate mesodermal fate whereas low concentrations generate more intermediate mesodermal tissue. Bmp expression is high in the dorso-lateral overlying ectoderm. In an

independent experiment, nephric duct formation can be inhibited if the overlying ectoderm is removed, yet duct formation is restored with exogenous Bmps [18]. The model proposed by James and Schultheiss suggests that factors within the axial mesoderm suppress the expression of intermediate mesodermal markers and that this suppression is lost at low concentrations of Bmps. In the *Xenopus* embryo, retinoic acid and activins are able to expand the pronephric region in animal cap assays, suggesting a positive role for these potential morphogens [19]. Similarly, independent studies have demonstrated that mouse embryonic stem cells express many markers of the intermediate mesoderm and its derivatives when cultured in the presence of activin A, Bmp-4, retinoic acid and lithium chloride [20–22]. Thus, the medio-lateral patterning events appear to be driven by opposing signals to specify the intermediate mesoderm at the interface between lateral plate and axial mesoderm.

If Pax2/8 mark the entire nephric region (Fig. 51.3), then there must be additional factors that specify the position of elements along the anterior-posterior (A-P) axis in the intermediate mesoderm. Such patterning genes could determine whether a mesonephric or metanephric kidney is formed within the Pax2 positive domain. Among the known regulators of A-P patterning are members of the HOX gene family, which are conserved among all metazoan. In mice, *Hox11* paralogs genes display functional redundancy, as neither *Hoxa11* nor *Hoxd11* mutants show any altered phenotype; conversely, *Hoxa11/Hoxd11* double mutants display kidney hypoplasia, though with variable penetrance. Mice that have deleted *Hoxa11*, *Hoxc11* and *Hoxd11* have no metanephric kidneys [23], however it is not clear whether this is truly a shift in A-P patterning or a lack of induction. The Hox paralogs genes seem to regulate the A-P patterning of the posterior intermediate mesoderm, as in the developing kidney Hox11 proteins interact with Pax2 and Eya1 to directly induce the expression of both *Six2* and *Gdnf* in the metanephric blastema [24].

A-P patterning of the intermediate mesoderm may also depend on the FoxC family of transcription factors. *Foxc1* and *Foxc2* have similar expression domains in the presomitic and intermediate mesoderm, as early as E8.5 [25]. As nephric duct extension progresses, *Foxc1* is expressed in a dorso-ventral gradient with the highest levels near the neural tube and lower levels in the BMP4 positive ventro-lateral regions. In *Foxc1* homozygous null mutants the anterior boundary of the metanephric mesenchyme, as marked by GDNF expression, extends rostrally [25]. This results in a broader ureteric bud forming along the A-P axis and eventual duplication of ureters. Similar defects are observed in compound heterozygotes of *Foxc1* and *Foxc2*, indicating some redundancy and gene dosage effects. Thus, *Foxc1* and *Foxc2* may set the anterior boundary of the metanephric mesenchyme, at the time of ureteric bud outgrowth, by suppressing genes at the transcriptional level.

Genes that function at the time of metanephric induction

Induction and conversion of the metanephric mesenchyme to renal epithelial requires the concerted action of many genes. In *Pax2* mutants, there is no evidence of ureteric bud outgrowth despite the presence of a nephric duct. Ureteric bud outgrowth is controlled primarily by the receptor type tyrosine kinase RET, which is expressed on the nephric duct epithelia, the secreted signaling protein GDNF, which is expressed in the metanephric mesenchyme, and the GPi linked protein GFRα1 which is expressed in both tissues. *Pax2* mutants have no ureteric buds because they do not express Gdnf in the mesenchyme and fail to maintain high levels of Ret expression in the nephric duct [26]. Despite the lack of bud, the metanephric mesenchyme is morphologically distinguishable in *Pax2* mutants. While lacking Gdnf, it does express other markers of the mesenchyme, such as Six2 [9]. *In vitro* recombination experiments using *Pax2* mutant mesenchyme, surgically isolated from E11 mouse embryos, and heterologous inducing tissues indicate that *Pax2* mutants are unable to respond to inductive signals [26]. Thus, *Pax2* is necessary for specifying the region of intermediate mesoderm destined to undergo mesenchyme-to-epithelium conversion. In humans, the necessity of *Pax2* function is further underscored as the loss of a single *Pax2* allele is associated

with renal-coloboma syndrome, which is characterized by hypoplastic kidneys with vesicouretral reflux [27].

A second essential gene for the conversion of the metanephric mesenchyme to epithelia is *Eya1*, a vertebrate homologue of the *Drososphila eyes absent* gene. In mice homozygous for an *Eya1* mutation, kidney development is arrested at E11 because ureteric bud growth is inhibited and the mesenchyme remains uninduced, though *Pax2* and *Wt1* expression appears normal [28]. However, two other markers of the metanephric mesenchyme, Six2 and GDNF expression, are lost in the *Eya1* mutants. The loss of Gdnf expression most probably underlies the failure of ureteric bud growth. However, it is not clear if the mesenchyme is competent to respond to inductive signals if a wild-type inducer were to be used *in vitro*. The *eyes absent* gene family is part of a conserved network that underlies cell specification in several other developing tissues. Eya proteins share a conserved domain but lack DNA-binding activity. The Eya proteins interact directly with the Six family of DNA-binding proteins. Mammalian *Six* genes are homologues of the *Drosophila sina oculis* homeobox gene. This cooperative interaction between Six and Eya proteins is necessary for nuclear translocation and transcriptional activation of Six target genes [29]. In humans, mutations in either *SIX1* [30] or *EYA1* [31] are associated with branchio-oto-renal syndrome, further underscoring these genetic and biochemical interactions.

The Wilms' tumor suppressor gene, *WT1*, is another early marker of the metanephric mesenchyme and is essential for its survival. Wilms tumor is an embryonic kidney neoplasia that consists of undifferentiated mesenchymal cells, poorly organized epithelium, and surrounding stromal cells. Expression of *WT1* is regulated spatially and temporally in a variety of tissues and is further complicated by the presence of at least four isoforms, generated by alternative splicing. In the developing kidney, WT1 can be found in the uninduced metanephric mesenchyme and in differentiating epithelium after induction [32,33]. Early expression of *WT1* may be mediated by Pax2 [34]. Initial expression levels are low in the metanephric mesenchyme, but become upregulated at the s-shaped body stage in the precursor cells of the glomerular epithelium, the podocytes. High WT1 levels persist in the adult podocytes. In the mouse, *Wt1* null mutants have complete renal agenesis [35], because the metanephric mesenchyme undergoes apoptosis and the ureteric bud fails to grow out of the nephric duct. The arrest of ureteric bud growth is most probably due to lack of signaling by the *Wt1* mutant mesenchyme.

The transcription factor Gata-3 is also required for proper expression of Ret in the nephric duct [36]. *Gata-3* mutations exhibit increased duct cell proliferation and misdirected ureteric buds [36,37]. Early expression of *Gata-3* in the intermediate mesoderm requires Pax2/8, though direct regulation has not been demonstrated. In humans, Gata-3 is associated with hypothyroidism, deafness, renal abnormalities, the so called HDR syndrome, which is a result of haploinsufficiency [38].

THE ESTABLISHMENT OF ADDITIONAL CELL LINEAGES

At the time of ureteric bud invasion, there appear to be at least two cell lineages established, the metanephric mesenchyme and the ureteric bud epithelia (Fig. 51.4). As branching morphogenesis and induction of the mesenchyme progresses, additional cell lineages are evident. The early E11.5 mouse metanephros contains precursors for most of the cell types present in the adult kidney, including endothelial, stromal, epithelial and mesangial cells. Molecular fate mapping studies have unveiled that all these cell types share a common *Osr1* positive progenitor cell population present in the embryo at E7.5. However, at the induction of the metanephric mesenchyme *Osr1* positive progenitors appears only to generate epithelial cells of the nephron [11]. *Osr1* is expressed in the mesoderm before its subdivision into intermediate and paraxial mesoderm. Interestingly, fate mapping experiments performed in chick embryos

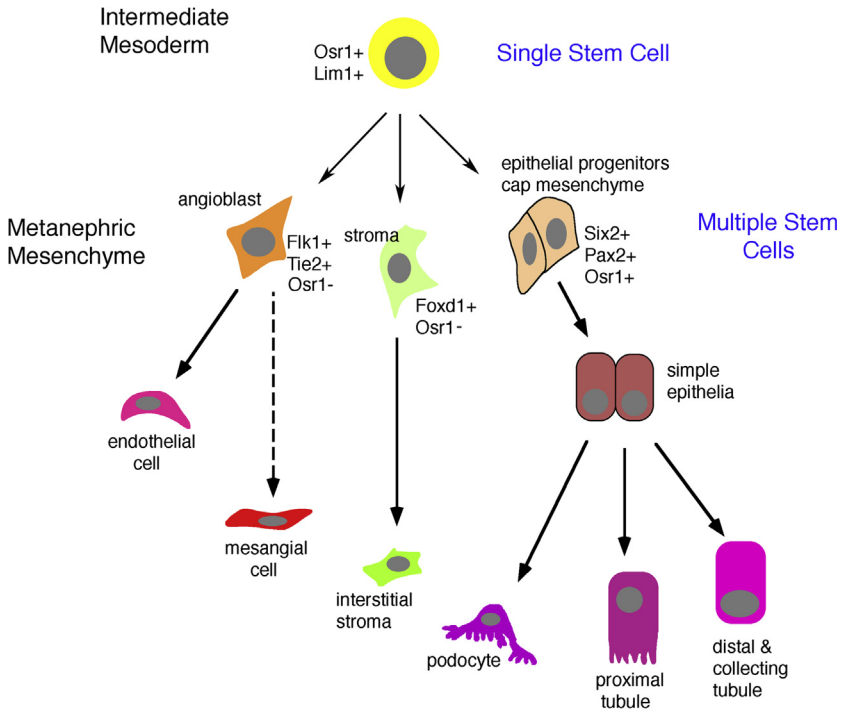

FIGURE 51.4

The major cell lineages of the kidney. Whether the kidney arises from a single renal stem cell or from multiple independent lineages remains to be determined. However, the basic differentiation scheme is becoming clearer. The cell lineage relationships are outlined schematically, with dotted lines reflecting ambiguity in terms of direct lineages. The metanephric mesenchyme contains angioblasts, stromal, and epithelial precursors. Stromal, endothelial and epithelial cells share a common precursor, the metanephric mesenchyme, but segregate at the time of induction. The epithelial cell precursors, found in the cap mesenchyme surrounding the ureteric bud tips, generate all epithelial cells present in the mature nephron.

have indicated that a large population of metanephric stromal cells arises from the paraxial mesoderm, whereas few cells seem to derive from the intermediate mesoderm [39]. Together, these studies suggest that although epithelial and stromal lineages share a common *Osr1* positive lineage, their fate become separate before the beginning of active nephrogenesis. The maintenance of both stromal and epithelial lineages is crucial for renal development, as the ratio of stroma to epithelia is a critical factor for the renewal of mesenchyme and the continued induction of new nephrons.

Epithelia versus stroma

What are the early events in the induced mesenchyme that separates the stromal lineage from the epithelial lineage? There seems to be at least two Wnt proteins involved in triggering renal tubulogenesis, Wnt9b and Wnt4: while the former ligand is expressed in the ureteric bud, the latter is expressed in pretubular mesenchymal aggregate and is placed downstream of Wnt9b signaling. Wnt genes encode a family of secreted peptides that are known to function in the development of many tissues. Mice mutant for *Wnt9b* fail to induce the mesenchyme, while the ureteric bud still undergoes early branching morphogenesis [40]. Mice homozygous for a *Wnt4* mutation exhibit renal agenesis due to growth arrest which occurs shortly after branching of the ureteric bud. Although some mesenchymal aggregation has occurred, there is no evidence of cell differentiation into a polarized epithelial vesicle. Expression of *Pax2* is maintained but reduced [41]. Genetic analyses suggest that Wnt9b is the first inductive signal that triggers renal tubulogenesis. Wnt9b activates Wnt4 which acts as an auto-inducer of nephrogenesis and is required to promote cell polarization in early mesenchymal aggregates [40]. Following induction the cells of the cap mesenchyme downregulate *Six2* and start expressing *Lhx1*, *Pax8*

and *Fgf8*. It has been demonstrated that Wnt9b and Wnt4 induce nephron development by activating the canonical Wnt signaling pathway, which depends on the cytosolic protein β-catenin and the TCF/Lef1 family of transcription factors. However, the canonical pathway is only transiently activated during nephrogenesis and must be downregulated in order to allow early pretubular aggregates to form polarized epithelial structures [42].

The transcription factor Foxd1 is expressed in uninduced mesenchyme surrounding the *Six2* positive cap mesenchyme, then becomes restricted to those cells not undergoing epithelial conversion following induction [43]. After induction there is little overlap between *Foxd1* and the *Pax2* expression domain, prominent in the condensing pretubular aggregates. Clear lineage analysis is still lacking, though the expression patterns are consistent with the interpretation that mesenchyme cells may already be partitioned into a *Foxd1* positive stromal precursor and a *Pax2* positive epithelial precursor prior to, or shortly after, induction. Mouse mutants in *Foxd1* exhibit severe developmental defects in the kidney that point to an essential role for *Foxd1* in maintaining growth and structure [43]. Early ureteric bud growth and branching is unaffected, as is the formation of the first mesenchymal aggregates. However, at later stages (E13–14) these mesenchymal aggregates fail to differentiate into comma and s-shaped bodies at a rate similar to wild-type. Branching of the ureteric bud is greatly reduced at this stage, resulting in fewer new mesenchymal aggregates forming. Bmp4 has been shown to inhibit nephron formation *in vitro*. In *Foxd1* mutant embryos, the ectopic presence of Bmp4 expressing cells in the kidney capsule accounts for mispatterning of the ureteric bud and the consequent delayed and disorganized nephrogenesis. In these mutants the kidney capsule fails to develop correctly and the kidneys remain fused in the pelvis [44]. Thus, the *Foxd1* expressing stromal lineage plays an important role in maintaining growth of both ureteric bud epithelium and mesenchymal aggregates. Perhaps factors secreted from the stroma provide survival or proliferation cues for the epithelial precursors, in the absence of which the non-self-renewing population of mesenchyme is exhausted. It is intriguing to point out that a recent study used time-lapse microscopy and fate mapping to demonstrate that the first pretubular aggregates are only vestigial, since they do not develop into mature nephrons, instead they rapidly degenerate following formation and become part of the stromal compartment [45].

Some survival factors that act on the mesenchyme have already been identified. The secreted TGF-β family member BMP7 and the fibroblast growth factor FGF2 in combination dramatically promote survival of uninduced metanephric mesenchyme *in vitro* [46]. FGF2 is necessary to maintain the ability of the mesenchyme to respond to inductive signals *in vitro*. BMP7 alone inhibits apoptosis but is not sufficient to enable mesenchyme to undergo tubulogenesis at some later time. After induction, exogenously added FGF2 and BMP7 reduce the proportion of mesenchyme that undergoes tubulogenesis while increasing the population of Foxd1 positive stromal cells [46]. At least after induction occurs, there is a delicate balance between a self-renewing population of stromal and epithelial progenitor cells, the proportion of which must be well regulated by both autocrine and paracrine factors. Whether this lineage decision has already been made in the uninduced mesenchyme remains to be determined.

The role of stroma in regulating renal development is further underscored by studies with retinoic acid and its receptors Rarα and Rarβ2. It is well documented that vitamin A deficiency results in severe renal defects [47]. In organ culture retinoic acid, which is the active form of vitamin A, stimulates the expression of Ret to dramatically increase the number of ureteric bud branch points, increasing the number of nephrons [48]. Genetic studies with *Rarα* and *Rarβ2* homozygous mutant mice indicate no significant renal defects when either gene is deleted. However, double homozygotes mutant for both *Rarα* and *Rarβ2* exhibit severe growth retardation in the kidney [49]. These defects are primarily due to decreased expression of the Ret protein in the ureteric bud epithelia and limited branching morphogenesis. Since Rarα and Rarβ2 are expressed both in stromal cells and the ureteric bud, *Ret* regulation could occur via either cell populations. This question has recently been answered by Rosselot and

colleagues using a dominant-negative retinoic acid receptor expressed in ureteric bud cells [50]. These authors have demonstrated that *Ret* expression is induced by retinoic acid produced in the stroma which in turn activates retinoic acid signaling in ureteric bud cells. Together, these findings support the hypothesis that paracrine signals between the stroma and the ureteric bud are required for maintaining *Ret* expression during nephrogenesis and that retinoids are required for stromal proliferation. Reduced expression of the stromal cell marker Foxd1, particularly in the interstitium of Rar double mutants, supports this hypothesis.

Cells of the glomerular tuft

The unique structure of the glomerulus is intricately linked to its ability to retain large macromolecules within the circulating bloodstream while allowing for rapid diffusion of ions and small molecules into the urinary space. The glomerulus consists of four major cell types, the endothelial cells of the microvasculature, the mesangial cells, the podocyte cells of the visceral epithelium, and the parietal epithelium. The development of the glomerular architecture and the origin of the individual cell types are just beginning to be understood.

The podocyte is a highly specialized epithelial cell whose function is integral to maintaining the filtration barrier in the glomerulus. The glomerular basement membrane separates the endothelial cells of the capillary tufts from the urinary space. The outside of the glomerular basement membrane, which faces the urinary space, is covered with podocyte cells and their interdigitated foot processes. At the basement membrane, these interdigitations meet to form a highly specialized cell-cell junction, called the slit diaphragm. The slit diaphragm has a specific pore size to enable small molecules to cross the filtration barrier into the urinary space, while retaining larger proteins in the blood stream. The podocytes are derived from condensing metanephric mesenchyme and can be visualized with specific markers at the s-shaped body stage. While there are a number of genes expressed in the podocytes, there are only a few factors known to regulate podocyte differentiation. These include the WT1 gene, which is required early for metanephric mesenchyme survival but whose levels increase in podocyte precursors at the s-shaped body stage. In the mouse, complete *Wt1* null animals lack kidneys but reduced gene dosage and expression of Wt1 results in specific podocyte defects [51]. Thus, the high levels of Wt1 expression in podocytes appear to be required and make these precursor cells more sensitive to gene dosage. The basic helix-loop-helix protein Pod1 is expressed in epithelial precursor cells and in more mature interstitial mesenchyme. At later developmental stages, Pod1 is restricted to the podocytes. In mice homozygous for a *Pod1* null allele, podocyte development appears arrested [52]. Normal podocytes flatten and wrap their foot processes around the glomerular basement membrane. *Pod1* mutant podocytes remain more columnar and fail to fully develop foot processes. Since Pod1 is expressed in epithelial precursors and in the interstitium, it is unclear whether these podocyte effects are due to a general developmental arrest because of the stromal environment or a cell autonomous defect within the *Pod1* mutant podocyte precursor cells.

Within the glomerular tuft, the origin of the endothelium and the mesangium has yet to be fully understood. At the s-shaped body stage, the glomerular cleft forms at the most proximal part of the s-shaped body, furthest from the ureteric bud epithelium. Vascularization of the developing kidney is first evident within this developing tuft. The origin of these invading endothelial cells has been studied in some details. Under normal growth conditions, kidneys excised at the time of induction and cultured *in vitro* do not exhibit signs of vascularization. However, hypoxygenation or treatment with vascular endothelial growth factor (VEGF) promotes survival or differentiation of endothelial precursors in these same cultures, suggesting that endothelial precursors are already present and require growth differentiation stimuli [53,54]. It is likely that VEGF secretion by podocyte precursor cells helps to attract neighboring endothelial cells into the proximal cleft [55]. The mesangial cells are located between the capillary loops of the glomerular tuft and have been referred to as specialized pericytes. The

pericytes are found within the capillary basement membranes and have contractile abilities, much like a smooth muscle cell. Genetic and chimeric analyses in the mouse have revealed a clear role for the platelet derived growth factor receptor (PDGFr) and its ligand (PDGF) in the development of pericytes. In mice deficient for either PDGF or PDGFr [56,57], a complete absence of mesangial cells results in glomerular defects, including the lack of microvasculature in the tuft. PDGF is expressed in the developing endothelial cells of the glomerular tuft, whereas the receptor is found in the presumptive mesangial cell precursors. Thanks to the development of cell-fate tracking techniques, the origin of both endothelial and mesangial cells of the glomerular tuft have recently become more clear. As discussed earlier in this chapter, Mugford and co-workers [11] used a temporal fate mapping strategy to demonstrate that descendents of *Osr1* positive cells present in the intermediate mesoderm originate most of all cell types of the adult kidney, including the epithelium of the nephron, interstitial mesenchyme, kidney capsule, smooth muscle, vasculature and pericytes. As kidney development goes on, the fate of *Osr1* positive cell descendants becomes more and more restricted in such a way that at the time of metanephric induction *Osr1* expression overlaps the *Six2* positive cap mesenchyme. Intriguingly, investigators from the same research group [6] have provided evidence that parietal epithelial cells and podocytes derive from the *Six2* positive the cap mesenchyme, whereas both pericytes and vascular endothelial cells originate from the cell population that had turned off *Osr1* expression at the onset of nephrogenesis. These studies strongly suggest that the epithelial lineage separates from mesangial and vascular endothelial progenitors prior to the beginning of nephron development.

STEM CELLS IN KIDNEY REGENERATION

The ability of renal epithelial cells to regenerate after injury has prompted much speculation regarding the source of adult renal stem cells and the potential for utilizing such stem cells to further enhance recovery from both acute and chronic renal failure. Acute tubular necrosis (ATN) is the most common cause of ARF in a clinical setting. Often the result of hypotension, surgical cross clamping of the aorta or renal arteries, exposure to toxicants or muscle trauma, ATN has been studied in humans and in a variety of well characterized animal models. The kidney has a remarkable capacity to recover even from an acute insult; however, in some circumstances the recovery seems to be inadequate [58]. The disease may therefore progress to CKD and, ultimately, lead to ESRD. Despite many advances in understanding the cell physiology of ischemic and toxic renal injury, the high frequency of mortality in the clinical setting has not dipped significantly below 50% [59]. In animal models, ATN is the result of sub-lethal damage that is characterized by Adenosine 5′-Triphosphate (ATP) depletion, mitochondrial dysfunction, loss of epithelial cell polarity, and loss of adhesion to extracellular matrix [60]. Such changes can trigger the intrinsic apoptotic response, most likely through cytochrome C release from mitochondria. Cells within the S3 segment of the proximal tubules and the thick ascending limb seem to be particularly sensitive to damaging agents [61–63]. Despite significant cell death after ischemia/reperfusion, folic acid, glycerol, or mercury chloride treatment, renal function in animal models of ATN can recover and proximal tubule morphology is restored if the extent of damage is sub-lethal.

Renal stem and progenitor cells

The process of proximal tubule regeneration in rodent models of ATN has been characterized in much detail. After clearing of cellular debris, cells begin to repopulate the damaged area within a few days. The proliferation of cells within the S2 and S3 segments is accompanied by the expression of many immediate early genes, such as *c-myc* and *AP1* [64], and the re-expression of developmental regulatory genes such as *Pax2* [65]. While it is clear that sub-lethal injury promotes cell proliferation and the expression of dedifferentiation markers along the damaged proximal tubules, the origin of these newly differentiating cells has been the subject of intense debate. There are at least two different models of tubular regeneration that

may explain the origin of these repopulating cells. The conventional model presumed that a subpopulation of viable, remaining cells could repopulate the damaged tubules [60,66]. Alternatively, the existence of a small population of renal stem cells within the environment of the adult kidney was postulated as a potential source of renewable epithelia after injury [67]. The latter model has been supported by several lines of evidence showing that the adult kidney hosts different populations of cells expressing stem or progenitor cell markers that appear to be involved in the process of regeneration. For instance, Gupta and collaborators isolated a population of renal multipotent progenitor cells from the adult kidney that, under particular culture conditions, expressed *Pax2* and the pluripotent marker *Oct4*. *In vivo* localization studies hinted these cells may have a tubular origin. When injected under the renal capsule of a rat model of ischemia-reperfusion injury, some cells seemed to be able to incorporate into damaged tubules; however, many cells also became logged in glomeruli and formed cellular casts [68]. Other investigators have suggested that renal progenitor cells may instead reside in the renal papilla. A population of slowly dividing cells capable of differentiating into multiple epithelial and parenchymal cell types in response to hypoxia have been identified in the papilla of adult rat [69,70]. These findings, however, have recently been contested by a study showing that slowly dividing papillary cells neither proliferate, nor migrate to the proximal tubules after ischemia-reperfusion injury [71]. In a different study, a progenitor cell population of papillary origin has been shown to be able to differentiate into myogenic, adipogenic, osteogenic and neural lineages in culture. Following inoculation into the renal parenchyma of an ischemia-reperfusion injury mouse model, these cells could engraft into damaged tubules and, to a lesser extent, into glomeruli [72]. A more recent study has prompted the hypothesis that the renal interstitium may well be a *niche* where stem/progenitor cells reside. Multipotent kidney progenitor cells were isolated using a transgenic strategy in which the last part of the sequence of *Myh9*, a gene expressed in all interstitial cells and encoding myosin heavy chain IIA, was exchanged with the sequence for Green Fluorescent Protein (GFP). The isolated cells expressed *Pax2*, *Wt1*, *Wnt4* and *Oct4*. Interestingly, when injected into the renal parenchyma of a mouse model of ischemia-reperfusion injury, multipotent kidney progenitor cells seemed to be able to incorporate into renal tubules and ameliorate renal function [73]. Renal progenitor cells have also been isolated from the glomerulus: as demonstrated by Sagrinati and colleagues [74], a subset of parietal epithelial cells expressing the stem cell markers CD24 and CD133 is present within the Bowman's capsule of the adult human kidney. A subsequent study unveiled that CD24 and CD133 cells represent a heterogeneous population hierarchically distributed within the Bowman's capsule: cells expressing CD24 and CD133, but not podocyte markers, were located at the urinary pole and were able to differentiate into both podocytes and tubular cells. A second population of CD24 CD133 progenitor cells positive for podocyte markers was found between the urinary pole and vascular pole of the Bowman's capsule and could only generate podocytes. Finally, a third population present at the vascular pole of the Bowman's capsule showed characteristics of terminally differentiated cells, as they failed to generate both podocytes and tubular cells. In addition, only the cells present at the urinary pole could ameliorate renal function in a mouse model of glomerulosclerosis [75].

The aforementioned studies strongly support the model whereby kidney regeneration following acute tubular injury is accomplished by different populations of renal progenitor cells that reside in different *niches* of the adult kidney. Nevertheless, as anticipated before, an alternative model hypothesizes that a subpopulation of viable cells that survived to injury could be accountable for repopulating renal tubules after damage. In an elegant study, Humphreys and colleagues used a genetic fate mapping strategy to address this hypothesis [76]. These authors developed a mouse strain in which the expression of the GFP-Cre recombinase fusion protein was driven by the *Six2* gene promoter, which is expressed in the cap mesenchyme at the onset of nephrogenesis [14]. Crossing of this mouse strain with a different mouse line carrying a reporter gene, such as *Lac-Z* or *Ds-Red*, allowed for heritably

labeling of all cap mesenchyme-derived cells. Therefore, all epithelial cells of the adult nephron, from the Bowman's capsule to the distal convolute tubule, permanently expressed the reporter gene. Conversely, all non-epithelial cells did not express the reporter gene, as they originated outside the cap mesenchyme. The rationale of this study was that a dilution of the marker following a complete cycle of injury and repair would indicate that unlabeled interstitial cells, or even circulating cells, contributed to the epithelial lineage and tubular regeneration. By contrast, if tubules retained the expression of the reporter gene, then repair of the damaged tubules would instead be accomplished by epithelial cells within the tubules. The results of this study showed that following ischemia-reperfusion injury about 95% of tubular epithelial cells retained the expression of the reporter gene, thus demonstrating that tubular regeneration is accomplished by intrinsic epithelial cells that undergo rapid proliferation following injury. These findings were further confirmed by the converse experiment, in which all interstitial cells were labeled by using a *FoxD1-Cre* driver: in this case the authors did not detect any increase in labeled tubular epithelial cells following renal injury. Nonetheless, this study does not answer the question of whether the tubular repair is carried out by a specialized population of intratubular progenitors, or whether it is the result of self-proliferation of surviving epithelial cells. In a follow-up study Humphreys and his team [71] made use of thymidine analogs to clearly demonstrate that following ischemia-reperfusion injury renal tubules are repopulated by a mechanism of self-division that involves tubular epithelial cells, most of which were non-lethally injured, and not by the presence of intratubular progenitor cells.

Bone marrow derived stem cells

Several investigators have pursued the potential of bone marrow derived cells as a source of renal stem cells. Two early reports demonstrated bone marrow derived proximal tubule cells in mice subjected to ischemia and reperfusion [77,78]. In these experiments, the majority of regenerated proximal tubule cells appeared to be derived from donor bone marrow stem cells either transplanted prior to or injected intravenously directly after injury. However, these findings lead to a great deal of skepticism and have since been disputed. The potential of whole bone marrow to contribute to proximal tubule regeneration many months after transplantation was examined in detail by Szczypka et al. [79], who found little evidence for bone marrow derived renal epithelial cells after induction of ATN by folic acid, despite numerous bone marrow derived leukocytes within the renal interstitium. Similarly, Duffield et al. [80] found no evidence for bone marrow derived renal epithelial cells after injury after careful examination of histological sections by deconvolusion microscopy. In a follow-up article, Lin et al. [81] were not able to demonstrate a significant fraction of bone marrow derived renal epithelial cells after injury, despite their promising initial findings [78].

In addition to whole bone marrow transplants, purified human mesenchymal stem cells have been used for testing renal replacement in animal models. Such cells have been recombined with developing rodent kidneys *in vitro* and *in vivo* and show the potential to differentiate into tubular epithelium [82,83]. Injection of mesenchymal stem cells in rodent models of ischemia reduces the severity of renal failure, although this does not appear to be due to transdifferentiation into epithelia [80,84]. Bone marrow derived cells were used to rescue a genetic defect in a Collagen IV chain (Col4A3), a mouse model of Alport's syndrome, such that the glomerular basement membrane was partially restored [85]. Again, this correction does not necessarily mean that bone marrow derived cells contributed to epithelial structures, rather replacement of capillary endothelial cells by genetically corrected bone marrow cells could help remodel the aberrant glomerular basement membrane. More recently, it was demonstrated that the infusion of human umbilical cord derived mesenchymal stem cells into a mouse model of ATN could ameliorate renal function and greatly reduce mortality [86], thereby suggesting that these cells may be of clinical relevance for the treatment of acute kidney injury. However, it is

important to point out that the renoprotective effect of bone marrow derived cells may be due to the secretion of protective factors in a paracrine manner, rather than being a consequence of cell engraftment into damaged renal structures and subsequent differentiation into tubular cells. For instance, Togel and colleagues noticed that mesenchymal stem cells injection into a rat model of ischemia-reperfusion injury stimulated the expression of anti-inflammatory cytokines and inhibited the expression of pro-inflammatory cytokines, and improved renal function [87]. Though, cell engraftment into the injured kidney was a very rare event . Mesenchymal stem cells released several renoprotective factors, such as VEGF, HGF and IGF-1 that reduced apoptosis in endothelial cells and stimulated cell proliferation [88]. Regardless of the cellular mechanisms involved, the data does point to a possible therapeutic potential for mesenchymal stem cells and other bone marrow derivatives in alleviating certain renal insults.

Human amniotic fluid stem cells

The use of human amniotic fluid stem cells (hAFSC) in renal replacement therapies has recently received great interest. hAFSC can be easily isolated through amniocentesis and propagated *in vitro* for more than 250 population doublings without showing obvious chromosomal rearrangements. These cells express several stem cell markers and were able to differentiate into a broad spectrum of lineages, such as osteogenic, endothelial, myogenic, adipogenic, hepatic and neural lineages [89]. When injected in immunodeficient mice after glycerol-induced tubular necrosis, hAFSC could engraft mostly into damaged tubules, started expressing markers specific of the renal lineage and improved renal function [90]. In a independent experiment Hauser et al. [91] noticed that the infusion of hAFSC into a similar animal model ameliorate kidney function, however cell engraftment occurred mainly in the interstitium and peritubular capillaries.

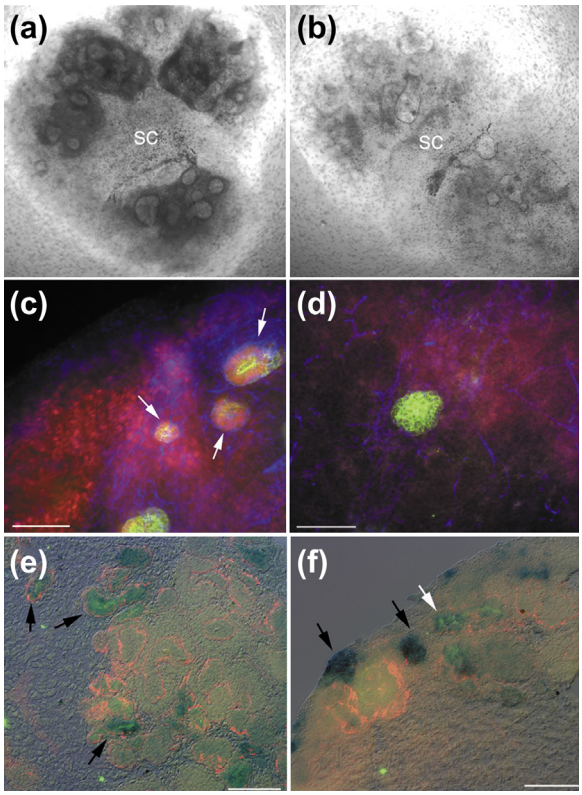

FIGURE 51.5
Embryonic stem cells can differentiate into renal epithelia. ES cells were allowed to form embryoid bodies and cultured with retinoic acid, Activin, and BMP7 (RA7, panels a, c, e) as described [20]. Control ES cells were allowed to form embryoid bodies but were cultured in media without additional differentiation promoting factors (b, d, f). a & b) Embroid bodies co-cultured with inducing tissue, i.e., dorsal spinal cord, show large three-dimensional epithelial structures when treated with RA7 but not with media alone. c & d) Epithelial structures generated from RA7 treated ES cells *in vitro* stain positive for Pax2 (red), E-cadherin (green) and laminin (blue), whereas controls show few Pax2 positive epithelia. e & f) RA7 treated lacZ positive cells (blue) injected into a developing kidney rudiment integrate into tubules (arrows) as indicated by staining for laminin (orange) and LTA lectin (proximal tubules, green). Many control ES cells remain as aggregates of mesenchyme (black arrows), although occasional ES cells are seen within tubules (white arrow).

Embryonic stem cells and induced pluripotent stem cells

An alternative source of renal stem cells may be the true embryonic stem (ES) cells isolated from the inner cell mass of the blastocyst. Upon injection into developing kidney rudiments, ES cells can contribute to tubular epithelium and interstitium suggesting that the local environment is conducive to differentiation of ES cells into renal derivatives [92] (Fig. 51.5). Furthermore, the contribution of ES cells to renal epithelia can be enhanced if the cells are first differentiated *in vitro* by mesodermal factors known to be important for early renal development [20,22]. A combination of retinoic acid, Activin, and BMP7 was shown to stimulate expression of early renal markers in embryoid bodies cultured *in vitro* (Fig. 51.5). Once these renal progenitor cells were injected into a developing kidney they were able to contribute exclusively to the renal proximal and distal tubules. Strikingly, ES cell derivatives were never found in the glomerulus, suggesting that an essential factor for podocyte differentiation was missing [20]. However, the use of ES cells in clinical practice may be limited by ethical concerns and the risk of uncontrolled growth and differentiation which may lead to the formation of teratomas.

The possibility of reprogramming fully differentiated adult cells into a ES-like state, thus obtaining induced pluripotent stem (iPS) cells, may have the potential to revolutionize regenerative medicine. iPS cells were originally generated by retroviral transfection of four genes, namely *Oct3/4*, *Sox2*, *Klf4* and *c-Myc*, into mouse and human fibroblasts [93,94]. iPS cells have similar properties to ES cells in terms of morphology, gene expression, differentiation ability, teratomas formation and are capable of forming chimeras when injected into blastocyst. Since embryo destruction is not required for iPS cells generation, it is more than plausible that their use in basic research and clinical applications will not raise ethical concerns. If iPS cells were to be used for regenerative medicine, the main challenge for renal replacement therapies would be to develop culture conditions that could induce iPS cells to differentiate only into desired renal cell types. Studies conducted on animal models of acute and CKDs will be strongly encouraged to evaluate the feasibility of using iPS cells for renal replacement therapies.

The above outlined experiments highlight some of the difficulties regarding development and cell lineage specification in the kidney. A prospective renal stem cell should be self-renewing and able to generate all of the cell types in the kidney, including epithelial, glomerular, mesangial, and stromal cells. Whether this can be achieved by a single cell or requires multiple progenitor cell types is still not clear. In simplest terms, all of the cells in the kidney could be generated by a single stem cell population as outlined in Fig. 51.4. Yet, even at the earliest stage of kidney development there are already two identifiable cell types, the ureteric bud epithelia and metanephric mesenchyme. In turn, at the onset of nephrogenesis the metanephric mesenchyme is already divided into at least two sub-compartments, the first being the cap mesenchyme which hosts epithelial precursors; the second, surrounding the cap mesenchyme, contains the precursors for endothelial and stromal cells. Regarding the repair of renal tissue, it is plausible that the most important lineage is the epithelia. Thus, if we consider the possibility of an epithelial stem cell the following points would be among the criteria for selection:

1) The cells would most likely be a derivative of the intermediate mesoderm.
2) The cells would express a combination of markers specific for the metanephric mesenchyme.
3) The cells should be able to contribute to all epithelial components of the nephron, both *in vitro* and *in vivo*.

The metanephric mesenchyme contains the renal progenitor cells but is essentially quiescent and does not proliferate in the absence of induction. However, growth conditions that mimic induction might be able to allow for the mesenchymal cells to proliferate while suppressing their differentiation into epithelium. If metanephric mesenchymal cells were able

to proliferate *in vitro*, the markers they might express should include: Pax2, Lhx1, Wt1, Gdnf, Six2 and Foxd1. Expression of these markers would indicate a mesenchymal cell that had not decided between the stromal and epithelial lineage. If cells express Pax2, Wt1, and Wnt4, but not Foxd1, they could be an epithelial stem cell. Such epithelial stem cells when injected into, or recombined with, an *in vitro* cultured metanephric kidney should be able to make all of the epithelial cells along the proximal-distal axis of the nephron. Such epithelial stem cells could prove significant in regenerating damaged tubules in acute and chronic renal injury.

At present, the complexity of the kidney still impedes progress in the area of tissue and cell based therapies. Not only must the right cells be made, they must be able to organize into a specialized three-dimensional tubular structure capable of fulfilling all of the physiological demands put upon the nephrons. Developmental biology can provide a framework for understanding how these cells arise and what factors promote their differentiation and growth. While we may not be able to make a kidney from scratch, it seems within the realm of possibility to provide the injured adult kidney with cells or factors to facilitate its own regeneration. Given the high incidence and severity of acute and chronic renal insufficiency, such therapies would be most welcome indeed.

INTRODUCTION

The rapid understanding of the cellular and molecular bases of organ function and disease processes will be translated in the next decade into new therapeutic approaches to a wide range of clinical disorders, including acute and chronic renal failure. Central to these new therapies are the developing technologies of cell therapy and tissue engineering, which are based on the ability to expand stem or progenitor cells in tissue culture to perform differentiated tasks and to introduce these cells into the patient either via extracorporeal circuits or as implantable constructs. Cell therapy devices are currently being developed to replace the filtrative, metabolic and endocrinologic functions of the kidney lost in both acute and chronic renal failure. This chapter summarizes the current state of development of a wearable or implantable bioartificial kidney (BAK) for full renal replacement therapy that may significantly diminish morbidity and mortality in patients with acute or chronic renal disease.

The kidney was the first solid organ whose function was approximated by a machine and a synthetic device. In fact, renal substitution therapy with hemodialysis or chronic ambulatory peritoneal dialysis (CAPD) has been the only successful long term *ex vivo* organ substitution therapy to date [1]. The kidney was also the first organ to be successfully transplanted from a donor individual to recipient patient as an isograft. However, the lack of widespread availability of suitable transplantable organs has kept kidney transplantation from becoming a practical solution in most cases of chronic renal failure.

Although long-term chronic renal replacement therapy with either hemodialysis or peritoneal dialysis has dramatically changed the prognosis of renal failure, it is not complete replacement therapy, because it provides only the filtration function (usually on an intermittent basis) and does not replace the homeostatic, regulatory, metabolic, and endocrine functions of the kidney. Because of the non-physiologic manner in which dialysis performs or does not perform the most critical renal functions, patients with end stage renal disease (ESRD) on dialysis continue to have major medical, social, and economic problems [2]. Accordingly, dialysis should be considered as partial substitution rather than renal replacement therapy.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00052-5

Tissue engineering of an implantable artificial kidney composed of both biologic and synthetic components could result in substantial benefits for patients by increasing life expectancy, mobility, and quality of life, with less risk of infection and with reduced costs. This approach could also be considered a cure rather than a treatment for patients. A successful tissue engineering approach to the kidney depends on a thorough knowledge of the physiologic basis of kidney function.

BASICS OF KIDNEY FUNCTION

The excretory function of the kidney is initiated by filtration of blood at the glomerulus, which is an enlargement of the proximal end of the tubule, incorporating a vascular tuft. The structure of the glomerulus is designed to provide efficient ultrafiltration of blood, to remove toxic wastes from the circulation yet retain important circulating components, such as albumin. The regulatory function of the kidney, especially with regard to fluid and electrolyte homeostasis, is provided by the tubular segments attached to the glomerulus. The functional unit of the kidney is therefore composed of the filtering unit (the glomerulus) and the regulatory unit (the tubule). Together they form the basic component of the kidney, the nephron. In addition to these excretory and regulatory functions, the kidney is an important metabolic and endocrine organ. Erythropoietin, active forms of vitamin D, renin, angiotensin, prostaglandins, leukotrienes, kallikrein-kinins, various cytokines, and complement components are some of the endocrinologic compounds produced by the kidney. Because of the efficiency inherent in the kidney as an excretory organ, life can be sustained with only 5–10% of normal renal excretory function. Accordingly, the approach to a tissue-engineered construct becomes easier to entertain, especially because only a fraction of normal renal excretory function is required to maintain life [3].

The process of urine formation begins within the capillary bed of the glomerulus [4]. The glomerular capillary wall has evolved into a structure with the property to separate as much as one-third of the plasma entering the glomerulus into a solution of a nearly ideal ultrafiltrate. This high rate of ultrafiltration across the glomerular capillary is a result of hydraulic pressure generated by the heart and vascular tone of the preglomerular and post-glomerular vessels as well as by the high hydraulic permeability of the glomerular capillary wall. The hydraulic pressure and permeability of the glomerular capillary bed are at least two times and two orders of magnitude higher, respectively, than those of most other capillary networks within the body [5]. Despite this high rate of water and solute flux across the glomerular capillary wall, this same structure retards the filtration of important circulating macromolecules, especially albumin, so all but the lower-molecular-weight plasma proteins are restricted in the passage across this filtration barrier [6–8].

This ultrafiltration process of glomeruli in normal human kidneys forms approximately 100 mL of filtrate every minute. Because daily urinary volume is roughly two liters, more than 98% of the glomerular ultrafiltrate must be absorbed by the renal tubules. The bulk of reabsorption, 50–65% occurs along the proximal tubule. Similar to glomerular filtration, fluid movement across the renal proximal tubule cell is governed by physical forces. Unlike the fluid transfer across the glomerular capillary wall, however, tubular fluid flux is driven principally by osmotic and oncotic pressures rather than hydraulic pressure. Renal proximal tubule fluid absorption is based on active Na+ transport, requiring the energy-dependent Na+/K+-ATPase located along the basolateral membrane of the renal tubule cell to promote a small degree of luminal hypotonicity [9]. This small degree of osmotic difference (2–3 mOsm/kg H_2O) across the renal tubule is sufficient to drive isotonic fluid reabsorption, due to the very high diffusive water permeability of the renal tubule cell membrane. Once across the renal proximal tubule cell, the transported fluid is taken up by the peritubular capillary bed, due to the favorable oncotic pressure gradient. This high oncotic pressure within the peritubular capillary is the result of the high rate of protein-free filtrate formed in the proximate

glomerular capillary bed [10]. As can be appreciated, an elegant system has evolved in the nephron to filter and reabsorb large amounts of fluid in bulk to attain high rates of metabolic product excretion while maintaining regulatory salt and water balance.

TISSUE-ENGINEERING APPROACH TO RENAL FUNCTION REPLACEMENT

In designing a bioartificial kidney for renal function replacement, essential features of kidney tissue must be utilized to direct the design of the tissue-engineering project. The critical elements of renal function must be replaced, including the excretory, regulatory transport, and endocrinologic functions. The functioning excretory unit of the kidney, as detailed previously, is composed of the filtering unit, the glomerulus, and the regulatory or transport unit, the tubule. Therefore, a bioartificial kidney requires two main units, the glomerulus and the tubule, to replace excretory and metabolic functions of the kidney.

Current technology has developed to replace the glomerular and excretory functions of the kidney via dialytic techniques, either hemodialysis (HD) or peritoneal dialysis (PD). HD utilizes biocompatible membranes and blood circuits; PD utilizes the peritoneal membrane and fluid circuits. Dialysis provides clearance of small molecules by diffusive flow across a semipermeable membrane and control of volume status by bulk flow of water and solutes through that membrane. These short-term effects are sufficient to abrogate the lethal acidosis, volume overload, and uremic syndromes which accompany renal failure but do not protect the patient from the increased mortality associated with dialysis-treated renal failure in either the acute or chronic form. These methodologies all address water and electrolyte balance functional replacement of the kidney. However, they fail to provide for the lost metabolic function. Thus the metabolic, endocrine, and immune roles of the functioning kidney are candidate mechanisms for the difference in survival noted above. The dialytic clearance of glutathione, a key tripeptide in free radical scavenging and protection against oxidant stress, the negative nitrogen balance and energy loss in the clearance of peptides and amino acids in dialysate, loss of oxidative deamination and gluconeogenesis in the tubule cell, and loss of cytokine and hormone metabolic activity by the kidney each impose substantial stress upon the dialyzed patient and as such are appropriate targets for improved renal replacement therapy. Because of this current dialytic renal replacement technology (RRT) only, and substitutes for the excretory function of the kidney, to develop more complete RRT, the last decade has been focused on tissue engineering the development of a renal tubule cell device to add the missing second component of RRT for more complete renal function.

As to the development of a tissue-engineered kidney, a step function approach towards a fully implantable bioartificial kidney (BAK) has been adopted. An initial focus was to develop an extracorporeal bioartificial kidney comprised of a conventional synthetic hemofilter with a renal tubule cell assist device (RAD) in an acute extracorporeal blood circuit. With success of this formulation, proof of concept for a wearable bioartificial kidney (WEBAK) combining PD with a bioartificial renal epithelial cell system (BRECS) has been recently achieved [11]. The final developmental step based upon prior success of the RAD in acute disorders and the WEBAK in preclinical models, is the current approach to design, fabricate and test in preclinical models a functional fully implantable bioartificial kidney (IBAK) [12]. The details of this progressive development sequence from acute short term RRT with cell therapy of WEBAK to IBAK are presented in the following sections.

Development of a renal tubule-assist device

Replacement of the multivariate tubular functions of the kidney cannot be achieved with inanimate membrane devices, as has been accomplished with the renal ultrafiltration process, but requires the use of the naturally evolved biologic membranes of the renal tubular epithelium. In this regard, the tissue engineering of a bioartificial renal tubule as a cell therapy

device to replace these missing functions can be conceived as a combination of living cells supported on synthetic scaffolds [13,14]. A bioartificial tubule can be constructed utilizing renal tubule progenitor cells [15,16], cultured on semipermeable hollow fiber membranes on which extracellular matrix has been layered to enhance the attachment and growth of the epithelial cells [17]. These hollow fiber synthetic membranes not only provide the architectural scaffold for these cells but also provide immunoprotection, as has been observed in the long-term implantation of the bioartificial pancreas in a xenogeneic host [18]. The successful tissue engineering of a bioartificial tubule as a confluent monolayer has been achieved in a single hollow fiber bioreactor system [13]. The scale-up from a single fiber system to a multifiber bioreactor seeded with porcine renal proximal tubule cells has also been successfully demonstrated [19]. Porcine cells were used initially because the pig is currently considered the best source of organs for both human xenotransplantation and immunoisolation cell therapy due to its anatomic and physiologic similarities to human tissue and the relative ease of breeding pigs in large numbers [20]. The potential risk of viral transmission across species, however, requires human cells for clinical use.

The scale-up from a single hollow fiber device to a multifiber bioartificial RAD has proceeded with porcine renal proximal tubule cells grown as confluent monolayers along the inner surface of polysulfone immunoisolating hollow fibers [19]. These hollow fibers are packaged in bioreactor cartridges with membrane surface areas as large as 0.7 m^2, resulting in a device containing up to 108 cells. *In vitro* studies of the RAD have demonstrated retention of differentiated active vectorial transport of sodium, bicarbonate, glucose, and organic anions [19]. These transport properties were suppressed with specific transport inhibitors. Ammoniagenesis and glutathione metabolism, which are important differentiated metabolic processes of the kidney, were also demonstrated in these devices. Synthesis of 1,25-dihydroxyvitamin D3 as a key endocrinologic metabolite was also documented. These metabolic processes were also shown to be regulated by important physiologic parameters and achieved rates comparable to those of a whole kidney.

The next critical step for clinical application of a renal tubule cell therapy device was to ascertain whether the RAD maintained differentiated renal functional performance, similar to that observed *in vitro*, and viability in an extracorporeal hemoperfusion circuit in an acutely uremic dog. The RAD was accordingly placed in series with a standard hollow fiber hemofiltration cartridge; the two cartridges had ultrafiltrate and post-filtered blood connections to duplicate the structural anatomy of the nephron and to mimic the functional relationship between the renal glomerulus and tubule (see Fig. 52.1). The successful

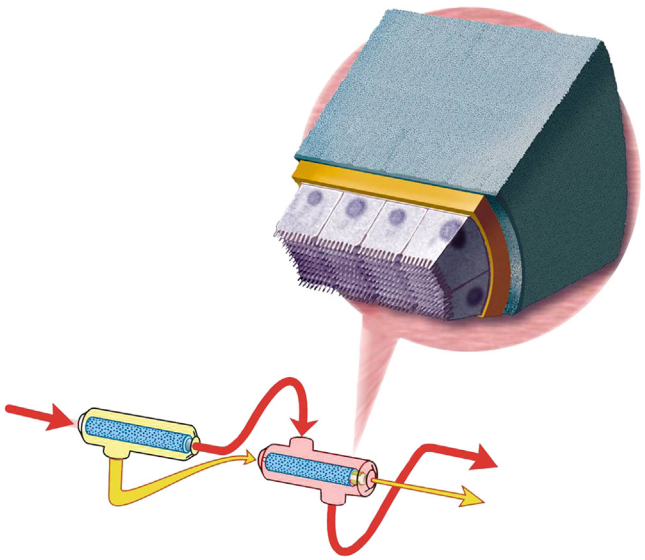

FIGURE 52.1
Schematic of an extracorporeal circuit of a bioartificial kidney used to treat patients with acute renal failure. The first cartridge is a hemofiltration cartridge in series with a renal tubule cell device (RAD). The ultrafiltrate is delivered to the luminal compartment of the RAD which contains the cells and the post-filtered blood is pumped into the extracapillary space of the RAD. The processed luminal ultrafiltrate from the RAD is discarded to waste and the processed blood is returned to the patient.

completion of this step has been reported [21]. Data show that fluid and electrolyte balances in the animals, as reflected by plasma parameters, were adequately controlled with the bioartificial kidney. In fact, plasma potassium and blood urea nitrogen levels were more easily controlled during RAD treatment as compared with sham control conditions. The step-up of oncotic pressure in the post-filtrate blood, which was delivered to the antiluminal space of the RAD, allowed the fractional reabsorption of sodium and water to achieve 40–50% of the ultrafiltrate volume, an amount similar to that seen in the nephron *in vivo*. Active transport of potassium, bicarbonate, and glucose by the RAD was demonstrated. Successful metabolic activity was also observed. These observations resulted in the steps for clinical testing utilizing an extracorporeal blood circuit to evaluate the RAD in a dramatic clinical disease state with substantive immediate medical need.

Bioartificial kidney in acute renal failure

Current therapy for ischemic or toxic acute kidney injury (AKI) or acute tubular necrosis (ATN) is predominantly supportive in nature. Uremia is treated with either intermittent hemodialysis or continuous hemofiltration, treatments that have had substantial impact on this disease process over the last 25 years. Patients with ATN, however, still have an exceedingly high mortality rate of greater than 50%, especially in sepsis [22], despite maintenance of normal electrolyte balance and improvement in the uremic state. The high mortality is caused by the propensity of these patients to develop systemic inflammatory response syndrome followed by multi-organ dysfunction syndrome [23]. The sequential failure of organ systems apparently unrelated to the site of the initial insult has been correlated with altered plasma cytokine levels observed in sepsis [24–26].

Because acute renal failure (ARF), secondary to ischemic or nephrotoxic insults, promotes AKI, predominantly due to renal proximal tubule cell injury, replacement of the functions of these cells during the episode of AKI, and in conjunction with hemofiltration, provides almost full renal replacement therapy. The addition of metabolic activity, such as ammoniagenesis and glutathione reclamation; endocrine activity, such as activation of vitamin D3 (low levels of which seem to correlate with high mortality rates in hospitalized patients) [27]; immunoregulatory support and cytokine homeostasis, may provide additional physiologic replacement activities to change the current natural history of this disease process [3].

Experiments investigated whether treatment with the bioartificial kidney with RAD would alter the course of ARF and AKI with sepsis in animal models. Mongrel dogs that underwent surgical nephrectomy-induced ARF were treated with continuous venovenous hemofiltration (CVVH) and either a RAD containing cells or an identically prepared sham non-cell cartridge. After four hours of therapy, 2 mg/kg intravenous endotoxin was infused over 1 hour to simulate gram-negative septic shock. Mean peak levels of an anti-inflammatory cytokine, IL-10, and mean arterial pressures were found to be significantly higher in cell-treated animals [28].

To further assess the effect of the bioartificial kidney containing the RAD in ARF with bacterial sepsis, dogs were nephrectomized and 48 hours later administered intraperitoneally with 3×10^{11} *Escherichia coli* cells per kilogram body weight [29]. Immediately after bacteria administration, animals were placed in a CVVH circuit with either a RAD with cells or a sham non-cell cartridge. RAD treatment maintained better cardiovascular performance, as determined by mean arterial blood pressure and cardiac output, for longer periods than sham therapy. All sham animals expired within 2–10 hours after bacteria administration, whereas all RAD-treated animals survived greater than 10 hours. Plasma cytokine levels in the bacteremic animals were assessed. Levels of IL-10, an anti-inflammatory cytokine, were significantly elevated in the RAD group as compared with the control group. A significant correlation between the rise in plasma IL-10 levels and the decline in mean arterial pressure was observed. The RAD maintained renal metabolic activity throughout the septic period [27].

In another study, pigs with normal kidney function were administered intraperitoneally with 3×10^{11} *E. coli* cells per kilogram body weight to induce septic shock. Animals were placed in a CVVH circuit containing either a RAD with cells or a sham non-cell cartridge with perfusion beginning immediately following bacterial administration. All animals developed ARF with anuria within 2–4 h after bacteria administration. RAD treatment maintained better cardiovascular performance, as determined by cardiac output and renal blood flow, for longer periods than sham therapy. Consistently, the RAD group survived longer than the controls (10 ± 2 hours versus 5 ± 1 hour, respectively). RAD treatment was associated with significantly lower plasma circulating levels of IL-6, a pro-inflammatory cytokine, and interferon-γ. These data demonstrate that septic shock results in early ARF and that RAD treatment in a bioartificial kidney circuit improves cardiovascular performance associated with changes in cytokine profiles and confers a significant survival advantage [30].

Phase I and II clinical experience with a human renal tubule-assist device

With these encouraging preclinical data, the Food and Drug Administration (FDA) approved an Investigational New Drug application to study the RAD containing human cells in patients with ATN receiving CVVH. Human kidney cells were isolated from kidneys donated for cadaveric transplantation but found unsuitable for such purpose because of anatomic or fibrotic defects. The initial results in the first 10 treated patients in this Phase I/II trial demonstrated that this experimental treatment can be delivered safely under study protocol guidelines in this critically ill patient population for up to 24 hours when used in conjunction with CVVH [31]. These data also indicate that the RAD maintains and exhibits viability, durability, and functionality in this *ex vivo* clinical setting. Cardiovascular stability of the patients was maintained, and increased native renal function, as determined by elevated urine outputs, temporally correlated with RAD treatment, a finding that requires additional study. The isolated and expanded human cells also demonstrated differentiated metabolic and endocrinologic activity in this *ex vivo* treatment. Glutathione degradation and endocrinologic conversion of 25-OH-D3 to 1,25-(OH)2-D3 by the RAD tubule cells were demonstrated.

All 10 patients were critically ill with ARF and multi-organ dysfunction syndrome, with predicted hospital mortality rates between 80% and 95%. One patient expired within 12 hours of RAD treatment because of his family's request to withdraw ventilatory life support. Another patient expired after a surgical catastrophe (toxic megacolon) required discontinuation of RAD treatment after only 12 hours. Of the remaining eight patients, six survived past 28 days with renal function recovery. The other two patients died from non-recoverable complications unrelated to RAD therapy and ARF, including fungal pericarditis and vancomycin-resistant enterococcus septicemia in one patient and ischemic colitis with bowel perforations in the other patient. Plasma cytokine levels suggest that RAD therapy produces dynamic and individualized responses in patients, depending on their unique pathophysiologic conditions. For the subset of patients who had excessive pro-inflammatory levels, RAD treatment resulted in significant declines in granulocyte-colony stimulating factor (G-CSF), IL-6, IL-10, and especially IL-6/IL-10 ratios, suggesting a greater decline in IL-6 relative to IL-10 levels and a lessened pro-inflammatory state. These results were encouraging and led to an FDA approved, randomized, controlled, open-label Phase II investigation, which was completed at 10 clinical sites to assess the safety and early efficacy of this cell therapy approach. The results were equally as compelling as the Phase I/II trial results.

Fifty-eight patients with ARF requiring continuous venovenous hemofiltration (CVVH) in the ICU were randomized (2:1) to receive CVVH + RAD ($n = 40$) or CVVH alone ($n = 18$). Despite the critical nature and life-threatening illnesses of the patients enrolled in this study, the addition of the RAD to CVVH resulted in a substantial clinical impact on survival compared with the conventional CVVH-treatment group. RAD treatment for up to 72 hours

promoted a statistically significant survival advantage over 180 days of follow-up in ICU patients with AKI and demonstrated an acceptable safety profile. Cox proportional hazards models suggested that the risk of death was approximately 50% of that observed in the CVVH-alone group [32]. A follow-up Phase IIb study to evaluate a commercial manufacturing process was not completed due to difficulties with the manufacturing process and clinical study design which led to a suspension of the clinical development of this approach [33].

Technological hurdles to commercialization of cell-based RRT

With the early clinical success of the RAD in RRT in AKI requiring dialytic therapy, two key missing components for the successful commercialization of cell-based therapeutic devices were identified. The first was the need for a reliable and consistent source of cells to manufacture thousands of these cell devices. The second was the requirement to develop a cost-effective manufacturing, storage and distribution process for these devices.

Cell sourcing

A key critical hurdle for any bioartificial organ program, including kidney replacement, is identifying a robust cell source for the replacement device. In this regard, a specific cell-based therapy requires several important methodologic choices and the solution of a number of technological problems. For cell-based therapies, large quantities of cells need to be expanded pathogen free, while maintaining uniformity in activity. Current approaches to ensure robust cell expansion and uniformity requirements are dependent on either stem/progenitor cells or transformed cells. The use of human embryonic stem (ES) cells versus adult stem cells is under rigorous societal debate, with the current political environment strongly favoring adult stem cell processes [34,35]. The plasticity of adult stem cells to transdifferentiate from one lineage pathway to another is also under careful scientific scrutiny. The early support for stem cell plasticity appears to be questioned by recent reports demonstrating stem cell fusion with tissue-specific differentiated cells, resulting in polyploidy rather than true stem cell transdifferentiation with normal diploid chromosomal numbers [36–38]. The ability of bone marrow stem cells to differentiate into a variety of cell types within the kidney, including glomerular and tubular elements, has been demonstrated [39]. These reports, however, demonstrate highly variable engraftment rates and inconsistent phenotypic differentiation. The issue of cell fusion in these experiments has not been addressed. Current cell-based approaches, therefore, are directed toward utilizing adult tissue-specific stem cell expansion, but the potential use of ES cells, as well as induced pluripotent stem cells (iPS) is also being aggressively pursued.

The utilization of transformed cells, including applications to deliver a gene product with gene therapy and iPS cells has recently come under intense scrutiny due to safety concerns. The autologous transplantation of genetically modified hematopoietic stem cells in children with adenosine deaminase deficiency, which leads to severe immunodeficiency, resulted in the development of acute leukemia in some of the patients due to genetic integration of the vector in the hematopoietic stem cells [40]. The ability to retrieve or deactivate these transformed cells following cell implantation is required to mitigate this high risk. Even the use of non-transformed cells may have safety concerns. Implantation of nerve cells in patients with Parkinson's disease leads to a high rate of severe and uncontrollable dyskinetic activity [41]; implantation of myoblasts into the heart has resulted in high rates of cardiac arrhythmias [42].

A choice between autologous and non-autologous human cells is also critical in the formulation of a cell-based application. Non-autologous cells must overcome natural host immunologic rejection processes. Since most indications preclude the use of immunosuppressant drugs to accommodate the discordant cell implant, immunoprotection of non-autologous cells has been approached with micro-encapsulation techniques using ultrathin

synthetic membranes to prevent entry of antibodies and immunocompetent cells of the host. Implantation of cellular micro-capsules has had limited success because of poor long term functional performance secondary to progressive loss of cell viability [43]. Success with short-term cell therapy utilizing hollow fiber bioreactors in an extracorporeal blood perfusion circuit for organ replacement therapy in acute disorders, including ATN, has been more forthcoming [21,29]. The use of autologous cells, although overcoming the immunologic barrier, has its own set of problems. Autologous approaches require obtaining the patient's own cells, expanding them *in vitro* in large quantities over several weeks, and then re-introducing the cells in a site-specific manner. Thus, each treatment is an individualized and non-scalable process, with substantial logistical and regulatory hurdles, including maintenance of the uniform quality of cells, avoidance of introduced pathogens during cell processing, and potential retrievability after implantation.

A final technologic hurdle for cell-based therapies is the maintenance of cell viability during long-term implantation. Maintenance of cell function depends on adequate nutrient and oxygen delivery to the cellular implant [44]. Creative approaches to induce and maintain formation of a neovascular capillary bed in and around the cell implant with various drug-delivery and cell scaffold formulations having been demonstrated experimentally but have not yet been successfully translated to the clinic [45]. An intravascular cell encapsulation implant approach looks promising, but requires further experimentation to determine its successful implementation [46].

Although cell-based therapy has substantial technological, regulatory, and ethical barriers, the potential to develop innovative treatments for a large number of clinical disorders, including acute and chronic renal diseases, is expanding rapidly. Progress in this field is highly dependent on an interdisciplinary approach at the interface of a number of scientific disciplines. This approach is at times empiric rather than reductive in nature, without full understanding of the manner in which cells may alter the complex pathophysiology of a systemic disorder. This limitation should not preclude continued efforts in this field. In fact, this empiric approach may result in unanticipated insights into basic biology, similar to those obtained in immunology as the field of human solid organ transplantation evolved. Cell therapy has the potential to creatively leverage nature's ability to provide new and much needed treatments to patients with acute and chronic diseases.

For renal tubule epithelial cells, cell sourcing issues from human sources has been overcome [47]. This recent development has demonstrated a dramatic increase in the yield of renal epithelial cells, exceeding 10^{16} cells/gm of kidney cortex from a healthy human source. This enhanced propagation methodology can easily produce over 100,000 devices per kidney and allow for autologous use of renal cells from a biopsy specimen from an individual.

Bioartificial renal epithelial cell system (BRECS): A cell therapy approach

The clinical efficacy of the cell-based, multifactorial approach of the RAD, which leveraged the metabolic and synthetic functions of stem/progenitor cells of the kidney directed toward a renal tubule cell fate is well established [30,48,49]. Cell sourcing and storage/distribution issues encountered during RAD manufacturing have now been addressed through the development of a new cell-based device called the bioartificial renal epithelial cell system. The BRECS is an example of a cell therapy device that maintains a high density of renal cells for therapeutic application within an extracorporeal circuit [50] (see Fig. 52.2). In comparison with other cell therapies involving the direct application or injection of stem cells into the body, the extracorporeal approach of the BRECS allows for cell therapy application while maintaining immunoisolation using a series of filters. Critical to the application of the BRECS for acute indications, the BRECS has been designed to enable cryopreservation of cells within the device in a therapeutically ready state, and the cells within the BRECS are from

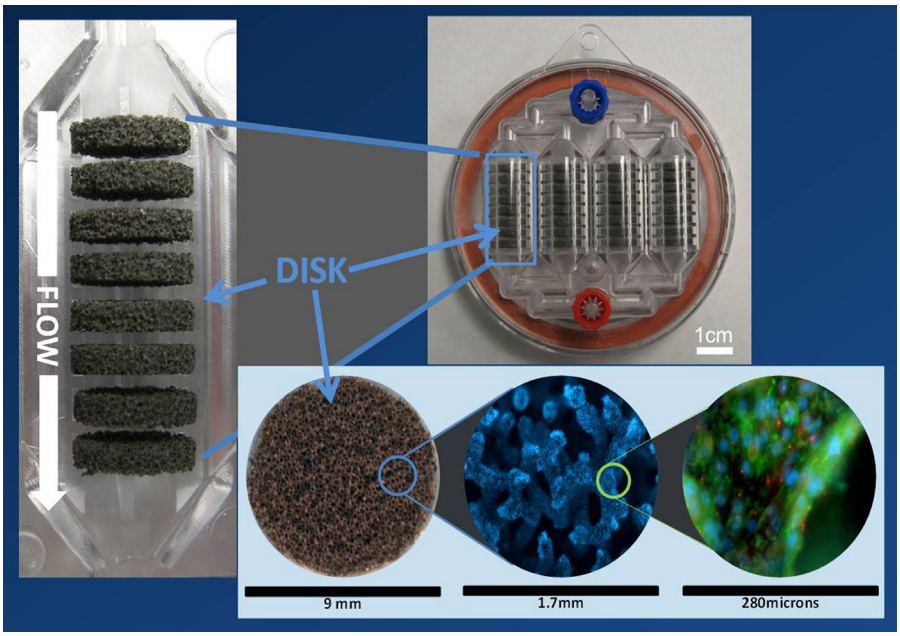

FIGURE 52.2
Previously cryopreserved human renal epithelial cells are reconstituted, followed by seeding onto disks which are then placed into BRECS culture. Post-culture, disks are counter-stained with DAPI (blue, 1.7 mm insert), zonula occludens (ZO)-1 (green, 280 micron insert) and AT-1 (red, 280 micron insert). The cryopreserved, reconstituted cells show the correct renal phenotype with positive ZO-1 and AT-1 staining, indicative of a polarized renal epithelium.

an allogenic source, which enables mass fabrication, cryopreservation for storage and distribution to meet on-demand clinical need.

In brief, the BRECS is a perfusion bioreactor that utilizes primary renal epithelial cells (REC) derived from the kidney, expanded from progenitor cells during *in vitro* culture. Cells are seeded on porous disks, which are placed within a media flow path within the BRECS. Renal progenitor cells are directed toward a renal tubule cell fate, and maintained in perfusion culture prior to therapeutic application. *In vitro* cell viability and metabolic activity were confirmed in the BRECS by measuring lactate production and oxygen consumption. Both metrics of metabolism were consistent throughout the duration of perfusion culture, with an estimated total cell number of over 10^8 cells [49]. Oxygen consumption rates in the nmol O_2/min per 10^6 cells range is similar to previously reported values for metabolically active cells [14].

REC in BRECS maintained renal differentiated phenotypic characteristics over time in perfusion culture, as evidence from human REC-seeded disks from BRECS units that were processed for immunohistochemical (IHC) analysis of selected renal cell differentiated markers, acetylated tubulin (AT-1) and zona occludens (ZO-1). AT-1, a marker for apical central cilia of proximal tubule cells, exhibited regular staining in central regions of cells grown on disks. ZO-1, a marker for epithelial tight junctions, displayed strong expression along the surface of the cells. ZO-1—positive tight junctions and punctate AT-1—positive central cilia are indicative of polarized epithelium and were evident in all disks tested [49].

Renal cell specific function of cells within BRECS has been tested using a non-destructive glutathione (GSH) degradation assay to assess one measure of catabolic function of the cells in the BRECS over time. Exogenous glutathione was supplemented in the BRECS perfusion media, and metabolic degradation of GSH was measured over a 60-minute period. GSH degradation rates in BRECS remained stable, ranging between 600 and 1200 nmoles/hr/BRECS over a 90 day period, indicative of sustained differentiated renal cell function in the device [47].

Cryopreservation and thaw of REC in BRECS was accomplished using a commercially available and FDA approved cryopreservation media. Post-cryopreservation cell retention was optimized when HTS-Purge solution, a hypothermic solution used to prepare cells for the extreme conditions of cryopreservation, was utilized as a pre-cryopreservation rinse buffer, in

combination with a controlled rate freezer, resulting in average cell retention of greater than 80% and viability of greater than 90% [47]. This technology allows for the storage and distribution of cell therapy for on-demand use for acute indications such as sepsis and acute renal failure.

Wearable bioartificial kidney (WEBAK)

A bioartificial kidney for long-term use in ESRD, similar to short-term use in ARF, would integrate tubular cell therapy and the filtration function of a hemofilter. As noted above, ESRD patients on conventional renal replacement therapy are at high risk for cardiovascular and infectious diseases. A recent clinical trial failed to show survival benefit from increased doses of hemodialysis above what is now standard care [51], suggesting that there are important metabolic derangements not adequately treated with conventional dialytic treatment. Data from the survival of renal transplant recipients, which far exceed those from the survival of age-, sex-, and risk-matched controls awaiting transplant, also suggest that there is some metabolic function provided by the kidney that transcends this organ's filtration function. Patients with ESRD display elevated levels of C-reactive protein (CRP), an emerging clinical marker, and pro-inflammatory cytokines, including IL-1, IL-6, and tumor necrosis factor alpha (TNFα) [52–54]. All these parameters are associated with enhanced mortality in ESRD patients. Specifically, IL-6 has been identified as a single predictive factor closely correlated with mortality in hemodialysis patients [52]. Although all ESRD patients could conceivably benefit from a bioartificial kidney, patients in the inflammatory stage who display elevated levels of certain markers of chronic inflammation (most notably IL-6 and CRP) would likely benefit most and will be the target population for clinical study in the near future.

For the ESRD patient population, however, there are obvious limitations in using an extracorporeal RAD connected to a hemofiltration circuit. Ideally, a bioartificial kidney suitable for long term use in ESRD patients would be capable of performing continuously, like the native kidney, to reduce risks from fluctuations in volume status, electrolytes, and solute concentrations and to maintain acid-base and uremic toxin regulation. Such treatment requires the design and manufacture of a compact implantable or wearable dialysis apparatus and the development of miniaturized renal tubule cell devices with long service lifetimes. The ideal design of the next-generation RAD would be like that of an implantable device similar to the pacemaker.

As an intermediary approach to a fully implantable BAK, a WEBAK formulation has been recently evaluated in both preclinical large animal models and in early clinical studies. The WEBAK is comprised of the use of sorbent based technologies to replace the excretory function of the kidney and the compact BRECS device described above to replace the metabolic function of the kidney [55]. This approach is displayed in Fig. 52.3.

Sorbent-based hemodialysis was developed in the late 1960s and introduced into the clinic in the 1970s. Sorbents provide the ability to reduce the large volumes of dialysis solutions utilizing highly purified water from 100–200 liters per dialysis sessions to as little as 6 liters of potable water. With sorbent dialysis, spent dialysis from the dialyzer cartridge is not discarded but is regenerated by processing the dialysate through the sorbent cartridge.

The sorbent cartridge has several layers of sorbent compounds which regenerate used dialysate into fresh, bicarbonate dialysate. The cartridge is based upon carbon binding, enzyme conversion and ion exchange. This compact and disposable regeneration process promotes this sorbent system to remove key uremic toxins and regenerate dialysate. Sorbent cartridges operate without a connection to a water supply or drain, promoting system mobility, portability and measurable RRT.

Attempts have been made to develop wearable dialysis systems to improve the portability of renal replacement therapies. Gura, Beizai, Ezon, and Polaschegg [56] have published research

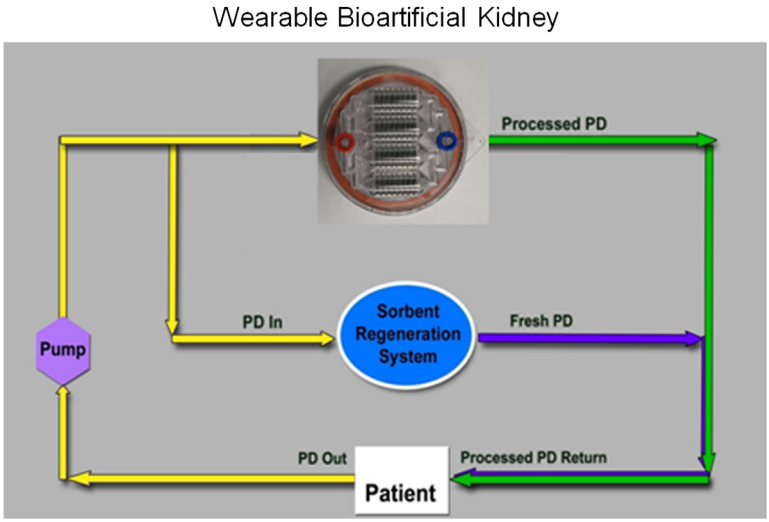

FIGURE 52.3
A circuit design for a WEBAK utilizing peritoneal fluid to maintain cell viability and functionality in the BRECS. Sorbent-based technology is used to regenerate peritoneal dialysis fluid for uremic toxin removal and fluid/electrolyte balance.

into a light-weight, wearable, continuous ambulatory ultrafiltration device consisting of a hollow fiber hemofilter, a battery-operated pulsatile pump, and two micropumps to control heparin administration and ultrafiltration. This device regenerates dialysate with activated carbon, immobilized urease, zirconium hydroxide, and zirconium phosphate, similar to the once commercially available regenerative dialysis (REDY) dialysis system. This approach requires continuous blood access to allow adequate ultrafiltration. Ronco and Fecondini [57] have described a wearable continuous PD system consisting of a double lumen dialysate line with a peritoneal catheter, a miniaturized rotary pump, a circuit for dialysate regeneration, and a handheld computer as a remote control. This latter approach utilizes continuous regeneration of PD fluid relying on continuous-flow PD systems [58–60].

As development towards a sorbent-based, wearable, continuous recycling flow PD is being made, the integration of renal epithelial cell therapy in the PD circuit to treat patients with ESRD is also being evaluated in large animal models of uremia.

Because a cell therapy device requires a continuous source of nutrients and oxygen, the use of blood circuits for this nutrient stream has been avoided due to clotting and infection risks. Accordingly, the use of recycling peritoneal fluid to maintain viability of a renal cell device has been conceived and successfully tested in a uremic sheep model. Further development of this approach of a WEBAK integrating the wearable sorbent dialysis system and renal cell device with recycling peritoneal fluid was dependent upon technologic improvements of human cell sourcing and compact cell device fabrication and storage. These technologic obstacles have been solved as detailed above. In this regard, a major limitation of the widespread adoption of renal cell therapy is the lack of a cryopreservable system to enable distribution, storage, and therapeutic use at point-of-care facilities. Building from the success of the initial renal tubule-assist (RAD), development of the BRECS allows for a device that functions as a combined bioreactor, cryostorage device, and cell therapy delivery system. *Ex vivo* large animal studies suggest using the BRECS in conjunction with standard hemofiltration or PD is a promising approach to treat both ARF and ESRD.

Implanted artificial kidney: successes and barriers

An implantable 'biohybrid' or bioartificial device has the potential to avoid both supply limitations to renal transplant and the burden of therapy of intensive maintenance dialysis [12]. The innovative combination of an implanted hemofilter and a bioreactor of renal cells would provide continuous small solute clearance along with metabolic functions of the proximal tubule, without the morbidity and burden of catheters and dialysis (see Fig. 52.4).

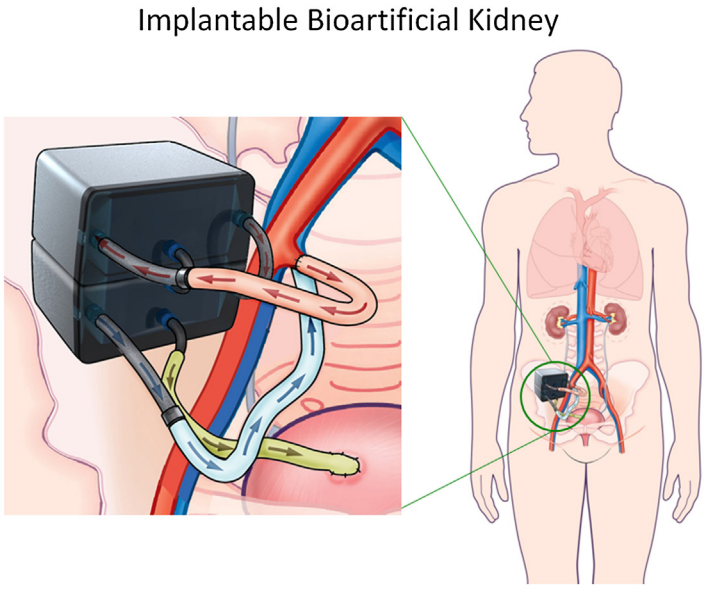

FIGURE 52.4
Concept illustration of implantable bioartificial kidney. The device consists of a silicon hemofilter for toxin filtration and a bioreactor of renal epithelial cells for metabolic and endocrine functions. *(Courtesy of Shuvo Roy.)*

Two factors limit miniaturization and implant of the hemodialysis circuit: the size and pump requirements of modern dialyzers, and the water volume required for dialytic therapy. Hollow fiber polymer membranes have been immensely successful in treating renal failure with extracorporeal therapies and are a lifesaving medical innovation. Hollow fiber dialyzers require super-physiologic driving pressures for blood circulation through the cartridge. The long cylindrical hollow fibers present a high resistance to blood flow, which rises further in the distal portion of the fiber as ultrafiltration increases hemocrit and viscosity, requiring energy-hungry roller pumps to circulate blood through the device. The pores in hollow fiber dialyzers are irregular, approximately cylindrical, and non-uniform in size, typically described as having a lognormal pore size distribution [61]. This polydispersity compromises the trade-off between permeability and selectivity: to prevent albumin leakage through the largest pores in the membrane, the majority of the membrane's pores need to be maintained much smaller than the desired cutoff target of the membrane. Similarly, a four hour dialysis treatment with a dialysate flow of 600mL/min consumes 144 liters of dialysate, which may have required an additional 200 liters of tap water to produce. Dialysate regeneration schemes are an attractive approach to limit water consumption, but require removal and replacement of sorbent cartridges, which precludes an implantable therapeutic strategy [62–64].

Control of pores enables high efficiency filtration

The natural filtration-reabsorption process of renal solute clearance as a model for a new approach to RRT includes the examination of the structure of the glomerular filter for clues to its performance. The kidney's filters appear to be uniform, elongated, slit-shaped structures, rather than the irregular and more cylindrically-shaped pores of polymer membranes. Indeed, nature appears to have evolved slit-shaped filters in a wide range of organisms, from the baleen palates of filter-feeding whales to the beaks of filter-feeding birds, such as shoveler ducks and flamingos. This particular geometry of uniform slits appears to optimize the permeability-selectivity trade-off [65]. The glomerular visceral epithelial cell or podocyte, which appears to be responsible for maintenance of the glomerular filtration barrier, does not assume the same differentiated phenotype in cell culture as it does *in vivo*, limiting its use so far in bioengineering of renal replacement. Thus, we turned to an entirely new technology toolkit, silicon nanotechnology, to develop a membrane incorporating these advantages. Micro-electromechanical systems (MEMS) is a toolkit that applies industrially mature manufacturing techniques from the semiconductor industry to produce precise miniature electromechanical

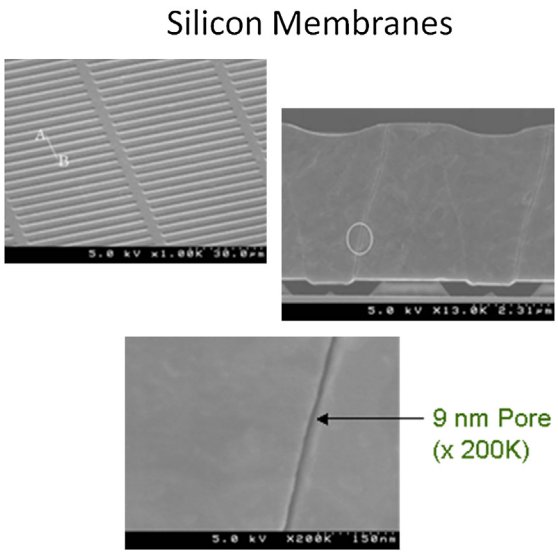

FIGURE 52.5
SEM images of silicon membranes with minimal pore size variation. These membranes can be coated with biocompatible thin films to provide highly selective filtrations of blood at very low driving pressures. *(Courtesy of Shuvo Roy.)*

devices such as pumps, valves, and sensors at low unit cost. Common commercial applications of MEMS include accelerometers for airbag sensors and inertial navigation, pressure sensors for medical and industrial use, and micro-mirror arrays for image projectors. MEMS technology can be used for the production of silicon nanopore membranes with slit-shaped pores that are tailored for implementation in a bioartificial kidney.

The fundamental membrane engineering challenge for the implantable artificial kidney is to simultaneously maximize water permeability while minimizing leakage of albumin and other important macromolecules. Prototyped ultrathin biomimetic silicone nanopore membranes using bulk and surface micromachining techniques derived from MEMS fabrication technology (see Fig. 52.5) and examined macromolecular transport from both analytical and experimental perspectives have been developed and reported [65–67].

Membranes with pore sizes from 5–90 nm were produced and perfused with solutions of a polydisperse tracer (Ficoll) and albumin to characterize their transport characteristics. Silicon nanopore membranes showed a distinct and predictable size-dependant and charge-dependent reduction in sieving coefficient [68]. Another set of experiments measured albumin transmission through membranes with different pore sizes to map the relationship between pore size and albumin retention. The observed sieving coefficients matched a combined electrical/steric hindrance model. Further, an analysis of the trade-off between selectivity (ability to reject albumin) and permeability (ability to transmit water) suggests that a membrane of slit-shaped pores outperforms a comparable membrane of cylindrical pores [65]. Data from the silicone nanopore membranes, when compared to data from polymer membranes, confirms that this theoretical advantage is experimentally observed as well (see Fig. 52.6).

Blood-material interactions can be controlled using hydrated polymer surface modifications

Silicon readily forms a thin oxide coating upon exposure to atmospheric oxygen. This silica film is negatively charged at physiologic pH and both absorbs plasma proteins and activates the coagulation cascade. One strategy to mitigate adverse blood-materials interactions is to modify the silicon surface with a highly hydrated polymer. Various organic polymers have been grafted to silicon surfaces and have been successful in demonstrating the feasibility of using silicon nanopore membranes coated with antifouling films for hemofiltration [69].

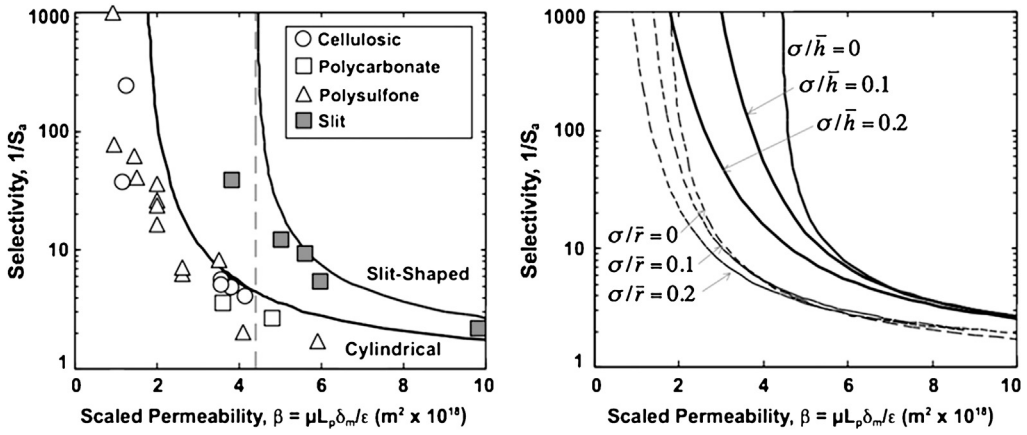

FIGURE 52.6

1. Selectivity-permeability trade-off for ultrafiltration membranes using albumin as the model protein. Open symbols represent data for polymer ultrafiltration membranes. Filled symbols represent data for novel silicon membranes with nanometer-size slit-shaped pores as discussed in the text. The data point shown at $\beta = 9.8\times10^{-18}$ m^2 is actually at $\beta = 20\times10^{-18}$ m^2 but has been moved to accommodate the scaling of the figure. Solid curves represent model calculations for membranes consisting of a parallel array of uniform cylindrical or slit-shaped pores. The dashed vertical line is the permeability of a slit-pore membrane with infinite selectivity. 2. Model calculations showing the influence of a membrane pore size distribution on the trade-off between selectivity and permeability for membranes with cylindrical and slit-shaped pores.

Next steps in implementation of the implantable artificial kidney

Significant preliminary data have been published documenting each of the three platform technologies necessary for an implantable bioartificial device that can provide enough small solute clearance to allow the patient with failing kidneys to avoid dialysis. Significant engineering challenges remain, but these challenges are not new to bioengineering. First and foremost, just as hemodialysis in the treatment of renal failure is more than the hollow fiber dialyzer alone, the design of the implanted device will have to be guided by the planned therapeutic strategy. Specific means for patients to self-monitor and reprogram device function will be critical for truly independent self-care using an implanted device. Lifecycle management of the device, including recognition of impending device failure and a minimally invasive approach to renewing or replacing failed components, modules, or cartridges seems essential. Selection of implant site will be guided by the paramount need to preserve vascular sites for future allografts. These challenges can be met and answered, just as they have been for other implanted devices, from corneas to ventricular assist devices. The remaining work to be completed is more than justified by the overwhelming burden of illness faced by patients with renal failure, the financial burden placed on payers for dialysis, and the revolutionary innovations already achieved in silicon nanopore membrane technology, polymer chemistry, and cell biology.

CONCLUSION

Despite all the advances in renal replacement therapies, a portable, continuous, dialysate-free artificial kidney remains the holy grail of renal tissue engineering. The enabling platform technologies discussed in this review advance this goal from a dream to the laboratory bench and even to the bedside. Future research in renal tissue engineering will need to focus on reproducing mechanisms of whole-body homeostasis. A high priority must be given to sensing and regulating extracellular fluid volume, even if only at the crude level of having the patient weigh him- or herself daily and adjust ultrafiltration and reabsorption by the bioartificial kidney. Chemical-field effect transistors (ChemFETs) offer the possibility of measuring electrolyte levels in a protein-free ultrafiltrate and reading out the potassium level to the patient, who could then alter diet or treat him- or herself with potassium absorbing resins.

The critical building blocks of an autonomous bioartificial kidney are advancing rapidly with revolutionary clinical trials currently underway at multiple medical centers. The technology with which to adapt these advances to a more autonomous, dialysate-free system is under development. In addition, progress has been made in the field of cryopreservation and thus the ability to manufacture, store and distribute bioartificial organs is advancing. The next decade, like the previous, will likely see quantum advances in renal tissue engineering.

CHAPTER 53

Genitourinary System

Anthony Atala
Wake Forest University School of Medicine, Department of Urology and Institute for Regenerative Medicine, Winston Salem, North Carolina

INTRODUCTION

The genitourinary system may be exposed to a variety of possible injuries from the time the fetus develops. Individuals may suffer from congenital disorders, cancer, trauma, infection, inflammation, iatrogenic injuries, or other conditions that may lead to genitourinary organ damage or loss and necessitate eventual reconstruction. Whenever there is a lack of native urologic tissue, reconstruction may be performed with native non-urologic tissues (skin, gastrointestinal segments, or mucosa from multiple body sites), homologous tissues (cadaver fascia, cadaver or donor kidney), heterologous tissues (bovine collagen), or artificial materials (silicone, polyurethane, Teflon). The tissues used for reconstruction may lead to complications because of their inherently different functional parameters. In most cases, the replacement of lost or deficient tissues with functionally equivalent tissues would improve the outcome for these patients. This goal may be attainable with the use of tissue-engineering techniques.

RECONSTITUTION STRATEGIES

The goal of tissue engineering is to develop biologic substitutes that can restore and maintain normal function. Tissue engineering may involve matrices alone, wherein the body's natural ability to regenerate is used to orient or direct new tissue growth, or it may use matrices with cells. When cells are used for tissue engineering, donor tissue (heterologous, allogenic, or autologous) is dissociated into individual cells, which are implanted directly into the host or expanded in culture, attached to a support matrix, and reimplanted after expansion. Ideally, this approach allows lost tissue function to be restored or replaced *in toto* and with limited complications [1–13].

THE ROLE OF BIOMATERIALS

Biomaterials in genitourinary tissue engineering function as an artificial extracellular matrix (ECM) and elicit biologic and mechanical functions of native ECM found in body tissues. Biomaterials facilitate the localization and delivery of cells and/or bioactive factors (such as cell adhesion peptides and growth factors) to desired sites in the body; define a three-dimensional space for the formation of new tissues with appropriate structure; and guide the development of new tissues with appropriate function [14]. While direct injection of cell suspensions without biomaterial matrices has been used [15], it is difficult to control the localization of transplanted cells.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00053-7

The ideal biomaterial should be biocompatible, promote cellular interaction and tissue development, and possess proper mechanical and physical properties. Generally, three classes of biomaterials have been used for engineering of genitourinary tissues: naturally derived materials, such as collagen and alginate; acellular tissue matrices, such as bladder submucosa and small-intestinal submucosa; and synthetic polymers, such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA). While naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition, synthetic polymers can be produced reproducibly on a large scale with controlled properties of strength, degradation rate, and microstructure.

VASCULARIZATION

A restriction of tissue engineering is that cells cannot be implanted in volumes exceeding 3 mm^3 because of the limitations of nutrition and gas exchange [16]. To achieve the goals of engineering large complex tissues, and possibly internal organs, vascularization of the regenerating cells is essential. Three approaches have been used for vascularization of bioengineered tissue:

1) Incorporation of angiogenic factors in the bioengineered tissue;
2) Seeding EC with other cell types in the bioengineered tissue; and
3) Prevascularization of the matrix prior to cell seeding.

Angiogenic growth factors may be incorporated into the bioengineered tissue prior to implantation, in order to attract host capillaries and to enhance neovascularization of the implanted tissue. Many obstacles must be overcome before large entire tissue-engineered solid organs are produced. Recent developments in angiogenesis research may provide important knowledge and essential materials to accomplish this goal.

PROGRESS IN TISSUE ENGINEERING OF UROLOGIC STRUCTURES

Tissue-engineering techniques are currently being investigated for the replacement of lost or deficient genitourinary structures, including urethra, bladder, male and female genital tissues, ureter, and renal structures.

Urethra

Various strategies have been proposed to regenerate urethral tissue. Woven meshes of PGA, without cells, have been used to reconstruct urethras in dogs [17]. PGA has been used as a cell transplantation vehicle to engineer tubular urothelium *in vivo*. Small-intestinal submucosa (SIS) without cells was used as an onlay patch graft for urethroplasty in rabbits [18], and a homologous free graft of acellular urethral matrix was also used in a rabbit model [19].

Bladder-derived acellular collagen matrix has proven to be a suitable graft for repairing urethral defects in rabbits. The created neourethras demonstrated a normal urothelial luminal lining and organized muscle bundles [20]. Results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction whose urethral defects were repaired with human bladder acellular collagen matrices [21] (Fig. 53.1). An advantage of this material over non-genital tissue grafts for urethroplasty is that it is 'off the shelf', eliminating the need for additional surgical procedures for graft harvesting and decreasing operative time and potential morbidity from the harvest procedure.

The above techniques, using non-seeded acellular matrices, were successfully applied experimentally and clinically for onlay urethral repairs. However, when tubularized repairs were attempted experimentally, adequate urethral tissue regeneration was not achieved, and complications, such as graft contracture and stricture formation ensued [22]. Seeded tubularized collagen matrices have performed better than their non-seeded counterparts in animal

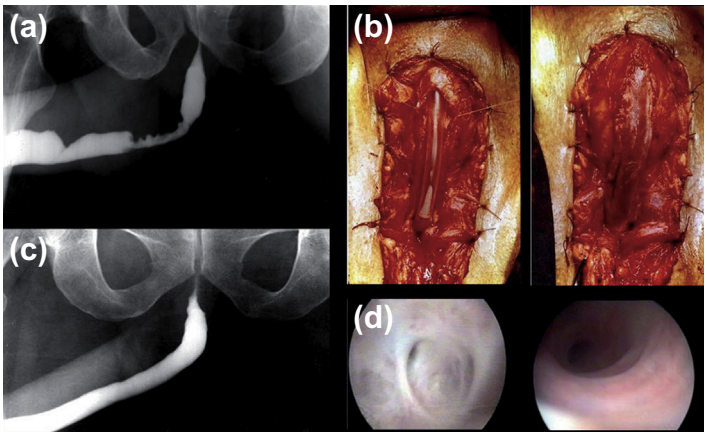

FIGURE 53.1
Tissue-engineered urethra using a collagen matrix. (a) Representative case of a patient with a bulbar stricture. (b) Urethral repair. Strictured tissue is excised, preserving the urethral plate on the left side, and matrix is anastomosed to the urethral plate in an onlay fashion on the right. (c) Urethrogram six months after repair. (d) Cystoscopic view of urethra before surgery on the left side and four months after repair on the right side.

studies. In a rabbit model, entire urethral segments were resected, and urethroplasties were performed with tubularized collagen matrices, either seeded or non-seeded. The tubularized collagen matrices seeded with autologous cells formed new tissue which was histologically similar to native urethra. Those without cells lead to poor tissue development, fibrosis, and stricture formation.

Most recently, we were able to show that synthetic biomaterials can also be used in urethral reconstruction when they are tabularized and seeded with autologous cells [23]. This group used polygycolic acid:poly(lactide-co-glycolic acid) scaffolds seeded with autologous cells derived from bladder biopsies taken from each patient. The seeded scaffolds were then used to repair urethral defects in five boys. Upon follow-up, it was found that most of the boys had excellent urinary flow rates post-operatively, and voiding cystourethrograms indicated that these patients maintained wide urethral calibers. Urethral biopsies revealed that the grafts had developed a normal appearing architecture consisting of urothelial and muscular tissue.

Bladder

Gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, these tissues are designed to absorb specific solutes, and when they come in contact with the urinary tract, multiple complications may ensue, including infection, metabolic disturbances, urolithiasis, perforation, increased mucus production, and malignancy [24]. Because of these problems, investigators have attempted alternative reconstructive procedures for bladder replacement or repair such as the use of tissue expansion, seromuscular grafts, matrices for tissue regeneration, and tissue engineering with cell transplantation.

TISSUE EXPANSION

A system of progressive dilation for ureters and bladders has been proposed as a method of bladder augmentation but has not yet been attempted clinically [25,26]. Augmentation cystoplasty performed with the dilated ureteral segment in animals has resulted in increased bladder capacity ranging from 190% to 380% [25]. A system to progressively expand native bladder tissue has also been used for augmenting bladder volumes in animals. Within 30 days after progressive dilation, neoreservoir volume was expanded at least 10-fold. Urodynamic studies showed normal compliance in all animals, and microscopic examination of the

expanded neoreservoir tissue confirmed a normal histology. A series of immunocytochemical studies demonstrated that the dilated bladder tissue maintained normal phenotypic characteristics [26].

SEROMUSCULAR GRAFTS

Seromuscular grafts and de-epithelialized bowel segments, either alone or over a native urothelium, have also been attempted [27,28]. Keeping the urothelium intact avoids complications associated with the use of bowel in continuity with the urinary tract [27,28]. An example of this strategy is to combine the techniques of autoaugmentation and enterocystoplasty. An autoaugmentation is performed, and the diverticulum is covered with a demucosalized gastric or intestinal segment.

MATRICES

Non-seeded allogeneic acellular bladder matrices have served as scaffolds for the ingrowth of host bladder wall components. The matrices are prepared by mechanically and chemically removing all cellular components from bladder tissue [29,30]. The matrices serve as vehicles for partial bladder regeneration, and relevant antigenicity is not evident. For example, SIS (a biodegradable, acellular, xenogeneic collagen-based tissue-matrix graft) was first used in the early 1980s as an acellular matrix for tissue replacement in the vascular field. It has been shown to promote regeneration of a variety of host tissues, including blood vessels and ligaments [31]. Animal studies have shown that the non-seeded SIS matrix used for bladder augmentation can regenerate *in vivo* [32].

In multiple studies using various materials as non-seeded grafts for cystoplasty, the urothelial layer regenerated normally, but the muscle layer, although present, was not fully developed [29,30]. Often the grafts contracted to 60–70% of their original sizes [33] with little increase in bladder capacity or compliance [34].

Studies involving acellular matrices that may provide the necessary environment to promote cell migration, growth, and differentiation are being conducted. With continued research, these matrices may have a clinical role in bladder replacement in the future. Recently, bladder regeneration has been shown to be more reliable using SIS derived from the distal ileum [32].

CELL TRANSPLANTATION

Cell-seeded allogeneic acellular bladder matrices have been used for bladder augmentation in dogs. Trigone-sparing cystectomy was performed in dogs randomly assigned to one of three groups. One group underwent closure of the trigone without a reconstructive procedure; another underwent reconstruction with a non-seeded bladder-shaped biodegradable scaffold; and the last underwent reconstruction using a bladder-shaped biodegradable scaffold that delivered seeded autologous urothelial cells and smooth muscle cells [12].

The cystectomy-only and non-seeded controls maintained average bladder capacities of 22% and 46% of preoperative values, respectively, compared with 95% in the cell-seeded tissue-engineered bladder replacements (Fig. 53.2). The subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42% total compliance). The compliance of the cell-seeded tissue-engineered bladders showed almost no difference from preoperative values that were measured when the native bladder was present (106%). Histologically, the non-seeded scaffold bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle fibers (Fig. 53.2b). The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle (Fig. 53.2c) [12]. Preliminary clinical trials for the application of this technology have been performed and are under evaluation.

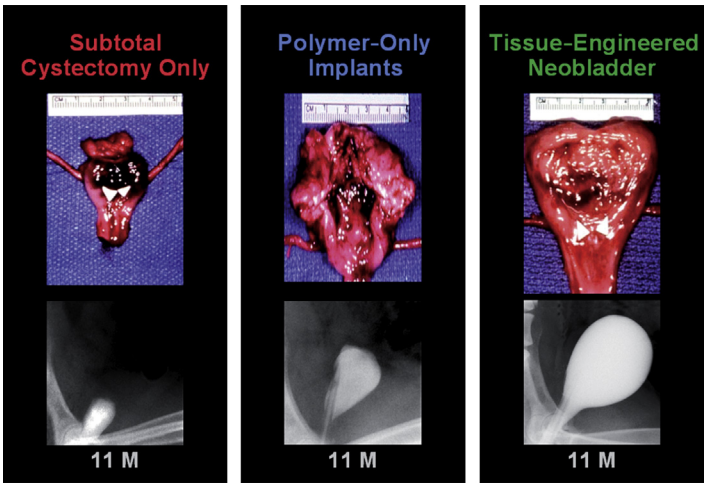

FIGURE 53.2
Comparison of tissue-engineered neobladders. Gross specimens and cystograms at 11 months of the cystectomy-only, non-seeded controls, and cell-seeded tissue-engineered bladder replacements. The cystectomy-only bladder had a capacity of 22% of the preoperative value and a decrease in bladder compliance to 10% of the preoperative value. The non-seeded controls showed significant scarring, with a capacity of 46% of the preoperative value and a decrease in bladder compliance to 42% of the preoperative value. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements, and the compliance showed almost no difference from preoperative values, which were measured when the native bladder was present (106%).

Genital tissues

Tissue engineering techniques have been used to reconstruct male and female genital tissues.

CORPORAL SMOOTH MUSCLE

Because one of the major components of the phallus is corporal smooth muscle, the creation of autologous functional and structural corporal tissue *de novo* would be beneficial. To examine functional parameters of engineered corpora, acellular corporal collagen matrices were obtained from donor rabbit penis, and autologous corpus cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded on the matrices. The entire rabbit corpora was removed and replaced with engineered scaffolds. The experimental corporal bodies demonstrated intact structural integrity by cavernosography and showed similar pressure by cavernosometry when compared with normal controls. The control rabbits (without cells) failed to show normal erectile function throughout the study. Mating activity in the animals with the engineered corpora appeared normal by 1 month after implantation. The presence of sperm was confirmed during mating and was present in all the rabbits with the engineered corpora. The female rabbits mated with the animals implanted with engineered corpora and also conceived and delivered healthy pups. Animals implanted with the matrix alone were unable to demonstrate normal mating activity and failed to ejaculate into the vagina [35].

ENGINEERED PENILE PROSTHESES

Although silicone is an accepted biomaterial for penile prostheses, biocompatibility remains a concern [36]. The use of a natural prosthesis composed of autologous cells may be advantageous.

A recent study using an autologous system investigated the feasibility of applying the engineered cartilage rods *in situ* [37]. Autologous chondrocytes harvested from rabbit ear were grown and expanded in culture. The cells were seeded onto biodegradable poly-L-lactic acid-coated PGA polymer rods and implanted into the corporal spaces of rabbits. Examination

at retrieval 1 month later showed the presence of well-formed, milky-white cartilage structures within the corpora. All polymers were fully degraded by two months. There was no evidence of erosion or infection in any of the implantation sites.

Subsequent studies assessed the long-term functionality of the cartilage penile rods *in vivo* [37]. To date, the animals have done well and can copulate and impregnate their female partners without problems.

FEMALE GENITAL TISSUES

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy or intersex disorders may not have sufficient uterine tissue for future reproduction.

We investigated the possibility of engineering functional uterine tissue using autologous cells [38]. Autologous rabbit uterine smooth muscle and epithelial cells were harvested, then grown and expanded in culture. These cells were seeded onto pre-configured uterine-shaped biodegradable polymer scaffolds, which were then used for subtotal uterine tissue replacement in the corresponding autologous animals. Upon retrieval six months after implantation, histological, immunocytochemical, and Western blot analyses confirmed the presence of normal uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging due to the paucity of available native tissue.

Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. The cells were seeded onto biodegradable polymer scaffolds, which were then implanted into nude mice for up to six weeks. Immunocytochemical, histological, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were noted in the tissue-engineered specimens, while the non-seeded structures were noted to be stenotic.

Ureter

Ureteral non-seeded matrices have been used as a scaffold for the ingrowth of ureteral tissue in rats. On implantation, the acellular matrices promoted the regeneration of the ureteral wall components [39]. In a more recent study, non-seeded ureteral collagen acellular matrices were tabularized, but attempts to use them to replace 3 cm segments of canine ureters were unsuccessful [40].

Cell-seeded biodegradable polymer scaffolds have been used with more success to reconstruct ureteral tissues. In one study, urothelial and smooth muscle cells isolated from bladders and expanded *in vitro* were seeded onto polyglycolic acid (PGA) scaffolds with tubular configurations and implanted subcutaneously into athymic mice. After implantation, the urothelial cells proliferated to form a multilayered luminal lining of tubular structures, while the smooth muscle cells organized into multilayered structures surrounding the urothelial cells. Abundant angiogenesis was evident. Polymer scaffold degradation resulted in the eventual formation of natural urothelial tissues. This approach has also been used to replace ureters in dogs [41].

Renal structures

Due to its complex structure and function, the kidney is possibly the most challenging organ in the genitourinary system to reconstruct using tissue-engineering techniques. However concepts for a bioartificial kidney are emerging. Some investigators are pursuing the replacement of isolated kidney function parameters with the use of extracorporeal units, while others are working toward the replacement of total renal function by tissue-engineered bioartificial structures.

EX VIVO RENAL UNITS

Although dialysis is currently the most prevalent form of renal replacement therapy, the relatively high rates of morbidity and mortality have spurred investigators to seek alternative solutions involving *ex vivo* systems.

To assess the viability and physiologic functionality of a cell-seeded device to replace the filtration, transport, metabolic, and endocrinologic functions of the kidney in acutely uremic dogs, researchers introduced a synthetic hemofiltration device combined with a renal tubular cell therapy device (containing porcine renal tubules in an extracorporeal perfusion circuit). Levels of potassium and blood urea nitrogen (BUN) were controlled during treatment with the device. The fractional reabsorption of sodium and water was possible, and active transport of potassium, bicarbonate, and glucose and a gradual ability to excrete ammonia was observed. These results demonstrated the technologic feasibility of an extracorporeal assist device that is reinforced by the use of proximal tubular cells [42].

Using similar techniques, a tissue-engineered bioartificial kidney — consisting of a conventional hemofiltration cartridge in series with a renal tubule assist device containing human renal proximal tubule cells — was used in patients with acute renal failure in the intensive care unit. Initial clinical experience with the bioartificial kidney and the renal tubule assist device suggests that such therapy may provide a dynamic and individualized treatment program as assessed by acute physiologic and biochemical indices [43].

IN VIVO RENAL STRUCTURES

Another method of improving renal function involves augmenting renal tissue with kidney cell expansion *in vitro* and subsequent autologous transplantation. The feasibility of achieving renal cell growth, expansion, and *in vivo* reconstitution with tissue-engineering techniques has been explored.

Most recently, an attempt was made to harness the reconstitution of renal epithelial cells to generate functional nephron units. Renal cells harvested and expanded in culture were seeded onto a tubular device constructed from a polycarbonate membrane connected at one end to a Silastic catheter terminating into a reservoir. The device was implanted into athymic mice. Histological examination of the implanted devices over time revealed extensive vascularization, with formation of glomeruli and highly organized tubule-like structures. Immunocytochemical staining confirmed the renal phenotype. Yellow fluid consistent with the makeup of dilute urine in its creatinine and uric acid concentrations was retrieved from inside the implant [9]. Further studies using nuclear transfer techniques have been performed showing the formation of renal structures in cows (Fig. 53.3) [44]. Challenges facing this technology include the expansion to larger, three-dimensional structures.

ADDITIONAL APPLICATIONS

Tissue engineering and cell therapy hold promise for a number of additional genitourinary applications.

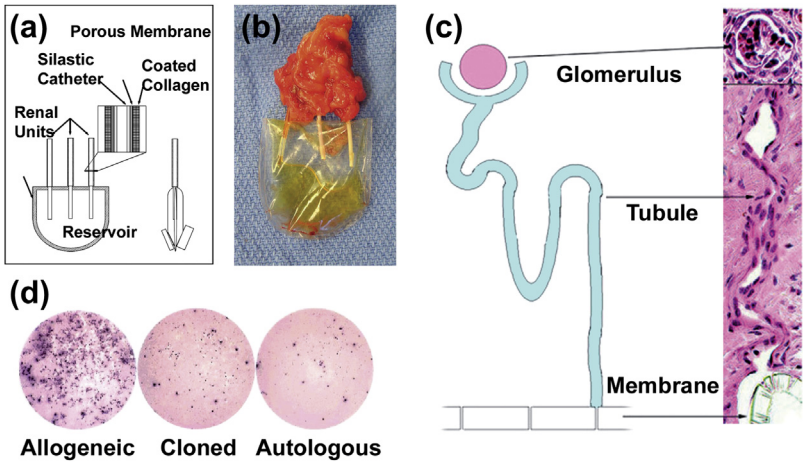

FIGURE 53.3

Creation of kidney tissue from therapeutic cloning and tissue-engineering strategies. (a) Illustration of the tissue-engineered renal unit. (b) Renal unit seeded with cloned cells, three months after implantation, showing the accumulation of urinelike fluid. (c) There was a clear unidirectional continuity between the mature glomeruli, their tubules, and the polycarbonate membrane. (d) Elispot analyses of the frequencies of T-cells that secrete IFN-gamma after primary and secondary stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts.

Fetal tissue engineering

Improved prenatal diagnostic techniques have led to the use of intervention before birth to reverse potentially life-threatening processes. Several strategies may be pursued to facilitate the future prenatal management of urologic disease. Having a ready supply of urologic-associated tissue for surgical reconstruction at birth may be advantageous.

Theoretically, once the diagnosis of the pathologic condition is confirmed prenatally, a small tissue biopsy could be obtained under US guidance. These biopsy materials could then be processed and the various cell types expanded *in vitro*. Using tissue-engineering techniques, reconstituted structures *in vitro* could then be readily available at the time of birth for reconstruction [45].

Injectable therapies

Both urinary incontinence and vesicoureteral reflux (VUR) are common conditions affecting the genitourinary system that can be treated with injectable bulking agents. The ideal substance for endoscopic treatment of VUR and incontinence should be injectable, non-antigenic, non-migratory, volume stable, and safe for human use.

Animal studies have shown that chondrocytes can be easily harvested and combined with alginate *in vitro*; the suspension can be easily injected cystoscopically; and the elastic cartilage tissue formed is able to correct VUR without any evidence of obstruction [46]. The first human application of cell-based tissue-engineering technology for urologic applications occurred with the injection of chondrocytes for the correction of VUR in children and for urinary incontinence in adults [47,48] (Fig. 53.4).

Using cell therapy techniques, the use of autologous smooth muscle cells was explored for both urinary incontinence and VUR applications [49].

The potential use of injectable, cultured myoblasts for the treatment of stress urinary incontinence (SUI) has also been investigated. Use of injectable muscle precursor cells has also been studied for treatment of urinary incontinence due to irreversible urethral sphincter injury or maldevelopment [50]. A clinical trial involving the use of muscle derived stem cells (MDSC) to treat SUI has also been performed with good results. Biopsies of skeletal muscle were

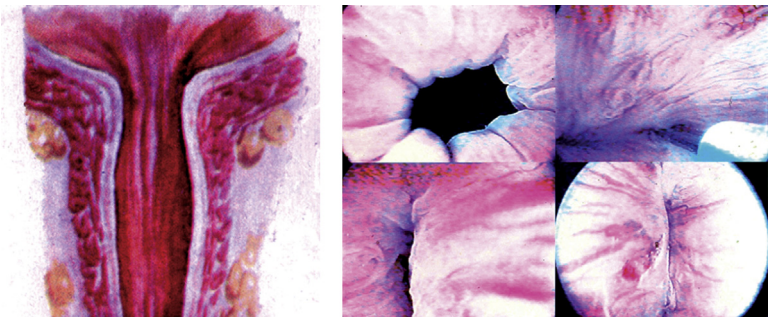

FIGURE 53.4
Tissue-engineered bulking agent. Chondrocytes are harvested and combined with alginate *in vitro*, and the suspension is injected cystoscopically as a bulking agent to treat urinary incontinence.

obtained, and autologous myoblasts and fibroblasts were cultured. Under US guidance, myoblasts were injected into the rhabdosphincter, and fibroblasts mixed with collagen were injected into the submucosa. One year following injection, the thickness and function of the rhabdosphincter had significantly increased, and all patients were continent [51]. These are the first demonstrations of the replacement of both sphincter muscle tissue and its innervation by the injection of muscle precursor cells.

In addition, injectable muscle-based gene therapy and tissue engineering were combined to improve detrusor function in a bladder injury model, and may have potential as a novel treatment option for urinary incontinence [52].

Testicular hormone replacement

Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment consists of periodic intramuscular injections of chemically modified testosterone or, more recently, skin patch applications. However, long-term non-pulsatile testosterone therapy is not optimal and can cause multiple problems, including erythropoiesis and bone density changes.

A system was designed wherein Leydig cells were microencapsulated for controlled testosterone replacement. Purified Leydig cells were isolated and encapsulated in an alginate-poly-L-lysine solution. The encapsulated Leydig cells were injected into castrated animals, and serum testosterone was measured serially; the animals were able to maintain testosterone levels in the long term [53]. These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone in situations where anorchia or testicular failure is present.

CONCLUSION

Tissue-engineering efforts are currently being undertaken for every type of tissue and organ within the urinary system. Most of the effort expended to engineer genitourinary tissues has occurred within the last decade. Tissue-engineering techniques require a cell culture facility designed for human application. Personnel who have mastered the techniques of cell harvest, culture, and expansion as well as polymer design are essential for the successful application of this technology. Before these engineering techniques can be applied to humans, further studies need to be performed in many of the tissues described. Recent progress suggests that engineered urologic tissues and cell therapy may have clinical applicability.

Dr. Atala is the W.H. Boyce Professor and Chair, Department of Urology, and Director, Wake Forest Institute for Regenerative Medicine, Wake Forest University School of Medicine, Winston-Salem, NC.

CHAPTER 54

Mesenchymal Stem Cells in Musculoskeletal Tissue Engineering

Peter G. Alexander, Heidi R. Hofer, Karen L. Clark and Rocky S. Tuan
Center for Cellular and Molecular Engineering, Department of Orthopaedic Surgery, School of Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania

INTRODUCTION

Nearly five decades ago, Friedenstein, et al. [1] described a population of non-hematopoietic cells isolated from human bone marrow with the *in vitro* ability to adhere, proliferate, and differentiate into chondrocytes, osteoblasts, and adipocytes. Such cells were identified in small amounts in multiple tissues throughout the body. Because of their differentiation properties and the ease of their isolation and *in vitro* expansion, these mesenchymal stem cells (MSCs) were naturally considered an attractive candidate progenitor cell type for tissue engineering and regenerative medicine applications. Extensive investigation has yielded knowledge about their biology, particularly tools for controlling their activity and cell fate that are critical to their clinical use. Beyond the three lineages originally identified, MSCs have been shown to differentiate into cells indicative of various mesenchymal lineages, including cellular phenotypes representative of the musculoskeletal tissues, such as cartilage, bone, muscle, ligament and tendon. A plethora of factors control the extensive proliferative and multipotent differentiation capacity of MSCs, including growth factors, cytokines, hormones, various soluble and insoluble signaling molecules, and transcription factors. Musculoskeletal tissues demand specific form and mechanical strength, and the success of a tissue-engineered outcome is thought to be dependent on the dynamic interactions between scaffolds, cells, and various physical and chemical environmental cues. By exploiting current knowledge of MSC differentiation, promising results have been generated towards engineered tissue replacements for cartilage, bone, osteochondral and other musculoskeletal tissues using MSCs. Further development and future clinical success, however, rely on significant knowledge-based improvements. The current understanding, recent advances, and remaining challenges for the deployment of MSCs for musculoskeletal tissue-engineering applications constitute the subject of this chapter.

MSC BIOLOGY RELEVANT TO MUSCULOSKELETAL TISSUE ENGINEERING

An ideal cell source for tissue engineering should exhibit the following characteristics: easy access and high availability of the source cells, capacity for extensive self-renewal or expansion

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00054-9

to generate sufficient quantity, the capacity to differentiate readily into cell lineages of interest upon instructive differentiation cues, and/or the ability to modulate the native environment to promote appropriate tissue repair and integration, including minimal immunogenic or tumorigenic ability. We will discuss below the intrinsic properties of MSC that determine their behavior, as well as external factors that affect the growth, differentiation, and the developmental outcomes of MSCs.

MSC identification

Since their initial description in the 1960s [1], MSCs have since been shown to possess the capacity to differentiate into cells characteristic of several mesenchyme-derived tissues, including cartilage, bone, fat, muscle, tendon, and hematopoietic-supporting marrow stroma (reviewed in [2–7]). In addition to these mesenchymal lineages, MSCs can also differentiate into other tissue types, including hepatocytes and neural tissues.

Experimentally, MSCs are identified first by their ability to adhere to plastic. Next, proliferative and differentiable MSCs are identified, at a minimum, by the expression of a combination of surface markers including STRO-1, SB-10, SH3 (CD73) and SH4 antigens as well as Thy-1 (CD90), TGF-β receptor type III endoglin (CD105), hyaluronic acid receptor CD44, integrin α1 subunit CD29, activated leukocyte-cell adhesion molecules (ALCAM, CD166), and possibly others [2,8]. MSCs are negative for the hematopoietic markers, CD19/CD79a, CD34, CD45, CD11b/CD14 and HLA-DR [2]. CD73, SH4 and STRO-1 antibodies recognize antigens that are present on MSCs and other cells but not hematopoietic cells (for review, see [9–11]). The presence of CD75, CD90, and CD105 and absence of hematopoietic markers, while not sufficient to fully identify an MSC, has been suggested by the International Society of Cell Therapy as the minimum positive criteria necessary to consider a potential cell an MSC [12]. It therefore remains a challenge to isolate MSCs specifically from a mixed cell population. Frequently, a combination of antibodies is used to retrospectively characterize the MSC phenotype. Inconsistency in the literature on the growth characteristics and differentiation potential of MSCs underscores the need for a clear functional definition of MSCs [13]; at present, the sole characteristic uniting disparate MSC sources is their ability to:

1) Proliferate: to self renew and remain in an undifferentiated state until provided the signal to differentiate, and
2) Differentiate along specific mesenchymal lineages when induced (Fig. 54.1).

Tissue sources of MSCs

While bone marrow remains the best studied tissue source for MSCs, MSC-like cells have been identified in a number of other tissues. The endogenous function(s) and exact location of these stem cells in the various tissues remain unclear; they are generally thought to participate in local tissue repair and regeneration. Bone marrow MSCs can give rise to stromal cells that support hematopoiesis *in vitro* and *in vivo*, possibly providing extracellular components as well as various growth factors and cytokines [14].

Although bone marrow is relatively easy to access, the potential donor site morbidity, pain, low cell incidence, and demands of cell therapy have prompted researchers to find alternative autologous sources for MSC isolation, which abound [9–11,15,16] (Table 54.1). MSC yield, proliferation rate, multipotency, differentiation potential, and the previously mentioned accessibility determine the usefulness of MSCs from different tissue origins. Although MSCs from different tissues show similar phenotypic characteristics, it is not clear if these are the same MSCs as they clearly show different propensities in proliferation and differentiation. For example, a study comparing human MSCs derived from bone marrow, umbilical cord blood, and adipose tissue showed that adipose tissue contained the highest number of MSCs while umbilical cord blood contained the lowest; however, umbilical cord blood-derived-MSC could be cultured longest and showed the highest proliferation capacity, whereas bone

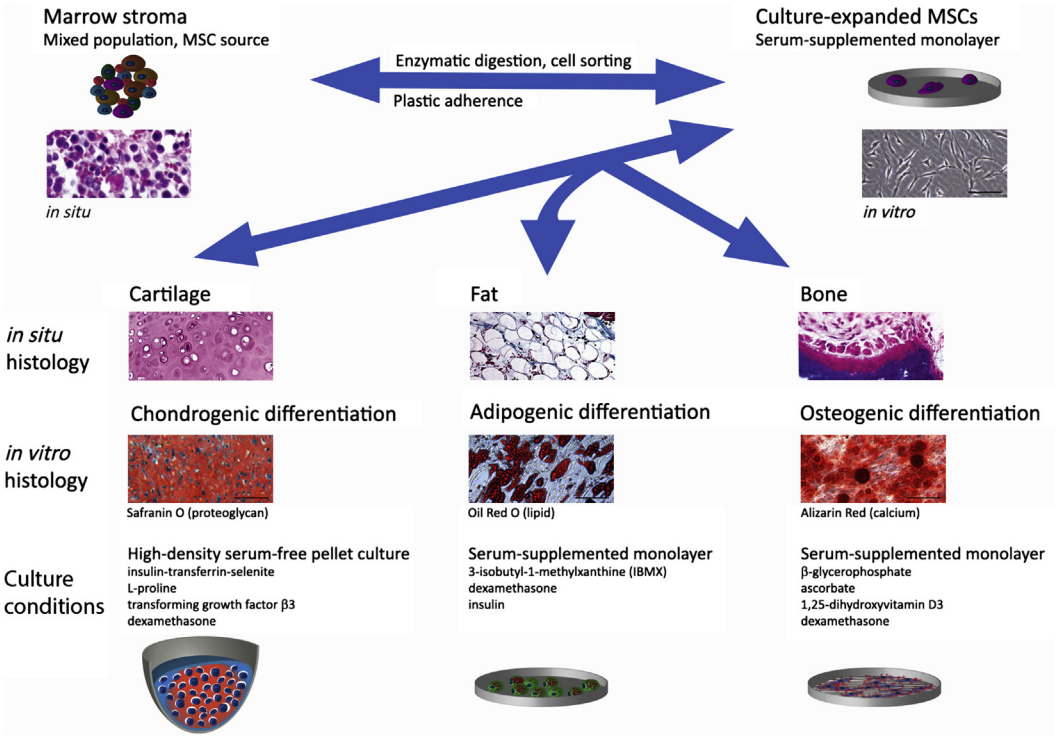

FIGURE 54.1

Minimum multilineage differentiation potential of mesenchymal stem cells. MSCs are able to differentiate into cell types of multiple lineages under appropriate conditions[a]; classically, these lineages include but are not limited to bone, cartilage, and fat. Bone marrow-derived MSCs, specifically, can repopulate the bone marrow stroma under certain conditions. Strong evidence exists that MSCs, once differentiated *in vitro*, can be dedifferentiated and subsequently used without harm to their multipotency. In addition to the standard lineages shown above, additional work suggests this transdifferentiation ability also applies to *in vitro* tenogenesis and musculogenesis[b]. *In situ* and *in vitro* histology is shown for phenotype comparison (scale bar = 100 μm). Adapted[c].

marrow derived-MSC showed the lowest proliferation capacity [17]. Sakaguchi et al. compared the properties of MSCs isolated from bone marrow, synovium, periosteum, skeletal muscle and adipose tissue, and found significant differences in their differentiation potentials [18]. MSCs from bone marrow, synovium, and periosteum showed greater chondrogenic activities, with synovium-derived MSCs exhibiting the highest capacity. Adipose-derived MSCs exhibit enhanced chondrogenesis if grown with excess FGF-2 then cultured for chondrogenesis with bone morphogenetic protein-6 (BMP6) [19,20]. With regard to osteogenesis, the rate of matrix mineralization was highest in bone marrow, synovium, and periosteum derived MSCs. Therefore, the optimal source of MSCs for therapeutic use for the musculoskeletal system remains to be determined.

In addition to tissue source, donor age and disease stage may directly affect MSC yield, rate of proliferation, and multipotency. Decreasing MSC number and proliferation rate as well as differentiation potentials were observed with increasing donor age [21]. MSCs isolated from osteoporotic women showed significantly reduced proliferative response and osteogenic differentiation [22]. With bone marrow MSCs, advanced osteoarthritis condition, regardless of age, had a significantly deleterious impact on proliferative capacity and chondrogenic and adipogenic activities when compared to healthy donors [23]. Decreases in MSC quantity and quality due to age and disease may limit the use of autologous MSCs in clinical settings,

warranting further study of allogeneic MSCs for tissue repair. In addition to disease transmission, these non-autologous tissues might carry the risk of immune rejection and allogeneic reaction by the host and will be discussed in detail later.

MSC isolation and *in vitro* culture

MSCs are rare in bone marrow, occurring with a frequency of 0.001–0.01 % of the total nucleated cells [5]. Various protocols of MSC isolation are available, and some are species specific. Human bone marrow MSCs can be isolated by simple direct plating after isolation from native tissue, sometimes involving enzymatic digestion. Frequently, this is performed with the layer of mononuclear cells obtained after Percoll or Ficoll density gradient centrifugation. With culture time and medium changes, non-adherent hematopoietic cells are washed away, and MSCs appear as small, adherent, spindle-shaped fibroblast-like cells. Surface marker-based positive selection or negative selection using either magnetic activated cell sorting (MACS) or fluorescence activated cell sorting (FACS) can further purify the MSC population. Positive selections have been based on the detection of markers that are expressed, albeit not exclusively, by MSCs; negative selection is based on the exclusion of markers that are expressed by hematopoietic cells, using antibodies against CD34, CD45 and CD11b, as mentioned above. Growth cocktails, designed to maintain the multipotent and proliferative capacities of MSCs vary widely, and typically involve culture in serum-supplemented Dulbecco's Modified Eagles Medium (DMEM) or α-Minimum Essential Medium (α-MEM) (Table 54.2).

After initial expansion, cultures are maintained at densities of 50–100,000 cells/cm^2 [4,24,25]. The extensive expansion capacity of MSCs depends on the harvesting techniques, culture conditions, and the health condition and age of the donor. Culture conditions, such as initial seeding density, play a role in the expansion capacity of MSCs. For example, higher proliferation profiles of MSCs was seen when plated at low initial plating density (1.5–3 cells/cm^2) but not at high density (12 cells/cm^2), resulting in a dramatic increase in the fold expansion of total cells (2,000-fold vs. 60-fold increase, respectively) [26].

MSC self-renewal and proliferation capacity

In vivo, MSCs remain in a mitotically quiescent state (G0 stage of the cell cycle) as demonstrated by analysis of fresh bone marrow cell harvests continuously exposed to tritiated thymidine labeling [27]. BrdU labeling of cells in a human trabecular bone explant culture also reveals that cell proliferation, including that of STRO-1 positive mesenchymal stem/progenitor cells, was inhibited completely within the explant tissue milieu [28]. Since most of the tissues/organs from which MSCs are derived exhibit a relatively slow turnover rate in the adult organism, it is not unreasonable to propose that self-renewal or proliferation of MSCs is normally suppressed *in vivo* in the course of tissue homeostasis, possibly regulated by intrinsic factors present in the tissue microenvironment and/or through direct or indirect interaction with neighboring cells.

In vitro cell cycle studies revealed that the majority of MSCs (between 78.7% and 96.45%) are in the G0/G1 phase of the cell cycle while a very small fraction of MSCs are engaged in active proliferation. During the exponential phase of cell growth, human MSCs isolated from bone marrow and fetal pancreas exhibited a similar population doubling time, ranging from 10 to 30 hours [29].

Unlike embryonic stem cells, MSCs do not expand indefinitely *in vitro* when cultured in the presence of serum, which could reflect on their intrinsic properties as adult stem cells or a suboptimal culture environment. After extensive propagation, MSCs change their phenotype from a fibroblastic shape to a more flattened morphology with extensive podia and actin stress fiber formation, a phenomenon usually referred to as 'replicative senescence'. Consistent with their limited expansion capacity, human MSCs do not express telomerase activity, and their telomere length is reduced as the cells grow older [30]. Furthermore, murine MSCs derived from telomerase knockout mice failed to differentiate into adipocytes and chondrocytes and lost telomere at late passage [31]. Therefore, telomerase activity and telomere maintenance appear to play a crucial role in maintaining the self-renewal and multidifferentiation potential of MSCs. Indeed, hMSCs stably expressing telomerase reverse transcriptase can undergo 80 [32,33] or 260 [34] population doublings without growth arrest.

In addition, growth factors also play a role in the expansion capacity of MSCs. Basic fibroblast growth factor (bFGF) can prolong the replicative capacity of hMSCs and increase total cell numbers by several fold when included in the basal culture medium [35]. Other growth factors and cytokines, including canonical Wnts, e.g., Wnt 3A [36], and interleukin-6 (IL-6) [37], have also been found to enhance the proliferative activity of adult human MSCs. Growth factor pre-treatment may also help define the differentiation potential of the cultured MSCs [38]. Detailed study of MSC biology and proliferation, as well as variations due to culture conditions, may further extend the number and potential efficacy of MSCs.

Skeletogenic differentiation of MSCs

MSC differentiation can be controlled by several factors including growth factors, hormones, and extracellular matrix molecules working through various signaling pathways. Relevant to musculoskeletal tissue engineering, *in vitro* chondrogenesis of MSCs, or cartilage formation, is accomplished by culturing the cells in a three-dimensional culture condition, either as pellet culture, micromass cultures, or three-dimensional scaffold, in the presence of a member of the transforming growth factor family (TGF-β1, TGF-β2, or TGF-β3, or bone morphogenetic proteins, BMPs) [35]. Supplementation with dexamethasone also promotes the expression of chondrocyte phenotype. Chondrogenesis is demonstrated histologically as well as on the basis of the expression of genes encoding cartilage matrix components, including aggrecan, collagen types II and IX, and COMP (cartilage oligomeric matrix protein) [39]. Control of MSC chondrogenesis will be discussed in more detail in the cartilage tissue engineering section of this chapter.

Osteogenesis, i.e., bone formation, can be induced *in vitro* by treating MSCs with the synthetic glucocorticoid dexamethasone, β-glycerophosphate, ascorbic acid, and 1,25-dihydroxyvitamin D_3. Alkaline phosphatase (ALP) activity and calcification of the extracellular matrix are typical markers used for detecting preosteoblasts and mature osteoblasts, respectively. Dexamethasone stimulates MSC proliferation and increases ALP activity of osteogenic hMSCs. Matrix mineralization only occurs in the presence of β-glycerophosphate, ascorbate, and dexamethasone, and is further enhanced by 1,25-dihydroxyvitamin D_3[40]. Although used less uniformly, a number of growth factors also contribute to osteoinduction. For instance, treatment of human MSCs with insulin-like growth factor 1 (IGF-1), epidermal growth factors (EGF), and vascular endothelial growth factor (VEGF) increases the activity of ALP and mineralization *in vitro*. On the other hand, platelet-derived growth factor (PDGF) has little inductive effect on hMSC osteogenesis [41].

Also relevant to tissue-engineering applications, osteogenesis can be stimulated *in vitro* by various physical stimulants, including mechanical stimulation, pulsed electromagnetic field (PEMF), and hydrostatic pressure [42–44]. Such models, in addition to offering insight into bone-forming processes, can also be used to analyze various injury mechanisms and to develop potential therapies.

Plasticity of MSCs

Plasticity/transdifferentiation refers to the ability of a cell type committed to and progressing along a specific developmental lineage to switch into another cell type of a different lineage through epigenetic reprogramming. As demonstrated by several studies, terminally differentiated cells can switch their phenotype under appropriate stimulations. For example, chondrocytes can become osteocytes [45,46], and adipocytes can convert to osteoblasts [47–49]. Since all of these cells are the mature progenies of MSCs, the conversion between each other might reflect the plastic property of MSCs. By using an *in vitro* differentiation strategy, we have demonstrated that human MSCs pre-committed to a given mesenchyme cell lineage can transdifferentiate into other cell types in response to inductive extracellular cues [50]. Understanding the molecular mechanisms that control the transdifferentiation potential of MSCs will facilitate the identification of regulatory factors, thus providing tools to manipulate adult stem cells for cell-based tissue-engineering applications. Recent evidence suggest that mesenchymal cell populations contain a subpopulation of multilineage stress enduring (MUSE) cells that possess pluripotency and may account for some of the plasticity observed [51].

MSC heterogeneity

Individual colonies derived from single MSC precursors exhibit a heterogeneous nature in terms of cell proliferation and multilineage differentiation potential. For instance, only a minor proportion of colonies (17%) derived from adult human bone marrow continued to grow beyond 20 population doublings, while the majority of the colonies exhibited early senescence [52]. There is also a marked difference in the differentiation capacity of MSC colonies. For example, Pittenger et al. [5] reported that only one-third of the initial adherent bone-marrow-derived MSC clones are multipotent to differentiate along the chondro-, osteo- and adipo-genic pathways (osteo/chondro/adipo). Furthermore, non-immortalized cell clones examined by Muraglia et al. [53] demonstrated that 30% of the *in vitro*-derived MSC clones exhibited a tri-lineage (osteo/chondro/adipo) differentiation potential, while the remainder displayed a bi-lineage (osteo/chondro) or uni-lineage potential (osteo). These observations are consistent with other *in vitro* studies using conditionally immortalized clones. Even derived from a single colony, cells seem to be heterogeneous. Kuznetsov et al. demonstrated that only 58.8% of the single colony-derived clones had the ability to form bone within hydroxyapaptite-tricalcium phosphate ceramic scaffolds after implantation in

immunodeficient mice [54]. Similar results were reported by using purer populations of MSCs maintained *in vitro* [52] as well as human trabecular bone derived MSCs [55]. Taken together, these results suggest that MSCs are heterogeneous with respect to their developmental potential, and place a significant challenge on selecting the most potent cells for clinical application in tissue regeneration.

There exist a number of inconsistencies and discrepancies among currently published results on MSCs, perhaps reflecting the heterogeneity of the population, different isolation and culture methods, as well as the different stimuli used for the differentiation procedures [13]. There has not been a single MSC specific marker to unequivocally identify MSCs, and there is heterogeneity in MSC populations. Most likely distinct and unrelated cells types are being studied, and only a subpopulation of the MSCs are true stem cells.

MSC effect on host immunobiology

Ideally, autologous MSCs would have advantages over allogeneic MSCs for regenerative medicine as autologous MSCs pose few immunological complications. Due to the low abundance of MSCs and the possible decrease in quantity as well as quality of the MSCs with age and disease, it is more feasible to consider using allogeneic MSCs for replacing or repairing damaged tissues. Before this is considered acceptable, it is important to understand how MSC elicit host immunological reactions. Allogeneic cells are normally detected and deleted by the host immune systems. However, MSCs have been surprisingly different in this aspect and offer several advantages, including possible immuno-modulatory, including immunosuppressive, effects on the host response.

The first immunological advantage of MSCs is that they are hypo-immunogenic and can evade host immune system, as shown by several *in vitro* experiments [56]. This makes MSCs attractive for allogeneic transplantation whose major limitation is host immune rejection. MSCs express low (fetal) to intermediate (adult) major histocompatibility complex (MHC) class I molecules and do not express MHC class II molecules on their cell surface [57,58]. The expression of MHC class I molecules helps to protect MSCs from deletion by natural killer cells. The lack of surface MHC class II expression gives the MSCs the potential to escape recognition by alloreactive CD4+ T cells. MSCs contain an intracellular pool of MHC class II molecules that can be mobilized onto cell surface by treatment with interferon-γ (IFN-γ). However, induced surface expression of MHC class II still does not render the MSCs immunogenic [58]. After differentiation, MSCs continue to express MHC class I but not class II molecules on their cell surface, and continue to be non-immunogenic [57,58].

Experimental evidence suggests that MSCs can interact directly with immune cells and modulate and suppress alloreactivity. MSCs inhibit T cell proliferation *in vitro* [59–61]. MSCs do not seem to express co-stimulatory molecules, CD40, CD40 ligand, CD80, and CD86 (formerly B7–1 and B7–2, respectively) and probably do not activate alloreactive T cells [61]. In fact, MSCs suppress T cell activation and proliferation. For example, MSCs have been shown to suppress CD4+ and CD8+ T cells in mixed lymphocyte cultures [59,61]. Even though T cell proliferation can be induced by exogenous co-stimulation, when they are co-cultured with MSCs in the presence of a stimulant, T cell proliferation is not observed [61]. MSCs can also induce apoptosis of activated T cells but not resting T cells [62]. Supporting these observations, Bartholomew [60] showed that allogeneic baboon MSCs inhibited the proliferation of lymphocytes *in vitro*, and prolonged skin graft survival *in vivo*. In addition to the effect of MSCs on T cells, MSCs can affect dendritic cell differentiation and maturation and interfere with their function [63,64]. They also alter the phenotype of natural killer cells, and can suppress the proliferation, cytokine secretion and cytotoxicity of these cells against MHC class I targets [65].

In addition to cell-cell interaction mediated inhibition, MSCs are capable of secreting soluble factors to create a local immunosuppressive environment. These factors have been shown to

include hepatocyte growth factor (HGF), TGF-β1, IL-10 and prostaglandin E2 [59,66]. When anti-HGF antibody and anti-TGF-β1 are included, MSC inhibition on T cell proliferation is lifted [59]. IL-10 is a cytokine for regulatory T cells and can suppress inflammatory immune response. Similarly, MSCs are shown to produce IL-10 either constitutively, or in co-culture, and MSCs can mediate the suppressive activities partially through secretion of IL-10 [64,66,67]. Collectively, this *in vitro* evidence has suggested that MSCs can interact with the various subsets of cells of the immune system, alter the response of the immune cells, and shift the response from a pro-inflammatory response to an anti-inflammatory response, possibly through inhibition of the pro-inflammatory cytokines such as IFN-γ and tumor necrosis factor-α (TNF-α) and stimulation of the immunosuppressive cytokines including IL-10 and prostaglandin E2 [66].

The role of secreted factors in the immuno-regulatory action of MSCs remains an actively investigated area [68,69]. Contradictory results exist as to which factors are important for this function. For example, although a role for IL-10, TGF-β, and prostaglandin E2 has been suggested, in other studies, none of these factors was found to be responsible for the immuno-suppressive action of MSCs [61]. Despite the discrepancies on the mechanism of action, the above studies suggest that MSCs can be transplanted between MHC incompatible individuals.

The *in vitro* studies showing that MSCs possess immuno-modulatory and immuno-suppressive activities suggest that MSCs can be potentially used *in vivo* for enhancing the engraftment of other tissues (e.g., hematopoietic stem cells), or for the prophylactic prevention and even possibly as a treatment of graft-versus-host-disease, to prevent rejection, and promote transplant and patient survival. Indeed, a search of clinicatrials.gov (October 29, 2012) returned 66 studies using the terms 'mesenchymal stem cell' and 'immune' [70]. However, before MSC treatment can be used as standard therapy on humans, more *in vivo* animal studies need to be performed, and the biology and mechanism of MSC immunomodulation effect need to be better elucidated.

Safety of using MSCs for transplantation

The ability of MSCs to undergo extensive self-renewal via proliferation raises some concern as to whether MSCs, after prolonged *in vitro* culture, can become tumorigenic. Although most MSC transplantations did not show obvious malignant transformation, there has been evidence suggesting otherwise. Rubio et al. [71] showed that although standard short-term *in vitro* culture (6–8 weeks) seems to be safe, MSCs can undergo spontaneous transformation after long-term culture of 4–5 months.

The immunosuppressive properties, especially the potential systemic immuno-suppressive ability of MSCs, bring caution to the use of MSCs under certain clinical conditions, such as cancer. Using a murine melanoma tumor model, it has been shown that co-transplantation of an MSC cell line (C3H10T1/2) favor tumor growth of subcutaneously injected B16 melanoma cells [72]. However this tumor promoting effect was not observed in another study of co-culture of a rat MSC line, MPC1cE, with rat colon carcinoma cells in a gelatin matrix. In this case, inhibitory effect of MSCs on the outgrowth of the tumor cells was observed [73]. The effect of MSCs on tumor growth requires further investigation to rule out the potential side effect of therapeutic use of MSCs [74].

MSCs IN MUSCULOSKELETAL TISSUE ENGINEERING

The musculoskeletal system of the human body is designed to sustain and maintain its form and function in the face of enormous load bearing demands throughout a normally active life. Form and mechanical strength are vital for the function of this system. The mechanical and biochemical properties of musculoskeletal system that define its structure and function also define the functional requirements of a tissue-engineered substitute. Successful tissue

engineering-based replacement of native tissues will likely require constructs that possess functional properties similar to those of the native tissues to minimize premature failure. There are two basic approaches in tissue engineering. The first one is *ex vivo* tissue engineering, in which the construct is cultivated *in vitro* to achieve appropriate functionality before implantation. The second approach is *in vivo* tissue engineering, in which the construct is allowed to mature *in vivo* for tissue repair and regeneration. For both approaches, three components govern the eventual outcome of tissue-engineered constructs: appropriate scaffold, instructive environment, and responsive cells.

Cartilage tissue engineering

The need for engineered cartilage arises from the fact that while the tissue often functions well through a lifetime of use, over 30% of adults in the US over 30 years of age have radiographic evidence of cartilage degeneration, with 9–10% of the US population aged 30 suffering symptoms of osteoarthritis of the hip or knee [75,76]. The total cost of osteoarthritis is estimated at $36 billion dollars per year in the USA alone [77], with >200,000 knee replacements performed each year. The intrinsic healing capacity of the native tissue is limited, and given the increasing incidence of osteoarthritis and increasing life expectancy of the population, there is a growing demand for novel repair strategies. Effective treatment of cartilage injuries may eliminate or forestall the need for joint replacement, thus enhancing the quality of life.

GENERAL PROPERTIES OF ARTICULAR CARTILAGE

Articular cartilage is the dense white tissue that lines the surfaces of joints and functions to transmit the high stresses associated with joint motion. The tissue consists of both a solid extracellular matrix (ECM) component as well as a fluid phase [78,79]. The solid ECM is composed of a dense network of specialized molecules that engender the unique mechanical properties of the tissue. Collagen content (predominantly collagen type II) of the tissue ranges from 5–30% by wet weight while proteoglycan content ranges from 2–10%. In addition to these major elements, the ECM also includes numerous minor collagens (e.g., types VI, IX, and XI), and linking molecules (COMP, hyaluronan, link protein, fibronectin). The highly charged ECM, and the proteoglycans in particular, trap a large amount of water within the cartilage matrix, which comprises the fluid component of cartilage matrix. Together, these elements make up the fluid-filled fibrous network with larger collagen fibers interwoven throughout an array of large proteoglycan aggregates (aggrecan core protein with its covalently linked keratin and chondroitin sulfate moieties) attached to long hyaluronan chains.

The exact composition of cartilage changes slightly but sequentially as one progresses from the surface zone to the calcified zone that interacts with the subchondral bone. The surface zone, that is well adapted to tensile forces, comprises relatively little matrix with finer fibrillar structure rich in the proteoglycan lubricin arranged parallel to the articular surface as revealed by polarized microscopy and the squamal morphology of the cells in this region. The deep zone, well adapted to compressive forces, comprise larger collagen fibrils with greater cross-linking arranged perpendicular to the articular surface. These core constituents change with age, resulting in the emergence of adult functional properties, and deteriorate with disease processes, such as osteoarthritis [80–82].

The cellular component of cartilage, the chondrocytes, comprises less than 10% of the tissue volume [83]. The sparse distribution of chondrocytes belies their critical importance in maintaining the balance between anabolic synthesis of ECM constituents and continual remodeling and degradation over time [84]. Chondrocytes display a rich transcriptional profile *in situ* [85], reflective of their specialized cartilaginous phenotype, which is lost when these cells de-differentiate with expansion in monolayer culture [86]. This process may be substantially reversed, with chondrocytes re-differentiating towards their mature phenotype when returned to three-dimensional culture [87]. However, the exposure to two-dimensional

expansion in culture leads to certain 'irreversible' phenotypic changes [88,89], such as the expression of collagen type I that leads to fibrosis, reducing the mechanical properties of the matrix comprising repair tissue or engineered cartilage, and harkening matrix and tissue degeneration.

The mechanical properties of articular cartilage are complex and underlie its ability to act as a low friction, weight-bearing surface over a lifetime of use. These properties are a result of both the solid (matrix) and fluid phases of the tissue. Regarding the solid, matrix phase, the dense, negatively charged, proteoglycan-rich ECM results in an equilibrium compression modulus of 0.2–1.4 MPa [90,91]. Meanwhile, the collagen content engenders a tensile modulus that is higher, ranging from 1–30 MPa [92,93]. Other structural elements of cartilage, including collagen type IX [94] and COMP [95], participate in the crosslinking of the collagen type II ECM, increasing matrix connectivity.

The highly charged ECM, and the proteoglycans in particular, trap a large amount of water within the cartilage matrix [96]. These electrostatic forces and the physiological cyclic loading (0.1–2 Hz) of the tissue maintain elevated interstitial fluid pressure. Fluid pressurization increases with contact and supports >90% of applied stress, shielding the matrix from excess deformation [97]. This fluid pressurization also results in a higher dynamic modulus than equilibrium modulus, stiffening the tissue with higher frequency and/or higher rate of loading. Finally, this fluid pressurization, coupled with molecules that participate in boundary lubrication, maintains the frictional coefficient of cartilage at extremely low values (lower than ice on ice), further protecting the tissue from excess wear with physiologic use [98,99].

CELLS FOR CARTILAGE TISSUE ENGINEERING

In the quest to repair or replace damaged articular cartilage, any replacement material, tissue or their composite must be fabricated to retain the complex mechanical properties described above. The development of such a material begins with the consideration and combination of appropriate and responsive cells, biocompatible and mechanically conductive scaffolds, and inductive environment for the optimal differentiation and proliferation of the cell type of interest. As discussed in this and other chapters, MSCs derived from various adult tissues have emerged as promising cell sources because of the ease with which they can be isolated and expanded and their multilineage differentiation capabilities.

When tissue engineering was originally proposed as a strategy for repairing diseased or damaged tissues [100], it was believed that articular cartilage would be one of the first successes in this new field, owing to its relatively simple composition (possessing a single cell type) and lack of neural and vascular supply. First approaches focused on the chondrocyte itself, postulating that as these cells make and maintain matrix *in vivo*, exogenous cells should be able to reconstitute the tissue when implanted. Indeed, early reports on high density chondrocyte monolayer culture demonstrated the development of high tensile moduli in thick cell sheets [101]. Early *in vivo* successes demonstrated enhanced repair when high density chondrocyte solutions were transplanted to focal defects beneath a periosteal flap [102], a procedure now commonly referred to as autologous chondrocyte implantation (ACI), and commercialized as the Carticel® method by Genzyme Biosurgery. While questions remain regarding the efficacy and cost-effectiveness of this approach [103], it nevertheless stands as the first clinically available tissue-engineering strategy to enhance cartilage repair. New embodiments of this cell-based approach have incorporated scaffold matrix for better cell retention (matrix-assisted ACI or MACI)[103a].

Although significant progress has been made in the production of engineered cartilage constructs with chondrocytes, several significant impediments exist that limit their clinical application. First, chondrocytes are present in limited supply, and are often of an aged and/or diseased state in patients presenting with osteoarthritis. While most tissue-engineering studies

in the literature report on newborn or juvenile derived chondrocytes, a recent study has shown that aged chondrocytes are less able to form functional constructs in agarose culture [104]. Finally, chondrocytes must be isolated from the joint tissue itself, a process that may further complicate an already damaged joint [105]. One opportunity for overcoming such concerns is the use of chondroprogenitor cells, such as adult MSCs. As described above, these cells are readily obtained from the adult bone marrow and other tissues, and retain a multilineage potential. These cells are expandable in culture [106], and may be grown in sufficient numbers to populate engineered scaffolds.

The use of MSCs for cartilage regeneration and tissue engineering has shown enormous potential and initial success. Of note, one current surgical strategy for enhancing the repair of cartilage defects is via microfracturing of the subchondral bone. This technique provides entrance for marrow elements, including MSCs, to the wound site, and has been shown to generate an enhanced, albeit fibrous, repair response [107]. MSCs have also been used as cellular therapeutics directly, via injection into the joint space (with and without a carrier matrix) in an undifferentiated state [108–110] and after differentiation down a cartilage lineage *in vitro* [111,112]. These cells may be further transduced to express morphogenetic proteins that drive their own chondrogenesis after implantation [113].

MSC CHONDROGENESIS

MSC chondrogenic potential

Control of chondrogenesis in MSCs is a complex and developing research area, with much of our understanding of the relevant molecules and processes stemming from a continuing elucidation of the events that control healthy cartilage homeostasis as well as cartilage formation in the developing limb. Elements including soluble factors such as growth factors, cytokines, hormones, various intracellular signaling pathways and transcription factors, environmental factors such as mechanical loading and oxygen levels, and seeding density all affect chondrogenic differentiation of MSCs.

The standard *in vitro* system of MSC chondrogenesis involves a three-dimensional culture of MSCs under the stimulation of a suitable chondrogenic stimulus. High density cultures of pellet or micromass are frequently employed, modeling early chondrogenesis in development where condensation of the early progenitor cells initiates the cascade of events leading to cartilage formation [114]. These MSCs can then effectively differentiate under standard chondrogenic conditions (serum-free medium supplemented with insulin-transferrin-selenite (ITS), ascorbate, proline, dexamethasone, and TGFα3). In addition, MSCs may also be seeded on various three-dimensional scaffolds to induce chondrogenesis. While the maintenance of a spherical shape in these scaffolds may be enough to induce a chondrogenic phenotype by MSCs, a chondroinductive growth medium is still required to realize the maximum chondrogenic potential of these cells. The hallmarks of an articular chondrocyte are initially high levels of Sox9 expression followed by ultimately high levels of collagen types II, IX, and XI and concomitant expression of aggrecan, COMP and link protein, among others. Together these extracellular components produce a highly crosslinked and hydrated matrix surrounding the cells and their pericellular and intercellular matrix. This phenotype represents the prehypertrophic state of cartilage in the parlance of developmental biology describing the growth plate, the cartilage anlage of the endochondral skeleton [114].

MSCs that have undergone chondrogenic differentiation assume a chondrocyte-like phenotype characterized by increases in proteoglycan deposition and expression of aggrecan, COMP, and collagen type II [115] as described above, and microarray analysis has shown that numerous other cartilage extracellular matrix elements increase in their expression as well [50,116,117]. A major challenge to articular cartilage engineering is to prevent the apparently natural progression of the cells down the path of chondrocyte hypertrophy, matrix

mineralization and apoptosis that promotes the ossification of the tissue to mature bone. In this latter process, cells express Runx2, collagen types I and X, and matrix degradative enzymes such as matrix metalloproteases (e.g., MMP13). These markers are also characteristic of osteoarthritic cells that can rapidly cause matrix degradation, scaffold and construct failure [118].

Signaling in MSC chondrogenesis

Growth factors that have regulatory effects on MSCs include members of the TGFβ superfamily, the IGFs, the fibroblast growth factors (FGF), and the PDGFs. Among these growth factors, members of the TGFβ family, including TGFβ1, TGFβ2, and TGFβ3, as well as BMPs are the most potent inducers to promote chondrogenesis of MSCs. For human MSCs, TGFβ2 and TGFβ3 were shown to be more active than TGFβ1 in promoting chondrogenesis [115]. BMPs, known for their involvement in cartilage formation, act alone or in concert with other growth factors to induce or enhance MSC chondrogenic differentiation. For example, BMP2, BMP4, or BMP6, combined with TGFβ3, induced the chondrogenic phenotype in cultured human bone-marrow-derived MSC pellets, with BMP2 seemingly the most effective [119]. Other growth factors, such as IGF, FGF, and PDGF, are important signaling molecules that mediate chondrocyte physiology rather than promoting chondrogenesis of MSCs, and therefore commonly work with TGFβs to promote chondrogenesis and enhance chondrocytic activities of differentiated MSCs. The pro-mitotic activity of the FGFs has also been exploited for cell expansion purposes [120]. Interestingly, FGF2-supplemented human MSCs proliferated more rapidly, and exhibited greater chondrogenic potential than untreated controls [121]. Canonical Wnt signaling has been shown to enhance MSC differentiation [122] and Wnt signaling in chondrogenesis has been shown to crosstalk with TGFβ signaling [123–125]. The current challenge in finding the most efficient growth factor(s) for MSC chondrogenesis is that the regulatory effects of signal molecules are dependent on property, dose, and timing of the molecules administered to the cells. This may explain some of the contradictory results regarding the effects of specific growth factors on chondrogenesis. Furthermore, the exact mechanisms of articular cartilage development *in vivo* remain unknown; however, we may surmise that it occurs in a very complex biochemical environment, and that some level of this complexity must be replicated *in vitro* in order to produce functional articular cartilage. Replication of this complexity begins in part with the application of growth factor cocktails, applied combinatorially or sequentially, and as the effects of growth factors are changed in the presence of other growth factors and environmental cues, the repetoire of pro-chondrogenic formulations are likely to become more confused before the field achieves clarification.

Growth factors act on cells and induce various intracellular signaling pathways to coordinate transcription factors and change cellular phenotype. The most important molecule intrinsic to the assumption of the cartilaginous phenotype is the transcription factor, Sox9. The role of Sox9 in cartilage formation was first observed in condensations in the developing mouse limb, and its presence is thought to be required for cartilage formation [126]. The expression of Sox9 is considered a master regulatory step of chondrogenesis defining the commitment of a cell such as the MSC down the chondrogenic lineage. The action of Sox9 is enhanced by the related molecules, sox5 and sox6 [127], with recent evidence suggesting that the exogenous introduction of the combination of the three is sufficient to induce chondrogenesis in a variety of cell types [128]. In human bone-marrow-derived MSCs, exogenous expression of Sox9 led to increased proteoglycan deposition and expression of link protein [129,130]. It has been shown that addition of BMP-2 resulted in dose-dependent increase in Sox9 expression in C3H10T1/2 cells, a mesenchymal progenitor cell line [131].

In addition to growth factors, several 'physical' environmental factors influence MSC chondrogenesis. These include, oxygen tension, mechanical loading and hydrostatic pressure. Articular cartilage is an avascular tissue, therefore nutrients and metabolites are provided via

diffusion from the synovial fluid and the subchondral bone and aided by the movement and resulting fluid flow in the joint. Oxygen tension in the deep zones of articular cartilage has been reported to be between 1−2% with an increasing oxygen gradient towards the articular surface [132,133]. Hypoxia is a positive regulator of the chorocytic phenotype and MSC chondrogenic differentiation. [134−136]. Regular, cyclic loading of cartilage is vital to its homeostasis *in vivo*, and cyclic loading has been shown to be chondroinductive *in vitro* [137−139] and even prevent the induction of hypertrophic markers *in vitro* [140]. Hydrostatic pressure itself, a component of the increased interstitial pressure experienced by cartilage under load, is chondro-stimulatory [141], although not in isolation, and its effects are quite variable between individuals [142]. These examples illustrate the value in understanding normal cartilage homeostasis in order to engineer better articular cartilage.

SCAFFOLDS FOR CARTILAGE TISSUE ENGINEERING

The three-dimensional substrate upon which the cells are grown can have profound effects upon MSC differentiation. Considerations include the materials composition, its structure and topography, and its biodegradability. In general, scaffolds may be made of natural or synthetic biomaterials and may be in the form of hydrogels, sponges, fibrous meshes and nanofibers. Only some of the many available scaffolds are appropriate for cartilage tissue engineering. Among artificial materials, poly-glycolic acid (PGA), poly-L-lactic acid (PLA), poly-ε-caprolactone (PCL) polyethylene oxide (PEO) and polyethylene glycol (PEG) among others have shown potential in cartilage tissue engineering (Fig. 54.2) [143−149]. These polymers may be employed as either sponges formed through phase separation and salt leaching or as micro- or nanofibers formed by electro-spinning. The small diameters of nanofibers closely match the geometry of collagen fibrils comprising a natural cartilage matrix, making these structures a potentially useful biomimetic scaffold [150]. The high porosity, high surface-to-volume ratio and their unique mechanical properties account for the popularity of these structures in cartilage engineering as well. In recent studies, natural materials such as chitin [151], collagens [152], hyaluronan [153], among others, have been processed into nanofibrous scaffolds. These biomaterials have the added value of providing natural epitopes for cell attachment as well as sites for covalent attachment of signaling molecules. Co-spinning different materials together can be useful in creating complex surface topographies, greater porosity, increasing biological activities, and adjusting mechanical properties of the resulting scaffold [154]. Finally, fibers may be spun directionally to yield the proper matrix alignment as

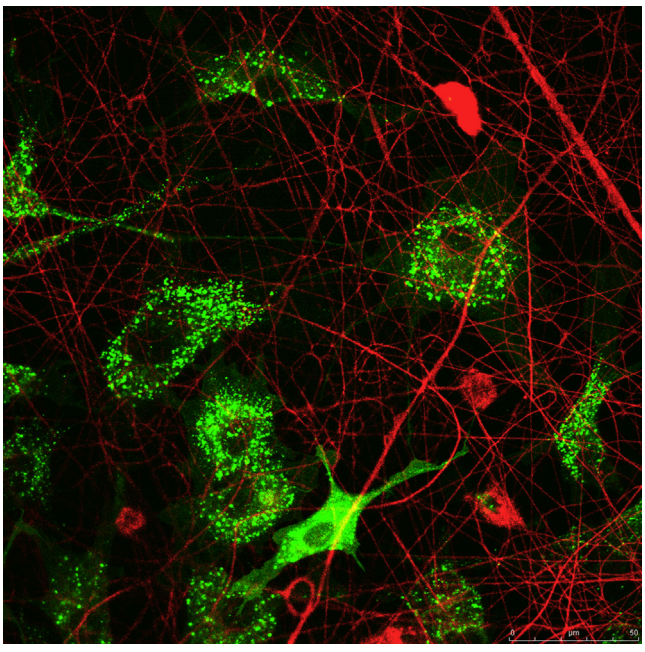

FIGURE 54.2
Confocal laser scanning fluorescence microscopy of adult human mesenchymal stem cells (MSCs; green) seeded on to an electrospun nanofibrous scaffold (red). MSCs appear to be well integrated within the nanofibrous matrix, interacting with individual fibers via cellular processes, as well as filling the 'pores' within the scaffold. Scale bar = 50 μm.

well as potentially transmit or absorb mechanical forces necessary to the protection and function of the tissue.

In addition to fibrous scaffolds, various biocompatible hydrogels have also been applied for the *in vitro* and *in vivo* growth of cartilage constructs. Hydrogels are three-dimensional, hydrophilic, polymeric networks capable of retaining large amounts of water or biological fluids and commonly used to mimic the chondrogenic environment. Frequently used hydrogels include synthetic materials such as PEG, self-assembling peptides, and natural materials including agarose [79,155,156], alginates [157–159], the cartilage matrix components collagen type I [160–162], collagen type II [163], hyaluronan-based gels [164,165], and fibrin gels [166,167]. The exploration of each of these scaffolds has contributed to our understanding of MSC chondrogenesis for tissue engineering.

Agarose gels have been employed extensively in cartilage tissue engineering and are unique in that they offer cells no epitopes for adhesion. The agarose maintains the cell in a spherical shape, which alone has been shown to maintain and even promote chondrogenesis. The otherwise inert agarose has been useful in elucidating the effects of mechanical loading, TGFβ exposure, and differences between chondrocytes and MSCs.

Synthetic PEG hydrogels, although relatively inert, have been shown to support cartilage tissue formation by both chondrocytes and MSCs [168,169]. Unlike many other synthetic polymers, PEG may be modified to include Arginine-Glycine-Aspartyl (RGD) and other bioactive peptides [170,171] to enhance viability [172] and chondrogenic differentiation of encapsulated cells [173], and to control the mechanical [174] and degradation [175] properties of the hydrogel itself. These features have made it a staple of tissue engineering. The inclusion of cartilage matrix molecules or peptide derivatives greatly enhances the PEG scaffold support of chondrogenesis and may be tuned to create multilayered constructs [176–178]. The addition of hyaluronan is particularly potent in inducing MSC chondrogenesis [179]. Not only is hyaluronan a natural component of cartilage, but it is also functionally involved in biological processes, including proliferation, morphogenesis, inflammation, and wound healing. Hyaluronan hydrogels also support chondrogenic differentiation of MSCs, making it a promising scaffold for cartilage regeneration [180].

FACTORS INFLUENCING OUTCOMES OF TISSUE-ENGINEERED CARTILAGE

Since the quality of the extracellular matrix and the mechanical properties of engineered constructs generally fall short of the characteristics of native cartilage, many studies have focused upon the combination of chondrogenic stimuli. The evolution of a tissue-engineered construct is a time-dependent process, controlled by numerous (and sometimes unanticipated) factors. These factors include an evolving cell phenotype, changing biochemical and biophysical environments, and continuous remodeling of the matrix from the engineered scaffold to native extracellular matrix. Two philosophies govern the engineering of each component. On the one hand, tissue engineers may strive to build and control each component throughout development of the construct. On the other hand, components and processes may be permitted to proceed as naturally as possible *in situ*. In both cases, a perfect scenario involves the development of all construct components in unison to ultimately form a functional tissue. The fact that no tissue-engineered construct based upon MSCs has successfully repaired articular surfaces over the long term shows that such a coordinated development is not occurring; it demands that we seek to understand each process better, particularly as they relate to each other.

In recent years, there has been a rapid growth in the number of studies analyzing the synergistic effects of various chondrogenic stimulants

1) Different growth factor combinations,
2) Scaffolds comprised of complex materials with different mechanical, biological and biodegradation properties,

3) The addition of mechanical stimulation and or hypoxia to the differentiation equation, and
4) The inclusion of various biological matrices including devitalized tissue matrices and blood fractions including platelet-rich plasma.

While clearly all components of the tissue-engineered construct are under continuous study and improvement, but the scaffold in particular is undergoing rapid evolution. Investigators have focused on how to recapitulate the multiple roles of native extracellular matrix including its roles in structural integrity, mechanotransduction, and repository and co-receptor for various signaling molecules. Towards this end, scaffolds have been decorated with peptide sequences derived from the bioactive motifs of collagen, fibronectin and laminin (among others) through adsorption or covalent bonding. These peptides have also been modified to include substrate sequences for specific proteolytic enzymes to allow targeted release, a property which is particularly useful when non-degradable scaffolds, such as agarose, are used.

Most bioresorbable scaffolds undergo a degree of degradation that is essentially incomplete during tissue regeneration. Growth factors may be incorporated in the scaffolds using microparticles of select composition, micelles, and composite structures with specific time-release profiles to deliver changing combinations of stimulatory factors to enhance the chondrogenic phenotype of the MSC. A major advance in the use of hydrogels has been the development of photo-polymerizable monomers that make hydrogels amenable to photo-stereolithography. This technique allows the design and fabrication of detailed internal and surface microarchitecture of large scaffolds such as those required for joint resurfacing. With precise spatial control, scaffolds can be loaded with microparticles of varying composition, tuned to release encapsulated growth factors at specified times. Thus, spatio-temporal specific differentiation of the seeded MSCs can be controlled to approximate and re-create the zonal organization of articular cartilage, osteochondral plug, or musculoskeletal entheses.

Despite such excellent design and fabrication strategies, many challenges remain in using such large complex scaffolds, including enhancement of cell survival as well as efficient and spatially targeted cell seeding. The latter may be largely overcome by centrifugation or vacuum aspiration, traditionally used to seed fibrous scaffolds, or direct incorporation of cells within the scaffold during fabrication, a technique commonly used with hydrogels. In the bottom-up approach to tissue engineering using photo-stereolithography, another challenge is the cytotoxic conditions generated by the UV-activation of photoinitiators during polymerization of the monomer solution. A solution has recently been reported by the development of a visible light-activatable photoinitator-based method of projection stereolithography [181].

Bone tissue engineering

Bone has a vigorous potential to regenerate itself after damage; however, the efficacious repair of large bone defects resulting from resection, trauma, or nonunion fractures still requires the implantation of bone grafts. Five hundred thousand surgical cases of bone grafting procedures are performed annually [182], and the demand for bone grafts is expected to be even greater over the next decade as the population ages. Natural bone grafts have been used extensively in clinical settings. Autografts, considered the gold standard for bone implantation, have the advantage of immunocompatibility over allografts and xenografts. However, complicating issues such as donor site morbidity, risk of infection, and the availability of bone tissue of the correct size and shape, limit the use of autografts in orthopedic applications. One possible remedy for the shortage of bone grafts is a functional tissue-engineered bone graft possessing one if not all of the following properties – an osteoconductive matrix, osteoinductive factors, and osteogenic cells [182].

MSCs are an attractive cell type for bone tissue engineering due to their extensive expansion and osteogenic differentiation capacities. Traditionally, MSCs are induced to undergo osteogenesis *in vitro* by the use of chemical supplements as described earlier. Growth factors, such as Wnt family members, have also been shown to play a role in osteogenesis [183]. *In vitro*, exposure of MSCs to Wnt3a-conditioned medium or overexpression of ectopic Wnt3a inhibits osteogenesis. The expression of several osteoblast specific genes, e.g., ALP, bone sialoprotein, and osteocalcin, was dramatically reduced, while the expression of Cbfa1/Runx2, an early osteoinductive transcription factor was not altered, implying that the Wnt3a-mediated canonical signaling pathway is necessary, but not sufficient, to completely block MSC osteogenesis. On the other hand, Wnt5a, a typical non-canonical Wnt member, has been shown to promote osteogenesis. Since Wnt3a promotes MSC proliferation during early osteogenesis, it is very likely that canonical Wnt signaling functions in the initiation of early osteogenic commitment by increasing the osteoprogenitor reservoir, while non-canonical Wnt drives the progression of osteoprogenitor to mature functional osteoblasts. The exact identity and actions of intracellular mediators of Wnt signaling in regulating MSC osteogenesis remain to be elucidated.

In order for MSCs to generate a successful bone graft, the cells require three-dimensional biomaterial scaffolds to secure them at the implantation site, provide physical protection, and maintain and direct tissue shape. In MSC-based bone tissue engineering, various biomaterial scaffolds have been evaluated for their potential as cell carriers. These scaffolds may be made from natural or synthetic materials that have been fashioned into structures with different shapes and sizes. In general, natural polymers, such as collagens, contain bioactive domains favorable for biological activities involved in tissue regeneration, whereas synthetic polymers, such as poly(α-hydroxyesters), feature controllable material properties that can approximate the physical properties of native tissue. Among the materials that have been used in bone tissue engineering, hydroxyapatite (HA) and their derivatives, such as β-tricalcium phosphate (β-TCP), are the most common scaffold materials for osteogenic induction of MSCs. Bioresorbable β-TCP based scaffolds, compared to HA based ones, showed comparable results on ectopic bone formation [184] and, moreover, both synthetic ceramics support osteogenic differentiation more efficaciously than demineralized bone matrix [185]. To improve the affinity of osteoconductive ceramics for cells, HA has been coated with bioactive peptides [186] or proteins [187], to enhance MSC attachment and osteogenic differentiation.

Composite scaffolds, composed of multiple materials, are expected to be physically and biologically superior to single-material-based scaffolds, as the properties of a composite may be programmatically varied by mixing different materials in various ratios. Both the composition and the relative ratio of the constituent materials can affect bone formation. HA has been used as a primary material combined with other materials such as TCP [188], poly-lactic-co-glycolic acid (PLGA) [189] and chitin [190] to produce various composite scaffolds. It was reported that scaffolds with different ratios of HA/TCP loaded with MSCs showed different extents of bone formation *in vivo*. Composites in which the HA/TCP ratio was designed to coordinate scaffold degradation with tissue deposition seemed optimal in promoting the greatest ectopic bone formation [191].

Finally, growth factors, cytokines, and other non-proteinaceous chemical factors are critical for osteogenic differentiation of MSCs, as mentioned earlier. To successfully augment bone formation, it is necessary to continuously introduce osteoinductive molecules, most of which have a short half-life, into the cell culture or the defect site. One strategy for enhancing bone formation is to use biomaterial scaffolds both as a cell carrier as well as a reservoir for the release of growth factors in a controllable manner. BMP2 is the most efficacious growth factor among the BMP family members, and has been incorporated in various forms of biomaterial scaffolds to induce osteogenesis in *ex vivo* cultures [192], or to stimulate bone formation *in vivo* [193], as well as in clinical applications (e.g., INFUSE® Bone Graft/LT-CAGE® Lumbar Tapered Fusion Device, Medtronic).

Osteochondral tissue engineering

Severe joint defects often extend to damage or destruction of subchondral bone, leading to associated pain and mechanical instability of the joint. Clinical results show that, even for a partial thickness cartilage defect, there are beneficial effects in exposing subchondral bone by drilling, as well as the incorporation of a bone layer as an anchor to securely integrate grafts with host tissue. Osteochondral grafts or plugs are used clinically in the treatment of both chondral and osteochondral defects.

Tissue engineering offers a promising alternative to autologous osteochondral grafts through the combination of biocompatible materials possessing widely varying physical properties with the multilineage differentiation potential of MSCs. Chondrogenesis and osteogenesis of MSCs require different physical and biochemical cues from matrices and soluble growth factors/cytokines, respectively. A commonly used approach is to fabricate cartilage and bone independently before integrating them together using sutures or glues. MSCs loaded into a hyaluronan or a TCP ceramic scaffold were separately induced to undergo chondrogenic or osteogenic differentiation, respectively. Then the two components were integrated together with fibrin sealant, becoming a single unit of an osteochondral construct [194,195]. One drawback with this method is the less-than-optimal integration between the chondral and osteo constructs; poor integration leads to discontinuous cell distribution at the interface and/or the possibility of eventual separation of the two components. Several groups have reported different alternatives to solve the problem of discontinuous interface. In one approach, MSCs after *in vitro* chondrogenic or osteogenic differentiation were loaded into two separate PEG hydrogel layers, then the cell-loaded PEG gels were photopolymerized together. Since the two components were combined before gel solidification, the osteochondral construct exhibited a less defined gap-line [196]. Another approach was to apply a press-coating process [197] to fabricate osteochondral constructs. A PLA scaffold was pressed into a high-density pellet of chondrogenically-induced MSCs then seeded at the opposite end with osteogenically differentiated MSCs. Macroscopically, the osteochondral composite consisted of a cartilage-like layer adherent to, and overlying, a dense bone-like component [198]. Since both cartilage and bone were produced in a single unit, no gap developed between the two tissues; instead, an interface resembling the native osteochondral junction was observed. Recent attempts have included the combination of MSCs encapsulated in microbeads of collagen type I, separately induced into osteogenic and chondrogenic lineages, with an interface consisting of undifferentiated MSCs, which resulted in a trilaminar osteochondral construct with an interzonal 'tidemark'-like structure [199].

The ideal scenario for the fabrication of bi-phasic osteochondral constructs would be to differentiate MSCs cultured in a single unit scaffold into chondrocytes on the top and osteoblasts on the bottom. To this end, the biomaterial scaffold should chemically and structurally support both chondrogenesis and osteogensis. Nanofibrous scaffolds morphologically resembling natural ECMs have been shown to successfully support both chondro- and osteogenesis of MSCs *in vitro* [200]. Another need for achieving this goal is a culture system in which an MSC-laden construct can differentiate into cartilage and bone simultaneously. A double-chamber bioreactor with a unique two-compartment design allowing the storage of different media was used to culture osteochondral constructs [201]. With this double-chamber bioreactor, it would be feasible to engineer an autologous osteochondral graft using MSCs by means of a nanofibrous scaffold.

Engineering other skeletal tissues with MSCs

In addition to their clear roles in engineering bone and cartilaginous tissues, MSCs may be readily applied for the repair of numerous other musculoskeletal tissues, including tendon and ligament repair. In early studies, it was observed that rabbit MSCs contract collagen type I carrier gels and that the delivery of these constructs to patellar and Achilles tendon defects

improved the biomechanical properties of the repair tissue as compared to acellular controls [202]. Newly emerging silk scaffolds that have been modified with RGD moieties and/or formed into nanofibrous scaffolds may also prove useful for tendon/ligament tissue engineering with MSCs [203]. Hybrid scaffolds consisting of silk and bFGF-releasing PLGA stimulated MSC proliferation and increased expression of tendon specific markers [204]. Studies applying tensional and torsional mechanical stimulations to MSC-seeded collagen gels *in vitro* have shown enhanced tenogenesis [205]. These studies suggest a potential role for MSCs in regenerative applications for tendon and ligament defects that may be modulated by the mechanical loading environment.

Another tissue in which exogenous MSC application has been used to effect repair is the fibrocartilaginous knee meniscus. It has been reported that intra-articular injection of MSCs derived from synovium [206] (absent a tissue engineering delivery vehicle) can have an ameliorating effect on meniscus degeneration. Similar results have also been shown when MSCs are seeded on various types of scaffolds and implanted into meniscal defects. These scaffolds included devitalized meniscal allografts [207] and fibrin glue [208], as well as, hyaluronan/gelatin [209] and hyaluronan/collagen [210] composite matrices. Clearly, MSCs can play a role in the reparative process of the meniscus, although the mode of their administration and the nature of the carrier materials require further optimization. Interestingly, multipotent mesenchymal cells have also been identified and isolated from bovine meniscus [211], suggesting that an endogenous reparative mechanism may reside in the meniscus.

Gene therapy in musculoskeletal tissue engineering

Gene therapy is a promising technique for disease treatment, in which genetically modified cells are transferred into or generated within individuals for therapeutic purpose. The cells with modified genes can be induced to differentiate into desired cell types or produce proteins needed for tissue repair. Although safety issues still remain, a likely future scenario is the merging of gene therapy, cell therapy, and tissue engineering for the treatment of musculoskeletal diseases.

There are two strategies that are currently used in gene therapy, viral transduction and non-viral transfection, and both strategies can be conducted *in vivo* and *ex vivo* [212]. *In vivo* gene therapy is simple but often lacks controlled tracking of the gene-modified cells and target site specificity. An attractive alternative is to combine gene therapy with tissue-engineering approaches to transduce or transfect cells of interest *ex vivo* and then use a carrier or scaffold to deliver these genetically modified cells to the target site. This approach offers the advantages of flexibility of target cell type and retainment of gene-modified cells at the site of interest. Gene transduction using viral vectors, such as retrovirus, adenovirus, and lentivirus, effectively modifies the host chromosome but raises concerns about mutagenesis and possible immune reactions. In contrast, a non-viral approach is safer but the efficiency of transduction is lower. More research efforts are needed to overcome the limitations associated with each approach. The ultimate goal is to develop a simple, safe, and effective means to transfer genes into cells of interest.

Currently, the most frequently applied example of gene therapy in bone and cartilage tissue engineering is the transduction/transfection of MSCs with BMP genes. BMPs play important roles in the regulation of osteogenic differentiation of MSCs and the production of bone matrix during bone formation. To overcome the short half-life of growth factors, MSCs are transduced or transfected with BMP genes for continuous protein expression *in vitro* and *in vivo*. BMP2 transduced MSCs were induced to differentiate into osteoblasts producing bone matrix and synthesize BMP2, thus attracting host cells to migrate and differentiate. Compared to control MSCs, the BMP2-producing MSCs effectively enhance bone formation, even at large defect sites like segmental femoral defects [213]. Similar results have also been reported

when BMP2 or BMP4 transduced MSCs were delivered to bone defects using different biomaterial scaffolds, such as demineralized bone matrix [213], gelatin [214], β-TCP [215], and calcium phosphate cement [216]. Currently several research groups are testing the effects of overexpressing a combination of factors such as BMP with VEGF, a potent inducer of angiogenesis [217]. The potential benefits of cartilage repair using gene therapy are also gaining recognition. For example, BMP7 transduced MSCs delivered by PGA scaffolds successfully regenerated cartilage, whereas the control non-transduced group did poorly [218], and BMP4 transduction induced chondrogenesis and enhanced cartilage repair [219].

CONCLUSIONS AND FUTURE PERSPECTIVES

Due to their ease of isolation, their capacity for undergoing *in vitro* proliferation to achieve a large number of cells for cell therapy, their ability to undergo lineage specific differentiation into musculoskeletal cells, and their potential immuno-modulatory advantages, MSCs present significant potential in musculoskeletal skeletal tissue engineering, which promises to bring hope to patients and surgeons alike for the generation of functional tissue substitutes. As discussed in this chapter, MSCs have been used in tissue engineering of a number of musculoskeletal tissues, including cartilage, bone, osteochondral constructs, ligament, and tendon. Currently, tissue-engineered constructs have not been readily accepted for clinical use to treat skeletal tissue defects. There clearly is a need for further research that combines concerted efforts of biologists, engineers, and clinicians. Critical to the success of these approaches is a better understanding of MSC biology. So far, there has not been a marker that can be used to unequivocally identify and prospectively select MSCs from various tissues. The factors that regulate phenotype transition, i.e., uncommitted *versus* differentiated phenotype, remain to be identified and studied. Additionally, the various growth factors, signaling pathways, and transcription factors that can influence MSCs to differentiate completely and stably into a desirable lineage require further elucidation. Despite our incomplete understanding of MSC biology, their use in musculoskeletal tissue engineering is of high potential. Current and future efforts in this area should focus on the fabrication of optimized scaffolds, systematic studies of the interplay of MSCs, scaffold and environmental factors, and the development of quantitative outcome measurements for tissue-engineered constructs. *In vivo* testing of the engineered construct serves as the gold standard for the long-term survival of the constructs, and warrants much greater attention. The immunosuppressive and anti-inflammatory effects of MSCs present a potentially powerful biological target for their use in allogeneic transplantation in the inflammatory environment of an injury site. With further research and development, the use of MSCs in tissue engineering is expected to bring to fruition a tissue substitute suitable for implantation to improve the quality of life of patients with debilitating musculoskeletal injuries.

Acknowledgments

CHAPTER 55

Bone Regeneration

Arun R. Shrivats, Pedro Alvarez, Lyndsey Schutte and Jeffrey O. Hollinger
Department of Biomedical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania

INTRODUCTION

Bone regeneration is a marvelous *pas de deux* of biology and biomechanics wrapped in discrete temporal events nurtured by a lush vascular cascade. The outcome of the highly complex process of regeneration is the *restoration of form and function*, ideally, enduring, to a bone insufficiency. Broadly, such an insufficiency may be stated as *any discontinuity in bone integrity, spanning microfractures, through macrofractures to developmental-congenital defects to avulsive trauma and surgical resection.*

An epochal question: How to harness the intrinsic regenerative capacity of bone? Bone regenerative tacticians have proposed a *deconstructive approach,* that is: What are the compositional elemental components of bone beginning with cells, extracellular matrices (organic and inorganic) and soluble signaling molecules? Further posing the questions: How do these compositional elements inspire the multi-tiered temporal osteogenic regenerative cascade? Is there a trigger factor? Are there co-factors?

The prototypic and conventional approach to bone regeneration for this chapter is to highlight bone regeneration by exploiting contemporary, albeit pedestrian approaches of autografts, allografts and xenografts. First, we will define these modalities and emphasize what is good about them and what is lacking. We will further offer consensus definitions of the biological and biomechanical properties of regeneration, stating specific performance parameters that define the temporal road map for the regenerative cascade. As such, we will exploit a *fracture healing model* as a prototype for the regenerative process. We will introduce key directional concepts that must be acknowledged for the rational design and development of a regenerative therapy. These concepts will include the *osteogenic biohemodynamic cascade* and for bone regenerative therapies, the importance of a *4D environmental blastema matrix* where embryogenesis is recapitulated. And lastly, we will offer stringent performance criteria with objective data to provide a framework for the rational design and fielding of a master tool kit for bone regenerative therapeutics.

CURRENT CLINICAL PRACTICES

We will begin with an explanation of the most commonly employed techniques for bone regeneration. At the current time, this practice revolves around natural (as opposed to synthetic) bone and its derivatives.

We will first establish a broad criterion for the generic term *graft.* We will carefully partition the term *graft* and *implant*; then abandon this rigor in favor of clinical jargon.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00055-0

Grafts contain cells; *implants* do not. Therefore, an *autograft* (recipient and donor being the same individual), contains *cells*. An *allograft* (recipient and donor being genetically matched individuals), contains *cells*. However, traditional tissue banking procedures effectively and efficiently remove cells from allo-stock bone, rendering the allo-stock product *acellular* and *non-immunogenic*. Consequently, such a product should be defined scientifically as an *alloimplant*. Nevertheless, clinical jargon has made an exception to the stringent scientific definition, and while incorrect, *allograft* has evolved as a clinically acceptable term for an acellular *allo-stock* product. Therefore, in this chapter, we will use the term *allograft* (despite the fact that the term *alloimplant* is scientifically correct).

In order to understand the rationale for the use of bone-derived products for regeneration, it is important to define the criteria by which we measure successful bone regeneration. Bone healing and subsequent new bone formation after the implantation of a graft occur through the processes of osteogenesis, osteoinduction and/or osteoconduction [1]. *Osteogenesis* is the process by which osteoblasts at the defect site express osteoid that subsequently mineralizes, yielding new bone. *Osteoinduction* is the induction of osteoprogenitor cells (or other non-differentiated cells) to differentiate down an osteoblast lineage. *Osteoconduction* is the property by which a graft supports the attachment of new osteoblasts and osteoprogenitor cells. In this situation, the graft must provide an interconnected structure through which new cells migrate and blood vessels form (i.e., angiogenesis). An ideal bone graft is characterized by all three of these phenomena and clinically will promote regeneration of bone that is physiologically and functionally indistinguishable from the pre-injury defect site.

Bone autografts are harvested from a *donor* site in a patient (usually the iliac crest) and implanted in that same patient at the bone deficient locale (i.e., *recipient* site) [2]. Autografts are considered to be the gold standard for bone grafting applications for several reasons. Firstly, autografts satisfy all three of the previously mentioned bone regeneration criteria — that is, they are osteoconductive, osteoinductive and promote osteogenesis. The autograft is intrinsically vascularized and may be co-harvested with a vascular pedicle. Consequently, the autograft provides an ideal combination of biological signals for integration of the new bone to the recipient site. Additionally, autograft is the patient's own tissue, thus mitigating the risk of immunological sequelae. However, there are drawbacks associated with the use of autografts: they are limited in quantity, shape restrictions often require extensive intra-operative modifications, and donor-recipient procedures require a 'harvesting' site on the same patient [3]. As with any surgery, surgical complications may include inflammation, infection, chronic pain and donor site morbidity [4].

Allografts are tissues harvested from healthy, prescreened human donors and are processed and preserved for implantation in a patient. The benefits of allografts include eliminating the need for a second surgical site on the patient requiring the graft. However, allogeneic bone (i.e., the *allograft* bone donated by the same species: human-to human) is not necessarily immunopriviledged and may activate an immune response in the new host [5]. Additionally, during tissue bank processing, allografts go through freeze-drying, 'washing' (to render the product cell-free), demineralization (partial or complete — residual mineral may be up to approximately 4–6%), and gamma-irradiation or ethylene oxide sterilization. While these techniques lessen the risk of disease transmission and immunological responses, they also reduce the osteogenic potential of the graft.

An alternative to auto- and allografts are *xenografts*: bone from non-human species. Xenografts are processed to ensure sterility and biocompatibility and this processing must mitigate disease transmission [6]. Xenogeneic bone is administered as a *bone void filler*. Examples of xenogeneic bone products include BioOss [7], an inorganic matrix from cows and XCM™ (Synthes), porcine organic bone matrix. While xenografts may have their uses in bone regeneration, the risks of disease transmission (however minimal they may be) and

ethical issues have limited their clinical appeal and thus, they have not really 'caught on' in the clinic.

Autografts and allografts have many clinical benefits and thus constitute a majority of bone graft procedures. However, recognized limitations have necessitated the search for alternatives. Therefore, laboratory inspired bone tissue-engineering approaches have been assiduously pursued. We emphasize that a rational approach to regenerative bone tissue-engineered products must be based on fundamental osteobiology. It is thus imperative to understand mechanisms, concepts and the guiding principles of the osteogenic cascade.

CONCEPTS AND DEFINITIONS

Our bodies have evolved sophisticated mechanisms to heal wounds. When injured, there are two distinct responses that can be initiated: *repair* and *regeneration*. *Repair* is the restoration of the continuity of tissues at the injury site, but not necessarily by the same cells and tissues that existed prior to the injury. *Regeneration*, however, is a series of biologically- and biomechanically-inspired events that produce restoration of form and function of the injured tissues to a state that is biologically and functionally indistinguishable from the pre-injury wound site [8].

The molecular-level biological agents involved in wound healing and regeneration are slowly being elucidated. Our collective understanding of these processes has increased. One area, however, that still causes confusion is the nomenclature in literature of biological factors, specifically between *growth factors* and *cytokines*. In this chapter, *growth factors* are defined as biologic agents whose actions are exerted on cells of mesenchymal lineage and *cytokines* are defined as agents acting on cells of hematopoietic lineages, including immune cells.

Biological factors are crucial for regenerative processes and can be classified into three categories – *autocrine*, *paracrine* and *endocrine*. *Autocrine* signaling refers to a cell releasing an agent that acts on the same cell type. *Paracrine* signals affect those cells that are in the same area as the cell from which the signal originated. *Endocrine* signals are those that must travel through the bloodstream in order to reach their target.

Biology is characterized by redundancy, which results in many similarities among responses of tissues to injury, particularly with respect to the biological agents [9,10]. One key difference between osseous and non-osseous (aka 'soft') tissues is their respective regenerative potential. Soft tissues *heal* exclusively by scar (i.e., fibroblast generated collagen) tissue formation, resulting in the restoration of tissue continuity at the injury site at the expense of the original tissue function. Osseous tissues, however, have the potential to regenerate to a state that is biologically and biomechanically indistinguishable from that derived from embryogenesis.

If bone would *always spontaneously regenerate* and overcome any manner of insufficiency/defect, this chapter on bone tissue regeneration would not be necessary. There are limitations to the regenerative potential of osseous tissue that renders defects (i.e., deficiencies: congenital, surgical, avulsive) greater than a certain size unlikely to regenerate [11]. This size has been defined as a *critical sized defect* (CSD), which is:

> 'the smallest size intraosseous wound in a particular bone and species of animal that will not heal spontaneously during the lifetime of the animal' [12,13].

The central question is: how do we extend our regenerative capabilities for sub-critical size defects to bone insufficiencies larger than the critical size?

The answer lies in elucidating, defining and understanding the differences in each of these pathways. Specifically, what is the osteogenic pathway for a critical sized defect? For a non-critical sized defect? Consequently, a prototypic pathway is an obligatory first step. Consequently, the next section introduces a *fracture healing model*. This model is defined by systematic processes of meticulously choreographed events that lead to bone regeneration. Bone tissue

engineers must exploit and recapitulate the complex process of fracture healing, capture the biological and biomechanical nuances in its evolution, and thus, define performance criteria for achieving bone regeneration in critical size defects with tissue-engineered products.

FRACTURE HEALING MODEL

In developing novel bone tissue-engineering tools, we seek to extend our bodies natural regenerative capabilities to include bone defects larger than the critical size. Fracture healing is the prototypic physiological model for bone regeneration. It is a multistage process that is characterized by complex, yet well-orchestrated, predictable steps in response to an injury. Fracture healing begins immediately following the injury and ends following the *remodeling* of the newly formed bone into mature bone. This process has components that recapitulate the processes of *de novo* bone formation during embryogenesis [14].

The process of fracture healing is a multi-phase, multi-tiered series of events segmented into four main steps:

1) The formation of a hematoma,
2) The migration and mitosis of mesenchymal cells,
3) Cartilage formation and substitution of cartilage by bone, and
4) Remodeling [15].

Immediately after a bone is fractured, the damage to local vasculature at the fracture site is responsible for producing a *hematoma*, or a blood clot. A hematoma is a localized collection of blood products including platelets, leukocytes, macrophages, fibrin and soluble biological growth factors and cytokines. This first phase of fracture healing, termed the *destructive phase*, lasts for about three days and is characterized by inflammation and local hypoxia [9].

The constructive phase of regeneration follows the destructive phase (Fig. 55.2) and begins roughly three days after the injury. It is characterized by new vasculature formation due to the migration and subsequent capillary formation of endothelial cells. Local hypoxia during the destructive phase is a stimulant for the formation of new blood vessels (i.e., angiogenesis). The formation of new vasculature allows for the recruitment of mesenchymal stem cells

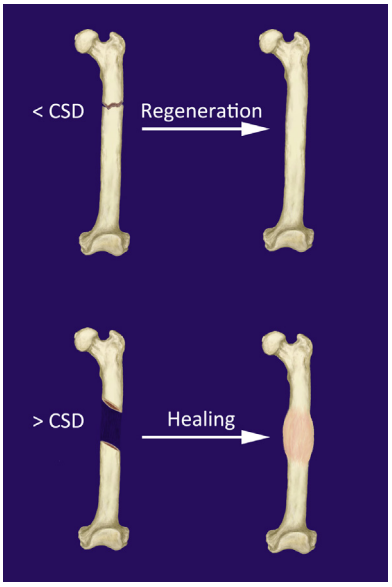

FIGURE 55.1
Bone will regenerate 'gaps' smaller than a critical size but when a 'gap' exceeds a certain volumetric dimension, the outcome of the healing process is fibrosis rather than osteogenesis.

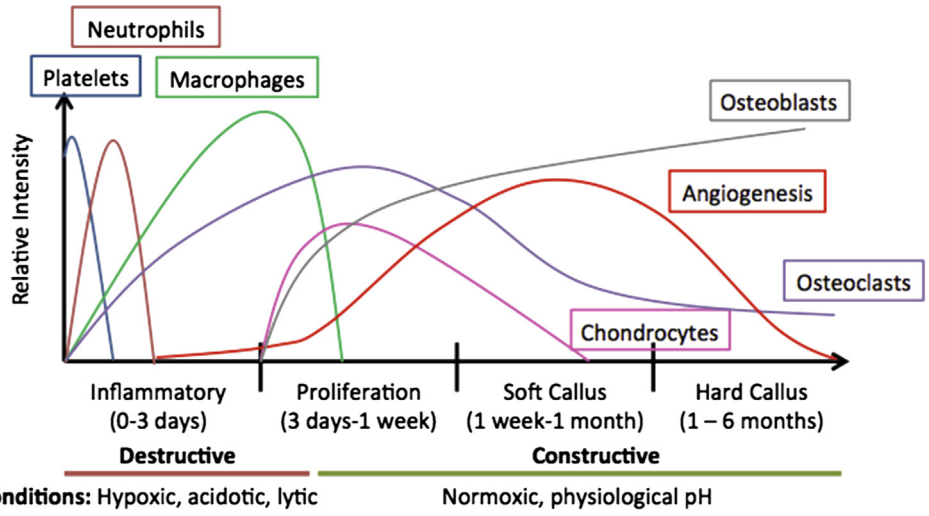

FIGURE 55.2
The temporal activity of key cell phenotypes and events during fracture healing.

(or pericytes: fusiform cells of the mesenchymal lineage that line blood vessels) that differentiate into chondrocytes and osteoblasts as well as providing the conduits for monocytic-derived *osteoclasts* [16,17]. The *chondrocytes* are responsible for cartilage matrix formation and the *osteoblasts* produce the new bone and the osteoclast-osteoblast coupling remodel that bone.

Granulation tissue condenses into a 'soft' callus that acts as a stabilizing buttress, supporting the bone fragments at the distal and proximal bone fragments. The elegance of this soft callus formation is that it provides the bone fracture site with a cartilaginous scaffold that acts as both a fixation and stabilization structure and a template for subsequent mineralization [18]. Chondrocytes in the soft callus undergo a programmed cell death (apoptosis); concurrently, osteoblasts deposit bone matrix (osteoid) to replace the soft callus. At the fracture locale, over the course of months to years, the bone is remodeled to a physiological status indistinguishable from the pre-fractured condition [19].

The processes driving the biology and biomechanics of bone regeneration at a fracture remain in large part, a mystery. There are many highly complex interactions among multiple cell types and mediated by soluble and non-soluble signaling agents that have not been sufficiently characterized and elucidated. *The profoundly compelling challenge for biomedical tissue engineers is to deconstruct the regenerative process of fracture healing and subsequently stitch those components together to produce osteo-regenerative therapies for applications in bone defects exceeding the 'critical size'.*

PERFORMANCE CRITERIA FOR BONE REGENERATION

We establish a goal for bone regeneration: Recapitulate the *Biohemodynamic Cascade* of fracture healing on a larger scale, one that may be applied to osseous regeneration of the critical sized defect. We then ask the following: How can we mimic fracture healing to develop therapies that consistently regenerate bone in gap defects? What must bone tissue engineering develop as a therapy to regenerate bone defects that exceed the ability of the body to spontaneously promote regeneration, that is, to regenerate bone in critically sized defects? The clinical requirements for bone regeneration demand that we develop products that outperform the existing standards set by autografts and allografts. We must develop a biologically- and biomechanically-based therapy that is osteo-angiogenic, that is: fulfills the parameters of the *biohemodynamic cascade* of fracture healing.

Our approach for achieving this is two-pronged: Since bones have an intrinsic ability for regeneration, our first mission is to design therapeutics that *do not interfere* with the natural regenerative processes. The body executes a network of biological and biomechanical

events that are highly complex; as such, we must not interfere with the intrinsic processes but rather, supplement them. The second tactic to our approach is that bone regeneration therapeutics must work *synergistically* with endogenously-driven healing cues. Therefore, we must carefully engineer therapeutics to match the biology and biomechanics of natural bone regenerative processes.

Safety

A fundamental requirement of any bone regeneration therapeutic is that it must do no harm to the patient. This is a basic ethical principle for scientists, clinicians and the corporate sector. Doing no harm to the patient includes ensuring the biocompatibility of bone regenerative therapeutics. When a bone therapeutic is implanted at the site of a bone insufficiency, the first interactions are with host blood and blood proteins. Therapeutics must not elicit either an acute or a chronic immunological response [20].

An additional factor affecting biocompatibility, and therefore the safety of a therapy, is the degradation properties of its materials. Therapeutics based on materials such as metals, ceramics and polymers may degrade in the body. Polymeric systems such as the polyalpha hydroxy acids degrade by hydrolysis or enzymatic processes. While we have already stressed the importance of biocompatibility *upon implantation*, of further importance is the biocompatibility *of degradation products*. Polyalpha hydroxy acids such as polylactide and polyglycolide degrade into lactic and glycolic acids, producing an acidotic environment. As such, it is crucial that therapeutic bone grafts degrade in a fashion that does not hinder bone regenerative activities.

Mechanical properties

We have discussed the importance of avoiding immunologic responses, but we have not yet mentioned the biomechanical requirements for a bone regeneration therapeutic. Initially, a bone defect site is in a state of dynamic instability, where structural integrity has been compromised but may still be subjected to loads. Consequently, the biomaterial must provide sufficient mechanical strength and be able to accommodate to tensile, compressive and shear forces. Moreover, the material must degrade in a coordinated temporal manner with the new bone formation as well as support the new vasculature. If a bone graft material is degraded too quickly (i.e., before the infiltration of bone begins — roughly four weeks after the injury), the area will fail to provide the requisite support. Conversely, if the material remains at the bone recipient site for longer than this four week window, it will impede regeneration. Furthermore, implanted materials in bone must support physiological loads, for which there is a biomechanical threshold. A material that exceeds this threshold will cause *stress shielding* of the bone and promote bone resorption. Many of the terms and end-stage properties stated above are well-known to bone tissue engineers. However, what is neither well-known nor precisely defined, are the *quantitative performance criteria* that match to 'sufficent strength', 'degradation' and 'how slowly or rapidly' a bone regenerative material should either be retained or degraded. An inadequate product will be engineered when specific performance criteria are lacking. Consequently, a focused effort must be made by bone tissue engineers to accurately and precisely define, with rigorous science, performance criteria for bone tissue-engineered product. Based on the timeline of fracture healing, an implanted material should be fully degraded by the formation of the soft callus, providing a target of roughly two to four weeks for full degradation [18].

Bone regenerative properties

General performance criteria for bone graft therapeutics must include properties of osteoconductivity, osteoinductivity and osteogenicity.

An osteoconductive graft will support the attachment and differentiation of the many different cell types that migrate to the defect site. One method for influencing osteoconductivity in synthetic grafts is by tailoring the hydrophilicity and hydrophobicity of the graft surfaces. These surface properties enable cell attachment and protein adsorption; however, they alone are not sufficient for a suitable therapeutic [21].

Another strategy for improving cellular adhesion to bone graft materials is to engineer peptide-based adhesion sequences, such as the arginine-glycine-aspartic acid (RGD) sequence and extracellular matrix components such as collagen, fibronectin [22], and vitronectin. Moreover, the inclusion of angiogenic growth factors in the composition, such as vascular endothelial growth factor and basic fibroblast growth factor, can contribute to the osteoinductive ability of a bone biomaterial [4]. This approach is akin to *compositional engineering*. Compositional engineering of bone regeneration therapies must comply with the temporal and dosing profile of the *osteogenic cascade* (Fig. 55.3). Specific biological factors are expressed at certain, designated time(s) during osteogenesis and bone regeneration. Moreover, there may be a waxing and waning of biological agents. These agents evoke an outcome driven by cell phenotypes that craft extracellular matrices resulting in tissue regeneration. We posit that bone 'gaps' less than a certain size will regenerate as a consequence of sufficient biological cues and cellular craftsmen; exceeding that certain size, that is, being critically sized, these 'gaps' will undergo fibrogenesis rather than osteogenesis. Consequently, only by following the *biological roadmap* with its meticulously timed and dosed boundaries that define the osteogenic cascade (Fig. 55.3), will the bone tissue engineer be able to produce a predictable and safe clinical outcome: bone regeneration of a critically sized defect.

Another approach to bone regeneration materials exploits *architectural engineering*. We define this as the physical properties that may be adjusted in a material to inspire bone regeneration. An example of architectural engineering is *pore structure* (i.e., *void volume*) [23]. Macroporosity (pore size >50 μm) has been shown to promote cell ingrowth as well as support angiogenesis. Microporosity (pore size <10 μm), on the other hand, plays a role in cellular signaling via transport of biologically active signaling agents [24]. A combination of the macro- and microporosity may sustain osteogenesis and angiogenesis [25] throughout the material, assuming those pores are *interconnected*. Further, pore size range, pore distribution and volumetric porosity comprise the three parameters available to the bone tissue engineer for modulating the design of a product that matches the intended clinical use. The design of a porous structure for bone regeneration is a delicate art as volumetric void volume is inversely related to overall strength of the material.

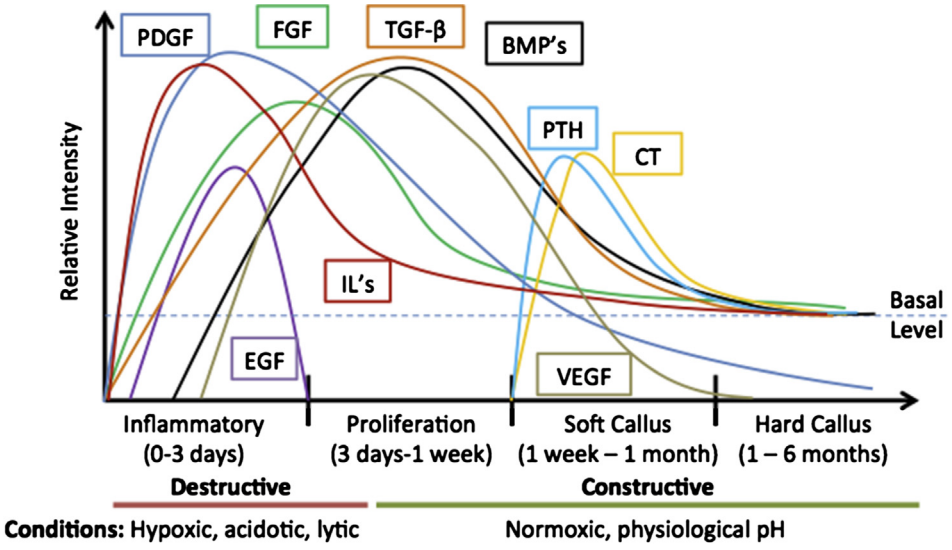

FIGURE 55.3
Relative levels of key biological factors in the bone regeneration cascade, compiled from multiple sources [9,15,18,26–28].

TABLE 55.1 Recommended temporal windows (given as days post injury) in which to deliver fracture healing biologicals based on extensive literature reviews [14,16,28–35]

Growth factor	Proposed delivery period
PDGF	0 – 3 days
VEGF	14 – 21 days, though required earlier as well
BMP	BMP-4: 3 – 5 days BMP-2: 3 – 21 days
PRP	0 – 5 days

Recapitulating osteogenesis within bone defect requires precise, dose-dependent external contributions. Therefore, we are obligated to pay attention to the specific spatial, dosing and temporal events that occur in fracture healing and embryogenic bone formation. By delivering cells and biological factors to a bone defect site, we may overcome the limitations in bone regenerative potential caused by an insufficiency. However, cells and biologicals must be delivered at the appropriate dose, times and with release profiles mimicking the osteogenic cascade (see Fig. 55.3, above). For example, the delivery of pro-inflammatory cytokines must occur within the first 72 hours after injury. If delivery of these cytokines is delayed, constructive phase events of bone regeneration may be impeded. Table 55.1 summarizes our recommended delivery times for several growth factors based on their consensus appearance in bone regeneration.

CLASSICAL RESEARCH APPROACHES

Now that we have highlighted the performance criteria for bone regeneration approaches, we will discuss current tactics in bone regeneration research. It is worth noting that in spite of the criteria provided above, there are many approaches to bone tissue regeneration. Moreover, owing to the tremendous complexity (and diversity of opinions) about the process of bone regeneration, it is naïve to assume a single approach either will fit all clinical indications or provide solutions in all circumstances. However, we underscore that contemporary efforts to promote bone regeneration focus on cells, biological factors and materials.

Cell-based approaches for bone tissue engineering

The antecedents for the cell phenotypes in bone regeneration trace their pedigree to hematopoietic and mesenchymal lineages. Cells that resorb bone, debris, and implant material – such as macrophages and osteoclasts – are derived from hematopoietic monocytes. Monocytes may diverge to either macrophages or osteoclasts depending on the biological environmental cues. Macrophages release cytokines to recruit mesenchymal cells for neovascularization, as well as orchestrate an anti-inflammatory, pro-healing environment [36]. Macrophages and monocytes, as well as the osteoclasts are marquis players during the *destructive phase* of bone regeneration.

During the *constructive phase,* mesenchymal cells differentiate to pre-osteoblasts. The periosteum and endosteum, as well as vascular lining pericytes [31], are the putative sources for the preosteoblast lineage. Biological cues for the progression of the differentiation of the precursor cells to pre-osteoblasts are under the aegis of bone morphogenetic proteins.

The regeneration of bone in a bone deficient site is a time-sensitive process; as such, if bone formation by osteoblasts does not occur in register with *soft callus* remodeling, the outcome will be fibrogenesis rather than osteogenesis. Moreover, mechano-transductive signals matched to bone will not occur: fibrous tissue is not biofunctionally equivalent to osseous tissue. Consequently, a 'pool' of programmable osteoblastic precursors must be localized to

TABLE 55.2 The advantages and disadvantages of commonly used biomaterials for bone regeneration

Material	Advantages	Disadvantages	References
Alginate	Can be used for drug delivery, cell encapsulation, wound dressing, anti-adhesion applications; biodegradable	Anti-adhesive, mechanically weak	[86–89]
Bone Mineral Matrix	Low immunogenicity, well documented success	Potential for disease transmission, decreased mechanical strength, limited supply	[88,90,91]
Chitosan Sponge	Can be used as a hemostat or to deliver soluble signaling molecules, biodegradable	Mechanically weak	[88,92,93]
Collagen Sponge	Biocompatible and osteocompatible, antigenicity can be weakened by removing telopeptides, biodegradable, adhesive, highly porous, can be incorporated with new tissue matrix or combined with other materials	Lack of rigidity (mechanically weak), potentially antigenic	[88,94,95]
Collagen-Ceramic composite	Biocompatible, biodegradable, degradation profile better than collagen alone, spatially adaptable, can control shape, higher stiffness than collagen sponge, increased particle and defect wall adhesion	Mechanically weak	[88,96–98]
Hyaluronic Acid	Can be used as a coating or to deliver cells or signaling molecules, low immunogenicity, hydrophilic, injectable	Low cell adhesion, mechanically weak	[88,99,100]
Hydroxyapatite	Moldable, can be used for coatings, high degree of tissue integration, creates undistinguishable unions with bone, low immune response	Risk of disease transmission, requires increased time for bony restoration	[88,101,102]
Polycaprolactone (PCL)	Can be used as delivery system, mechanical properties can be adjusted	Hydrophobic, degrades slowly	[88,103–105]
Poly(lactice-co-glycolic acid) (PLGA)	Can be used as a delivery system, biodegradable, mechanical properties and biodegradation kinetics are suited for bone applications	Acidic Degradation products	[88,106–108]
Polyphosphazenes	Fine-tunable degradation profile, thermosensitive, injectable, supports cell attachment	Acidic degradation products	[88,107,109]
Polyurethane	Biostable, biocompatible, adjustable mechanical properties (durability, toughness), cost effective	Risk of toxic degradation products	[88,107,110]
Tyrosine-derived Polycarbonates	Biodegradable, cell-impermeable, low immunogenicity, can be used as a delivery system, mechanical properties (stiffness and strength) suited for bone applications, cost effective	Hydrophobic	[88,111–113]

the healing bone regenerative domain (i.e., by chemoattraction), expanded in quantity (the process of mitogenesis) and modulated to an end-stage phenotype (i.e., undergo differentiation) to produce the desired outcome: restoration of form and function. The timing of this event is but one of many 'key' movements in the dynamics of osteogenesis. Sources for osteoblastic precursor cells include mesenchymal stem cells (MSCs), adipocytes and perivascular pericytes populations contiguous to the bone wound. The tempo of regeneration must be orchestrated by a meticulous sequence between these inducible cell populations and the cueing biological signals that will produce osteoblasts. Exploiting osteoblast precursor populations is the inspiration for dedicated cell-based therapies for bone regeneration.

The bone-marrow-derived mesenchymal stem cells (BMSCs) are commonly used considered the 'gold standard' [37–39]. Bone-marrow-derived mesenchymal stem cells have been used for gap bone defect treatments and purportedly improve short-term and long-term healing [40,41]. However, there are limitations to BMSCs for bone regeneration that include the postoperative painful sequelae from the 'collection' procedure, the uncertainty about the quantity of cells necessary for a predictable outcome, variability of cell quantity that may be harvested from patients and ambiguity regarding the actual quantity of viable cells that have been implanted in the recipient site. Moreover, the lack of standardization and rigor associated with the reports on bone-marrow-derived stem cell treatments have led to controversy and vocal opposition for the clinical merit of the procedure. Despite significant clinical and scientific deficiencies of the procedure, aspirated BMSCs remain the 'gold standard', albeit somewhat lusterless.

The research on induced pluripotent stem (iPS) cells has made progress over the last five years. It is exciting that an individual's epithelial cells could be secured, for example, and de-differentiated to stem cells and subsequently modulated to an osteogenic differentiation pathway. Reports suggest iPS cells will differentiate into osteoblasts and produce bone either by being cultured in differentiation media or by viral induction of the *Runx2* gene [42,43]. With iPS cells, however, a significant drawback to their therapeutic potential is their tendency to form teratomas, even after being differentiated down an osteogenic pathway; in the future this may be solved by irradiation of the iPS cells or by a refinement of iPS production [44].

Adipose derived stem cells offer another source for autogenous MSCs. While the procedure to collect the stem cells is more invasive than needed for iPS cells, the harvested tissue is one that most patients would be more willing to endure. The adipose derived mesenchymal stem cells (ADSCs) have the advantage of undergoing less processing steps before becoming osteoblasts and – since they are already differentiated into a mesenchymal lineage – have less of a risk of accidentally becoming non-osseous cells. Studies have reported that ADSCs can undergo osteogenic differentiation, but do not produce mineralized matrix [45,46]. A more sophisticated understanding of ADSCs will be needed before this type of therapy advances into the clinic.

Human umbilical cord derived MSCs (UCMSCs) are readily available, can be harvested inexpensively with no donor site morbidity and can differentiate to osteoblasts [47]. UCMSCs may be harvested from the Wharton's jelly post-partem. The UCMSCs expand easier in culture than BMSCs [48] and have been increased 300-fold in culture without loss of differentiation potential [49]. Furthermore, UCMSCs have the advantage of being *immunopriviledged* due to immunosuppressive isoforms of HLA, as well as the ability to suppress splenocytes and T cells [50,51]. This biological phenomenon allows these UCMSCs to be matched with a wider range of tissue-types, providing allografts to patients with rare immunotypes. Moreover, studies suggest hUCMSCs may differentiate into osteoblasts and produce mineralized matrix, however, the outcome is less robust than that produced by hBMSCs [49,52,53].

Biological therapies for bone tissue engineering

Earlier in this chapter we provided an overview of the fracture healing process that operated on a macroscopic scale. The emphasis was placed on the 'big-picture' events at the bone defect site. Therefore, we will now emphasize selective molecular cues that play a role in the osteogenic cascade. We will note the harmonized release of biologicals among multiple cell phenotypes that direct the osteogenic process and lead to bone regeneration

The dynamic fate of biological signaling molecules at a bone defect underscores the four-dimensional nature of bone regeneration. Consensus abounds on the three spatial dimensions (X, Y and Z) of *volumetric bone* regeneration'; however, there also exists the crucial temporal aspect. Consequently, we emphasize that bone regeneration must be viewed as a *dynamic four dimensional process*. Biological signaling molecules function effectively for a limited window of time to elicit an appropriate outcome on a dedicated target cell. Consequently, it is important to engineer the delivery of biological signaling agents in a bone regeneration therapy with a precise understanding of their temporal pathways during natural bone regeneration [18].

The biological signaling agents we examine in this chapter can be broadly classified into the following categories:

1) Pro-inflammatory cytokines,
2) Growth and differentiation factors, and
3) Angiogenic factors.

Pro-inflammatory cytokines are active following bone injury and establish and maintain the initial *destructive environment*. Growth and differentiation factors function during the *destructive and constructive phases* while angiogenic factors are focal points during the re-vascularization of the injury site. The focus of this section will be on growth and differentiation factors along with angiogenic factors. There are many growth factors that belong in this group and in an effort to provide a more meaningful summary of the most likely factors that will be encountered in the clinic, we will down-select to specific factors based on known effects and published data regarding the bone regenerative processes.

We begin with the *destructive phase* of fracture healing that is characterized by an acidotic, hypoxic environment. The primary cell types in this environment are platelets, lymphocytes and macrophages, which release fibroblast growth factor (FGF), transforming growth factor-β (TGF-β), and platelet-derived growth factor (PDGF).

Members of the FGF family are present in the wound site for up to three weeks, and as such, have a broad range of activities [35]. Chief among these activities is the stimulation of endothelial cell migration and subsequent angiogenesis. FGFs affect the migration and proliferation of chondrocytes during the *constructive phase* of bone regeneration [54]. TGF-β growth factors functions as a mitogen for fibroblasts, marrow stem cells and pre-osteoblasts. Both FGF and non-bone morphogenetic protein (BMP) members of the TGF-β super family of proteins propel bone regeneration up to several weeks post injury.

PLATELET-DERIVED GROWTH FACTOR

PDGF is a dimeric growth factor composed of monomers linked by a disulphide linkage. Four individual chains (A, B, C, and D) combine to make five dimers (AA, AB, BB, CC and DD) of which one dimer in particular — BB — plays a key role in bone regeneration [30]. During embryogenesis, PDGF promotes formation and differentiation of somites, which are mesodermal structures that eventually mature into precursors for bone, muscle and skin [55]. Following an injury to bone, PDGF is released from macrophages and the α-granules of platelets and is a potent chemoattractant and mitogenic factor for cells of the mesenchymal lineage. At the site of injury, PDGF will recruit fibroblasts, endothelial cells, osteoblasts as well

as cells of the immune system. PDGF is active for the first 72 hours after injury and as such, is an exemplary candidate for delivery early in the regenerative process [35]. Additionally, as a promoter of angiogenesis, PDGF plays a role in the re-vascularization of the bone defect site [29].

PDGF is secreted by platelets, macrophages, osteoblasts and fibroblasts. In addition to its mitogenic and chemoattractive properties, PDGF will increase osteoprotegerin expression in vascular smooth muscle cells (an inhibitor of osteoclasts) and functions during embryonic development [56]. As a modulator of early-stage wound and fracture healing, PDGF has a significant impact on recruiting (i.e., functioning as a *chemoattractant)* cells to the fracture site. As such, it is a strong candidate for delivery within 72 hours of bone injury.

PLATELET-RICH PLASMA

Platelet-rich plasma (PRP) provides an interesting alternative to the delivery of PDGF alone. PRP consists of a centrifugated blood fraction that contains a concentration of platelets that is often several fold greater than physiological platelet concentrations at wound sites [57]. This concentrated solution is achieved through a multi-step centrifugation to separate platelets from other cells found in blood. In the fracture healing model, the recruitment of immune cells as well as cells of the mesenchymal lineage begin with the release of PDGF from platelets. Consequently, the logic for the clinical application of PRP is that while one cannot precisely mimic the composition of the growth factors endogenously released by platelets in an osseous wound, increasing the concentration of platelets at the site may augment the healing process [58]. That is, there will be an increase in the presence of downstream growth factors such as Angiopoietin-2, endodermal growth factor (EGF), TGF-β1, FGF-2, and predominantly, PDGF and Vascular endothelial growth factor (VEGF). It is generally accepted that many of these factors are necessary for bone regeneration. Purportedly the administration of PRP will assure the appropriate healing milieu composition is available and suitable for the regenerative process [58]. Moreover, there is the argument that PRP is autogenous, patients, as their own donor-recipient pair, consequently, will benefit. Regrettably, the notion of PRP effectiveness has been met with skepticism. An absence of rigorously designed scientific and clinical studies and a proliferation of anecdotal 'evidence' have significantly diminished possible benefits. Controversy over PRP has mitigated against clinical acceptance where successful outcomes seem to be segregated to localized clinical practices.

Nevertheless, given the strong biological rationale for the use of PRP in bone regeneration therapies, it is somewhat surprising to see that its use has resulted in controversial results in literature [57,58]. There are a few potential explanations for the range of reported results. Firstly, the method of preparation of the PRP may differ in many of these studies, leading to invalid comparisons among results. Another explanation for the discrepancies could be variations in the administered dose of PRP. Like any 'drug', PRP functions optimally when present within a certain therapeutic range [59] and studies report using different concentrations [60,61]. In spite of this controversy, PRP remains an intriguing option for growth factor-based augmentation of bone regeneration, particularly when administered immediately following injury.

VASCULAR ENDOTHELIAL GROWTH FACTOR

VEGF is angiogenic and includes agents of the angiopoietin pathway. Of these major angiogenic regulators, VEGF is particularly important for bone regeneration [62]. As a major regulator of both *vasculogenesis* (i.e., spontaneous formation of blood vessels) and *angiogenesis* (i.e., the sprouting of new blood vessels from existing vessels), VEGF plays an important role in bone tissue regeneration [63]. Vasculogenesis, the *de novo* formation of vascular networks, speaks to the similarities that exist between fracture healing and embryonic bone development. However, with respect to bone regeneration, the angiogenic capabilities of VEGF are of

more interest in this application – that is, there is a heightened need for the creation of blood vessels from pre-existing vasculature during bone regeneration.

VEGF is expressed in hypertrophic chondrocytes, but not in resting or proliferating ones [19]. During osteogenic healing, the soft callus is invaded by blood vessels, resulting in the transformation of a predominantly cartilaginous matrix into osseous tissue. This underscores the importance of vascularization of the soft callus as it allows for it to be gradually replaced by woven bone. With regards to temporal expression, VEGF is expressed predominantly 14 to 21 days following injury [35]. As such, it is a viable candidate for delivery to the bone wound site during the early remodeling and mineralization phases of bone regeneration.

Upregulation and delivery of VEGF inhibitors prevent osteogenesis [64]. Additionally, the inhibition of VEGF receptors impairs the healing of bone defects in mice [32]. VEGF has been shown to function in a synergistic fashion with another group of proteins called the bone morphogenetic proteins [31]. That is, VEGF alone does not promote bone regeneration but rather, it acts in a coordinated way with BMPs to increase the recruitment of mesenchymal stem cells to the defect site and promote their differentiate into active osteoblasts. Studies report that the *dose* of VEGF administered to the injury site needs to be finely tuned in accordance with BMP delivery to avoid adverse effects [65]. With respect to promoting *osteoinduction*, VEGF is an excellent candidate for inclusion in porous scaffolds. Its local release in a programmed profile titrated to bone regeneration may be an effective strategy in treating gap bone defects [65].

BONE MORPHOGENETIC PROTEINS

No chapter on bone regeneration would be complete without inclusion of the BMP family. Marshal Urist discovered bone morphogenetic proteins and determined that demineralized bone matrix induced bone formation as a consequence of its endogenous BMP [66]. Urist's epochal work opened a therapeutic paradise; however, it is a paradise that includes peril for the unwary. We will in this section, underscore the *good, bad and ugly* regarding the therapeutic applications of recombinant human (rh)BMP.

While the actions of BMPs have been known for decades, its specific mechanisms of action were elucidated only just recently [67]. BMPs function by binding to type I and I serine/threonine kinase receptors and activating intracellular signal transduction through SMAD proteins 1, 5 and 8. These signals, when translocated into the nucleus, lead to an upregulation of osteoblast transcription factors such as RUNX2 (or core binding factor 1), COL1A1 (Collagen Type I), and OSX (Osterix) among others (see Fig. 55.4).

The most potent members of the BMP family involved in bone regeneration appear to be BMP-2, -4, and -7 homodimers [68,69]. BMPs are active 'early' in the osteogenic cascade. BMP-4 is predominantly active from zero to five days following injury, with its peak closer to day 5. BMP-2 is active throughout the entire bone regeneration process, culminating in the remodeling of the woven bone to lamellar and Haversian bone and BMP-7 is active following day 14.

The cellular targets of BMPs include pluripotent mesenchymal cells, bone marrow cells, pre-osteoblasts, myoblasts, fibroblasts and neural cells. Key markers of osteoblast upregulation include alkaline phosphatase, osteocalcin, osteopontin and osteonectin – the presence of these markers can be used as indicators of cell differentiation from precursors to the osteoblastic lineage [70]. The effects of BMPs on precursor cells are dose-dependent. It is well documented that appropriate doses of BP can induce differentiation of precursor cells into osteoblasts, as well as stimulate cartilage formation and alkaline phosphatase activity [33]. However, 'low' BMP concentrations *in vitro* may promote differentiation into adipocytes. The general effects of BMP on osteoblasts and periosteal cells, however, involve an increase in DNA synthesis activity and the transcription of genes involved in the synthesis of bone matrix proteins.

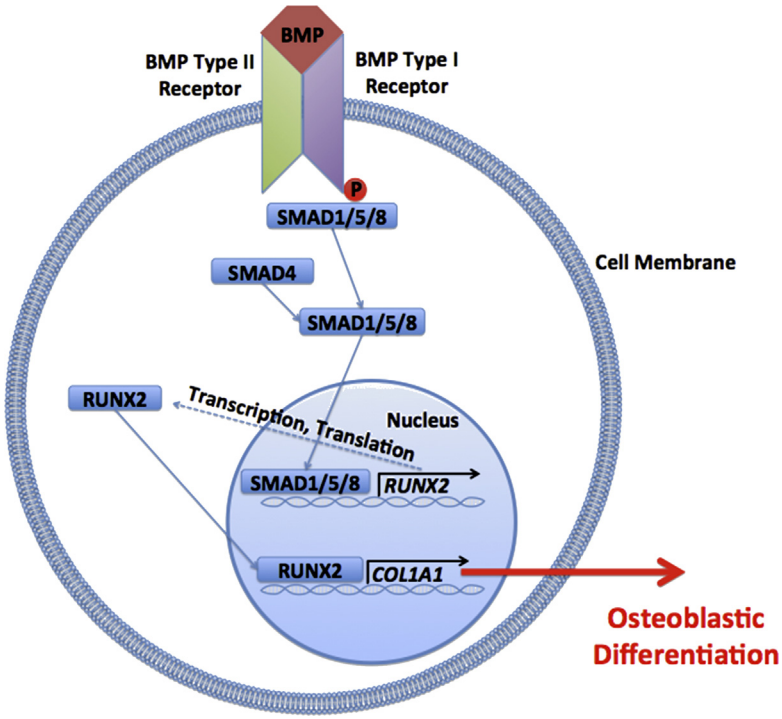

FIGURE 55.4

Key components of the BMP signaling pathway, ultimately leading to bone formation. The *COL1A1* gene is just one of many genes activated downstream of *RUNX2*. Other key markers include Osterix, Alkaline Phosphatase, Osteocalcin, Osteonectin and Bone Sialoprotein though the exact mechanisms by which each of these becomes activated is not yet understood.

The evidence for the role BMPs in bone regeneration is overwhelming. There is a plethora of examples where BMP delivery to bone deficient sites promotes regeneration in a variety of animal models [71–75]. Such overwhelming evidence inspired an industry to focus on clinical applications for BMP though perhaps the rush to the clinic affected judgment. Specifically, the compelling clinical utility of BMP must be countered with caution for potential sinister outcomes. For example, BMPs have been detected in osteosarcomas [76]. In osteosarcomas, the question is whether BMP expression is an effect or a cause of the tumor. Further, a concern with rhBMP's in the clinic has been the supraphysiological dose for clinical effect. The therapeutic effectiveness of rhBMP requires milligram dosing. Consequently, off target effects have been reported with supraphysiological dosing, including calcification of heart valves, heterotopic bone formation, airway obstruction, neuropathies. These outcomes underscore the ineffectiveness of the rhBMP delivery system as well as the potency of rhBMP to promote uncontrolled clinical sequelae.

Biomaterial therapies for bone tissue engineering

One method for the precise, controlled delivery of biologicals and cells to a bone defect site is through their sequestration within synthetic bone graft materials. Synthetic biomaterials allow for the incorporation of cells and biological factors that will have release kinetic profiles and dosing levels matching the physiological profiles of the osteogenic cascade. The following is a focused summary of frequently used biomaterials for bone regeneration.

BIOACTIVE INORGANIC MATERIALS

Currently, there is a wide range of inorganic materials available, with a similar composition to the inorganic matrix of bone, that have gained clinical interest. Among these materials are hydroxyapatite, tricalcium phosphate and bioactive glasses [77,78]. Bioactive inorganic materials, certain ceramics and bioglasses can undergo a time-dependent kinetic modification to their surfaces [79,80]. However, the brittle nature of these materials cannot match bone and, therefore, they are not suitable for load-bearing applications.

POLYMERS

Polymers, whether biological or synthetic, have also attracted clinical enthusiasm. The ability to modify the physical, mechanical and compositional properties of polymers allows for a design with specific clinical targets. Among the most commonly used biological polymeric materials are collagen-based polymers and hyaluronic acid [81]. However, there are concerns regarding the potential risk of disease transmission, immunogenicity, sourcing and relatively weak mechanical properties of these materials [82]. Commonly used synthetic polymers include polycaprolactone (PCL), polyurethane, poly(lactic-co-glycolic acid) (PLGA), and tyrosine-derived polycarbonates. These polymers may be processed using clever synthesis and manufacturing techniques exploiting porogen leaching, phase separation, fiber meshing and microsphere sintering to make 3D-engineered constructs [82–85].

VISION FOR BONE REGENERATION

When designing practical therapeutics for bone regeneration, it is necessary to be cognizant of the regulations set forth by the United States Food and Drug Administration (FDA). The design and validation of therapeutics targeted for the clinic begins on a lab bench but ends with the treatment of patients in hospital operating rooms. As such, we must anticipate regulatory oversight.

However, this is a delicate art; components of the contemporary bone regenerative tool kit are clearly not the answer, but radical new concepts often invoke vociferous and contrary responses from the FDA. In essence, we must strive to achieve a more effective treatment than is currently available but at the same time, be mindful of the eventual reaction from the FDA. This section highlights some novel approaches to bone regeneration that we embrace as steps in the right direction.

The approach for bone tissue regeneration should focus on the complex phenomenon of wound healing, which requires a 4D structure (time, is the 4th element), competent bone-forming cells, and biological stimulants [114]. Contemporary approaches emphasize materials that may deliver a signaling molecule in synchrony with the wound healing and bone regeneration cascades [115]. The most commonly used medical device for recombinant human bone morphogenetic protein-2 (rhBMP-2) delivery is Medtronic's InFuse™, which is essentially a collagen sponge. InFuse™ is currently FDA-approved for maxillary alveolar bone augmentation (i.e., sinus lift procedures) and single level posterior lateral spinal fusion and is an example of a therapy that combines a growth factor-based approach with biomaterial delivery. Another FDA-approved therapy is GEM21S™, which is a rhPDGF-BB and a beta-tricalcium phosphate matrix. GEM21S™ is FDA-approved for periodontal regenerative procedures. In contrast to a single growth factor approach, is a strategy to deliver multiple biological cues to promote osteogenic differentiation as well as the incorporation of growth factor binding peptides, proteins and glycosaminoglycans into scaffolds [82]. However, the daunting challenge with this approach, in addition to achieving the appropriate temporal release profiles, is a regulatory obstacle.

An alternative to the signaling molecule delivery approach is the acceleration of bone healing via a construct made from extracellular matrix (ECM) components, which naturally deliver osteoinductive proteins and signaling cues. Two promising strategies for accomplishing this are to fabricate a scaffold from demineralized bone matrix [116] or to deliver *in vitro* synthesized ECM from marrow stromal cells (MSCs), osteoblasts, or fibroblasts to the fracture site [117]. Materials may be coated with ECM from MSCs or with an adhesive peptide such as fibronectin to promote osteogenic differentiation upon implantation [117,118].

A unique approach to bone regeneration is the use of microparticles to deliver DNA plasmids or siRNAs into cells to induce (or prevent) osteogenic differentiation. Just as upregulating RUNX2 and OSX — two transcriptional regulators for bone formation — may incite osteoblast

lineage progression and in turn, bone formation, silencing RUNX2 and OSX may have the opposite effect. Therefore, siRNAs have been used against these two transcription factors to prevent ectopic ossification [119–121]. A more relevant tactic for promoting bone regeneration is delivering siRNAs against known inhibitors of osteogenic differentiation such as TWIST1. Alternative pathways for promoting bone regeneration are parathyroid hormone (PTH) 1–34 amino acid sequence and BMP-2 signaling. However the advantage of delivering siRNAs and plasmids over other signaling molecules is their stability and a lower risk of eliciting off target effects.

Gene therapy, which was originally proposed for correction of genetic defects, has been reported to induce the expression of molecules that can promote a regenerative response [122]. The most common gene therapies use vectors to enhance the expression of a particular gene [123]. Viruses have been explored as gene delivery vectors, with retroviruses, adenovirus, lentiviruses and adeno-associated viruses being the most promising vectors [124–128]. However, the immunogenic potential of these vectors, as well as the risk of dysregulating normal gene function has kept them from advancing to the clinic [129,130]. Regardless, the natural abilities of viruses to bypass cellular defenses and modify host DNA make them a very powerful tool for guiding the fate of cells at the defect site.

Hydrogels, another bone regeneration therapy option, can be used to deliver cells with the potential to differentiate into bone or vasculature. In order to prepare these implants, cells are seeded in hydrogel constructs and cultured in bioreactors. After the appropriate maturation period, the construct is implanted into a bone defect. Natural hydrogels, such as collagen and hyaluronic acid, have the intrinsic physical and biological characteristics of ECM; they are able to direct cellular function and interact with osteoprogenitors at the implant site [131]. However, the limitations of working with natural hydrogels include difficulty in processing and tailoring them for specific purposes. Additionally, hydrogel degradation products may invoke an immune response. On the other hand, synthetic materials, such as poly-N-isopropylacrylamide (poly-NIPAM), can be manufactured into hydrogels with consistent, reproducible properties. The downside of synthetic hydrogels, however, is minimal cell interaction, and the requirement of tailoring them to direct cellular function [131].

CONCLUSION

Bone is complex tissue-organ system that presents many challenges in the quest to augment its regenerative capabilities. In spite of its natural ability to regenerate, there are limitations to the endogenous regenerative potential. We must harness the intrinsic regenerative capacity of bone and extend it to bone insufficiencies that do not spontaneously regenerate. At this point, we have begun to slowly elucidate the molecular-level biological signals involved in bone regeneration. However, in order to advance bone regeneration therapeutics with twenty-first century science, there is a crucial need to aim for more ambitious, radical lines of research. The *status quo* of autografts, allografts and xenografts are no longer adequate and necessitate the search for transforming alternatives. The majority of current research into bone therapeutics focuses on individual cell-, growth factor- and materials-based approaches that are rather pedestrian and there is a need for radical, innovative strategies.

We offer some starting points: namely, to design therapeutics that work *synergistically* with natural bone regenerative mechanisms. A key component of this approach involves minimizing the interference with these processes that often occurs as a result of implants lacking biocompatibility. Both the implant materials and its degradation products must not extend the destructive phase of bone regeneration. At the same time, it must support the physiological loads associated with bone tissue, though there is a fine threshold for achieving this. The implant must degrade in a coordinated temporal manner with the formation of new bone at

the defect site. Finally, the implant must be osteoconductive, osteoinductive and osteogenic to enhance bone regeneration at the defect site.

In conclusion, in this chapter we highlighted the advantages and disadvantages of contemporary bone regenerative methods. We discussed the importance of the fundamentals of basic osteobiology as a requisite road map for the design and development of bone therapies. We provided our vision for bone regeneration and identified clinical performance criteria that must be defined and met. Finally, we shared some visionary approaches to bone regeneration. It is our hope that this chapter provides some guidance towards improving the regeneration capabilities of the structural *tour de force* that is bone.

Acknowledgments

We would like to acknowledge members of the Bone Tissue Engineering Center at Carnegie Mellon University, specifically April Watt, Eric Hsu, and Amy Donovan for contributing Figures 1, 2 and 3.

CHAPTER 56

Tissue Engineering for Regeneration and Replacement of the Intervertebral Disc

Robby D. Bowles[1], Koichi Masuda[2], Lawrence A. Bonassar[3] and Lori A. Setton[1,4]

INTRODUCTION

The intervertebral disc (IVD) is the fibrocartilaginous part of a 'three-joint complex' that governs motion, flexibility and weight-bearing in the spine (Fig. 56.1). As part of this complex, the disc undergoes a lifetime of 'wear and tear' that contributes to multiple IVD disorders of enormous consequence for human disability and suffering. These IVD disorders are poorly understood musculoskeletal pathologies characterized by multiple anatomic features including internal disc disruption, loss of IVD height, IVD tears, IVD dehydration, and the generation of herniated disc fragments [1–3]. These anatomic features may associate with nerve root compression or irritation, spinal canal narrowing (stenosis or spondylolisthesis), or facet joint impingement that contribute to symptoms of low back pain, neurological deficits and disability that affect between 4 to 33% of the US population annually and has a mean global lifetime prevalence of 38.9% [4–8]. Like most cartilaginous tissues, the IVD is an avascular and alymphatic structure that exhibits little to no capacity for repair following injury, and experiences aging-related cell density losses that may further limit biologically-mediated repair [9]. The extreme mechanical demands on the IVD may also contribute to tissue failure and degeneration, due to the high magnitudes of compressive, tensile and shear stresses and strains that result from joint loading, muscle activation and spinal flexibility. As a result, strategies to intervene in the progression of IVD disorders are met with significant biological and mechanical challenges that frustrate success.

Numerous surgical procedures have been developed to treat IVD disorders that almost completely rely upon reducing motions across the disc space to restore stability during weight-bearing. A very large number of devices have been developed that promote bony fusion

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00056-2

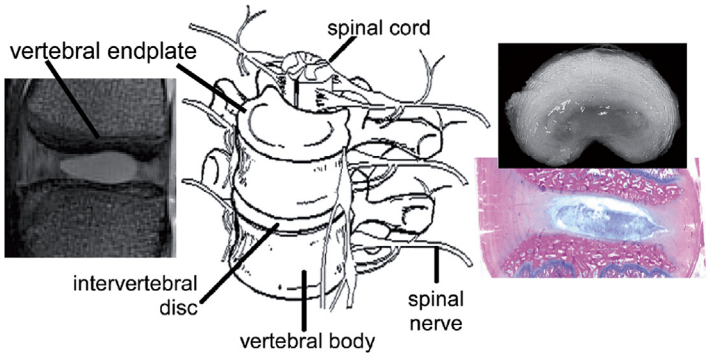

FIGURE 56.1

Schema of spinal motion segment illustrating location of intervertebral disc between superior and inferior vertebral bodies. Image at left MRI appearance of immature lumbar disc with characteristic intense nucleus pulposus region. processes across the disc space, with lesser attention being given to mobile-bearing artificial disc replacements and dynamic stabilization devices that allow but limit motions [10]. In cases where the pathology permits, removal of extruded IVD fragments may be performed in a procedure termed a discectomy. Together these procedures comprise more than 300,000 in-patient hospitalizations annually in the USA alone [11]. The clinical practitioner would not typically entertain the idea of fusing or plating most pathological joints in the body, such as the hip, knee, or shoulder, although this is our twenty first century standard of care for the pathological IVD. There exists an obvious need to develop alternative strategies to not only treat the consequences of IVD disorders, but also to detect and limit the progression of symptomatic IVD pathology.

Success with cellular therapies for articular cartilage regeneration, gene therapy, and *in vitro* regeneration of cartilaginous tissue, has raised hope for tissue-engineered treatments for IVD disorders. Tissue-engineered approaches to IVD regeneration have been focused around implantation of cell-supplemented or acellular biomaterials that may partially or fully replace the IVD structure, as well as delivery of cells or bioactive factors designed to promote the natural repair process. In this chapter, a review of these tissue-engineering strategies will be provided along with evaluations of their adaptation and implementation for treatment of IVD disorders.

IVD STRUCTURE AND FUNCTION

In all structures of the IVD, the extracellular matrix provides physical and biochemical cues that regulate cell-mediated repair or breakdown in mature or aging tissues [12,13]. The native matrix organization and interaction with the local IVD cell population will be important considerations in the design of any tissue-engineered regeneration strategy. The IVD is composed of a centrally situated and gelatinous tissue, the nucleus pulposus, that differs substantially from the more fibrocartilaginous anulus fibrosus, on the radial periphery (Fig. 56.2). On both superior and inferior faces is a cartilaginous endplate that provides an intimate mechanical and biophysical connection between the vascularized vertebral bone and the avascular IVD. Both the anulus fibrosus, with a vascularized periphery, and the cartilaginous endplates are believed to be important routes of nutrient transport to all cells of the IVD [14,15]. Given the very low cell density of the IVD, maintenance of both cellularity and a generous nutrient supply are often held to be critical to a successful biologically-based regenerative strategy.

The immature nucleus pulposus is highly hydrated (>80% water) with extracellular matrix components that include randomly organized type II collagen fibers and multiple forms of

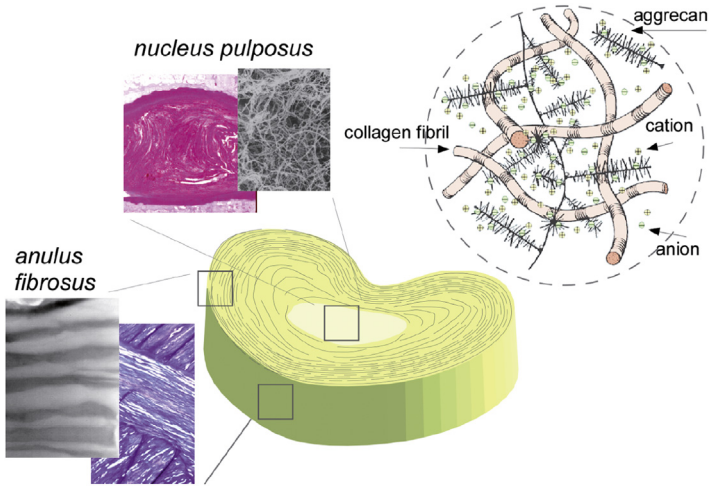

FIGURE 56.2

Schema of different zones and microstructures comprising the intervertebral disc. Anulus fibrosus insets of macroscopic appearance and stained section illustrate the lamellar structure of the tissue. The lamella are comprised of aligned collagen fiber bundles that are oriented with alternating angles of ±60°. Nucleus pulposus insets of a stained section and scanning electron micrograph illustrate the randomly organized network of fine collagen fibers and gelatinous nature of the tissue. Circular inset contains a schema of building blocks for these cartilaginous tissues that include banded type I and type II collagen fibrils, aggrecan and smaller proteoglycans, water and multiple ionic species.

negatively charged proteoglycans (Table 56.1 [16]). A population of large and highly vacuolated cells is present in the nucleus pulposus during development and growth, with a shift towards a more chondrocyte-like cell population by age seven [17–19]. Like all IVD regions, the nucleus pulposus contains multiple collagenous and non-collagenous proteins including types III, V, VI, and IX collagens, elastin, fibronectin and laminin [20,21,22,23–25]. The nucleus pulposus is largely loaded in compression (Fig. 56.3) and experiences high interstitial swelling and fluid pressures, that arise from joint loading and a high density of osmotically active, proteoglycan-associated negative charges [26,27]. Nachemson and co-workers showed, as early as the 1960s, that this interstitial fluid pressure is greater than 0.5MPa (or ~5 times atmospheric pressure) in the nucleus pulposus region [28–30]. An early loss of hydration or tearing in the nucleus pulposus [3], often detected as a loss of MR signal [31], is believed to contribute to a loss of fluid pressurization in the IVD that may lead to herniation or stenosis with aging [32–34]. With loss of fluid pressurization, the load distribution to the anulus

TABLE 56.1 IVD composition and mechanical properties

	Water (% wt)	Collagen (% dry wt)	Proteoglycan (% dry wt)	Other proteins (% dry wt)	Compressive modulus (MPa)	Shear modulus (MPa)	Tensile modulus (MPa)	Interstitial pressure (MPa)[a]

Ranges reported for compositional features and mechanical properties for nucleus pulposus and anulus fibrosus tissue regions of the non-degenerate intervertebral disc. Both composition and mechanical properties of the disc vary substantially with region and with degeneration. Additional mechanical features important to tissue function, such as failure strength, are not shown here.

[a]*Reported also as peak hydrostatic pressures, or swelling pressures.*

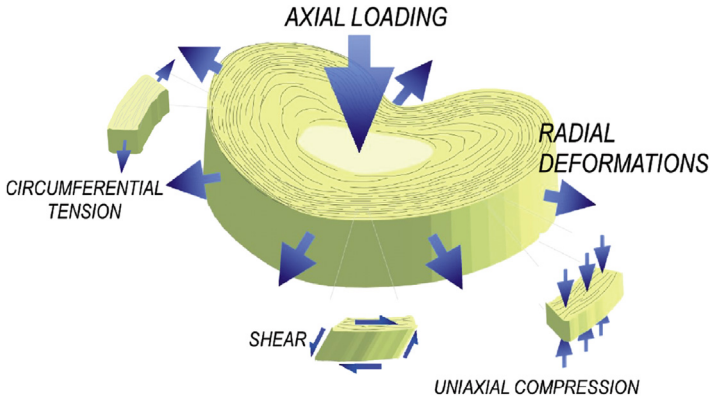

FIGURE 56.3

Axial compressive loading of the intervertebral disc gives rise to a radial deformation, or 'outward bulge', as the disc deforms in response to the compressive load. The high tensile stiffness of the healthy anulus fibrosus in the circumferential direction acts to restrict this outwardly directed deformation. Tissues of the disc will be variably loaded and experience a combination of compression, tension and shear, as shown. Pressurization of the central and gelatinous nucleus pulposus is an important mechanism for load support and load transfer to the anulus fibrosus, and contributes to maintenance of disc height.

fibrosus will shift from a characteristic outward 'bulging' of the anulus to one of inward displacement [29,35–37]. Partial or complete removal of the nucleus pulposus, occurring in some discectomy procedures, may lead to a loss of disc pressurization and disc height that will transfer loads to facet joints of the spine, increase segmental range of motion and impact overall spinal stability. Restoration of this interstitial swelling pressure in the nucleus pulposus, or restoration of MR signal intensity, is an oft-cited criterion for restoration of a healthy functioning disc.

The anulus fibrosus is a lamellar, fibrocartilaginous structure that is highly organized into distinct lamellae [38,39] of highly oriented, and largely type I collagen containing fiber bundles [40,41]. Type II collagen concentration increases towards the innermost region of the anulus fibrosus, as the concentration of type I collagen is diminished. As with the nucleus pulposus, the anulus fibrosus contains proteoglycans within the collagenous extracellular matrix, although at lesser concentrations that vary from outer to inner regions of the tissue. The collagen reinforcement within the anulus fibrosus resists the tensile loads that arise during physiological joint motions, and the swelling effects, that give rise to significant anular bulging and deformation. Consequently, the anulus fibrosus has a very high stiffness in tension, with moduli that vary with the angle of orientation along the principal collagen fiber direction (Table 56.1 [42–47]). Cells of the anulus fibrosus originate from the mesenchyme and exhibit many characteristics of fibroblasts and chondrocytes [13,48–51]. These cells are sparsely distributed in the mature IVD and exhibit very little intrinsic ability for self-repair. Disorders of the IVD that involve displacement or herniation of an IVD fragment are believed to arise from tears in the anulus fibrosus region, and discectomy procedures frequently involve removing a portion of this anulus tissue. Some tissue-engineering strategies are being developed around restoration of healthy anulus fibrosus function or composition (see Anulus fibrosus (AF) Cell-Biomaterial Implants section) in part motivated by a need to repair damage subsequent to intra-discal cell or biologics delivery (see Nucleus pulposus (NP) Cell-Biomaterial Implants section).

The hyaline cartilage endplates of the IVD are important structures that transmit and distribute loads of the spinal column to the discs. Because of their direct contact with the both the anulus fibrosus and the nucleus pulposus, the endplates are believed to be an important route of nutrient transport, particularly to cells of the nucleus pulposus [15,52–55]. With aging, the cartilage endplate will thin, as it undergoes mineralization and eventual replacement by bone. This mineralization of the endplate is thought to impede diffusion and nutrient flow to the

disc, principally the nucleus pulposus that is lacking in an alternate short diffusion pathway. Endplate changes, such as sclerosis, fracture or modified vascularity may be detected by magnetic resonance imaging (MRI) changes [56], and are believed to contribute to symptomatic IVD degeneration [2,57,58]. Thus, tissue-engineering strategies that preserve the health of the endplate without inducing additional damage are believed to be critical to restoring IVD function.

BIOMATERIALS FOR NUCLEUS PULPOSUS REPLACEMENT

In situ hydrating polymers

The complexity of the IVD with its three distinct sub-structures and multiple pathologies, together with very harsh loading conditions and mechanical requirements, has led to challenges for engineering tissue replacements. The concept that nucleus pulposus changes are an important contributor to IVD disorders has led to an initial focus on use of acellular biomaterials for restoration of the nucleus pulposus tissue or function [59–61]. In this section, attention will be given to strategies developed around the concept of using '*in situ* hydrating', synthetic polymers to restore nucleus pulposus hydration and consequently, IVD disc pressure and disc height. The device with the longest clinical history is based on a co-polymeric hydrogel encased in a polyethylene fiber jacket (polyacrylonitrile and polyacrylamide, PDN™, Raymedica Inc., Fig. 56.4). When implanted in a dessicated state, the polymers absorb water while the polyethylene jacket restricts excessive swelling of the polymer. Similar concepts have been developed based on implantation of pre-formed devices constructed from semi-hydrated poly(vinyl) alcohol (Aquarelle™, Stryker Spine Inc.), a co-polymer of poly(vinyl alcohol) (PVA) and poly(vinyl pyrrolidone) (PVP) [62], or modified poly(acrylonitrile) reinforced by a Dacron mesh [63] (NeuDisc™, Replication Medical). The design goal is to exploit implant swelling pressure to restore the high compressive stiffness of the IVD, which is lost upon dehydration or denucleation of the nucleus pulposus [64]. Controlling interstitial hydration of the polymer is important for this class of polymers, however, as excessive swelling can cause implant stiffness and endplate overloading. The relevant stiffness is that measured after placement of the implant, with stiffness values reflecting both the material behaviors of the implant as well as the integration with the containing anulus fibrosus and endplates. An additional concept that has promoted development of these devices is an ability to maintain disc height.

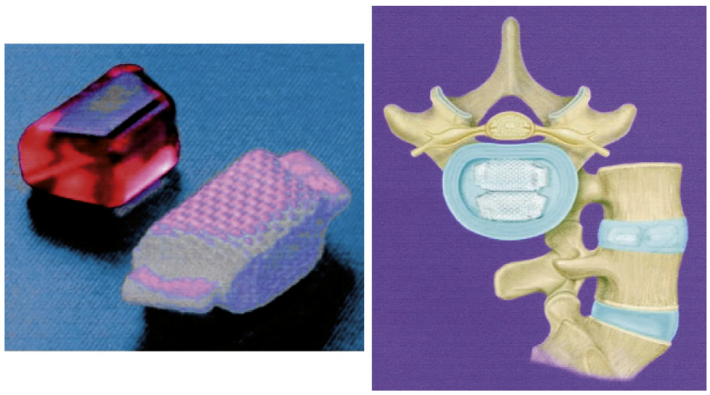

FIGURE 56.4
(Left) Prosthetic disc nucleus (PDN, Raymedica) shown on left composed of an *in situ* swelling synthetic polymer. The pellet is encased in a polyethylene jacket that restricts water imbibition, shown adjacent to the pellet. (Right) The PDN is designed to fit into either the anterior portion of the vacated disc nucleus or the posterior portion. Shown is a schematic of placement of both anterior and posterior components within the nucleus pulposus disc space. *(Modified from Klara and Ray, Spine 2002)*

As with many tissue replacements, there is a long list of requirements that must be satisfied for biomaterials to be used in this application, including the need to achieve:

1) 'Favorable mechanical stiffness' or mechanical properties matched to that of the native structure; in particular, the compressive stresses generated must not exceed the failure strength of the adjacent endplate, in order to avoid endplate fracture or subsidence of the device, IVD height loss, and associated problems;
2) Integration with adjacent structures in order to promote load transfer, minimize device migration or extrusion, and restore stability for the motion segment;
3) Durability, or an ability to maintain physical support over millions of cycles of loading;
4) Minimal generation of wear debris, if appropriate;
5) Standards of biocompatibility; it must not elicit systemic, cellular or immuno-toxicity.

Some of the polymeric devices for nucleus pulposus replacement have experienced device extrusion, endplate failure and endplate sclerosis after implantation, and clinical evaluation has been discontinued. These observations are thought to relate to a mismatch in mechanical stiffness that leads to excessive endplate loading, and poor integration associated with device migration [65,66].

In situ forming polymers

Injectable polymer systems, such as polymers that will undergo a physical transition to a gel-like or solid-like form via crosslinking or thermal or pH-induced transitioning, have been evaluated for placement into a vacant nucleus pulposus space [62,67–70]. Many of the requirements for success of this strategy are similar to that described above, with additional requirement that the polymers must provide the benefit of minimally invasive insertion into the disc space. While many *in situ* forming polymers have been developed for preclinical and clinical evaluation based on varying chemistry platforms, the descriptions below will reveal a tale of failure at the clinical trial stage. Nevertheless, the lessons learned from these diverse strategies provide great insights into the challenges associated with nucleus pulposus replacements.

In situ curing polyurethane is one widely studied *in situ* curing polymer that has been delivered to the disc space through an inflatable polyurethane 'balloon' in order to contain excessive swelling. Despite promising clinical results in Europe, failure to obtain Food and Drug Administration (FDA) approval resulted in the bankruptcy of Disc Dynamics. Despite such failures, a number of *in situ* forming polymers are still under investigation. DiscCell™ (Gentis) is a polymerized water in oil emulsion composite that is capable of curing in 5–7 minutes after delivery to the disc space and reproducing the viscoelastic behavior of the nucleus pulposus (NP). An alternative approach is based on use of chemically crosslinked biopolymers that can form following injection into the IVD space. Nucore™ (SpineWave Inc.) is a protein hydrogel developed from a silk and elastin peptide containing a sequence that is chemically crosslinked at the time of injection [65]. This crosslinking confers an extra stiffness to protein polymers that is necessary to achieve satisfactory stiffness values for a disc implant. This implant system has been able to maintain disc stiffness and to restore disc height when implanted, providing evidence that successful integration is being achieved upon injection. Furthermore, systems composed of native IVD polymers, such as the elastin peptide sequences, may confer some additional benefit as recognized components of the body.

Virtually all of the above-described strategies are focused on approaches to reconstruct the nucleus pulposus following the observation that loss of tissue hydration and structure is a dominant contributor to intervertebral disc degeneration. However, introduction of these biomaterials into the nucleus pulposus via needle puncture necessarily disrupts the structurally intact anulus fibrosus, which can be a significant contributor to disc degeneration [71,72]. For this reason, recent attention has focused on the development of biomaterials

strategies for anulus repair, using sutures [73], anchored sutures [74], polyethylene annular closure devices [75], mesh [76], and PMMA injections [77]. These approaches are promising as they move through clinical trials of implant feasibility in the current period, but their ability to promote repair long term may be limited and they may require tissue-engineering solutions to repair the AF.

CELL-BIOMATERIAL CONSTRUCTS FOR IVD REGENERATION

A persistent limitation of acellular, materials-based replacements of the IVD is their biologically-mediated, or mechanically-induced failure due to the harsh loading conditions and bioactivities of cells within the disc space. These challenges are rooted in the fact that the materials used for such applications have no capacity for self-renewal nor self-repair. This has led to increasing interest in tissue-engineering methods to regenerate new IVD *in situ* or to transplant IVD tissue that has been generated *ex vivo*. Such strategies have been employed to augment repair of other types of cartilage, most notably articular cartilage, and meniscus, which share some features of the harsh biologic and mechanical loading environment within the IVD.

NP cell-biomaterial implants

As in other cartilage tissue-engineering applications, a main strategy for IVD regeneration has been the inclusion of cells with biomaterials to enable production and long-term maintenance of newly generated tissue. Biomaterials that enable appropriate cellular phenotypes and matrix biosynthesis, and that sometimes enable polymeric degradation or resorption, have been proposed as alternative implantable biomaterials and have been studied largely *in vitro*. The goals for use of these scaffolds are similar to that for other biomaterial implants, with the added requirements that the biomaterial must generate no cytotoxic or immunogenic degradation or breakdown fragments and that new matrix formation is enabled. Studies of cell-biomaterial constructs cultured *in vitro* have demonstrated potential for many materials (Table 56.2), including thermosensitive gels such as chitosan, modified chitosans and elastin-like polypeptides [78–81], self-associating gels composed of agarose, collagen and fibrin [82–84] or modified forms of these same materials, native tissue constructs such as intestinal submucosa [85], crosslinkable alginates, polyethylene glycol, poly(glycolic acids) and more [86–91]. *In vitro* studies with these materials are based on evaluating new matrix formation and sometimes degradation characteristics, through culturing native disc or other cell types within these matrices. Hydrogels, such as alginate and gelatin, have been used most commonly for engineering nucleus pulposus tissue, likely due to the fact that such materials reasonably approximate the gel-like properties of the native tissue. Cells of different origin, including native IVD cells, stem cells and chondrocytes, are capable of synthesizing and depositing collagen and glycosaminoglycans within these hydrogels although there is little agreement upon the targeted composition necessary to achieve a satisfactory tissue construct. This is a particularly challenging determination for the intervertebral disc as the matrix contains varying amounts of both types I and II collagen, so that the exclusive presence of type II collagen does not serve as a phenotypic matrix marker as is the case for articular cartilage.

Anulus fibrosus (AF) cell-biomaterial implants

Efforts to regenerate anulus fibrosus have also involved gels such as alginate, agarose, gelatin and collagen as well as fibers or sponges made from materials such as poly(glycolic) acid, polylactic acid, poly(ε-caprolactone), collagen, silk, hyaluronic acid and/or glycosaminoglycans. Oftentimes, the same scaffolds evaluated for nucleus pulposus cells are also studied with cells of the anulus fibrosus, with findings that generally illustrate the importance of cell origin in determining the resultant extracellular matrix synthesis. A common observation, however, is that cells of either origin that are maintained in a rounded morphology tend to generate more

TABLE 56.2 Representative IVD tissue engineering studies

Material	Cell type	Cell source	Cell density	*In vitro/in vivo*	Assessment
PCL [1]	AF, NP	bovine	5 x 10^3 /cm^2	*in vitro*	Histology, SEM, gene expression
Alginate [2]	AF, NP	porcine	4 x 10^6/ml	*in vitro*	DNA, ECM analysis
Gelatin/C6S/HA [3,4]	NP	human	20 x 10^6/ml	*in vitro*	Histology, DNA, ECM analysis, gene expression
CPP [5,6]	NP	bovine	16 x 10^6/cm^2	*in vitro*	Histology, mechanical analysis
Agarose, collagen [7]	AF	human	0.2 x 10^6/ml	*in vitro*	Histology, ECM analysis
Gelatin, PLA [8]	NP	porcine	5 x 10^6/ml	*in vitro*	Histology, ECM analysis, gene expression
Collagen/GAG [9,10]	AF	canine	40 x 10^6/ml	*in vitro*	Histology, ECM analysis
Collagen/HA [11]	AF,NP	bovine	13 x 10^6/ml	*in vitro*	Histology DNA, ECM analysis, gene expression
Alginate [12,13]	AF,NP	porcine	1–10 x 10^6/ml	*in vitro*	Histology, gene expression, mechanical analysis
Collagen [14]	AF	lapine	10 x 10^6/ml	*in vivo*	Histology

type II collagen, characteristic of hyaline cartilage, whereas those that are cultured in an elongated morphology generate more type I collagen (Fig. 56.5).

A main challenge has been reproducing the intricate lamellar arrangement of collagen fibers that give the anulus fibrosus its unique mechanical properties and the cells their unique morphology. For this reason, anulus tissue-engineered materials have moved toward scaffolds that mimic the apparent collagen architecture. Some investigators have developed synthetic and natural polymeric scaffolds with anisotropic features such as an oriented honeycomb structure [92], aligned collagen gel fibers [84], oriented electrospun fibers [93–96], and oriented silk fibers [97]. One approach is based on engineering AF to contain oriented and lamellar electrospun PCL fibers with tensile mechanical properties on the order of native AF [98] (Fig. 56.6). These results are indeed suggestive of the potential to engineer anisotropic collagenous tissues.

Efforts to tissue engineer AF have been constructed in combination with NP tissue-engineering techniques to produce composite TE-IVD implants (see next section), as well as with the hope

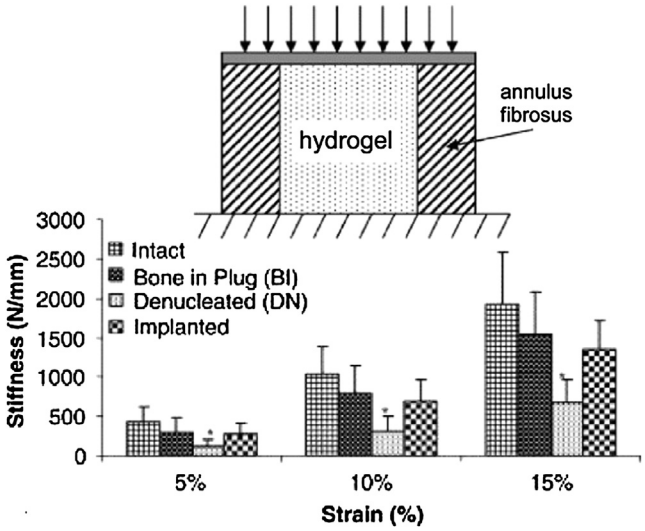

FIGURE 56.5
Top: (Left) Anulus fibrosus cells are highly elongated in the outermost regions of the tissue, but adopt a more rounded morphology in the inner tissue regions, as shown (Middle). (Right) When anulus fibrosus cells are embedded in an alginate hydrogel, they assume a rounded morphology and express matrix proteins associated with chondrocytes such as type II collagen and aggrecan (Bottom). *(bottom figure modified from Le Maitre et al., Arth Res Therapy 2005 with permission)*

to repair degenerated or disrupted AF. One such study demonstrated the usefulness of using a tissue based strategy to repair an AF defect by patching AF defects with small intestinal submucosa (SIS) anchored by titanium bone screws [99]. The SIS patch produced new integrated tissue at the defect site and increased the capacity of the IVD to pressurize post anulotomy and increased disc hydration compared to anulotomy-only levels after 24 weeks in an ovine model. In another study aimed at producing a tissue-engineering strategy to repair AF defects, genipin crosslinked fibrin hydrogels were developed that demonstrated mechanical properties on the order of AF, maintained cell viability, and could maintain adhesion to native AF tissue under physiological load [100]. Many of the AF tissue-engineering strategies discussed previously are being considered for AF defect repair. However, most of these promising studies have been performed *in vitro* and will need to demonstrate effective repair of annular defects *in vivo* before being advanced to the clinic.

Composite cell-biomaterial IVD implants

Cell-based regeneration of the IVD *ex vivo* is complicated by the inherent multi-component structure of the IVD, which includes two distinct regions, the anulus fibrosus and the nucleus pulposus. Given this added complication, it is not surprising that there are fewer examples of efforts to engineer in integration of the multiple components of the IVD *ex vivo*. This can prove to be a critical limitation, as integration is needed to insure proper load transfer and to limit damaging motions during disc loading. However, seminal studies in humans have demonstrated the successful transplantation of IVD allografts in place of herniated cervical IVDs [101]. At a five year follow up, the IVD allografts had maintained stability and mobility while the patients showed no signs of significant cervical pain. This suggests that composite cell-biomaterial IVD implants are a worthwhile endeavor. In studies conducted by Bonassar and co-workers, IVD regeneration was attempted in the native disc space of an athymic rat with a fully integrated scaffold combining contracted collagen gels as a scaffold for anulus fibrosus, and a crosslinked alginate hydrogel as a scaffold for nucleus pulposus tissue [102,103] (Fig. 56.7). Primary cells for culture within each scaffold region were derived from the corresponding native IVD tissues, and the resultant cell-laden scaffolds were implanted in place of the native disc in athymic rats for a period of six months. Results illustrate spatially-directed matrix regeneration with extracellular matrix that exhibited distinct morphologies, contained native levels of collagen and glycosaminoglycans, and was functionally integrated with native tissue. In biomechanical tests, the motion segments containing the composite tissue-engineered discs were found to have a compressive modulus and permeability to flow similar to the native motion segments. Thus, this approach illustrated an ability for cell-laden

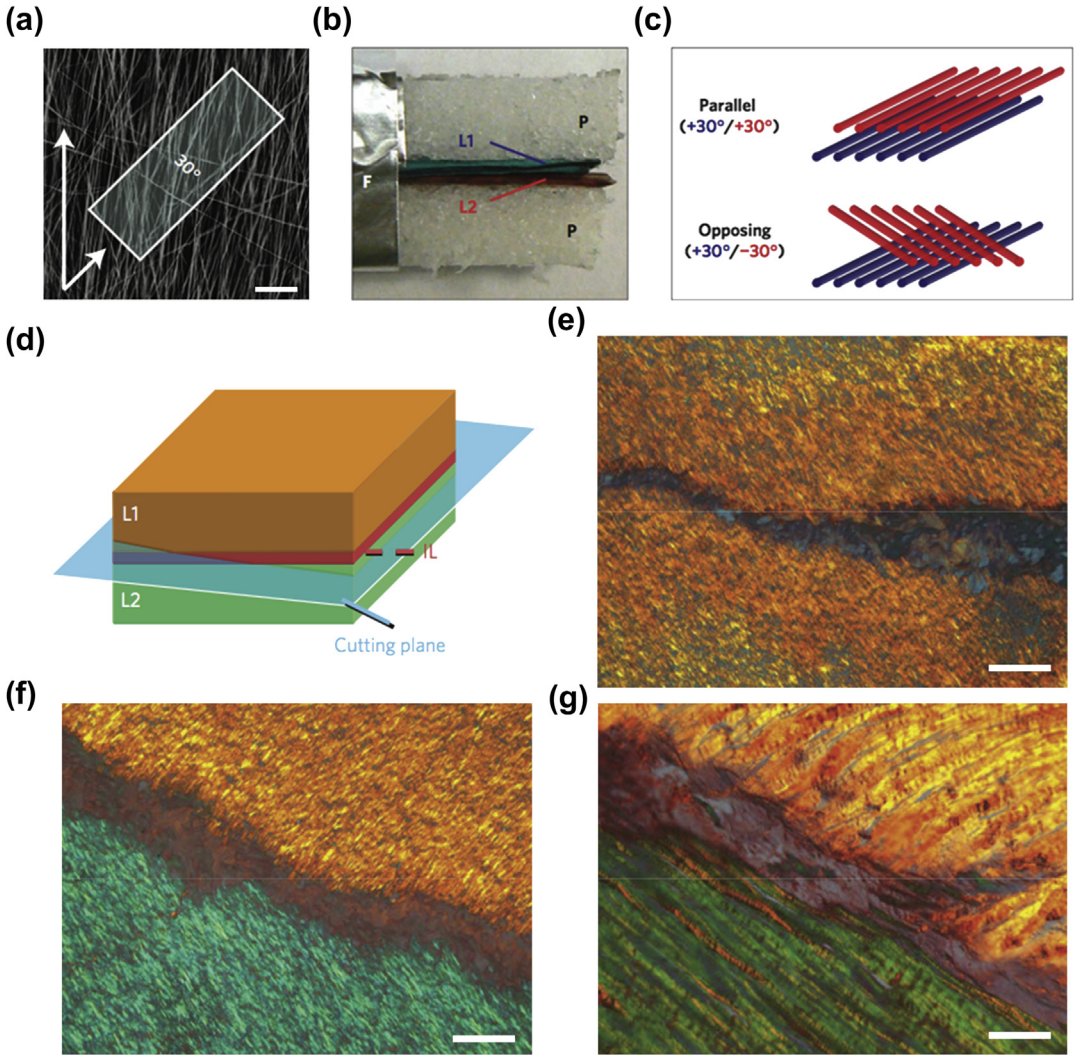

FIGURE 56.6

Fabrication of fiber oriented AF tissue constructs. (a) Scaffolds were excised 30° from the prevailing fiber direction of electrospun nanofibrous mats to replicate the oblique collagen orientation within a single lamella of the annulus fibrosus. Scale bar: 25 μm. (b) At zero weeks, MSC-seeded scaffolds were formed into bilayers between pieces of porous polypropylene and wrapped with a foil sleeve. P: porous polypropylene; F: foil; L1/2: lamella 1/2. (c) Bilayers were oriented with either parallel (+30°/+30°) or opposing (+30°/−30°) fiber alignment relative to the long axis of the scaffold. (d) Sections were collected obliquely across lamellae, stained with Picrosirius Red, and viewed under polarized light microscopy to visualize collagen organization. When viewed under crossed polarizers, birefringent intensity indicates the degree of alignment of the specimen, and the hue of birefringence indicates the direction of alignment. L1/2: lamella 1/2; IL: inter-lamellar space. (e) After 10 weeks of *in vitro* culture, parallel bilayers contained co-aligned intra-lamellar collagen within each lamella. (f, g) Opposing bilayers contained intra-lamellar collagen aligned along two opposing directions (f), successfully replicating the gross fiber orientation of native bovine annulus fibrosus. (g) In engineered bilayers, as well as the native annulus fibrosus, a thin layer of disorganized (non-birefringent) collagen was observed at the lamellar interface. The distribution of collagen fiber orientations was determined by quantitative polarized light analysis [45]. Scale bars: 200 μm (b,c), 100 μm (d). *(Figure modified with permission from Nerurkar et al. Nature Materials, 2009)*

scaffolds to regenerate integrated functional extracellular matrix with some of the functional and compositional features of the native tissue in the native disc space.

Recent studies have further explored development of composite IVDs using a variety of materials and techniques. Composite IVDs have been produced with anulus fibrosus composed of polyglycolic acid/polylactic acid (PGA/PLA), electrospun poly-L-lactic acid (PLLA), contracted collagen gel, silk, electrospun polycaprolactone (PCL), and demineralized bone matrix gelatin and nucleus pulposus composed of alginate, hyaluronic acid, hyaluronic acid/fibrin, agarose, silk hydrogel, and collagen II/hyaluronate/chondroitin-6-sulfate

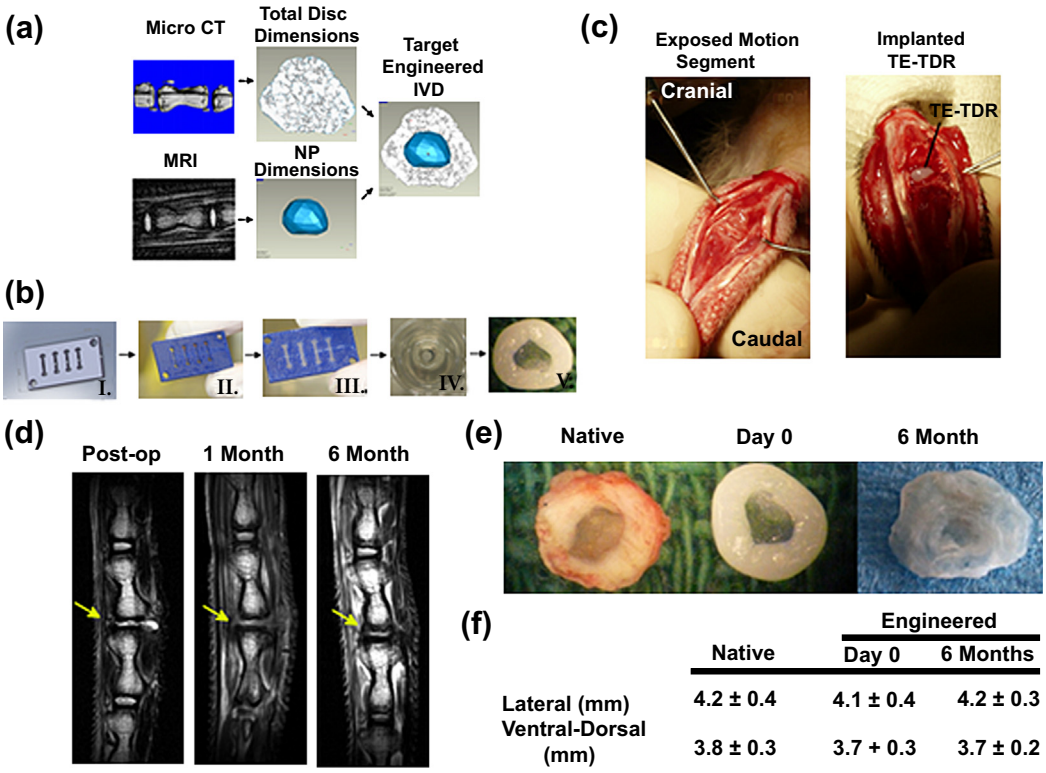

FIGURE 56.7

(b) Fabrication of TE-IVD. (i) NP dimensions used to design injection molds via computer-aided design. (ii) Injection mold 3-D printed out of acrylonitrile butadiene styrene plastic. (iii) Cell-seeded alginate was injected into mold, removed, (iv) placed in center of 24 well plate, and cell-seeded collagen was poured around alginate NP. (v) After 2 wk of culture, cell-seeded collagen contracts around the NP to form composite TE-IVD. (c) Intraoperative images showing exposed caudal 3/4 disc space and implanted TE-IVD. (d) T2-weighted MRI of implanted disc space (marked by yellow arrows) and adjacent native levels immediately postoperative, at 1 month, and 6 month after implantation. (e) History of TE-IVD in native disc space. Intraoperative photo showing explanted native IVD next to the TE-IVD (day 0) that was implanted in its place and TE-IVD after being implanted into native disc space for 6 mo. (f) Size of engineered IVD compared to native IVD. Measurements were taken along the lateral and ventral-dorsal planes of the engineered and native IVD. Engineered IVD measurements were taken at day zero prior to implantation (n =12) and compared to explanted native discs (n = 12). Engineered IVD measurements were also taken after 6 months of implantation (n = 12). *(Reprinted with permission from Bowles et al. PNAS, 2011).*

[97,102,104–108]. In one of the earliest examples of an integrative tissue-engineering approach, investigators generated nucleus pulposus tissue *in vitro* by culturing primary bovine nucleus pulposus cells at high density upon a calcium polyphosphate substrate, in order to mimic the natural integration of the nucleus pulposus against the vertebral endplate (Fig. 56.8 [109]). The nucleus pulposus cells formed tissue with a proteoglycan, but not collagen content matched to that of the native nucleus pulposus. Importantly, functional properties in some testing configurations approached that of the native tissue. Additional work will be required in adapting these integrative tissue-engineering approaches to insure that mechanical integration with adjacent tissues is adequate, but these studies focused on generating integrated nucleus-bone or nucleus-anulus are an important step in illustrating feasibility for this approach.

Assessment of the success of IVD tissue-engineering efforts is critical to moving this technology toward clinical application. A majority of studies have focused on generating new IVD *in vitro*, with fewer documenting tissue formation and integration in preclinical evaluations *in vivo*. To date, the most common tool for assessment of newly generated IVD tissue has been histology, although analysis of gene expression and extracellular matrix composition has been frequently employed to confirm the appropriate phenotypic behavior in engineered IVD. *In vitro* studies have laid the foundation for necessary and/or sufficient characteristics of a successful

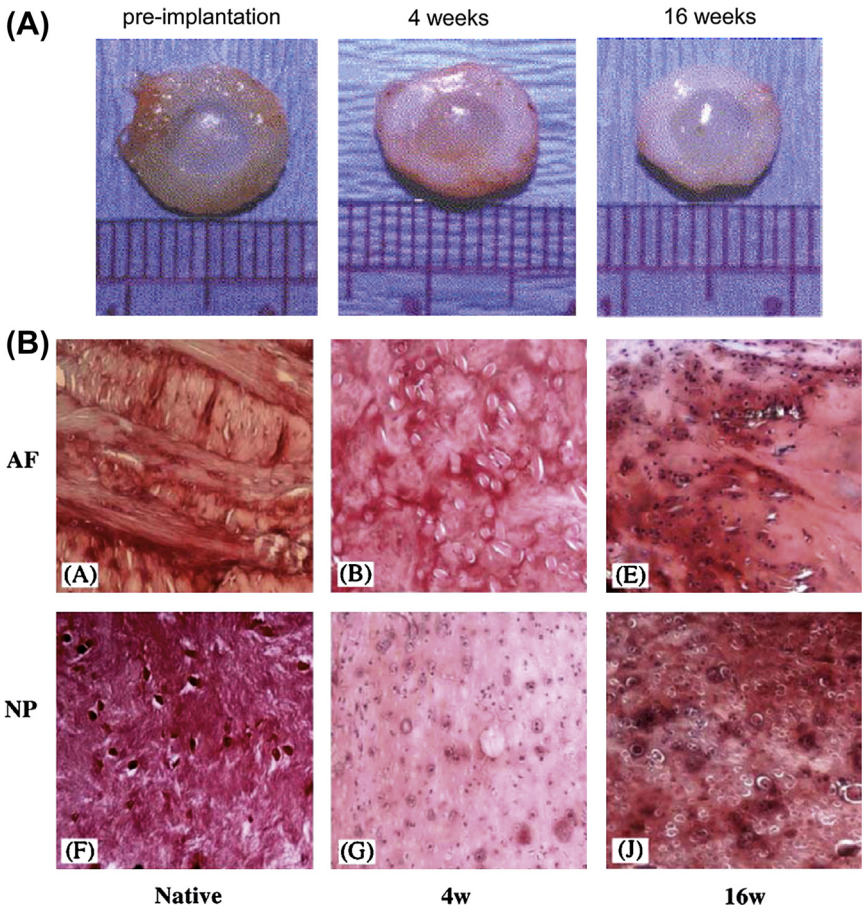

FIGURE 56.8
Histological appearance of *in vitro*-formed tissues showing newly generated nucleus pulposus (NP) tissue. Histological appearance of (a) *in vitro*-formed cartilage at two weeks (time at which the NP cells would be seeded); (b) *in vitro*-formed NP-cartilage—calcium pyrophosphate composite (triphasic construct) at eight weeks following seeding of chondrocytes; and (c) *in vitro*-formed cartilage tissue alone (biphasic construct) at eight weeks. Biomaterials V27, 2006, pp. 397–405).

scaffold for anulus fibrosus and nucleus pulposus replacement. From these studies, for example, it is evident that a high starting cell density, and a high degree of initial matrix stability is essential for promoting long term construct stability and matrix accumulation to eventually restore mechanical function and swelling pressure [110]. Mechanical analysis of engineered IVD tissue is essential in assessing the formation of functional IVD tissue, however, both for nucleus pulposus implants that must restore spinal stability, as well as anular repair strategies that must withstand repeated cycles of nucleus pressure. *In vivo* studies may also evaluate an ability to restore disc height as a common outcome variable, as well as clinical MRI imaging to access *in vivo* tissue hydration. *In vivo*, largely preclinical work has begun to verify that engineered IVD tissues may eventually be capable of restoring disc height, maintaining spinal stability and flexibility, and retarding disc degeneration in pathological tissues.

CELLULAR ENGINEERING FOR INTERVERTEBRAL DISC REGENERATION

Given the relatively small numbers of studies in the area of IVD tissue engineering, there is a surprising amount of breadth to not only the biomaterials, but also the cell sources

utilized for regeneration. The question of cell source is of particular note for IVD tissue engineering, given that the availability of autologous disc cells is extremely low in the adult, and that the phenotype of cells varies so substantially with both spatial position and with age. In animals studied for IVD tissue engineering *ex vivo*, the origin of cells in the nucleus pulposus may be partly notochordal or mesenchymal, depending on the age of the animal in question. As such, the choice of species used as a source of cells may be quite important. Due to the ease of availability, porcine and bovine cells are the most commonly used, with other efforts reporting the use of cells of canine, lapine, and ovine origin as well as human. However, cells derived from bovine or ovine tissues may be exclusively mesenchymal in origin while those derived from porcine, lapine or rodent tissues may be largely notochordal. These phenotypic differences add an additional and unique complicating factor for investigators studying preclinical models for IVD tissue regeneration.

Given the very limited availability of native IVD cells that can be effectively harvested for tissue engineering, there has been interest in using other cells as sources for these efforts. The primary target for other sources has been stem cells derived from sources such as bone marrow [111], embryonic cell lines [112] and adipose tissue [113]. A major challenge in this approach has been the development of methods to guide the development of stem cells toward phenotypes found in the IVD (see next section). This has been attempted through manipulation of the culture medium and gas conditions [114], as well as co-culture with primary cells from the IVD [115–117]. The more recent development of induced pluripotent stem cells (IPSC) has also provided the possibility for an additional cell source for cell delivery to treat musculoskeletal disorders [118,119]. In comparison to use of adult primary disc cells derived from often pathological or degenerated IVDs, the use of autologous mesenchymal stem cells or progenitor cells may be most promising to the future of *ex vivo* tissue-engineering strategies that rely upon cell supplementation.

In addition to origin, cell density is also known to have a profound effect on the efficacy of the tissue-engineering process. Here there has been a great deal of variability in protocols, with studies reporting densities of delivered cells ranging from $0.2–50 \times 10$[6] cells/ml. While the lower end of this scale is likely more reflective of the actual cell density in nucleus pulposus tissue, the densities at the higher end of the scale are more in line with those known to be effective in generating other types of cartilage [120]. A critical concern for disc tissue regeneration, particularly in the case of strategies that employ high cell densities, is the issue of nutrient and gas supply necessary to maintain cell viability and health. The IVD is both avascular and alymphatic, meaning that the transport of nutrients and oxygen is driven largely by diffusion from the vascularized periphery and through the vertebral endplates [14,15,121–123]. It is noteworthy that calcification and endplate changes in the degenerating IVD can lead to impaired nutrient transport, which is linked to decreased cell viability [53,54,124]. Thus, supplementation of scaffolds with very high cell densities may not be optimized for long term survival in the largely hypoxic and glucose-poor, lactate-rich environment within the IVD (Fig. 56.9). This concern has been expressed for cell-laden IVD scaffolds, but has not been directly addressed nor investigated as an issue in IVD tissue regeneration.

Cellular supplementation in the IVD

If the local environment within the IVD is conducive to the survival of cells, direct cell supplementation without biomaterial scaffolds may hold promise for IVD repair. This strategy has been pursued by several groups in preclinical studies, using either IVD cells, chondrocyte-like cells, or progenitor cells. In the first reported work, nucleus pulposus cells from the rabbit were inserted following removal of nucleus tissue, and showed some beneficial effects in inhibiting the degenerative IVD changes of nucleotomy [125]. Similar procedures have also shown the effectiveness of autologous disc cell implantation in both a sand rat

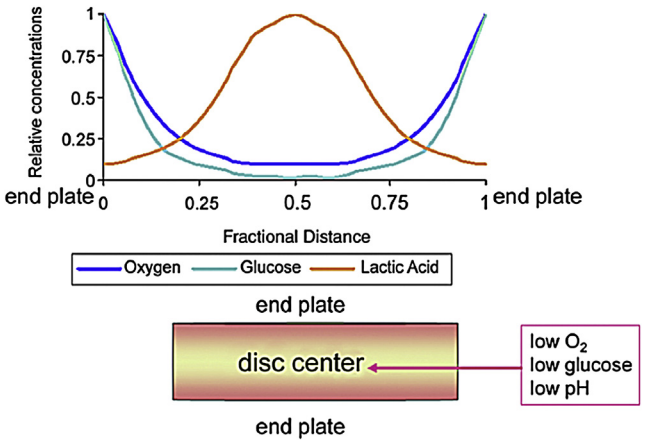

FIGURE 56.9
Schematic showing the concentrations of oxygen, glucose, and lactic acid across the disc from end plate to end plate. *(Reprinted with permission from Grunhagen et al. JBJS, 2006).*

model of spontaneous disc degeneration [126] as well as a canine model of disc degeneration [127]. Furthermore, work by Nomura and co-workers has shown that supplementation with allogeneic nucleus pulposus cells did not induce any appreciable host-versus-graft rejection response, and also retarded disc degeneration in a rabbit nucleotomy model [128].

Limitations will always exist in obtaining sufficient numbers of autologous or allogeneic disc cells from a single site, as well as concerns about impaired cellular activity for the native cells. Some studies have thus focused on using co-culture of nucleus pulposus and anulus fibrosus cells to stimulate cell metabolism prior to re-insertion [129]. These approaches were shown to be effective in delaying some degenerative features such as the loss of disc architecture following re-insertion of the 'activated' cells in a rabbit model. Still, other studies have focused on delivery of cells through delivery of allograft tissues based on the concept that preservation of extracellular matrix is an equally important criteria for regeneration [109,130,131]. Indeed, nucleus pulposus cell insertion has been shown to result in a slightly poorer outcome than insertion of the allograft nucleus pulposus tissue itself, indicating that inclusion of the extracellular matrix in an allograft may be as or more important than the absolute number of cells inserted [128]. These findings have led to the development and investigation of matrix-based cell carriers derived from hyaluronan, laminins, collagen and engineered polypeptides [132,133].

Beginning in 2002, a prospective, controlled, multicenter study was undertaken to compare autologous disc cell transplantation plus discectomy against discectomy alone [134]. The interim analysis of the first 28 patients at two years showed a clinically significant reduction of low back pain in the transplantation group compared to the discectomy group, suggesting a potential benefit of the cell transplantation strategies described above. Little is understood about the mechanism by which the cell supplementation provides this benefit, although disc hydration but not disc height was found to be higher in the patients receiving the cell transplantation compared to the discectomy group. This clinical study led to the development of at least one product termed ADCT, or autologous disc chondrocyte transplantion with or without a hydrogel carrier (NOVOCART), that has been widely used and approved in Germany since 2008. The advancement of these new therapeutic modalities underscores the role of autologous cell-mediated biological factors in regulating symptoms with IVD pathology, and illustrates a potentially important role for sustaining cell viability of the IVD in inhibiting this pathology.

Clinically, the autologous re-insertion of the nucleus pulposus cells into the degenerative disc remains challenging [135]. As a source of cells for transplantation, mesenchymal stem cells (MSCs) that can be harvested from a patient's own bone marrow or adipose tissue are a possible candidate [114,136,137]. *In vitro*, the differentiation of MSCs into nucleus pulposus-

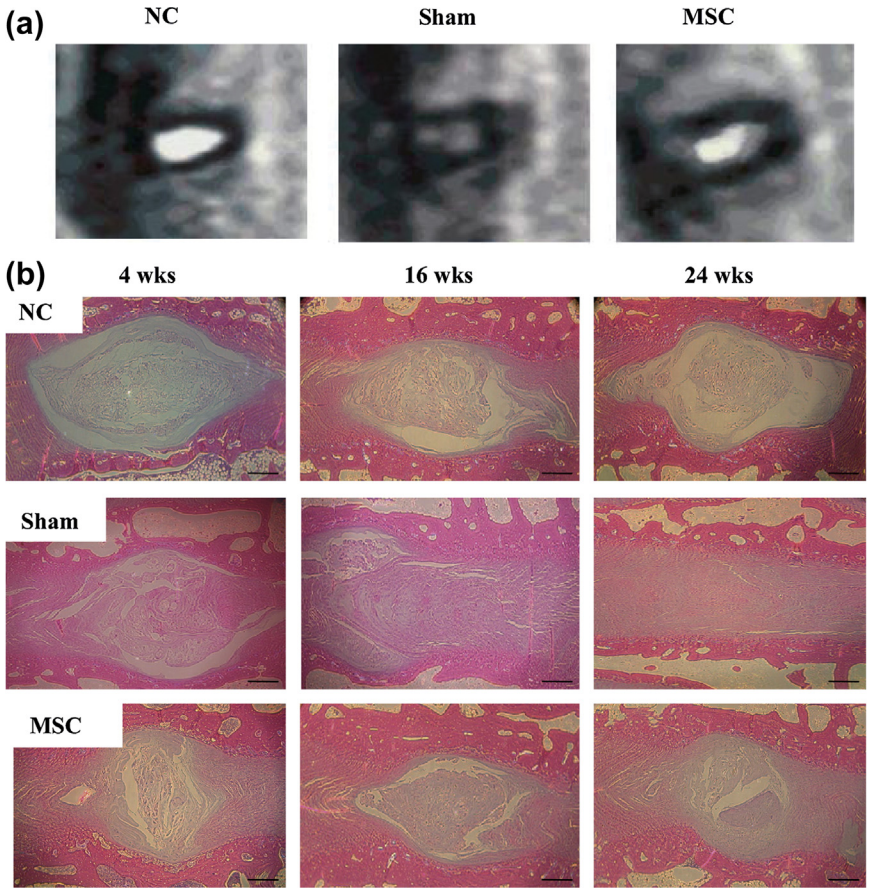

FIGURE 56.10
MRI image of normal control, sham (disc degeneration model) and MSC transplanted rabbits taken 26 weeks post induction of degeneration (24 weeks after MSC transplantation in MSC transplanted animals). Images of sham and MSC transplanted animals are among the best model obtained by means of degeneration and restoration. Significant recovery of T2-weighted signal intensity is seen in discs of MSC transplanted discs compared to very low signal intensity in sham. The arrows indicate the garlic oil supplement capsules used for standardizing control. (graciously provided by Dr. Sakai) Fig. 56.11. Histological changes seen over after MSC transplantation in discs. Left = 4 weeks and right = 24 weeks after transplantation. Control group discs show oval shaped nucleus with no collapse of the inner annular structure. Sham operated disc show collapse of the inner annulus morphology from four weeks (six weeks after induction of degeneration). Fibrotic change in the nucleus due to cell invasion from the surrounding region is completed at 24 weeks. MSC group discs showed relatively preserved inner annulus structure with minimal fibrosis in the nucleus region. Bar = 200μm. *(Graciously provided by Dr. Sakai)*

like or chondrocyte-like cells has been shown under hypoxic and high osmotic conditions, [114] and also with TGF-β stimulation [138]. Preclinical studies have followed injection of autologous MSCs embedded in atellocollagen gel as well as direct injection of MSCs into rabbit or rat models of IVD degeneration, and observed an ability for these cells to differentiate or regenerate matrix [137,139,140]. In one set of studies, transplantation of MSCs with an atelocollagen carrier into the rabbit discs effectively maintained disc height, MR signal intensity and the histological appearance of the nucleus pulposus and anulus fibrosus regions at 24 weeks after transplantation (Fig. 56.10) [139]. Some of the positive outcomes observed for tissue regeneration in the animal models may arise from factors released from MSCs, or direct contact with MSCs, which may enhance metabolism of native disc cells [141,115]. These findings have supported expansion of the use of MSCs into clinical trials, including one by Mesoblast Limited that has been cleared for Phase 2 clinical trials in the United States to test the delivery of adult mesenchymal precursor cells to the degenerated disc. We will have much to learn from these early studies of clinical outcomes following MSC delivery to the pathological disc, with findings and protocols that are likely to advance future research.

GROWTH FACTORS AND OTHER BIOLOGICS FOR INTERVERTEBRAL DISC REGENERATION

In vitro studies

Disc cells modulate their activity by a variety of substances, including cytokines, growth factors, enzymes and enzyme inhibitors in a paracrine and/or autocrine fashion [142]. Tissue-engineering approaches to disc regeneration have been based on attempts to upregulate important matrix proteins (e.g., aggrecan), or to downregulate pro-inflammatory cytokines

[e.g., interleukin-1 (IL-1); tumor necrosis factor-α (TNF-α)] [143–150] and matrix-degrading enzymes [e.g., matrix metalloproteinases (MMPs); aggrecanases] [135,151–153]. The delivery of these modulating biologic agents, with and without scaffolds and/or through cell transplantation, has been the subject of many years of efforts in tissue engineering. *In vitro* studies have shown that the rate of matrix synthesis or gene expression for matrix proteins, principally proteoglycan or collagen, can be increased several-fold in IVD cells in the presence of one or a combination of these growth factors: supplemental transforming growth factor-β (TGF-β) [154,155] and its sub-type TGF-β3 [156–158], osteogenic protein-1 (OP-1; otherwise known as bone morphogenetic protein-7, BMP-7) [90,159–161], BMP-2 [162,163], BMP-12 [164], growth and differentiation factor-5 (GDF-5) [165,166], epidermal growth factor (EGF) [155,167], or insulin-like growth factor-1 (IGF-1) [168]. Other studies have demonstrated the potential of these growth factors, as well as platelet-derived growth factor (PDGF), to reduce cell apoptosis [162,155,169] and to promote cell proliferation [155,170]. Several recent studies examined the effects of the *in vitro* co-stimulation of IVD disc cells by two or more growth factors. In micromass cultures of fetal outer anulus cells, TGF-β1 and IGF-1, both alone and in combination, stimulated the synthesis of sulfated glycosaminoglycans, and collagen types I and II [171]. While TGF-β1 and BMP-2 each had strong anabolic effects on nucleus pulposus cells cultured in an atelocollagen scaffold, there were no additive or synergistic effects on cell proliferation and matrix synthesis [172]. Autologous platelet-rich plasma (PRP), which contains a variable mixture of growth factors, including TGF-β1, PDGF, and IGF-1, has also been shown to be an effective stimulator of cell proliferation, proteoglycan and collagen synthesis, as well as proteoglycan accumulation, when added to porcine IVD cell cultures *in vitro* [173]. In human nucleus pulposus cells, a 'growth factor cocktail' of TGF-β1 at 1 ng/ml in PRP induced cell proliferation and differentiation and promoted the *in vitro* formation of tissue-engineered nucleus pulposus [174].

In a different approach, supplementation of IVD cell cultures with a naturally-occurring anti-inflammatory molecule, interleukin-1 receptor antagonist (rhIL-1Ra), has been shown to inhibit the downregulation of biosynthesis induced by the pro-inflammatory cytokine, IL-1 [173]. Pre-treatment of nucleus pulposus cells with both IL-1Ra and a fusion protein between IL-1Ra and an elastin-like polypeptide (ELP) reduced the expression of MMP-3 and the aggrecanase, ADAMTS-4, when the cells were subsequently treated with IL-1 [175]. The *in vitro* application of rhIL-1Ra to degenerated human disc tissues reduced levels of enzymes, MMP-3, -7, and -13, implicated in the degradation of the IVD [176]. The incubation of herniated human disc tissues with IL-1Ra or an antibody inhibitor of TNF both decreased levels of active MMP-3, indicating that these inhibitors may have an effect on the resorption of herniated discs [177]. The inhibition of p38 mitogen-activated protein kinase (MAPK) in IL-1-activated nucleus pulposus cells reduced the production of factors associated with the catabolic effects of IL-1 and TNF-α [178]. An extension of that study revealed that the IL-1 upregulation of gene expression of MMP-3, IL-1, and IL-6 was reduced, while the IL-1 downregulation of matrix protein gene expression and proteoglycan synthesis was reversed in nucleus pulposus cells [179].

These above *in vitro* studies illustrate that both stimulatory factors, as well as anti-inflammatory or anti-catabolic factors, may be considered for therapeutic purposes in IVD regeneration. Overall, the potential for biologics to assist in matrix regeneration through controlling both cell metabolism and cell number has been established and paved the way for more recent studies evaluating these biologics *in vivo*.

In vivo studies: growth factors

Protein injection into the disc space is relatively simple and practical and has been the most widely studied of all approaches for delivery of growth factors and biologics for IVD regeneration. Walsh and co-workers reported the *in vivo* effect of single or multiple injections of several growth factors, including basic fibroblast growth factor (bFGF), GDF-5, IGF-1 or TGF-β,

in mouse caudal discs with degeneration induced by static compression [180]. Fibrochondrocyte aggregates were observed at four weeks in the nucleus of discs that received a single injection of GDF-5 and multiple injections of TGF-β, while a single injection of IGF-1 may have elicited an early, transient response at one week and bFGF treatment had little effect [180]. A statistically significant increase in disc height four weeks after GDF-5 treatment was also reported and the authors suggested that GDF-5 and TGF-β are mitogens for anular chondrocytes [180].

A single intradiscal administration of recombinant human OP-1 (rhOP-1) into normal rabbit discs *in vivo* resulted in increased disc height and proteoglycan content in the nucleus pulposus regions in comparison to a saline injection control group [181]. In an animal model of disc degeneration caused by needle puncture of the anulus fibrosus, an injection of rhOP-1 (100 μg/disc) restored disc height, structural change, and mechanical properties (Fig. 56.11) [182,183]. In another rabbit model of disc degeneration, a single injection of recombinant human osteogenic protein-1 (rhOP-1) (100 μg/disc) significantly reversed the decrease in disc

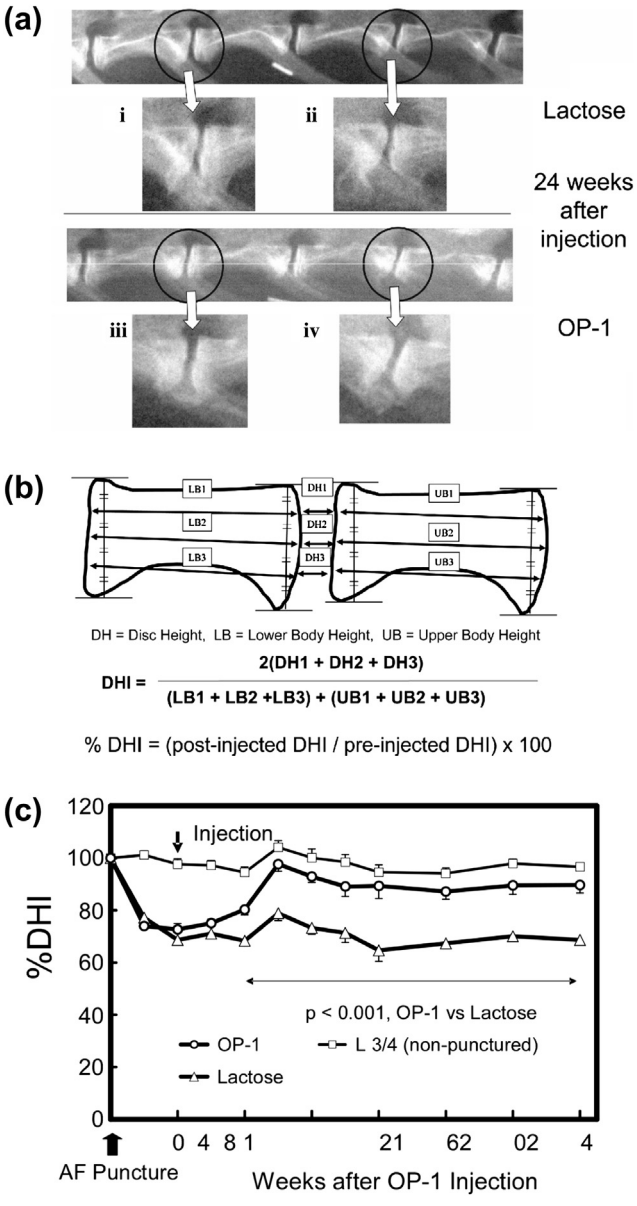

FIGURE 56.11

IVDs of rabbit lumbar spines were subjected to anular puncture by an 18-gauge needle to induce disc degeneration. Four weeks after the initial puncture, the vehicle (5% lactose, 10 μL) or OP-1 in 5% lactose (100 μg/10 μL at each level) was injected into the center of the nucleus pulposus. (a, top) Radiographs at the 24 week time after injection with lactose; (a, bottom) Radiographs of rabbit IVDs following injection with OP-1 in the experimental group, shown at 24 weeks after injection. (b) Method for radiographic measurement of disc height (DH). The average IVD height (DHI) was calculated by measurements obtained from the anterior, middle, and posterior portions and divided by the average of adjacent vertebral body heights. LBH indicates lower body height; UBH, upper body height. (c) Changes in the IVD height index (DHI) after the anular puncture and OP-1 injections. As shown, %DHI of injected discs in the OP-1 group was significantly higher than in the lactose injected control group by 4 weeks ($p < 0.001$, repeated ANOVA). This difference %DHI was maintained out to later periods.

height following chondroitinase ABC chemonucleolysis; the reversal was sustained for up to 16 weeks, and resulted in a significantly higher proteoglycan content compared to the vehicle control group [161]. The *in vivo* efficacy of rhOP-1 has been confirmed in a rat model of chronic compression of tail IVDs; under continuous compression load the injection of rhOP-1 resulted in an increase of the extracellular matrix, as observed by histology, in the degenerated discs [184]. An extension of that study confirmed that a direct injection of OP-1 into the chronically compressed rat tail IVDs induced anabolic and anti-catabolic activities, as documented by reduced immunostaining for aggrecanase, MMP-13, TNF-α, and IL-1β [185].

The effectiveness of direct protein delivery was also confirmed in experiments using rhGDF-5, where a single injection of rhGDF-5 resulted in restoration of disc height, and improvements in MRI and histological grading scores in the rabbit anular puncture model of disc degeneration [165]. In this model, a single injection of rhGDF-5 significantly suppressed the mRNA expression of cytokines (IL-1β, IL-6, TNF-α), catabolic enzymes [a disintegrin and metalloproteinase with thrombospondin motifs 4 (ADAMTS4), cyclooxygenase-2 (COX-2)], and pain-related molecules [nerve growth factor (NGF), vascular endothelial growth factor (VEGF)] by punctured discs. In a thrombin injection (10 U) rabbit model of disc degeneration evaluated with quantitative T1ρ MRI, T1ρ values of the nucleus pulposus of rhGDF-5 treated discs were similar to values of the control level at 12 weeks [186].

In a rabbit anular stab model of disc degeneration, an intradiscal injection of BMP-2 resulted in degenerative changes that were more frequent and severe than with the saline control and promoted hypervascularity and fibroblast proliferation, but had no effect on new bone formation or fusion of the IVD after 12 weeks; the authors suggest that rhBMP-2 may be involved with a response to injury after an anular tear [187]. In an anular stab ovine large animal model of disc degeneration, the simultaneous injection of rhBMP-13, which plays a role in spinal column development and promotes the expression of chondrogenic marker genes in a variety of cell types, was protective against loss of disc height and cells from the disc, and resulted in increased levels of disc extracellular matrix proteins compared to anular stab alone [188]. The *in vivo* application of PRP-impregnated gelation hydrogel microspheres (PRP-GHMs) has been evaluated in a nucleotomy rabbit model of disc degeneration. Histological and immunohistochemical studies revealed that the structure of the IVD and the accumulation of proteoglycans were preserved by the injection of PRP-GHMs, but not in PRP alone and saline controls [189]. An extension of these studies in this model, reported that:

1) Disc height and water content were preserved in PRP-GHMs-treated IVDs in MR images,
2) The mRNA expression of proteoglycan core protein and type II collagen was significantly higher, and
3) The number of apoptotic cells in the nucleus pulposus were lower after PRP-GHM treatment compared with other treatment groups (PRP-saline, saline-GHM, puncture only) [190].

In vivo studies: other biologics

LinkN is an *in vivo* proteolytic degradation byproduct of proteoglycan aggregate stabilizing link protein. The effect of the intradiscal administration of the synthetic peptide of LinkN, which stimulates proteoglycan and collagen synthesis of IVD cells *in vitro*, was evaluated in the rabbit anular puncture model of disc degeneration and was shown to partially restore disc height, increase anabolic extracellular matrix gene expression, and reduce catabolic gene expression [170]. In a recent study in a large animal model of disc degeneration, the disc architecture and mechanical properties of surgically denucleated porcine (minipig) IVDs injected with a fibrin sealant, which promotes IVD cell proliferation and matrix synthesis, were preserved [191]. In addition, fibrin also inhibited fibrosis of the nucleus pulposus, increased proteoglycan synthesis, reduced secretion of pro-inflammatory cytokines and increased the synthesis of the pro-resolution factors, TGF-β and IL-4[191]. Nasto and co-

workers have recently demonstrated that inhibition of NFκB activity via intra-peritoneal injection of Nemo Binding Domain peptide reduced proteoglycan loss in disc degeneration observed in a mouse model of accelerated aging [192].

Summary

These studies are important for demonstrating that biologic manipulation of IVD cells *in vitro* may translate to an observed effect *in vivo*, and that direct protein delivery may be useful for promoting new matrix formation in the absence of cell delivery. It is noteworthy that the studies using rhOP-1 and rhGDF-5 also provide documentation of preclinical measures such as disc height, disc mechanics and MRI appearance that may be important for translating these technologies to non- or minimally-invasive clinical outcomes for patient treatment. Indeed, data for the *in vitro* studies have led to an investigational new drug study that has been initiated to test the safety and effect of injections of rhOP-1 into the disc space.

GENE THERAPY FOR INTERVERTEBRAL DISC REGENERATION

While the studies described above illustrate a range of proteins considered as possible therapies for IVD regeneration, it is important to consider the unavoidable limitations of protein delivery to the disc space. Issues such as protein half-life or solubility, the need for a proper carrier, need to preserve mechanical environment or cell numbers, and/or the presence of inhibitors are all factors that can be expected to affect the therapeutic efficacy of protein delivery *in vivo*. A consideration for the use of recombinant protein therapies is also cost, as some disc pathologies and the need to inhibit disc degeneration may be chronic in nature or require multiple treatments. Gene therapy has been advocated as a therapeutic alternative for the delivery of biologics in disc regeneration [193–196]. DNAs that encode specific proteins may be delivered into the cells by viral or non-viral transfection, with the result that these cells produce proteins to, theoretically, prolong the duration of action. The first successful attempt for *in vitro* gene transfer was reported for chondrocyte-like cells from the endplate of the IVD using a retro-viral mediated technique [193]. An *ex vivo* approach was used based on harvesting host cells, infecting these host cells *in vitro*, selecting and enriching infected cells, and finally returning these cells to the host. This approach avoids problems associated with low cell numbers and transfection efficiencies, but is both challenging and costly to perform. Nevertheless, because a decrease of cells by apoptosis or necrosis is considered to be associated with advanced disc degeneration, cell supplementation with genetically manipulated cells will continue to hold promise for disc regeneration.

Adenoviral vectors often possess high titers and infectivity and are able to infect non-dividing cells such as IVD cells. Adenoviral-mediated gene transfer to human IVD cells has been shown to be efficient and to produce transcripts across non-degenerative to degenerative cell types, using adenovirus carrying lacZ (Ad/CMV-lacZ) or luciferase 'marker' genes (Ad/CMV-luciferase), as well as Sox9 (Ad/Sox9-GFP), GDF-5 and TGF-β1 adenoviral constructs [197,198]. Yoon and co-workers also used adenoviral vector to transfer LIM mineralization protein-1 (LMP-1) to rat IVD cells *in vitro* and observed an increase of BMP-2 and BMP-7 gene expression and protein production, and proteoglycan synthesis [196]. The feasibility of using direct *in vivo* adenoviral-mediated gene transfer to disc cells has also been demonstrated using the lacZ, TGF-β, LMP-1 and Sox9 genes [196,197,199], finding transgene expression to be present or to exert a biological effect on biosynthesis, often for several weeks.

In addition to upregulation of anabolic factors, inhibition of catabolic processes has also been studied using gene therapy for IVD regeneration. Wallach and co-workers reported that gene transfer of the tissue inhibitor of metalloproteinase-1 (TIMP-1), an inhibitor of catabolic enzymes, can increase proteoglycan accumulation within pellet cultures of human IVD cells [200]. LeMaitre reported that human disc cells infected with Ad-IL-1 receptor antagonist (Ad/IL-1Ra) were resistant to IL-1 [201]. When *in vitro* infected cells were injected into disc

explants *in vitro*, IL-1 receptor antagonist protein expression was also increased and maintained for the two week time period investigated. Recently, RNA interference has been demonstrated to downregulate gene expression *in vitro* in NP cells and *in vivo* in the rat coccygeal IVD [202] and degenerated rabbit IVD [203]. The use of RNAi technology is promising for the downregulation of deleterious catabolic gene expression in disc degeneration.

There are significant concerns about adenoviral vector use clinically, however, that may include significant toxicity when used in spinal applications [204,205]. These concerns have led investigators to begin consideration of adeno-associated viral vectors [206] and baculoviral vectors, the latter which may be non-toxic [207]. Both approaches may provide safe alternatives for future disc therapies, although much work remains. Also to avoid safety concerns found with viral gene transfer, several non-viral methods for direct gene transfer to cells have been proposed. Preliminary reports using microbubble-enhanced ultrasound gene therapy [208] and a 'gene gun' method [209,210] have shown that introduction of a marker or growth factor gene could be accomplished and provide sustained gene expression without need for viral vectors. Transfection efficacy with non-viral means is lower, however, than that in viral transfection and further investigation will be needed to apply these in a clinical setting. Nevertheless, both viral and non-viral transfection methods have pros and cons. Safety and immunological reactions, as well as the control of expression in viral-mediated gene therapy, are potential problems. The comparatively low immunologic exposure of the healthy disc and its low cellularity seem to suggest that safety with gene delivery of therapeutic agents is a lesser concern in the IVD. Cells are needed to transduce the biological effect, however, so that transplantation of *ex vivo* transfected cells may be an important part of the future potential for gene therapy in the IVD. Additionally, due to the proximity of the target to the spinal cord, significant harm can occur due to failure to control delivery, as seen with paralysis in rabbits due to accidental gene delivery in the intradural space [205]. During this time, work continues on identification of broader and diverse molecular targets that can be useful for gene delivery in the treatment of IVD regeneration.

CONCLUDING REMARKS

Efforts to regenerate and replace the tissues of the intervertebral disc have virtually exploded over the last two decades, although the field remains in its infancy. The complexity of the diverse degenerative and pathological processes that affect the IVD, as well as the intrinsic complexity of the heterogeneous disc structures, demands that multiple strategies be developed for treatment of the IVD. Partial IVD replacements using acellular, pre-formed or *in situ* formed biomaterials have the longest history of development and are important for defining procedural outcomes that will be relevant to long term functional success. Development of strategies use cells, biologics, or gene therapy is often focused upon restoration of a single tissue source, such as nucleus pulposus or anulus fibrosus, and with or without biomaterial scaffolds. However a growing number of tissue-engineering solutions have been proposed to integrate two dissimilar tissues in the repair process, and additional work to promote integration amongst native, neo-generated and implanted tissues will be critical to restoring IVD function. Many of the identified strategies derive largely from knowledge gained in cartilage tissue engineering, although the differing cellular, functional and structural requirements of the IVD suggest that custom approaches are needed. Advances in IVD cell biology are needed to enable the identification of novel therapeutic targets, to select for classes of biomaterials, and to suggest appropriate drug delivery strategies, as disc cell phenotype, cell-biomaterial interactions, and the biology of aging for these cells, are still poorly understood. While a diverse array of molecules, cell sources and materials are suggested as appropriate for IVD regeneration, additional work is needed to reveal some common and unique themes in human IVD cell responses that focus research on IVD specific strategies.

Currently underway clinical trials of autologous cell therapies or autologous protein products will pave the way for later generations of cellular and biologic-based therapies, as they are expected to illustrate the unique challenges of treating the pathologic and aged human IVD. The next decade promises great advances in the translation of basic and applied sciences to the clinical treatment of IVD regeneration and replacement.

CHAPTER 57

Articular Cartilage Injury

J.A. Buckwalter, J.L. Marsh, T. Brown, A. Amendola and J.A. Martin
Department of Orthopedics and Rehabilitation, University of Iowa College of Medicine, Iowa City, Iowa

INTRODUCTION

In an effort to decrease the risk of post-traumatic osteoarthritis, surgeons and scientists have been seeking ways to prevent progressive joint degeneration following injury. Surgeons have used operative treatments, including penetrating subchondral bone, soft-tissue grafts, and cell transplants, to stimulate restoration of damaged articular surfaces, with variable results. This chapter covers recent advances in the use of artificial matrices, growth factors, and immature chondrocytes or stem cells to promote cartilage repair as well as work suggesting that several biologic agents, including capsase inhibitors, antioxidants, and anti-inflammatory drugs may minimize the effects of mechanical damage to chondrocytes.

Mechanical loading of articular surfaces which exceeds the tolerance of those surfaces damages chondrocytes and their matrix; damage that can cause joint degeneration leading to the clinical syndrome of post-traumatic osteoarthritis. The risk of post-traumatic osteoarthritis depends on the type and severity of the injury and also on the repair and remodeling of the damaged articular surfaces. Three classes of joint injuries can be identified, based on the type of articular surface damage:

1) Chondral damage and in some cases subchondral bone damage that does not cause visible disruption of the articular cartilage,
2) Mechanical disruption of the joint surface limited to articular cartilage (chondral ruptures or tears), and
3) Mechanical disruption of articular cartilage and subchondral bone (articular surface fractures).

In most instances, chondrocytes can repair damage that does not disrupt the articular surface if they are protected from further injury. Mechanical disruption of articular cartilage stimulates chondrocyte synthetic activity, but this response, with few if any exceptions, fails to repair the tissue damage. Disruption of articular cartilage and sub-chondral bone stimulates chondral and bony repair. The osteochondral repair response usually heals the bony injury, but the chondral repair tissue does not duplicate the properties of normal articular cartilage.

Normal pain-free movement depends on the unique properties of the articular cartilage that forms the bearing surfaces of synovial joints [1]. Degeneration of this remarkable tissue causes osteoarthritis: joint pain and dysfunction that limits mobility [2,3]. The mechanisms, frequency, and natural history of articular surface injuries are poorly understood, but it is clear that these injuries can lead to post-traumatic osteoarthritis [1,4–6]. Limited awareness of chondral and osteochondral injuries and difficulty in diagnosing these injuries makes it

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00057-4

impossible to determine accurately their incidence, or their relationship to the development of joint degeneration [1,7,8]. However, arthroscopic examinations of injured knee joints suggest that closed articular surface injuries occur frequently [9,10]. One group of surgeons arthroscopically examined 85 knees with traumatic hemarthrosis but absent or negligible ligamentous instability [9]. Twenty percent of these knees had articular surface defects. In many patients cartilage injuries occur in association with injuries to other joint tissues, including menisci, ligaments, joint capsule and synovium. In these people the cartilage injury may be overlooked; even when it is identified it is difficult to distinguish the effects of the cartilage injury from the effects of the injuries to the other tissues. Damage to articular surfaces that does not result in visible disruption of articular cartilage or subchondral bone is not easily detected, although it probably occurs far more frequently than chondral and osteochondral fractures [4,6].

Recent advances in methods of diagnosing articular surface injuries, including arthroscopy and magnetic resonance imaging [11–13], combined with reports of new methods of stimulating cartilage repair or regeneration and osteochondral transplantation have increased interest in these injuries. Clinical evaluation of patients with articular surface damage and determining the appropriate role of these new treatments or the need for any treatment requires an understanding of the mechanisms of these injuries and their natural history. This chapter discusses the relationship between articular surface injury and joint degeneration, mechanisms of articular surface injuries, the responses of articular surfaces to injury and approaches to preventing joint degeneration following joint injury.

ARTICULAR CARTILAGE INJURY AND JOINT DEGENERATION

The end stage of post-traumatic osteoarthritis, the osteoarthritis that follows joint injury, is identical to that of primary osteoarthritis, but patients with post-traumatic osteoarthritis are often young or middle-aged adults and have a well-defined precipitating insult [14,15]. Clinical experience and epidemiologic studies show that meniscal, ligament, and joint-capsule tears, joint dislocations, and intra-articular fractures increase the risk of the progressive joint degeneration that causes post-traumatic osteoarthritis [14,16,17]. Participation in sports that expose joints to high levels of impact or torsional loading also increases the risk of joint degeneration [8,15].

The risk of osteoarthritis following joint injury varies with the type of injury: meniscal and ligamentous injuries have a lower risk than intra-articular fractures. Gelber et al. [14] found that 13.9% of those who had a knee injury (including meniscal, ligamentous or bone injuries) during adolescence or young adulthood developed knee osteoarthritis, as compared with 6.0% of those who did not have a knee injury. A study of patients who suffered ligamentous and meniscal injuries of the knee reported that they had a tenfold increased risk of osteoarthritis compared with patients who do not have joint injuries [18]. Intra-articular fractures have the greatest risk of osteoarthritis. Depending on the severity of the injury and on the joint, the risk ranges from about 25% to more than 50% of patients [15,19].

The time interval between joint injury and the development of osteoarthritis varies from less than a year in patients with severe intra-articular fractures to a decade or more in some patients with ligamentous or meniscal injuries [15,19]. Because many joint injuries occur in young adults, the population of patients with post-traumatic osteoarthritis includes many individuals under 50 years of age. But older individuals may have an increased risk of osteoarthritis after joint injuries. Studies of patients with intra-articular fractures of the knee show that patients older than 50 years of age have a two- to four-fold greater risk of developing osteoarthritis than younger patients; patients over 40 years who have acetabular fractures and patients over 50 years who have displaced ankle fractures may also have a greater risk of OA than younger patients who have similar injuries; and age increases the risk of knee-joint degeneration after anterior cruciate ligament injury [15,20].

MECHANISMS OF ARTICULAR CARTILAGE INJURIES

Understanding the mechanisms of articular surface injuries requires appreciation of how loads and rate of loading affect articular cartilage [6,21]. Slowly applied loads and suddenly applied loads differ considerably in their effects. The articular cartilage extracellular matrix consists of water and a macromolecular framework formed primarily by collagens and large aggregating proteoglycan [1]. The collagens give the tissue its form and tensile strength, and the interaction of aggregating proteoglycans with water gives the tissue its stiffness to compression, resilience, and probably its durability. Loading of articular surfaces causes movement of fluid within the articular cartilage matrix that dampens and distributes loads within the cartilage and to the subchondral bone [22]. When this occurs slowly, the fluid movement allows the cartilage to deform and decreases the force applied to the matrix macromolecular framework. When it occurs too rapidly for fluid movement through the matrix and deformation of the tissue, as with sudden impact or torsional joint loading of the joint surface, the matrix macromolecular framework sustains a greater share of the force. If this force is great enough, it ruptures the matrix macromolecular framework, damages cells, and exceeds the ability of articular cartilage to prevent subchondral bone damage by dampening and distributing loads.

In vivo, expected and unexpected and slow and sudden movements or impacts may differ in the amount of force transmitted to joint surfaces. Muscle contractions absorb much of the energy and stabilize joints during slow, expected movements or impacts. Sudden or unexpected movements or impacts may occur too rapidly for muscle contractions to stabilize joints and decrease the forces on the articular surfaces. For this reason, sudden and unexpected movements or impacts can transmit greater forces to joint surfaces.

Acute or repetitive blunt joint trauma can damage articular cartilage and the calcified cartilage zone-subchondral bone region while leaving the articular surface intact [4,23–26]. The intensity and type of joint loading that can cause chondral and subchondral damage without visible tissue disruption has not been well defined. Physiologic levels of joint loading do not appear to cause joint injury, but impact loading above that associated with normal activities but less than that necessary to produce cartilage disruption can cause alterations of the cartilage matrix and damage chondrocytes [4,23,24,26–28]. Experimental evidence shows that loss of proteoglycans or alteration of their organization (in particular, a decrease in proteoglycan aggregation) occurs before other signs of cartilage injury following impact loading. The loss of proteoglycans may be due either to increased degradation of the molecules or to decreased synthesis. Significant loss of matrix proteoglycans decreases cartilage stiffness and increases its permeability. These alterations may cause greater loading of the remaining macromolecular framework, including the collagen fibrils, increasing the vulnerability of the tissue to further damage from loading. These injuries may cause other matrix abnormalities besides loss of proteoglycans, such as distortions of the collagen fibril meshwork and disruptions of the collagen fibril proteoglycan relationships and swelling of the matrix), and they may injure chondrocytes [4,26].

Currently there is no clinically applicable method of detecting alterations in cartilage matrix composition such as decreased proteoglycan concentration and increased water concentration; however, new imaging techniques may provide methods of assessing articular cartilage composition. When probing the articular surface, surgeons sometimes find regions of apparent softening that may result from alterations in the matrix, and devices are being developed that will allow *in vivo* measurement of articular surface stiffness. Combined with information about cartilage composition, these measurements may make it possible to better define injuries to the articular surface that do not result in visible tissue disruption.

Disrupting a normal articular surface with a single impact requires substantial force, presumably because of the ability of articular cartilage and subchondral bone to dampen and distribute loads. A trans-articular load of 2170 newtons applied to canine patellofemoral joints

caused fractures in the zone of calcified cartilage visible by light microscopy and articular cartilage fissures that extended from the articular surface to the transitional or superficial radial zone of the articular cartilage [24]. A study of the response of human articular cartilage to blunt trauma showed that articular cartilage could withstand impact loads of up to 25 newtons per square millimeter (25 MPa) without apparent damage. Impact loads exceeding this level caused chondrocyte death and cartilage fissures [29]. The authors suggested that reaching a stress level that could cause cartilage damage required a force greater than that necessary to fracture the femur. Another study [30] measured the pressure on human patellofemoral articular cartilage during impact loading, and found that impact loads less than the level necessary to fracture bone caused stresses greater than 25 MPa in some regions of the articular surface. With the knee flexed 90°, 50% of the load necessary to cause a bone fracture produced joint pressures greater than 25 MPa for nearly 20% of the patellofemoral joint. At 70% of the bone fracture load, nearly 35% of the contact area of the patellofemoral joint pressures exceeded 25 MPa, and at 100% of the bone fracture load 60% of the patellofemoral joint pressures exceeded 25 MPa. These latter results show that impact loads can disrupt cartilage without fracturing bone.

Other experimental investigations show that repetitive impact loads split articular cartilage matrix and initiate progressive cartilage degeneration [31–33]. Cyclic loading of human cartilage samples *in vitro* caused surface fibrillation [32], and periodic impact loading of bovine metacarpal phalangeal joints *in vitro* combined with joint motion caused degeneration of articular cartilage [34]. Repeated overuse of rabbit joints *in vivo* combined with peak overloading caused articular cartilage damage, including formation of chondrocyte clusters, fibrillation of the matrix, thickening of subchondral bone, and penetration of subchondral capillaries into the calcified zone of articular cartilage [33]. The extent of cartilage damage appeared to increase with longer periods of repetitive overloading, and deterioration of the cartilage continued following cessation of excessive loading. This latter finding suggests that some cartilage damage is not immediately visible.

An investigation of cartilage plugs also showed that repetitive loading disrupted the tissue and that the severity of the damage increased with increasing load and increasing number of loading cycles [35]. Two hundred and fifty cycles of a 1,000 pounds per square inch compression load caused surface abrasions. Five hundred cycles produced primary fissures penetrating to calcified cartilage, and 1,000 cycles produced secondary fissures extending from the primary fissures. After 8,000 cycles, the fissures coalesced and undermined cartilage fragments. Higher loads caused similar changes with fewer cycles. The experiments suggested that repetitive loading can propagate vertical cartilage fissures from the joint surface to calcified cartilage and cause extension of oblique fissures into areas of intact cartilage.

Clinical studies have identified articular cartilage fissures, flaps, and free fragments and changes in subchondral bone similar to those produced experimentally by single and repetitive impact loads [4,36]. In at least some patients, acute impact loading of the articular surface or twisting movements of the joint apparently caused these injuries. In other patients, the cartilage damage may have resulted from repetitive loading. Magnetic resonance imaging of joints soon after an acute impact or torsional load occasionally shows changes in subchondral bone consistent with damage to the zone of calcified cartilage and subchondral bone, even when the articular surface is intact [11,12,13,37].

Clinical experience suggests that chondral ruptures or tears and osteochondral fractures result from similar impact and twisting-joint injuries, but they tend to occur in different age groups, and some individuals may have a greater risk of chondral tears. Chondral tears generally occur in skeletally mature people, while osteochondral fractures typically occur in skeletally immature people or young adults. This difference may result from age-related changes in the mechanical properties of the articular surface, including the uncalcified cartilage, the calcified cartilage zone, and the subchondral bone. That is, age-related alterations in the articular cartilage matrix decrease the tensile stiffness and strength of the superficial zone; and the calcified cartilage zone-subchondral bone region mineralizes fully following completion of

skeletal growth, presumably creating a marked difference in mechanical properties between the uncalcified cartilage and the calcified cartilage subchondral bone region. Taken together these changes probably increase the risk of ruptures of the superficial-cartilage matrix and of these ruptures extending to the calcified cartilage subchondral bone region. Genetically determined abnormalities of the articular cartilage may also increase the risk of chondral ruptures from a given impact or torsional load, but the relationships between known genetic abnormalities of articular cartilage and cartilage properties have not been well defined.

RESPONSE OF ARTICULAR CARTILAGE TO INJURY

Articular surface injuries can be classified based on the type of tissue damage and the repair response:

1) Cartilage matrix and cell injuries, that is, damage to the joint surface that does not cause visible mechanical disruption of the articular surface;
2) Chondral fissures; flap tears, or chondral defects, that is, visible mechanical disruption of articular cartilage limited to articular cartilage; and
3) Osteochondral injuries, that is, visible mechanical disruption of articular cartilage and bone [1, 4, 38–40]) (Table 57.1).

Matrix and cell injuries

Acute or repetitive blunt trauma, including excessive impact loading, can cause alterations in the articular cartilage matrix, including a decrease in proteoglycan concentration and possibly disruptions of the collagen fibril framework. Injuries that do not cause an apparent articular cartilage injury, including joint dislocations or ligament and joint capsule tears, may have associated damage to the articular cartilage cells and matrix [41]. The ability of chondrocytes to sense changes in matrix composition and to synthesize new molecules makes

TABLE 57.1 Chondral and osteochondral injuries

Injury	Clinical presentation	Repair response	Potential for healing
Damage to chondral matrix and/or cells and/or subchondral bone without visible disruption of the articular surface	No known symptoms, although subchondral- bone injury may cause pain Inspection of the articular surface and current clinical imaging methods for articular cartilage lesion may of injury Imaging of subchondral bone may show abnormalities	Synthesis of new matrix macromolecules Cell proliferation?	If the basic matrix structure remains intact and enough viable cells remain, the cells can restore the normal tissue composition If the matrix and/or cell population sustains significant damage or if the tissue sustains further cannot detect this type damage, the lesion may progress to cartilage degeneration
Cartilage disruption (chondral fractures or ruptures)	May cause mechanical symptoms, synovitis, pain, and joint effusions	No fibrin clot formation or inflammation Synthesis of new matrix macromolecules and cell proliferation, but new tissue does not fill the cartilage defect	Depending on the location and size of the lesion and the structural integrity, stability, and alignment of the joint, the lesion may or may not progress to cartilage degeneration
Cartilage and bone disruption (osteochondral fractures)	May cause mechanical symptoms, synovitis, pain, and joint effusions	Formation of a fibrin clot, inflammation, invasion of new cells, and production of new chondral and osseous tissue	Depending on the location and size of the lesion and the structural integrity, stability, and alignment of the joint, the lesion may or may not progress

it possible for them to repair damage to the macromolecular framework [42]. It is not clear at what point this type of injury becomes irreversible and leads to progressive loss of articular cartilage. Presumably, the chondrocytes can restore the matrix as long as the loss of matrix proteoglycan does not exceed what the cells can rapidly produce, if the fibrillar collagen meshwork remains intact, and if enough chondrocytes remain viable. When these conditions are not met, the cells cannot restore the matrix, the chondrocytes will be exposed to excessive loads, and the tissue will degenerate.

Chondral injuries

Acute or repetitive trauma can cause focal mechanical disruption of articular cartilage, including fissures, chondral flaps or tears, and loss of a segment of articular cartilage [4]. The lack of blood vessels and lack of cells that can repair significant tissue defects limit the response of cartilage to injury [39,43]. Chondrocytes respond to tissue injury by proliferating and increasing the synthesis of matrix macromolecules near the injury. But the newly synthesized matrix and proliferating cells do not fill the tissue defect, and soon after injury the increased proliferative and synthetic activity ceases.

Osteochondral injuries

Unlike injuries limited to cartilage, injuries that extend into subchondral bone cause hemorrhage and fibrin clot formation and activate the inflammatory response [39,40,43]. Soon after injury, blood escaping from the damaged-bone blood vessels forms a hematoma that temporarily fills the injury site. Fibrin forms within the hematoma and platelets bind to fibrillar collagen. A continuous fibrin clot fills the bone defect and extends for a variable distance into the cartilage defect. Platelets within the clot release vasoactive mediators and growth factors or cytokines (small proteins that influence multiple cell functions, including migration, proliferation, differentiation, and matrix synthesis), including transforming growth factor beta and platelet-derived growth factor. Bone matrix also contains growth factors, including transforming growth factor beta, bone morphogenic protein, platelet-derived growth factor, insulin-like growth factor I, insulin-like growth factor II, and possibly others. Release of these growth factors may have an important role in the repair of osteochondral defects. In particular, they probably stimulate vascular invasion and migration of undifferentiated cells into the clot and influence the proliferative and synthetic activities of the cells. Shortly after entering the tissue defect, the undifferentiated mesenchymal cells proliferate and synthesize a new matrix. Within two weeks of injury, some mesenchymal cells assume the rounded form of chondrocytes and begin to synthesize a matrix that contains type II collagen and a relatively high concentration of proteoglycans. These cells produce regions of hyaline-like cartilage in the chondral and bone portions of the defect. Six to eight weeks after injury, the repair tissue within the chondral region of osteochondral defects contains many chondrocyte-like cells in a matrix consisting of type II collagen, proteoglycans, some type I collagen, and noncollagenous proteins. Unlike the cells in the chondral portion of the defect, the cells in the bony portion of the defect produce immature bone, fibrous tissue, and hyaline-like cartilage.

The chondral repair tissue typically has a composition and structure intermediate between that of hyaline cartilage and fibrocartilage; and it rarely, if ever, replicates the elaborate structure of normal articular cartilage [1,38,44,45]. Occasionally, the cartilage repair tissue persists unchanged or progressively remodels to form a functional joint surface. But in most large osteochondral injuries, the chondral repair tissue begins to show evidence of depletion of matrix proteoglycans, fragmentation and fibrillation, increasing collagen content, and loss of cells with the appearance of chondrocytes within a year or less. The remaining cells often assume the appearance of fibroblasts as the surrounding matrix comes to consist primarily of densely packed collagen fibrils. This fibrous tissue usually fragments and often disintegrates, leaving areas of exposed bone. The inferior mechanical properties of chondral repair tissue may be responsible for its frequent deterioration [1,43]. Even repair tissue that successfully fills

osteochondral defects is less stiff and more permeable than normal articular cartilage and the orientation and organization of the collagen fibrils in even the most hyaline-like cartilage repair tissue does not follow the pattern seen in normal articular cartilage. In addition, the repair tissue cells may fail to establish the normal relationships between matrix macromolecules, in particular, the relationship between cartilage proteoglycans and the collagen fibril network. The decreased stiffness and increased permeability of repair cartilage matrix may increase loading of the macromolecular framework during joint use, resulting in progressive structural damage to the matrix collagen and proteoglycans, thereby exposing the repair chondrocytes to excessive loads and further compromising their ability to restore the matrix.

Clinical experience and experimental studies suggest that the success of chondral repair in osteochondral injuries may depend to some extent on the severity of the injury, as measured by the volume of tissue or surface area of cartilage injured and the age of the individual [46]. Smaller osteochondral defects that do not alter joint function heal more predictably than larger defects that may change the loading of the articular surface. Potential age-related differences in healing of chondral and osteochondral injuries have not been thoroughly investigated, but bone heals more rapidly in children than in adults, and the articular cartilage chondrocytes in skeletally immature animals show a better proliferative response to injury and synthesize larger proteoglycan molecules than those from mature animals [42,47–51]. Furthermore, a growing synovial joint has the potential to remodel the articular surface to decrease the mechanical abnormalities created by a chondral or osteochondral defect.

PREVENTING JOINT DEGENERATION FOLLOWING INJURY

Orthopedic surgeons routinely perform extensive surgical procedures, some having substantial complication rates, in an effort to restore the alignment and congruity of articular surfaces following intraarticular fractures [19]. The purpose of these procedures is to decrease residual joint incongruity and thereby to decrease focal elevations of contact stress, presumed to be responsible for post-traumatic osteoarthritis. These widely accepted practices are based largely on the assumption that joints are less likely to develop osteoarthritis if the peak stresses on focal areas of the articular surface are reduced. However, there is little evidence to guide surgeons in determining how much stress the articular surface can tolerate, in the form of either acute impact or chronically increased stress, and the potential for human joints to repair and remodel the articular surface after injury is poorly understood.

With better understanding of the role of mechanical forces in the pathogenesis of osteoarthritis, clinical and basic research could be focused on developing new, minimally invasive, and non-surgical treatments of joint injuries that have a high risk of post-traumatic osteoarthritis and on treatments that prevent or delay the development of joint degeneration in patients at high risk of post-traumatic osteoarthritis. There is increasing evidence that biologic interventions can decrease mechanical stress-induced chondrocyte damage. For example, the work of D'Lima and coworkers [52–54] shows that capsase inhibition can decrease mechanically induced chondrocyte and apoptosis, and Haut and colleagues have reported that P188 surfactant can limit chondrocyte necrosis following impact loading [55,56]. Other investigations show that antioxidants can prevent mechanically induced chondrocyte damage [57,58].

PROMOTING ARTICULAR SURFACE REPAIR

Better understanding of articular cartilage injuries and recognition of the limitations of the natural repair responses have contributed to the recent interest in cartilage repair and regeneration [4,39,43,59–61]. In the last three decades clinical and basic scientific investigations have shown that implantation of artificial matrices, growth factors, perichondrium,

periosteum, and transplanted chondrocytes and mesenchymal stem cells can stimulate formation of cartilaginous tissue in synovial joint osteochondral and chondral defects [1,59,61–65].

Penetration of subchondral bone

Experimental and clinical investigations show that penetration of subchondral bone leads to formation of fibrocartilagenous repair tissue on the articular surfaces of synovial joints [46,59,66–69]. In regions with full-thickness loss or advanced degeneration of articular cartilage, penetration of the exposed subchondral bone disrupts subchondral blood vessels, leading to formation of a fibrin clot that fills the bone defect and usually covers the exposed bone surface [46,59]. If the surface is protected from excessive loading, undifferentiated mesenchymal cells migrate into the clot, proliferate, and differentiate into cells with the morphologic features of chondrocytes [70]. In most instances, over a period of six to eight weeks they form bone in the osseous portion of the defect and fibrocartilagenous tissue in the chondral portion [39,71,72]. Initially, the chondral repair tissue can closely resemble articular cartilage in gross and light-microscopic appearance, but it fails to duplicate fully the composition (especially the types and concentrations of collagens and proteoglycans), structure, and mechanical properties of normal articular cartilage, and in many instances it deteriorates with time [1,38,39,43].

Surgeons currently use a variety of methods of penetrating subchondral bone to stimulate formation of a new cartilaginous surface, including arthroscopic drilling and abrasion of the articular surface and making multiple small-diameter defects or fractures with an awl or similar instrument, a method referred to as the microfracture technique [36,59,66,67,71,72,73]. Multiple authors report that these procedures can decrease the symptoms due to isolated articular cartilage defects of the knee in a majority of patients [36,66,67,71,73,74,75,76].

Periosteal and perichondrial grafts

The potential benefits of periosteal and perichondrial grafts include introduction of a new cell population along with an organic matrix and some protection of the graft or host cells from excessive loading. Animal experiments and clinical experience show that perichondrial and periosteal grafts placed in articular cartilage defects can produce new cartilage [59,76]. O'Driscoll has described the use of periosteal grafts for the treatment of isolated chondral and osteochondral defects and demonstrated that these grafts can produce a new articular surface [63,64,77,78]. Other investigators have reported encouraging results with perichondrial grafts [79,80]. However, one study suggests that increasing patient age adversely affects the results of soft-tissue grafts. Seradge et al. [81] studied the results of rib perichondrial arthroplasties in 16 metacarpophalangeal joints and 20 proximal interphalangeal joints at a minimum of three years following surgery. Patient age was directly related to the results. One hundred percent of the patients in their twenties and 75% of the patients in their thirties had good results following metacarpophalangeal joint arthroplasties. Seventy-five percent of the patients in their teens and 66% of the patients in their twenties had good results following proximal interphalangeal joint arthroplasties. None of the patients older than 40 years had a good result with either type of arthroplasty. The clinical observation that perichondrial grafts produced the best results in younger patients [81] agrees with the concept that age may adversely affect the ability of undifferentiated cells or chondrocytes to form an articular surface or that with age the population of cells that can form an articular surface declines [42,47,51].

Cell transplantation

Transplantation of cells grown in culture provides another method of introducing a new cell population into chondral and osteochondral defects. Experimental work has shown that both chondrocytes and undifferentiated mesenchymal cells placed in articular cartilage defects

survive and produce a new cartilage matrix [1,82–85,106]. In addition to these animal experiments, orthopedic surgeons have used autologous chondrocyte transplants for treatment of localized cartilage defects [68,86–90]. Proponents of this procedure report that it produces satisfactory results, including the ability to return to demanding physical activities, in as many as 90% of patients [68,89].

Artificial matrices

Treatment of chondral defects with growth factors or cell transplants requires a method of delivering and in most instances at least temporarily stabilizing the growth factors or cells in the defect. For these reasons, the success of these approaches often depends on an artificial matrix. In addition, artificial matrices may allow, and in some instances stimulate, ingrowth of host cells, matrix formation, and binding of new cells and matrix to host tissue [91,92]. Investigators have found that implants formed from a variety of biologic and nonbiologic materials, including treated cartilage and bone matrices, collagens, hyaluronan, chitosan, fibrin, carbon fiber, hydroxlyapatite, porous polylactic acid, polytetrafluoroethylene, polyester, and other synthetic polymers, facilitate restoration of an articular surface [1,59,92–94]. Lack of studies that directly compare different types of artificial matrices makes it difficult to evaluate their relative merits, but the available reports show that this approach may contribute to restoration of an articular surface.

Growth factors

Growth factors influence a variety of cell activities, including proliferation, migration, matrix synthesis, and differentiation. Many of these factors, including the fibroblast growth factors, insulin-like growth factors, and transforming growth factor betas, have been shown to affect chondrocyte metabolism and chondrogenesis [46,59,96,97]. Bone matrix contains a variety of these molecules, including transforming growth factor betas, insulin-like growth factors, bone morphogenic proteins, platelet-derived growth factors, and others [46,95]. In addition, mesenchymal cells, endothelial cells, and platelets produce many of these factors. Thus, osteochondral injuries and exposure of bone due to loss of articular cartilage may release these agents, which affect the formation of cartilage repair tissue, and they probably have an important role in the formation of new articular surfaces after currently used surgical procedures, including penetration of subchondral bone. Local treatment of chondral or osteochondral defects with growth factors has the potential to stimulate restoration of an articular surface [97–100]. Despite the promise of this approach, the wide variety of growth factors, their multiple effects, the interactions among them, and the possibility that the responsiveness of cells to growth factors may decline with age [47,49–51,101] have made it difficult to develop a simple strategy for using these agents to treat articular surface injuries. However, development of growth factor-based treatments for isolated chondral and osteochondral injuries in combination with other approaches, including use of artificial matrices and cell transplants, appears promising [61,102].

Anti-inflammatories

Severe post-traumatic synovitis is associated with joint injuries that cause OA [103]. Joint injury results in increases in pro-inflammatory cytokines in synovial fluids, which promote cartilage degeneration (ref). A recent clinical study indicated that anti-cytokine therapy relieved acute knee pain in patients with ACL tear [104], a result suggesting that such treatments could protect the joint from inflammatory damage. Why damage to joint tissues results in cytokine elevation and inflammation is unclear. However, results from studies of other organ systems show that inflammation is triggered by cell death resulting from tissue injury [105]. These observations strongly suggest that antioxidants, or drugs that downregulate immune responses to cell death, could block joint inflammation following a wide variety of joint injuries.

CONCLUSION

Articular surface injuries are a significant unsolved problem. They are common, the value of current treatments is uncertain, and many of these injuries initiate progressive joint degeneration, a condition recognized as post-traumatic osteoarthritis. Surgeons attempt to decrease the risk of post-traumatic osteoarthritis by restoring joint stability, congruity, and alignment following injury. In addition, to promote repair and remodeling of damaged articular surfaces, they penetrate subchondral bone and insert periosteal and perichondral grafts and autologous chondrocytes. The results of these procedures vary considerably among patients, and there is limited information concerning the long-term outcomes. However, the available studies of people who have suffered joint injuries indicate that even with optimal current treatment the risk of post-traumatic osteoarthritis is high following chondral tears and articular surface fractures. For this reason there is a clear need to improve the treatment of joint injuries. Clinical and experimental studies show that chondrocyte and mesenchymal stem cell transplantation, synthetic matrices, growth factors, and combinations of these treatments have the potential to restore articular surfaces. Other investigations suggest that biologic interventions may minimize chondrocyte damage due to mechanical forces. The most dramatic improvements in the treatment of articular surface injuries are likely to come from approaches that help maintain chondrocyte viability and function, restore joint stability and congruity, and promote articular surface repair and remodeling following joint injury.

INTRODUCTION

According to legend, the first homotransplantation of an entire limb was performed by Saints Cosmas and Damian, as depicted by the artist, Fra Angelico [1]. Indeed, the concept was described in writing even earlier:

> 'The Lord God cast a deep sleep on the man, and while he was asleep, he took out one of his ribs and closed up its place with flesh. The Lord God then built up into a woman the rib that he had taken from the man' [2].

The number of research centers undertaking tissue engineering has waxed and waned, but overall, has steadily increased. While potential applications have broadened, the basic concept that the repair and regeneration of biological tissues can be guided through application and control of cells, materials, and chemoactive proteins has remained the same. As emphasis continues to shift toward the use of stem cells, and manipulation of the local environment to minimize inflammation, maximize cell survival and to direct development, tissue engineering continues to be an interdisciplinary field, requiring the interactions of physicians, and physical, chemical and biologic scientists, and engineers.

The ultimate goal is to utilize cells from a relatively small sample or from a universal donor source, expand them *in vitro*, and deliver them associated with a template, into an environment conducive to new tissue growth, and in a configuration that will generate a new functional tissue. The ability to achieve this goal requires a keen understanding of extracellular matrix, structural framework and regulation of cell development and chemofactors in the local environment.

In 1908, Lexer [3] described attempts at tissue engineering of structural tissue in his report of the use of freshly amputated or cadaver allografts for joint reconstruction. Several decades later, Huggins published his results concerning the search for bone morphogenic proteins.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00058-6

In 1965, Urist demonstrated the generation of one structural tissue; that is, bone by means of auto induction [4]. He described 'wandering histiocytes, foreign body giant cells, and inflammatory connective cells' being 'stimulated by degradation products of dead matrix to grow in and repopulate the area of an implant of decalcified bone'. The process, as described by Urist, is followed immediately by auto-induction, in which both the inductor cells and the induced cells are derived from ingrowing cells of the host bed. Differentiation of the osteoprogenitor cell was felt to be elicited by local alterations in cell metabolic cycles.

Later, in the 1970s, Dr. W.T. Green [5] described a series of experiments devoted to the generation of new cartilage. In one study, chondrocytes, seeded onto sterile bone spicules, were implanted into nude mice. Although the experiments were not entirely successful, Green correctly postulated that the advent of new biocompatible materials might enable cells to be seeded onto synthetic scaffolding and implanted into animals to generate new functional tissue.

Over three decades a number of reports involving the generation replacement of bone and cartilage have appeared in the literature. Unfortunately, many of the studies were performed in immune compromised animal models. Living cells were delivered on alloplastic implants to produce bone [6]. Cartilage growth, whether achieved by use of cell suspensions alone [7–10], cell attachment to naturally occurring matrices [11,12] from perichondrium [13] or peptide stimulation [14] had been described only in minute quantities until the early 90s. Prior to 1990, new cartilage was generated only in association with, and/or confined to, a defect in underlying bone or cartilage, and was devoid of specific shapes. Guided growth of new hyaline cartilage in significant amounts, not associated with endogenous bone or cartilage [15], was then demonstrated in immune compromised animal models [16,17]. During the next decade, the principles of tissue engineering were applied to many organ systems, with a great deal of attention being focused on orthopedic and maxillofacial applications as well as engineering of bone [18] new cartilage [19], tendon [20] and ligament [21].

At the turn of the millennium, new reports related to manipulating the local environment to achieve better cells survival and engraftment appeared. The use of mesenchymal stem cells (MSCs) in combination with tissue specific mature cells was reported with much success [22]. The MSCs were shown to not necessarily develop into the tissue, but to modulate the local environment to reduce inflammation and improve cell survival. Studies related to the mechanisms of inflammation, and how to modulate them have arisen in the last decade [23]. It is this author's opinion that the use of 'resolvins' to minimize inflammation will be tremendously helpful in advancing the field.

At the same time, descriptions of many stem cell types have arisen, including embryonic stem cells, (ESCs); much attention has been given to marrow derived stem cells, fat derived stem cells and MSCs. Reports of induced pluripotent stem cells (iPSCs) [24] seemed to give new promise to the fields of tissue engineering and regenerative medicine. Unfortunately, they have met with significant obstacles, as their potential was explored. By 2012, the biology of stem cells was re-evaluated. New reports challenged 'dogma' of the last decade. The ability of mature cells to revert to a stem cell state via a natural process following injury gives a new direction for the challenges faced in tissue engineering [25]. 'Stress altered cells' (SACs) appear to have the same, or better potential than ESCs for tissue-engineering applications, in that they are autologous, and have been shown to have the potential to generate cells representative of all three germ layers.

MATERIALS DEVELOPMENT

The development of matrices to serve as templates for cell attachment/suspension and delivery continues to progress. While initial efforts focused on the use of collagen as a natural matrix for cell delivery, a large degree of its early success was reported in the development of skin

equivalents, primarily the dermal component [26]. Ultimately, the generation of skin products proved to be one of the more difficult challenges.

Cartilage, bone and ligament studies first also focused on using natural extracellular matrix (ECM) proteins such as collagen as structural support for cell transplantation.

Poor mechanical properties and variable physical properties with different sources of the protein matrices have hampered progress with these approaches. Concerns arose regarding immunogenic problems associated with the introduction of foreign collagen. Also, there were inherent biophysical constraints in collagen used as scaffolding. For example, cartilage grown from cells seeded on collagen had to be confined in a rigid 'well' such as underlying bone or cartilage, because of collagen's non-moldability.

Xenografts or animal-derived collagen devices have also been studied. Although they have advantages related to availability, decreased risk of transmission of infectious diseases, and avoiding damage to the patient's healthy tissues, the preparation of the grafts apparently affects significantly their biomechanical properties, and the possibility of rejection can still limit their use. Tendon autografts and allografts are currently the most commonly used substitutes to reconstruct injured ligaments or tendon. Allografts, however, still face the risk of potential transmission of infectious diseases [27,28], and some of the techniques used to sterilize them present the possible risk of affecting the biomechanical characteristics of the grafts. Tendon autografts are perhaps the most commonly transplanted tissue structures. Their biological and biomechanical characteristics serve their purpose relatively well, considering that usually they rely on creeping substitution by the host's cells of a frequently inert organic scaffold from which most cells have usually disappeared. Autografts however, present with the disadvantage of creating a secondary morbid site during harvesting, and the fact that a functioning structure has to be removed from its original site for use in a nearby or remote site. Synthetic devices to replace or reinforce biologic materials were also studied as scaffolds, with the belief that fibrous tissue formation could be induced to form ligamentous and tendinous tissues. One hypothesis theorized that, in the presence of a tensile force, immature fibrous tissue so formed will gradually mature, with its fibers oriented functionally. However, this is disputed by reports [29,30] that the induced tissue is characterized by a chronic foreign body reaction and by disorderly collagen fibers. The use of carbon fiber-derived scaffolds that are eventually replaced by fibrous tissue to ultimately replace the lost function of a tendon or ligament was extensively studied in the 1970s and 1980s [31,32]. Nevertheless, the fact that carbon particles did not disappear completely and were eventually found in regional lymph nodes even several years later their use discouraged its use [33]. Later, carbon fibers were shown to somehow inhibit tendon fibroblast growth [34] concluding that collagen fibers do not significantly contribute to the tensile strength of carbon fiber composite ligaments and tendons. Entirely synthetic materials have also been used to replace or augment tendinous grafts in the treatment of injuries to the ligaments in the knee. Histological and biochemical have demonstrated that Dacron-induced fibrous tissue more closely resembles scar [35] or granulomatous tissue than to neoligament and has been shown to elicit a foreign body inflammatory reaction.

By the 1990s, the use of synthetic naturally occurring polymers as matrices for cell transplantation exploded. It was believed that synthetic scaffoldings had the advantages of being biocompatible as well as biodegradable. Synthetic polymer scaffolds provide intrinsic structure to the transplanted composite. This allows engineering of matrix configuration to meet the biophysical limitations of mass transfer. Synthetic matrices would in theory give one the flexibility to alter physical properties and potentially facilitates reproducibility and scale-up. The configuration of the synthetic matrix could be manipulated to vary the surface area available for cell attachment as well as to optimize the exposure of the attached cells to nutrients. The surface area to mass ratio could be altered or the porosity of differing configurations can be changed. The size of the pores of polymers of the same porosity can be altered to increase or decrease the intrinsic strength and elasticity of the polymer matrix, as well as,

compressibility or creep recovery. The chemical environment surrounding a synthetic polymer could be manipulated in a controlled fashion as the polymer is broken down. The potential exists to continuously deliver nutrients and hormones that can be incorporated into the polymer structure. The rate of degradation of the polymer matrices and the environment into which the cells are implanted could be manipulated by systematically altering the surface chemistry of the polymers, creating an acidic or basic environment as they degrade. For instance, polyaminocarbonates cause a local basic environment, while polyglycolic acid and polyanhydrides cause a local acidic environment. Polyanhydrides and polyorthoesters show surface erosion, other polymers show bulk erosion. Synthetic polymers also offer the advantage of being able to be consistently reproduced, and thus varying quality is not a problem.

It was possible to match the mechanical properties of the material with that of the tissue. Consequently, scaffolds for bone often contain ceramic hydroxyapatite, which has high stiffness like bone, while scaffolds for cartilage and tendon tend to be made from more compliant polymers.

Synthetic polymers are also useful, due to their good processing characteristics. They have a range degradation times from very short (days) to long (several months). Typically, they are configured in the form of fibrous meshes, porous sponges or foams, or hydrogels. The more common polymers used in fibrous meshes and foams include: the linear polyesters including polyglycolic acid (PGA), polylactic acid (PLA), and polycarpolactone (PCL); polyethylene glycol (PEG); and natural polymers such as collagen and hyaluronic acid (HA). Polymeric hydrogels have the distinct advantage of being injectable, which allows the delivery of the construct to be less invasive and thereby reducing surgical risks. Employment of these types of polymers also ensures delivery of an even distribution of a precise number of cells. They can be configured to provide mechanical support the cells to maintain their specific phenotype, without inhibiting migration. Common hydrogel substrates include the copolymers of polyethylene oxide and polypropylene oxide known as pluronics and natural polymers including alginate and agarose. The delivery of a known concentration of cells is simplified when using a hydrogel, where 100% of the cells are encapsulated within the delivery system, as compared to the fibers, where cell delivery is dependent on cell attachment. The hydrogels also allow the suspended cells to be uniformly distributed throughout the volume of polymer delivered. In contrast, the distribution of cells in the polymer fiber or foam scaffold is not uniform and difficult to predict.

Some materials were designed to play a more active role in guiding tissue development. Instead of merely holding cells in place, these bioactive matrices were designed to encourage cell attachment to the polymer through cell surface adhesion proteins. Studies have been undertaken, designed to identify features of a substrate to which different cell lines could be anchored and that were important for maintaining cell function. Identification of these properties allowed scientists to incorporate them into appropriate polymer scaffolds to be used for transplantation. For example, when some cell types are cultured under conventional conditions, such as on plastic or collagen coated dishes, gene transcription is depressed and cell specific mRNA declines, while the mRNA of structure related genes increases many fold. By contrast, when cultured on ECM, rich in laminin, type IV collagen some cell types exhibit increased longevity and maintenance of several cell specific functions. The capability of gene transcription persists when cells are cultured on extracellular gel matrix. Cell shape and function are altered by varying the coating density of any of a variety of different naturally occurring ECM substrates on bacteriologic plates. Some cell types, exhibit a rounded morphology when cultured on low density ECM, while an increase in ECM coating density results in more spreading of the cells and epithelial like morphology [36] as well as affecting the cells ability to enter the synthetic phase and continue through the cell cycle. Some cell types could be switched between

programs of growth and differentiation simply by modulating the ECM coating density, thereby altering the substratum's ability to resist cell-generated mechanical load. These and other studies also suggest that cell shape, which might be altered by manipulation of the physicochemical properties of the polymer, may be important in determining cell function.

These principles in combination with our studies led us to conclude that the matrix to which specific cell types cells are attached *in vitro* is one of the most important variables in the engineering of new functional tissue. Polymers can be synthesized to have an integrin polypeptide sequence (RGD) in the backbone [37–39] or which are constructed entirely of polypeptide sequences [40]. This allows the scaffold to effectively mimic the extracellular matrix and induce attachment of cells directly to the material. This may be particularly important in tissues which bear mechanical loads, since it would allow physical stimuli to be sensed by the cells in the developing tissue in a more physiologic manner.

Unfortunately, while all these concepts are valid, synthetic scaffolds may not possess all of the necessary factors to drive cells to the tissues desired. Efforts to provide growth factors and the hormonal environment normally associated with the tissue to be generated have increased by providing decellularized ECM in combination with synthetic scaffolds [41]. I believe that the optimal scaffold will ultimately prove to be a combination of decellularized ECM and synthetic scaffolds, both solid and as hydrogels.

The process of assembling an engineered structured tissue centers on the identification of an optimal cell source, and the function desired.

Expansion of the most effective cell population *in vitro* is critical in the process of building a construct. In the process, it is important to ensure that the expanded cell population expresses its phenotypic function. This is of great concern for chondrocytes, which dedifferentiate upon repeated passaging [42].

New approaches to expanding populations of chondrocytes continue to be explored. One new, very promising approach is to alter mature chondrocytes to a stem cell state, and then expand those *in vitro* [25]. They can later be induced to develop into mature chondrocytes for use in the construct to be implanted.

The formation of tissue is also greatly influenced by the scaffolds to which the cells are attached, as evidenced by the re-expression of the chondrocyte phenotype in agarose after dedifferentiation during monolayer culture [43]. As the tissue develops, the new ECM alleviates the need for a synthetic template.

It is known that periosteum multiply well *in vitro*. Implants seeded with periosteal cells initially generate what appears to be cartilage, both grossly and histologically, within the first few weeks after implantation. In time, such implants mature to form new bone containing the cellular elements of bone marrow. The rate of the morphogenesis from cartilage to bone correlated with the site into which the cell-polymer construct has been implanted, and seems to be related to the vascularity of the site. In contrast, chondrocyte seeded implants generate cartilage that does not undergo a morphogenesis to bone; regardless of the site and the duration of time in which they had been implanted.

When bone defects are surgically created in both weight bearing and non-weight bearing bones and are filled with polymers seeded with chondrocytes, periosteal cells, polymer alone, or nothing at all, either cartilage, bone, or scar tissue is generated.

Bone is composed of donor cells embedded within recipient interstitium and blood vessels. Scaffolds to deliver cells and grow new bone have included ceramics and polymers. Ceramic materials are useful because they have long degradation times *in vivo*, often of the order of years. One of the first synthetic scaffolds used in tissue engineering was a fiber based scaffold

composed of non-woven mesh of fibers of PGA, 15 microns in diameter, with average inter-fiber interspaces of 150–200 microns. This was a polymer construct that had worked very well for the generation of tissue-engineered cartilage. Two other degradable scaffolds, with which there is a large body of data, are injectable hydrogel systems, one being calcium alginate, and the other, a reverse thermosenstive co-polymer, referred to as pluronics, composed of polyethylene and polypropylene oxide.

The quality of new tissue-engineered cartilage is not only a function of optimal matching of the cell type to the polymer matrix employed, but also of the animal species studied. In nude recipients for example, the fiber system is an excellent scaffold for the generation of cartilage, while injectable hydrogels seem to be superior when engineering the same type of cartilage in immune competent animals using autologous cells.

In immune compromised animals little inflammation is seen, and very good structural tissues is generated when chondrocytes are delivered in pluronics. This is in contrast to the use of calcium alginate to deliver the cells. When transplanted in alginic acid, the chondrocytes are encapsulated in the vehicle which seems to impair cell replication, and takes a long period of time to degrade. When chondrocytes are delivered in pluronics, the polymer degrades much more rapidly, allows for cell replication with minimal inflammatory response, and generates excellent cartilage in higher species using autologous cells. The generation of bone is optimized by the use of calcium alginate. The engineered tissue appears to extract the calcium from the hydrogel as it undergoes morphogenesis to bone. By using calcium alginate as a vehicle for delivery of periosteal cells, the ability to make scaffolds in specific shapes, such as the distal femur of a rat, which resultant generation of tissue-engineered bone of the same shape has been demonstrated. A vascularized pedicle of tissue-engineered bone has been successfully generated in athymic animals by molding synthetic scaffolding, seeded with periosteal cells, around a vascular bundle. This vascularized pedicle of bone can then be transplanted into a large bone defect. Note that the histologic specimen is very similar to normal bone, to that point that it appears to contain a Haversian system.

Some studies have focused on the generation of new bone and cartilage in immune competent animals using autologous cells, as well as the ability to generate composite structures of bone and cartilage. In such models, there is a relatively large degree of inflammation associated with the procedure that results in extensive cell death and poor tissue formation. The use of MSCs in combination mature autologous bone or cartilage cells may modulate the local environment into which mature tissue specific cells are delivered, and increase cell engraftment and tissue formation [44]. Alternatively, other studies target the use of pharmacologic agents to reduce inflammation during the perioperative period of the implant, to decrease cell death and increase engraftment.

CONCLUSION

The field of tissue engineering is growing, albeit, as a somewhat slower pace than previously predicted. While the number of scientific studies is tremendous, the number of translational studies that will lead to human applications are far fewer. Acquisition and application of new knowledge in the fields of stem cell biology, and inflammation will help overcome these hurdles. Manipulations of the local environment in combination with taking advantage of the natural ability of the cells to develop in such environments to reconstitute as functional tissue, optimizing intercellular signaling mechanisms and a directed expression of genes may ultimately driving the principles of tissue engineering toward human applications. It is our hope to optimize cell development, scaffolds and the local environment to generate functional replacement tissue. Advances in an ever growing number of related fields will ultimately allow us to fully utilize this ability.

INTRODUCTION

People are progressively aware of the positive impact of physical activities for the maintenance of their long-term quality of life. However, thousands of women and men experience joint injuries, including the loss of a ligament or tendon while practicing a sport or after giving an intense physical effort. The severity of a ligament and tendon injury will dictate the surgical approach to apply for optimal tissue repair and functional recovery. Tissue engineering has led to the development of new connective tissue repair strategies to reduce the morbidity associated with the use of healthy ligaments and tendons as replacement parts [1]. Synthetic, semi-synthetic, or natural scaffolds are under development to establish optimal conditions for permanent replacement of torn ligaments and tendons. In the case of Achilles tendon injury, the type of surgical repair depends on the size of the gap between the tendon ends. Small gaps will involve stitching both ends together, but a larger gap will require the use of an autograft – called tendon transfer, notably the flexor hallucis longus, or a graft taken from a cadaver [2–3]. The anterior cruciate ligament (ACL) of the knee joint, one of the strongest ligaments of the body, is also the target of traumatic injuries. Unfortunately, its healing potential is apparently limited, and the surgical options for its replacement are frequently associated with knee instability, pain, or muscular weakness. Rupture of the ACL affects over 175,000 patients per year worldwide [4]. Unfortunately, the torn ACL is most frequently replaced by an autologous healthy knee tendon; using the central portion of the patellar tendon or using gracilis and semitendinous tendon grafts. Tissue engineering could provide a potential solution to this issue. However, the reconstruction of connective tissues involves particular technological challenges. A tissue-engineered ligament or tendon would be an ideal graft, but only if they have some essential features. First, biocompatibility of the bioengineered graft will determine its level of integration at the graft site. Second, the ultrastucture of its scaffold is critical for cell colonization, before and/or after implantation. Third, the biomechanical features of the tissue-engineered graft must be adequate to sustain the physiological stresses that will be applied on its structure after grafting. Finally, the regeneration and remodeling of the graft is expected to occur following *in situ* post-implantation, leading to functional recovery, and therefore, this may require prevention of the material becoming a scar tissue with inferior properties due to a host response. Our research group has developed a bioengineered ACL (bACL) that seems to possess these advantageous characteristics and may

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00059-8

eventually be used for torn ACL replacement in humans. The tissue-engineering approach and concepts to produce ligament and tendon substitutes or promote their healing are presented in this chapter.

HISTOLOGICAL DESCRIPTION OF TENDONS AND LIGAMENTS

Tendons connect bones and muscles, while ligaments join one bone to another. The literature used to describe the histological structures of fascia, tendons, and ligaments is similar. They are dense connective tissues consisting of fibroblasts surrounded by type I collagen bundles [5,6]. This may explain why patellar tendon and tensor fascia have frequently been used to replace a torn ACL of the knee joint [7]. The central quadriceps tendon autograft was reported as a promising alternative for ACL reconstruction. However, some pain, loss of motion, knee instability, and other problems can be associated with this approach [8], according to the type of trauma and depending on variables unique to each individual [9]. The success of such grafts depends on the revascularization of the transplanted tissues progressively surrounded by a synovial membrane, rich in vessels [7]. The tendon would finally gain some ligament properties, and the word ligamentization was applied by Amiel et al. [10], to describe this physiological phenomenon studied *in vivo* post-grafting. However, this term is likely not correct as the transplanted tendon gradually becomes more of a scar (initial cell death, infiltration of exogenous cells and blood vessels, altered matrix molecule composition) rather than becoming a ligament. Both ligaments and tendons normally consist mainly of closely packed and thick collagen fibers (predominantly type I, with a small proportion of type III collagen, except where a tendon goes around a boney prominence [11], but also include small quantities of glycosaminoglycans (dermatan sulfate and hyaluronic acid) [12]. Tendon collagen fibrillogenesis is initiated early in development by fibroblasts [13]. Fibrils are embedded in an organized, hydrated proteoglycan matrix and crosslinked through aldol or Schiff base adducts between aldehydes on one or more of the α-chains of the collagen molecules and aldehydes or amino groups on adjacent chains or molecules [14]. Such crosslinks contribute to the tensile strength of the fibrils and, thus, to the tensile properties of the whole tendon [14]. The aldehyde-derived crosslinks are found in two forms: Some are unstable in dilute acids and others are stable [14]. The ratio of one form to the other varies in different tissues, generally increasing with aging. Data reported by Amiel et al. [5] suggested that ligaments are more metabolically active than tendons, having higher DNA content, larger amounts of reducible crosslinks, and more type III collagen, as compared with tendons. They also contain slightly less total collagen than tendons and more glycosaminoglycans, particularly close to the joint [5]. Extracellular matrix fibers in ligaments are oriented parallel to the longitudinal axis of both tissues [5]. For example, the ACL is composed of multiple fascicles, the basic unit of which is type I collagen [15]. The collagen fibrils are non-parallel but are themselves arranged into fibers oriented roughly along the long axis of the ligament in a wavy, undulating pattern ('crimp'), which slowly straightens out as small loads are applied to the ligament [15]. To give an example of the forces applied on such tissues *in vivo*, the ACL usually supports loads of about 169 newtons and ruptures around 1,730 newtons [15]. An elongation of only 6% (about 2 mm) of human ACL (about 32 mm long) is reported to be the limit beyond which damage must be expected [16]. Tendons and ligaments are innervated for proprioceptive functions [17–19]. Thus, the main challenge associated with the production of bioengineered tendons and ligaments is to obtain strong and functional tissues.

This challenge is further complicated by the fact that not all tendons or ligaments are identical [20]. That is, they are uniquely designed to operate within specific loading environments and thus, the Achilles tendon, patellar tendon and those of the shoulder are quite different in some respects. Similarly, the medial collateral ligament and the ACL operate in quite different biological and mechanical environments. An additional aspect of ligaments and tendons that is relevant is the fact that ligaments are mainly passive structures involved in joint

stabilization, and thus many of them operate in the low load (~5%) 'toe' region of their stress-strain curves. In contrast, tendons are active structures responsible for joint motion as part of the muscle-tendon-bone complex and operate in more of the 'linear' region (~50–80%) of their stress-strain curves. Finally, another variable which needs to be factored into the tissue engineering approach is related to the fact that following injury to a ligament or tendon, the remaining joint tissues can adapt (e.g., the joint as an organ concept) [21], leading to a new set point for the joint and thus, the requirements for the tissue-engineered construct.

BIOENGINEERED TENDON AND LIGAMENT SUBSTITUTES

Damaged ligaments are graded on a severity scale. The grade 1 sprain indicates that the ligament is mildly damaged. It has been slightly stretched, but remains functional and able to help keep the knee joint stable (likely due to the fact that it is a passive structure operating at the low toe region of the stress-strain curve). A grade 2 sprain stretches the ligament and it becomes loose, and some function may be lost. This is often referred to as a partial tear of the ligament. The grade 3 sprain is most commonly referred to as a complete tear of the ligament. The ligament has been split into two pieces, resulting in an unstable knee joint. Similarly, acute tendon injury has been classified into three grades. The primary grade describes tendinitis that includes inflammation and swelling in the tendon. The secondary grade involves a partial tear of the tendon causing pain and weakness. Finally, the tertiary grade is a complete rupture of the tendon with loss of function. The complete rupture of any tendon or ligament requires tissue transfer and/or an intervention that promotes healing (e.g., surgery and/or immobilization plus other interventions). The transfer of a healthy ligament or tendon involves morbidity. The use of allograft substitutes (taken from cadavers) overcomes the need for autologous tissues, avoiding donor-site morbidity. However, this approach does have limitations, including risks of disease transmission, graft rejection and inflammation [22,23]. Tissue engineering offers the opportunity to target and control various biophysiological parameters of tissue development to make it competent for implantation; for example, collagen fibers and cells can be aligned in culture under defined conditions (Fig. 59.1) [24–27]. Perhaps most importantly, bioengineered tissue substitutes are expected to respond and adapt to the unique environmental mechanical stresses that occur following implantation *in vivo* [18,27–29], as well as the biological environment (e.g., extra- vs. intra-articular environment, male vs. female, age-related factors, and co-morbidities in the elderly such as diabetes).

ACL replacement

Some tendons and ligaments are at the top of the list in terms of injury frequency and problems to repair, replace, or heal. As often reported, in contrast with the medial collateral ligament, ACL regeneration is hampered *in vivo* [30,31]. Moreover, certain anatomic factors may predispose people to ACL injury [9]. In the young and active population, reconstruction is often the best therapeutic option. In United States alone, more than 120,000 patients per year undergo tendon or ligament repairs [32]. Almost any sport that involves jumping, cutting or twisting has an inherent risk of an ACL rupture [6,21]. The completely torn or disrupted ACL does not appear to heal very well, at least to the extent that healing leads to a return to function [29,33]. The therapeutic options for ACL reconstruction include three categories of ACL substitutes:

1) Synthetic prostheses,
2) Allogenic natural substitutes (ACL excised from cadavers), and
3) Natural autografts (central portion of the patellar tendon or hamstring tendon of the patient).

Unfortunately, none of these surgical alternatives provides a long-term optimal solution. Synthetic material implantation was a very popular surgical technique in the 1980s, but it frequently led to implant degeneration and failure [34–36]. Joint laxity occurs with synthetic prostheses about 12 months post-surgery, including long-term failure due to synovitis,

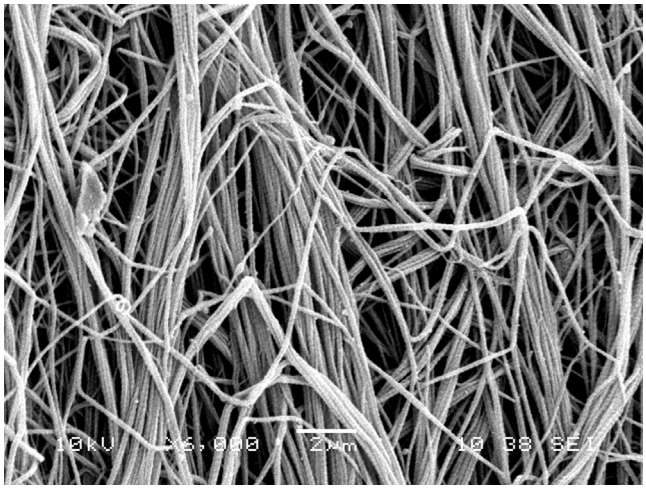

FIGURE 59.1

bACL native collagen scaffold. Photomicrograph taken during scanning electron microscope analyses of an acellular bACL bovine type I collagen scaffold that shows the alignment of the fibers in response to static tension applied for 24 h on the tissue in culture (×6000).

arthritis, and mechanical deterioration. For these reasons, synthetic prostheses are not the first option chosen [35]. However, some new biosynthetic materials are under investigation [37,38]. Assuming proper processing techniques, autografts using the patellar tendon, quadriceps tendon-patellar bone, or the hamstring tendons avoid immune rejection problems [39,40]. Permanent attachment of ACL prosthesis to bone is of critical importance. Over the last decade, the best solution has been the bone-patellar tendon-bone grafts [41]. Unfortunately, ligament translation or laxity is observed post-surgery [40], adding to the morbidity associated with the partial loss of a healthy tendon, chronic knee pain, loss of motion, knee instability, quadriceps weakness, and patella rupture [8]. Little is known about the physiological and pathological events that regulate the histological organization of ACL *in vivo*. It is well recognized that a delay of six weeks after injury is required before ACL surgery is performed. In fact, it is better to perform surgical intervention of the ACL when the nearly normal range of motion of the knee has returned and inflammation has been mostly eliminated [42]. This delay could be long enough to allow for the production of a bioengineered ACL *in vitro* with the required characteristics.

Decellularized and acellular ACL grafts

Decellularized allogeneic ACLs have been investigated as potential grafts for torn ACL replacement [43]. All decellularization treatments affect the tissue ultrastructural and mechanical properties of the remaining scaffold. The abrasive effects of detergents on the tissues to be decellularized can modify their protein contents and consequently, these ultrastructural alterations may impair cell adhesion, migration and proliferation by generating an unrecognizable environment for the cells. In fact, one of the main problems associated with this option for ACL replacement is the presence of dead cells in these tissues. They must be effectively eliminated to reduce the risks of immune rejection post-grafting. Detergents are often used to reach this goal, but they can also alter the structure of the scaffold and the quality of the collagen fibers that support the tissues. Moreover, residual traces of detergents cannot be totally eliminated from the allografts, potentially hampering repopulation of the implants by host cells *in situ* post-grafting. Acellular scaffolds produced *in vitro* overcome these issues but in the end both acellular and decellularized implants will have to be entirely colonized by host cells post-implantation to regenerate and maintain its functional features *in situ* [44]. Such processes slow down the integration of the grafts and their functional recovery [18].

Recent studies have shown that depending on the cells and available growth factor concentrations, repopulation of decellularized scaffolds remains difficult to achieve [45]. Animal experimentation could be initiated to evaluate the histological and biomechanical properties of ACL substitutes seeded with fibroblasts as compared to grafts populated with other sources of cells [18,28]. The phenotypic stability of stem cell-derived fibroblasts would have to be monitored during several passages in culture before considering cellularization of bACLs with these cells. Stem cell-derived fibroblasts, expected to show faster doubling times and a longer lifespan than fibroblasts *in vitro*, may differentiate into various cellular phenotypes in response to the physiological environment and the biomechanical stimuli that characterized functional knee joints. Therefore, until long-term animal experimentation is performed and the results validated, it may be premature to use stem cells to populate tendon and ligament grafts. However, some experiments performed in a sheep model were recently reported as successful at six months post-grafting [19]. Indeed, the success of tissue-engineering procedures also depends on the choice of an appropriate biomaterial [46]. However, further work is still needed to validate the best clinical application of each option.

Tissue-engineered ACL grafts

To overcome the drawbacks associated with ACL repair and healing, several efforts have been made to produce a bioengineered ACL model over the last decade [47–49]. Selecting the right scaffold for the starting point to build a bACL is going to impact the outcome. The use of native collagen for the production of tissue-engineered ligaments leads to a better understanding of the mechanisms responsible for its secretion by the cells, its assembly, and its remodeling. Thus, collagen alone or with cells isolated from the tissue of origin was used to produce different three-dimensional human tissue models *in vitro* [25,50–53]. The main goal behind such achievements was to exploit the tissue-engineering approach to create body parts using natural scaffolds and implant them permanently *in vivo*, where their histological and functional properties should be improved by local and systemic stimuli. The first bACL entirely reconstructed *in vitro* and grafted *in vivo* was developed by seeding autologous ligament or skin fibroblasts in a hydrated collagen matrix [18,27,28,54]. This bACL is anchored with two bones, since bone-to-bone insertion is reported as the most secure method for ligament fixation [7,10]. Such an ACL substitute is a good tool to study connective tissue repair and the environmental and cellular factors that may affect collagen alignment, crosslinking, and remodeling *in vitro* [44]. The main differences between such bACL and other ligament models are the following advantages:

1) It contains living ACL fibroblasts that contract, synthesize, and initiate remodeling and organization of the extracellular matrix in which they are initially seeded in culture;
2) It could be a very useful tool to study connective tissue repair *in vitro*, since the cells can maintain their activities for at least two months in culture;
3) It is produced without chemical crosslinking agents and synthetic material; and
4) It avoids healthy ligament or tendon donor-site morbidity.

Such an ACL substitute would highly reduce the risk of immune reactions and infections, and promote permanent graft integration post-transplantation. This approach also eliminates the risks for chemical cytotoxicity and the production of foreign molecules due to mechanical friction, which could occur *in vivo*, in the situation of its eventual use as an ACL substitute [34]. It may also become a therapeutic alternative for the torn ACL replacement, considering the promising outcomes observed *in vivo* post-implantation in the caprine model [18,28].

Matrix remodeling and gain of strength in response to mechanical stimuli

Various research groups have shown that fibroblasts seeded in collagen gels can degrade and reorganize the surrounding extracellular matrix and adopt a specific orientation in a

contracted collagen lattice as a function of culture conditions and time [55–63]. Several studies have also shown that application of mechanical stimuli to biological tissues can produce ultrastructural and histological content variations in response to the stimuli. For instance, it is well known that ligament remodeling depends on the mechanical stresses to which it is subjected *in vivo* [10]. In addition, bACL produced thus far have collagen and cells aligned in a parallel direction to the stresses exerted [27,28,54]. Finally, Huang et al. [24] have previously reported that the mechanical properties, along with the ultrastructure of ligament equivalents, change in response to mechanical strengthening *in vitro*. Similar observations were made following *in vitro* elongation studies on rabbit ACL [64]. Thus, it is possible and structurally relevant to induce the parallel alignment of the matrix fibers that compose the scaffold of a tissue-engineered ACL substitute in culture. This alignment can be achieved by subjecting the bACL to static or dynamic longitudinal stretching *in vitro* [27]. We previously reported that fibroblasts isolated from human ACL biopsies and seeded in a collagen matrix can secrete and reorganize matricial fibers in response to static tension [54]. Collagen lattices seeded with fibroblasts gain strength *in vitro* after being subjected to cyclic traction over a few days in culture, with stretching amplitudes varying from 0–30 mm at a frequency of up to 1 Hz [54,65]. Rupture and stiffness assays allow the measurement of the strength of the tissue in culture, before and after stretching stimulation [24,65–69].

Native collagen scaffolds for tissue-engineering applications

Collagen is the main constituent of tendon and ligament scaffolds. Thus, it is the protein of choice to use for the development of tissue-engineered grafts. Collagen can be extracted from animal skin or other connective tissue and purified, or it can be synthesized from human or animal cells grown in monolayers for 3–4 weeks, to obtain sheets of collagen seeded with cells according to the self-assembly approach [70]. Native collagen type I polymerizes *in vitro* and the resulting network can be lyophilized to gather fibers together and strengthen its structure (Fig. 59.2a). When rehydrated, despite fibers being arranged in bundles, the strength of the resulting collagen scaffold is sub-optimal and does not compare with the strength of the native ligament or tendon. Therefore, to produce a graftable tendon or ligament substitute made of native collagen, a resorbable threading core must be added to reinforce it in order to enhance the survival of the grafted tissue. For example, we have used polyglyconate MAXON surgical thread (size 3–0), resorbable within six weeks post-grafting, to reinforce tissue-engineered ACL grafts [28]. Following rehydration of the lyophilized central core in fresh DMEM, a second coating of collagen seeded with live cells is applied as described earlier (Fig. 59.2b). A bilayered bACL is thus obtained with a rehydrated central core and a living, cell-populated outer layer. The bACLs are viable prior to implantation, since the fibroblasts progressively contract the outer collagen layer *in vitro*. The resultant bACLs are kept in culture for about a week until grafted into their respective hosts. After a year *in situ* post-grafting in a goat knee joint, the bACL shows many macroscopic features comparable to those of the contralateral native ACL (Fig. 59.2c). Interestingly, results obtained at six months post-implantation showed that the collagen scaffold of the bACL contained nerves endings, sign of proprioceptive restoration (Fig. 59.3). Similarly, highly organized fibrocartilage colonized by chondrocytes was observed at the bone-ligament junction at six months post-grafting (Fig. 59.4). Such observations strongly suggest that chondrocytes or their precursors migrated, proliferated, and became differentiated in the collagen scaffold of the bACL grafts *in vivo* [28]. Collagen I will likely remain the best matrix component to initiate development of biocompatible scaffolds for tendon and ligament bioengineering. The use of *de novo* synthesized collagen sheets has also led to the successful integration of a stem cell seeded ACL graft [19]. Collagen remodeling starts in culture and continues post-grafting, leading to major gains in ultimate strength and rigidity. Such properties can be measured using proper mechanical devices (Fig. 59.4).

Tissue-engineered Achilles tendon

Chronic tears of the Achilles tendon with a resultant gap between the torn ends exceeding 6 cm are a surgical challenge [71]. Treatment of tears to the Achilles tendon with various tendon graft transfer strategies have been reported in the current literature, including free gracilis [71] and autologous peroneus brevis tendon [72] grafts. At 8 to 15 years post-engraftment, many patients retained good functional results, despite a permanently impaired ankle plantar flexion strength and decreased calf circumference [71,72]. The use of free semitendinosus tendon has also led to good clinical and functional outcomes, and is deemed to be safe [73]. However, the possibility to permanently graft a strong tissue-engineered Achilles tendon would be very useful in order to spare autologous healthy tendons in these patients. Various strategies to produce Achilles tendon substitutes using a collagen matrix [74], silk-collagen scaffolds [75], and connective tissue stem cells [75,76] are in progress. The combination of the tissue-engineering approach with conventional treatments might lead to the development of new options to promote effective long-term Achilles tendon repair [77].

Tissue engineering and rotator cuff repair

The rotator cuff is a sensitive tendon complex of the shoulder which is involved when sustaining high levels of force during weight lifting. Soft connective tissues weaken with age and rotator cuff tears may occur as a result of acute trauma, repetitive overhead work, or sports activity, with increased risk during aging. In fact, tears affect 40% or more of people aged older than 60 years, and repair failure rates of 20% to 70% remain a significant clinical challenge [78]. Dermal grafts are often used for rotator cuff repair and augmentation. Compared to surgery without augmentation, acellular human dermal matrix augmentation of large (>3 cm) rotator cuff tears involving two tendons showed better repair with more frequent intact cuffs detected as determined by gadolinium-enhanced MRI. Intact repairs were found in 85% of the augmented group and 40% of the non-augmented group ($P < .01$) [79]. Tissue-engineering strategies to improve rotator cuff healing include the use of scaffolds, growth factors, and cell seeding, or a combination of these approaches. Scaffolds have been the most common strategy investigated to date [78].

Animal models

Many of the features of a tissue-engineered tendon or ligament depend on the type of biomaterials that are used to compose its scaffold. The potential and the functionality of any reconstructed tissue must be assessed in animal models [33]. This is the critical step to evaluate the feasibility, the viability, and the potential factors contributing to graft failure associated with all new ligament and tendon replacement strategies under development [29].

Small animals such as rat models are often used to study tendons of the shoulder's rotator cuff [80]. Rabbit and goat models have been used to assess torn ACL replacement strategies [18,27,81,82]. A major advantage of the rabbit remains the wide choice of antibodies and biomarkers commercially available to analyze the various constituents of ACL substitutes post-grafting and *ex vivo*. The main limitation of this model is its size, and the fact that it does not compare well with the anatomy and functioning of the human knee joint. The goat is larger and the size of its knee joint is close to the human structures. This facilitates development of a preclinical protocol for the implantation of a new type of ACL replacement. However, significant differences are observed between the magnitude of force experienced by the goat ACL and its anteromedial and posterolateral bundles when compared with the corresponding human ACL. Nonetheless, the caprine model is widely used for ACL characterization (Fig 59.5) [83]. More recently, the sheep is another large animal that can be used to assess the level of integration of tissue-engineered ACL substitutes in knee joint [19]. The most challenging preclinical model to study ACL repair is certainly the dog knee joint. As in humans, spontaneous ACL injuries are frequently observed in large dog knee joints. The medial meniscus is commonly damaged along with the ACL. The canine model also involves several other issues, including early osteoarthritis development after a torn ACL injury [84]. For this reason, an ACL substitute tested with success in the canine knee joint would certainly indicate serious potential for use in the human knee. As well, success in the canine model could also have veterinary implications for prevention of osteoarthritis development in valuable companion, working and show animals.

Thus, there are a number of preclinical models available to assess and validate tissue-engineered ACL constructs. A similar range of models are also available for investigating tendon constructs. However, some tendons such as the Achilles tendon may be structurally different in some species, so consideration must be given to the relationship of a construct to the analogous human tissue since repair of injuries in humans is a priority.

CONCLUSION

Recent advances in bioengineering and cell/molecular biology have led to revolutionary new therapeutic applications in many medical fields. Tissue-engineered tendons and ligaments

are under development to provide valuable alternatives and support to conventional reconstructive surgery.

The main advantages of bioengineered tendon and ligament substitutes stem from their capacity to be integrated *in situ* post-grafting, being progressively modulated by the living cells that migrate from the tissues of the host into the scaffold of the bioengineered graft. In the case of bioengineered grafts seeded with living cells prior to implantation, extracellular matrix constituents are secreted and organized in culture [28]. Such remodeling of the graft's ultrastructural features contributes to accelerate its integration post-grafting [18].

This chapter was meant to give the reader an overview of the recent achievements and approaches that combine cell biology and tissue-engineering concepts to produce tendons and ligaments in culture. These bioengineered tissues will indeed have to be optimized prior to human transplantation. However, investigators involved in this domain have not yet started to exploit all the possibilities offered by such a new biotechnological concept. For instance, gene therapy might find some interesting applications by introducing living transfected cells within various types of bioengineered tissues.

Despite the fact that challenges lie ahead for those aiming at reproducing tissues and organs *in vitro*, we can all be hopeful, looking at the ongoing advances reached in various medical fields through tissue bioengineering [32]. It is quite probable that in the near future, people will benefit from bioengineered tendon and ligament substitutes. Their production would start in a laboratory and reach its final completion in a human body. Most importantly, engineering of tendons and ligaments would avoid the need for detrimental harvesting of the patient's tissues used for transfer. This approach may allow the surgical interventions to be performed by arthroscopy, instead of more invasive approaches. In addition, the risk of bioengineered tissues being rejected post-grafting is minimized when produced with autologous cells. That is the joint ultimate goal shared by researchers and clinicians in the various research teams around the world. Such a realization would certainly revolutionize the present therapeutic approaches for tendon and ligament implantation.

Acknowledgments

The authors want to express their sincere gratitude to Dr. Albert Normand, a devoted orthopedic surgeon, who was the first to propose the concept of bACL development *in vitro*. They also thank Lina Robayo for technical assistance. This work was supported by the Canadian Institutes for Health and Research, the Natural Sciences and Engineering Research Council of Canada, the Canadian Foundation for Innovation, the Canadian Arthritis Society and the Fondation des Hôpitaux Enfant-Jésus et Saint-Sacrement.

CHAPTER 60

Skeletal Tissue Engineering

Daniel T. Montoro, Derrick C. Wan and Michael T. Longaker
Hagey Laboratory for Pediatric Regenerative Medicine, Division of Plastic and Reconstructive Surgery, Department of Surgery, Stanford University School of Medicine, Stanford, California

INTRODUCTION

With an aging US population, skeletal tissue injury and loss from trauma or disease represents a burgeoning socioeconomic burden to the healthcare system. Skeletal related injuries and diseases represent a significant portion of this cost; according to data from the 2007 US Health Cost and Utilization Project, there were approximately 1 million hospital admissions for appendicular skeletal fractures in the USA, with an aggregate cost of over $26 billion [1]. Furthermore, skull and facial fractures contributed an additional $1.3 billion. Of all fractures, approximately 10% are complicated with impaired healing [2]. With the culmination of developments in materials science, bioengineering, stem cell biology, and molecular biology, the potential of tissue engineering to accelerate bone regeneration offers an exciting new option for addressing the reconstruction of osseous defects.

The clinician is confronted with an array of large bone defects resulting from trauma, resection of malignancies, nonunion of fractures, and congenital malformations. Autografts remain the best option for reconstructing bony defects because they provide osteogenic cells, osteoinductive factors, and a lattice needed for bone regeneration. They can be obtained from a patient's calvarium, ribs, iliac crest, distal femur, greater trochanter, or proximal tibia. Autografts, however, subject the patient to inherent risks of surgery during harvest. In a retrospective study of autografts harvested from the iliac crest, a complication rate nearing 10% was found, including infection, fracture, large hematomas, pain, paresthesia, and nerve injury [3]. Furthermore, autografts are a relatively scarce resource and are limited by the amount of bone that can be removed without causing undue morbidity to the donor site. In situations where autografts are not sufficient or possible, allogeneic bone from donors or cadavers may be used. Allografts, however, may be accompanied by the risk for disease transmission, immunologic rejection, and graft-versus-host disease.

As an alternative, ceramics and metals are bone substitutes available to repair skeletal defects. Each, however, have their own associated problems. Metals provide immediate mechanical support, but fail to integrate with surrounding tissue [4]. Metals are also at higher risk for infection and fatigue loading. Ceramics, mimicking the inorganic composition of bone, tend to integrate well, but possess low tensile strength and are very brittle. Numerous other synthetic materials have been developed to aid in bone reconstruction, including the use of plaster of Paris, polymer-based substitutes, and bioactive glass.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00060-4

The wide range of options available for osseous reconstruction is indicative of the many advances made in biomaterials, but also reflects the inadequacies of any single method. As such, tissue engineering holds great promise for being able to more adequately address the issue of repairing bone defects. The delivery of osteogenic cytokines is already employed clinically, specifically BMPs, for the induction of bone regeneration. The ultimate translational goal, however, is to deliver both osteogenic cells and cytokines via a biologically active scaffold, in order to heal a bony defect in an accelerated fashion.

This chapter will begin with an overview of distraction osteogenesis, a modality that translates directed mechanical force into endogenous bone formation, to emphasize the important role of the mechanical environment in bone formation and to highlight the growth factors which play a role in inducing bone formation. This chapter will then discuss the necessary components of bone tissue engineering, namely candidate cell types, osteogenic cytokines, and scaffolds, with an emphasis on recent developments.

DISTRACTION OSTEOGENESIS

Distraction osteogenesis provides a model for the study of endogenous bone formation in large skeletal defects. First described by Alexander Codivilla in 1905 for limb lengthening and later codified by Gavril Ilizarov in the 1950s, distraction osteogenesis represents an endogenous form of bone tissue engineering [5,6]. New bone is formed during the process of separating osteogenic fronts with gradual but constant mechanical force. As a first step, an osteotomy is usually performed on the bone of interest, followed by application of rigid fixation. This is followed by a variable latency period of several days, during which a soft callus forms between the two osteogenic fronts. Gradual distraction is then applied, followed by stable fixation/consolidation, until a robust osseous regenerate is formed. It is thought that the mechanical forces applied by distraction can contribute to bone formation by induction of cytokines that guide mesenchymal cells in the bony gap to differentiate along an osteogenic lineage. Distraction osteogenesis not only triggers bone formation, but also stimulates local angiogenesis as part of the process [7].

Much research has been devoted towards characterizing the association between stress and strain patterns with bone formation. Correlating tensile force measurements with histology, Loboa et al., demonstrated that the greatest amount of bone formation occurs during active distraction, the period of greatest strain [8]. Loboa went on to further characterize the forces of distraction, using finite element analysis models created from three-dimensional computed tomography image data of rat mandibles at different phases of distraction osteogenesis [9]. The models described patterns of moderate hydrostatic stress within the gap, predictive of intramembranous ossification, and patterns of mild compressive stress in the periphery, consistent with endochondral ossification. These data derived from finite element analysis were consistent with previous histological findings.

Great interest surrounds research characterizing how mechanical forces may be translated into molecular signals that promote bone regeneration. Tong et al. described the role of focal adhesion kinase (FAK), a regulator of the integrin-mediated signal transduction cascade, in distraction osteogenesis [10]. In a rat model of mandibular distraction osteogenesis, immunolocalization of FAK in regions of new bone formation secondary to distraction was observed, but was absent in the control groups where new bone formation occurred without distraction [10]. Similarly, recent work has also co-localized c-SRC, a kinase involved with activation of the mechanical transduction complex (p130), in regions of bone regeneration secondary to distraction osteogenesis [11]. While signaling molecules involved with transduction of mechanical forces are being identified, further work elucidating the mechanisms of these messenger molecules is required to clarify the influence of the mechanical environment on skeletal tissue engineering.

Distraction osteogenesis has also emphasized the multitude of growth factors which participate in bone regeneration. Elucidation of their roles and mechanisms will be a key element in successful tissue engineering. Transforming growth factor β-1 (TGF-β1), a potent growth factor known to stimulate osteoblast proliferation, has been demonstrated to have increased expression after osteotomy [12]. Immunohistochemistry revealed that TGF-β1 is localized to osteoblasts, primitive mesenchymal cells, and the extracellular matrix during the active distraction phase.

Insulin-like growth factor-1 (IGF-1) has also been implicated to play a role in the early stage of distraction osteogenesis. IGF-1 has been shown both *in vitro* and *in vivo* to stimulate osteoprogenitor cell mitosis and differentiation. In a canine tibia lengthening model, serum levels of IGF-1 increased initially during the early distraction period, followed by elevations in local IGF-1 at the region of distraction [13]. Schumacher et al., also presented evidence supporting the role of IGF-1 in early distraction, where periosteal IGF-1 levels in the rat tibia were increased only during active lengthening [14]. Exogenous addition of IGF-1 in a rabbit model of mandible distraction osteogenesis resulted in increased bone formation compared to control groups [15].

Like TFG-β1 and IGF-1, studies have also shown FGF to mediate bone formation in distraction osteogenesis. Immunohistochemical staining of sheep mandibles revealed FGF-2 staining in the region of distraction, with greater staining in animals found during high-rate distraction [16]. Exogenous administration of recombinant human FGF-2 to a rabbit model of callotasis bone lengthening, during the end of the distraction period, increased the mineral content of the callus [17].

Lastly, BMPs, known mediators in bone formation, have been localized to regions of successful distraction osteogenesis. In examining femoral lengthening in rats, gene expression levels of BMP-2 and BMP-4 were found to be elevated during the period of distraction [18]. Likewise, in distraction osteogenesis of rabbit tibia, immunohistochemical staining revealed intense BMP-2, -4, and -7 staining in fibroblast-like cells and chondrocytes during the distraction phase [19]. This was confirmed in membranous bone, where analysis of the bone regenerate from mandibular lengthening in rabbits revealed BMP-2 and BMP-4 to be highly expressed in osteoblasts during distraction and in chondrocytes during consolidation [20]. Repeated local application of BMP-2 during distraction osteogenesis in a sheep model has been shown to significantly enhance the rigidity and architecture of the callus, indicating that enhancement of the endogenous mechanism may improve the clinical outcome of the procedure [21].

Distraction osteogenesis is thus a useful modality for translating discrete applications of mechanical force into molecular signals that induce skeletal regeneration. This process is not without its own morbidities, however, such as soft-tissue infection, osteomyelitis, pintract infection or loosening, and patient discomfort [22]. Distraction osteogenesis is also limited by the large hardware necessary to accomplish distraction, and by the length of time required for large defects. Given these considerations, work continues on the development of alternative cell-based bone tissue engineering strategies to address large osseous defects.

CRITICALLY SIZED DEFECTS

In the search for optimal elements of successful skeletal tissue engineering, the critically-sized defect has proven to be an indispensable tool for evaluating the performance of various constructs in the *in vivo* context. Critically-sized defects are bone defects that fail to heal without intervention. They provide an easily accessible and quantifiable platform to evaluate the performance, dosages, and combinations of various cellular sources, osteogenic cytokines, and scaffolds.

Well described bone defect assays include calvarial intramembranous bone, endochondral long bone, and mandible segmental defects [4]. The calvarial model is particularly useful in evaluating constructs for craniofacial defects, given the relative ease in handling of the calvarial plate and support provided by the surrounding intact bone, absolving the need for fixation. And, as it bears minimal mechanical load, the influence of exogenous forces on the investigation of specific cellular elements is reduced. Long bone segmental defects can also be created in the radius, where the ulna provides endogenous fixation of that limb. Alternatively, in situations where load bearing of the construct is desired, femur defects can be used.

All of these models are accessible to serial radiographic examination of the amount and density of mineralization through the use of modalities such as plain films and micro-computed tomography. Histomorphometric analysis, however, allows cellular level resolution and evaluation of bone resorption, changes in endogenous structure, and quality of the bone regenerate [4]. Serving as functional *in vivo* bone regeneration assays, critically-sized defects allow researchers to assess the rate and degree of bone healing for individual components of a bone construct and the combined effects of multi-modality treatments.

CELLULAR THERAPY

The two broad categories of populations available as sources of osteoprogenitor cells include osteoblasts and multipotent cells. Osteoblasts are cells committed along a bone lineage and readily form mineralized matrix. They are not, however, an ideal cellular source for skeletal tissue engineering given the limited number of cells available, low expansion rate, and donor site morbidity.

Stem cells, on the other hand, have the ability for prolonged division while maintaining the capacity to differentiate along multiple lineages with proper biological cues [23]. Resident stem cells can be found in many adult tissues, and are active in endogenous mechanisms of repair and regeneration. Isolation, characterization, and utilization of these cells have provided many new promising treatment options. Embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) maintain differentiation capability across all cell types and lack dedicated differentiation pathways. Outside of strict culture conditions, these cells spontaneously differentiate, resulting in tumor formation *in vivo*. A growing body of work, however, has shown progress toward harnessing their differentiation potential for regenerative therapies [23,24].

Postnatal stem cells have been identified in bone marrow, periosteum, muscle, fat, brain, skin and umbilical cord blood [4]. Though the limits of their differentiation potential have not been rigorously defined, research in this area has demonstrated the capacity of these postnatal progenitor cells to differentiate along multiple lineages. The most commonly studied source of postnatal multiprogenitor cells is from the bone marrow. The major components of bone marrow consist of hematopoietic and mesenchymal stromal cells. The hematopoietic component provides progenitors which will differentiate into all the mature blood cell phenotypes. Bone marrow mesenchymal stromal cells (BMSCs) are easily isolated from hematopoietic components because of their unique adherent quality to polystyrene culture dishes. Substantial work has demonstrated the ability of BMSCs to be guided along multiple mesenchymal lineages, including bone, cartilage, muscle, ligament, tendon, and stroma [25]. BMSCs have been shown, *in vitro*, to differentiate along an osteogenic pathway when cultured in the presence of dexamethasone, ascorbic acid, and β-glycerophosphate [25].

BMSCs have been successfully applied across multiple animal models for skeletal tissue engineering. Oghushi and colleagues implanted bone marrow cells loaded on calcium phosphate ceramics into critically-sized defects of rat femurs and found higher rates of complete bone union and accelerated healing in the bone marrow cell group compared to controls [26]. Similar results were shown by Bruder et al., where human BMSCs, seeded on a ceramic carrier,

were implanted into femur defects of athymic rats. Defects with BMSC implants healed and were significantly stronger under mechanical loading conditions than defects implanted with cell-free ceramics [27]. In a rabbit calvarial model, BMSC seeded on a fibrin scaffold demonstrated osseous regeneration similar to control implants seeded with osteoblasts [28].

Although the use of BMSCs is attractive for tissue engineering, it is limited by the low frequency of mesenchymal stem cells within bone marrow stroma. Analysis of human bone marrow aspirates have found that the incidence of BMSCs can be as low as 1 in 27,000 cells [29]. Furthermore, the procedure of acquiring bone marrow is a painful one. Other limitations on the use of BMSCs include the need for sera and growth factor supplements for *in vitro* expansion prior to use. Although subject to debate, BMSCs from older animals have also been observed *in vitro* to form less bone than that from young animals, however, this may be a reflection of differences in proliferative ability.

An alternative mesenchymal cell population composed of adipose-derived stromal cells (ASCs) has been isolated from the stromal component of adipose tissue and has been similarly demonstrated to be multipotent [30]. This work describes the isolation of an adherent cell population from human adipose tissue and induction of these cells from multipotent into adipogenic, chondrogenic, osteogenic and myogenic lineages. Comparison of surface marker antigens have demonstrated a similar expression profile between ASCs and BMSCs [30]. Osteogenic differentiation conditions were also found to be identical to that for BMSCs. Confirmation of osteogenic differentiation was obtained with alkaline phosphatase and von Kossa staining, as well as expression of bone-related genes, including Cbfa-1, alkaline phosphatase, osteopontin, and osteocalcin [30]. As an abundant multipotent cell population, ASCs are attractive candidates for reconstruction because they can be procured in large numbers from individuals with minimal morbidity, and used in an autologous fashion for tissue regeneration or reconstruction [31]. Additionally, because adult ASCs have been shown to retain osteogenic differentiation capabilities, despite some attenuation of proliferation with age, ASCs remain a viable cell therapy candidate in older patients [32].

Lee et al. demonstrated the *in vivo* ability of ASCs to differentiate into bone by implanting polylactic glycolic acid (PLGA) scaffolds seeded with predifferentiated rat ASCs subcutaneously [33]. Bone formation was demonstrated 8 weeks later by tissue morphology on hematoxylin-eosin staining and immunohistochemical staining for osteocalcin. The efficacy of ASCs in healing osseous defects was first demonstrated in a model of critically-sized calvarial defects in mice [81]. Significant bone formation was demonstrated by X-ray, histology, and molecular imaging following implantation of ASC seeded on hydroxyapatite-coated PLGA scaffolds into calvarial defects. Significant bone formation was seen in the defect at two weeks, with complete bony bridging by 12 weeks. Comparison of defects implanted with ASC seeded scaffolds versus BMSC seeded scaffolds demonstrated similar rates of bone formation. This experiment established an important proof of principle that ASCs could contribute to bone formation in a critically-sized, skeletal defect in mice. Human ASCs were shown to stimulate bone regeneration in critically-sized defects in both rat and mouse models [35,36].

When isolated from the vascular fraction, ASCs exist as a mixed cell population with subgroups possessing varying differentiation capabilities. For the purposes of skeletal reconstruction, subpopulations with increased capabilities and responsiveness toward osteogenic differentiation are desirable. Though *in vitro* culture of ASCs can cause drift in the surface expression profile, there has been some level of success using fluorescence-activated cell sorting to enrich for an osteogenic subpopulation. A CD105 enriched osteogenic fraction has been shown to have enhanced responsiveness to osteogenic differentiation *in vitro*, demonstrated by alizarin red and alkaline phosphatase staining, and faster healing of a mouse critical calvarial defect than the unsorted population [37]. In addition to cell surface drift, recent attempts to further enrich osteogenic cells with additional surface markers has resulted in prohibitively low yields.

Isolating subpopulations on factors such as mechanical properties, however, have been shown to provide an additional or alternative method for enrichment [38].

Current research in skeletal regeneration is exploring the *in vitro* manipulation of ASCs in order to enhance osteogenesis prior to transplantation. Reduction of the BMP-2 signaling antagonist, noggin, was shown to increase osteogenic signaling *in vitro* and accelerate bone regeneration in mouse critically-sized calvarial defects [39]. The combination of strategic scaffold design and cytokine treatment, both discussed in the following sections, provide additional avenues for the enhancement of ASC transplants for bone regeneration.

In contrast to the lineage-restricted potential of stromal cells, work has also been done with pluripotent stem cells for skeletal tissue engineering. Despite the broad differentiation potential of ESCs, ethical and political controversies have fueled pluripotent cell research toward adult-derived induced pluripotent stem cells for tissue engineering [40]. Overexpression of key embryonic genes in differentiated cells stimulates chromatin remodeling and altered gene expression, resetting cells to an embryonic-like state of pluripotency [24]. While iPSCs have the capacity to spontaneously differentiate across all three primary germ layers, researchers are developing methods to drive differentiation of iPSCs into pure populations of a single lineage for developmental research, drug screening and disease modeling, and for cell and tissue replacement. Barriers to use of iPSC technology for clinical applications include availability of a large autologous cell source, efficiency and safety of reprogramming, defined optimal culture conditions, efficiency of directed differentiation, tumorigenicity risk, and stability and immunogenicity of transplant. Since the discovery of how to generate human iPSCs by Yamanaka and colleagues [24] significant progress has been made in addressing clinical hurdles. This section will review some of the recent breakthroughs and ongoing research relevant to skeletal reconstruction.

A number of adult tissues, from skeletal muscle stem cells to circulating T cells, can serve as a source of patient-specific cells for iPSC reprogramming [41,42]. Notable for reconstructive surgeons, fibroblasts from skin biopsies and ASCs from liposuction aspirate provide readily available, large quantity cell sources that can readily yield iPSCs [43]. Initial reprogramming experiments used lentiviruses expressing cancer-related genes c-Myc and Klf4, and transcription factors Oct4 and Sox2, introducing risk of insertional mutagenesis at the sites of viral integration and downstream tumorigenic risk from continued oncogene expression [44]. A variety of reprogramming methods have successfully improved on lentiviral technology using non-integrating minicircle plasmids [45], microRNA [46], stabilized mRNA [47] and nucleotide-free recombinant protein [48]. Though these methods result in lower efficiency of reprogramming than the lentivirus, they carry a reduced risk of mutagenesis and have better safety profiles.

Important to engineering of skeletal bone, iPSCs have been demonstrated to respond robustly to osteogenic inductive media containing β-glyerophosphate and ascorbic acid to form osteoblasts *in vitro* [49]. This study initiated differentiation of mouse iPSCs into mesodermal lineage with embryoid body suspension culture and withdrawal of cytokines before adherent plating in osteogenic media. Over a period of embryoid body culture and two passages in osteogenic media, differentiation to an osteogenic lineage was demonstrated with qPCR for *RUNX2* and *Col1a1* genes, and functionally confirmed with Von Kossa and Alizarin Red stains. Embryoid body culture methods and TGFβ-1 treatment caused spontaneous differentiation of iPSCs toward MSC lineage and significantly increased the amount of mineralization after treatment with osteogenic media [82].

For the application of iPSCs *in vivo*, cells must be differentiated sufficiently to avoid uncontrolled and undesired proliferation, or be driven by a robust differentiation program. MSCs derived from iPSCs were shown to give rise to adipogenic, chondrogenic, and osteoblastic lineages *in vitro*. When the iPSC-MSCs were transplanted into critical calvarial defects,

observed stimulation of new bone bone growth, and histomorphological analysis demonstrated participation of these cells in osteogenic healing of the defect [51]. Transgenic iPSCs expressing SATB2, a gene critical in normal bone development, transplanted directly into a mouse critically-sized calvarial defect resulted in new bone growth and no incidence of teratoma [52]. Though it may be an unexpected result that overexpression of a single gene is sufficient to both turn off self-renewal and drive osteogenesis, the calvarial niche is composed of high concentrations of cytokines and bone progenitors which might act in cooperation with transgene expression. Preliminary data from our own laboratory supports the result that delivery of undifferentiated iPSCs on a biobimetic scaffold, in conjunction with osteogenic factors, is sufficient to both strongly drive osteogenic differentiation and dramatically decrease the incidence of teratoma formation.

Research granting agencies, both private and public, have dedicated significant funds to advancing the translation of stem cell applications toward clinical trials and therapeutic development. Continued work to advance tissue-specific stem cell, BMSC, ASC, ESC, and iPSC transplantation toward the actualization of novel therapies will need to address challenges of immune privilege and rejection, the establishment of standard operating protocols for defined culture and storage conditions, tailoring cell/scaffold combinations for specialized craniofacial regions, and defined predictability of graft retention and integration into host. As these are active areas of research undergoing continuous rapid advancements, the field continues to hold promise for future skeletal reconstructive applications.

CYTOKINES

Studies from developmental biology and distraction osteogenesis have revealed a host of growth factors involved in cell proliferation, differentiation, adhesion, and migration during bone formation. An understanding of these interactions will undoubtedly allow for their use in bone tissue engineering. Successful skeletal tissue engineering will likely involve the incorporation of or stimulation by appropriate cytokines combined with the delivery or recruitment of an osteoprogenitor population.

Already in use clinically, BMPs seem to be the most promising candidate cytokine in skeletal tissue engineering. Members of the TGF-β superfamily, BMPs were originally isolated by Urist from bovine bone extracts and found to induce ectopic bone formation subcutaneously in rats [53]. This large group of proteins, comprising nearly one third of the TGF-β proteins, has also been found to be involved in mesoderm induction, skeletal patterning, and limb development. BMPs are known to control both intramembranous as well as endochondral ossification through chemotaxis and mitosis of mesenchymal cells, induction of mesenchymal commitment to osteogenic or chondrogenic differentiation, and programmed cell death [54]. BMPs transmit their signals via ligand binding to the heteromeric complex of type I and II serine/threonine kinase receptors on the cell surface. The ligand signal is then transduced intracellularly via activation of SMAD (signaling, mothers against decapentaplegic) proteins, which subsequently migrate to the nucleus to effect gene expression. BMP signaling has also been demonstrated to be transmitted via the MAP-kinase (mitogen-activated protein) pathway.

BMP-2, -4, -6, -7, and -9 are known to be the most osteoinductive. It is thought that BMPs regulate osteoblast differentiation via increased transcription of core-binding factor-1/Runt related family 2 (Cbfa1/Runx2, a molecule known to be necessary for commitment along an osteoblastic lineage [55]. These osteoinductive BMPs have been demonstrated to stimulate osteogenic differentiation in multiple cell lines, including fibroblasts, chondrocytes, BMSCs, and ASCs. The effect of BMPs has also been noted to be concentration dependent; at low concentrations, they foster chemotaxis and cellular proliferation, but at high concentrations, BMPs induce bone formation [56]. In culture and *in vivo*, BMP-2/6, BMP-2/7, and BMP-4/7 heterodimers have been shown to more effectively enhance osteogenesis than homodimer

combinations [57,58]. BMP-2 has been approved for use by the Food and Drug Administration for surgical reconstructions, and though some controversy exists over clinical outcomes, most studies show that treatment with BMP-2 has promising clinical efficacy.

Fibroblast growth factors (FGFs) consist of a highly conserved family of 24 known peptides that transmit their signals via a family of four transmembrane tyrosine kinases. FGF-2, the most abundant ligand of the family, is known to increase osteoblast proliferation and enhance bone formation *in vitro* and *in vivo* [59]. In FGF-2 haploinsufficient and null mice, decreased bone mineral density has been observed and correlated with decreased expression of FGF receptor-2 and Runx2 at a molecular level [60]. Application of exogenous FGF-2 rescued bone nodule formation in osteoblast cultures from these FGF-2 mutant mice.

Insulin-like growth factors IGF-1 and IGF-2 are 7.6 kD polypeptides that have been demonstrated to stimulate bone collagen synthesis, as well as osteogenesis and chondrogenesis. A transgenic mouse with upregulated IGF expression in osteoblasts resulted in increased bone formation of the distal femur as compared to control mice [61]. Of interest, however, histology did not reveal an increase in the number of osteoblasts, suggesting that IGF-1 increased the activity of existing bone progenitor cells. Conversely, in an IGF-1 null transgenic mouse model, the size and bone formation rates of the knockout mice were significantly reduced as compared to their wild-type littermates [62].

Platelet derived growth factor (PDGF), a 30 kD polypeptide, has also been demonstrated to be a potent stimulus for osteoblast proliferation, chemotaxis, as well as collagen activity. The utility of PDGF *in vivo* has been shown with enhanced bone formation after local application to tibial osteotomies in rabbits and canine mandibles after periodontal surgery. PDGF, commonly used in chronic wounds, is now being studied clinically in periodontic indications. A recent multi-center trial demonstrated that the application of recombinant human PDGF in a tricalcium phosphate matrix resulted in significantly increased periodontal bone formation [63].

The recruitment of blood vessels is important for the support of newly forming tissue. Application of VEGF to both intramembranous and endochondrial bone defects results in increased blood vessel formation, ossification, and new bone in mouse and rabbit models [64]. Putatively through a direct autocrine effect, VEGF was also demonstrated in this study to play a role in osteoblast differentiation. Inhibition of VEGF by application of a receptor neutralizing agent diminished blood vessel formation and osteogenesis.

A direct comparison of the ability of VEGFA, BMP-2, and FGF-2 to enhance intramembranous bone healing in a critical calvarial defect showed that application of each of these cytokines increases proliferation of osteoblasts and progenitors in the defect region [65]. While all three cytokines significantly enhanced healing of the defect, VEGFA and BMP-2 increased angiogenic support, while the effects of FGF-2 were independent of new blood vessel formation. Supporting the hypothesis that angiogenesis is critical to calvarial bone healing, VEGFA and BMP-2 application also resulted in the most bone formation, with nearly complete healing in a mouse critically-sized defect at three weeks [65].

SCAFFOLDS

The challenges of incorporating cytokines in skeletal tissue engineering involve identifying cell populations and molecules that stimulate and participate in bone formation, but the effectiveness of these treatments is largely based on the mode of delivery, effective dosages, and compatible carrier mechanisms. Advances in materials science have provided an abundance of innovations for developing an appropriate carrier for these cells and molecules. In the selection of a biomimetic scaffold for engineering bone, the material should be osteoconductive, osteoinductive, biocompatible, and biodegradeable without eliciting an

immune response. Osteoconductivity refers to the ability of the graft to support the attachment of cells and allows new cell migration and vessel formation. The osteoinductive quality of scaffolds describes their ability to induce undifferentiated stem cells or progenitor cells along an osteogenic lineage. The challenge in designing the structure of scaffolds is to maximize the porosity of the scaffold to promote cellular and neovascular ingrowth, while maintaining the structural integrity of the lattice [4]. Potential matrices can be generalized into three categories: natural, mineral-based, and synthetic polymers.

Natural scaffolds include the use of collagen, hyaluronic acids, calcium alginate, and chitosan, and are typically biodegradable. In many instances, they exhibit osteoinductive properties, exclusive of cells or cytokines. Implantation of collagen type I alone into critically-sized defects of rat mandibles resulted in partial bone healing [66]. The disadvantage of natural scaffolds is their lack of mechanical stability, hence, their limited utility for use in load-bearing regions of the skeleton. The use of natural scaffolds in humans is also limited by the biochemical changes often induced by sterilization procedures.

Mineral-based scaffolds include calcium phosphate ceramics and bioactive glass. Calcium phosphate ceramics are available as hydroxyapatite or β-tricalcium phosphate, with hydroxyapatite most closely mimicking the structural and chemical characteristics of the mineral component of bone. Tricalcium phosphate is marked by a high-dissolution rate that accelerates material resorption and elicits an immune response, while hydroxyapatite has high chemical stability. Mineral-based scaffolds provide an oseteoinductive signal to encourage differentiation of progenitor cells along an osteogenic lineage. There is, however, great variability in the quality of calcium phosphate ceramics to support osteogenesis due to the difficulty in reproducibly creating these scaffolds [67].

Polymer scaffolds, including polylactic acid, polyglycolic acid, polydoxanonone, and polycaprolactone, have been engineered to provide a greater ability to withstand mechanical forces. These lattices are marked by their incredible strength. They are also designed to be biodegradable via hydrolysis as a result of their local mileau. Polymer scaffolds allow ingrowth of bony tissue but lack osteoinductive properties. The combination of structural stability of polymer scaffolds with mineral coating results in an osteoconductive niche with enhanced architectural strength.

Hydrogels represent another class of polymer scaffolds. They are formed by polymerization and crosslinking of molecules like acrylic acid, and N-isoproplylacrylamide [68]. Hydrogels are an attractive option because of their temperature dependent physical properties. They can be designed to be gelatinous at room temperature, but take on more rigid qualities at body temperatures. This property allows for the administration of tissue-engineering constructs via injection. Hydrogels also allow for relatively easy chemical manipulation of individual peptides, making them bioavailable as free molecules in the matrix or tethered for sustained release. Incorporation of Arginine-Glycine-Aparganine (RGD) peptide motifs on these polymers has been demonstrated to enhance osteoblast adhesion and proliferation [69]. By combining collagen hydrogels with PLGA microparticles to deliver osteogenic MSCs, researchers have demonstrated a cell delivery mechanism that is elastic enough to adapt to the shape of a defect, but will mineralize and acquire structural rigidity in the presence of differentiating cells [70]. Another group has used a hybrid scaffold by combining an osteoconductive load-bearing polymer matrix with a peptide hydrogel providing controlled release of rhBMP-2 [71]. Cells seeded in this scaffold demonstrated increased expression of bone differentiation markers in the group with rhBMP2 tethered within the hydrogel compared to an untethered control group during *in vitro* culture. Hybrid gels thus provide for multiple reconstructive goals including structural integrity, sustained release of cytokines, support of cell differentiation, and are promising candidates for actualizing large defect reconstruction.

Electrospinning has emerged as a novel method to construct scaffolds that closely mimic natural extracellular matrix. Nanowoven fibers are generated by shooting a jet of polymer

solution through a high electric field [50]. Adjusting the polymer solution and the electric field allows the fiber diameter and porosity to be controlled with high precision. Osteogenic materials or cytokines can be incorporated into this scaffold, accurately reproducing surrounding bone matrix as well as osteoinductive factors. Silk fibroin fiber scaffolds incorporating BMP-2 and nanoparticles of hydroxyapatite demonstrated higher mineralization of human MSCs cultured on these scaffolds than controls *in vitro* [50]. Electrospun biodegradable fibers seeded with amniotic-derived MSCs were used to generate allogeneic fetal bone grafts with more consistent *in vivo* reconstructions of craniofacial defects than prosthetic repairs in a rabbit model [72].

TISSUE ENGINEERING IN PRACTICE

Current clinical applications for tissue engineering are limited to the delivery of BMP cytokines and cytokine-scaffold devices. A significant criticism of these applications is the high doses of cytokines necessary to obtain clinical relevance and the resulting costs associated with manufacturing recombinant human BMPs. Concern also exists about the rare, but reported incidences of high blood pressure and even myocardial infarctions in animal models, which could be explained by an immunologic response to the cytokine-scaffold constructs [34].

The Infuse® Bone Graft/LT Cage® fusion device is currently in use for tibia fractures, lumbar fusion, and oral maxillary procedures (Medtronic Sofamor Danek, Minneapolis, MN). This product involves an absorbable, bovine collagen implant soaked with recombinant human BMP-2 (rhBMP-2). Humans require supraphysiologic doses ranging from 0.4 to 1.5mg/mL of rhBMP-2 to form new bone. Because of the high doses, there have been concerns about uncontrolled bone growth around the implantation site or cancer, given links of osteosarcoma with BMP activity [73]. A clinical study of Infuse® in 74 consecutive patients revealed radiographic fusion was 100% at 12 and 24 months, in which no bone overgrowth or sarcomas were observed. The study was significantly weakened, however, by the lack of a control group [74]. Off-label use for some procedures in the cervical and lumbar spine have been reported to cause complications including tissue swelling, seroma, ectopic bone formation, paralysis and death [75,76]. This has led many surgeons to reconsider the broad use of Infuse® for off-label applications.

Recombinant human BMP-2 (rhBMP2) has also been used in patients requiring maxillary sinus floor augmentation, in preparation for enodosseous dental implants. In one study, rhBMP-2 was applied to the maxillary sinus floor on an absorbable collagen sponge at 0.75 and 1.5mg/mL [77]. Radiographic evaluation for bone mass in the maxillary sinus floor revealed that rhBMP-2 was able to induce bone formation, but it proved less effective than autogenous bone grafting in fostering osseous formation. Notably, however, rates of successful placement of dental implants were similar between the bone graft treatment arm and patients receiving rhBMP-2 [77].

Recombinant human BMP-7 (rhBMP-7) has also been approved by the FDA for clinical use in cases where previous treatment with autograft failed (Stryker Orthopedics, Mahwah, NJ). It is also delivered via a bovine collagen matrix and has been approved for the treatment of nonunion in the tibia of at least nine months, secondary to trauma, in skeletally mature patients. In a small case series report, the use of rhBMP-7 in five patients who had failed allografts did not result in any significant healing [78]. Recombinant human BMP-7 has also been in clinical use to aid intertransverse process fusion in the lumbar spine [79]. In a putty formulation consisting of rhBMP-7, bony fusion rates were comparable to groups treated with autograft. They did not report any adverse events, ectopic bone formation, or systemic toxicities associated with use of this product over a two year period. Clinical trials are currently being conducted on BMP-7 to test the therapeutic effects on matrix protein restoration, pain reduction, and biomechanical function after vertebral disk injection [80].

CONCLUSION

The intersection of advances in stem cell biology, molecular biology, biochemistry, bioengineering, and materials sciences has brought to the forefront the ability of regenerative medicine to address problems of skeletal defects. Efforts are furthered by continued research on the functions and interactions of osteogenic cytokines, as well as the identification of postnatal osteoprogenitor cells in bone marrow and adipose tissue. The influence of nanotechnology on scaffold design and the advancements of growth factor releasing scaffolds and hydrogels are promising developments to avoid the need for supraphysiologic doses.

Efforts also need to be directed toward developing methods to provide vascular support of large osseous constructs, potentially through the use of pro-angiogenic agents. Further investigation into identifying and enriching osteoprogenitor populations from adult stem cells along with continued advancements in pluripotent cell research may translate into human clinical trials and more available tools for reconstructive surgeons. Given the immense biomedical burden of skeletal defects and the significant developments in skeletal tissue engineering, osseous regeneration provides a promising and attainable goal that will be achieved through interdisciplinary collaboration.

CHAPTER 61

The Nervous System

Lorenz Studer
Center for Stem Cell Biology, Developmental Biology Program, Memorial Sloan–Kettering Cancer Center, New York, New York

INTRODUCTION

Over the last few years pluripotent stem (PS) cells including embryonic stem (ES) and induced pluripotent stem (iPS) cells have emerged as a powerful tool to study brain development and function *in vitro* and *in vivo*. The isolation of ES cells [1] and iPS cells [2–4] of human origin has further stimulated ES cell research directed towards cell therapeutic applications assessing the potential PS cells as a source of a wide-range of somatic cell types affected by disease. The central nervous system (CNS) has been proposed as one of the prime targets for PS cell-based therapies, due to early successes in directing PS cell towards neural fates, due to the experience with fetal tissue transplantation in neurodegenerative diseases and due to the devastating nature of many CNS diseases that often lack efficient alternative treatments. Some of the most striking advantages of PS cells as compared with any other cell type are: extensive self-renewal capacity and differentiation potential, access to the earliest stages of neural development, and ease of inducing stable genetic manipulations.

The mammalian brain is one of the most complex biological structures known. The study of brain function in the normal and diseased brain is therefore a daunting task. However, an understanding of the basic elements that give rise to the extraordinary cell diversity in the brain is an important step towards that end. Developmental biology has taught us that all the cells of the CNS are derived from a small set of neuroepithelial cells that sequentially give rise to the various neuronal and glial subtypes that comprise the CNS and peripheral (PNS). ES cells provide a powerful model system to study developmental neurobiology, to test hypotheses on how neural identity and regional specification is established, and how neural stem cells decide to undergo neuronal or glial differentiation programs. Protocols for the directed differentiation of ES and iPS cells into specific neuronal or glial subtypes can serve as a cell-based developmental screen to identify novel genes involved in specific aspects of CNS development, and to assess the role of known genes under conditions that can bypass embryonic lethality often observed when studying gene function *in vivo*. This interplay between ES cell and developmental biology is mutually beneficial and will hopefully result not only in novel insights for basic biology, but will also provide a comprehensive framework of differentiation strategies for cell therapeutic applications. While work with mouse ES cells has pioneered this approach, human PS cells have developed into a particularly interesting tool given the lack of alternative model systems for the study of early human neural development and the drive to develop directed differentiation protocols for applications in human disease modeling [5] and in regenerative medicine [6].

This review will provide a short introduction to neural development, followed by a section on neural stem cells, contrasting their advantages and limitations for both basic and clinical

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00061-6

applications with the use of ES cells. Subsequently, we will introduce the various strategies available for inducing neural differentiation in mouse ES cells, and we will give various examples of neuronal, glial and neural crest specification *in vitro*. This section will be followed by a brief summary of published work on lineage selection via surface makers and cell types specific promoters, a strategy that can be used as an alternative or in parallel to directed differentiation protocols. A synopsis of the current studies of neural differentiation in human and non-human primate ES cells will be followed by more general remarks on the potential for ES cells to address developmental questions via cell-based screens. The final section will summarize recent work with ES cells for cell therapeutic applications in preclinical models of neural disease.

NEURAL DEVELOPMENT

A basic understanding of neural development is a prerequisite for developing rational strategies of stem cell differentiation. The neural plate is derived from the dorsal ectoderm and is induced by 'organizer' signals derived from the underlying notochord. The dominant model of neural induction is the default hypothesis. This hypothesis states that neural tissue is formed spontaneously in the absence of bone morphogenetic protein (BMP) signaling during early gastrulation, while exposure to BMP signals causes epidermal differentiation [7]. Accordingly, signals emanating from the organizer essential for neural induction are BMP inhibitors such as Chordin [8], Noggin [9], and Follistatin [10] and cerberus. However, there are also reports indicating that FGF signals emanating from precursors of the organizer prior to gastrulation are involved in a 'pre-pattern' of neural induction via activation of Sox3 and ERNI [11]. Subsequent studies have identified Churchill (ChCh), a zinc finger transcriptional activator induced by low doses of fibroblast growth factor (FGF) signaling, which inhibits the meso-endoderm-inducing effects of FGF and sensitizes cells to BMP signals, thereby acting as a switch from gastrulation to neurulation [12]. Other essential players during neural induction are IGF [13] and Wnt signaling [14,15].

After the formation of the neural plate, cells undergo a well-defined set of morphological and molecular changes, leading to the formation of neural folds and neural tube closure. This is followed by orchestrated waves of neural proliferation and differentiation. Of particular importance in determining specific neural fates are signals which provide regional identity both in the antero-posterior (AP) and dorso-ventral (DV) axis, and also define domains of distinct expression of homeodomain proteins and bHLH transcription factors. The leading hypothesis of AP axis specification states that anterior fates are established as a default during early neural induction, while FGF, Wnt and retinoid signals are essential for establishing posterior cell fates (for review see [16]). DV identity is determined by the antagonistic action of sonic hedgehog (SHH) secreted ventrally from the notochord and floor plate and BMPs from the roof plate (for review see [17]). There is ample evidence from explant studies (e.g., [18–20]) – and more recently from ES cell differentiation studies [21–25] – which confirm such a concentration-dependent role of SHH in defining specific progenitor domains within the neural tube by activating class II genes in the ventral spinal cord [26]. However, genetic studies with SHH/Gli3 [27–29], or SHH/Rab23 [30] double mutant mice have shown that dorso-ventral patterning can occur in the absence of SHH, questioning an exclusive role for SHH gradients in DV patterning. Work has demonstrated that the timing of DV patterning is controlled by the antagonistic action of FGF and retionid signals [31], with FGF signals inhibiting the establishment DV homeodomain transcription factors [31]. Other findings have suggested a more specific role for FGFs in inhibiting dorsal gene expression [32] and have identified retinoids as an activator of class I genes [32] essential for DV patterning. A SHH antagonistic concentration dependent role for BMPs in dorsal neural patterning has been proposed from work with explants *in vitro* (e.g., [33], [34]) and partly confirmed in ES cell differentiation studies [23]. While some *in vivo* data from genetic ablation studies [35] and work in transgenic mice that

overexpress the BMP receptor type 1a (BMPR1a/Alk3 under control of the regulatory elements of the nestin gene [36] are compatible with a dorsal patterning role for BMPs, loss of function studies of BMPR1b suggested a much more limited role for BMPs in selectively determining choroids plexus fate [37]. In addition to BMPs Wnt signals might also contribute to dorsal neural patterning; particularly the establishment of the neural crest [38].

Subsequent differentiation of patterned neural precursor cells occurs in a stereotypic fashion with neurons being born first followed by astroglial and oligodendroglial differentiation. Onset of neuronal differentiation is controlled via inhibition of the Notch pathway that represses proneural bHLH genes (for review see [39,40]). Astrocytic fate is established via activation of Jak/Stat signals, which exert an instructive role on multipotent neural progenitor to drive astrocytic differentiation [41,42]. However, recent insights into the neurogenic properties of radial glial [43] cells as well as the identification of adult neural stem cells as a cell expressing astrocytic markers [44] suggest a more complex and dynamic interaction between neural stem cell and astrocytic fates. Oligodendrocytes were believed to derive from bi-potent glial precursor termed O2A progenitors [45] or from other glially committed precursors [46]. However, more recently data have emerged that suggest a lineage relationship between motor neurons and oligodendrocytes in the spinal cord [47,48], as well as GABAergic neurons and oligodendrocytes in the forebrain [49,50] due to their shared requirement for expression of the bHLH gene Olig 2. A review of the developmental signals that control the various neuronal subtypes is beyond the scope of this current chapter, but some of the necessary signals will be discussed in the individual chapters in the section Derivation of ES- and IPS-cell-derived neurons. Excellent reviews on the specification of catecholaminergic and neurons [51], ventral and dorsal spinal cord neuron subtypes [52,53], and forebrain patterning [54–57] are available for a more in depth discussion of this topic.

NEURAL STEM CELLS

The isolation of neural stem cells provided a first step towards developing rational strategies for *in vitro* neuronal and glial differentiation. Neural stem cell culture systems had a significant influence on protocols of directed neural differentiation from ES cells. We therefore briefly highlight some of the basic neural stem cell techniques, with a view towards discussing commonalities and discrepancies between the two *in vitro* differentiation strategies. Neural stem cells have been isolated both from the developing and adult brain (for review see [58–61]). Over 20 years of intensive research have convincingly demonstrated the capacity of neural stem cells for self-renewal and multi-lineage differentiation into neurons, astrocytes and oligodendrocytes; the three major CNS lineages. However, while many tissue specific stem cells, such as hematopoietic stem cells, are capable of differentiation into all progeny within an organ system [62], neural stem cells typically do not give rise to all neuronal subtypes present in the adult brain but are largely limited to the production of GABA and glutamaterigic neurons after long-term expansion [63,64]. Early attempts at isolating and propagating neural stem cells *in vitro* were based purely on selective growth and proliferation condition. The most commonly used method is the neurosphere culture system [65–67]. Under these conditions neural precursors are grown at low density and allowed to proliferate as free-floating spheres in the presence of epidermal growth factor (EGF) and FGF-2. Human neurospheres cultures are typically supplemented with LIF [68] in addition to EGF and FGF-2. Neurospheres can be formed from single cells and the capacity for neurosphere formation is often used as an assay to test stem cell properties of neural cells. For example, the isolation of prospectively identified neural stem cells based on surface markers such as AC133 [69], Lex1 [70] or combinations of surface markers [71] was largely based on the ability of the cells to form neurospheres *in vitro*. These data need to be interpreted cautiously, as neurosphere formation is not necessarily a true test of stemness, and neurospheres do contain many differentiated cells in addition to the presumptive progenitor/stem cell population. In fact studies have

demonstrated that neurospheres are formed more efficiently from transient amplifying populations than from true stem cells in the adult subventricular zone (SVZ) [72] and that neurosphere formation is prone to a number of technical pitfalls that need to be carefully considered when using this assay to define neural stem cell properties.

An alternative approach to the neurosphere technology is the growth of neural precursor/stem cells as monolayer culture attached on a matrix – typically fibronectin or laminin – in the presence of FGF2 [74,75] or FGF/EGF [76]. These conditions are more amenable for studying the precise lineage relationship, and allow for precise manipulations at the single cell level. In fact complete lineage trees for single cortical stem cells have been worked out under such conditions [77]. Among the most important limitations of current neural stem cell technology are the limited *in vitro* control of neural patterning and neuronal subtype specification.

The derivation of midbrain dopamine neurons has served as a model for these difficulties. Functional midbrain dopamine neurons can be derived from short-term expanded precursor cells isolated from the early rodent and human midbrain [78–80]. However, long-term expansion causes a dramatic loss in the efficiency of midbrain dopamine neuron generation [81]. Several strategies have been developed in an attempt to overcome these problems, ranging from exposure to complex growth factor cocktails [82,83] to changing oxygen levels [209] to the transgenic expression of Nurr1 [84,85] a key transcription factor during midbrain dopamine neuron development [86–88]. However, none of these approaches has succeeded in deriving midbrain dopamine neurons that exhibit full functionality *in vitro* and *in vivo* from naïve long-term expanded neural stem cells. While the mechanisms of the restricted neuronal differentiation potential remain to be elucidated, cell types most difficult to derive from neural stem cells are neurons born at developmental stages prior to stem cell isolation. This suggests that the competence of the precursor population to generate these neuronal subtypes might be lost, or that the environmental co-factors required for appropriate neuron subtype specification are missing. Alternatively, the mitogens used for propagation of the neural precursor cells might select for progeny incapable of generating early neuronal subtypes, bias competent precursors into a non-competent state or directly deregulate the neural patterning state as recently suggested for FGF-2 expanded precursors in the spinal cord [89]. Possible future solutions might consist of isolating neural stem cells at an earlier developmental state, and defining conditions that allow these cells to retain early competency for patterning factors, the identification of growth factors that do not bias neuronal subtype or are able to reinduce competence in later precursors, or completely novel patterning strategies that can bypass current limitations in neuronal subtype potential. One early example in this direction is the growth of midbrain-derived precursors in the absence of FGF2 but in the presence of SHH and FGF8 as well as TGFβ3 [90], a combination capable of increasing midbrain dopamine neurons generated *in vitro*, but still with limited capacity for cell expansion. While these problems continue to hamper *in vitro* differentiation studies with primary neural stem cells ES cells offer a simple and efficient alternative solution to overcome such concerns. Furthermore, several recent studies have shown the derivation of either neural stem cells (for review see [91]) or differentiated dopamine neurons [92–94] directly from fibroblasts using extrinsic expression of lineages specific transcription factors.

NEURAL DIFFERENTIATION OF MOUSE ES CELLS AND IPS CELLS

ES and iPS cells are PS cells capable of virtually unlimited *in vitro* proliferation at the undifferentiated stage, overcoming many of the problems associated with instability of stem cell phenotype observed in tissue specific stem cells including neural stem cells. In addition to their proliferation potential, ES cells offer many additional important advantages for both basic and applied research, such as their ease of genetic manipulation, access to the earliest stages of neural development, and their comprehensive differentiation potential. The cell fate potential of ES cells is most vividly illustrated upon injection of ES cells into the developing blastocyst,

where PS progeny contribute to all tissues including the germline. Neural differentiation has been one of the best-studied *in vitro* differentiation pathways in PS cell research. This is in part due to the ease by which ES cells give rise to neural progeny, but also due to the potential of the neural progeny for cell therapeutic applications in the CNS. The use of PS cells in regenerative medicine got a significant boost with the discovery of human ES cells [1,95] and the induction of iPS cells in mouse [96] and human [2–4] somatic cells.

Neural induction

The initial requirement for generating defined neural subtypes from ES cells is appropriate control of neural induction. There are at least three main strategies for neural induction of ES cell *in vitro* to induced neural differentiation in mouse ES cells: embryoid-body- (EB) based systems, stromal feeder mediated neural induction and protocols based on default differentiation into neural fates.

EMBRYOID-BODY-BASED PROTOCOLS

EBs are formed upon aggregation of ES cells in suspension cultures. The interactions of cells within the EB causes cell differentiation in a framework that mimics normal development, particularly the steps of gastrulation. Accordingly, derivatives of all three germ layers can be found in EBs (Doetschman et al. 1985 [96a], for review, see Weiss and Orkin, 1996 [96b]), and EB culture is often used as a first screening tool to demonstrate pluripotency in putative ES cell lines. While the derivation of neural progeny is inefficient under basic EB conditions, a number of protocols have been developed to enhance neural induction and to select and expand EB-derived neural precursors

The first EB-mediated neural differentiation protocol was based on exposure to retinoic acid (RA) for four days after EBs had been formed for four days in the absence of RA (the so-called 4−/4+ protocol [97]). RA is a vitamin A derivative, released primarily by surrounding mesodermal cells, and it exhibits a strong neural induction and patterning effect (for review, see Maden 2002 [96c]). Many variations on the basic protocol have been developed [98–100]. However, no clear mechanistic understanding of the action of RA in EBs has emerged, and the overall cell composition under these conditions remains quite heterogeneous. One major additional concern in RA-based neural induction protocols is the concomitant effect of RA on AP patterning mediated through activating the Hox gene cascade [101].

An alternative EB-based strategy is the exposure to conditioned medium derived from hepatocarcinoma cell line (HepG2), which appears to induce neuroectodermal fate directly [102]. Accordingly, HepG2 treated aggregates do not express endodermal or mesodermal markers but directly give rise to neural progeny expressing progenitor markers such as Sox 1, 2, and nestin. The active component within HepG2 conditioned medium remains to be isolated. Some evidence indicates that at least two separable components are responsible for this activity, and one of these components is apparently a known extracellular matrix molecule [102]. Unlike the RA protocols, HepG2 conditions are not thought to bias neural subtype composition towards specific AP or DV fates. However, no detailed studies are available that have addressed this issue experimentally or developed neural subtype specific protocols.

A third strategy for achieving neural induction is a RA-free EB-based protocol that subjects EB progeny to neural-selective growth conditions [22, 103,104]. Neural selection from EB progeny is achieved under miminal growth conditions in a serum free medium supplemented with insulin, transferrrin and selenite (ITS medium). Under these conditions most EB-derived cells die and a distinct population of immature cells emerges that expresses increasing levels of the intermediate filament nestin. These nestin+ precursors can be replated and directed towards various neuronal and glial fates using a combination of patterning, survival and lineage promoting factors (see sections Derivation of ES- and IPS cell derived neurons and ES-derived glia). This technique is quite robust and highly modular for generating a wide

variety of neural subtypes (see below). Moreover, commercially available kits have become available that provide a simple entry point for setting up the system. However, ES cell line specific differences in the efficiency of neural induction can occur, particularly at stage III of differentiation (selection of nestin+ precursors from EBs in ITS medium) and can be limiting for some applications [21, 105]. Finally, the most widely used EB technology to date for inducing neural fates from PS cells is the serum free EB (SFEB) technology [106]. Under those conditions, neural fates are induced directly without evidence of inducting other germ-layers during EB formation. This is a highly efficient protocol that can be adapted to generate a broad range of neural lineages, including hypothalamic [107], pituitary [108] retinal [109] or cortical [106] lineages.

STROMAL FEEDER MEDIATED NEURAL INDUCTION

Bone marrow-derived stromal cell lines have been used for many years to support the growth of undifferentiated hematopoietic stem cells [110–113], acting in part via expression of the membrane protein mKirre, a mammalian homolog of the gene *kirre* of *Drosophila melanogaster* [114].

Interestingly, many of the stromal cell lines which support hematopoietic stem cell growth exhibit neural inducing properties in co-culture with mouse ES cells [21,115]. Stromal cell lines with the highest efficiencies of neural induction are typically at the preadipocytic stage of differentiation. The main activity resides within the cell surface of the stromal cells and does not diffuse efficiently over long distances [115]. The molecular nature of this stromal-derived inducing activity remains poorly characterized. The efficiency and robustness of neural induction using stromal feeder cells is high compared to alternative protocols [21] and differentiation appears to occur without any bias towards regional specification or neuronal versus glial fate choice [21,23].

NEURAL DIFFERENTIATION BY DEFAULT

Co-culture free direct neural differentiation protocols are based on the default hypothesis proposing that in the absence of cell-cell signaling, particularly in the absence of exposure to BMPs, ectodermal cells will adopt a neural fates [7]. Two independent studies with mouse ES cells confirmed that under minimal conditions in the absence of BMP but in the presence of a required endogenous FGF signal, neural induction does occur in non-adherent [116] or adherent [117] monocultures. The adherent monoculture system has developed into a particularly powerful system for generating neural [61] and forebrain cortical lineages that appear by default [118] or upon inhibition of endogenous SHH [119] signaling. The development of those refined culture systems has been particularly useful for defining the minimal molecular requirements that drive neural fate specification in early development.

DERIVATION OF ES AND iPS Cell-Derived Neurons

Neuronal differentiation occurs rapidly upon neural induction of mouse ES cells. The efficiency of neuronal versus glial differentiation varies widely. Neuronal subtype specification can be influenced by the mode of neuronal induction. This is particularly the case for RA induction protocols that are known to induce the Hox gene cascade in a dose-dependent fashion and promote hindbrain and spinal cord fates at the expense of forebrain differentiation. The basic strategy for achieving neuronal subtype differentiation relies on the application of signals that mimic early patterning events in the embryo to define AP and DV domains within the body axis of the developing embryo. AP patterning is thought to involve factors that actively posteriorize regional identity including RA, FGFs and Wnts. DV patterning is thought to be controlled by the antagonistic action of SHH and BMP signals. While early mouse ES cell differentiation strategies yielded neurons not well characterized and typically of GABA or glutamatergic origin, more refined protocols have been developed

recently for many neuronal subtypes. Protocols for a selection of neuronal subtypes are discussed in more detail below.

Midbrain dopaminergic neurons

Derivation of midbrain dopamine neurons from ES cells has been of particular interest, due to the clinical potential for dopamine neuron transplants in treatment of Parkinson's disease (for review see [120,208]). Protocols for the dopaminergic differentiation of mouse ES cells closely follow findings obtained in explant studies that identified FGF8 and SHH as critical factors in midbrain dopamine neurons specification [20,121–123]. The effect of SHH/FGF8 on ES-derived neural precursors was first described using an EB-based five-step differentiation protocol [22]. Under these conditions, up to 34% of all neurons expressed tyrosine hydroxylase (TH) the rate-limiting enzyme in the synthesis of dopamine. However, the effect of SHH and FGF8 was relatively modest and did not exceed that of another dopamine neuron promoting factor, ascorbic acid (AA, Vitamin C) [22,81]. A further increase in dopamine neuron yield was obtained in ES cells overexpressing Nurr1 [24]. Nearly 80% of all neurons express TH under these conditions, and the expression of midbrain dopaminergic markers remains stable even after transgenic expression of Nurr1 has been silenced. Midbrain dopaminergic differentiation was also obtained using co-culture of ES cells on the stromal feeder cell line (PA6) [115]. PA6 cells mediated neural induction yielded dopaminergic differentiation in up to 16% of all neurons without requiring any exposure to exogenous SHH and FGF8 but in the presence of AA. These results were initially interpreted as PA6 exhibiting a specific action promoting dopamine neuron fate in addition to its neural inducing properties [124]. However, later studies demonstrated that there is no irreversible bias towards the generation of midbrain dopamine neurons using PA6, but neural precursors derived under these conditions remain highly amenable to AP and DV patterning [21,23]. When combining stromal feeder mediated neural induction with exposure to SHH/FGF8 about 50% of all neurons express TH [21] without requiring any transgene such as Nurr1 to further push dopamine neuron phenotype. Numbers of TH neurons need to be interpreted carefully in all *in vitro* differentiation studies, as TH is an unreliable marker for identifying dopamine neurons. TH is also expressed in other catecholaminergic neurons including noradrenergic and adrenergic cells, and it is induced in many cell types under various conditions including cell stress, hypoxia and exposure to a variety of growth hormones. It is therefore essential that studies reporting on the derivation of midbrain dopamine neurons provide additional markers and evidence of dopamine neuron function *in vitro* and *in vivo*. We have discussed these parameters in detail in recent and past reviews on this topic [125,210]. However, *in vitro* derived dopamine neurons generated under these conditions and selected for expression of Nurr1::GFP express all the known markers of endogenous midbrain dopamine neurons and can be used as a tool for discovering novel genes associated with midbrain dopamine neuron lineages [126].

The derivation of TH neurons has also been achieved using a monolayer default neural induction protocol [117]. However, the efficiency of dopamine neuron induction under these conditions remained unclear. In contrast, more recent studies using overexpression of key transcription factors such as LMX1A [204], or more sophisticated patterning strategies [127] can yield *bona fide* mouse midbrain dopamine neurons at high efficiencies.

Serorotergic neurons

The developmental origin of serotonergic neurons is closely related to that of midbrain dopamine neurons. Both neuronal subtypes are dependent on signals emanating from the isthmic organizer [51]. Accordingly, serotonergic neurons are a major 'contaminating' neuronal subtype in protocols aimed at the derivation of midbrain dopaminergic cells. Protocols specifically designed to increase serotonergic versus dopaminergic differentiation have been based on the exposure to FGF4. Application of exogeous FGF4 preceding FGF8 and SHH application ectopically induces serotonergic neurons in explant culture [20]. While

application of FGF4 to neural precursors in the presence of FGF2 at stage IV (neural precursor cell proliferation) of the multistep EB differentiation protocol does not yield a significant increase in serotonergic differentiation [22], FGF4 added in the absence of FGF2 however, causes a dramatic shift from dopaminergic to serotonergic differentiation [24]. Efficient derivation of hindbrain serotonergic neurons using stromal feeder mediated neural induction also involves early FGF4 exposure in the absence of FGF2, followed by FGF2, FGF8 and SHH application [21]. Novel strategies to refine serotonergic differentiation protocols might make use of novel basic developmental insights that demonstrated the importance of the transcription factor Lmx1b in serotonergic differentiation [128], and studies in zebrafish where several novel genes have been isolated that affect the proportion of dopaminergic versus serotonergic neurons including the elongation factor foggy [129] and the zinc finger protein too few [130]. While cell therapy might be not a primary goal for optimizing serotonergic differentiation protocols , the derivation of ES-derived serotonin neurons may provide insights into brain development and offer an unlimited source of cells for pharmacological screens in a neurotransmitter system involved in various psychiatric disorders [131–134].

Motor neurons

Development of spinal motor neurons has been studied in great detail using a variety of mouse loss of function ad chick gain of function models as well as explant culture systems (for review see [17,52]). A more advanced understanding of the developmental signals involved in motor neuron specification and a wealth of reagents available for their phenotypic characterization make the derivation of motor neurons from ES cells an obvious target. Early studies have demonstrated that cells expressing markers of motor neurons can be generated using an EB induction protocol in combination with RA exposure (2−/7+) [99]. More systematic approaches using RA exposure in combination with exogenous SHH to promote ventral fates have yielded ES-derived motor neurons at high efficiency and provided a demonstration of how developmental pathways can be harnessed to direct ES cell fate *in vitro* [25]. By creating an ES cell line, which expresses GFP under the control of the motor neuron specific gene HB9, these ES cell-derived motor neurons could also be readily identified and purified. The *in vivo* properties of ES-derived motor neurons were demonstrated upon transplantation into the spinal cord of early chick embryos. ES-derived motor neurons were detected in the ventral spinal cord, extended axons and innervated nearby muscle targets [25].

Efficient derivation of motor neurons has also been achieved using stromal feeders such as PA6 [23] or MS5 cells [21] in combination with SHH and RA treatment. An important challenge for *in vitro* motor neuron differentiation protocols is the selective generation of motor neurons of distinct AP and columnar identity as demonstrated recently using RA-dependent and RA-independent motor neuron induction conditions [135]. Recent insights from developmental biology studies will provide a good starting point towards that end [136,137]. The potential of ES-derived motor neurons for future therapeutic applications in spinal cord injury or amyotrophic lateral sclerosis (ALS) will heavily rely on the ability to generate precise motor neuron subtypes *in vitro*. Additional requirements are controlling axonal outgrowth, target selection and specificity of muscle innervation. One particularly useful approach might be the genetic or pharmacological manipulation of ES-derived motor neurons to overcome growth inhibitors present in an adult environment, a strategy used successfully to overcome growth inhibition of primary dorsal root ganglion cells upon activation of the cAMP pathway [138,139].

GABA neurons

GABA cells are the main inhibitor neuron type within the brain and are found at high densities in basal forebrain structures, particularly in the striatum. The presence of GABAergic neurons during ES cell differentiation *in vitro* has been reported under various conditions

including the classic 4−/4+ EB-based differentiation protocols [97], which yields approximately 25% GABA neurons [140]. Interestingly, protocols with shorter periods of RA-free EB formation followed by extended RA treatment (2−/7+) select for motor neurons rather than GABA neurons [99]. This suggests that the timing of RA application might be crucial for neural fate specification. The presence of GABA neurons has also been reported under default neural induction conditions [117].

Directed differentiation to GABA neurons has been achieved using a stromal feeder-based approach [21]. Neural induction on MS5 is followed by neural precursor proliferation in FGF2 and subsequent exposure to SHH, FGF8. The delayed application of FGF8 and SHH promotes ventral forebrain identities, as determined by the expression of the forebrain-specific marker FOXG1B (BF-1) [141], and the increase in GABAergic differentiation [21]. In addition to forebrain striatal and cortical GABA neurons there are many other types of GABA neurons in various brain regions including the thalamus [142], midbrain [143] and cerebellum [144]. Recent studies have demonstrated the efficient derivation of cerebellar GABA-ergic neuron lineages from mouse ES cells such as granule cells and Purkinje neurons [145–147]. Other examples of the generation of specific subtypes of GABA neurons include the directed differentiation of cortical interneuron lineages using an SFEB-based strategy in combination with ventral patterning, and lineage selection using an Lhx6::GFP reporter line [148]. GABA neurons are highly relevant for a variety of neurological disorders including Huntington's disease, epilepsy, and stroke, and their dysfunction may also be implicated in neurodevelopmental and neuropsychiatric disorders such as autism or schizophrenia.

Glutamate neurons

Glutamate neurons can be readily obtained at high efficiencies from mouse ES cells. For example in the Bain protocol [97] approximately 70% of all neurons are glutamatergic and ES-derived neurons with N-methyl-D-aspartate (NMDA) and non-NMDA receptor subtypes have been described [149]. Very similar neuron subtype compositions have been obtained with various related protocols [100,150]. More detailed phsyiological data on glutamatergic neurons have been reported after co-culture of ES-derived neurons on hippocampal brain slices [151]. Cortical glutamatergic projection neurons are also readily obtained in monolayer or SFEB culture systems that recreate aspects of cortical neurogenesis *in vitro* [106,118,119]

Other neuronal and neural subtypes

The presence of about 5% glycinergic neurons has been reported using the classic 4−/4+ EB protocol [97,140]. However, directed differentiation into this main inhibitory neuronal subtype in the spinal cord has not been demonstrated. Other interesting neural types generated from ES cells are precursors of the otic anlage [152], pituitary lineage [108] or ES-derived cells capable of recreating optic cup morphogensis [109].

Neural crest differentiation

The neural crest is a transient structure formed from the most dorsal aspects of the neural tube of the vertebrate embryo. It contains migratory cells that form the peripheral nervous system, including sensory, sympathetic and enteric ganglia, large parts of the facial skeleton as well as various other cell types including Schwann cells, melanocytes and adrenomedullary cells. ES cells provide a powerful assay for the study of neural crest development *in vitro*. In early studies, the main strategy for deriving neural crest-like structures from ES cells was based on the exposure to BMPs (BMP2, BMP4 or BMP7) following neural induction. The feasibility of this approach was demonstrated for mouse and partly non-human primate ES cells using the PA6 stromal feeder cell system [23]. This study showed the development of both sensory as well as sympathetic neurons in a BMP dose-dependent manner. The derivation of smooth muscle cells required growth in chicken extract in combination with BMP withdrawal. No

melanocytes or Schwann cells could be obtained under these conditions [23]. However, more recent studies suggest that activation of Wnt signaling is particularly critical for the efficient induction of neural crest lineages in particular in studies using human ES cells [153,154].

ES-DERIVED GLIA

Neural progenitors derived from mouse ES cells can be readily differentiated into astrocytic and oligodendroglial progeny under conditions similar to those described from primary neural precursors. The first reports on the glial differentiation of mouse ES cells were based on the 4−/4+ EB protocols [97,98] or multistep EB differentiation protocols [103]. Most of the glial progeny under these conditions are astrocytes with only few immature oligodendrocytes present. However, subsequent studies have defined conditions for the selective generation of both astrocytes and oligodendrocytes.

Oliogodendrocytes

Highly efficient differentiation into oligodendrocytes was reported first using a modified multistep EB-based protocol [104]. ES-derived neural precursors were expanded with FGF2 followed by FGF2 + EGF and FGF2 + platelet-derived growth factor (PDGF). These conditions yielded a population of A2B5+ glial precursors that are capable of differentiation into both astrocytic (∼36% GFAP+) and oligodendrocytic (∼38% O4+) progeny upon mitogen withdrawal. The 4−/4+ EB RA induction protocol has recently been optimized for the production of oligodendrocytic progeny. This study [155] demonstrated efficient selection of neural progeny by both positive (Sox1-eGFP) and negative (Oct4-HSV-Thymidine kinase) selection, oligodendrocytic differentiation in RA-induced EBs after expansion in FGF2, followed by dissociation and replating in serum-free medium containing FGF2 and SHH. The final step involved SHH and FGF2 withdrawal and the addition of PDGF and thryoidhormone (T3). Under these conditions ∼50% of all cells express oligodendroglial markers. Optimized conditions for oligodendrocyte differentiation using HepG2 or default neural differentiation protocols have not yet been reported. However, stromal feeder mediated induction, initially thought to bias towards neuronal progeny [115], can be readily adapted to derive oligodendrocytes at very high efficiencies and without requiring any genetic selection [21].

Astrocytes

Highly efficient differentiation of ES cells into astrocytes has been recently reported using stromal feeder mediated neural induction, followed by sequential exposure to FGF2, bFGF/EGF, EGF/CNTF and ciliary neurotrophic factor (CNTF). Over 90% of all cells expressed the astrocytic marker GFAP under these conditions [21]. Significant numbers of GFAP cells were also obtained using HepG2 mediated neural differentiation [102] or multistep EB protocols [104]. Glial progenitors obtained with a multistep EB protocol were recently 'transplanted' *in vitro* into hippocampal slices and revealed that full physiological maturation of ES-derived astrocytes can be achieved upon interaction with an appropriate host environment [156]. Under these conditions ES-derived astrocytes integrated seamlessly into host astrocytic networks tightly coupled via gap-junctions.

LINEAGE SELECTION

Lineage selection based on surface markers or the cell type specific expression of promoter-driven selectable markers provides an alternative approach to directed *in vitro* differentiation protocols. The use of genetic markers in ES cells is particularly attractive due to ease of inducing stable genetic modifications and the availability of large libraries of transgenic and gene targeted mice and ES cells. Efficient purification of neural progeny from mouse ES cells *in vitro* was demonstrated via positive selection using a Sox1-EGFP knock-in cell line [206] and

combined with negative selectable marker controlled by endogenous Oct4 locus [155]. Other ES lines successfully used for the genetic identification and purification of neural precursor, neuronal and glial progeny *in vitro* include a tau-eGFP knock-in cell line, a GFAP transgenic line [157], GAD-lacZ knock-in ES cells [158], BF1-lacZ knock-in ES cells [21], and ES cell lines driven under the regulatory elements of the Nestin gene [159,160]. Promoter-driven lineage selection for motor neuron fate *in vitro* includes ES cell lines expressing eGFP in the Olig2 locus [161] or as a transgene under the HB9 promoter [25]. In the case of midbrain dopamine neurons, we have described the use of reporter lines that mark sequential stages of dopamine neuron lineages from the precursor stage (Hes5::GFP) to post-mitotic dopamine neuron precursors (Nurr1::GFP), to the specified midbrain dopamine neuron lineage (Pitx3::YFP) [125]. Those reporter lines have been particularly useful for defining optimized grafting protocols and for gene discovery studies [125,162]. Finally, cortical interneuron precursor lineages can be captured using an Lhx6::GFP reporter line that has been particularly useful for lineage selection in cell transplantation studies.

NEURAL DIFFERENTIATION OF HUMAN AND NON-HUMAN PRIMATE ES CELLS

Neural differentiation potential was readily observed when primate ES, or ES-like cells were first established in both monkey and human ES cells [95,163], as well as in human EG cells [164] and monkey parthenogenetic stem cells [165]. However, the derivation of purified populations of neural progeny from human ES cells required more systematic studies. A highly efficient protocol for the neural differentiation of human ES cells was based on a modified multistep EB approach [166]. ES cells are aggregated short-time (~4 days) and subsequently replated under serum-free conditions in the presence of FGF-2. Under these conditions, neural precursors can be readily identified based on the formation of multilayered epithelia termed rosettes. It was suggested that such rosettes might mimic neural tube like structures *in vitro*. These neural precursor cells can be enzymatically separated from the surrounding cell types and grown to purity under neurosphere-like conditions in the presence of FGF-2. Differentiated neural progeny derived from these neurosphere-like structures are neurons and astrocytes. The main neuronal subtypes are GABAergic and glutamatergic phenotypes [166] (see also [167]). A similar spectrum of differentiated progeny was obtained when human ES-derived neural precursors were obtained after spontaneous neural differentiation by overgrowth of undifferentiated cells [207]. Rosette-like structures were manually isolated under microscopic view and subsequently grown and passaged under neurosphere-like conditions. A third strategy that yielded differentiated cell populations enriched for neural precursors was based on a modified EB RA induction protocol, followed by lineage selection in attached cultures using serum free conditions and supplementation with bFGF [168].

Protocols that yield better control over neuronal subtype specification are still in development, but first examples have been provided for deriving midbrain-like dopamine neurons from non-human primate ES, [165,169,170]. Interestingly, PA6 mediated neural induction caused differentiation into retinal pigment epithelial cells [169] in addition to neural differentiation and the derivation of TH+ neurons. A bias towards eye differentiation was not observed with standard mouse ES protocols using stromal feeder cells. However, more systematic efforts have identified conditions that yield eye-like differentiation in mouse ES cells [171], suggesting that eye phenotypes can be obtained not only with human ES cells but also mouse ES cells.

One interesting difference between human and mouse ES cell differentiation is the presence of large numbers of rosette-like structures during the early stages of neural differentiation in human ES cells, while these structures are more rarely observed during mouse ES cell differentiation. Human ES cell-derived neural rosettes can be isolated and propagated *in vitro* as rosette (R-)NSCs [172]. R-NSCs express a set of specific markers such as PLZF that distinguish them from previously described NSC populations. Furthermore, early stage R-NSCs retain the

ability to adapt a broad range of region-specific fates in response to appropriate anterior-posterior and DV patterning cues [172]. However, those properties are unstable using currently described methods for R-NSC maintenance. A similar human ES-derived rosette-like cell has been described that retains developmental potential after long-term expansion [173]. Those long-term (lt-) NSCs are highly neurogenic even after extensive *in vitro* expansion and retain some limited patterning potential towards various midbrain/hindbrain lineages. However, in contrast to R-NSCs those cells appear to be unable to generate forebrain neuronal lineages.

A key breakthrough in the last few years was the identification of defined neural induction protocols in human ES and IPS cells. Based on the developmental principles, we have shown that inhibition of BMP signaling in combination with the inhibition of TGFb signaling yields neural fates at very high efficiencies and without the need for neural-inducing feeders or EB formation [174]. Those dual-SMAD inhibition conditions can be triggered using small molecules and have become a new standard in the field. We and other groups have adapted the dual-SMAD protocol to a wide variety of conditions and CNS and PNS lineages. Some of those key lineages include human ES cell-derived midbrain dopamine neurons [175], floor plate cells [176], neural crest lineages [153,174] and sensory neurons [174], motor neurons [177] or cortical forebrain neurons [178,179] to name only a few. The rapid progress in directing neural specification of human ES and iPS cell raises intriguing possibilities for their use in human disease modeling and in cell therapy.

THERAPEUTIC PERSPECTIVES

One of the driving forces behind deciphering the developmental program that controls cell fate specification is the hope that such insights could be harnessed for generating specialized cells for therapy and for human disease modeling. However, despite the excitement about the potential of ES and iPS cells for application in regenerative medicine, there are only a limited set of examples where human translation is currently being contemplated. Similarly, while there is a large body of work showing the feasibility of modeling human neural disease using iPSC technology [5], there are only few examples in the nervous system and beyond where this approach has yielded novel potential therapeutic targets. While a discussion on the current state of human neural disease modeling is beyond the scope of the current review, I will briefly summarize some progress in the area of cell therapies and specific applications in regenerative medicine

Parkinson's disease (PD)

One of the most widely discussed applications is the derivation of unlimited numbers of dopamine neurons from human ES cells for the treatment of Parkinson's disease. PD is particularly attractive for cell transplantation due to the relatively defined pathology that mainly affects midbrain dopamine neurons, and the largely unknown etiology that currently precludes causative treatment. At the onset of clinical symptoms, the majority of midbrain dopamine neurons have already died, providing further rationale for a cell replacement approach. The first ES cell-based study which showed functional improvement in 6OHDA lesioned rats, an animal model of PD, was based on the transplantation of low numbers of largely undifferentiated mouse ES cells isolated after short-term differentiation in EB cultures [205]. Spontaneous differentiation into large numbers of neurons with midbrain dopamine characteristics was observed. However, the clinical relevance of this approach is rather limited due to the high rate of tumor formation (>50% of the animals with surviving grafts developed teratomas).

Remarkable functional improvement was obtained after transplantation of dopamine neurons derived from mouse ES cells overexpressing Nurr1 [24]. This study was based on a multistep EB differentiation protocol. In addition to behavioral restoration in 6OHDA lesioned rats,

this study demonstrated *in vivo* functionality via electrophysiological recordings from grafted dopamine neurons in acute brain slices obtained from the grafted animals. However, transgenic expression of Nurr1 may complicate clinical translation and it does not necessarily yield an authentic midbrain dopamine neuron fate [180]. Functional recovery with dopamine neurons derived from naïve mouse ES cells has been reported in using mouse ES cells [21], nuclear transfer ESCs [21] and iPS [182] cells. Successful grafting of ntES-derived dopamine neurons provided a first example of therapeutic cloning in neural disease [21,172]. The differentiation of human ES cells into midbrain dopamine neurons was first reported using a stromal feeder-based approach [183]. However, transplantation studies of human ES cell-derived dopamine neurons has been hampered over the last few years by the poor *in vivo* survival/maintenance of the dopamine neuron phenotype. Only recently, we were able to develop a novel strategy for midbrain dopamine neuron induction [175] that is based on the dual-SMAD inhibition protocol [174]. Using this novel protocol, which generates midbrain dopamine neurons via a floor plate intermediate [176], we were able to report highly efficient *in vivo* survival of midbrain dopamine neurons in Parkinsonian mice, rat and rhesus monkey hosts [175] and very robust functional effects associated with behavioral recovery.

Several issues remain to be addressed before clinical trials with human ES cell-derived dopamine neurons should be initiated. Twenty years of fetal tissue research have demonstrated that fetal midbrain dopamine neurons can survive and function long-term (>10 years [184]) in the brain of Parkinson's patients. However, these studies have also shown limited efficacy in placebo-controlled clinical trials and demonstrated potential for side effects [185,186]. Stem cells will have to learn from the fetal tissue transplantation trials and better define and address the critical parameters that can take cell therapy in PD to the next level [120]. However, the ability to derive highly purified populations of authentic substantia nigra type dopamine neurons from human ES cells [175] is an important step on this road, and major efforts are geared toward clinical translation in the near future.

Huntington's disease (HD)

Similar to PD, the pathology in HD preferentially affects selective neuronal subtypes, particularly GABAergic medium spiny neurons, the main neuron subtype in the striatum. Fetal tissue transplantation trials [187–189] provide experience on how to design stem cell-based approaches for the treatment of HD. However, unlike in PD, grafted cells are required to reconnect, not to local targets within the striatum, but to project from the striatum to the targets in the globus pallidus and the substantia nigra pars reticulata. Data on whether fetal tissue grafts have been able to re-establish such long-distance connections in patients remains controversial. Recent studies have demonstrated the feasibility of generating medium-spiny type striatal GABA neurons from human ES cells [190–192] with solid evidence of *in vivo* survival and function [192].

However, transplantation into the HD brain remains daunting given the large distance in the human brain that would need to be reconnected by striatal grafts. Therefore it remains to be determined whether the main use of human ES and iPS cell-derived striatal neurons is cell therapy or in using those cells for modeling HD *in vitro*, an approach that has shown considerable promise.

Spinal cord injury and other motor neuron disorders

Traumatic or degenerative injuries to the spinal cord are often devastating and irreversible. Cell replacement using stem cells has been touted as prime application of stem cell research. However, the complexity of cell therapy in spinal cord injury is enormous and far from resolved. Motor neurons are one of the main cell types affected by spinal cord injuries and by various degenerative diseases such as ALS, Lou Gehrig's disease). The efficient

derivation of motor neurons has been reported from mouse and human ES cell sources, [25,193,194]. However, the integration of ES-derived motor neurons *in vivo* has been mostly addressed via xenografts into the developing chick spinal cord [25,135]. The application of ES-derived motor neurons in the adult CNS and in animal models of spinal cord injury or motor neuron disorders remains challenging with only a small number of cells surviving [194].

However, there is compelling evidence that neural stem cell population and oligodendrocyte precursor cells can engraft in animal models of spinal cord injury and induce functional improvement in the host animal. While the specific mechanisms of action in those studies remain to be determined [195], the field is rapidly moving towards testing those cells in early stages clinical trials given the devastating nature of the disease and preliminary evidence for the safety of those cells from *in vivo* studies.

Stroke

Cell replacement therapies for treating stroke are complicated by the fact that the cell types lost in the disease differ considerably from patient to patient depending on the exact location of the stroke within the brain. Nonetheless, several groups have pursued transplantation studies using ES-derived cells in stroke models. Early work has shown that grafted ES cells can survive in a rat stroke model induced by transient ischemia via occlusion of the middle cerebral artery. This study used non-invasive imaging to track cells by high resolution magnetic resonance imaging (MRI) after transfection with ultrasmall superparamagnetic iron-oxide particles [196]. More recent studies have focused on the use of primary or ES-derived neural stem cell populations and shown functional effects of neural stem cell grafts [197]. While the mechamism of action of those grafts are complex [198,199] and remain poorly understood, there are active ongoing efforts to translate those efforts into human patients.

Demyelination

The capacity of mouse ES-derived progeny to remyelinate *in vivo* was first demonstrated after transplantation of highly purified ES-derived glial progenitors into the spinal cord of *md* rats [104] that lack the X-linked gene encoding myelin proteolipid protein (PLP), an animal model of Pelizaeus-Merzbacher Syndrome. This study showed impressive *in vivo* differentiation results and yielded large grafts comprised of myelinating oligodendrocytes. However, the grafted cells were not able to extend the short lifespan of these animals, precluding detailed functional analyses. A second study demonstrated remyelination after grafting purified oligosphere cultures derived from 4−/4+ EBs into the spinal cord of shiverer mice or into the chemically demyelinated spinal cord [200].

In the case of human ES cell-based studies, there was a lot of excitement about the potential use of ES-derived oligodendrocyte precursors for applications in spinal cord injury with the idea to remyelinate denuded axons [201]. This study evolved into the first human ES cell-based clinical study in spinal cord injury patients. However, those studies are not being further pursued by the company involved (Geron), and the ability of those cells to remyelinate the human CNS remains to be determined. In fact those early human ES cell-derived oligdendorcyte precursors expressed very immature markers and did not remyelinate very efficiently *in vivo*. More recently, better defined protocols for generating oligodendrocyts were developed [202], but those protocols are difficult to scale and require up to 100 days of *in vitro* differentiation. Nevertheless, human ES-derived oligodendrocytes transplanted after long-term *in vitro* differentiation have shown remarkable *in vivo* remyelination efficiencies and induced functional recovery in shiverer mice [203]. Those studies indicate considerable promise for future clinical translation.

Other diseases

Several disease models that have been approached with fetal neural progenitors have not yet been tested using ES cell-based approaches. These include epilepsy and enzymatic deficiencies such as lyosomal storage diseases. Other CNS disorders such as Alzheimer's disease have been touted as future applications for ES cell therapy. However, at the current stage of research, the challenges for cell therapy in Alzheimer's disease seem to be overwhelming and it appears more likely that the role for ES cells might be in providing cellular models of disease rather than for cell replacement.

CONCLUSION

The development of protocols that allow the directed differentiation from ES and IPS cells to specific neural fates provides an essential basis for all PS cell-based approaches in neural repair. Over the last few years, directed differentiation protocols have rapidly progressed, and neural induction is now a routine procedure for studies in both mouse and human PS cells. In fact it is conceivable that over the next 5–10 years there will be strategies to generate any neural cell type of interest using a combination of directed differentiation protocols, transcription factor based programming and lineage selection. Access to all major neural lineages will greatly improve our ability to design rational cell-based strategies in regenerative medicine. However, those applications should remain limited to disorders that are amenable to cell replacement based on an understanding of the disease process. Some of the key examples include cell replacement in PD, eye disorders or demyelinating conditions. A potentially even broader range of applications for PS derived cell types is their use in human disease modeling. The ability to generate patient specific neurons from a myriad of neural disorders should offer novel insights into disease mechanisms and enable the development of cell-based pharmacological screens. Finally, one of the most important contributions is the use of PD-derived cells as a basic research tool that allows us to unravel step by step the complex signals that govern the development of single pluripotent ES cells to the amazing diversity of cell types that comprise the mammalian CNS.

CHAPTER 62

Brain Implants

Lars U. Wahlberg
NsGene, Inc., Providence, Rhode Island

INTRODUCTION

Even though regulatory approved cellular brain implants are not yet available, experimental data strongly support the use of brain implants and tissue-engineering concepts in the treatment of brain disorders and promise new disease modifying medical products for patients. Various cellular implants have already been applied in the clinic in proof-of-concept studies in Parkinson's disease (PD) [1], Huntington's disease (HD) [2], Alzheimer's disease (AD) [3], epilepsy [4] and stroke [5]. PD is a major target for brain implants and is highlighted in this chapter as a disease example to illustrate the tissue-engineering concepts applied to date.

Despite the longstanding success of many drugs for PD, such as L-dihydroxyphenylalanine (L-DOPA) therapy, the current treatments of PD do not stop the progressive dopamine neuron dysfunction and cell death. Over time, patients on chronic L-DOPA therapy develop both progressive symptoms and drug-induced side effects and require additional treatment options. In the early 1990s, surgical treatments initially developed during the 1950s, such as the ventrolateral pallidotomy for Parkinsonian rigidity, were rejuvenated [6]. With improvements in imaging and surgical techniques, ablative procedures have yielded excellent results in selected PD patients. Implantable neural stimulators, which inhibit neuronal transmission in local areas by high frequency stimulation, have more recently replaced much of the ablative therapies and can yield good therapeutic results without inducing permanent lesions in the brain [7]. Despite successful applications of neurosurgical procedures for the treatment of PD, these procedures are based on the inhibition or destruction of normal neurons to compensate for the disease damage. They do not address the biology of the underlying disease itself and, albeit successfully applied in many patients, the destruction or inhibition of normal tissue is not an optimal treatment for neurological disorders. There is therefore a need for new treatment strategies that can address the pathology more directly and offer disease modifying effects. Fortunately, the accumulated knowledge of the pathological processes, molecular and cell biology, biomaterials, imaging, and surgical procedures make it now possible to implement disease modifying tissue-engineering concepts to the treatment of PD and other neurological diseases.

In many untreatable neurological disorders, the progressive loss of neurons and their associated function is the primary underlying cause for the symptoms of the disease. Therefore, various cell implant strategies have been designed to either **replace** the neurons or their function or to **protect and/or regenerate** the function and health of the diseased neurons, or a combination of both (Fig. 62.1).

Clinical applications to replace the dopaminergic function in patients with PD have so far utilized primary tissues or cells. Dopaminergic neurons derived from stem cells and more sophisticated tissue-engineered implants have not yet been applied in the clinic but rapid

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00062-8

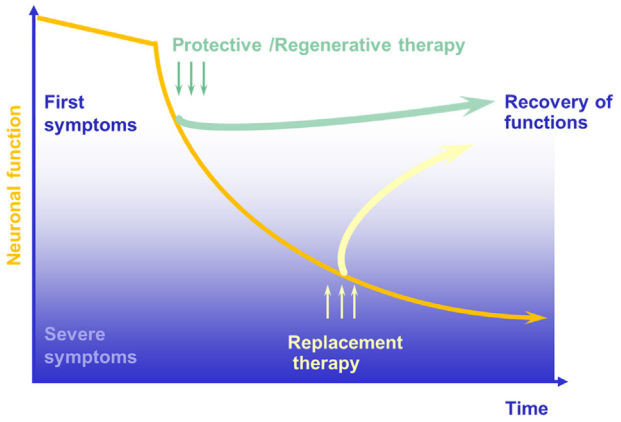

FIGURE 62.1

The concepts of cell replacement and protection/regeneration are depicted. A loss of neurons or their function (orange line) occurs with aging but in a disease, such as PD, neuronal loss is accelerated and after a while, the loss is significant enough to cause symptoms of the disease. At this stage, further deterioration could be prevented by protecting the neurons and the system could even be improved by applying regenerative factors to the diseased host cells. After significant loss of neurons, regeneration of the host system is not possible. However, the implantation of cells capable of replacing the function of host cells could be possible. Both approaches have been applied in Parkinson's disease and a combined treatment of neuroprotection/regeneration with replacement may be achieved in future brain implants.

progress in preclinical efforts is being made. In neuroprotective or restorative strategies, cellular implants secreting either endogenous or engineered growth factors or cytokines have successfully been applied in animal models and even in the clinic for amyotrophic lateral sclerosis (ALS) [8], Huntington's disease (HD) [9], and Alzheimer's disease (AD) [10–12].

This chapter reviews some of the cell replacement and regenerative brain implants applied in the clinic and touches on what may be developed in the future.

CELL REPLACEMENT IMPLANTS

Primary tissue implants

As mentioned above, oral L-DOPA therapy is the main treatment for PD. L-DOPA is a precursor to dopamine that passes the blood-brain barrier and is mainly taken up by the dopaminergic neurons that convert L-DOPA to dopamine and increase their dopamine production and storage. However, with the progressive loss of dopaminergic neurons, the L-DOPA therapy eventually becomes ineffective and severe fluctuations in the ability to initiate movements occur. Because L-DOPA can increase the production of dopamine and alleviate the symptoms of PD, a reasonable therapeutic approach may be to implant dopamine or L-DOPA secreting cells in the relevant areas of the brain (striatum).

Considering this idea, the first clinical transplantation for PD using a cellular brain implant was performed at the Karolinska Hospital in Stockholm, Sweden in the early 1980s [13]. Autologous dopamine-secreting adrenal chromaffin cells were harvested from one of the patient's adrenal glands and successfully transplanted to the striatum. The procedure was adopted very quickly by the medical community and initial reports indicated good clinical results. With time though, other studies showed poor survival of the cells and minimal positive clinical effects, resulting in the cessation of the treatment [14]. However, the concept of cellular brain implants had made its definite entry into the clinic and many lessons were learned along the way.

At about the same time as the first chromaffin cell transplants were made in Stockholm, a promising cell transplantation strategy for PD was developed by Anders Björklund and co-workers at Lund University in southern Sweden [4]. They collected discarded aborted fetal

tissue and dissected out the ventral mesencephalon to create cell suspensions containing developing dopaminergic neurons for transplantation experiments. After several years of extensive validation of the concept in animal models, cells were transplanted to the striatum of two PD patients [15]. The first results were safe but relatively unimpressive prompting modifications to various parts of the experimental procedure, and a second pair of patients transplanted about one year later fared much better [16]. These patients showed positive clinical recovery starting about four months after the procedure. Positron emission tomography (PET) data indicated that the grafts survived and took up and secreted dopamine. More than 10 years after the procedure, one of the patients showed persistent graft viability on PET scanning and required only minimal L-DOPA therapy [17,18]. To date, more than 300 patients have been transplanted with fetal ventral mesencephalic tissue at different centers around the world with some encouraging results. However, the lack of suitable donor material, the heterogeneity of the tissues and preparations, and the inability to industrialize the process, have all made it difficult to make standardized medical trials and therapy geared for a large number of patients. Two controlled trials with fetal transplantation showed only minimal efficacy and some patients developed movement side effects (dyskinesias) that appear related to the grafting procedure [19,20]. More recently, it has been observed that grafted fetal neurons may be able to survive for many years after surgery but these same grafted neurons are subject to the same pathological processes that underlie the loss of endogeneous dopaminergic neurons in PD [21]. Therefore, fetal transplantation as a therapy for PD is no longer actively pursued and cell replacement strategies for PD are awaiting alternative cells and implants that lend themselves to a reproducible industrial process applied in well controlled trials. It also should be noted that clinical trials with porcine-derived ventral mesencephalic cells that did lend themselves to a more rigorous industrial process also failed in clinical trials (Pollack, 2001). With concerns regarding the transmission of animal diseases to humans (zoonosis), few if any additional clinical applications of animal-derived cellular brain implants are being contemplated. In fact, the use of animal-derived products in the manufacturing of human brain implants should be avoided to the largest degree possible to minimize safety concerns. Despite disappointing results in the clinical application of both chromaffin and fetal derived primary tissues from both human and pig sources, the experimental work surrounding primary tissue transplantation in PD demonstrated several important points that continue to facilitate the development of tissue-engineered implants for the treatment of PD and other neurological disorders.

1) Allogeneic cells can survive over many years in the brain after a relatively brief initial immunosuppression therapy (18 months) but xenogeneic (porcine) implants do not.
2) Grafted neurons can integrate, function, and interact with the host brain in a physiological and reciprocal manner.
3) Trial designs and outcome measures have been developed that facilitate safety and efficacy measures in the clinic.
4) Surgical techniques have been developed that allow for the safe injection and implantation of cells and tissue-engineered products in the brain.
5) Imaging techniques have been developed to evaluate the implantation and function of the brain implants.
6) Animal models have been developed to translate and scale-up experimental brain implants for the clinic.

Cell line implants

As mentioned above, important drawbacks using primary tissues are its limited supply, its heterogeneity, and the difficulty and prohibitive costs to implement the necessary good manufacturing principles (GMP) for harvesting, manipulation, storage, and later use. For example, fetal transplantation experiments for PD required fresh tissue from 4–8 donors resulting in procedural difficulties and poor quality control and may help explain the poor

and variable efficacy outcomes in controlled trials. Therefore, the ability to expand and store cells in cell banks is paramount to creating allogeneic cell alternatives to primary tissue sources. The expansion of normal and genetically unmodified cells derived from tissue donations can give rise to expandable primary cell lines potentially useful for brain implantation with or without further manipulation. The primary cell lines normally retain a limited number of cell cycles but allow for the proliferation of enough cells to transplant hundreds to thousands of patients from a single donor. Cultured primary cells can be expanded while retaining normal genotypes and phenotypes with normal contact inhibition and differentiation behaviors. These cells are therefore relatively safe to use, and the formation of tumors or other abnormal behaviors are relatively unlikely.

Retinal pigmented epithelial (RPE) cells derived from the retinas of organ donors can make primary cell lines with limited expansion capacity and have been evaluated in clinical trials for PD. The RPE cells secrete L-DOPA and are thought to function by increasing the intrastriatal L-DOPA concentration and subsequent conversion to dopamine by residual dopaminergic nerve endings and glia. These cells are grown and transplanted on gelatin microcarriers to improve survival and prevent immune rejection. A report on a clinical pilot trial showed that these implants were well tolerated and safe [22]. However, a recently completed Phase II trial failed to reveal any evidence of efficacy [23] and earlier published autopsy results demonstrated poor cell survival at six months [24].

A more versatile source of expandable primary cell lines capable of making various replacement neurons or glia are mitogen responsive human neural progenitor/stem cell cultures that can be isolated from various regions of aborted and adult human central nervous system (CNS) tissues and expanded for more than one year *in vitro*. These cells are often grown as 'neurospheres' and can be expanded in defined and animal-free media containing growth factors [25]. These cells can form the three major phenotypes of the nervous system (neurons, astrocytes, and oligodendrocytes) *in vitro* and *in vivo* and show excellent survival without the formation of tumors *in vivo*. These human neural stem cell-containing cultures have been transplanted to various regions in animals and survive, integrate, migrate, differentiate, extend neurites, and arborize [26]. Even though the cells tend to retain the markers consistent with the anatomical region from which they were isolated [27], the cells can be manipulated with epigenetic and genetic factors to make specific cellular subtypes potentially useful for cell replacement implants. For a PD application, relevant nigral dopaminergic neurons need to be generated from these cells. However, so far only dopaminergic neurons with limited differentiation have been generated [28] although improvements are consistently being made [29].

In addition to neurospheres, adherent primary cell lines of neurogenic glia have been made from both mouse and human developing neural tissues that display a glial phenotype during expansion but are capable of generating neurons during differentiating conditions [30]. Similarly, so called NS cells, expressing glia and stem cell markers have been derived from ES cells and appear to differentiate into similar neural phenotypes as the adherent glia and neurosphere cultures [31]. The adherent cultures may have an advantage over neurospheres from an industrial point of view as adherent cells can be readily cloned, expanded, and have shown to retain their phenotype during expansion without differentiating into a heterogeneous mixture of progenitors. It is currently unclear if neurospheres or adherent NS cells can be made into dopaminergic neurons suitable for replacement therapy in PD. Reportedly, clinical applications in Batten's disease with unmanipulated human neurosphere cell lines are currently being explored [32].

In general, all primary cell lines derived from tissue stem cells have a large but limited expansion potential and show senescence [33,34]. This may be due to the successive loss of immortal stem cells through the asymmetric division into progenitors (as seen in neurospheres) or alternatively, the stem cells themselves have a limit to their proliferation.

Both mouse and human ES cells defy the normal senescence of primary cells and can be expanded from a single clone indefinitely without losing pluripotentiality [35]. From an industrial and tissue-engineering perspective, this feature is extremely attractive as a single donation could give rise to a cell line source with the capacity to make all organs of the body in unlimited numbers. One major drawback of ES cell-derived products, however, is that the ES cell itself cannot be implanted but needs to undergo the relevant development *in vitro* to make suitable cells for transplantation, e.g., dopaminergic neurons for PD or islet cells for diabetes mellitus. As it is difficult to make pure cultures without retaining one or more undifferentiated ES cell, both the risk of heterogeneous cell preparations and the risk of tumorigenesis need to be overcome to develop ES cell-derived brain implants [36]. For neural applications, the recently described NS cell may become a progenitor of choice for brain implant products as it is restricted to the neural lineage and can be expanded as a clonal cell line. It is currently unclear if the undifferentiated NS cell is immortal like its parental ES cell or if it displays senescence as its neurosphere counterpart.

Cell replacement strategies using cell lines need to employ differentiation or selection methods in order to make the relevant replacement cell, e.g., dopaminergic neurons for a PD application. The generation of functioning human dopaminergic neurons *in vivo* akin to those derived from primary VM tissues has been difficult to achieve. Although neurons with the dopaminergic machinery can be made from both growth factor expanded human neurospheres and genetically immortalized committed dopaminergic neuroblasts, it has been difficult to achieve survival and function *in vivo* [28]. Interestingly, even though ES cells would hypothetically need more steps to be differentiated into dopaminergic neurons for a PD application, relatively short-step protocols that use developmental signals involved in the rostrocaudal and ventrodorsal specification of the midbrain can push mouse ES cells into functional dopaminergic neurons in a rat model of PD [37,38]. Studies have also identified important transcription signals involving the Lmx1a and MSX homeobox genes that when overexpressed in ES cells under the nestin promoter can yield dopaminergic neurons with markers consistent with substantia nigra neurons [39]. Transplantation of these dopaminergic neurons in a rat model of PD yields excellent survival, neurite extension, and function consistent with results from primary VM tissues. However, similar to the human ES cells [36], these cells also form tumors *in vivo*. These findings may pave the way forward to make relevant 'nigral' dopaminergic neurons from human ES cells and neural stem cell cultures in the not too distant future but also shows the need for adult and fetal derived neural stem cell sources that do not form tumors.

CELL PROTECTION AND REGENERATION IMPLANTS

The use of primary tissues or cell lines in cell replacement approaches are aimed at making transplantable mimics of the cells lost in the disease process. In PD, the use of chromaffin cells, dissected developing ventral mesencephalon, RPE cells, or stem cells have all been aimed at replacing or augmenting the dopaminergic function. However, primary tissues, cell lines, and genetically modified cells also produce secreted factors that can influence the nearby host or transplanted cells in potentially beneficial ways. Several growth factors are endogenously made by cells including fibroblast growth factors, transforming growth factors, and interleukins that can have neuroprotective and regenerative effects on nearby nerve cells. Custom therapeutic cell lines can also be made by genetic engineering to secrete specific growth factors such as nerve growth factor (NGF), glial cell line-derived neurotrophic factor (GDNF), ciliary neurotrophic factor (CNTF) that when implanted in relevant anatomical areas can affect specific neuronal populations in neuroprotective and regenerative ways (*ex vivo* gene therapy). To protect the transplanted cells from immune rejection and to allow for the retrieval of the therapeutic cell implants an encapsulated device can be used.

Cell implants secreting endogenous factors

A carcinoma cell line derived from a human testicular teratocarcinoma isolated from a metastasis in a patient has been used in clinical applications to treat the neurological sequelae of stroke [40]. This immortal cell line is pluripotent and can be induced to stop dividing and to differentiate into a neuronal phenotype using retinoic acid. A preparation of this cell line was investigated in the clinic for the treatment of ischemic stroke based on animal data suggesting that the post-injury transplantation of this cell line into an infarcted area can improve recovery. The mechanisms surrounding this effect are unclear but are likely related to beneficial factors released from the cells. In a study in patients with lacunar stroke in a randomized controlled Phase II trials at the University of Pittsburgh, USA the therapy with this cell line failed to meet the efficacy endpoints. The transplantation of a cell line derived from a human cancer has obvious risks associated with it. Importantly, the approval of this trial demonstrates that cell transplantation for severe neurological disorders is seen as a reasonable strategy by the regulatory agency, as long as safety and some efficacy can be demonstrated in animal models.

Other groups are investigating the transplantation of immortal cell lines but are using genetic engineering to immortalize cells. Advances in genetic engineering have made it possible to extend the number of doublings a primary cell line can go through by inserting various oncogenes and cell cycle regulators. This allows for the selection, clonal expansion, and banking of a large number of cells. Besides the genetic modification, these cells retain otherwise normal genotypic characteristics. ReNeuron, a British biotechnology company, has made immortal human neural stem cells that have shown regenerative effects in stroke models [41] and have initiated clinical trials in stroke patients [42]. Similarly, StemCells Inc., is using growth factor expanded human neurosphere cell lines in a strategy to treat Batten's disease, a rare neurometabolic disorder, with the idea that the endogenous enzymes and factors made by the stem cells will have a therapeutic effect [32,42]. Lastly, implanted autologous mesenchymal stem cells are being studied in clinical trials for stroke [43] and potentially in neurodegenerative disorders [44].

The use of non-specific neuroprotective and regenerative strategies based on the implantation of cells with unclear mechanisms may pose regulatory problems as the risk benefit analyses become difficult to make. For example, even though positive results were inferred from the published trial with the human teratocarcinoma derived cell line in stroke, the clinical data were not convincing enough to continue clinical development [45]. In this trial, no significant adverse events or tumors were reported but, if it they had occurred, a major set-back for tissue-engineered brain implants could have been the result. The risk benefit analysis is often difficult and the predictive value and scale-up issues by the use of animal models are not straight forward. The regulatory agencies have therefore a real dilemma and, similar to the setbacks experienced in the field of gene therapy, a push to do clinical trials with poorly characterized cell preparations and mechanisms in patients desperate for a treatment may cause significant adverse events that can create set-backs for the whole field of tissue engineering. On the other hand, a too restrictive regulatory body may make the hurdle of bringing potentially beneficial but complex tissue-engineered products into the clinic too costly and difficult. These regulatory issues are hard to resolve but as experience with cell-containing implants build, it is likely that the decision making and risk benefit analyses will improve. Some of the clinical trials using primary autologous cells such as hematopoietic or mesenchymal stem cells derived from the bone marrow can also by-pass regulatory scrutiny and only need approval by a local ethics committee. Unfortunately, this has led to the initiation of clinical trials based on very little evidence of preclinical beneficial effects causing potentially false hopes, personal expenses, and potentially harmful side effects to patients desperate for therapy.

Cell implants secreting engineered factors (*ex vivo* gene therapy)

As PD involves a slow and progressive degeneration of dopaminergic neurons a protective and/or regenerative strategy could be applied. Many protein factors have been shown to

protect fetal dopaminergic neurons both *in vitro* and *in vivo* and one of the most powerful factors is glial cell line-derived neurotrophic factor (GDNF) [46]. This factor promotes the survival (neuroprotective effect) and neurite extension (regenerative effect) of dopaminergic neurons both *in vitro* and *in vivo*. Based on positive animal data, GDNF has been tried in humans in two separate randomized clinical trials [47,48]. The first trial used monthly intracerebroventricular bolus injections of GDNF and failed to meet both safety and efficacy endpoints. The second trial employed intrastriatal infusion of GDNF and albeit safe, did not meet the efficacy endpoints. This is an unfortunate outcome for patients suffering from PD and critics of the trial have indicated that inconsistencies in catheter design and other parameters may explain the poor results [49]. From both the clinical and animal data, it appears necessary to deliver the GDNF in low but chronic doses to the dopaminergic nerve endings within the striatum in order to have a regenerative effect. It is currently the view of many that implantation of genetically modified cells, encapsulated cells, or the use of viral vectors may be better at delivering GDNF than utilizing available pumps and catheters. Safety concerns with unregulated and unstoppable gene therapeutic approaches may favor the use of a tissue-engineered product based on an implantable and retrievable encapsulated cell biodelivery of GDNF. Of note, however, Ceregene, inc. has completed a Phase II clinical trial demonstrating safety of AAV-mediated delivery of Neurturin (a GDNF analog) in PD patients [50] and has recently initiated a follow on trial. It is beyond the scope of this chapter to expand on the topic of *ex vivo* and *in vivo* gene therapy but it is important to mention that the delivery of growth factors to the brain via implants is an important cornerstone of tissue-engineering strategies for brain repair.

Encapsulated cell implants

The implantation of naked cells has the advantage of allowing for migration, integration and the formation of neurites and synapses in replacement strategies. The migration and homing mechanisms that neural stem cells display in models of stroke and glioma may also be utilized to deliver regenerative or tumoricidal agents respectively in genetically modified cells. However, naked cells cannot readily be removed and if a potent protein factor is being delivered to the brain, the inability to stop the treatment may pose a problem if untoward effects are noted or if the regenerative treatment is only needed for a limited amount of time. A device containing encapsulated cells that secrete the factor combines the advantages of cell and gene therapy with that of the safety of a retrievable device. One of the types of encapsulated cell devices is depicted in Fig. 62.2 and consists of a hollow fiber membrane that surrounds a core of cells seeded on a polymer matrix that in turn is attached to a tether.

These encapsulated cell implants are true tissue-engineered devices that combine genetically modified cell lines with artificial scaffolding enclosed behind an immunoprotective membrane. The polymeric membrane excludes larger molecules and cells but allows for the bi-directional passage of nutrients and transgene products. The encapsulated cells can thus be protected from immune rejection, making allogeneic or even xenogenic transplantation possible and immunosuppressive therapy unnecessary. The host is also protected from the implanted genetically modified cells and the risks of gene transfer or tumor formation are greatly diminished. The tether allows for handling, implantation, and removal. These devices can be implanted intraparenchymally, intracerebroventricularly, or intrathecally depending on the application. Cellular survival and continuous production of factors have been demonstrated for at least 12 months in the brain allowing for long-term delivery of therapeutic factors [11,51]. Encapsulated devices secreting GDNF have been studied in rodent models for PD and have shown both neuroprotective and neuroregenerative effects on dopaminergic cells [52]. A recent Phase I trial in Alzheimer's patients was completed demonstrating safe and targeted delivery of NGF to the brain using encapsulated, genetically modified ARPE-19 cells. The cells survived for up to12 months with no evidence of inflammation or device displacement [10,11].

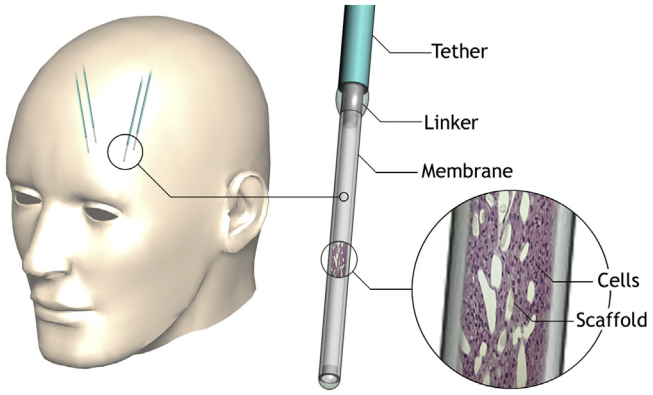

FIGURE 62.2

A schematic of the implantation of four encapsulated cell implants in the human basal cholinergic forebrain is depicted. The tip of the implant houses a human immortal cell line engineered to secrete the therapeutic protein (in this particular application NGF). The cell line is grown on a three dimensional synthetic scaffolding and the cellular core receives nutrients and oxygen from the surrounding brain interstitial fluid via the semipermeable membrane. In turn, the therapeutic protein can diffuse from the implant tip in a few millimeter wide radius into the surrounding brain at the implant target and the associated diseased neurons. The membrane protects the engineered cells from immune rejection and the entire device can be removed or replaced through the use of the tether anchored beneath the skin at the skull bur hole level. The sections are stained with hematoxylin and eosin. The implant measures approximately 1 mm in diameter.

Other investigators have published data on using encapsulated choroid plexus cells in the treatment of Huntington's disease [53] and PD [54]. These cells are reportedly therapeutic by secreting various endogenous factors that have neuroprotective and regenerative effects. The application of the choroid plexus cells in this study was made with an injectable micro-encapsulated cell configuration. In this setting, the encapsulation provided immunoprotection for the porcine-derived primary choroids plexus cells. Unlike the macro-encapsulation described above, these devices would not be retrievable and may be less suited for applications in which the treatment may need to be stopped.

Controlled release implants

Acellular synthetic polymeric brain implants that are able to deliver protein factors or other drugs to the CNS have also been developed [55,56]. These systems normally release drugs by degradation- or diffusion-based mechanisms over an extended time (weeks) but cannot sustain release over a long time (months), which is possible with cellular-based systems.

Appropriately designed, polymeric controlled release devices have several possible applications and could for example support the survival and integration of transplanted cells. Furthermore, a polymeric system can support the sequential release of growth factors that may be necessary to fully support the stepwise differentiation of immature cells. This concept could become applicable to transplanted neural stem cells that may lack important embryonic developmental signals in the adult brain.

COMBINED REPLACEMENT AND REGENERATION IMPLANTS

From a tissue engineering point of view, the future goal is to make replacement organs for the body that can take over the function of a failed organ or structure in an anatomically and physiologically correct manner. And even though it would be difficult if not impossible to make entirely new brains, it should become possible to not only replace cells but also to make new axonal pathways and restore the correct connections.

The transplantation of fetal dopaminergic cells to the striatum is called heterotopic transplantation. This means that the dopaminergic cells are transplanted into an anatomical region different from their normal location, which is the substantia nigra. The heterotopic implantation of dopaminergic neurons may result in the loss of important normal innervation and feedback loops. Many transplants for PD may thus only work as simple cellular pumps that increase the striatal dopamine levels. Although simplicity is desired, an ultimate strategy to treat PD could be to transplant the dopaminergic neurons to their anatomically correct position (homotopic), regenerate the nigrostriatal axonal pathway, and induce terminal sprouting and innervation of the striatal target neurons. This would regenerate the appropriate connections and represent a more physiologic strategy.

An initial approach may be to provide survival factors to the implanted cells. Even in the most optimal VM grafts applied heterotopically in PD, the total fraction of surviving dopaminergic neurons was only about 10–20% [57]. This required a large number of donors (4–8) to assure enough surviving cells for a clinical effect. The combination of VM grafts with a neuroprotective and regenerative effect of GDNF is therefore a logical idea. Experimental data indeed show that the application of GDNF delivered by encapsulated cells in combination with either rat or human VM grafts increase both the survival, neurite extension, and innervation of the striatum in a rat model of PD [58,59]. Similarly, it would be expected that GDNF would have survival and regenerative effects on dopaminergic cells derived from ES or other stem cells when placed *in vivo*. A combined approach with dopaminergic grafts and encapsulated cell implants secreting GDNF may therefore be contemplated in future transplantation studies in PD.

A large challenge for tissue-engineering approaches in the treatment of neurological disorders is the regeneration of axonal pathways. Axons between the cell bodies and their targets often extend for several centimeters in the brain and close to one meter between the brain and the lumbar spinal cord neurons in an adult. Compared to the relatively short distances that the axons had to grow during development, the regeneration in the adult may pose a particular challenge. Fortunately, science has made progress in this area and what was though impossible only a few years ago now seems more feasible. Several molecules are now known to both promote and guide axonal outgrowth. As mentioned, GDNF is a strong promoter of axonal outgrowth of dopaminergic neurons. In addition, certain extracellular matrix (ECM) proteins, such as laminin, can guide axonal outgrowth [60] and extensive nigrostriatal reconstruction has been accomplished using bridges of striatal tissues in combination with fetal mesencephalic grafts placed in the substantia nigra [61]. The finding that the central myelin and glial scars are inhibitory to axonal outgrowth, has led to the identification of various inhibitory molecules that can be manipulated in various ways with inhibitors and enzymes [62]. From a tissue engineering point of view, the combination of replacement cells with regeneration channels or scaffoldings capable of releasing survival and neurite promoting factors and coated with molecules that facilitate axonal outgrowth, may thus become a future reality. In combination with nanotechnology, synthetic bridges can be made that promote extensive fiber regeneration and functional restoration [63].

Even though there mounting data show that axonal bridges can improve axonal growth in animal models, these methods have not been applied to humans. As the cellular building blocks become better refined, it is likely that more 'true' tissue-engineered brain implants will enter the clinic. These types of implants could have great potential use for regeneration in many areas of the CNS, particularly the spinal cord.

DISEASE TARGETS FOR BRAIN IMPLANTS

As mentioned, PD has been a major target for cellular brain implants. However, many other neurological disorders should become amenable to tissue-engineered implants.

In Huntington's disease (HD), several neuronal populations slowly degenerate and cause the clinical signs of choreiform movements and progressive dementia. HD is inherited as an autosomal dominant disease and the responsible mutation has been located to chromosome 4. Carriers of the disease can therefore be screened for and identified before the onset of symptoms. This makes a neuroprotective strategy for HD an attractive possibility, where the delivery of neurotrophic factors could prolong the symptom-free interval. One such factor is CNTF that protects striatal neurons in both rodent and non-human primate models of HD [64]. Considering these results, a small clinical proof-of-concept trial using an intracerebroventricularly placed encapsulated cell device secreting CNTF was completed [9]. The study indicated that the placement was safe and would warrant additional trials. However, data also suggested that improved devices and an intrastriatal implantation approach may improve the efficacy. This approach may be taken in future trials.

Cell replacement strategies have also been tried in HD [2]. Primary fetal striatal tissue transplantation for HD has been performed at a handful of centers in the world. Long-term follow up has described mild improvements in some of the implanted patients [65]. Because the number of implanted patients is few, it is currently difficult to draw any major conclusions regarding the clinical efficacy of transplantation for HD. One possible advantage over PD is that the transplantation for HD involves homotopic implantation, which at least theoretically should allow for the differentiation of the fetal tissue using normal environmental cues. However, in HD, multiple sets of neuronal populations degenerate including both cortical and striatal neurons. The homotopic transplantation for HD may thus require more extensive regeneration of axonal pathways than in PD.

Other diseases that could be amenable to the implantation of cells within the brain are the myelin disorders. Animal experiments have shown the ability of neural tissue, purified oligodendrocytes, oligodendrocyte precursors, immortalized glial cells, and neural stem cells to remyelinate areas of demyelination [66].

One substitute for oligodendrocytes may be to transplant growth factor expanded Schwann cell (the myelinating cell of the PNS). This is based on the fact that patients with CNS myelin disorders do not display demyelination of the peripheral nervous system. In fact, remyelination of central axons may spontaneously occur by ingrowth of Schwann cells from the periphery. An intriguing therapeutic possibility is therefore to grow Schwann cells from a nerve biopsy and expand these cells in culture. In turn, these cells could be transplanted into demyelinated areas in the same patient. Physiologically, this may not be the best strategy as Schwann cells only myelinate single axons, whereas an oligodendrocytes myelinate multiple axons. However, animal data indicate that, for a limited volume, Schwann cells can remyelinate and restore function to central demyelinated areas. Based on the animal data, a small clinical study was performed. Reportedly, the Schwann cell transplants did not survive but the procedure appears to be safe [67]. It is currently unclear if new trials with Schwann cells are to be expected.

One of the most common neurological disorders is epilepsy that affects about 1−2% of the population. Epilepsy is characterized by recurrent abnormal electrical discharges in the brain affecting subparts of the brain or generalizing to deeper parts in the brain resulting in unconsciousness. A subgroup of these patients has temporal lobe epilepsy that is generated by a loss of neurons and an imbalance of inhibitory and excitatory neurotransmitters in the hippocampal formation. In medically intractable cases, this disease can sometimes be treated surgically with the removal of the medial hippocampus and the abnormal area. This procedure eliminates or reduces the frequency of seizures in selected patients but involves a major surgical procedure and the ablation of normal tissue. A less invasive procedure may be to implant inhibitory cells in the seizure focus that would raise the seizure threshold [4]. This idea is supported by animal experimentation data that indicate that locus coeruleus grafts and the local delivery of inhibitory substances such as GABA can increase the seizure threshold.

However, with the lack of suitable cells, such as GABA producing cells, transplantation for focal epilepsy has not been as extensively studied as for some of the aforementioned disease targets. Recent preclinical studies have suggested that interneuron precursor cells derived from the medial ganglionic eminence may be a source of inhibitory GABAergic neurons perhaps providing a useful source of transplantable cells for epilepsy [68].

Other disease indications that may benefit from brain implant strategies include stroke, brain injury from trauma, Alzheimer's disease, and rare disorders such as cerebellar degeneration and inherited metabolic disorders. Besides the brain, the spinal cord and retina are potential targets for similar approaches.

SURGICAL CONSIDERATIONS

The surgical implantation of most brain implants involves the use of stereotactic techniques. The stereotactic method (stereotaxis) in brain surgery was established in the beginning of this century and is now well established in neurosurgical practice [6]. It involves attaching a rigid frame (stereotactic frame) to the skull followed by imaging such as MRI. Attached markers (fiducials) create a three-dimensional coordinate system in which any point in the brain can be defined and related to the frame with high precision. In the operating room, the markers used during imaging are replaced with holders that guide the instruments. It is a relatively simple neurosurgical procedure often done under local anesthesia and mild sedation. The procedure is therefore safe and relatively painless. The patients are usually discharged from the hospital after an overnight observation.

CONCLUSIONS

In this chapter, various brain implants have been described that may have potential to treat PD and other neurological disorders using tissue-engineering strategies. Most of the current literature describes the transplantation of various primary cells such as fetal tissue. Tissue-engineering principles and cell lines have only more recently been introduced. Applications using growth factor support, genetic engineering, scaffolds, extracellular matrices, and encapsulation have all been able to improve the survival and function of the brain implant. The ultimate implants are yet to be developed and may combine stem cells, genetically modified cells, controlled delivery devices, axonal bridges, scaffolds, and encapsulated cells.

Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

INTRODUCTION

The use of brain signals for interaction as well as for controlling robots and prosthetic devices has gained increasing attention over recent years. This is a rapidly emerging field of multi-disciplinary research called *brain-machine interfaces* (BMI), or *brain-computer interfaces* (BCI), which has seen impressive achievements over the past few years —prototypes for writing messages with a virtual keyboard [1—5], playing brain games [3,6—8] and even controlling robots or wheelchairs [9—15]. A BMI monitors the user's brain activity, extracts specific features from the brain signals that reflect the intent of the subject, and translates their intentions into actions — such as closing the prosthetic hand, or selecting a letter from a virtual keyboard — without using the activity of any muscle or peripheral nerve. The central tenet of a BMI is the capability to distinguish between different patterns of brain activity, each being associated to a particular intention or mental task. Hence, adaptation is a key component of a BMI, because, on the one hand, users must learn to modulate their brainwaves so as to generate distinct brain patterns, while, on the other hand, machine learning techniques need to discover the individual brain patterns characterizing the mental tasks executed by the user. This chapter provides an introduction to the field of BMI, with a particular focus on principles for reliable and long-term operation of neuroprostheses. For a more detailed coverage of BMI, the interested reader can refer to references [16—18].

BMI technology offers a natural way to augment human capabilities by providing a new interaction link with the outside world. In this respect, it is particularly relevant as an aid for patients with severe neuromuscular disabilities, although it also opens up new possibilities in human-machine interaction for able-bodied people. Fig. 63.1 shows the general architecture of a brain-actuated device such as neuroprostheses for motor restoration and recovery. Brain activity, electroencephalogram (EEG) signals in this example, is recorded with a portable device. These raw signals are first processed in order to extract some relevant features, which are then passed on to a mathematical model (e.g., statistical classifiers/regression or neural networks). This model computes, after some training process where it finds the prototypical patterns of brain activity associated to each mental command, the user's intention, and this is transformed into an appropriate action to control the device. Finally, visual feedback, and maybe other types of feedback such as haptic stimulation [19] or intracortical microstimulation [20,21], informs the subject about the performance of the neuroprosthesis so that they can learn appropriate mental control strategies and make rapid changes to achieve the task.

This chapter is organized as follows. First, we will review the different kind of brain signals that can be recorded as input for a BMI. Then, we will discuss a series of principles to build efficient BMIs that are independent of the particular signal of choice. These principles concern the

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00063-X

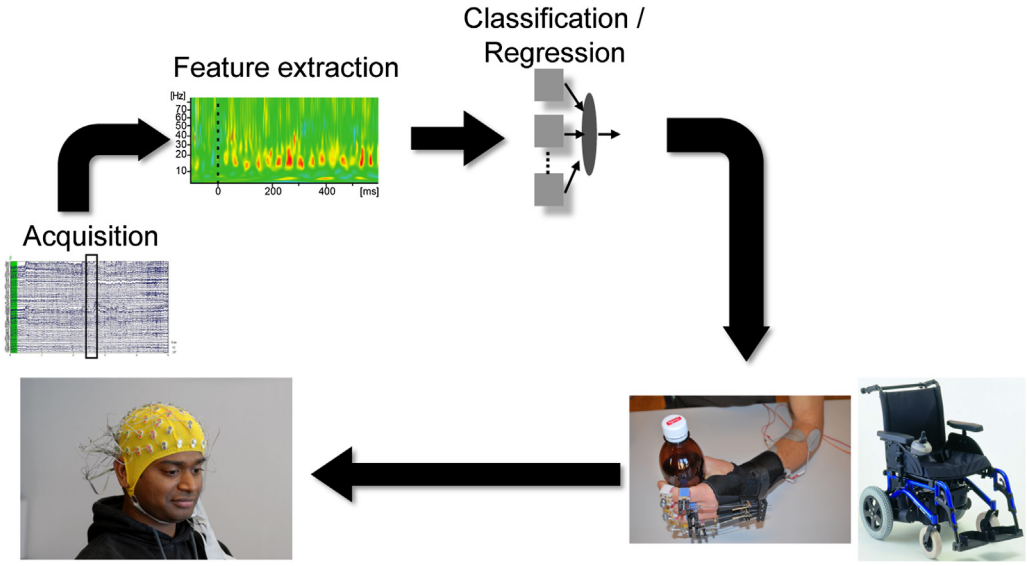

FIGURE 63.1

General architecture of a brain-computer interface (BMI) for controlling devices such as a hand orthosis, or a motorized wheelchair. In this case the BMI measures electroencephalogram (EEG) signals recorded from electrodes placed on the subject's scalp.

nature of electrical brain correlates more suitable to control neuroprosthetic devices and to promote motor rehabilitation, the use of machine learning techniques, and the design of context-aware BMIs. We will conclude discussing some future research directions in the field of BMI.

BMI SIGNALS

A BMI may monitor a variety of brain signals, such as electrical, magnetic or metabolic. Magnetic fields can be recorded with magnetoencephalography (MEG), while brain metabolic activity — reflected in changes in blood flow — can be observed with positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and near-infrared spectroscopy (NIRS). Unfortunately, MEG, PET and fMRI require sophisticated devices that can be operated only in special facilities. Moreover, metabolic signals have long latencies and thus are less appropriate for interaction. Brain electrical activity, on the other hand, can be recorded with portable devices and has an excellent time resolution — we can detect changes in brain activity at the millisecond range — what makes it the natural candidate for a BMI. We can record electrical brain activity invasively or non-invasively. The former technique employs microelectrode arrays implanted in the brain which record the activity of single neurons (single unit activity, SUA) or from small neuronal populations (local field potentials, LFP). The overall concerted activity of neuronal populations can also be recorded (semi-) invasively with electrodes placed on the surface of the brain (electrocorticography, ECoG). Non-invasive electroencephalographic (EEG) activity is recorded from electrodes placed on the scalp. It measures the synchronous activity of thousands of cortical neurons. LFP, ECoG and EEG signals are similar in nature, although at different levels — microscopic, mesoscopic and macroscopic, respectively.

Invasive approaches (LFP and SUA) produce very detailed information, what may allow decoding of complex movement intentions [12,20,22–26]. However, we need to record from many electrodes and different areas to capture the global set of motor parameters, which are encoded in a rather distributed brain network. Also, implanted microelectrode arrays damage brain tissue, and so signals do not last long. Consequently, one area of active research is

the design of safe biophysical interfaces that, in addition, should be ultralow power and wireless. On the other hand, since they are recorded on the scalp, non-invasive EEG signals suffer from a reduced spatial resolution and increased noise. In particular, EEG can be contaminated with muscular — such as subtle facial movements — and ocular artifacts that, ideally, must be filtered out. Alternatively, we must ensure that the selected control features are proper brain signals and not generated partially, or completely, by non-brain sources.

The spatial resolution of EEG can be greatly improved by means of spatial filters that estimate the electrical activity originated in radial sources immediately below each recording electrode. Such filters are known as surface Laplacian, and require a large number of electrodes and a spherical spline model. Other examples of spatial filters are common average reference (CAR) and Laplacian, which compute an approximation of the surface Laplacian. The former removes, for each electrode, the average activity over all electrodes. The latter subtracts, for each electrode, the mean activity of its four nearest neighboring electrodes. The use of spatial filters should be an essential step in the design of an EEG-based BMI, as they have largely been shown to yield significant increases in performance. Another way to increase the spatial resolution of raw EEG is to estimate the cortical activity from the scalp EEG, thus unravelling the contributions of different small cortical areas that are picked up and mixed by a single scalp electrode [27,28].

Analysis of human ECoG is attracting significant interest as, being semi-invasive, it blends the advantages of both approaches: high spatial resolution and simple surgery with minimal health risks. Although not largely used because of limited access to patients — who undergo neurosurgery for epilepsy or brain tumor — during short periods of time, initial results show high potential [29–32].

VOLUNTARY ACTIVITY VS. EVOKED POTENTIALS

A BMI can exploit signals associated with external sensory stimulation — such as visual flashes or auditory tones — or with endogenous voluntary decision processes — such as the onset of a movement. In the former case, the brain reacts with so-called evoked potentials. Two different evoked potentials have been widely explored in the field of EEG-based BMI; namely P300 [2,13,33–35] and steady-state visual evoked potential (SSVEP) [36,37]. P300 is a potential evoked by an awaited infrequent event that appears at centro-parietal locations along the midline of the scalp, independently of the sensory stimulation modality. As its name indicates, it is a positive wave peaking at around 300 ms after task-relevant stimuli. The amplitude of the P300 depends on the frequency of stimulus occurrence — less frequent stimuli produce larger responses — and task relevance. Visual evoked potentials (VEP) reflect electrophysiological mechanisms underlying the processing of visual information in the brain and vary in response to changes in visual stimuli. SSVEP are VEP induced by a stimulus repeated at a rate higher than 6 Hz. An SSVEP is composed of a series of components over the visual cortex whose frequencies are exact integer multiples of the stimulus frequency.

Evoked potentials are, in principle, easy to pick up. The necessity of external stimulation does, however, restrict the applicability of evoked potentials to a limited range of tasks. This is particularly the case when controlling robotics devices and for motor rehabilitation. In both cases, BMI has to rely upon brain correlates of voluntary mental activity, which users can modulate at different frequency ranges — or rhythms. Populations of neurons can form complex networks with feedback loops, which give rise to oscillatory activity. In general, the frequency of such oscillations becomes slower the larger the size of the synchronized neuronal assemblies. A particularly relevant rhythm can be recorded from the central region of the scalp overlying the sensorimotor cortex during the imagination of body movements. Correlates of imaginary movements can be recorded at any scale —microspopic, SUA and LFP, mesoscopic, ECoG, and macroscopic, EEG. Apart from their different degrees of spatial

resolution, microscopic and mesoscopic signals also have a broader bandwith (up to 300−500 Hz) than macroscopic signals (normally, less than 100 Hz).

In the case of frequencies below 2 or 4 Hz, we can observe slow cortical potentials (SCP). The analysis of SCP is usually done in the temporal domain. Notably, SCP measured with scalp electrodes was the basis of the first demonstration of a BMI for lock-in patients [1], who learned to modulate its amplitude. The negative amplitude of SCP is related to the overall preparatory excitation level of a given cortical network − the more negative the more active. Another example of SCP that can be observed in the EEG is the so-called Bereitschaftspotential (BP), or readiness potential − a slow negative shift over the controlateral motor cortical area starting around 400−500 ms before the onset of a movement. This makes the readiness potential particularly relevant for motor rehabilitation. However, being close to DC, its presence in single trials seems to be elusive. Nevertheless, it has been recently shown that it allows detection of self-paced reaching movement intention in single trials with humans, including stroke patients [38]. Readiness potentials are also present in intracranial LFP [39] as well as in ECoG [40]. In the former case, intracranial LFP recorded from the supplementary motor area (SMA) in an epileptic patient yielded high recognition rates in the detection of self-paced reaching movements well before the onset. The intention to execute a self-paced movement has also been decoded from SUA in humans [41], where it observed progressive neuronal recruitment in the SMA over 1500 ms before subjects made the decision to move. As a last observation, recent experiments have shown the possibility to decode 3D arm trajectories from scalp SCP [42].

Most spontaneous BMI rely on variations of brain rhythms at higher frequencies than SCP. In the case of EEG and ECoG, imagination of limb movements gives rise to amplitude suppression − event-related desynchronization, ERD − of Rolandic μ (8−12 Hz) and β (13−28 Hz) rhythms over the controlateral limb motor cortical area [43]. This imagination-related ERD shows different time courses in the two bands. In the μ band the ERD recovers to baseline level within a few seconds. On the other hand, the central β activity displays a short-lasting ERD followed by an amplitude increase − event-related synchronization, ERS. In particular, ERD has been largely exploited to build BMIs where subjects imagine movements of their left vs. right hand or arm, or upper limbs vs. feet. References are too numerous to cite them all, but see references [4,5,9,10,15,19,27−30,44,45]. Apart from these 'classical' imagined movements of hands, arms and feet, recently researchers have also shown the feasibility of recognizing different wrist movements [46,47]. Also, as mentioned before, recent results show how it is possible to decode 3D arm trajectories from EEG [42,45] as well as basic grasping patterns such as hand closing/opening [15,48] and finger extension [49,50]. Although more work remains to be done in this area, its combination with functional electrical stimulation and light exoskeletons (see Fig. 63.2) is quite relevant for motor restoration and even rehabilitation in spinal cord injury and stroke patients.

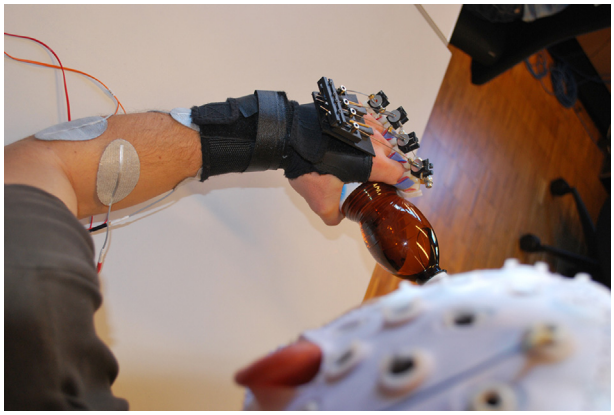

FIGURE 63.2
Example of a BMI for the restoration of grasping. The BMI is combined with functional electrical stimulation that activates the subject's peripheral nerves under the electrodes and contracts the corresponding muscles for hand closing and opening. This operation is further facilitated by the use of a light passive hand orthosis that synchronizes finger movements so as to generate natural grasping patterns.

Finally, because of its higher spatial resolution and broader frequency range, ECoG also seems to carry information about different motor parameters, such as movement kinematics [31,40,51,52], that could provide finer control of neuroprostheses and could greatly help in motor rehabilitation. As mentioned before, the decoding of complex movement intentions has been largely demonstrated with the use of intracranial recordings (LFP and SUA) [12,20,22–26].

MUTUAL LEARNING

A critical issue for the development of a BMI is training – i.e., how users learn to operate the BMI. Some groups have demonstrated that some subjects can learn to control their brain activity through appropriate, but lengthy, training in order to generate fixed EEG patterns that the BMI transforms into external actions [1,45]. In this case the subject is trained over several months to modify the amplitude of a pre-specified parameter of their brain signals, from EEG to fMRI. An alternative approach is to relieve the user of any training by using machine learning techniques to rapidly find individual patterns of brain activity associated with the mental commands the user wants to convey [53]. The drawback of this approach is that the BMI must be recalibrated at the beginning of every session. Most BMI systems lie in between these two extreme approaches, since they adopt a mutual learning principle, where the user and the BMI are coupled together and adapt to each other. Different groups have shown that, in this case, humans can learn to operate the brain-actuated device very rapidly, in a few hours which are normally split over a few days [8,9,30,42].

Mutual learning facilitates and accelerates the users' training process thanks to the use of statistical machine learning techniques that both select relevant, stable features and build optimal models to decode the user's intention. Feature selection yields user-specific brain components – normally spatio-frequency features for rhythmic activity or spatio-temporal for evoked potentials – that maximize the separability between mental commands [54,55]. In addition, because of the non-stationary nature of brain signals, selected features must also be stable over time. These initial features represent those brain components that the user can naturally modulate and, via feedback received during online BMI training, learn to control quickly and voluntarily. Selection of stable features can be enhanced by removing non-stationary brain sources [56].

Although there are reports of users who keep a stable level of performance over months and even years, BMIs suffer from the natural variability of brain signals due to changes in background activity and learning. This calls for the use of online adaptation techniques to keep the BMI tuned to drifts in the signals [57–62].

CONTEXT-AWARE BMI

Independently of the kind of BMI signal (SUA, LFP, ECoG or EEG), paradigm (voluntary activity or evoked potential) and learning approach, users cannot sustain high levels of performance over long periods of time. This is mainly due to the natural variability of brain signals. Furthermore, EEG-based approaches yield low throughput. As a consequence, it seems that current state-of-the-art BMI technology is insufficient for full dexterous control of complex applications like neuroprostheses. Nevertheless, we can cope with those limitations and achieve reliable mental control by designing context-aware BMIs [63]. Such a BMI collects information about the state of the device (e.g., position and velocity of the cursor or neuroprosthesis), as well as its environment (e.g., icons in the screen or potential targets and obstacles perceived by the prosthesis' sensors), and combines this with the user's mental commands. In this approach, the smart brain-controlled device interprets and executes the mental commands with respect to the context, thus enabling the performance of complex tasks even with a reduced, scattered set of commands. Furthermore, any eventual decrease in mental

FIGURE 63.3
Brain-controlled wheelchair. Users can drive it reliably and safely over long periods of time thanks to the incorporation of shared control (or context awareness) techniques. This wheelchair illustrates the future of intelligent neuroprostheses that, as our spinal cord and musculoskeletal system, works in tandem with motor commands decoded from the user's brain cortex. This relieves users from the need to deliver continuously all the necessary low-level control parameters and, so, reduces their cognitive workload.

control is compensated for, up to a certain degree, by the smart device. Examples of context-aware BMIs are neuroprostheses such as robots and wheelchairs [9,11,14,64,65], as well as smart virtual keyboards [66,67] and other assistive technologies (AT) software with predictive capabilities. Remarkably, in the case of the control of complex devices such as a telepresence robot, this approach yields similar performance to manual control despite the fact a BMI is not a perfect control channel. This was the case not only for expert BMI users, but also for novel BMI subjects [65] and users with physical disabilities [68]. Fig. 63.3 shows our brain-controlled wheelchair.

A common form of context awareness is shared control, a technique widely used in robotics, where the user and the smart device share responsibilities in choosing the final action to be executed that best matches the user's intent. For example, it requires quite precise control to drive a wheelchair in a home environment (scattered with chairs, tables, doors, etc.). Also, it can take a long time to navigate between rooms. In a shared control BMI, the user delivers high-level mental commands such as left, right and forward, which the wheelchair interprets based on the contextual information from its sensors to compute the actual motor commands (speed of the motors) to travel smooth trajectories and avoid obstacles. In such a way, shared control can facilitate the operation of the device by inferring goals, reducing the cognitive workload (the user does not need to care about all the low-level details), inhibiting pointless mental commands (e.g., driving zig-zag), preventing critical situations (e.g., collisions), and determining meaningful motion sequences (e.g., for an arm neuroprosthesis).

FUTURE DIRECTIONS

Current BMI technology, in particular EEG-based approaches, enables the operation of simple brain-actuated devices over short periods of time. Increasingly complex prototypes are being developed and demonstrated. No doubt this will represent an important achievement for motor-disabled people. Yet, robust and natural brain interaction with more complex devices, such as neuroprostheses, over long periods of time is a major challenge.

A related issue is the development of practical BMI technologies that can be brought out of the lab and into real-world applications in order to improve the lives of countless disabled individuals. For this we need to confirm the benefit of BMI for disabled people beyond laboratory conditions. Only a few studies have been conducted up to now. In addition, we have to design novel hardware and sensors as well as principled approaches.

One of the main barriers to the wide use of BMI technology is the limitation of today's electrodes, both invasive and non-invasive. In the former case, they damage brain tissue and do not last long before they lose signal. Consequently, one area of active research is the design of safe biophysical interfaces that, in addition, should be ultralow power and wireless. In the latter case, EEG signals suffer from a reduced spatial resolution and increased noise when measurements are taken on the scalp. Significant worldwide research is taking place on algorithms to improve EEG analysis and decoding. Another of the shortcomings of today's EEG technology, which is essentially the same as that of 30 to 50 years ago, is the need for conductive gel to reduce impedance. Success of BMI, although still modest, is creating a market for new sensors that will make the use of EEG-based systems much easier and robust over long periods of time. Examples of this new technology are dry electrodes that do not require any gel and can be integrated into aesthetic helmets [69], as well as skin sensors that can remain operational for months, if not years [70]. An associated challenge, however, is ways to develop new techniques to analyze the signals they will measure, which will probably differ from those from conventional electrodes.

Apart from addressing new sensors, and its associated signal processing techniques, we should also develop new principles to make BMI work effectively for disabled people. In this respect, it seems natural to combine BMI with existing AT [71]. This is called a hybrid BMI — a combination of different signals including at least one BMI channel [71,72]. Thus, it could be a combination of two BMI channels but, more importantly, also a combination of BMI and other residual biosignals (such as electromyographic, EMG) or special AT input devices (e.g., joysticks, switches, etc.). Recently, we have introduced a general architecture and a common software framework for hybrid BMIs [73]. Importantly, shared control (context-aware techniques) is a key component of the hybrid BMI, as it will shape the closed-loop dynamics between the user and the brain-actuated device so that tasks can be performed as easily and effectively as possible.

CHAPTER 64

Spinal Cord

John W. McDonald, Visar Belegu and Daniel Becker
Departments of Neurology and Physical & Rehabilitation, Johns Hopkins School of Medicine, and International Center for Spinal Cord Injury, Kennedy Krieger Institute, Baltimore, Maryland

INTRODUCTION

Spinal cord injury is a major medical problem because there currently is no way to repair the central nervous system and restore function. In this chapter, we focus on embryonic stem cells as an important research tool and potential therapy. We quickly review the epidemiology, functional anatomy, and pathophysiology of spinal cord injury and then discuss spontaneous regeneration and current limitations on repair. We also summarize features of spinal cord development that might guide restoration strategies. We then review studies that have utilized embryonic stem cells in spinal cord repair. We conclude that progress has been good, that knowledge is still too limited, and that harnessing the potential of stem cells will be important for solving the problem of spinal cord injury.

THE PROBLEM

Nearly 12,000 people in the United States suffer a traumatic spinal cord injury (SCI) every year, and about a quarter of a million Americans are living with this devastating condition (National Spinal Cord Injury Statistical Center, Birmingham, Alabama, 2012). There are also four to five times as many spinal cord injuries caused by medical conditions, such as multiple sclerosis, a common disorder that destroys the myelin insulation on nerves in the cervical spinal cord. Other medical causes include amyotrophic lateral sclerosis (ALS; Lou Gehrig's disease), polio and post-polio syndrome, human T-lymphotropic virus type 1 (HTLV-1), human immunodeficiency virus type 1 (HIV-1), metabolic deficits such as of vitamin B-12, as well as causes of myelopathy, such as stenosis and disk herniation [1]. The worldwide incidence of traumatic and non-traumatic SCI is greater per capita than in the United States.

The consequences of SCI depend on the level at which the cord is damaged. Generally, injuries in the neck produce tetraplegia, with loss of bowel and bladder function, whereas lesions in the thoracic or lumbar area may cause paraplegia, also with bowel and bladder dysfunction. In its severest form, SCI causes complete paralysis and loss of sensation throughout the body, inability to control bowel and bladder function, trouble controlling autonomic functions such as blood pressure, and inability to breathe or cough. The long-term disability from SCI results not only from the initial loss of function but also from the complications that accumulate. Up to 30% of individuals with SCI are hospitalized every year for complications [2], such as severe spasticity, infections (lung, skin, bowel, bone, urinary tract), osteoporosis and pathologic bone fractures, autonomic dysreflexia, and heterotopic ossification [1,3]. Another major long-term complication is muscle wasting. This results from disuse and the absence of nerve impulses, which are critical for maintaining junctions between nerves and

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00064-1

muscles [4,5]. Therefore, patients who maintain their body in the best condition for nervous system repair will benefit most from future therapeutic strategies.

SPINAL CORD ORGANIZATION

Unlike the brain, the spinal cord has its white matter (nerve axons) on the outside and gray matter (cell bodies) on the inside (Fig. 64.1). The gray matter houses neurons that project to their level of the periphery to control movement and receive sensory signals. The white matter carries axonal connections to and from the brain, and half of all those axons are myelinated. In general, the spinal cord has much less potential for regeneration than the peripheral nervous system. Moreover, most traumatic SCIs also injure the incoming and outgoing (afferent and efferent) peripheral nerves at the injury level. In most cases, however, the caudal cord remains intact beginning several segments below the injury level. Circuitry in those segments can produce reflexes by activating a ventral motor neuron to produce muscle contraction when it receives a sensory stimulus from the periphery of the body (Fig. 64.1).

The distal spinal cord also contains groups of nerve cells that generate the patterns of activity needed for walking and running. Finally, there are central pattern generators, which govern particular motor functions in the periphery that are quite complex in nature and well controlled. Interested readers are referred to recent monographs on this subject [6–9]. Because the upper spinal cord plays only a limited role in controlling these pattern generators, people with injury to the cervical spine can walk or ride a stationary bicycle if their muscles are stimulated appropriately. The existence of additional pattern generators has also been predicted. For example, the phrenic nucleus, housed at C3 through C5 in the upper neck, appears to generate the pattern of movements needed for respiration. Unfortunately, this part of the spine is a common site of traumatic injury.

INJURY

Traumatic injury occurs when broken fragments of bone and ligament impinge on the soft spinal cord, which is no wider than the thumb. The cord responds by swelling until it

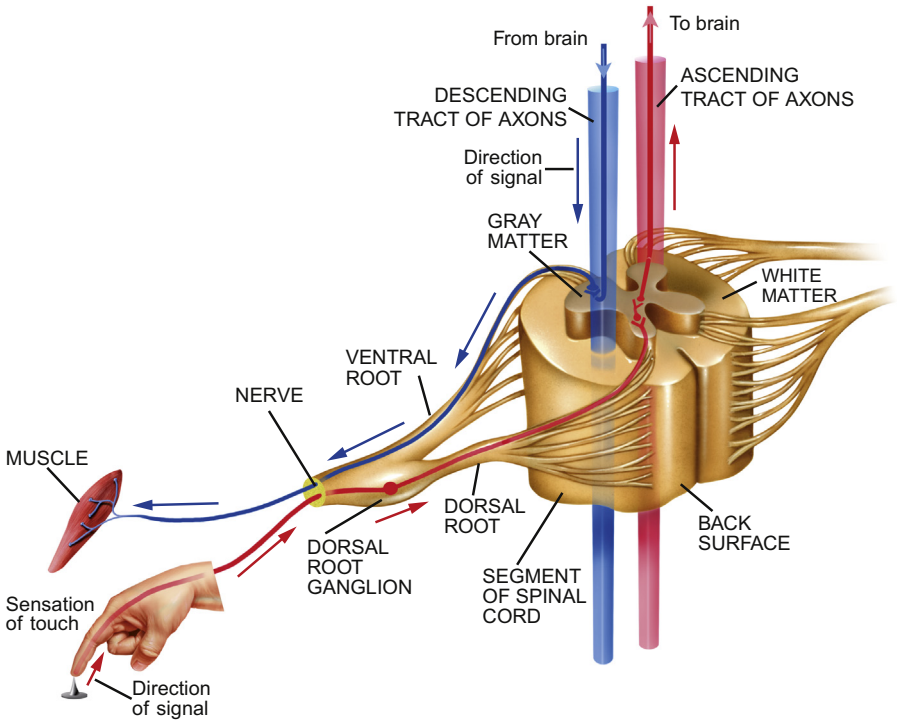

FIGURE 64.1
Organization of the spinal cord. A segment of cord reveals the butterfly-shaped gray matter at the core and an outer ring of white matter. The main components of the gray matter are neuronal cell bodies and glial cells and blood vessels. The white matter also contains astrocytes and blood vessels, but it consists mostly of axons and oligodendrocytes (glial cells that wrap axons in white, insulated myelin). Axonal tracts that ascend in the cord, such as the one shown in red, convey sensory messages received from the body; the descending tracts (blue) carry motor commands to muscles. *(Reproduced with permission of Alexander and Turner Studio, FL. © 2002 Edmond Alexander.)*

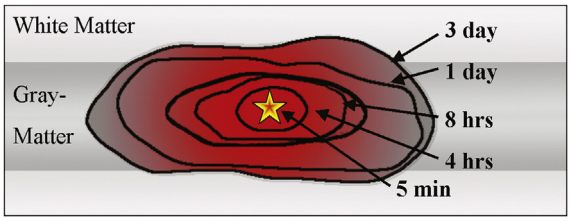

FIGURE 64.2
Evolution of primary to secondary spinal cord injury. Following the initial trauma, the injury site enlarges rapidly as a consequence of secondary injury, particularly over the first 24 hours.

encounters resistance from the bony canal of the spinal column. The swelling that compounds the initial injury reduces venous blood flow, causing a secondary venous infarct in the central part of the cord. This initiates a cascade of events that injures neighboring tissue. During this secondary phase, which occurs in the first 24 hours after the primary phase, cells die by excitotoxic necrosis (caused by release of harmful concentrations of chemicals from other cells) as well as by apoptosis (cell suicide), causing the initial injury site to enlarge rapidly into a hole in the middle of the spinal cord (Fig. 64.2). Because a donut-like rim of viable tissue usually remains at the level of injury, SCI preferentially affects gray matter.

A second wave of much delayed cell death occurs during the weeks after an SCI [10]. It removes mostly oligodendrocytes (the cells that wrap nerve axons in a fatty layer of myelin) from adjacent white matter tracts. Since each oligodendrocyte myelinates 10 to 40 different axons, loss of one oligodendrocyte leads to exponential loss of myelin. As a result, nerve axons cease to function because they cannot conduct electrical impulses when this insulating sheath is lost. This progressive phase of secondary injury is a good target for potential therapies, such as neuroprotective stem cell transplantation.

The problem does not stop with the secondary wave of cell death, however. An injured, underactive nervous system may be unable to adequately replace cells, particularly housekeeping cells called glial cells, which normally turn over. Therefore, individuals with SCI may experience a slow, progressive loss of neurological function over very long periods in addition to complications from their initial injury. It is important to consider this potential for further loss of function when designing therapeutic regimens.

SPONTANEOUS REGENERATION

Not long ago, the adult nervous system was believed to have no capacity for repair or regeneration. Now a growing body of evidence indicates that the capacity for spontaneous regeneration may be much greater than previously perceived. Data obtained since the 1960s have demonstrated that new cells are added to the nervous system continually; these cells include neurons in at least two brain regions, the hippocampus and the olfactory bulb [11,12]. Moreover, glial cells are frequently born and are capable of regeneration [13,14]. Recent work has shown that severed or intact axons can sprout even long after injury [15,16].

Nonetheless, our ability to maximize spontaneous regeneration is currently limited. The recent detection of endogenous stem cells within the spinal cord raises hope that such cells can be harnessed to repair the damaged spinal system. Although the birth of new neurons from these progenitors has never been demonstrated within the spinal cord [17], new glial cells, including oligodendrocytes and astrocytes, are continually being added. In fact, injury stimulates cell birth. Our laboratory recently showed that nearly 2 million cells are born in the spinal cord each day, though most eventually die [18]. Collectively, these data suggest that cell turnover does occur in the nervous system, albeit much more slowly than in other organs of the body. Moreover, we recently showed that patterned neural activity, generated by repetitive tasks such as cycling, can stimulate cell birth, suggesting that behavioral modification could be important for maximizing cord regeneration and functional recovery [18].

CURRENT LIMITATIONS AND APPROACHES TO REPAIR AND REDEFINING GOALS

Although some limited spontaneous regeneration is known to occur [19,20], dramatic self-repair of the nervous system does not take place. A growing body of evidence suggests that factors in the nervous system actively inhibit regeneration. Such factors include inhibitory proteins in the cord, which guide re-growing connections, and scar tissue, which contains chondroitin sulfate and other proteoglycans [21]. Reduced production of growth factors that stimulate regrowth also limits regeneration.

Figs. 64.3 and 64.15 outline the general strategies for repairing the damaged spinal cord. Note that a complete cure of nervous system injury is not practical or required. Partial repair translates into proportionally greater recovery of function. For example, only about 10% of the functional connections are required to support locomotion in cats [22], and humans missing more than half the gray matter in the cervical spinal cord can still walk and run fairly normally.

One repair strategy is to transplant stem cells or other biomaterials to fill the cyst that forms at the eye of the injury. This cyst acts as a physical barrier to the growth of anatomically intact axons in the surrounding donut of white matter. The lost cells include segmental motor neurons, sensory neurons, oligodendrocytes, and astrocytes. Although it is possible for endogenous cells to give birth to new oligodendrocytes and astrocytes, this response is limited; moreover, it has not so far been possible to obtain new neurons in the spinal cord from endogenous cells [17].

As well as filling-in the cyst, it may be necessary to repair axons that no longer function properly because they have lost their myelin or have been inappropriately myelinated. Several

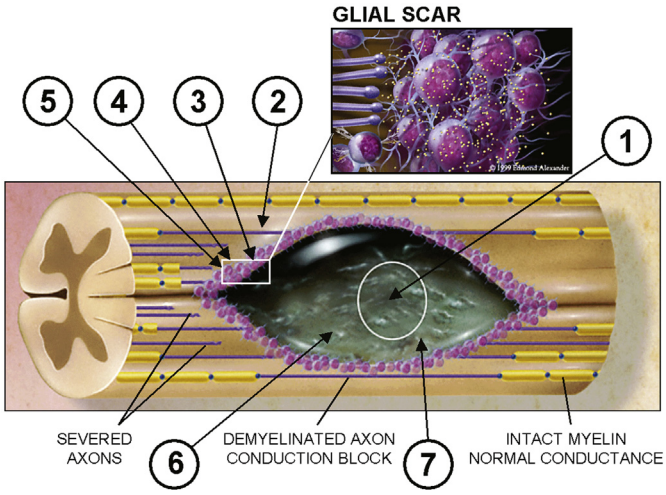

FIGURE 64.3

Common strategies toward regeneration of the damaged spinal cord. (1) Prevention of progression of secondary injury: Necrotic and apoptotic cell death would be prevented by anti-excitotoxic drugs and anti-apoptotic treatments. (2) Compensation for demyelination: Chemicals that prevent conduction block in demyelinated areas and agents that encourage surviving oligodendrocytes to remyelinate axons would be provided. Lost oligodendrocytes would be replenished. (3) Removal of inhibition: Agents that block the actions of natural inhibitors of regeneration or drugs that downregulate expression of inhibitory proteins would be provided. (4) Promotion of axonal regeneration: Growth factors that promote regeneration (sprouting) of new axons would be provided. (5) Direction of axons to proper targets: Guidance molecules would be provided or their expression would be increased in host cells. (6) Creation of bridges: Bridges would be implanted into the cyst to provide directional scaffolding that encouraged axonal growth. (7) Replacement of lost cells: Cells capable of generating all cell types (progenitor cells or embryonic stem cells) would be implanted. Substances that induce undifferentiated cells to replace dead cells would be provided. Also, cells that had been genetically engineered to deliver regenerative molecules would be transplanted. *(Reproduced with permission of Alexander and Turner Studio, FL. © 2002 Edmond Alexander.)*

approaches have been used to overcome this problem, which can manifest itself as a segmental conduction block. For example, potassium channels on dysfunctional axons can be blocked pharmacologically, and preexisting or transplanted oligodendrocytes and their progenitors can be encouraged to make new myelin [23,24].

Another strategy is to remove or mask the effects of proteins in the glial scar around the cyst that actively inhibit the regrowth of new connections. Antibodies that block the inhibitory effects of these proteins promote sprouting [25]. Alternatively, cells might be delivered to the cyst to digest inhibitory proteins in the scar; or the initial expression of such proteins might be inhibited. Moreover, certain growth factors promote the self-repair of physically broken connections. These factors can be provided exogenously or by transplanting genetically altered cells that release them [19,26,27].

It is important to understand the feasibility of various repair strategies and to redefine appropriate goals of repair. If one ranks the foregoing strategies in terms of likely success [1], it becomes clear that it will be very difficult to persuade axons to regrow across a lesion, extend all the way down the spinal cord, and make connections with the appropriate target cells. Remyelination seems much more feasible because it occurs continually at a steady rate in the damaged spinal cord. It is important to investigate all possible strategies, however, because some will materialize sooner and some later. Most importantly, we must understand that multiple strategies delivered over time will be more important than the elusive magic bullet.

When defining appropriate goals for therapy, improving patients' quality of life must surely rank first. To this end, strategies that limit complications are important. Moreover, individuals with SCI often value small gains in function more highly than larger gains, such as walking. Thus, the top goal for most patients is recovery of bowel, bladder, or sexual function. Distant seconds include recovery of respiratory function for those whose respiration is impaired and use of a single hand for those without hand function [1]. Paradoxically, most animal models focus on recovering the ability to walk. This is both the least appropriate goal and the most difficult.

SPINAL CORD DEVELOPMENT

To understand spinal cord regeneration, it is necessary to understand spinal cord development. In humans, oligodendrocytes are found in cultures of fetal spinal cord at 7 and 12 weeks of gestation [28,29]. Myelination begins at 10 to 11 weeks of gestation [30,31] and continues throughout the second year of life [32,33]. Signals derived from axons regulate the growth of progenitor cells and the survival of oligodendrocytes [34]. For example, sonic hedgehog (SHH), a protein synthesized by notocord and floor plate cells, induces the differentiation of motor neurons in the ventral cord [35], and SHH signaling induces oligodendrocyte precursors (OP) to emerge in the embryonic spinal cord [36]. Platelet-derived growth factor (PDGF) is a potent regulator of OP migration and proliferation, while insulin-like growth factor (IGF-1) acts on both neurons and oligodendrocytes. Other locally synthesized growth factors appear to control the balance between OP proliferation and differentiation [37].

Many different neuronal phenotypes arise from various progenitor pools during central nervous system (CNS) development, but most of the pathways are poorly understood. One of the best described is the generation of spinal motor neurons [38], which involves several steps. Through signaling pathways that enable cells to respond to external cues (pathways involving bone morphogenetic protein [BMP], fibroblast growth factor [FGF], and Wnt), ectodermal cells obtain a rostral neural character [39]. In response to caudalizing signals, such as retinoic acid (RA), these progenitors acquire a spinal positional identity [40]. Through the ventralizing action of SHH, spinal progenitor cells gain their motor neuron phenotype [41].

These findings raise the question of whether embryonic stem (ES) cells can be directed along specific pathways to produce specific neural cell populations for CNS repair. In fact, very

encouraging steps have already been taken. Early reports revealed the possibility of generating cells with motor neuron characteristics from ES cells [42]. Later, Wichterle and colleagues demonstrated that signaling factors operating along the rostrocaudal and dorsoventral axes of the neural tube to specify motor neuron fate *in vivo* could be harnessed *in vitro* to direct the differentiation of mouse ES cells into functional motor neurons [43].

EMBRYONIC STEM CELLS

ES cells have unique features that are important for spinal cord repair. They represent every cell type in the body and are the earliest stem cells capable of replicating indefinitely without aging, and their DNA can be modified easily, even in single cells. They also fulfill two criteria that are essential for nervous system repair through transplantation:

1) They normally belong in the spinal cord; and
2) They contain the recipient's own DNA, obviating the need for immunosuppression, which cannot be used in spinal cord patients because of the increased incidence of infections.

Several methods are available for obtaining ES cells. The most common is *in vitro* fertilization, which requires a fertilized egg and therefore produces cells that differ genetically from the host. A second strategy involves somatic nuclear transfer, which takes a nucleus from a somatic cell, such as a skin cell, and transfers it to a fertilized egg whose nucleus has been removed (Fig. 64.4a) [44]. The subsequent ES cells therefore contain only the genetic material of the recipient. Another possibility for women is parthenogenesis [45], which tricks an egg into thinking it is fertilized, allowing it to begin duplicating its DNA (Fig. 64.4b). Although this process is unable to create a viable embryo, (because factors derived from sperm are necessary for pre-implantation), it can produce normal cells.

INDUCED PLURIPOTENT STEM CELLS

The newest and most promising method to date is based on induced pluripotent stem cells (iPSC). iPSCs were first generated by inducing fibroblasts into an embryonic-like state with respect to their morphology and differentiation potential [46,47]. This is achieved by ectopic expression of transcriptions factors through different methods and use of small molecules that aid the reprogramming process [48].

The applicability of patient specific iPSCs ranges from:

1) generation of *in vitro* models for neurological disorders,
2) The generation of drug screening assays, and
3) Autologous cell replacement in neurological disorders of various etiologies.

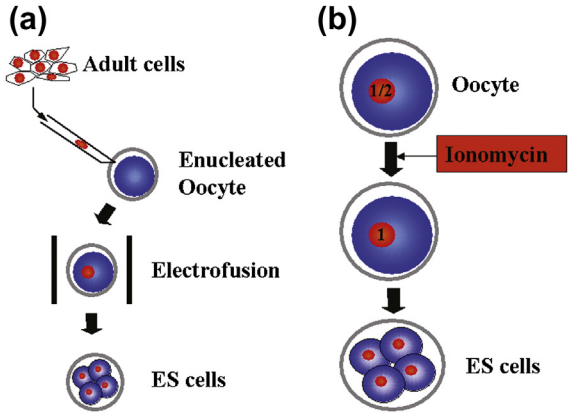

FIGURE 64.4
ES cells can be made by *in vitro* fertilization and two additional methods: (a) Somatic nuclear transfer: Donor cells are placed under the zona pelucida into the perivitelline space of enucleated oocytes. The cell nucleus is introduced into the cytoplast by electrofusion, which also activates the oocyte. It can then be grown to the blastocyst stage to harvest the ES cells. (b) Parthenogenic activation: For activation, oocytes are briefly exposed to a calcium ionophore such as ionomycin. The resulting cell can mature for ES cell harvest.

The first challenge in using patient specific iPSCs, generating differentiation protocols, has been overcome. To date human iPSCs have been differentiated into components of each germ layer *in vitro* and to form teratomas in immune deficient mice [49]. Additionally, IPSCs have been directly differentiated into neural progenitors [50], neurons [51,52], pancreatic insulin-producing cells [53], and hepatocytes [54].

The first human patient specific iPSC line to be derived from a patient with a neurological disorder came from an ALS patient in an advanced age of 83. These iPSCs were differentiated into motor neurons effectively creating an *in vitro* human model of ALS [55]. Another group generated ALS patient specific iPSC lines from three patients that carried a mutation in Tar DNA binding protein-43 (TDP-43), a protein that when mutated is found in cytosolic aggregates in the motor neurons of ALS patients that have the sporadic form of the disease. iPSC-derived motor neurons formed cytosolic aggregates containing TDP-43 and were used to screen compounds that rescue the ALS-associated phenotype through assays that included measurements of insoluble TDP-43, neurite length quantification, and TDP-43 mRNA. The screen identified anacardic acid, a histone acetyltransferase inhibitor, as a substance that rescued motor neurons from the abnormal ALS phenotype. Interestingly, while there were clonal differences within iPSCs derived from different patients as well as iPSCS from the same patient, the ability of anacardic acid to rescue the abnormal motor neuron phenotype was consistent in the two iPSC lines used in this work [56].

The generation of iPSCs has applicability in studying the differences in the pathogenesis of neurological diseases where the etiology of the disease is different as is the case with Parkinson's disease (PD) where only 10% of patients have the inheritable form of the disease while the rest manifest the sporadic form. Differentiation of iPSCs into dopaminergic neurons from patients with idiopathic PD and patients with familial PD carrying a G2019S mutation in the Leucine-Rich Repeat Kinase 2 (LRRK2) gene showed that when cultured for a short amount of time (indicating a young age) only the iPSCs with LRRK2 mutations manifested α-synuclein-containing intraneuronal inclusions known as Lewy bodies. However, when cultured for longer periods of time (indicating aging) iPSC-derived dopaminergic neurons generated from patients with idiopathic and familial PD showed signs of neurodegeneration caused by deficient autophagic machinery. Importantly, this work reports on the generation of iPSC-based model of PD that recapitulates pathological features of idiopathic and familial PD, and has the potential to be used for identification of pathogenic mechanisms of PD, and can be used to screen drugs that rescue the abnormal phenotype of dopaminergic neuron phenotype [57].

The therapeutic potential of iPSCs for autologous neural cell replacement has shown to be promising. When transplanted in utero, iPSC-derived neural precursors extensively migrate and differentiate into neurons and glial cells of the developing brain. The transplanted iPSC-derived motorneurons can be found primarily in the septum, striatum, hypothalamus and midbrain as well as olfactory bulb, cortex and thalamus but not cerebellum and brainstem. The engrafted neurons generate various neuronal subtypes such as glutamatergic neurons, GABAergic neurons, and catecholaminergic neurons that functionally integrate into the brain; the glial cells display glial phenotype and are glial fibrillary acidic protein (GFAP) positive. Preclinical studies show that transpantated iPSC-derived neural precursors in a rodent model of PD differentiate into dopaminergic neurons in the substantia nigra and induce functional recovery. However, this study highlighted the issue of teratoma formation as this was observed in the animals that did not recover in function [58].

Teratoma formation from transplanted iPSC-derived neural precursors was an issue in another preclinical study. Transplantation of iPSC-derived neural precursors in a rodent model of SCI resulted in teratoma formation. However, this problem was resolved by choosing an iPSC-derived neural precursor cell line that had no teratoma-forming activity. Transplantation of 'safe' iPSC-derived neural precursors in a rodent model of SCI promoted functional recovery. In the injured spinal cord, the engrafted cells differentiated into neurons,

oligodendrocytes and astrocytes. The engrafted cells that had differentiated into mature oligodendrocytes were integrated into myelin sheath whereas cells that differentiated into astrocytes promoted serotonergic innervation of the dorsal cord. Therefore, this preclinical study suggested the possibility that remyelination of demyelinated axons by the grafted 'safe' iPSC-derived oligodendrocytes contributed to the functional recovery of the grafted animals. The other contributing mechanism for functional recovery suggested here is axonal regrowth supported by the grafted 'safe' iPSC-derived astrocytes. Importantly, this study demonstrated the potential of iPSC for use in the repair of the injured spinal cord as well highlight the need for the evaluation of the iPSCs prior to transplantation [59].

The generation of iPSCs is delivering on the promise of creation of patient specific cells for therapeutic transplantations. The general consensus in the scientific community was that unlike hESCs the use of iPSCs in autologous transplantation-based therapeutic approaches would not face any immune related issues and that their tumorogenic potential will be reduced by the use of non-integrating episomal vectors [60], viral-free systems to generate these cells [61] or pre-transplantation characterization [59]. However, an examination of immune rejection in inbred C57BL/6 showed that iPSC lines derived from C57BL/6 fibroblasts through retroviral approach or episomal approach are immunogenic in these mice. C57BL/6 iPSC-derived teratomas in syngeneic recipients were regressed, had T cell infiltration and tissue damage. Global gene expression analysis revealed noticeable abnormal gene expression in C57BL/6 iPSC-derived teratomas that could induce T cell-dependent immune response in syngeneic recipients [63]. While this data is concerning for clinical applications of iPSCs, more preclinical studies are needed to establish the immunogenicity of autologous iPSCs particularly in an immune-privileged environment of the CNS.

ALTERNATIVE TRANSPLANTATION OPTIONS

Many studies of spinal cord repair have involved differentiated cells. The earliest studies used peripheral nerve grafts to demonstrate that the nervous system has the capacity to regenerate but that the environment in the CNS is not permissive [62]. Substantial progress has been made with transplantation of peripheral nervous system cells and non-nervous system cells, including genetically engineered fibroblasts, bone marrow cells, glial cells, neurons, and mixtures of glia and neurons [64–67]. In general, fetal sources of cells have been the most successful because derivatives of postnatal and adult cells are less able to withstand neural transplantation. One recent exception has been neural stem cells derived from the adult CNS [68].

Another very active area of investigation is transdifferentiation [69]: isolating cells from organs other than the nervous system and transforming them into neural progenitor cells. Although initial progress suggested that this strategy might work with many types of tissue, the problem of cell-to-cell fusion may have dampened enthusiasm for this approach [70]. Suffice it to say that transdifferentiation has not yet produced cells suitable for CNS transplantation, although clearly the potential exists.

EMBRYONIC STEMS CELLS AND THE NEURAL LINEAGE

Several protocols are available for converting ES cells into neural lineage cells. However, protocols for mouse and human cells differ because the constraints of the human ES cell system have not yet been clearly defined (Fig. 64.5). Differentiating murine ES cells traditionally begins with floating spheres called embryoid bodies. These bodies are akin to the neural spheres of stem cells obtained from the adult CNS. Retinoic acid is a key induction agent for producing neural progenitors from mouse ES cells [71]. Neural cells resembling anatomically normal neurons, astrocytes, and oligodendrocytes from the CNS can easily be derived from mouse ES cells using these protocols (Fig. 64.6).

Immunofluorescence (green), Hoechst 33342 (blue). Scale bar d—e = 100 μm.

EMBRYONIC STEM CELL TRANSPLANTATION

Use of ES cells for neural transplantation is in its infancy, and only a very limited amount of work has been completed with the spinal cord. These early studies have relied on transplantation during the embryonic [43], postnatal [73,74], and adult [74—76] periods in the normal or injured spinal cord. Overall, they demonstrate that ES cells have a remarkable ability to integrate into the injured region of the cord and differentiate appropriately.

A study by Thomas Jessell and colleagues provides exceptional evidence that ES cells can participate in the normal development of spinal cord cells, including motor neurons [43]. It demonstrated that developmentally relevant signaling factors can induce mouse ES cells to differentiate into spinal progenitor cells and then motor neurons through the normal developmental pathway (Fig. 64.7). Thus, the signals that promote the differentiation of neural stem cells *in vivo* are also effective when applied to ES cells. This group further demonstrated

(a) Whole-mount preparation of stage-35 chick embryonic rib cage. ES cell-derived eGFP+ motor axons contact intercostal muscles. (b, c) Coexpression of synaptobrevin (Syb) and vesicular acetylcholine transporter (VAChT) in the terminals of eGFP+ motor axons at sites of nerve contact with muscle. The anti-Syb and -VAChT antibodies recognize mouse but not chick proteins. (d) Neurofilament (NF) and eGFP expression in motor axons that supply intercostal muscles. eGFP+ axons lack NF expression. The terminals of eGFP+ axons coincide with clusters of acetylcholine receptors, defined by α-bungarotoxin (αBTX) labeling. (e) Coincidence of synaptotagmin (Syn) expression in eGFP+ motor axon terminals and αBTX labeling. (f) Coincidence of synaptobrevin (Syb) expression in eGFP+ motor axon terminals and αBTX labeling. *(From Wichterle et al. (2002). Reproduced with permission.)*

that motor neurons derived from ES cells can populate the embryonic spinal cord, extend axons, and form synapses with target muscles (Fig. 64.8). Therefore, they not only participate in normal development but also grow appropriately when transplanted into the embryonic spinal cord, targeting muscle. Thus, inductive signals in normal pathways of neurogenesis can direct ES cells to form specific classes of CNS neurons.

Oliver Brustle, Ian Duncan, and Ron McKay were the first to transplant progenitors derived from ES cells into the adult and embryonic spinal cord [74]. They demonstrated that ES cells that are transplanted into brain and spinal cord of normal adult animals can differentiate into oligodendrocytes that can myelinate axons. They generated OP efficiently by first supplementing cultures of ES cells with fibroblast growth factor (BFGF) and epidermal growth factor and later including PDGF. About 38% of the cells in the resulting cultures were oligodendrocytes. To investigate whether these oligodendrocytes could myelinate *in vivo*, cells grown in the presence of BFGF and PDGF were injected into the spinal cord of one-week-old myelin deficient rats, a model for a human myelin disorder. Two weeks after transplantation, numerous myelin sheaths were detected in six of the nine affected rats. The original 100,000 cells had migrated widely, and they made myelin with appropriate ultrastructure. Therefore,

chick motor neuron marker protein SC1 (i, j). eGFP−, NCAM+ axons cross the floor plate but do not project out of the spinal cord (arrows, g, h). (k—n) Transverse sections of thoracic spinal cord at stage 27, after grafting of embryoid bodies grown with RA (2 μM) and anti-Hh antibody (5E1, 30 μg/mL). No mouse-derived motor neurons were detected by either eGFP (K) or a mouse-specific anti-HB9 antibody (l). In contrast, many mouse-derived NCAM+ (m) and Lim2+ (n) interneurons are present. (o—q) Transverse sections through stage 27 spinal cord at thoracic (o, p) and lumbar (q) levels after grafting embryoid bodies enriched with motor neurons. eGFP+ motor neurons are concentrated in the ventral spinal cord. Ectopic eGFP+ motor neurons are located within the lumen of the spinal cord. eGFP+ axons exit the spinal cord, primarily via the ventral root, and project along nerve branches that supply axial (o—q), body wall (o, p), and dorsal and ventral limb (q) muscles. The pathway of axons is detected by neurofilament (NF) expression. eGFP+ axons are not detected in motor nerves that project to sympathetic neuronal targets. *(From Wichterle et al. (2002). Reproduced with permission.)*

glial precursors derived from ES cells and transplanted into the neonatal rat spinal cord migrated over several millimeters and differentiated into myelinating oligodendrocytes and astrocytes.

This group also transplanted precursors derived from ES cells into the cerebral ventricles of developing rodents (embryonic day 17) [74]. Three weeks later, proteolipid protein (PLP)-positive myelin sheaths were evident in a variety of brain regions. The cells' exogenous origin was confirmed by *in situ* hybridization with a probe to mouse satellite DNA. Importantly, there was no observable evidence of abnormal cellular differentiation or tumor formation.

In the same year, John McDonald, David Gottlieb, and Dennis Choi demonstrated for the first time that ES cells that had been induced to become neural cell precursors could be successfully transplanted into the injured spinal cord [75]. Examination of the spinal cord nine days after 1 million precursor cells were transplanted into a cyst caused by contusion injury showed that the cells had survived, grafted, migrated long distances, and differentiated into the three principle neural cell types: neurons, astrocytes, and oligodendrocytes (Figs. 64.9 and 64.10). This group also demonstrated that transplantation was associated with a significant and sizable improvement in function. Their study was the first demonstration that transplanted embryonic precursors can successfully repair the damaged adult nervous system, an important finding, given that conditions in the damaged adult nervous system are much less favorable for regeneration than those in the neonatal spinal cord. Subsequently, Liu and colleagues [76] demonstrated that precursors derived from ES cells and transplanted into the injured adult nervous system can remyelinate neurons in an anatomically appropriate manner (Fig. 64.11). Furthermore, they showed that oligodendrocytes derived from ES cells functioned normally, myelinating multiple axons in culture, just as they do in the normal nervous system (Fig. 64.12). Using patch clamp analysis, Jim Huettner and John McDonald later demonstrated that the physiologic characteristics of such oligodendrocytes are similar to those of oligodendrocytes taken from the adult spinal cord (Fig. 64.12c and Fig. 64.13). Oligodendrocytes derived from ES cells represent the entire oligodendrocyte lineage, from early OP to mature, myelinating oligodendrocytes.

In culture, neurons derived from ES cells differentiate rapidly and spontaneously create neural circuits with anatomical (Fig. 64.14) and physiological evidence of excitatory and inhibitory synapses [72,77,78]. Substantial neural differentiation is also evident *in vivo* in the model of contusion injury [75], where neurons show extensive axonal outgrowth with presumptive

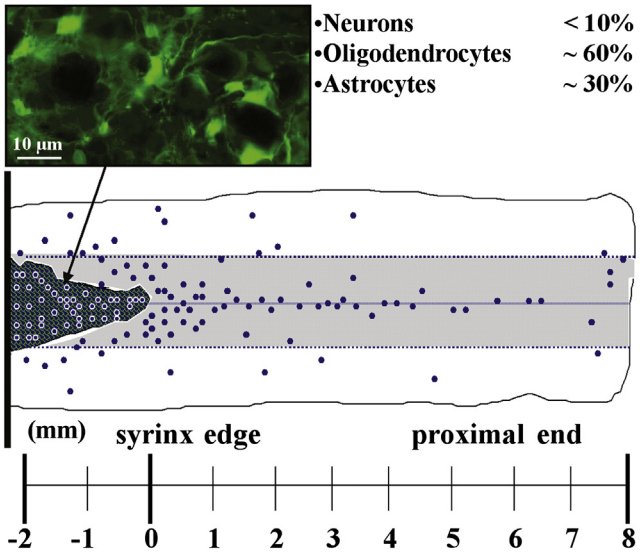

FIGURE 64.9
In the contusion-injured spinal cord of the rat, ES cell-derived neural precursors survive, migrate, and differentiate following transplantation. The schematic demonstrates the relative distribution of ES-derived cells two weeks after transplantation into the central cavity nine days after spinal contusion injury. The cavity is partially filled, and cells have migrated long distances. Most of the distant cells are identified as oligodendrocytes, while astrocytes and neurons remain restricted to the transplantation site. Left top inset shows GFP-expressing ES cell-derived neural cells.

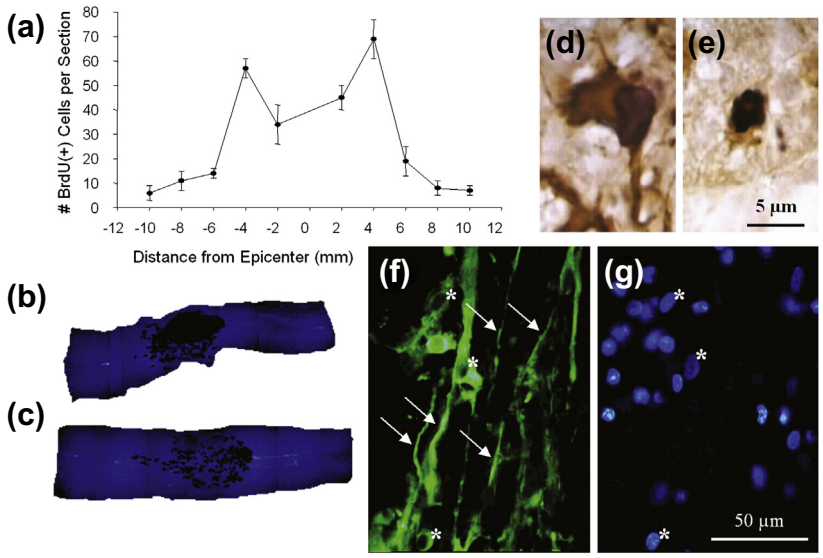

FIGURE 64.10

BrdU-labeled ES cell-derived cells two weeks after transplantation. Mean ± SEM BrdU-labeled nuclei per 1 mm segment in longitudinal sections. (a). Hoechst 33342-labeled sections 42 days after injury, transplanted with vehicle (b) or ES cells (c) nine days after injury. BrdU-positive cell colabeled with GFAP (d). BrdU-labeled cell colabeled with APC CC-1 (e). The mouse-specific marker epithelial membrane antigen (EMA) indicates processes (arrows) emanating from embryonic stem (ES) cells (f). morphological evidence of synapse formation. Moreover, immunological evidence of cholinergic, serontonergic, GABAergic, glycinergic, and glutamatergic neurons has been obtained *in vitro* and *in vivo* (data not shown).

Implantation, survival, and migration of transplanted ES cell-derived precursors in the damaged spinal cord have been verified with real-time polymerase chain reaction (PCR) and also by using magnetic resonance imaging (MRI) to track oligodendrocytes prelabeled with paramagnetic agents. In both cases, migration up to 1 cm from the transplantation site was evident [79].

After other groups demonstrated that multiple rounds of transplantation can deliver different types of stem cells to the CNS, our group systematically evaluated intravenous, intraventricular, intrathecal, and interparanchemal transplantation of embryo bodies derived from ES cells using our 4−/4+ protocol (four days in culture without retinoic acid followed by four days with retinoic acid). Although some of the cells that were transplanted intravenously entered the CNS, they remained in blood vessels and showed only limited neural differentiation. Intracerebral ventricular administration enabled some transplanted ES cells to be incorporated into the CNS, but this approach had to be discontinued because the cells obstructed the third and fourth ventricles, causing hydrocephalus. However, we made a remarkable observation when we transplanted a large number of ES cell-derived neural precursors intrathecally into the lumbar spine [80]. Three to four months later, ES cells were observed in well-formed tissues surrounding the lumbar sacral nerve roots and extending down the sacral canal. Further evaluation clearly showed that the cells had differentiated into tissue that bore a remarkable resemblance to some components of the normal spinal cord. For example, extensive myelination and cells resembling cholinergic motor neurons were observed. Zones of the peripheral nervous system were also clearly demarcated from the CNS. These results were quite surprising because intraparenchymal transplantation into the spinal cord characteristically produces abnormal macro-organization of cells. Thus, this was the first demonstration that transplanted ES cells can organize themselves into CNS-like tissues. It will now be important to understand the constraints required to produce this degree of self-organization.

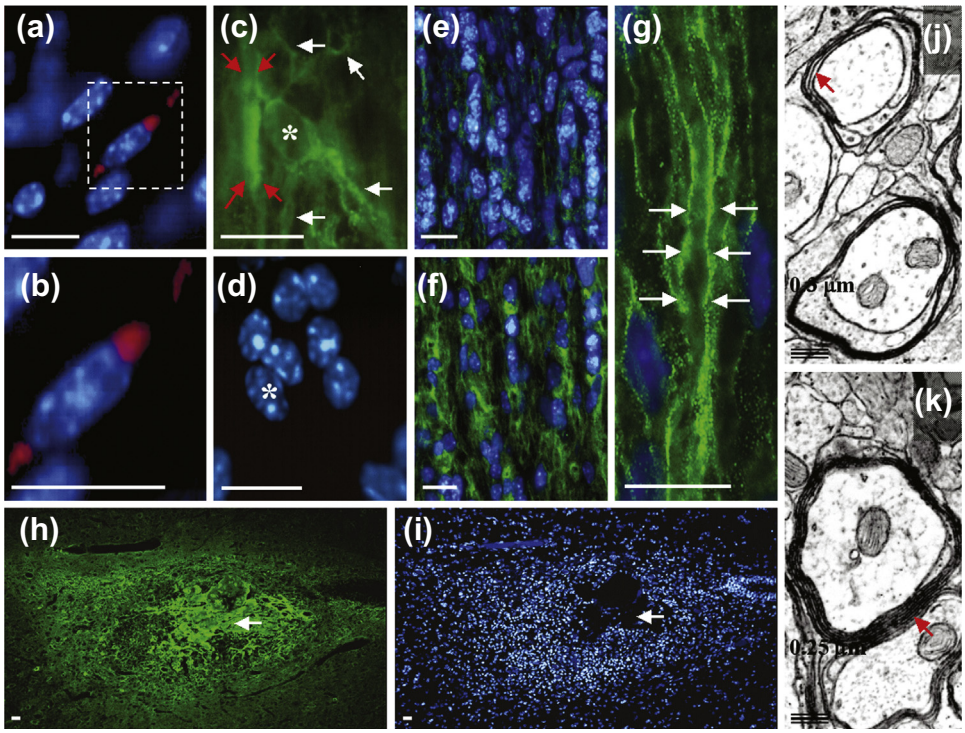

FIGURE 64.11
Cells derived from ES oligospheres can migrate and myelinate axons when transplanted into dysmyelinated spinal cords of adult Shiverer mice, which lack the gene for myelin basic protein (MBP). Transplanted cells were identified by cell tracker orange (CTO) epifluorescence (red) or immuno-reactivity for MBP (green). Hoechst 33342 (blue). CTO-labeled cells aligned with native intrafascicular oligodendrocytes in white matter (a, b). An ES cell-derived (MBP+) oligodendrocyte (asterisk) with longitudinally oriented processes (white arrows) is shown in panels c and d. Red arrows mark probable myelination around an adjacent axon (c). Little MBP immunoreactivity is seen in white matter in a longitudinal section of spinal cord from a mouse that received a sham transplantation (e). A gradient of MBP immunoreactivity centers on the site of ES cell transplantation (f). Panel g (high magnification) shows intrafascicular oligodendrocyte nuclei (blue) and MBP immunoreactivity (green), two indications of axonal myelination (white arrows), in white matter from a mouse transplanted with ES cells. The spatial distribution of MBP immunoreactivity one month after ES cell transplantation is shown at low magnification (h), with corresponding Hoechst 33342 counterstaining (i). White arrows indicate the center of the transplanted site. Transmission electron microscopy shows four loose wraps of myelin, the maximal number of layers typically seen around axons in control animals (red arrow, j), and nine or more compact wraps around axons from the transplanted area (red arrow, k). Shiverer-mutant mice lack a functional MBP gene that is required to form mature compact myelin; therefore, the presence of mature compact myelin is a standard for transplant oligodendrocyte-associated myelin. Scale bars: a–i = 10 μm; j, k = 0.3 μm. *(Reproduced with permission from Liu et al. (2000).)*

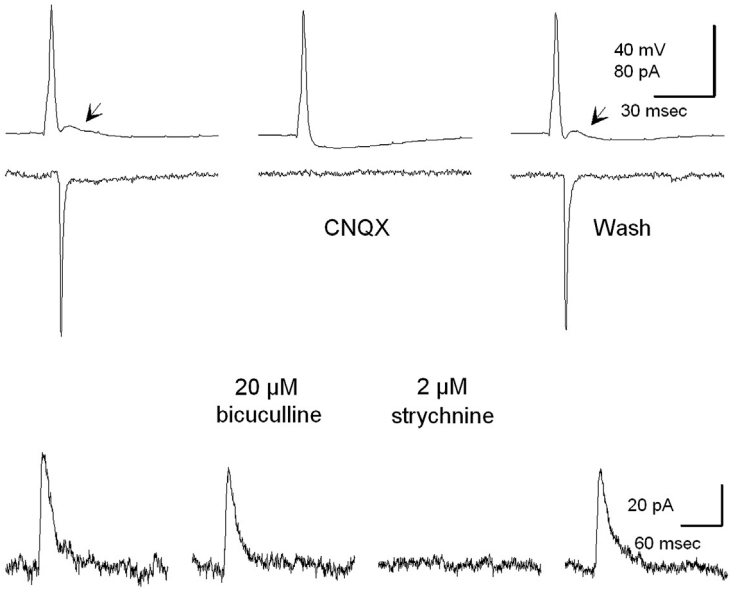

FIGURE 64.13

Excitatory (top) and inhibitory (bottom) synaptic transmission between neurons derived *in vitro* from mouse ES cells. Action potentials were evoked in the presynaptic neuron by current injection. Excitatory post-synaptic currents, blocked by superfusion with the selective glutamate receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX; 10 micromolar), were recorded under voltage clamp. Arrows point to an autaptic excitatory synaptic potential that is also blocked by CNQX. Inhibitory synaptic currents were evoked in a different ES cell pair and tested sequentially with the antagonists bicuculline and strychnine, which are selective for gamma-aminobutyric acid (GABA) and glycine receptors, respectively. For this cell pair, only the post-synaptic currents are shown. Transmission was blocked by strychnine, indicating that glycine was the transmitter. Other presynaptic cells evoked bicuculline-sensitive synaptic currents, indicating that GABA mediated transmission (not shown).

NOVEL APPROACHES TO CNS REPAIR

Most neural transplantation studies, including those using ES cell-derived neural progenitors, have used cells to replace cells lost after injury. Given that we do not know which types of differentiated cells are required for repair, neural precursors may be ideal for this purpose because environmental clues can decide their developmental fate [68,76,81]. Moreover, such precursors can serve as bridges to support axonal regrowth [64].

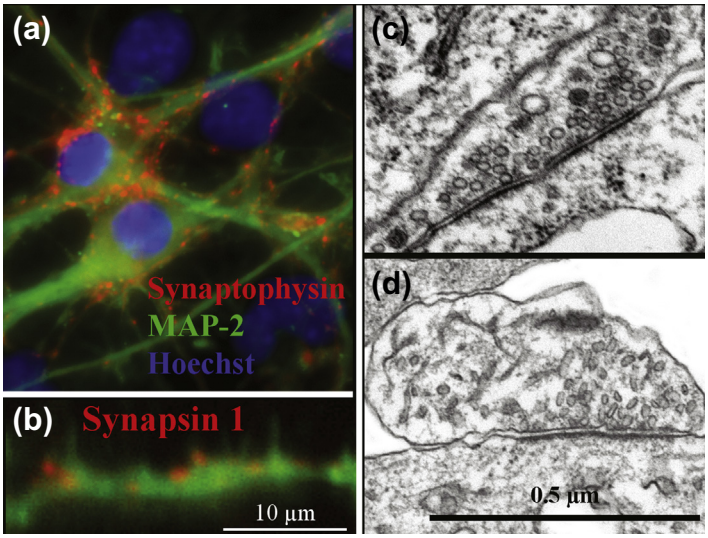

FIGURE 64.14

ES cells differentiate into neurons that spontaneously create neural circuits. Presumptive presynaptic sites (red) oppose dendrites (green) in (a) and (b). (c) and (d) demonstrate ultrastructural characteristics of synaptic profiles *in vitro*.

To try to overcome the physical and chemical constraints imposed by the injured nervous system, ES cells are often genetically altered so they will deliver growth molecules, such as neurotrophin-3, after transplantation [19,24,81], and they are particularly well suited to this task. McDonald and Silver recently adopted a novel approach to overcoming restraints by showing that early progenitors of ES cells can phagocytize key inhibitory molecules in glial scar tissue [82]. These cells therefore created an inhibitor-free bridge over which axons rapidly sprouted from the transplant into normal cord. By nine days after transplantation, axons from the graft had grown up to 1 cm — a rate of more than 1 mm per day! This rate is similar to that seen in the normal embryo [83].

Another novel approach is to use stem cell transplantation to limit the secondary injury that occurs after nervous system injury [84]. For example, we demonstrated that transplanting ES cells can limit the delayed death of neurons and oligodendrocytes. Since most transplantations are performed at the time of injury, it is possible that many of their results may be attributable to this neuroprotective role. It seems clear that even genetically unmodified ES cells release large quantities of growth factors.

Although replacing lost neurons is difficult, it might be possible to use neuronal replacements to create bridging circuits across the injury site. Descending axons could synapse onto ES cell-derived neurons that subsequently synapsed onto key pattern generators in the lower spinal cord. More global delivery of neurotransmitters via synaptic or non-synaptic mechanisms might enhance functions such as locomotion. Previous work by others has demonstrated that release of noradrenergic and serotonergic neurotransmitters can stimulate and enhance the central pattern generator for locomotion [85]. More recent work indicates that release of brain-derived neurotrophic factor and neurotrophin-3 can perform this function [86].

Because ES cells are embryonic in nature, neural progenitors derived from them may be able to reprogram the adult CNS so that damage can be repaired [87]. ES cells are also unique in that they have the potential to replace cells derived from multiple embryonic germ layers. In the CNS, it will be important to replace lost non-neural cells as well as neural cells to regain normal CNS function, such as neovascularization. Growing recognition of the link between neovascularization and neurogenesis is strengthening this approach. We found that ES cells in transplanted 4−/4+ embryoid bodies differentiate into both neural cells and vascular endothelial cells (unpublished observations).

In the embryo, stem cells differentiate into motor neurons and grow toward muscle, where they form neuromuscular junctions. Using ES-derived motor neurons to replace lost motor neurons at injured segments will not enhance function because chronically denervated muscle is unable to reassemble functional neuromuscular junctions. However, transplantation might avoid the long-term muscle wasting that results from denervation. To maintain denervated muscle, for example, it might be possible to transplant ES cells into the distal nerve stump or directly into the muscle. Once in place, the transplanted cells could differentiate into motor neurons. If they were genetically altered, the motor neurons could be selectively removed once the repair was properly achieved.

More recent studies are beginning to combine stem cells, including ES cells, with biomaterials. The advent of nanotechnology should further enhance this approach [88,89].

Finally, remyelination is one of the most pragmatic approaches to restoring function to the damaged spinal cord (Fig. 64.15). Because many potentially functional connections remain in the outer donut of surviving tissue, appropriate remyelination could substantially improve function. One must consider, however, that dysmyelination rather than demyelination is the biggest problem in the damaged nervous system. Often, inappropriate myelination is more harmful than no myelination at all.

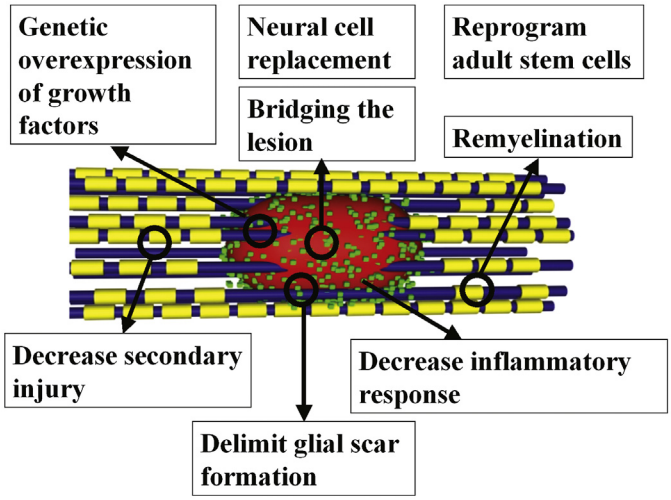

FIGURE 64.15

Novel approaches to spinal cord repair using ES cells. Remyelination is one of the most pragmatic approaches to restoring function to the damaged spinal cord. ES cell-derived precursors can serve as bridges to support axonal regrowth. They can phagocytize key inhibitory molecules in glial scar tissue. These cells therefore created an inhibitor-free bridge over which axons sprouted rapidly from the transplant into normal cord. Newly generated neurons can be used to create bridging circuits across the injury site. ES cell transplantation can limit the secondary injury. To try to overcome the constraints of the injured nervous system, ES cells are often genetically altered so that they will deliver growth molecules, such as NT3, after transplantation. Because ES cells are embryonic in nature, their progenitors may also be able to reprogram the adult CNS to optimize spontaneous host regeneration. Replacement of non-neural cells as well as neural cells will be important for regaining normal CNS function, such as neovascularization. ES cells can have similar applications in the peripheral nervous system.

TOWARD HUMAN TRIALS

Some of the animal studies described previously have prompted early human safety trials of ES cell transplantation. Most have focused on PD, where unforeseen exaggeration of dystonia has limited advances in transplantation therapy [90]. Phase I/II human trials for repairing the spinal cord are also under way. They include transplantation of porcine-derived stem cells for the purpose of remyelination (Diacrin) as well as allogeneic transplantation of olfactory ensheathing glia (Carlos Lima; Lisbon, Portugal). Although safety data are not yet available, it is important to note that such trials are paving the way for further uses of ES cells. With the recent advent of human ES cells, human transplantation appears more feasible. The California based research company Geron performed the first human ES cell research trial approved in the United States for individuals with acute traumatic SCI. A total of four patients were treated in this study. Unfortunately the company dropped its study in November 2011 amongst financial concerns. To date there have been no safety problems reported.

Considering the recent advancements in generating induced pluripotent stem cells raises the possibility that ethically acceptable procedures for human stem cell generation is on the horizon that will hopefully lead to quick translation into clinical care.

CONCLUSIONS

Studies of neurotransplantation for repairing the damaged nervous system are making good progress. Early animal studies showed that mouse ES cells can replace neurons, astrocytes, and oligodendrocytes, instigate appropriate remyelination, and even improve locomotion. As is the case for all transplantation studies, however, the mechanisms underlying functional improvement remain unclear. Nevertheless, ES cells offer a novel approach to deciphering these mechanisms. For the first time, ES cell genetics is allowing investigators to track

transplanted cells that have been engineered to express green fluorescent protein. This and other types of genetic modification permit one to track the integration and differentiation of ES cells, assess behavioral recovery, selectively remove the cells to see whether recovery wanes, and insert more cells to see if functional recovery occurs anew. This proof of principle will be required to identify mechanisms in neural repair.

Although it is impossible to predict the future of the field, it is clear that IPS and human ES cells are tools that will revolutionize neurobiology and neural transplantation by providing the unprecedented ability to selectively deliver key growth and regulatory factors. Also, ES cell transplantation promises to be one of the greatest potential therapies for chronic nervous system disorders. Only the future will reveal its full potential for treating human disease and disability, but it is possible to say with confidence that ES cells will have a major impact on repairing the human CNS within our lifetimes.

Acknowledgments

We would like to thank the people in our laboratory who have contributed to this work over the years and also our collaborators: Jeff Bulte; Dennis W. Choi, David I. Gottlieb, David Gutmann, Chung Hsu, Mark F. Jacquin, and Gene Johnson and Carl Lauryssen. This team obtained a program project grant from the National Institutes of Health (NIH; NS39577) to evaluate the potential of ES cells to repair SCI. We would also like to thank our animal technicians, who express rodent bladders three times daily, seven days a week, including holidays and our TC staff, who passage ES cells every other day, endlessly. This work was supported by NINDS and NIDCR grants NS39577, NS40520, NS45023, and DE07734.

INTRODUCTION

Deafness is the USA's number-one disability, with hearing loss affecting more than 35 million individuals. Hearing loss can have a genetic cause, be acquired from causes such as ototoxic drugs, noise overstimulation or disease/trauma, or can arise from a combination of genetic and environmental influences such as occurs with age-related hearing loss. Close to one half of all hearing losses are thought to be of genetic etiology. Acquired deafness on average affects one in four to five individuals, but the incidence increases significantly with age when presbycusis (age-related hearing loss) becomes a major problem in the elderly population, affecting one in three over the age of 65 and 50% of individuals over the age of 75.

An improved understanding of the mechanisms underlying genetic, acquired and 'mixed' deafness has driven development of new interventions and treatments as well as refinement of previous approaches to prevent hearing loss and restore hearing after deafness. Hearing loss induced by cochlear damage from overstimulation, ototoxic drugs, trauma, infections and/or aging can be reduced by relieving oxidative stress to the cochlea with antioxidants and enhancing endogenous protective systems with agents such as neurotrophic factors and heat shock proteins. Genetic modification to induce regeneration of hair cells following their loss has now been shown in animal models and may become clinically feasible, with development of safe and effective vectors. Use of endogenous stem cells and placement of exogenous stem cells is being developed as a strategy to replace lost hair cells or auditory nerve and to supplement remaining function. Survival factors can be applied to the cochlea to improve auditory nerve survival following deafness and to induce regeneration of its peripheral processes. Major advances have also been made in region specific delivery of therapeutics to the cochlea to allow these interventions, including gene transfer, microcannulation and biomaterials placed into the middle ear or directly into the cochlea. Auditory prostheses are being refined, with significant improvements occurring in cochlear prostheses as well as in development of central auditory prostheses. Prostheses can also provide a mechanism for application of therapeutics through microchannels. Biomaterials on and associated with prostheses not only can improve their function and histocompatability but also can provide a means for delivering therapeutics. The strategies for tissue-engineering interventions based on recent scientific discoveries are the focus of this chapter.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00065-3

INTERVENTIONS TO PREVENT HEARING LOSS/COCHLEAR DAMAGE

Oxidative stress

Oxidative stress, the overproduction of reactive oxygen species (ROS; free radicals) in the cell, has now emerged as a common mechanism by which many traumatic insults, including noise and ototoxic drugs cause damage to the inner ear. The formation of ROS, such as super-oxide, hydroxyl radical, and nitric oxide, may occur by different mechanisms depending upon the stress, but in each it appears to occur early and throughout the traumatizing events. ROS can be formed by non-enzymatic reactions via redox-active iron complexes of drugs [1,205] and by enzymatic reactions in the cell. On the cellular level, oxidative stress may originate in the mitochondria [2] or may be due to activation of NADPH oxidase via Rho-GTPases, a primary source of super-oxide radicals [3].

In an unchallenged cell, ROS are products and by-products of normal metabolism and are contained within a physiological range (redox homeostasis) by endogenous antioxidant systems. An excess of ROS, however, will cause cellular damage, ultimately triggering cell death pathways of apoptosis and necrosis. Because tissue levels of endogenous antioxidants can be influenced by external manipulations, ROS mediated hearing loss is a potential target for interventions to prevent or reduce hearing loss.

Prevention of ototoxicity

Aminoglycoside antibiotics, including neomycin, kanamycin, tobramycin, amikacin, and gentamicin and the chemotherapy anti-cancer agent cisplatin (CDDP) are the most common drugs causing hair cell loss and, consequently, hearing loss (ototoxicity). Although this review will emphasize the cochlear effects of ototoxic agents, we should note that aminoglycosides can also cause vestibular toxicity and loss of balance. ROS increase significantly in inner ear tissues following aminoglycoside treatment both in organ explants and *in vivo* [205]. Conversely, cellular antioxidant defense system constituents, such as glutathione, decrease after aminoglycoside treatment [4].

The resulting redox imbalance resulting from increased ROS production and decreased antioxidant function then initiates competing signaling pathways of cell death and survival. involving intracellular organelles such as mitochondria and lysosomes and a network of interfacing signaling systems based on enzymatic actions (e.g., activation of proteases) and changes in gene expression (e.g., via transcription factors or epigenetic modifications). Indicative of this complexity, cell death by aminoglycosides includes both apoptosis and necrosis of hair cells in cochlear and vestibular organs [5–7]; and both caspase-dependent and caspase-independent pathways appear to contribute to hair cell pathology. Caspase-3 has also been implicated in hair cell death, primarily in *in vitro* models of explant cultures and isolated cells or in the vestibular system (e.g., reference [8]). The pro-apoptotic mediator c-Jun NH2-terminal kinase (JNK) apoptotic pathway is often involved, since pharmacological inhibitors (e.g., CEP-1347) can offer some protection *in vitro* from aminoglycosides [9,10]. Like the caspase pathway, involvement of the JNK pathway is reported mostly in cultured explants but may contribute to the overall pattern of cell death *in vivo*. A dominance of caspase-independent cell death emerges in a chronic drug treatment model, where the onset of cochlear deficit is delayed and continues to develop after the cessation of treatment, akin to the clinical situation. In this model, activated calpain and cathepsins are the major mediators of cell death [3]. Most recently, inhibitors of histone deacetylation have emerged as promising candidates for clinical application. Two histone deacetylase inhibitors, trichostatin and butyrate, can reduce gentamicin ototoxicity in experimental models by inhibiting the epigenetic histone modifications induced by aminoglycoside treatment.

The establishment of the mechanisms underlying both apoptotic and necrotic cell death in ototoxicity provides a basis for a rational approach to prevention. For example, small synthetic molecules designed to inhibit one of the many steps in the apoptotic cascade can potentially stave off cell death. For a clinical application, however, a systemic application of such powerful signaling molecules may have far-ranging physiological consequences, particularly when applied to drug treatment, which may last for weeks. Local gene therapy, the process of virally introducing a gene into a tissue may be more suitable in such a situation [11]. However, given the complexity of cell death mechanisms, targeting a single pathway may not be sufficient as the inhibition of one might be bypassed by the activity of others.

The currently most applicable method of prevention is antioxidant therapy, which has become a successful clinical approach to many pathologies that involve free radicals. This type of intervention would also act directly on the ROS upstream of the ensuing cell death pathways and therefore suppress toxic mechanisms at the very onset. A wide variety of antioxidant molecules have been shown to attenuate ototoxicity *in vivo* constituting the most compelling support for ROS as major mediators of aminoglycoside induced hearing loss [1,7,205]. The attenuation achieved in animal models can be dramatic. For example, a gentamicin-induced hearing loss of 60−80 dB could be reduced to a negligible loss of 10 dB or less [12]. Since neither the serum levels of the drugs nor their antibacterial efficacy are compromised, antioxidant therapy provides a promising approach for a clinical application.

A clinically feasible prophylactic therapy requires drugs that by themselves are non-toxic and easily administered to the patients. One such example that emerged from laboratory studies is salicylate, the active ingredient of aspirin [13]. The efficacy of aspirin was tested in a randomized double-blind and placebo-controlled study in patients receiving gentamicin for acute infections [14]. Fourteen of 106 patients (13%) met the criteria of hearing loss in the placebo group, while only three out of 89 (3%) sustained a hearing loss in the aspirin group, for a 75% reduction in the incidence of ototoxicity. Aspirin did not influence gentamicin serum levels or the course of therapy. The protection against gentamicin-induced hearing loss with aspirin was confirmed by a second clinical trial [15]. Although aspirin is widely used in the United States as a daily prophylaxis against myocardial infarction, as well as for treatment of inflammation, fever, and pain, aspirin carries with it a small risk of gastrointestinal side effects. Other antioxidants utilized in clinical trials to date include vitamin E and N-acetylcysteine (NAC). NAC reduced hearing losses in a small study of patients receiving gentamicin for bacteremia and in a study of peritonitis patients receiving aminoglycosides for peritoneal dialysis [16,17]. In contrast and despite success in animal studies, vitamin E did not reduce hearing loss in a clinical study, underscoring the complexity of aminoglycoside responses in humans and the potential pitfalls of translation of animal studies to clinical medicine [18]. Cisplatin (CDDP) also generates ROS as well as reactive nitrogen species in the cochlea and several antioxidants have been shown to provide protection from CDDD induced ototoxicity including L-methionine, NAC, glutathione and ebselen [19]. Susceptibility to ototoxicity can be influenced by factors such as diet (e.g., [4], [20]) as well as genetic influences such as the mitochondrial mutations that can render people hypersensitive to aminoglycosides [21].

Prevention of acoustic trauma

The mechanisms of acoustic trauma-induced pathology are potentially more complex than those of drug-induced ototoxicity, including not only the formation of ROS but also vasoconstriction and direct mechanical damage to the organ of Corti [22]. In addition, the sources of noise trauma can be highly variable, ranging from a single high-energy impact, such as an explosion, to impulse noise to chronic noise exposure at various levels of intensity. Each of these conditions may induce variations in the mechanism of ROS formation or variations on cell death and survival pathways. Furthermore, while a protective therapy can be timed with drug administration, patients may report noise-induced hearing loss days, months,

or years into the trauma. To what extent a delayed intervention may be successful is yet another question that remains to be accurately resolved.

There is good direct evidence that ROS are formed in the inner ear following intense sounds, specifically in the stria vascularis and the organ of Corti. Indicators of ROS formation can be detected at the onset of the noise exposure and may persist for hours or even days following the exposure. Attesting to the importance of endogenous antioxidants, decreased glutathione in the inner ear enhances noise trauma, while dietary supplementation with glutathione attenuates these effects [22,23].

While the precise origin of ROS in the cochlea following noise exposure remains somewhat speculative, there are several sources most likely to contribute. A surge of super-oxide radicals followed by chain reaction formation of other free radicals (via Fenton-type reactions) may be due to increased mitochondrial activity, a prolonged tissue hypoxia due to vasoconstriction and a rebound hyperfusion [24]. Reactive nitrogen species may also arise from the activation or induction of the enzyme nitric oxide synthase. The different isoforms of this enzyme serve a variety of physiological processes in normal tissue metabolism, and the product of the enzymatic reaction, nitric oxide, is an important second messenger molecule. When produced in excess, not only is nitric oxide potentially damaging as a free radical, but it can also combine with super-oxide to produce the highly reactive and destructive peroxynitride. Nitric oxide levels can rise after noise exposure [25,26], perhaps as a consequence of an enhanced release of excitatory amino acids [27,28], and may contribute to the overall pathophysiology of noise-induced hair cell loss.

Multiple cell death pathways — partly independent and partly overlapping — may be triggered by a spectrum of radicals generated in response to noise. The fact that both necrosis and apoptosis are observed in noise trauma attests to the existence of multiple cell death pathways. This notion is also supported by the emergence of caspase-dependent and caspase-independent cell death pathways and the involvement of transcription factors that code for different signaling cascades, such as AP-1, endo-nuclease G, and the calcineurin-related activation of BCL-2 family proteins [22].

Restoring redox balance is therefore one of the potential means of intervention in noise-induced hearing loss, the other being a manipulation and interference with cell death pathways. The latter has been done successfully in animal experimentations *in vivo* [9,29], but similar concerns may arise here as in the prevention of drug-induced hearing loss, in that such systemic intervention in important physiological processes may have unwanted consequences. Other approaches successful in animals may also be impractical for the clinic. For example, the upregulation of antioxidant defenses by systemically administered R-phenyl isopropyl adenosine has adverse physiological effects [30]. A local application may bypass such a problem but is more invasive and affords less control over drug concentrations.

As with ototoxicity, antioxidant therapy is currently the most applicable approach for prevention and/or treatment of noise-induced hearing loss (NIHL), with a variety of drugs as possible protective agents (see reference [31]). NIHL can be attenuated effectively by scavengers such as super-oxide dismutase and allopurinol, antioxidants, and iron chelators and by antioxidant drugs that may have clinical appeal, such as ebselen or *N*-acetylcysteine (NAC) [32]. Multidrug combinations are promising, for example, acetyl-l carnitine with d-methionine or NAC [33,34]. Alternative strategies aimed at vasodilation and providing adequate blood flow to the cochlea during noise exposure may also indirectly relate to ROS formation. Drugs such as pentoxifylline and sarthran improved blood flow to the cochlea and also reduced the temporary effects of noise exposure [35,36]. Magnesium supplementation can maintain cochlear blood flow under noise exposure and reduces the resulting hearing loss [37]. A combination called 'ACE-Mg' consisting of several antioxidants (Vitamins A, C and E) acting by different mechanisms and magnesium as a potential vasoactive agent has proven effective in preventing NIHL in animals [38,39] and is now in clinical trials [39].

The translation from animal models to practical situations in humans has been partially successful in tests on populations exposed to high levels of noise during military exercises and leisure activities. These studies also clearly show the influence of genetic and physiological condition on susceptibility to noise trauma and the limitations that these factors impose on protection. Daily supplementation with magnesium reduced the incidence of permanent threshold shifts (PTS) in military recruits from 21.5% to 11.2% [40] and, likewise, reduced temporary threshold shifts (TTS) in a group of young volunteers [41]. However, the severity of PTS was negatively correlated with monocyte Mg^{2+} content regardless of treatment. As another example, NAC showed significant protection on TTS in subjects with null genotype in glutathione S-transferase (GST) T1 and M1 [42]. In contrast, a group of nightclub visitors taking NAC sustained the same TTS as the control group [42a]. Ongoing trials on US Army and Navy recruits are currently exploring the efficacy of NAC and of ebselen [31] and ACE-Mg [39].

While most strategies for interventions rely on applying the protective treatment prior to or concomitant with noise exposure, recent evidence indicates that the formation of free radicals continues for days following noise exposure and that, consequently, an antioxidant treatment may still be effective for a short period post-exposure [22].

Anti-inflammatory agents

There is increasing evidence that inflammation contributes to the loss of sensorineural elements from both ototoxic drugs and noise and anti-inflammatory agents are therefore another approach to prevention and treatment [43]. Reducing the inflammatory response by controlling the STAT-dependent pathways decreased cisplatin ototoxicity [44]. Likewise, the corticosteroid dexamethasone has been shown to provide protection against several ototoxic agents as well as the trauma from insertion of a prosthesis into the cochlea [45,46] as well as providing protection from noise [47]. It should also be kept in mind that the immune response can play an important and necessary role in response to stresses to the cochlea, when considering prevention and there may be occasions when enhancement rather than reduction provides benefit.

Heat shock proteins

Heat shock proteins (HSPs) provide another natural protective mechanism against various forms of stress. HSPs can achieve their protective role by influencing the stress-related denaturation of proteins (either reducing the denaturation or enhancing renaturation and regaining the correct tertiary structure), as chaperones or through an influence on cell death cascades. Several families of HSPs (commonly designated by their molecular weights) include HSP 25/27, HSP32, and HSP 70/72. Expression of the inducible form of HSP 70 in the cochlea has been shown in response to heat, transient ischemia, noise, and ototoxic drugs [48,49]. This expression is generally found in the sensory hair cells and is transient, peaking three to seven hours following the stress. HSP 27 is found constitutively (without the need for induction by stress) and has a more widespread distribution, not only in sensory hair cells, but in supporting cells and the lateral wall tissues [50]. The levels increase following stress. HSP32 has a small constitutive expression and is also upregulated following stress in hair cells and stria vascularis [51].

A protective role for HSPs in the inner ear is suggested by two types of studies. In one type of study, HSP levels are upregulated by an initial innocuous stress, either low-level noise [52] or controlled heat [53], followed by a noise exposure that would normally cause a significant hearing loss. Either pre-exposure resulted in a significant (30-dB) reduction in noise-induced hearing loss and hair cell loss. Similarly, pre-exposure to a heat stress protected hair cells in the utricle from aminoglycoside induced loss [54]. Geranylgeranylacetone, a drug that can induce induction of heat shock protein 70 (Hsp70) provided protection from noise-induced [55] loss of hair cells and hearing. Celastrol induced upregulation of HSPs was shown to protect

against aminoglycoside induced hair cell loss in the utricle via HSP32 induction [56,57] used transgenic mice that overexpress HSP70 to show protection from aminoglycoside (kanamycin) induced hair cell loss and hearing loss. Heat shock factor 1 (HSF1) is a major transcription factor for the HSPs, present in hair cells and stria vascularis in the rodent cochlea [58], and in mice in which HSf1 has been knocked out there is decreased protection from noise, with increased hearing loss and increased loss of hair cells [59,60].

Neurotrophic factors

Neurotrophic factors play an important role in the development of the cochlea, in regulating differentiation of sensory and neuronal elements, as well as in the formation of afferent and efferent connections (for review see references [61,62]). Many neurotrophic factors and/ or their receptors remain in the mature cochlea, including Glial Cell Derived Neurotrophic Factor (GDNF), Neurotrophin 3 (NT3), and Brain Derived Neurotrophic Factor (BDNF) (see [62,63], for reviews), where they play a role in cellular homeostasis. Neurotrophic factors can have a protective action against stress through a mitigating influence on ROS or intervention in the cascade of events induced by reactive oxygen species (ROS) formation. As a case in point, removal of neurotrophic factors leads to an increase in ROS and cell death through the apoptotic pathways discussed previously. While removal of neurotrophic factors is pro-apoptotic, neurotrophic factors themselves can induce pro-survival pathways and provide protection. Neurotrophic factors may reduce oxidative stress-driven increases in intracellular Ca^{2+} [64] through induced expression of calcium-binding proteins [65] or antioxidant enzymes [64].

Studies have shown that infusion of neurotrophins into the inner ear fluids prior to stress provides protection from hearing loss (for reviews, see references [49,66]). When levels of glial line-derived neurotrophic factor (GDNF) or neurotrophin 3 (NT3) are increased in the inner ear prior to noise overstimulation or the administration of ototoxic drugs there is significant protection, with decreased hearing loss and hair cell loss, [66–71]. This protection is less effective if the neurotrophic factors are provided after the stress rather than before, suggesting that they play a greater role in protection than in repair. BDNF and FGF were less effective in preventing hair cell loss [70,72].

HAIR CELL REGENERATION BY TRANSDIFFERENTIATION

Birds and other non-mammalian vertebrates can regenerate hair cells spontaneously [73,74]; using a mechanism of transdifferentiation, with or without a proliferative stage [75–78]. In contrast, once hair cells of the mammalian cochlea are lost, they will not regenerate spontaneously [79]. Placing new hair cells in ears with severe or complete hair cell loss has been a major goal of tissue-engineering efforts, because the only possible way to restore hearing via biological means is by replacing the missing hair cells. The main approaches for replacing hair cells are introduction of new cells from an exogenous source such as stem cells, or converting endogenous cells that have a non-sensory phenotype to become new hair cells. Methods for generating stem cells and guiding their differentiation to the hair cell phenotype have been recently reviewed [80,81], and the challenges for incorporating these cells into the target tissue (the deaf auditory epithelium) are now being addressed. The discussion of stem cell therapy for inner ear disease is found in a dedicated section of this chapter, below. This section reviews approaches for inducing transdifferentiation of existing (endogenous) cochlear cells to become new hair cells. This approach, once successful, may be applicable to deafness due to most causes, with the exception of hereditary deafness, because the impact of the mutation is not addressed by transdifferentiation therapy. Several extensive and recent reviews on hair cell replacement strategies are available [82–86].

Hair cells and supporting cells develop from common progenitor cells [87]. Their phenotype is determined by a set of genes expressed in a sequence and influencing neighboring cells in an

interactive way, with additional influence of microRNAs [88]. Some of the genes that signal for the differentiation of hair cells have been identified [87,89,90–94]. Knowledge of the developmental genes that regulate the proliferation and differentiation of hair cells during development is essential for designing hair cell regeneration strategies, because reactivation of these developmental signals is likely needed to induce a phenotypic change in the non-sensory cells. Technological means for manipulating gene expression in the mature ear are also necessary. Progress in these two fields, developmental biology and manipulation of gene expression, has allowed for important recent breakthroughs in the advance toward inducing cochlear hair cell regeneration.

The function of several gene families in hair cell development has been characterized by manipulating expression of these genes in mice. In general, these transgenic manipulations use several strategies for increasing or decreasing levels of gene expression, in fashions that can be temporally regulated and cell specific. The Cre-loxP technology has been especially useful for inducing conditional gene expression inhibition in a cell specific manner in the inner ear [95]. With the use of mouse transgenesis, it is possible to eliminate generation of hair cells [90,96] or to induce ectopic hair cell formation next to the organ of Corti [97,98].

One of the genes most commonly used for altering the number of hair cells in a cochlea is *Atoh1*. *Atoh1* is a gene encoding a transcription factor that is necessary and sufficient for hair cell differentiation in the developing epithelial ridges [90,96,99]. Since *Atoh1* is a master regulator gene for hair cell development, manipulating its expression levels has been used to generate new hair cells both in transgenic animals and by overexpression using other methods. Ectopic expression of *Atoh1* is able to induce the formation of clusters of hair cell and supporting cells outside the area of the organ of Corti in explants [90]. Similarly, ectopic hair cells could be found after virally mediated expression of *Atoh1* in non-sensory areas of the auditory epithelium in a mature guinea pig ear *in vivo* [100,101] and in culture [102]. Together, these studies have shown that the non-sensory cells retain the competence to respond to developmental genes and to convert to new hair cells after the onset of deafness, but the ability of the auditory epithelium to respond to overexpression of Atoh1 appears to diminish in mature animals and after the tissue is severely traumatized [103,104].

New hair cells induced by overexpression of *Atoh1* had the surface morphology of hair cells but their detailed morphology was immature [101,105]. Nevertheless, new hair cells that are generated by *Atoh1* overexpression appear to be electrophysiologically active, and several aspects of the maturation process recapitulate the normal development of hair cells [104,106]. These data are encouraging for our future ability to improve auditory thresholds in human ears treated with hair cell regeneration.

The transition from lab work to clinically feasible methods will depend on resolving several difficulties related to:

a) Gene delivery methods,

b) Limited response in mature animals and

c) Lack of response in ears with severe deafness.

The first challenge, gene delivery, has been partly met by the demonstration that adenovirus (or other) vectors that are inoculated into the scala media induce expression of transgenes in the supporting cells, as demonstrated in guinea pigs, rats and mice [107–109]. Still, this route of inoculation is not easily accomplished in the human ear. Designing treatment for ears that have been deaf for some time or suffered a severe trauma that leads to formation of a flat epithelium in place of the organ of Corti is a major challenge, because many of the ears presenting for therapy have some or many areas with a flat epithelium. While treatment with *Atoh1* alone induces no regeneration in the flat epithelium [103], it is possible that combining the transdifferentiation step with forced cell proliferation in the organ of Corti or its

vicinity will yield better morphological and physiological restoration of the tissue. Finally, to advance such therapies toward clinical applications, it will be necessary to test and optimize efficiency and safety, enhance the efficiency in ears that have been deafened for a long time, assess the physiological gains versus side effects (tinnitus, distortion) and design a way to introduce the transgene specifically to the target cells. It is also likely that non-viral methods for inducing gene expression in the cochlea will become available and feasible. Among these methods are nanoparticles that carry genetic material, and siRNA for blocking expression of specific genes at the RNA level [110–115].

Non-viral strategies for manipulating pathways that determine the phenotype of cells in the auditory epithelium have several advantages, especially reduced risk of side effects associated with viruses and increased ease of delivery. For instance, reagents that can mimic Atoh1 action and induce transdifferentiation may be attractive alternatives to viral vectors. Notch signaling molecules are excellent targets for manipulations via viral or non-viral reagents because of their developmental roles in generating the mosaic pattern of hair cells and supporting cells in the organ of Corti [116,117]. Manipulating their levels in developmental stages has resulted in addition of supernumerary hair cells [116,118–120]. Augmentation of the number of hair cells produced by Atoh1 was noted when Notch signaling was inhibited with DAPT 22573692. Blocking Notch signaling in mature animals was not as effective but the ability to induce formation of a small number of hair cells is nevertheless promising [121]. Once we unveil the changes that occur in supporting cells as they differentiate and mature, we could design measures to increase their responsiveness to transdifferentiation therapy. It is possible that combined influence of Notch inhibition and *Atoh1* overexpression will also yield regeneration of hair cells in mature and traumatized ears.

While the first and most basic goal may be generation of new inner hair cells that can depolarize the auditory nerve once an acoustic signal is detected, better hearing could be accomplished if some outer hair cells were also regenerated, and they could improve thresholds and tuning. It appears that the duration of *Atoh1* gene expression may determine whether a cell becomes inner or outer hair cell [122]. There may be cell-cell interactions as well as cell autonomous developmental choices that influence the responses of individual cells in the differentiating tissues, such that introducing *Atoh1* into the tissue may have an outcome beyond the proper cell that expresses the gene [104,123]. Other considerations include the route of gene transfer, choice of vector, limiting gene expression to the target cells and reducing side effects in the ear and elsewhere.

Because hair cell loss depletes the cell population in the organ of Corti, some of the genetic manipulations performed on mice were aimed at influencing proliferation in the cochlea. This is important because it may be possible for some of the new cells to become new hair cells without any further exogenous manipulations. In the normal mature ear, the $p27^{Kip1}$ gene is expressed in non-sensory cells and keeps them quiescent [124,125]. Mice with deficient expression of the $p27^{Kip1}$ gene exhibit an excessive number of hair cells in the organ of Corti. It appears that in the absence of cell cycle arrest, cells continue to proliferate after they normally would have stopped, had $p27^{Kip1}$ been active. Interestingly, mice with this induced mutation have a severe hearing loss, despite the large number of hair cells [125,126]. It is currently unclear whether the hearing deficiencies are due to dysfunction of the hair cells proper, or due to more general cochlear pathologies related to presence of ectopic hair cells. Inhibition of the cell cycle can also be removed by blocking expression of other genes, including Ink4d and Rb1 [127–129], leading to supernumerary hair cells and supporting cells in the tissue. The ability to use genetic manipulation for inducing proliferation in the organ of Corti is a considerable breakthrough that can be combined with transdifferentiation therapy and lead to feasible clinical applications.

The likelihood of treating an ear with severe to complete loss of hair cells and regenerating it to the state of a new, youthful and perfect ear is very low. Would incomplete/partial regeneration

be an acceptable and practical goal? It is likely that placing a population of new inner hair cells that is functional and innervated and large enough to provide useful auditory signals to the auditory nerve would be an outcome superior to that provided by prosthetic electrical stimulation. To reach this goal, it will be necessary to define and design regenerative therapy that is reliable, consistent, permanent and safe.

LOSS OF AUDITORY NERVE CONNECTIONS AND AUDITORY NERVE

The connection between inner hair cells and the auditory nerve is very sensitive to loss from the excitotoxicity generated by over-release of the inner hair cell transmitter, glutamate. This excitotoxicity can be induced by noise overstimulation or trauma to inner hair cells from hypoxia, changes in inner ear fluids or conditions that induce ROS in the hair cells. This can result in a 'bursting' and loss of the unmyelinated portion of the peripheral process of the auditory nerve, normally connecting to the inner hair cell. While there is potential for regrowth and reconnection [28] there is also potential for permanent loss leading to subsequent death of the auditory nerve somata (spiral ganglion neurons) and loss of the central nervous system connection in the cochlear nucleus. A typical inner hair cell may have connections to 10–30 auditory nerve peripheral processes (this varies depending on the position in the cochlear spiral and between species). Studies have shown that a mild to moderate level noise that produces only a temporary loss of hearing and no loss of sensory cells can still result in 20–30% of these connections being lost, reducing the dynamic range of auditory nerve responsiveness [130,131]. Drugs shown to reduce excitotoxicity in the cochlea [28] or in other regions could provide a means to reduce this loss.

When there is loss of inner hair cells, a series of pathophysiological changes follow, including scar formation, a loss of the peripheral processes of the auditory nerve, and, over time, a substantial loss of the auditory nerve itself. This loss of auditory nerve is related to the loss of survival/maintenance factors, including the deafferentation-associated loss of neural activity and the loss of neurotrophic factors that had been released by hair cells and other cochlear elements lost during the scar process. Loss of these survival/maintenance factors causes these auditory neurons to enter into the cell death cycle.

Cochlear prostheses depend on direct stimulation of the auditory nerve, so auditory nerve survival is of major importance. The auditory nerve loss can be blocked or reduced either by blocking the cell death pathway or by replacing the survival/maintenance factors. Thus, activity can be replaced by direct cochlear electrical stimulation E1 with a cochlear prosthesis, and auditory nerve survival is enhanced [132–137]. Stimulation may serve as a survival factor through activation of voltage-gated ion channels and/or through upregulation of autocrine factors, including neurotrophic factors. Neurotrophic factors can be infused into the cochlear fluids, to replace those that are lost and this is even more effective than electrical stimulation in enhancing auditory nerve survival following deafness [66,138–141]. The combination of electrical stimulation and application of neurotrophic factors is more effective than when either is applied singly [142,143].

There is also interest in inducing regrowth of peripheral processes of the auditory nerve. Cochlear prostheses might have reduced thresholds if their target is closer, making them more energy efficient and reducing battery requirements. If regrowth can be directed toward specific sites on the cochlear prostheses, this might also allow a greater number of channels to be used, resulting in more and better frequency separation. Studies have now shown that infusion of neurotrophic factors BDNF, NT-3, and FGF can induce regrowth of the peripheral process of the auditory nerve that regress following inner hair cell loss [52,144–146]. Thus, neurotrophic factors can serve not only to enhance survival of the auditory nerve but also to restore its peripheral processes, although different factors may be necessary for most effective treatment(s). Directed regrowth remains a challenge.

GENETIC DEAFNESS

One in 1,000 newborns suffers from hearing impairment. In developed countries, more than half of the afflicted babies are deaf for genetic reasons. Genetic inner ear impairments can be non-syndromic, affecting only hearing, or syndromic, with multiple defects occurring in several body systems. Many of the genes for deafness, as well as their products, have now been identified, with mutation of connexins being the most common cause of non-syndromic deafness in people. Many stereocilia-related mutations have also been found, including in several myosins and adhesion proteins [147]. Identification of the genes that are mutated in families with genetic inner ear impairments is important not only for diagnostic purposes, but also for the potential for prevention and cure. Probst et al. [148] demonstrated that in transgenic 'shaker-2' mice destined (genetically) to become deaf, insertion of the wild-type (correct) myosin MYO15 gene sequence into the fertilized egg corrected the genetic deficit, leading to normal inner ear structure and function in the adult mouse. This demonstrated that addition of the correct copy of the gene can rescue the inner ear from genetic deficits. Another approach is to silence genes when a genetic hearing disorder is a consequence of gain of function mutations and siRNA can be delivered to the cochlea to accomplish this function (see [149] for review). Mutation of a gap junction protein (GJB2) will result in deafness in humans and in mouse models, delivery of SiRNA to suppress expression of the mutated protein resulted in prevention of loss of hearing [150].

METHODS OF THERAPEUTIC INTERVENTION

With effective treatments for protection from acquired deafness and treatment following deafness identified, the next challenge is the methods for providing these interventions.

Cochlear prostheses

Auditory prostheses can provide direct stimulation of the auditory pathways for return of hearing following deafness. In severe and profound sensorineural hearing loss, the sensory cells of the cochlea are destroyed. Cochlear prostheses bypass the damaged receptor epithelium and electrically excite the auditory nerve fibers directly. The development of the cochlear prosthesis has been the success story of the field of neuroprotheses. It has provided a therapy for the profoundly deaf, where none previously existed. The first FDA-approved inner ear implants, approximately 30 years ago, were single-channel devices that provided crude input and were an aid to lip reading. Now multichannel devices, combined with many advances in signal-processing strategies, routinely provide intelligible speech perception with open set speech discrimination and even use of the telephone in the majority of implant recipients (e.g., references [151,152]). With the success of cochlear implant performance and the low risk associated with its placement, the age at which implantation is considered has decreased to where very young children receive implants and show benefit from early placements, taking advantage of critical periods for auditory system development. There is also increasing bilateral placement to allow binaural hearing, important for spatial localization [153,154,206]. Recently the candidate pool for cochlear implants has expanded to include people with remaining hearing. Shorter implants provide electrical stimulation in the basal cochlea and acoustic stimulation remains possible in the more apical cochlea. These 'hybrid electrodes' allow acoustic – electrical hearing with improved speech recognition, particularly in noise and subject also report better appreciation of sounds such as musical melodies [155].

Central auditory prostheses

Central auditory prostheses can be advantageous when the cochlea is not suitable for implantation, when there is insufficient auditory nerve survival, or when auditory nerve must be removed in patients with VIII nerve tumors (acoustic neuroma). While a peripheral cochlear implant allows for more 'normal' auditory pathway processing, the central implants can take

advantage of the tonotopic organization of auditory nuclei for frequency separation. Central auditory prostheses can also have reduced thresholds because of the close proximity to neurons as well and increased dynamic range. Cochlear nucleus implants have been successfully applied in many subjects, with excellent performance possible [156,157] in non-tumor patients however when there is a tumor (the most frequent need for central auditory prostheses) the complications of the tumor and its removal can compromise the long-term function of the cochlear nucleus implant (e.g., reference [158]). Auditory prostheses have also been applied in the inferior colliculus in both humans and in animal models [207] with animal models showing improved thresholds, increased dynamic range, and better frequency discrimination than cochlear implants [159].

Gene therapy

Gene therapy is used to manipulate levels of specific proteins in cells and tissues. It can also be used to inactivate specific proteins or to overexpress them. In most cases, this is accomplished either by introducing a foreign gene into the target cells or by using siRNA approaches. Viral vectors are the most efficient vehicles for gene transfer. Adenovirus, herpes simplex virus, adeno-associated virus, and lentivirus can mediate gene transfer into cells of the inner ear [82,160–165]. For example, mice lacking vesicular glutamate 3 (VGLUT3) are born deaf and adenoassociated virus mediated gene transfer of VGLUT3 into inner hair cells can partially restore normal cochlear morphology and hearing [166].

Gene transfer protocols can be used either for influencing the target cell proper, or to accomplish secretion of diffusible factors that act in a paracrine way. Example for the former is the overexpression of Atoh1 for inducing transdifferentiation of supporting cells to new hair cells. Examples for therapy with genes encoding secreted and diffusible proteins include neurotrophin therapy, used for protection of epithelial and neural elements in the cochlea [11,71,167,171].

One of the main goals of gene therapy is finding treatment for hereditary deafness. This would involve introducing the wild-type gene into the cells that are affected by the mutation, or using siRNA for treating dominant negative mutations. Use of siRNA has been used successfully in mouse models to silence dominant negative mutations (see [149] for review) and use of bovine adenoassociated virus restored *connexin26* gene expression and protein in cochlear organotypic cultures from mice with a dominant negative form of a Connexin26 mutation, providing proof of concept for *in vivo* application [172].

Biopolymers and scaffolding

Biopolymers can be synthesized that contain both the protein sequence for silk, to provide strength and flexibility, along with sequences of functional domains that naturally occur in the extracellular matrix protein to confer specific biological properties [173]. These can be 'spun' in microstructured thin films on the surface of prosthetic devices. Biopolymers can be produced that contain the sequence of fibronectin or laminin to provide a biological 'glue' (for neurons and epidermal cells, respectively), which can then be coated on implants. This can, in turn, be used to influence and stabilize the neuroprobe-tissue interface or to attach transformed cells for *ex vivo* gene transfer (see later). The biopolymer can also be used for timed release of specific factors. Thus a prosthesis could be providing electrical stimulation while releasing one or more chemical factors through microchannels (see later) and other factors through diffusion out of the biopolymer. Specific placement of biopolymer and microchannels can also provide different factors to different regions. A timed release can also be accomplished using nanoparticles that can be placed into the cochlear fluids (e.g., [208], [174]). These can be designed with different sizes, shapes and release properties and can also be designed to target specific cochlear elements. They can also be placed directly on prostheses.

Microcannulation — miniosmotic pumps

The fluid spaces of the cochlea provide for a closed environment well suited to receive local delivery of chemicals. Local delivery provides improved access and avoids the side effects that systemic delivery could entail. The model of miniosmotic pumps with cannula into the inner ear fluid of scala tympani or into the middle ear with access through the round window has been developed in animals models (e.g., [175]) and effectively utilized for local application of chemicals that provide protection from acquired deafness or enhanced survival of auditory nerve (see earlier sections). While devices for fluid delivery to the inner ear can be developed for human application [176–178], most recent efforts have focused on combining fluid delivery with cochlear prostheses (see later section).

Middle ear drug release

The middle ear more easily accessible than the inner ear fluids and drugs can be delivered into the middle ear through the tympanic membrane (ear drum). This can be for middle ear infections but can also cross the round window and diffuse into the cochlear fluids. Slow release formulations have been developed that can be placed close to round window for this purpose [179].

Combinations: prostheses with microchannels

Studies now show that combining electrical stimulation and chemical delivery is more effective in enhancing auditory nerve survival following deafness than either applied by itself [142,143]. Moreover, more patients with some residual hearing have been shown to benefit from cochlear implants and more patients with surviving hair cells are now considered candidates for cochlear implants. These subjects would benefit from protection of these remaining hair cells from the trauma of cochlear prosthesis insertion. There is also the potential of inducing regrowth of peripheral processes toward the stimulation sites, which could lower thresholds and enhance selectivity and separation. Therefore recent efforts have been made by cochlear implant manufacturers and research groups to develop cochlear prostheses capable of both electrical stimulation of the auditory nerve and delivery of pharmaceuticals into the cochlear fluids [180]. These have been successfully applied in animal studies [143], and clinical application is beginning.

Prostheses with biopolymers and *ex vivo* gene transfer

Another approach to delivery from prosthesis is to place cells capable of secreting the substance of interest directly onto the prosthesis, where they can deliver to cochlear fluids after placement into scala tympani. With *ex vivo* gene transfer, cultured cells are transformed to produce a specific gene product and placed into a specific area of the body for region-specific release. One problem has been that the transformed cells can migrate to a different region. With the use of biopolymers with fibronectin or laminin, transformed cells (e.g., fibroblast and fibronectin; Schwann cells and laminin) can be securely attached by the biopolymer to a neuroprobe or prosthesis, which is then inserted into the region of interest. The cells will then remain in place and have their highly localized action. One such study has recently shown the ability of BDNF, secreted by cells attached to the implant, to enhance survival of spiral ganglion neurons in a deafened guinea pig ear [169]. It may also be possible to place stem cells (discussed in more detail in the next section) on a prostheses, either to release drugs of interest or as new neurons close to the stimulation sites that can create a new connection either directly to the central auditory system or to remaining spiral ganglion neurons.

Stem cells

The use of stem cells, exogenous or endogenous, provides the potential to treat deafness by replacing lost hair cells or lost auditory nerve. Embryonic stem cells or stem cells derived from

bone marrow can be induced to reach a hair cell-like phenotype [181–184] or an auditory nerve-like phenotype [185] *in vitro*. In addition *in vivo* studies have shown that mouse embryonic stem cells can be placed into the cochlear fluids of scala tympani or directly into the auditory nerve, survive, differentiate into a neuronal phenotype [186–190], and can migrate into the remaining spiral ganglion cell population [191]. Stem cells that reach a neuronal phenotype will send processes that re-innervate hair cells [192,193] and have recently been shown to make connections in the cochlear nucleus and improve auditory brain stem responses [209]. Differentiation into an auditory nerve-like phenotype typical of SGN can be improved by genetically engineering the stem cells to produce factors that guide auditory nerve differentiation during normal development and/or by providing neurotrophic factors that influence development of the SGN phenotype [189]. Patch clamp physiological studies of these cells *in vitro* demonstrate depolarizations within only days with spiking and appropriate K^+ and Na^+ currents within five days [194].

Induced pluripotential stem cells (IPSCs) provide another option for generating sensory cell and/or auditory nerve replacement and recent studies have shown success in inducing IPSCs into generating sensory hair cell-like characteristics [81,195]. Finally, endogenous progenitor/stem cells have now been identified in the inner ear of both animals and human which may be induced to regenerate tissues of the inner ear. In animals endogenous pluripotential cells have been identified in regions of both the sensory cells and auditory nerve cell bodies in both the auditory and vestibular regions of the inner ear [196–201]. In human temporal bones, endogenous mitogen responsive cells have been identified in regions of auditory nerve cell bodies [197,202]. In animal and humans these cells demonstrate the properties of stem cells to form spheres and self-renewal [202,203]. In animal studies these cells have been demonstrated to give rise to hair cells, neurons and glia [204]. However, the ability of endogenous cells to form spheres and to spin off new stem cells decreases with postnatal age, particularly for cells from the organ of Corti [203]. Isolated adult human cells *in vitro* are induced to form spheres, proliferate, and differentiate into neuron-like phenotype by neuronal growth factors. This provides the potential that these cells can be cultured and placed into the cochlea to replace hair cells or auditory nerve, or perhaps they can be induced to differentiate *in vivo* to provide replacement. Indication that this later may be possible has recently been show by Watanabe [200], who demonstrated that in young adult mice, *in vivo*, exposure to damaging noise levels induced a proliferation of nestin expressing cells in the region of the organ of Corti. These new cells did not go on to become new mature hair cells; the challenge is to identify the factors that will drive that final step.

CONCLUSIONS

Major advances in our understanding of the molecular mechanisms underlying deafness and of the factors that influence and modulate its expression and progression have occurred since the mid-1990s. We can expect, as progress in these areas continues, that this knowledge will form the basis for *molecular otology*. Novel tissue-engineering-based therapeutic interventions may become a major part of the practice of otolaryngology in the twenty first century.

CHAPTER 66

Stem Cells in the Eye

Mike Boulton[1], Julie Albon[2] and Maria B. Grant[1]
[1] Department of Ophthalmology, Indiana University School of Medicine, Indianapolis, Indiana
[2] School of Optometry and Vision Sciences, Cardiff University, Cardiff, UK

INTRODUCTION

The eye is a complex organ consisting of epithelial, mesenchymal, connective and neural tissue. Vision is dependent on carefully regulated structural and functional integration of these tissues. Over the last two decades it has become increasingly apparent that there are a number of stem cell niches in ocular tissues which are important in maintenance and repair. This review will consider our current knowledge of ocular stem cells and reflect on their therapeutic potential in repairing damage to ocular tissue.

CORNEAL EPITHELIAL STEM CELLS

Limbal stem cells (LSCs) are crucial to corneal epithelial tissue repair and regeneration throughout the life of the adult cornea (see [1–3]). The ability of LSCs to self-renew and generate daughter cells, which undergo progressive differentiation until they are shed from the surface as terminally differentiated cells, supports the concept of 'stemness' in the cornea.

The corneal epithelium is the outermost layer of the cornea, whose functions include transparency, and protection from the external environment. The corneal epithelium is essential to the corneal functions of transparency, refraction and protection. It consists of a stratified multilayered (5–7 layer) epithelium, that is continually renewed from a population of relatively undifferentiated cells that reside in the basal cell layer of the corneal limbus. The limbus is defined as a narrow ring of tissue situated between the cornea and conjunctiva, terminating anteriorly at Bowman's membrane. The limbus, as is appropriate for all stem cell niches, offers both physical protection and nourishment to the stem cells that reside there. The deep undulations of the Palisades of Vogt ensure that the LSCs are hidden and protected from any hostile external environment, while the nearby limbal blood vessels provide nourishment. In addition, melanin in LSCs is thought to protect against ultraviolet light and reactive oxygen species. LSCs are slow-cycling cells that self-renew and produce transient amplifying cells (TACs). The TACs differentiate into postmitotic cells as they move centripetally toward the central cornea and upwards from the basal corneal epithelial cell layer, before being shed from the epithelial surface as terminally differentiated flattened superficial cells [4,5].

Interestingly, a recent study by Dua et al. [6] suggests that the limbal stem cell niche may extend beyond that originally thought. They termed this novel anatomical structure, which formed cords of ABCG2-positive epithelial cells, extending from the limbal palisades; *'the limbal epithelial crypt'*. Further studies are required to determine the 'stemness' of cells derived from this structure.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00066-5

The limbal stem cell niche

Evidence in support of the limbus as a niche for stem cells that renew the corneal epithelium has been described in several studies. The migration of limbal pigmented cells towards the central cornea in a wound healing response provided evidence for the existence of LSCs in the Palisades of Vogt [7]. The fact that cells, in the limbal niche, are slow-cycling [8], relatively undifferentiated cells [9,10], and when cultured *in vitro* have a higher proliferative potential than those of cultured central or peripheral corneal epithelial cells [11–13] provided further evidence. The distribution of LSCs does not appear to be uniform; the population of LSCs differs according to region, with the greatest number being in the superior and inferior cornea [14]. A single, unipotent LSC self-renews and produces a TAC. The TACs proliferate to produce more TACs dependent on requirement (e.g., proliferation will be increased during corneal regeneration following wounding). Each stem cell is capable of producing TACs throughout ones lifetime but it is likely that a proportion of LSCs remain in the resting state of Go for at least part of their lifetime [8,15,16]. Following wounding, LSC proliferation rate can be upregulated by as much as 8–9 fold [8,17,18] within 12 hours compared to a two-fold increase in TACs following central epithelial injury [8]. Epithelial cell proliferation rate is highest in the peripheral cornea in comparison to both central cornea and limbus [11,19]. The change in frequency and number of TAC divisions represents a shortening of cell cycle time triggered by cell injury and loss upon wounding [8,17].

As for other stem cell niches, the adjacent stromal environment plays a critical role in defining stem cell destiny. The precise molecular mechanism by which the stromal niche regulates limbal stem cell fate is unclear, although it is likely to be due to intricate interactions between the stem cell and its microenvironment [20,21], as well as short and long range signals.

Differential regulation of LSCs and TACs

The regulation of stem cell homeostasis typically involves various short and long range, internal and external factors. The environments that encompass LSCs and TACs differ in various ways, and are important in determining cell fate in each region [22,23]. Important definers include the differences that exist between the basal substrate that underlies these cells in the limbus and peripheral corneal peripheral cornea. Differences include distinct laminin isoforms, collagen IV α-chains [24,25] and the basement membrane-related AE27 BM antigen [26].

Cytokines are well known to modulate both corneal epithelial and stromal wound healing responses [27], through a number of mesenchymal-epithelial interactions [28–30]. It is almost certain that they play similar roles in the regulation of LSCs and TACs. Dependent upon the mesenchymal-epithelial interaction they are involved in, cytokines can be assigned to groups. Epithelial cells secrete Type I cytokines (transforming growth factor-β (TGFβ), Interleukin 1β (IL1β), Platelet-derived growth factor-BB (PDGF-BB)) to modulate fibroblasts, mediators of both epithelial and fibroblasts are Type II cytokines (Insulin-like growth factor 1 (IGF1), TGFβ1, TGFβ2, bFGF), and corneal epithelial cells produce Type III cytokines (keratinocyte growth factor (KGF), hepatocyte growth factor (HGF)). Interplay between epithelial cells and stromal fibroblasts in the cornea and limbus is likely to influence cell behavior and phenotype [28–32]. A good example is the presence of TGFβ 1, 2 and 3 and receptors in the limbal epithelium. TGFβ inhibits LSC proliferation [31] and may therefore serve to influence stem cell maintenance in the limbus. Stem cell regulation by many cytokines/growth factors has been reviewed and reported by various investigators [33–39]. In addition we have recently shown that Notch/Jagged/Delta interactions play a key role in TAC differentiation [40].

Evidence of corneal epithelial cell plasticity

The plasticity of adult corneal epithelial cells is implied by their ability to alter phenotype in response to signals from the embryonic dermis [41]. These findings suggest that corneal epithelial cells can be reprogrammed. The 'screw' model of stem cell behavior suggests that adult TACs, once differentiated, under certain signals, can be induced to revert to their original 'stemness' [42,43]. In the above study, adult corneal epithelial cells appear to have matured (after de-differentiation) into cells that express epidermal specific keratin 10. The corneal epithelial cells responded to signals and directions of their new environmental niche, such that their fate was redirected to allow participation in hair-follicle morphogenesis [41,44]. The mechanisms that control these processes are still to be determined.

The potential for epithelial cell differentiation into a neural cell phenotype has also been suggested. However, since the embryonic corneal epithelium is derived from the neural ectoderm, it is not surprising that a subset of epithelial cells express the neural marker, nestin [45] or that Notch 1 expression can be induced in cultured limbal epithelial cells [46].

The pursuit of a corneal stem cell marker

General stem cell characteristics that are exhibited by corneal LSCs define their stem cell status. The slow-cycling nature of LSCs was first recognized by the detection of label-retaining cells in the basal cell layer of the limbus [8]. The lack of differentiation of a subset of cells within the basal cell layer of corneal limbus adds to their potential for being stem cells. The relatively undifferentiated status of LSCs has been demonstrated by their lack of the epithelial differentiation markers, 64 kDa cytokeratin 3 (CK3), and the cornea-specific cytokeratin 12 [10, 47,48] in the limbal basal epithelium, compared to localization to all layers of the corneal and suprabasal cells of limbal epithelium. In addition, LSCs are small and round, and have features suggestive of a more primitive phenotype (reviewed by Schlotzer-Schrehardt and Kruse [49]).

The TACs are rapidly-cycling cells, with limited proliferative activity, which, like stem cells, can be upregulated in corneal wound healing. At the corneal margin, basal cells co-express vimentin and cytokeratin 19 [50], and as the TAC migrates across the limbo-corneal margin, the cells express differentiation features: cytokeratin 3 and 12 [9,23,47]. Lavker et al. [51] identified peak proliferative activity in this zone.

As with many tissues that are derived from stem cells, to date, a definitive marker which characterizes the limbal stem cell is yet to be identified. However, a number of negative differentiation markers and putative stem cell-specific markers have been investigated and are comprehensively reviewed by Wolosin et al. [52] and Schlotzer-Schrehardt and Kruse [49]. Table 66.1 demonstrates some of the markers described that may be used to discriminate basal limbal epithelial cells from basal corneal epithelial cells. Used, in combination, these markers have potential in limbal stem cell isolation and characterization of differentiation state.

A number of putative stem cell markers have been suggested, but most are not solely expressed in a subpopulation of cells in the basal cell layer of the limbus, or are highly expressed in

TABLE 66.1 Positive and negative markers of limbal basal epithelial cells

Negative markers of LSCs	Limbal basal cell markers
K12/K3	ABCG2
Connexin 43	K19
P-cadherin	Vimentin
Involucrin	Integrin α9
Integrins α2, α6, β4	KGF-R
nestin	metallothionein

the limbal basal epithelium (i.e., also positive for corneal basal cells). Alpha-enolase is present in basal cells of the embryonic cornea [18] and was observed in basal limbal epithelial cells [53,54]. However, its potential as a stem cell marker was low, as alpha-enolase is expressed in basal cells (non-stem cells) of several stratified epithelia and was also detected in basal cells of the peripheral cornea. Pellegrini et al. [55] indicated the transcription factor p63 as a potential keratinocyte stem cell marker. However p63 did not appear to be exclusive to stem cells, as low levels were occasionally observed in peripheral corneal basal cells. Also, p63 was identified at low levels in meroclones (young TACs) compared to holoclones (stem cells) [55].

Epithelial tissues are suggested to consist of around 0.4% adult stem cells. In the limbus, estimations for the stem cell population that maintains the corneal epithelium indicate less than 10% of the basal limbal epithelial cell population [51] or 100 cells in the rodent cornea. Like other stem cells, a subpopulation (known as side population cells) of limbal epithelial cells, approximately 0.4%, are able to efflux Hoescht 33342, a property attributable to the ATP-binding cassette transporter G2 [52,56–58]. Interestingly, de Paiva et al. [57] and Umemoto et al. [58] demonstrated conflicting results in the potential of side population cells to proliferate and form colonies *in vitro*. Umemoto et al. [58] reported that the discrepancy in findings was due to the non-colony forming side population cells being arrested in G0/G1, having no telomerase activity and thus representing a quiescent stem cell population in the basal cell layer of the limbus. A study of rabbit limbal epithelial side population (SP) cells concurred: the SP cells represented 0.73% of the population, were small, undifferentiated and non-cycling, and could be induced to enter the cell cycle upon wounding [59].

The potential for tissue engineering of LSCs in ocular surface disease

In corneal pathologies such as traumatic injuries (chemical and thermal burns), contact lens-induced keratopathy, Stevens Johnson syndrome and ocular pemphigoid [60,61], the absence or depletion of LSCs results in failure of corneal epithelial formation. Instead, persistent epithelial defects, neovascularization, scarring, ulceration, and in some instances corneal perforation, results. In such cases, corneal transplantation, which involves full-thickness transplant of a central corneal button (without inclusion of the limbal region), will not restore vision.

Several investigators have harnessed the proliferative potential of corneal and limbal epithelial cells for therapeutic purposes [13,37,62–64]. Limbal epithelial cells have a higher proliferative potential than cells in the peripheral and central cornea and clonogenicity studies have confirmed that holoclones (derived from stem cells) have the greater capacity for clonal expansion than meroclones and paraclones [13]. Clinically, cells derived from this region have led to successful limbal transplantation with the formation of a stratified corneal epithelium [63–65]. In the absence of the limbal epithelium, conjunctivalization of the cornea results in an abnormal corneal surface [66,67].

Initially, autologous conjunctival transplantation was performed to treat limbal deficiency-related ocular surface disease [68–70]. However, since the discovery that 'conjunctival transdifferentiation' does not occur [67,71,72], other methods were investigated. Keratoepithelioplasty describes the transplant of lenticules of peripheral cornea [5], and in 1989 the first human conjunctival limbal autograft was performed [73]. Kinoshita et al. [74] then introduced the concept of transplantation of LSCs in rabbits. Human limbal stem cell autografts utilise the limbal cells of the healthy contralateral eye, whereas bilateral disorders necessitate stem cell allografts isolated from living tissue-matched eyes or non-matched cadaver eyes.

Next, the field progressed to *ex vivo* expansion of LSCs. This concept minimized the risk of limbal stem cell deficiency in the donor eye [74], since only a small biopsy was required and allograft rejection was reduced due to the elimination of Langerhan cells during culture [75]. Pellegrini et al. [62] reported the first successful autologous graft for unilateral severe

ocular surface disease, using cultivated corneal epithelial stem cells. A number of substrates for the culture of epithelial stem cells have been introduced, including fibrin, amniotic membrane and thermo-responsive plastic. The later allows cultivated epithelial cells to be released on change of temperature so that only the epithelial sheets are transplanted [76]. The fibrin gel, used by Rama et al. [77] as a carrier, is degraded following transplant, whereas the amniotic membrane appears to persist following transplantation [78].

Preserved amniotic membrane has been used for several years, in combination with limbal transplantation to promote ocular surface reconstruction in patients suffering from severe ocular surface disease. The benefits of transplanting amniotic membrane in transplantation include: provision of growth factors important in re-epithelialization, anti-inflammatory effects, inhibition of conjunctival fibrosis [79] and anti-bacterial properties. It is also postulated that the amniotic membrane (AM) provides the LSCs with a new niche [80]. A number of studies have evaluated the use of intact AM versus denuded AM (epithelial cell removed) as a substrate for limbal stem cell culture [8–83]. Limbal epithelial cells have been shown to demonstrate stem-like properties when cultured on intact AM, including slow-cycling and lack of expression of the differentiation markers CK3, CK12 and connexin 43. However, cultivation on a denuded AM showed increased limbal epithelial cell migration and produced a better stratified epithelium [83]. If denuded AM is used to cultivate epithelial cells, growth arrested 3T3 feeder layers are required to synthesize the growth factors that were previously produced by AM epithelial cells.

Bio-engineered epithelial tissue equivalents have been derived from both limbal explants and cell suspensions isolated from limbal epithelium [83]. Both techniques generate epithelial cell sheets that express CK3 and CK12, although more evident in superficial cells of the cell suspension-derived sheets. The latter also resulted in the formation of a greater number of desmosomes, smaller basal intercellular spaces and secure attachment via hemidesmosomes to the underlying basement membrane. The use of the air-interface method of culture, whereby the level of media is reduced to below the epithelial cell surface ensures that a well differentiated, stratified epithelial tissue is available for transplantation.

Ex vivo expanded cells have been used, in both allograft and autografts, to promote repopulation of the recipient cornea by donor-derived cells to facilitate restoration of epithelial integrity and vision [63,64,81,82,84,85]. In the case of allografts, immunosuppression is required to prevent epithelial rejection.

Donor epithelial cells have been identified in the recipient bed for up to 30 months after limbal allograft transplantation [86], but the long-term duration of donor-derived epithelial stem cell viability remains uncertain [86–88]. Although successful long-term clinical outcome has been described in limbal allografts, donor epithelial cell survival could not be detected [89]. Whether donor limbal stem cell survival is sustained or activation of resident recipient stem cells occurs on re-establishment of niche signals has yet to be confirmed.

Tissue-engineered stem cells from other tissues as an alternative to limbal epithelial cells

ORAL MUCOSA

Nakamura et al. [90] pioneered the idea of using *ex vivo* expanded oral mucosal cells in autologous grafts to reconstruct the corneal epithelium of a rabbit. As with limbal epithelial cells cultured *ex vivo*, oral epithelial cells were enzymatically isolated from oral mucosal biopsies and cultured on denuded AM using the air-lift culture system. The epithelial tissue equivalent, which was generated after 2–3 weeks culture, showed cornea-like properties with expression of CK3 (but not CK12), and the formation of a 5–6 layered stratified epithelium with desmosomes, hemi-desmosomes and tight junctions. Subsequently, the feasibility of using oral mucosa to treat corneal epithelial pathology in humans has been confirmed [91–93].

BONE MARROW STEM CELLS (BMSCS)

Bone marrow-derived CD34+ progenitor cells have been identified in the cornea, particularly in the stroma [94]. This suggests that BMSCs may play a role in stromal maintenance and repair. Transplantation of bone-marrow-derived human mesenchymal stem cells (cultivated on human amniotic membrane) onto the ocular surface of a chemically damaged rat cornea demonstrated a novel idea for therapeutic reconstruction of the ocular surface. However, it appeared that the mesenchymal stem cells did not differentiate into corneal epithelial cells, but served to suppress inflammation and angiogenesis [95].

The bioengineered cornea

The idea of a bioengineered cornea has arisen with corneal equivalents being reconstructed from corneal cell lines. Griffith et al. [96] reconstructed a human cornea from immortalized cells. The resultant corneal equivalent behaved similarly to a normal cornea with respect to morphology, transparency, ion and fluid transport, and gene expression. However, bioengineering for the production of a replacement implant for wounded or diseased human corneas is still at the investigatory stage and requires further development in order to produce a bioimplant with the same tensile strength and durability as a normal cornea. Perhaps using LSCs, hematopoietic stem cells (HSCs) or combinations thereof in the future will overcome some of these problems and obviate the need for immortalized cells lines. The ideal artificial implant is likely to be a composite of biomaterials and cells, to provide a transparent, flexible, but strong biocompatible implant, which can withstand surgical procedures, as well as normal day to day mechanical stresses. To this purpose the chemically cross linked collagen-glycosaminoglycan biomatrix [97] and naturally occurring biomaterials (e.g., coral or sponges) have been suggested.

Stem cells in the corneal endothelium and conjunctival epithelium

While the first part of this chapter has concentrated on LSCs, there is evidence for other stem cell populations in the anterior segment of the eye. The conjunctival epithelium, like the corneal epithelium, undergoes constant renewal. The source of the population of stem cells is controversial, with different reports localizing stem cells to the fornix, palpebral and mucocutaneous zones. Evidence demonstrating slow-cycling cells with higher proliferative capacity in these regions [72,98,99], together with clinical observations, supports this concept. Unlike the stem cells of the corneal epithelium, conjunctival stem cells are not unipotent, as they differentiate into either a mucin secreting goblet cell or epithelial cell. Wolosin et al. [52] suggest that the different epithelial phenotypes of the conjunctiva and cornea are under the control of genes present in only one of the two epithelia. In addition, Whikehart et al. [100] proposed the existence of a stem cell niche in the posterior limbus between the endothelium and trabecular meshwork that supplies both trabecular meshwork and corneal endothelium. Furthermore, Kawasaki et al. [101] have described clusters of corneal epithelial cells residing ectopically in human conjunctival epithelium.

RETINAL PROGENITOR CELLS

It has been extensively reported that stem cells exist in the retina of fish and amphibians and that these cells add to the retina throughout their lifetime [102]. Furthermore, these cells, which are located to the ciliary-retinal interface, are also able to regenerate a complete retina, including retinal pigment epithelium (RPE), under appropriate experimental conditions [103]. By contrast, the neural retina and RPE in mammals are largely developed by the early postnatal period and show no evidence of the adult regeneration observed in fish and amphibians [102,104].

Surprisingly, retinal progenitor cells were not identified in mammals such as mouse, rat, cow and human until 2000 [105,106]. These retinal progenitor cells which are located at the

ciliary marginal zone represent only about 0.2% of pigmented cells in the ciliary margin. These progenitors display many of the properties associated with stem cells;

1) They are multipotent,
2) They can self-renew,
3) They are proliferative and express the neuroectodermal marker nestin.

Other potential markers can include CD133, CD15, Notch, Numb and FGFR4 (see Young, 2005 [107]). These retinal progenitor cells can clonally proliferate *in vitro* to form spherical colonies of cells that exhibit differentiation markers for a variety of cell types including photoreceptors, intermediate neurons and Muller glia [105,108]. Thus it would appear that these progenitors have the potential, given the right environment, to be engineered into the morphological and functional layers associated with the retina.

The inability of these ciliary margin progenitor cells to renew retinal cells in the postnatal period in mammals indicates that the progenitor cells find themselves in an inhibitory environment. Little is known about what regulates retinal progenitor cells, but transcription factors such as Pax6, Six3, Rx1, Chx10 and Hes1 [105,109] are strongly implicated, as well as the cyclin-dependent kinase inhibitor protein, $p27^{Kip1}$ [110]. Growth factors such as FGF2, EGF and IGF-I have all been reported to regulate proliferation but their precise role remains equivocal [104–106,110]. Furthermore, it appears from studies in the chick that Muller glia have the potential to become neurogenic retinal progenitor cells [92]. Furthermore, Muller glia cells appear to play an important role in the generation of multipotent precursor cells from embryonic retinal cells [108].

The identification of adult retinal progenitor cells opens the possibility that these cells can, given the appropriate cues, be engineered for transplantation in retinal degenerations such as retinitis pigmentosa and age-related macular degeneration [111]. Due to the limited number of retinal progenitor cells and the difficulty in isolating them, investigators have concentrated on investigating the incorporation and differentiation in the retina of transplanted brain-derived neural progenitor cells [112–114], embryonic retinal progenitor cells [115], bone marrow-derived stem cells [116] and embryonic stem cells from the inner mass of the mouse blastocyst [117]. While these studies, largely carried out in rodents, provide proof of principle for stem cell transplantation, differentiation and integration in the host retina, they do emphasize that the correct inductive cues are essential for a successful outcome. Studies in the pig have shown that retinal progenitor cell xenografts to the pig retina can result in integration and differentiation [118]. Furthermore, recent research has shown that retinal progenitor cells can be isolated and greatly expanded *ex vivo*. When grafted into the degenerating retina of dystrophic mice, a subset of retinal stem cells developed into mature neurons, including cells expressing photoreceptor markers [107,119]. Not only was rescue of photoreceptors observed but there was also integration of donor cells and animals showed improved light responsiveness. Despite these successes cell delivery, survival of transplanted cells and regulated differentiation of grafted cells need to be optimized if we are to regenerate a fully functional adult retina.

BONE MARROW STEM CELLS

Although not resident in the eye it appears that bone marrow stem cells (BMSCs) play an important role in retinal homeostasis and repair. Adult BMSCs are mostly quiescent cells that comprise ~0.05–0.1% of the bone marrow [120–122]. Adult HSC expand and differentiate exclusively in the bone marrow, from which they can be mobilized into the bloodstream. At the same time, BMSCs may divide to yield undifferentiated progeny with identical BMSC characteristics, fulfilling the two criteria for a stem cell: self-renewal and the ability to give rise to differentiated progeny. Cell-cell and cell-matrix interactions are crucial to the proliferation and differentiation of HSCs in the bone marrow niche. Depending on the circumstances,

HSCs can travel from the marrow into the circulation in large numbers, a process termed mobilization [123]. However, Kucia and Ratajczak [124] propose that in addition to BMSCs, the bone marrow also harbors versatile subpopulations of tissue-committed stem cells (TCSCs) and perhaps even more primitive pluripotent stem cells. Exogenous administration of granulocyte colony stimulating factor (G-CSF) is the standard method of inducing stem and p 123 cells. The chemokines interleukin 8 (IL-8) [125] and stromal-derived factor 1 (SDF-1) [126] both participate in G-CSF-mediated stem cell mobilization. SDF-1, as well as VEGF and PlGF (vascular endothelial growth factor and placental growth factor, respectively), induce osteoclasts to secrete the metalloprotease MMP-9, whose action results in the shedding of the membrane-bound cytokine stem cell factor (SCF) from the bone marrow, releasing it into the circulation.

Upon activation, BMSCs proliferate and differentiate into progenitor cells which can be found in the peripheral blood [127]. These progenitor cells may then differentiate further as required. BMSCs have been reported to have the potential to differentiate into a variety of other tissues, including liver [128], muscle [129] and neuronal cells [130–132], thus demonstrating a role for stem cell plasticity in tissue maintenance and repair. Recent studies support the possibility that BMSCs may also have broad potential to differentiate into various ocular cell types [133,134]. Lethally irradiated mice were reconstituted with HSCs from mice homozygous for green fluorescent protein (GFP+) and subjected to laser-induced Bruchs membrane rupture. GFP+ retinal pigment epithelial cells, astrocytes, macrophages/microglia, pericytes and vascular endothelial cells were observed in or adjacent to the wound site, confirming that HSCs have the capacity to differentiate into cells expressing different ocular phenotypes.

Postnatal neovascularization has previously been considered synonymous with proliferation and migration of pre-existing endothelial cells resident within parent vessels, i.e., angiogenesis [135]. However, Asahara et al. [136] identified cells derived from bone marrow that were capable of differentiating into neovasculature as $CD34^+$ expressing cells. Thus, these cells presumably are key mediators of endothelial repair. We and others have demonstrated that HSCs provide functional hemangioblast activity during retinal and choroidal neovascularization [137–141] and that HSCs give rise to a variety of lineages including the $CD34^+$ endothelial progenitor cells (EPCs). This mechanism of endothelial repair represents a significant source of cells for neoangiogenic vessels. Defects in EPC function appear to be responsible for the development and persistence of acellular capillaries in diabetic retinopathy, since lack of repair of acellular capillaries contributes to the development of retinal ischemia and represents an irreversible step in the progression of this disease [142,143]. EPCs isolated from patients with Type 1 diabetes have a decreased rate of migration and incubation with a nitric oxide (NO) donor alters the EPC cytoskeleton, normalizing their rate of migration. EPC migration can be stimulated by activation of growth factor receptors [120,144–148] such as vascular endothelial growth factor 1 and 2 (VEGFR1 and VEGFR2) and cytokine receptors such as CXCR4 (receptor for SDF-1 [147,149–151]. Inhibiting SDF-1 has been shown to reduce the degree of stem cell involvement in induced neovascularization [152]. It also appears that autologous bone marrow-derived lineage negative HSCs containing endothelial progenitors stabilizes and rescues retinal blood vessels in two mouse models of retinal degeneration [153]. Interestingly, this regeneration of retinal vessels was accompanied by neurotrophic rescue of the retina and preservation of cone vision.

THE POTENTIAL FOR STEM CELLS IN OCULAR REPAIR AND TISSUE ENGINEERING

The realization of the existence of undifferentiated cells, which self-renew and show plasticity, in adult tissues offers great potential in the treatment of both ocular and non-ocular diseases. It is now becoming evident that both intraocular and extraocular stem cells have the ability to play a critical role in the maintenance of ocular tissues. Furthermore, the plasticity

of these cells means that they can be engineered to repair injured or diseased ocular tissues. Corneal LSCs are now routinely used in the restoration of the injured ocular surface and BMSCs hold great promise in the repair of retinal damage.

Ocular stem cells are an ideal starting point for tissue engineering of ocular tissues and offer a means of therapeutic intervention in a variety of pathologies involving cell/tissue loss (e.g., age-related macular degeneration, retinitis pigmentosa, glaucoma and diabetic retinopathy). The future will tell if these stem cells can be used to deliver normal genes to correct genetic abnormalities in specific ocular tissues.

CHAPTER 67

Corneal Replacement Tissue

Kathryn L. McCabe and Robert Lanza
Advanced Cell Technology Inc., Marlborough, Massachusetts

INTRODUCTION

It is estimated that over 10 million people globally were visually impaired or blind due to the lack of available treatment for corneal diseases or corneal injury in 2010 [1]. Over 90% of all untreated eye diseases are found in developing countries. The gold standard of treatment for many corneal diseases is transplantation of either a partial or full thickness donated cornea. Treatment for corneal diseases in countries with well established health care systems is routine. However, the need for donated corneas outpaces the supply, and the need is likely to increase as the population ages.

Obtaining high quality donor corneas in countries such as the United States relies on an extremely well run eye banking system that is not universally available. Adding to the cost and constraints of donor cornea transplantation is the need for extensive and expensive toxicological testing that is necessary to prevent the spread of pathogens. This is further compounded by the problem of donor quality, which decreases as the donor population ages due to the decline in corneal endothelium function. Ironically, treatments such as Laser-Assisted in situ Keratomileusis (LASIK), used to surgically improve vision by altering the shape of the cornea, currently make the cornea ineligible for donation. Lastly, religious and cultural factors limit the scope of organ donation and therefore the availability of donor corneas available for transplantation. In an effort to overcome this shortage of donated tissue, researchers and clinicians are using stem cells and tissue-engineering methods to manufacture corneal layers or even completely bioengineered corneas.

CORNEA: OVERALL STRUCTURE

Why is the cornea so critical for vision? The cornea protects the entire eye from the harsh external environment and acts as the first 'lens' of the eye. The cornea and tear film provide over 80% of the focusing power to the retina, with the lens providing the remainder [2]. Light bends or refracts as it enters the tear film and cornea. The light is then refocused by the lens onto the retina. The retina converts the light rays into nerve impulses which are then transmitted to the brain in the process of visual transduction. To understand how the cornea provides these important functions for vision, it is necessary to first explore the structure of the cornea.

The cornea is a dome shaped structure at the front of the eye that appears to be relatively simple when initially examined (Fig 67.1a). However, closer inspection reveals a complex structure that consists of three cell layers and two membranes that are optically transparent (Fig. 67.1b). The first outermost cell layer is the epithelium, the middle is the stromal layer,

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00067-7

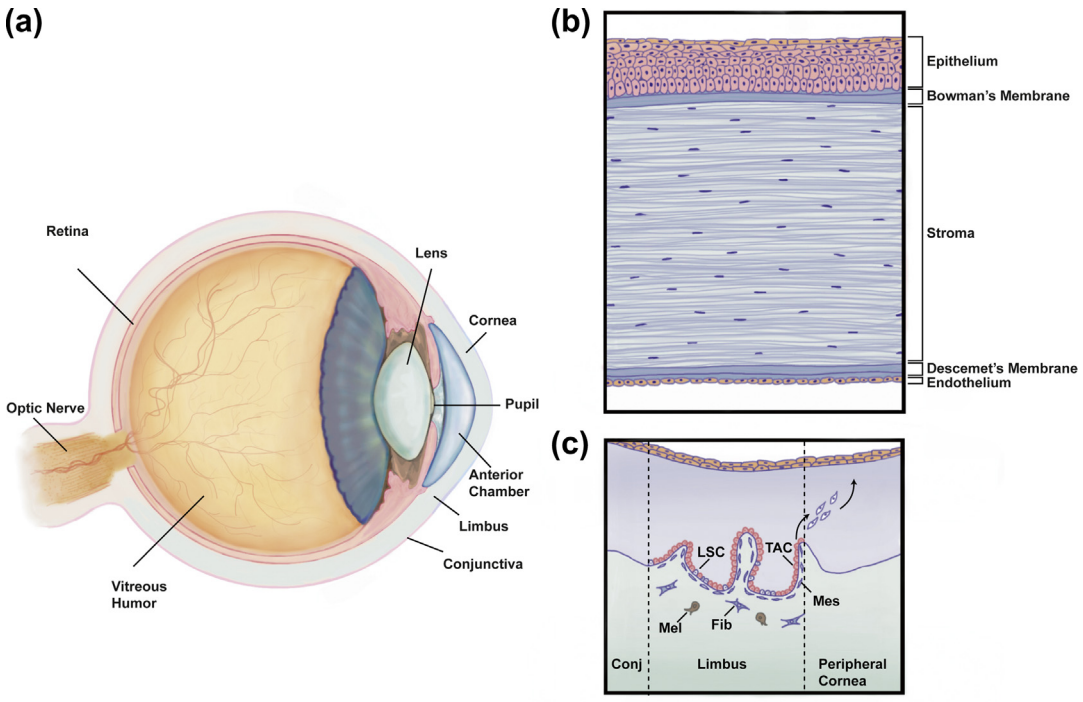

FIGURE 67.1

The anatomy of the eye, cornea, and limbus. a) The cornea forms a clear, dome structure at the front of eye necessary for protection and refraction of light. b) The cornea is an optically transparent multilayered structure consisting of three cell layers and two membranes. The outermost cell layer is the epithelium, Bowman's membrane is in between the epithelium and the stroma, followed by the thickest layer, the stroma. Descemet's membrane lies between the stroma and the innermost cell layer of the cornea, the endothelium. c) The limbus is the niche where the limbal stem cells reside, which is responsible for replenishing the epithelium. The limbus is at the junction of the conjunctiva and the peripheral cornea. Limbal stem cells undergo asymmetric division to produce the transient amplifying cells (TACs) that have a high proliferative capacity. TACs migrate from the limbus to the peripheral cornea to reside in the epithelial cell layer. The progeny of the TACs go onto make the cell types of the epithelium, which are sloughed off and replaced. Conj=conjunctiva; Fib=fibroblast; LSC= limbal stem cell; Mel=melanocyte; Mes=mesenchymal cell; TAC= transient amplifying cell.

and the deepest is the endothelium. The epithelial and stromal layers are separated by Bowman's layer, a collagen-containing membrane. Similarly, Descemet's membrane can be found separating the stroma layer from the endothelium. These three cell layers and Bowman's and Descemet's membranes, along with sensory innervation, are the first and critical interface of the process of visual transduction and also protects the eye from environmental insult and injury.

EPITHELIUM: PROTECTS EYE FROM NOXIOUS STIMULI AND THE ENVIRONMENT

The epithelium consists of a superficially multilayered structure of 5–6 layers of cells that are replenished on an approximately weekly basis. The corneal epithelium has many characteristics that differentiate it from other types of squamous epithelium. The corneal epithelium is a smooth, wet, apical surface that is regular in thickness and must be transparent to be functional. It is highly innervated to sense and prevent damage to the cornea or other eye structures, yet needs to perform routine functions common to other epithelia, such as be resistant to abrasion, prevent fluid loss and restrict pathogen access, as well as respond rapidly to wounding. Structurally the outer layer contains 3–4 cells layers of flattened squamous cells, 1–3 layers of mid-epithelial cells such as wing cells, and a single layer of columnar basal

cells. The basal cells are anchored by a complex system of collagen links to the basement membrane and the underlying stroma [3]. The corneal epithelial cells are replenished by the limbal epithelium stem cells. The corneal epithelium thus provides challenges to the tissue engineer who must replicate a complex biological structure, addressing the need for continuous replacement of the epithelial cells due to wear and tear, and maintaining integrity as a barrier, and being optically transparent.

STROMA: PROVIDES STRENGTH AND TRANSPARENCY

The stroma makes up about 90% of the thickness of the cornea and is relatively acellular, with only 3–10% of the volume consisting of stromal keratocytes. Structurally, the stroma is comprised of tightly packed parallel collagen fibrils that have a small, uniform diameter. Other extracellular matrix components can be found in the stroma such as glycosaminoglycans and fibronectin. There is a global as well as a local organization of the fibrils that are regular in size and shape and aligned within individual lamella. Scarring of the stroma is common after injury because of the disruption of the orderliness of the collagen as well as the transformation of distal keratocytes that can become motile and mitotically active fibroblasts [4]. Optical transparency is lower when the local organization of collagen fibrils is disturbed, and can result in loss of vision. The stroma provides the tissue engineer two major challenges that can at times be mutually exclusive: high tensile strength with optical clarity.

ENDOTHELIUM: MAINTAINS PROPER DEHYDRATION AND NUTRITION

The endothelium is the thinnest of all the corneal layers, but is critical for the function of the cornea. The relative dehydration of the cornea is necessary to maintain optical clarity. The endothelium is thought of as a 'leaky' pump, where some substrates are allowed to leak from the stroma due to the swelling pressure while others are actively pumped out to keep the cornea relatively dehydrated. The pumping function of the endothelium has several requirements including $Na^{+}K^{+}$ ATPase, $HCO3^{-}$, Cl^{-}, and carbonic anhydrase activity. The majority of the nutrients of the cornea are supplied by the corneal endothelium, but the aqueous humor and tear film also provide nutrition to the cornea. Glucose transporters in the endothelium selectively allow nutrients from the aqueous chamber to feed the stromal keratocytes and the epithelial cells. The pumping functions are very metabolically taxing, thus the endothelium has a high concentration of mitochondria to power these functions. The density of the mitochondria should cause opacity, however, the endothelial cells are very thin, such that the optical path length is short, so little light is scattered as it passes through the endothelium [5].

APPROACHES TO ENGINEERING CORNEA

The cornea is an incredibly well-engineered structure that has both high refractive power and high tensile strength all while being optically transparent. Its two major functions, light refraction and protection of the eye, are difficult to achieve simultaneously from engineered sources. Therefore, researchers have recently taken two main approaches that utilize tissue engineering (Fig. 67.2). The first is to use tissue culture to expand or create the desired cell population, and the second is to provide a support structure for the cornea to repopulate with native cells. The first approach of tissue culture can use cornea cells grown in a sheet and then transplanted as a sheet. Alternatively the cells can be dissociated and injected into the anterior chamber or desired cornea layer (Fig. 67.2a). The second main approach provides a biomimetic or a biosynthetic device that allows the native cornea cells to slowly stimulate endogenous corneal regeneration (Fig. 67.2b). These types of devices should not be confused with the fully artificial corneas or keratoprostheses, such as the Boston keratoprosthesis. Keratoprostheses are used in restricted cases such as where human donor tissue has failed

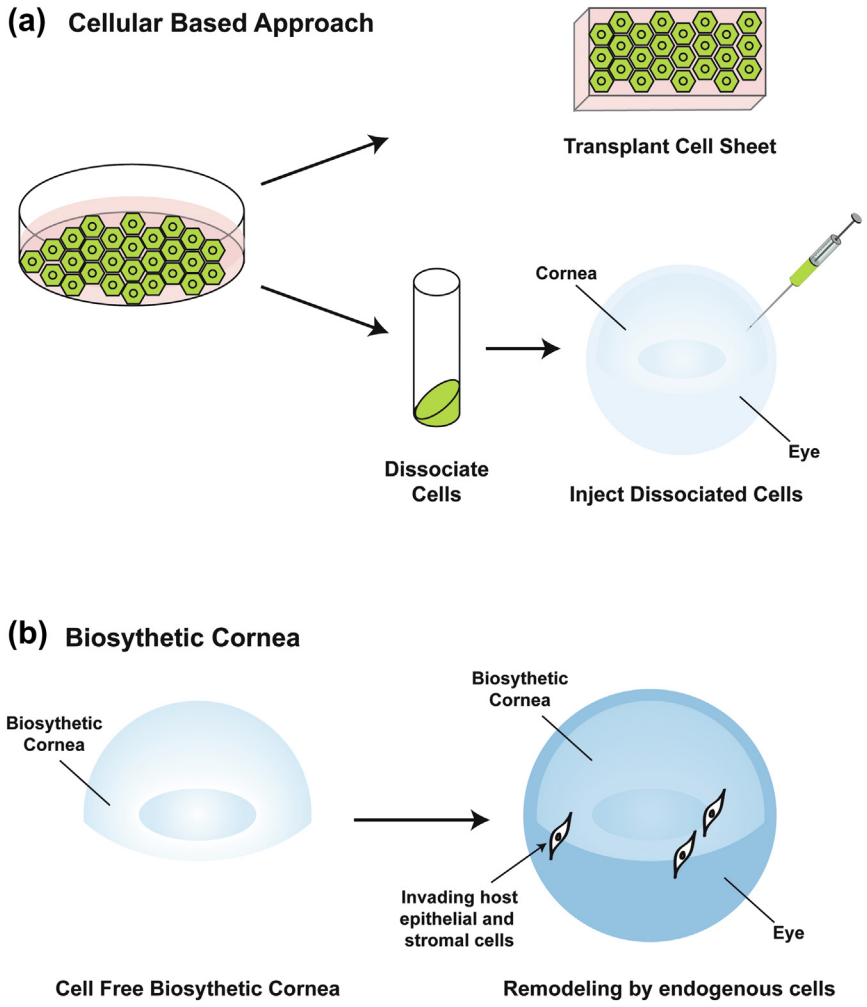

FIGURE 67.2
Two major approaches to utilize tissue engineering for corneal replacement. a) The cellular based approach employs cell culture to expand and then differentiate adult or embryonic stem cells into the desired population of corneal cells. Cells can then be transplanted as a sheet or injected into the cornea as dissociated cells. b) The biosynthetic cornea is a cell free construct that allows for slow regeneration of the epithelial and stroma layers from the patient's own cornea. The endogenous cells invade the biosynthetic cornea and remodel the matrix to make it a hospitable environment for the host cells.

repeatedly or the cornea can no longer be supported by the pathological eye. Keratoprostheses can be valuable tools for improving vision, but the high complication risks make them unsuitable for the majority of indications and will not be discussed further in this chapter [6]. Each of these approaches may prove useful in different cornea disease indications [7]. Additionally, the combination of cell culture derived cells with a biosynthetic device may one day result in a completely bioengineered cornea.

CURRENT PROGRESS: EPITHELIUM

Of all the cornea layers, the most progress has been made with the corneal epithelium. Work done by Pellegrini and colleagues [8] first demonstrated the power of tapping into the natural abilities of adult stem cells residing in the eye for treatment of limbal stem cell disease. Under normal conditions, the outer layer of the cornea, the corneal epithelium, is continuously replaced as cells are shed. Although there is some controversy regarding whether there is a single (limbus) or multiple locations (limbus and central cornea) of the corneal epithelial stem cells [9–11]. The consensus is that the majority of the stem cells required for regeneration of the epithelium reside in the limbus [12]. These are referred to as limbal stem cells (Fig. 67.1c). The limbal stem cells can replicate themselves as well as provide the highly proliferative but restricted potential transient amplifying cells. The transient amplifying cells in turn give rise to the basal cells. The basal cells will then mature to become the wing cells and eventually the outermost epithelial layers, which are shed as needed. If the limbus is

affected by disease or injury, the limbal stem cells are lost or depleted, making the normal regeneration of the corneal epithelium impossible. In limbal stem cell disease, transplantation of a cornea is not indicated since the improvement will only be temporary. Without resident limbal stem cells, recovery of the epithelium will only be transient, since the epithelial cells are normally continually replaced, and the transient amplifying cells have a limited capacity to do so, and the transient amplifying cells need to be replaced. Once the existing proliferative potential of the existing transient amplifying cells are depleted, the epithelium will be lost, which results in a recurrence of vision loss and pain.

Pelligrini and colleagues set out to test in human if their methods of expanding limbal stem cells *in vitro* could be utilized in the treatment of limbal stem cell diseases. Expansion of an adult stem cell population can be difficult, such that progenitor cells are amplified but the stem cells either make a very small percentage of total cells, or are lost entirely. Therefore it is critical to be able to identify the percentage of stem cells in the *in vitro* expanded culture. Like other adult stem cell populations, the identification of limbal stem cells by molecular markers remains elusive and inexact. Limbal stem cells are typically identified by the expression of positive stem cell markers such as ABCG2, negative for a cell differentiation markers like Cytokeratin 3, small cell size, and a high nuclear to cytoplasm ratio. Although there were several other groups that have utilized similar techniques in a clinical setting [13], the use of high expression of ΔNp63α as an important quality control measure has allowed for greater success in the clinic [14]. Not surprisingly, the higher the percentage of true limbal stem cells as opposed to progenitors in the expanded cultures resulted in a higher success rate. Additionally, strict patient inclusion was also a reason for increased success, since a hostile microenvironment is not conducive to successful transplantation [15]. Currently, there are several clinical trials using limbal stem cells worldwide, with anticipation of this technique being tested in the United States in the next few years pending regulatory review.

Other cell sources for corneal epithelium

There are many cases where using an *in vitro* expansion of an autologous graft is not indicated such as bilateral limbal stem cell deficiency, bilateral chemical scarring of the limbus, or where the risk of damaging the contra-lateral eye during the harvest is too high. Other research groups have explored alternative sources to limbal stem cells including cells derived from patient derived oral mucosal cells [16,17] and limbal stem cells derived from embryonic stem cells [18–20]. In particular, clinical trials using oral mucosal cells have been completed, with ongoing improvements resulting in enhanced patient outcomes [21]. However long-term studies will be necessary to judge the efficacy of these types of techniques in replacing endogenous limbal stem cells.

CURRENT PROGRESS: STROMA

The stroma makes up about 90% of the thickness of the cornea and is mostly acellular. From an engineering prospective, it is a highly organized transparent collagenous-based scaffold with cells scattered throughout. The stromal keratocytes are required to maintain the structure by providing the appropriate replacement proteins and enzymes. From a clinician's view, it is a tissue that responds to injury by usually scarring. Although stromal injury can heal without scarring, it is not uncommon for the resolution of a scar occurs over a long period of 1–3 years, and there is a high probability that any scarring is permanent.

It is not clear why the stroma only sometimes heals scar free. Perhaps it is dependent on the response of the resident population of the adult keratocyte stem cells, and when those cells are properly activated, scarring is minimized. In a developing chick embryo, there is limited evidence that the developing stroma may have a larger capacity to heal scar free [22]. Other epithelial systems such as embryonic cutaneous tissue have a well established ability to heal scar free [23]. One might speculate that the higher number of stromal keratocyte stem cells

in the embryo could account for the apparent discrepancy between embryonic and adult methods of injury resolution. A key question for tissue engineers is whether the power of adult keratocyte stem cells can be harnessed to heal a scarred stroma or perhaps into generate an entirely new stroma.

The quest to identify an adult keratocyte stem cell population was taken up by several groups in recent years. The majority of attempts resulted in the observation of multipotent keratocyte progenitors in a variety of species by utilizing a sphere forming assay, rather than the desired keratocyte stem cells [24–26]. However, Du and colleagues [27] took an alternative approach, in which the cells were cultured and then sorted by flow cytometry to isolate the stem cells. In this way, they were able to find a 'side population' of cells that expressed ABCG2, a common marker of presumptive stem cells. They were able to concentrate the cells, and then adjust the culture conditions to maintain that particular small subpopulation of cells. The keratocyte stem cells were stable as stem cells as indicated by their expression of stem cell markers and a large number of population doublings. When the keratocyte stem cells were challenged by appropriate differentiation conditions, stromal keratocytes were generated in large numbers. Additionally, the stem cells maintained their embryonic nature by showing their neural crest origin, such that when the cells were exposed to neural or chondrocyte differentiation media, the cells could generate neurons or chondrocytes respectively [27].

The next step was to identify the potential of the multipotent stem cells derived from adult corneal stroma. The initial studies indicated that the cells when exposed to keratocyte differentiation media would produce keratocan, aldehyde dehydrogenase 3A1, and keratan sulfate. However, it did not appear that the cells were making a stromal collagenous matrix in a typical 2D culture. The thought was that the keratocytes would require a three-dimensional structure in order for the cells to start producing the collagenous matrix. The cells grown as pellets without rigid scaffolding were able to express a large set of genes similar to stromal keratocytes and produce an extracellular matrix (ECM) that resembles that made by keratocytes [28].

The complexity of producing a collagen-based multilayered lamellae to generate a strong transparent stroma may take some time and technological breakthroughs. A smaller, but important hurdle was to determine whether adult keratocyte stem cells could remodel a disorganized stroma. To test the function of the keratocyte stem cells, the cells were injected into the stromal cell layer of a lumican null mouse. Lumican is a proteoglycan linked to about half of the keratin sulfate in the stroma and is thought to regulate fibril growth and diameter. In the absence of lumican in the mouse, large collagen fibril aggregates form, which both alter lamellar structure and increase light scatter, with opacity changes that mimic stromal scarring in humans. Interestingly, the injection of keratocyte stem cells can rescue this phenotype, such that the stromal thickness and collagen fibril organization is indistinguishable from wild type mice [29]. The authors argue that this remodeling of the stroma is not a wound healing response; rather it recapitulates the initial formation of the stroma. The authors temper the idea that a direct cell therapy approach may not be feasible in the human due to two important differences between the mouse and human cornea. Notably, the mouse stroma is considerably thinner, thereby making it more experimentally accessible, and more importantly, the human stroma contains extensively cross linked collagen which may make it more resistant to remodeling [29]. The complexity of the global and local organization of the collagen fibrils in the human stroma may make it one of the last layers to be bioengineered in the cornea and the feasibility will be further discussed in the biosynthetic cornea section.

CURRENT PROGRESS: ENDOTHELIUM

The corneal endothelium provides the tissue engineer with several challenges to overcome: an extremely limited supply of endogenous endothelial progenitors, the need to have the layer function for decades, a complex multi-component endothelial pump function, and the

transparent Descemet's membrane. Some species, such as cows and rabbits, have a corneal endothelium that can regenerate, however the human and non-human primate endothelium do not. When human corneal endothelial cells die, the adjacent cells are thought to migrate to the wound and expand their cell diameter to repair the damaged endothelium without replicating. The limited capacity of the human and non-human primate corneal endothelial cells to proliferate has only been observed *in vitro*. The peripheral endothelium appears to have a greater (but still limited) potential to divide *in vitro* compared to the central corneal endothelium [30–32]. Additionally, this limited *in vitro* capacity to proliferate is generally restricted to younger human endothelium (<30 years old) [30]. Overcoming the lack of proliferation has been a major focus for many laboratories addressing the need for providing corneal endothelium for transplantation.

The endogenous human corneal endothelial cell has a finite lifespan, such that the density and number of corneal endothelial cells naturally declines with age with an approximate 0.6% decrease each year [33]. There is an average density of 3,500–4,000 cells/mm^2 at birth [34] which declines to 2,300 cells/mm^2 by age 85 [33]. Other factors such as disease, eye surgery, UV exposure, and contact lens use can all speed the decline of the corneal endothelium. The minimum density of corneal endothelium for function is thought to be around 500 cells/mm [2]. Below that amount, the endothelium does not have enough pumping power to maintain the relative dehydration of the cornea, which leads to it becoming cloudy. Therefore, the tissue engineer also needs to consider the natural effects of aging as well as external factors such as surgery to ensure that the endothelial cell density and the pumping function of transplanted cells is high enough to have a lasting impact.

Another confounding aspect to consider when engineering the corneal endothelium is Descemet's membrane. This membrane is a collagenous fiber layer between the corneal endothelium and the stroma that is first formed during development. In the embryo, it is about 3 μm thick with periodic banding of collagen fibers bound in a latticework of 110 nm intervals. Postnatally, the structural appearance changes and the membrane is continually, but slowly formed over the person's lifetime, to approximately 10 μm in thickness in adults [35]. In general the overall composition of the proteins of embryonic and adult Descemet's membranes are very similar, with some proteins changing their apical or basal localization in the adult [36]. Interestingly, two proteins that are only expressed embryonically, Tenascin C and Fibrillin-1, appear to also be present in disease states such as bullous keratopathy and Fuch's endothelial dystrophy [37,38]. Alterations in the protein composition can disrupt the transparency of the membrane, such is the case in Fuch's disease, where extracellular matrix deposits called guttae along with endothelial cell death results in loss of vision [39]. In the current corneal transplantation method, the host's endothelium and Descemet's membrane is removed and replaced by the donor tissue. Will the tissue engineer need to provide a Descemet's membrane when replacing the corneal endothelium? In some corneal endothelial diseases, it may be possible to leave the host membrane intact while removing the diseased endothelium. However, in Fuch's disease where there are multiple central guttae, it would be expected that the diseased membrane would also need to be removed to effect sufficient restoration of vision.

The concept of expanding and replacing the corneal endothelium in animal transplantation models was explored by Jumblatt [40] and shortly after by Gospodarowicz [41,42]. Both groups tested whether the cultured rabbit or bovine endothelial cells were functional in an *in vivo* model where the endothelium had been removed. The entire cornea was removed from the donor and then seeded with the cultivated corneal endothelial cells. Then the entire cornea with the exogenously derived endothelium was transplanted into a new donor animal. These experiments showed the potential feasibility of expanding an adult endothelial cell culture, until it was realized that these species are not representative of primates. The true sticking point of the method for clinical use is to find a reliable and sustainable source of human corneal endothelial cells.

The corneal endothelium of several species has the capacity to divide and expand in culture. However, human and non-human primate corneal endothelia have a very limited capacity for division if the phenotype and function are to be maintained. To override the lack of expansion, approaches have included transformation of endothelial cells with viruses to promote immortalization [43,44], disturbing the balance of cell cycle regulators [45,46], finding spontaneous transformations that result in immortalized human corneal endothelial cell lines [47], and optimization of culture conditions [48–50]. The first three types of approaches have serious drawbacks for use in the clinic, such that viral transformations, overexpression of exogenous genes, or aberrant karyotypes, since approval by regulatory committees may prove to be overly burdensome and have a real chance of causing cancer in humans. Therefore, either corneal endothelial cells should be generated from another cells source or the methods used for *in vitro* expansion of adult corneal endothelial cells need vast improvement.

Progress from the initial promising studies in the 1970s has been understandably slow, due to the low proliferative capacity as well as the limited supply of human corneal endothelium for experimentation. Experiments done by the Kinoshito and Koizumi laboratories have made significant progress; getting closer to an engineered endothelium by utilizing the non-human primate as a model system. By applying the lessons learned from the non-human primates, improved human culture techniques have made it feasible to test these expanded cultures for transplantation into humans. One such improvement is use of the small molecule, Y27632. Y27632 is known for one of its ability to inhibit rho-associated protein kinase (Rock) but may also affect other signaling pathways. Y27632 can improve survival, proliferation, and attachment of corneal endothelial cells *in vitro* [49]. Separate experiments have shown that the inhibitor can help heal corneal endothelial wounds when applied as an eye drop as well as improve the survival of transplanted corneal endothelial cells [51–53]. The progress they have made is quite substantial; however, there are real limitations in the ability to scale cells up to clinical grade production, due to the restrictions in the expansion from high quality donor tissue, donor age, donor tissue availability, and performing quality control between relatively small lots of cells.

Another approach to solving the problem of generating enough corneal endothelium in large lot size is to convert human embryonic stem cells into corneal endothelial cells. Although still in the research phase, it is possible to convert large numbers of human embryonic stem cells into corneal endothelium that express typical markers (i.e., Col8A1, AQP1) and phenotype of corneal endothelial cells in culture, such as the tight junction marker, Zo-1 (unpublished data, Fig. 67.3). Further experimentation is needed to test the function and safety of human embryonic stem derived corneal endothelial cells *in vivo*. It is likely that the culmination of work from many laboratories in the last 40 years will soon result in the clinical testing of corneal endothelial cells for transplantation.

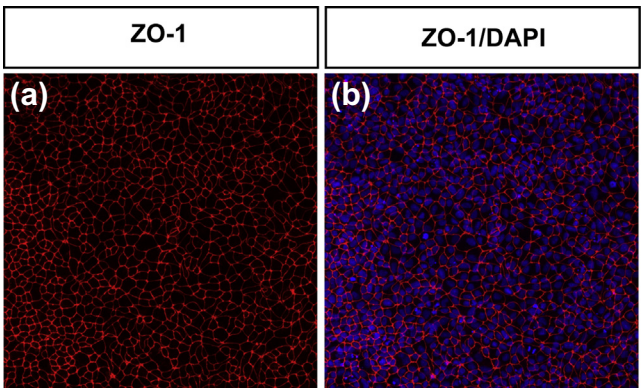

FIGURE 67.3
Corneal endothelial cells can be derived from human embryonic stem cells. a) Confluent monolayer of cells express the tight junction marker, Zo-1 (red), typical polygonal and hexagonal corneal endothelial cells. b) Merge of Zo-1 (red) and the nuclear marker 4′,6-diamidino-2-phenylindole (DAPI) (blue). *(Unpublished data, McCabe, 2012).*

CURRENT PROGRESS: BIOSYNTHETIC CORNEAS

A goal of several laboratories is to ultimately generate a fully bioengineered cornea that would replace or repair the corneal epithelium, stroma, and endothelium. Work done by the Griffith laboratory has been ground breaking in the advancement in finding alternatives to the traditional corneal transplant. The endogenous limitations of repair and regeneration of the quiescent endothelium, as discussed above, has led to the focus for partial thickness bioengineered corneas for the time being, namely for the epithelium and stroma. The proof of concept for a biosynthetic cornea begun in 1999 with the use of a cross linked porcine collagen-chrondroitin sulfate substrate was performed *in vitro* [54]. Subsequently, improvements on the scaffold used included pure human source collagen to eliminate the possibility of introduction of prions [55]. Their efforts resulted in the first human phase I clinical trial for a biosynthetic cornea. The 500 μm thick biosynthetic corneal substitutes were composed of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide that was cross linked recombinant human collagen [56,57]. The implants were stably integrated into the host in all 10 cases with no adverse complications such as neovascularization, inflammation, or rejection being noted. Most of the patients had regeneration of the epithelium within 1−3 months. Interestingly, the presence of fine superepithelial nerves were observed along with a concomitant partial return of sensitivity within 3−6 months in 6 out of the 10 operated corneas. Significant re-innervation was still occurring 12−24 months post-surgery. These studies showed the tolerability of such implants, however, the remodeling of the collagen in the implant was significantly variable, which led to unpredictable clinical outcomes, where visually acuity either increased, remained unchanged, or decreased.

Further research is needed to produce a transparent stroma of even thickness. Saeidi and colleagues [58] may have pinpointed a problem with utilizing a disorganized collagen scaffold as a foundation for building a stroma. The essence of the idea is that in the stromal layer naturally forms in the absence of a scaffold, so by letting the biosynthetic stroma develop in a scaffold free system there may be improved outcomes. They argue that in embryo, the formation of collagen scaffold in the stroma occurs in a rapid manner, in direct opposition to scar formation which occurs over a much longer time-scale. Most approaches have attempted to generate of the stroma by capitalizing the stromal repair process. The inherent problem with this approach is that the repair process normally results in scarring. It has been suggested to take a different approach by attempting to mimic the *development* of the cornea, rather than the imperfect repair process.

Understanding the nature of collagen deposition in the stroma is likely to provide the breakthrough needed to generate a flawless biosynthetic stroma. There are two main concepts concerning the way that the keratocytes go about collagen deposition; the fibripositor and the liquid crystal collagen models. In the fibropositor model, the monomers of collagen are formed into fibrils within the cells, which are released to form pre-organized extracellular matrix. The liquid crystal collagen model relies on the confinement and concentration of the collagen monomers into a liquid crystalline pattern that condenses into regular arrays of fibrils. Regardless of the actual mode, whether fibripositor or liquid crystal, new collagen deposition is likely to be disrupted by introducing a disorganized scaffold as the foundation to be remodeled by newly invading stromal keratocytes. These types of studies demonstrate the need for the tissue engineer to go beyond the initial idea of simply generating large numbers of the cells that make up the three cell layers of the cornea, but to also take into consideration the potential roles of the environment (i.e., growth factors, artificial matrix, cell-cell contact) as well as the timing of the formation of the layers in the hope to generate a bioengineered cornea.

SENSORY INNERVATION: IMPORTANT FOR CORNEAL HEALTH

The cornea is one of the most highly innervated tissues in the body. Corneal innervation is important for the proper functioning of the cornea and impacts the cornea in a variety of ways,

including sensation, proliferation, wound healing, epithelial integrity, secretion of the tear film, and protection of the eye as a whole [59]. The innervation of the epithelium and stromal layers allows the cornea to sense temperature, pain, and pressure. Without proper sensory innervation, the cornea and the eye are at increased risk of damage by noxious stimuli. Alterations of innervation in the cornea from neurotrophic keratitis may lead to a reduction of the tear film, and the resultant disease of dry eye where the patient can suffer excruciating pain. Additionally, it is important to remember that corneal nerves are needed to help maintain the ocular surface integrity by releasing factors such as nerve growth factor (NGF) and Substance P to promote epithelial health. In fact, new data suggests that the innervation of the limbal epithelium helps maintain limbal stem cells and their niche [60], thus adding to the long list of important functions of corneal innervation.

The loss and deterioration of corneal innervation can result in neurotrophic corneal diseases caused by corneal nerve injury and disease, trauma to ocular nerves either by injury or surgery, and brainstem diseases. Patients who have had cornea transplantations have altered and limited re-innervation of the cornea. Additionally, patients who chose to use laser treatment to alter corneal shape to improve vision also have alternations, and potentially, complications due to poor re-innervation. It is clear that innervation of the cornea is important for protection and maintenance of a healthy cornea, but the knowledge of how to alter absent or abnormal innervation is limited [59]. This leaves the tissue engineer with a dilemma: should re-innervation be guided by the slow endogenous process in adults or increased to the speed found during development, or perhaps prevented from occurring? The approach taken should be tempered with what is known about the role of innervation of the formation of cornea.

Many developmental biologists would argue that if you want to replace a structure in an adult, one should first understand how that structure was built in the first place. The origins of the majority of corneal nerves are sensory, and are derived from the neural crest component of the trigeminal ganglion [61]. Additional sympathetic and parasympathetic inputs are from the superior cervical ganglion with some minor contributions from the ciliary ganglia [62–64]. Studies in adult mammals have revealed no major differences in innervation of the cornea [59,65–67]. Until recently, it was assumed that cornea innervation in the mouse embryo occurred in the same manner of the developing chick and human. However, McKenna and Lwigale [61] have shown that there are key differences in the process; namely the nerve bundles entering the cornea enter through four quadrants, rather than the typical entrance through the pericorneal ring found in human and chicken embryos. There are combinations of secreted factors and their receptors such as Semaphorin/Neuropilin as well as Slit/Robo interactions that are important for the formation of the pericorneal nerve ring, such that the cornea initially repulses the axons until the proper entry time [68–71]. The tissue engineer may want to mimic the development of innervation by strategically placing growth factors on the biosynthetic cornea to guide the re-innervation in cases where pre-existing conditions exist or complications arise.

CONCLUSIONS

Complex economic, ethical, and religious factors prevent millions of people from receiving much needed treatment for blinding corneal diseases and injuries. The standard treatment for many forms of corneal blindness is partial or full thickness transplantation of donor cornea. The shortage of donor corneas has and will continue to limit the number of patients who can be treated for corneal disease worldwide. Researchers and clinicians have turned to bioengineering and regenerative medicine to find alternatives to the donor cornea. The use of adult limbal stem cells in the treatment for limbal stem cell disease will likely alter the vision of patients in the near future. The potential is present for the use of stromal keratocyte stems to alter scars, however, a fully engineered stem cell derived stroma is likely in the more distant future. The use of biosynthetic corneas for partial thickness transplantation also shows

significant promise. And finally, the use of either expanded adult corneal endothelial cells or stem cell derived corneal endothelium provides hope for those who suffer from corneal endothelial diseases. It seems likely that these technologies will be used either alone or in combination to replace the need for donor derived cornea transplantation in the coming years.

Definitions

Age-related macular degeneration (AMD) AMD is a condition that affects older adults which results in a loss central vision due to damage of the retina, specifically the macula. It is classified into two forms. The dry (non-exudative form) is characterized by drusen and changes to the retinal pigment epithelium (RPE), including hyperpigmentation and geographic atrophy. In the wet (exudative) form, blood vessels grow up from the choroid underneath the retina.

Stargardt's Macular Dystrophy (SMD) SMD is the most common inherited juvenile macular degeneration that causes progressive loss of central vision in adults under the age of 50. It can be associated with several different genes and inheritance patterns, but the vast majority of cases are autosomal recessive due to a defect in a transporter protein expressed by the rod outer segments.

Retinitis Pigmentosa (RP) RP is a group of hereditary disorders that diffusely involve photoreceptor and RPE function characterized by progressive visual field loss and abnormal electroretinogram (ERG), which shows loss or marked reduction of both rod and cone signals.

Diabetic Retinopathy (DR) DR is a frequent cause of blindness in the United States. Its prevalence increases with the duration of diabetes and patient age. Potential vision loss in patients with DR is due to macular edema (capillary leakage), macular ischemia (capillary occlusion), and the sequelae from ischemia-induced neovascularization.

Orphan Diseases An orphan disease is any disease that affects a small percentage of the population. There is no specific cutoff that defines a disease as an orphan disease.

EPIDEMIOLOGY — PREVALENCE AND CAUSES OF LOW VISION

In 2010, an estimated total of 733 million people worldwide were visually impaired (VI); defined as best-corrected visual acuity (BCVA) worse than 6/12 or 20/40. Worldwide, the five major causes of blindness are uncorrected refractive error (50%), cataract (23%), glaucoma (6%), age-related macular degeneration (AMD) (5%), and diabetic retinopathy (3%). The total worldwide financial cost of VI was estimated to be $3 trillion in 2010. AMD caused $0.3 trillion (12%) of the total financial cost of VI. It is projected that by 2020 there will be approximately 929 million people with VI worldwide — an increase of 27% from 2010 [1].

An estimated 937,000 (0.78%) of Americans older than 40 are blind ($\geq$ 6/60 or $\leq$ 20/200 BCVA in their better-seeing eye). An additional 2.4 million Americans (1.98%) are visually impaired. The leading cause of blindness among Caucasians is AMD (54.5% of the cases)

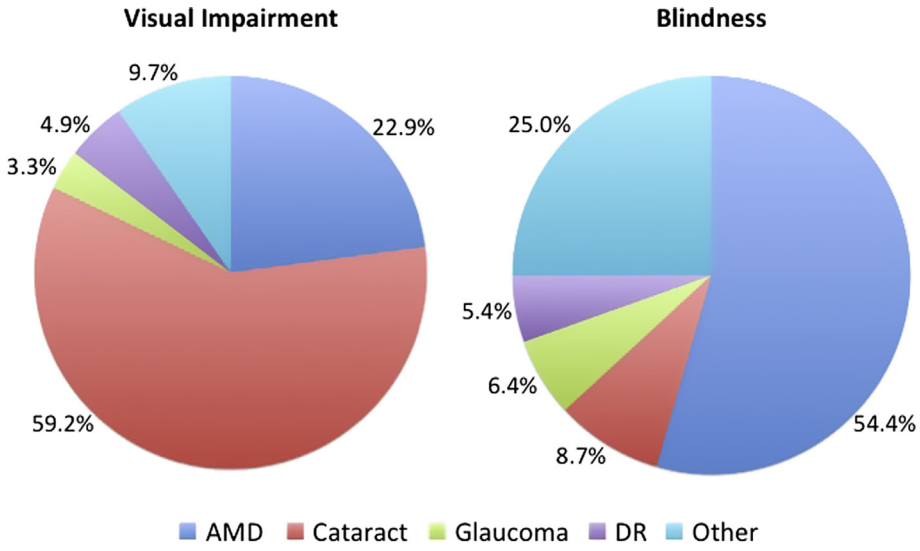

FIGURE 68.1
Causes of visual impairment (best-corrected visual acuity < 6/12 or < 20/40) and blindness (best-corrected visual acuity < 6/60 or < 20/200) in Caucasians.

while among black persons, cataract and glaucoma accounted for more than 60% of blindness (Fig. 68.1). The number of blind persons in the United States is projected to increase by 70% to 1.6 million by 2020, with a similar rise projected for low vision [2].

AMD affects 10–20% of people older than 65 years and is the leading cause of severe visual impairment in the elderly population in industrialized nations [3]. It is estimated that 1.75 million individuals have AMD. Of these, 1.22 million have neovascular AMD in at least one eye, 973,000 individuals have geographic atrophy (GA) in at least one eye, and 7.3 million individuals have large drusen in either one or both eyes. The estimated number of individuals in the United States with AMD is projected to increase by more than 50% from 1.75 million in 2000 to 2.95 million in 2020. Australia is estimated at present to have 130,000 cases of AMD; Western Europe has 3.35 million cases of AMD [4].

Hereditary retinal degenerations, such as retinitis pigmentosa (RP), are major causes of blindness in the Western world, with a prevalence of 1 in 2,000 individuals [5]. The progressive loss of vision is due to mutations in more than 100 identified genes and affects different cellular compartments in either the photoreceptor cells (PRCs) themselves or the underlying RPE [6].

While anti-angiogenesis therapies are available for neovascular AMD, no treatment exists for GA due to AMD and hereditary retinal degenerations.

NEUROSENSORY RETINA AND RETINAL PIGMENT EPITHELIUM — ANATOMY AND BACKGROUND

The neurosensory retina is a light-sensitive tissue lining the inner surface of the eye. Originating as outgrowths of the developing brain, the retina is the only part of the central nervous system (CNS) that can be visualized non-invasively. The embryogenesis of the neuroretina occurs during the first month of life. The optic vesicle extends from the forebrain, which consists of a single layer of neuroectodermal cells. This invaginates to form a bi-layered optic cup aligned apices to apices. Posteriorly, the inner layer of neuroectoderm becomes the sensory retina while the outer layer becomes the RPE. The macula appears at the end of the fourth week, but the foveal pit forms late in embryonic life and continues to mature in early childhood. A normal foveal pit is required to obtain 20/20 visual acuity and the induction of the foveal pit requires normal RPE.

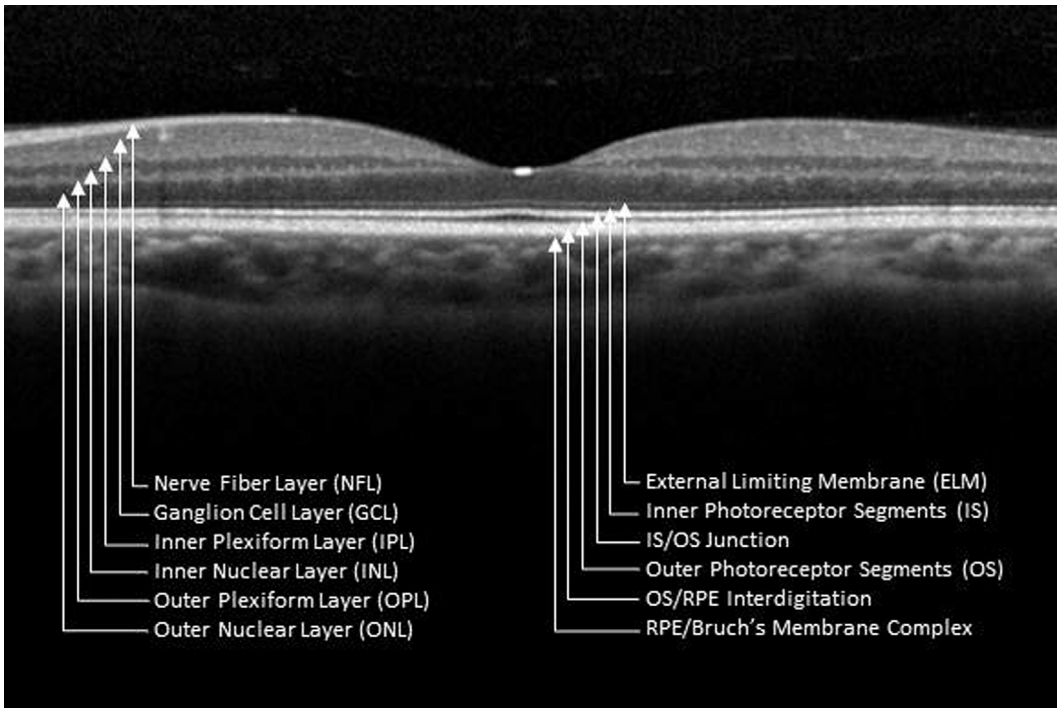

FIGURE 68.2
Retinal layers on Optical Coherence Tomography (OCT).

The neural retina consists of the inner limiting membrane (ILM), nerve fiber layer (NFL), ganglion cell layer, inner plexiform layer (IPL; synaptic processes between bipolar cells and ganglion cells), inner nuclear layer (INL; nuclei of bipolar, horizontal, amacrine, and Muller cells), outer plexiform layer (OPL; synaptic processes between bipolar cells and photoreceptors), outer nuclear layer (ONL; nuclei of the rods and cones), the external limiting membrane (ELM; formed by cell junctions between photoreceptors and the terminal optical processes of Muller cells), and photoreceptor (PR) layer (rod and cone cells) (Fig. 68.2).

The macula is the specialized region of the retina responsible for high-resolution visual acuity. This region is about 5.5 mm in diameter and is centered approximately 4 mm temporal and 0.8 mm inferior to the center of the optic disk. Anatomically, it can be defined as the central part of the posterior retina that contains xanthophyll pigment and two or more layers of ganglion cells. At its center, the umbo, the neural retina consists only of the ILM, Henle's fiber layer, the ONL, the ELM, and the PR outer and inner segments.

The retinal pigment epithelium (RPE) is a monolayer of polarized hexagonal cells densely adherent to one another as well as to the underlying Bruch's membrane, and is adjacent to the PR layer. The RPE has many functions, including phagocytosis of outer-segment disks in photoreceptor renewal, transportation of metabolic waste from the retina into the choriocapillaris, absorption of light and heat, and secretion of growth factors essential for proper differentiation of photoreceptors during development.

In the macula, RPE cells appear smaller in diameter with a higher cell density and broader and flatter in the periphery [7]. Macular cell densities also seem to increase throughout life [7], despite higher central apoptotic activity [8], suggesting the migration of peripheral RPE cells may compensate for the death of macular RPE cells. RPE cells of the macula have a higher melanin content and higher activity of lysosomal enzymes acid phosphatase and cathepsin D [9]. Whether this phenomenon is a functional adaptation to local microenvironments or an irreversible epigenetic process is unclear. This will be an important point to elucidate, for if the RPE mosaic were predetermined, then autologous peripheral cell transplantation would not be ideal.

The retinal blood vessels supply the inner half of the retina and the choriocapillaris supplies the RPE and outer retinal layers. Both have a blood-retinal barrier analogous to the blood-brain barrier. The outer blood-retinal barrier is maintained by the RPE; it blocks the inward migration of small molecules from the choriocapillaris into the subretinal space via tight junctions (zonula adherens and adjacent zonula occludens), both situated near the apex of the cell and encircling it. Specialized tight junctions (zonulae occludens) between individual retinal vascular capillary endothelial cells constitute the inner blood-retinal barrier. The subretinal space is therefore considered an immune-privileged site [10].

THE EYE AND THE RPE

Our significant dependency on sight makes good vision directly related to quality of life. This makes the eye and vision-threatening diseases an area of interest. The eye is unique in that there are *in vivo* endpoints, such as visual acuity and imaging modalities, which are measureable to assess successful engraftment of transplanted cells. Spectral-domain optical coherence tomography (OCT) allows *in vivo* histopathologic visualization of the retinal layers, while autofluorescence imaging allows *in vivo* assessment of the health and function of the RPE cells. The anatomy of the eye also makes it an ideal target organ for cell transplantation and tissue engineering. As mentioned above, the distinctive vascular system of the retina allows the subretinal space to be considered an immune-privileged site.

In the eye, degeneration of neural cells in the retina is a hallmark of such widespread ocular diseases as AMD and RP. In these diseases, the primary cause of blindness is the loss of photoreceptors, which can result from dysfunction in either the PRCs or the underlying RPE that supports their survival.

Damage to the RPE resulting in atrophy is a critical feature of AMD. RPE cell death occurs presumably via apoptosis associated with the loss of cell attachment [11]. Data suggest that widespread oxidative damage occurs in the retina of patients with advanced GA [12]. Therefore, oxidative damage is thought to play a major role in advancement of RPE loss. Additional reports support a role for the immune system, including complement activation in the development of drusen and the pathogenesis of AMD. Degenerative changes within the neurosensory retina and/or choriocapillaris occur simultaneously with RPE atrophy [13].

The RPE cell exhibits an apico-basal polarity necessary for transportation of water, ions, and nutrients [14]. Water and ions are constantly pumped from the apical to basolateral surface of the RPE [15], thus maintaining retinal adhesion [16]; nutrients such as glucose, retinol and fatty acids are actively taken up by the RPE from the blood and either utilized within the cell or transported to the PRCs [17]. As previously mentioned, the RPE is a key metabolic coordinator for PRCs in the phagocytosis of PR outer segments, which in turn enables regeneration of rhodopsin molecules in the visual cycle of vitamin A [18,19]. Proper epithelial polarity is also essential for transport of glucose, retinol, and other nutrients from blood to the photoreceptor, and electrolytes from the subretinal space to the choroid [20]. Thus, success of RPE transplantation also depends on the ability of the transplanted cells to establish polarity after transplantation and perform the complex functions of the RPE. It is a logical target cell for transplantation as the RPE layer is anatomically isolated and is a self-contained monolayer that can be readily assessed with a retinotomy to the subretinal space.

In retinal degeneration, the replacement of diseased RPE would be critical to protect or rescue the adjacent PRCs and vice versa. Kwan successfully transplanted photoreceptors in a mouse model of retinal degeneration, which reconstituted outer segments and allowed these mice to perform simple light-dark discrimination testing [21]. Replacing photoreceptors is far more challenging than replacing RPE cells because the connections between photoreceptors and neurons are lost, and also because of the potential scarring response.

RPE TRANSPLANTATION

The concept of RPE transplantation evolved out of improved human RPE cell culture experiments by Flood [22]. This was followed by several studies in which cultured human RPE cells were transplanted into monkey eyes [23,24]. Later, the therapeutic potential of RPE transplantation was demonstrated in the Royal College of Surgeons (RCS) rat model in the late 1980s [25]. These rats have a mutation in the MERTK, an enzyme necessary for RPE-specific phagocytosis of the photoreceptor segments. Their impaired ability to perform phagocytosis leads to photoreceptor dysfunction and death; retinal atrophy occurs within two months of birth, and by three months of age these animals become fully blind. Transplantation of cultured immortalized human RPE has been shown to improve photoreceptor survival and also prevented the onset of secondary degenerative events in these animals [26]. Dissociated retinal epithelial cells obtained from the retinas of normal, congenic pigmented strain of rats were transplanted onto Bruch's membrane in the subretinal space of RCS rats and were also shown to be fully capable of phagocytosing host outer segments, thus preventing subsequent retinal atrophy [25].

Attempts at RPE transplantation in humans were then performed by Peyman in two cases of terminal AMD [27]; the first case utilized an autologous flap and demonstrated visual improvement, whereas the second used allogeneic homologous RPE cells with no report of visual improvement.

Allogeneic RPE cells and sheets for AMD

Transplantation of both intact sheets of RPE and suspensions of isolated individual RPE cells have been attempted as treatments for AMD. Among the earliest attempts, Algvere et al. treated five AMD patients with a patch of cultured human fetal RPE placed in the foveal area after membrane excision [28]. At three months follow-up, four of five cases lost fixation and developed macular edema, suggesting rejection. At 12 months follow-up, most of the patients had experienced mild visual loss compared to their preoperative vision [28]. A subsequent experiment transplanted circular patches outside the fovea in four eyes of atrophic AMD with the intention that the fovea might become overgrown with RPE or a rescue effect may occur. At one year, there was no adverse or beneficial effect on visual function [29]. Finally, a cell suspension of concentrated dissociated fetal human RPE has been used in seven cases of atrophic AMD. Rejection developed with 50,000 RPE cells (after 8–12 months) and with 500,000 cells (after three months). Two eyes, which received 20,000 and 200 cells, did not show rejection at one year but there was also no visual improvement [30].

Other studies have shown that allogeneic RPE cells do not attach to senescent Bruch's membrane efficiently and do not undergo proliferation and spreading to fill in the defect [31,32]. Even under circumstances in which allogeneic RPEs do attach and proliferate on aged Bruch's membrane, their ability to survive long-term is compromised [33].

Graft rejection is a serious concern in allogeneic transplants. Initial reports on RPE allografts in the RCS rat suggested that there was no rejection in eyes at one year follow-up [34]. Subsequent studies, however, demonstrated chronic rejection mediated through MHC II expression [35]. It was also reported that the immunologic response was related to the number of transplanted cells and increases over time [36,37]. Consequently, strategies to improve RPE graft survival were attempted with disappointing results [38,39].

Autologous RPE cells and sheets for AMD

Autologous transplantation, in cell suspension or as a patch of RPE and choroid, seems an obvious solution to avoid graft rejection. Autologous transplantation with iris pigment epithelial cells has been documented for use in patients with AMD and RP. Preliminary results suggest use of these cells may help preserve but not improve visual function [40–43]. In one trial, 20 patients with exudative maculopathy underwent surgical removal of choroidal

neovascularization combined with transplantation of autologous iris pigment epithelial cells to the subretinal space [43]. After three years of observation, one patient had significant visual acuity improvement, 13 were unchanged, and three patients had vision loss. Vascular membranes did not recur. In 1997, Rezai attempted to use autografts of iris pigment epithelium (IPE) to replace defective RPE [44]. IPE has the ability to phagocytose PRC outer segments [45] but at a much slower pace [46]. The use of IPE autografts is especially appealing due to the ease of harvesting the cells from a peripheral iridectomy. Transplantation can then be scheduled at an optimal time, even years later, as it has been shown that cryopreserved IPE does not lose function during long-term storage in liquid nitrogen [47]. Some degree of visual improvement has been reported as well as prevention of further vision loss [41,42,48]. However, IPE has also been shown to be incapable of expressing essential enzymes of the retinoid visual cycle [49].

Several studies have also investigated harvesting of RPE cells from the posterior retinal areas. In a prospective study of 14 eyes (13 patients) with AMD, Binder et al. applied a subretinal technique with gentle mobilization and aspiration of RPE cells from the nasal retina and reported improvement in BCVA of two or more lines in 57.1% [50]. Similar results were shown in a larger prospective study of 53 eyes in patients with foveal choroidal neovascularization, who were not eligible for laser or photodynamic therapy [51]. Improvement of visual acuity by two or more lines was seen in 53.8% of patients receiving an autologous transplantation of RPE cells compared to 21.1% of patients who had excision alone. This study demonstrated total cell numbers harvested ranging from 11,000 to 29,000 with constant harvesting efficacy (6165 $\pm$ 746 cells/DD) and high cell viability (82.0 $\pm$ 6.9%). This established that reasonable numbers of highly viable RPE cells suitable for autologous RPE transplantation can be efficiently harvested from small retinal areas [52]. Light and electron microscopy of the debridement site revealed extensive disruption of the ONL with only remnants of inner segments remaining. The choriocapillaris was replaced with extensive collagen deposition. Some areas had no RPE while others had thickened Bruch's membrane. In contrast, microscopy of the transplanted site showed the presence of RPE with normal shape, polarity, and pigmentation with basal infoldings and apical villi surrounding PR outer segments. The cells were arranged in a monolayer in some areas, while other areas revealed multilayers. The choriocapillaris was present and appeared normal [53]. Binder also described a surgical technique for transplantation of the RPE suspension via subretinal cannula. In a pilot study, 14 eyes underwent subretinal surgery for foveal choroidal neovascularization (CNV) with simultaneous transplantation of RPE harvested from the nasal subretinal area of the same eye. After a mean observation of 17 months, BCVA improved two or more lines in 57.1%, remained the same $\pm$ one line in 7.1%, and useful reading acuity between Jaeger 1 and 4 points was achieved in 21% [50]. Van Meurs et al. described a different approach, wherein 80,000–160,000 RPE cells were mechanically removed from the retinal periphery and translocated under the macula following the submacular injection of 2 μg poly-L-lysine to promote cell adhesion. Of the eight cases studied, vision remained unchanged in five eyes but deteriorated in three because of retinal detachment (RD) and proliferative vitreoretinopathy (PVR) [54].

Transplantation of intact RPE sheets has also been described, with mixed results. The benefit of sheets over suspension is that RPE sheets provide a means of transplanting an organized polarized patch of RPE. Several studies reported disappointing results due to formation of multilayers with folding and contraction of the sheet following transplantation [55,56]. Van Meurs reported stabilization of vision or mean gain of one line in patients for whom he performed full thickness RPE-choroid transplantation after CNV removal [54]. A major limitation of the autologous RPE patch graft is obtaining a desirable graft size. Further, the RPE-choroid sheet method is very traumatic and predisposes to the observed high PVR complication rate [57]. MacLaren et al. examined long-term results of AMD patients who underwent surgery for (CNV) and simultaneously received a macular RPE translocation. Although RPE choroidal grafts survived five to six years post transplant, visual acuity

continued to decrease in three of four patients followed and all patients lost foveal fixation [58].

Autologous RPE transplantation may be limited as these cells carry the same genetic information to that which may have led to the AMD manifestation. Whether the transplanted cells can adhere to damaged Bruch's membrane in AMD patients, which is a process that is essential for survival and function, remains another area of concern [32,59,60].

STEM CELLS IN RETINAL DEGENERATION

Tissue replacement in the body occurs by two physiologic mechanisms. One is the replacement of differentiated cells by newly generated populations derived from residual cycling stem cells (SCs). The second mechanism is the self-repair of differentiated functioning cells, thus preserving their proliferative activity.

SCs are of interest because of their plasticity and the capacity to self-renew and give rise to specialized cell types. They remain uncommitted and self-renewable until they receive a signal to develop into distinct cell types. Retinal SCs may restore vision in patients who have degenerative retinal disease by two possible means: 1) repopulation of damaged retina, and/or 2) rescue of retinal neurons from further degeneration [61]. Recent reports have demonstrated the ability of human neonatal photoreceptor precursors to differentiate and integrate into the ONL in both the intact and the degenerating retina of mature mice [62,63]. Evidence has shown that photoreceptors and embryonic retinal tissue, when transplanted into the subretinal space, can form new synapses with existing host neurons. MacLaren et al. showed that timely selection of the progenitors is essential for success; the optimal result occurred when selected cells were biochemically committed but not yet morphologically differentiated [63].

Adult stem cells

Adult SCs are committed SCs or progenitor cells from various tissues in both adult animals and humans. For cell replacement therapy in the ocular system, the isolation and characterization of murine retinal SCs (RSCs) in 2000 represented an important step forward [64,65]. These cells were localized in the pigmented ciliary margin and were able to clonally proliferate *in vitro* to form spherical colonies that differentiated into retinal-specific cell types, including rod photoreceptors, bipolar neurons, and Muller glia. Similar cells were later identified in other mammalian species, including pigs and humans, but proliferated to a lesser extent than fetal or ESC-derived retinal stem cells [66,67]. Retinal stem cells were also discovered within the iris epithelium as described above.

Adult bone marrow-derived stem cells

Bone marrow (BM)-derived SCs (BMSCs) are multipotent SCs that differentiate into cell types from the germ layer of their origin. However, unlike embryonic stem cells, which are pluripotent, or can give rise to any cell type of the body, BMSCs have a limited range of differentiated derivatives. The following subsets of SCs can be found in the BM:

1) Hematopoietic SCs (hSCs), the source of all blood cells;
2) Mesenchymal SCs (MSCs), non-hematopoietic stromal cells that differentiate into mesenchymal tissues; and
3) Tissue-committed SCs (TCSCs) that are already committed to neural, cardiac, and other lineages [68,69].

A mouse model study showed that adult BMSCs could upregulate some of the RPE markers *in vitro* and can home onto focal layers of induced RPE damage in a mouse model and form a monolayer of MITF-positive cells on the Bruch's membrane [70].

Embryonic stem cells

Embryonic stem cells (ESC) are pluripotent cells that can give rise to all of the cell types in the body. Thus, ESC could be seen as a universal cell source for regenerative medicine, and multiple studies have shown their ability to produce functional cells of various types, which were successfully used in different animal disease models. Human ESCs show the following characteristics:

1) They can be isolated from blastocysts, morula-stage embryos, or even from a single blastomere without embryo destruction;
2) They proliferate indefinitely *in vitro*;
3) They maintain a normal euploid karyotype over extended culture;
4) They differentiate into derivatives of all three germ layers;
5) They express high levels of markers of pluripotency such as Oct-4, NANOG, Rex-1, TRA-1−60, TRA-1−81, SSEA-3, SSEA-4, alkaline phosphatase, and
6) They show telomerase activity [71].

Numerous differentiated cell types have been derived from ESCs, including neural tissue, endothelial cells, blood cells, cardiomyocytes, and hepatocytes. Schraermeyer and colleagues were the first to demonstrate that subretinal injection of mouse ESCs into RCS rats can prevent PR degeneration [72], yet these transplanted mouse ESCs produced teratomas when transplanted into various adult tissue sites [73,74]. Klimanskaya et al. demonstrated reproducible generation of RPE from human embryonic stem cells (hESCs) [75], which were capable of extensive photoreceptor rescue in the RCS rat model [76,77]. The hESC-derived RPE (hESC-RPE) cells were transplanted into the subretinal space of RCS rats at six weeks of age, when the photoreceptors were still alive as assessed by various visual tests (optomotor response, luminance threshold, ERG). While the control (sham-injected) animals were completely blind, hESC-RPE recipients showed a remarkable rescue of the photoreceptors as demonstrated by vision tests and also confirmed histologically. In control animals, the ONL of the photoreceptor was gone or diminished to 1−2 cell layers thick, whereas in the operated rats, multiple (5−7) layers of photoreceptors were preserved. The cells integrated into the host's RPE layer and stained positive with two RPE-specific markers, RPE65 and bestrophin. They also stained negatively with human-specific proliferating cell nuclear antigen (PCNA), indicating lack of continued cell division among the donor cells. They demonstrated long-term survival by remaining viable for over 100 days after transplantation. The photoreceptor rescue effect in RCS rats was seen with as few as 20,000 cells and became more pronounced at 50−100,000 [77].

hESC-RPE also provided a similar rescue of the photoreceptor in a mouse model of Stargardt's disease (ELOVL4 mutation) [77]. In untreated ELOVL4 mice, visual acuity deteriorated as photoreceptor degeneration progressed. Subretinal transplantation of hESC-RPE cells improved visual acuity compared to controls at all time points, which was found to be statistically significant. No tumor formation or abnormalities were observed in these studies.

In 2012, Schwartz et al. transplanted the first human patients with hESC-RPE in the course of Phase I/II clinical trials [78]. The cells used for the trial were produced under Good Manufacturing Practices (GMP) and passed multiple safety criteria. They were shown to be free of human and certain animal pathogens, have normal karyotype, and were free of contaminating pluripotent cells. When injected into immune-deficient NIH III mice [78], hESC-RPE did not proliferate beyond three months after transplantation as demonstrated by staining for Ki-67, integrated into the host's RPE layer, and exhibited characteristic morphology and baso-lateral organization of bestrophin, typical for mature polarized RPE (Fig. 68.3); no tumors or other abnormalities were detected after nine months post-transplantation. These data indicated that transplanted hESC-derived RPE could be safe and efficacious in a host. Two patients, one with dry AMD and one with Stargardt's disease, were injected subretinally with 50,000 viable hESC-RPE cells in suspension. The patients underwent pars plana

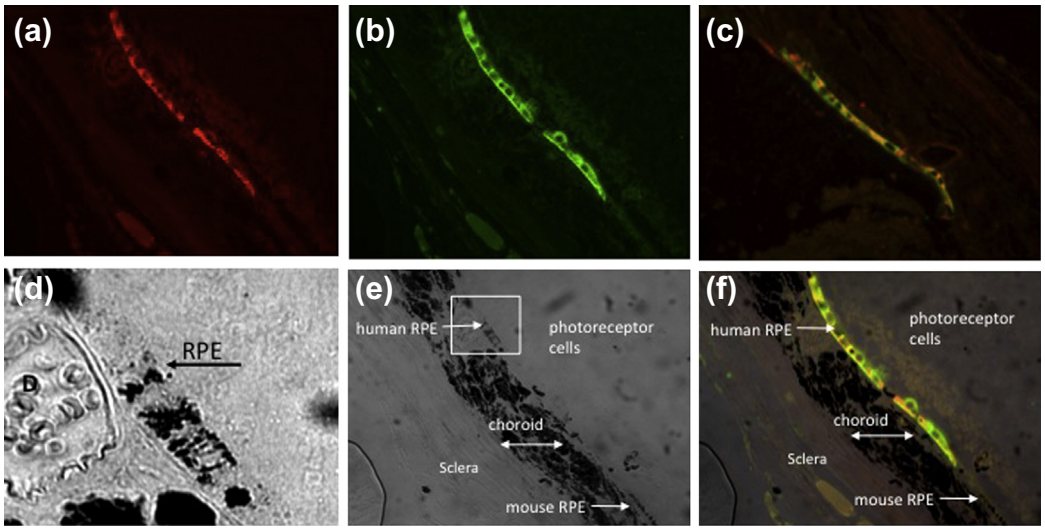

FIGURE 68.3

Survival and integration of RPE generated from hESC-MA09 into NIH III mouse eye after nine months. Section stained with anti-human mitochondria (a) and anti-human bestrophin (b). Notice precise co-localization of human mitochondria and bestrophin staining in the same cells (c: a and b merged) and absence of staining in mouse RPE (f: a, b, c, and e merged). Frame on the bright field image (e) is enlarged in (d) to show morphology of human RPE. Magnification 200x (a—c, e, f) and (d) is additionally magnified 4.5x.

vitrectomy with induction of a posterior vitreous detachment at the optic nerve. The hESC-RPE cells were injected into the subretinal space with a 38-gauge cannula, creating a subretinal bleb. Initial observations revealed no adverse events, including no signs of hyperprofileration, tumorigenicty, ectopic tissue formation, or apparent rejection.

DELIVERY OF CELLS

Currently, the two most popular methods of delivering stem cells into the eye are the intravitreal and subretinal routes. The intravitreal route delivers stem cells into the eye through an injection using a small-gauge needle. This method is technically easier and less invasive than the subretinal route. However, the cells have to migrate through the vitreous and inner retina to the outer retina. There are also no means of directing the cells toward the target treatment area.

Subretinal transplantation strategies include grafting RPE sheets on a BM prosthesis and subretinal injection of cell suspension. As mentioned earlier, RPE cell suspensions may fail to survive or function on the damaged BM [32, 59,60]. Formation of multilayered clumps that damage the overlying neural retina has also been reported [79,80], which could also be a concern for hESC-derived RPE cell suspensions.

The use of biological and tissue-engineered membranes

It was been shown that the survival of donor RPE *in situ* is impaired when cells are plated onto aged Bruch's membrane or Bruch's membrane from AMD donors [33,81]. Thus, many groups have tried to address this issue by providing a RPE carrier substrate to serve as either a temporary or permanent BM prosthesis. Amniotic membranes appear to provide a suitable growth surface for RPE and IPE, both *in vitro* and *in vivo* [82—85]. Human RPE cultured on dispase-treated amniotic membrane [83] showed differentiated phenotype and upregulated gene expression for RPE65, Retinaldehyde-binding protein 1 (CRALBP), bestrophin, and Tyrosinase-Related Protein 2 (TRP-2) as well as production of vascular endothelial growth factor (VEGF), thrombospondin-1 and pigment epithelial derived factor (PEDF). Morphology of cadaver human RPE was retained when cultured on amniotic membrane [85]. Interestingly, when IPE was cultured on amniotic membranes, it showed an upregulation of genes important for RPE function, such as PEDF, bestrophin, and RPE65, and subretinal transplantation of IPE sheets on amniotic membranes

showed a significant rescue of photoreceptor in RCS rats [84]. RPE maintained its phenotype in culture on ILM [86], elastin-like recombinamer (ELR) films, which have an integrin-binding domain RGD [87], and Bombyx mori silk fibroin (BMSF). RPE cultured on anterior lens capsule was also successfully transplanted *in vivo* [88].

Artificial membranes need to be inert to prevent rejection, porous to allow diffusion of small and large molecules, and have a suitable RPE attachment surface. One such membrane is a synthetic mesh-supported submicron parylene-C membrane (MSPM) [89]. The permeability of parylene-C membranes to macromolecules is similar to the permeability of Bruch's membrane. hESC-RPE cells cultured on these membranes, adhered, proliferated, and formed a monolayer of polarized epithelia typical for RPE with microvilli. A study comparing several matrix candidates performed in pig eyes showed that parylene-C membranes as well as polyethileneglycol did not produce any significant disturbance to the retinal anatomy [90]. Other substrates which hold promise as a matrix include cross linked collagen [91], cryoprecipitate [92], and synthetic matrices such as poly-L-lactic-acid/poly-lactic-co-glycolic-acid (PLLA/PLGA) [93,94] and surface modified poly(hydroxybutyrate-co-hydroxyvalerate) thin films [95]. Corneal endothelial cell-produced extracellular matrix and conditioned medium improve survival of human RPE on aged Bruch's membrane, which suggests another possible tool to boost the efficacy of RPE transplantation for AMD patients [96,97].

An important observation we made in the course of experiments for optimization of hESC-RPE preparation for human clinical trials was the correlation of RPE pigmentation, i.e., maturity, with its post-thaw attachment and survival *in vitro* as well as with survival after passing through the injection needle [78]. Cells with higher pigmentation level had a lower overall survival rate, and an optimal melanin level was found that correlated with high survival of the cells *in vitro* [78] and the efficacy of photoreceptor rescue *in vivo* [77]. The low rate of success of transplantation of human RPE – both fetal and adult, allogeneic and autologous – could be partially attributed to the phenotype of freshly harvested cells that are highly pigmented and have mature tight junctions, which may take too long to disrupt during cell isolation, and therefore damage the cells prior to transplantation. An important advantage of hESC-RPE cells is that its phenotype can be modulated in culture to the desired standard by harvesting them when they are still 'underpigmented' to ensure optimal cell survival.

CONCLUSIONS AND FUTURE DIRECTIONS

As the rates of visual impairment and blindness continue to rise, so does the importance of finding a feasible therapy. Regardless of the underlying etiology of the retinal degeneration, the common endpoint is loss of the photoreceptors and underlying RPE. Cellular replacement strategies offer a promising solution in the treatment of retinal degeneration. Success of these strategies is contingent on finding a viable source of replacement cells, establishing a safe technique for delivery, survival of transplanted cells within the host, restoration of normal retinal architecture, and stabilization or improvement in vision. Over the past two decades, there have been many advances in RPE cell replacement strategies. These studies have elucidated potential mechanisms, as well as challenges and drawbacks. Recent advances in stem cell therapy, though early in their development, offer a promising and exciting prospect for replacement therapies.

INTRODUCTION

This chapter provides an overview of visual system properties in health and disease, with an emphasis on the stages in visual-signal processing that are most commonly affected by disease and dysfunction. It then provides an overview of current approaches to vision restoration and of approaches that promise to migrate from the lab to the clinic in the coming years. In a third section, the potential roles for engineered cells and tissues in this restoration process are discussed. The chapter closes with an estimate of the developments that can be expected to occur in the next 5–10 years.

Twenty years ago, the best hope vision researchers had for the enhancement of impaired vision was to build a better magnifier, by integrating optics and electronic image processing. Since then, restoration of vision to functionally blind individuals has become not just an engineering target, but a realistic goal for which engineering milestones are being set and reached. The role of tissue engineering in this field may as yet be modest, but it has great promise, as will become clear in the following pages.

In this chapter's overview of approaches to the restoration and enhancement of impaired vision in human patients, inspired by tissue-engineering principles and related technologies, we argue that the nature of eye disease and the fragility and complexity of ocular tissues such as the neural retina do not (yet) lend themselves to application of the techniques emerging in the repair of other tissues. Thus, while some of the approaches presented here can function independently of tissue engineering as presented elsewhere in this volume, they at least complement those engineering approaches and lend themselves to future integration. This is particularly true in the areas of cell transplantation and neural prosthesis development, presented in the later part of this chapter, but to a lesser extent also for the optical and optoelectronic aids presented.

VISUAL SYSTEM, ARCHITECTURE, AND (DYS)FUNCTION

Human vision is mediated by one of the most highly developed sensory systems found anywhere in nature. Its capacity to combine high spatial resolution near the center of fixation with a wide peripheral field of view, accurate depth perception, color discrimination, and light-dark adaptation over 12 orders of magnitude is unparalleled. Every stage in the system is organized to accomplish this. The photoreceptor layer in the retina provides the high signal

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00069-0

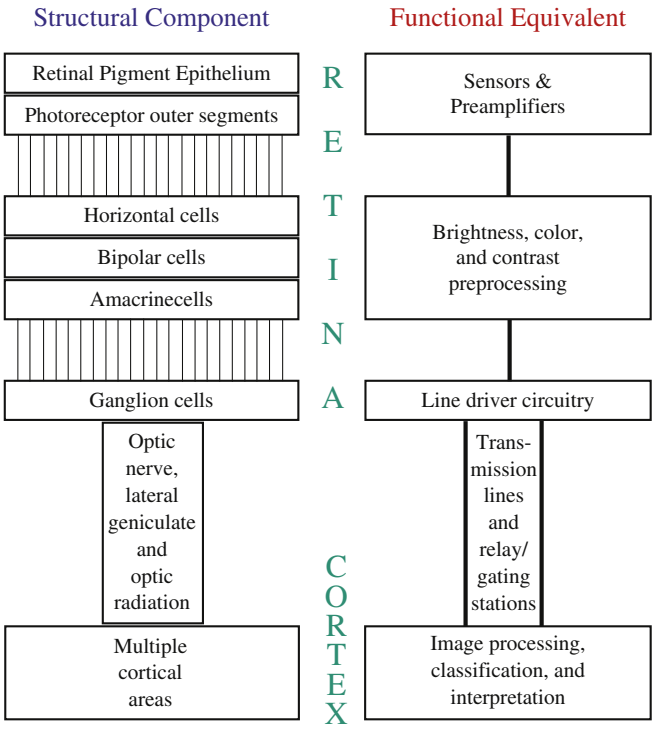

FIGURE 69.1
Schematic representation of the visual system: The outer retina (RPE and photoreceptor layers) form the sensor array, followed by several inner retinal preprocessing stages, the ganglion cell transmission stages, and further central processing stages in subcortical and cortical brain centers.

amplification of the rods required for night vision and the dense packing of three cone types required for detailed central and color vision. The intricate local preprocessing performed by subsequent retinal cell layers augments these functions by performing brightness and color comparisons and helps to condense the information stream acquired by over 100 million photoreceptors, to allow transport across a mere 1 million fibers in the optic nerve to the visual centers in the brain, where further parsing and interpretation of the image takes place.

From a functional point of view, the visual system can be understood as depicted in Fig. 69.1: with sensors, preamplifiers, preprocessors, transmission lines, and several central processor stages. The two most crucial stages in this process — the conversion from light into chemical and electrical signals, and the signal transmission from the eyes toward the brain — are also the most vulnerable ones. Light conversion and signal amplification in the photoreceptors require a highly complex interplay between the molecules inside these cells and ion channels and other permeable structures in the cell membrane. These components participate in interlocking cycles of conversion and regeneration and are assisted by surrounding cells — in particular the retinal pigmented epithelium (RPE) cells, which provide nutrients to, and digest cell membrane discarded from, the photoreceptors. Any step in this intricate process can easily be disrupted by nutritional deficits, overexposure to short-wavelength light (presumably causing oxidative changes), attacks by pathogens, and especially genetic miscoding of one or more participating molecules. Since the mid-1980s, the list of mapped (>225) and identified (>185) gene loci has grown at an ever-increasing rate. For each identified gene there may be multiple mutations, often leading to distinct disease phenotypes; for an up-to-date list of the known mutations leading to loss of outer retinal function, see the Retnet website [1]. Not only do such mutations directly cause impaired signal transduction, but the additional energy demand, presence of abnormal molecules, and excess shedded cell membrane may exceed the RPE cells' support capacity, which inexorably leads to degeneration of both photoreceptors and RPE cells. The most common group of disorders caused by genetic miscoding of molecules involved in the phototransduction cycle is jointly known as retinitis pigmentosa (RP), while another group is caused by a breakdown of RPE function in the central retina due to either a genetic defect (Stargardt macular dystrophy) or

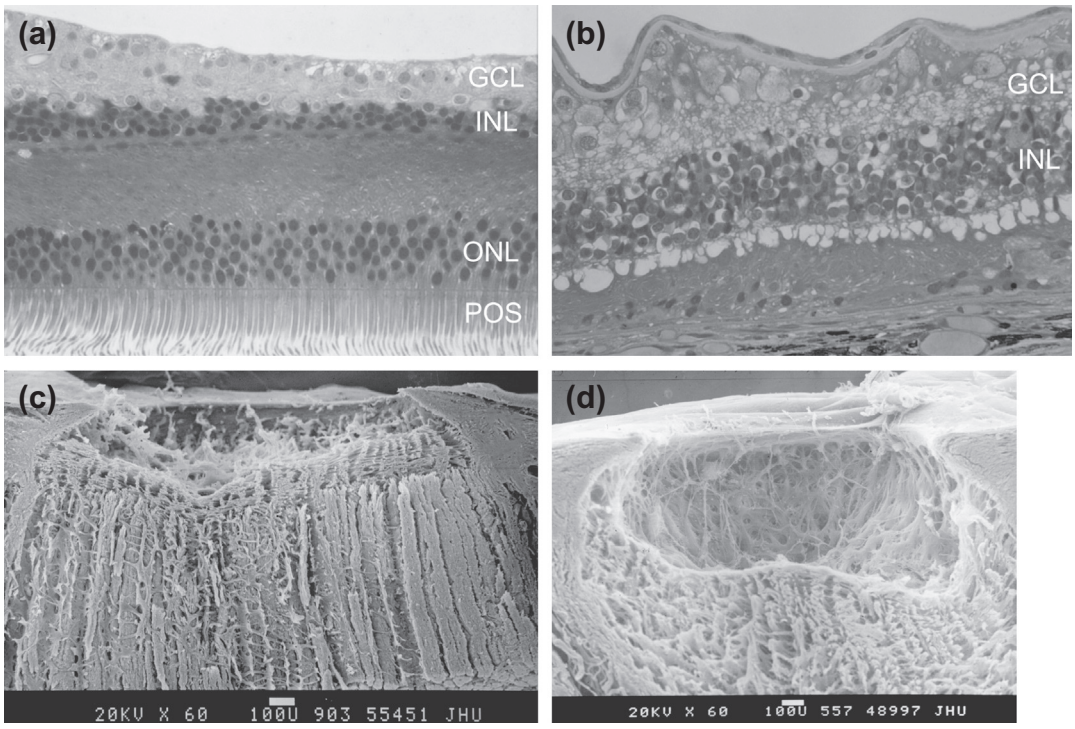

FIGURE 69.2

Representative samples of ocular morphology in healthy and diseased conditions. (a) Cross section through the retina near its center (fovea), showing healthy photoreceptor outer segments (POS), multiple layers of photoreceptor cell nuclei in the outer nuclear layer (ONL; labeled black), bipolar cell nuclei in the inner nuclear layer INL) and ganglion cell bodies in the ganglion cell layer (GCL). (b) Retina of a patient with a long history of retinal degeneration, and bare light perception in the last years of life, showing lack of photoreceptor outer segments and cell bodies in comparison with (a). (c) Scanning electron microscope cross section of the optic nerve head, showing healthy appearance of the support structure, the lamina cribrosa. (d) Optic nerve head from a patient with long history of glaucoma, showing compression of the lamina cribrosa and embedded nerve fibers (RGC axons). *Micrographs C and D courtesy of Harry A. Quigley, M.D., the Johns Hopkins Univ., Baltimore, MD.*

a combination of genetic predisposition and environmental factors (age-related macular degeneration, AMD). Jointly, all these disorders are known as retinal degenerations (Figs. 69.2a and b).

Retinal neurons communicate in a variety of ways, with ion-gating channels fulfilling a role in reaching and maintaining an operating level (also known as the adaptation state) and neurotransmitters and gap junctions fulfilling the principal messenger roles in carrying information in chemical and electrical form, respectively. The loss of outer retinal function, and therefore of neurochemical and electrical signal transmission to the inner retina, will affect secondary retinal cells (horizontal, bipolar, amacrine, and ganglion cells) but not necessarily threaten their survival. Until a few years ago, morphometric studies of donor retinal tissue such as that shown in Fig. 69.2b suggested survival of bipolar and ganglion cells at rates of 80% and 30% in the macula [2] and 40% and 20% at eccentricities up to 25° [3], respectively, in retinas practically devoid of photoreceptors. In recent years, a series of highly detailed and elegant microanatomical studies using a technique called computational molecular phenotyping (CMP) [46] has demonstrated that the connectivity patterns of these inner retinal cell populations are fundamentally altered by the degeneration process (Fig. 69.3). Survival of these cells is predicated on their continued activity, and this they accomplish through the formation of new axonal and dendritic branches and through self-organization into clusters called microneuromas. These new and functionally random connections allow spontaneous oscillations to occur: in the absence of meaningful input signals from the erstwhile photoreceptors, RP patients may experience such spontaneous activities as photopsias, or 'light shows' [4].

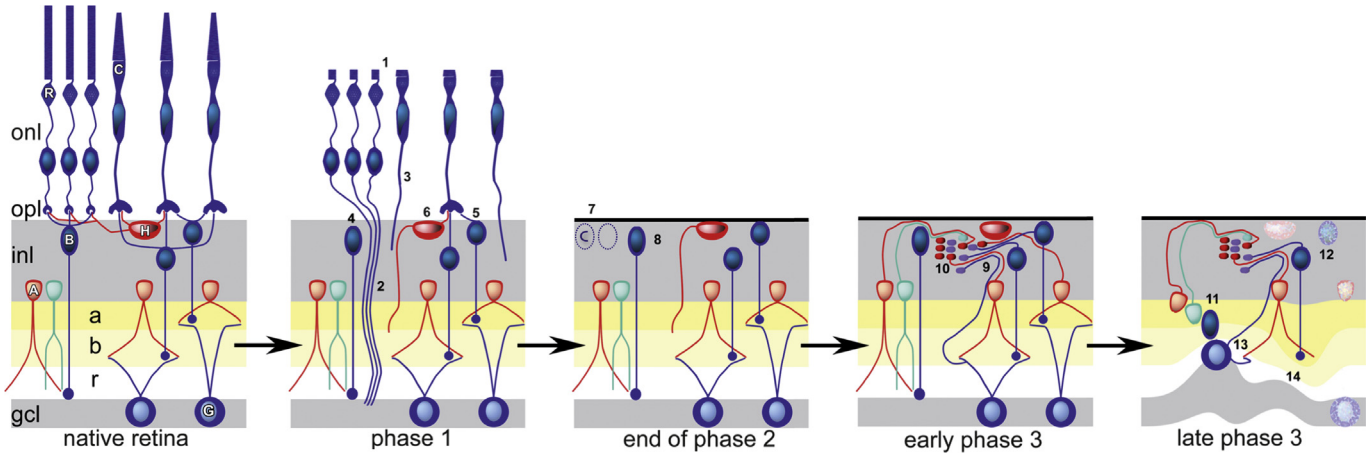

FIGURE 69.3

Simplified schematic of possible alterations during retinal remodeling. The first panel shows a representative 'native' mammalian retina with its basic complement of rods (R) and cones (C) driving bipolar (B) and horizontal (H) cells. In turn, bipolar cells drive amacrine (A) and ganglion cells (G) of the proximal retina to form the major cone OFF (sublayer a), cone ON (sublayer b) and rod ON (sublayer r) zones of the inner plexiform layer (IPL). Remodeling occurs in phases, as indicated under each panel. In phase 1, rod and cone stress lead to truncation of outer segments (1) and, in some instances, extension of rod (2) and cone (3) axons deep into the inner nuclear (inl), inner plexiform and even ganglion cell (gcl) layers. Both rod and cone bipolar cells truncate their dendrites (4,5) and some rod bipolar cells may transiently switch to surviving cones (not shown). Horizontal cells also send axons into the inner plexiform layer (6). Phase 2 is a complex period of cell death, ablation of the outer nuclear layer (onl), and resolution of the distal margin of the neural retina into a largely confluent glial seal (7) formed by the distal processes of Müller cells. Surviving neurons may continue to alter their phenotypes by changing receptor expression patterns (8) and some cone cells may even escape cell death (C). Neural remodeling becomes even more extensive during phase 3, with formation of complex axon fascicles (9) and new synaptic complexes termed microneuromas (10). As remodeling continues throughout life, some neurons begin to migrate along glial columns (11), others die (12), and the inner plexiform layer becomes transformed through new synapse formation (13) and laminar deformation (14).

At the retinal output signal transmission stage, where retinal ganglion cells (RGCs) convert the neurotransmitter signals into electrical spike trains that travel along RGC axons toward the thalamic relay nuclei and other brain areas, the system is vulnerable to mechanical insults rather than to genetic dysfunction: injury to the optic nerve (trauma), increased pressure inside the eye (crushing the fragile axon fibers at the optic nerve head [glaucoma]), and inflammation (optic neuritis) or impaired blood supply (ischemic neuropathy) of the optic nerve itself. Each of these can impair or interrupt the signal-carrying capacity of optic nerve fibers (Figs. 69.2c/d).

In addition to damage occurring at these distinct stages, more generalized damage to the retina can occur. Common mechanisms for this are the leakage of capillaries in diabetic retinopathy and the interruption of the blood supply to the inner retina (retinal vascular occlusive disease), especially in individuals with a predisposition toward the development of blood clots. Each of these can lead to widespread cell death in the inner nuclear and ganglion cell layers throughout the affected area. Vascular occlusive disease provokes angiogenesis: New retinal vessels sprout in response to growth factors signaling ischemia, but these vessels tend to leak and damage the retina's fragile structure. Diabetic retinopathy is a major cause of preventable blindness in the developed world and increasingly in developing countries as well.

CURRENT AND NEAR-TERM APPROACHES TO VISION RESTORATION

As in all biomedical engineering, approaches to restore function can be based on interruption of the disease process and tissue regeneration (autologous or grafted), or on hybrid techniques combining biological tissue with synthetic materials and devices. To support

the cells affected by disease or injury, neuroprotective substances, growth factors, and genetic modifications of cell function may be used, postponing or preventing further loss of function. In addition, as long as usable function remains, one can strengthen the stimulus and internal response signal, counteracting visual impairment as much as possible.

If little or no sensor function remains, one can seek to restore it in limited form through newly grown or transplanted photoreceptors and/or RPE cells, through a prosthetic device that will electrically stimulate the remaining secondary retinal cells, or through man-made tissues that mimic photoreceptor function. At the RGC level, substitution for lost signal transmission may be sought through protection of any remaining cells and administration of factors promoting axon regeneration. This may require the use of synthetic tissues and factors enabling reconnection of axons with central structures — or through *in situ* growth of new cells, promoted to differentiate into RGCs and to send new axons through the optic nerve.

In preliminary form, many of these approaches exist in the laboratory or are entering clinical testing, while others are merely ideas. In the following sections, both existing and prospective methods are presented.

Enhancing the stimulus through optoelectronic and optical means

Most of these devices are based on a combination of optical and electronic image enhancement techniques. Their common principle of operation is to improve visibility of the image to the diseased retina, through magnification, contrast and/or color enhancement, and filtering or feature extraction. Early incarnations, such as the low vision enhancement system — LVES; no longer in production; see Fig. 69.4a and Massof [5] — used optical magnification, zoom, automatic focus, and — for applications limited by available contrast, such as face recognition — analog image enhancement. These techniques have been adopted by more lightweight and cosmetically attractive video visors, such as the Jordy (Fig. 69.4b; Enhanced Vision Systems, Huntington Beach, CA) that enjoy considerable popularity among

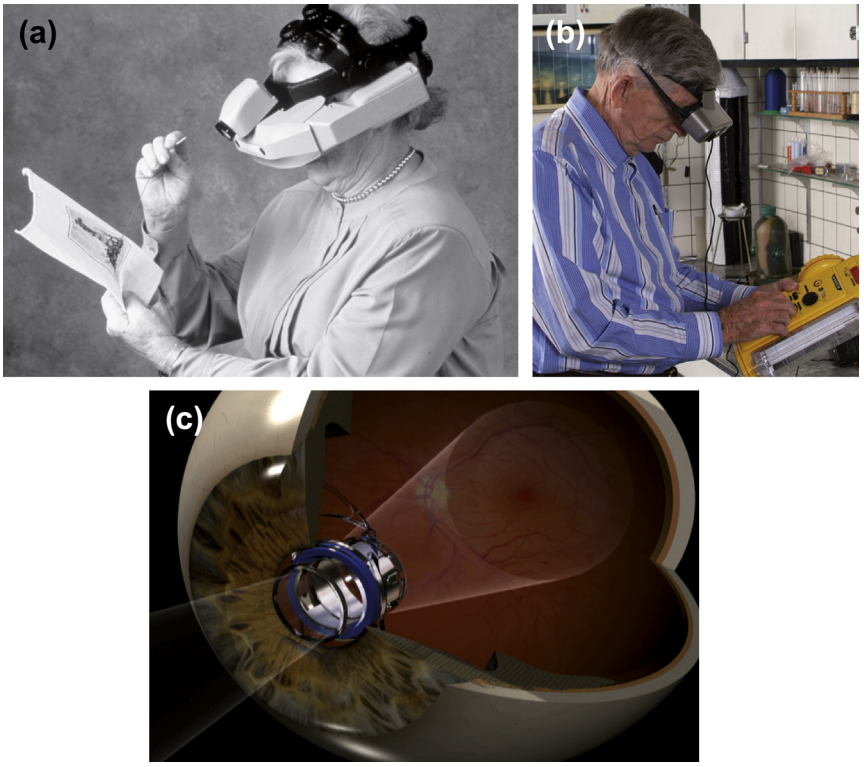

FIGURE 69.4
(a) The Low Vision Enhancement System (LVES), developed at the Johns Hopkins University's Lions Vision Center, with support from NASA and the Department of Veterans Affairs, is a characteristic example of optoelectronic vision enhancement systems. This system features binocular orientation cameras, a centrally placed 1.5—10× zoom camera with automatic focus, and a binocular projection path with 36°×48° field of view and built-in refractive correction and alignment for the wearer. (b) The Jordy video visor has a narrower field of view, but is much lighter thanks to its LCD screens, and has a full color display. Photo courtesy of Enhanced Vision Systems. patients with severe visual impairment. More advanced image processing techniques, such as digital feature enhancement and gaze-contingent remapping, will allow wearers to avoid losing crucial information in blind areas of the visual field. Such image processing techniques are now feasible, but cost and cosmetic considerations have thus far limited their application. Another limitation of current versions is the product of field of view and angular resolution, i.e., the number of pixels across the screen. The expectation is that the widespread penetration of high definition video and telepresence applications in industry and entertainment will enable cost-effective application of this technology to low vision aids. Similarly, cosmetic and weight factors will improve as smaller, lighter, and more luminous flat panel displays become available.

A useful property of the cameras in portable video visors is their built-in automatic gain control, resulting in constant internal image brightness over a wide range of environmental illumination levels. Among other properties, this makes the image acquisition and processing stages of these systems highly suitable as sensors and preprocessors, respectively, for prosthetic and tissue-based image enhancement systems.

Optical systems can also be used to increase the visibility of the stimulus. One such system, approved by the United States Food and Drug Administration (FDA) for clinical application in 2011 and aimed at patients with a large central scotoma (blind spot) in both eyes due to advanced AMD, is an implantable miniature telescope (IMT™, Fig. 69.4c; VisionCare Ophthalmic Technologies, Saratoga, CA), placed behind the iris in the location of the crystalline lens. It provides one eye with a magnified view of the central visual field, while the other eye is not implanted, to preserve the wide peripheral view of the fellow eye.

Following an adaptation and rehabilitation training period of three to six months, most wearers have no difficulty switching between the magnified view in the implanted eye and the unenhanced view in the fellow eye. Note that this is a true prosthetic device, since it is permanent.

Visual prostheses based on electrical tissue stimulation

As was already mentioned, retinas with severe degeneration of the sensor layer retain high numbers of secondary cells. In analogy with the principle of operation of the cochlear prosthesis, i.e., restoring limited hearing through stimulation of spiral ganglion cells in the cochlea [6], this provides the opportunity to convey rudimentary vision to the degenerated retina by a prosthetic device stimulating remaining secondary cells with a two-dimensional array of microelectrodes, reminiscent of the images produced by dot matrix printers a few decades ago [7]. From an engineering point of view, one can envisage a range of possible approaches (stimulation electrodes under vs. over the retina; fully integrated photosensing, image processing and stimulating systems vs. external image capture and processing linked to an intraocular stimulating matrix, to name a few) but also a host of questions arise concerning biocompatibility, signal processing, and power management.

The most pressing question, regarding the feasibility of conveying visual imagery to patients blind from retinal degeneration, has been answered affirmatively. In a series of experiments started at Duke University in 1992, continued from 1993 until 2000 at Johns Hopkins, and since then confirmed through similar experiments at Harvard University and in several German university clinics, volunteers with end-stage RP – whose remaining vision was limited to, at best, light perception – as well as several patients with advanced AMD have participated in tests where, during a surgical procedure under local anesthesia, the inner surface of the retina was electrically stimulated with small and brief biphasic current pulses applied through a single electrode or multiple electrodes [8–10]. Among the most salient findings are the subjects' ability to see small punctate light flashes (phosphenes), whose perceived location corresponds exactly to that of the stimulation, and the ability to see simple

patterns of multiple phosphenes when multiple electrodes are activated simultaneously. Stimulation at rates greater than 40–60 pulses per second is perceived as continuous stimulation, and perceived stimulus intensity increases with pulse duration and amplitude as well as repetition rate. Independent tests in blind volunteers and in amphibian retina [11] have demonstrated that stimulus pulses 1 ms or longer in duration preferentially stimulate the (deeper) bipolar cells rather than the (more superficial) RGCs.

Over the past few years, research in this field has moved from acute experiments to chronic implant models, and academic research has joined forces with start-up companies and in some cases government labs to develop dedicated technologies enabling chronic implants. A good example is the relocation of the implant group formerly at Johns Hopkins University to the Doheny Retina Institute at the University of Southern California, the founding of Second Sight Medical Products LLC (SSMP; Sylmar, CA) as a corporate partner, and the collaboration of these two entities with laboratories at state universities (e.g., the University of California in Santa Cruz (Fig. 69.5a), San Diego, and Berkeley) and in the US Department of Energy (Oak Ridge, Sandia, Livermore). The SSMP-led consortium, with cumulative private and public funding levels of $100M each, introduced the 16-electrode Argus 16 to clinical testing in 2003, and the 60-electrode Argus 2 in 2007. Following a clinical trial with 30 end-stage RP patients in the US and Europe, the Argus 2 was approved for routine clinical implantation in Europe in 2011, with a more limited approval in North America, under a humanitarian device exemption by the US Food and Drug Administration, granted in early 2013. Recipients of the device during the clinical trial have demonstrated the ability to localize and track objects [12,13] and recognize high-contrast letters and short words [14].

Simultaneously, several other groups are pursuing intraocular prosthetic devices. Such devices come in two variants. Stimulating 'photodiode arrays', typically placed under the retina (subretinally) and stimulating electrode arrays with external image capture and preprocessing, placed either subretinally or epiretinally (adjacent to the nerve fiber layer). The latter, more common, prosthesis type is being pursued by an additional group in the United States – Harvard/MIT [9] – and by two groups in Germany: Intelligent Medical Implants AG (Fig. 69.5b) and a consortium of German universities [15]. All three groups have designed prototypes with 50 or more electrodes and wireless transmission to the freely moving eye, but only the IIP group has been able to test several such prototypes in a series of clinical pilot studies [16]. A number of other groups, most notably in Japan, Korea, and Australia, are experimenting with similar implant designs. Some of these groups seek to stimulate the retina from outside the eyeball, to avoid the risk associated with retinal surgery, while accepting the reduced resolution inherent in the greater separation between electrodes and target cells. Others are testing electrodes that penetrate through the scleral wall of the eye, in order to bring the stimulus charge as close as possible to the target cells.

The less common type of retinal prosthesis, a subretinal chip that uses photovoltaic elements for image capture in the location once occupied by the native photoreceptors, is conceptually simpler but in practice more challenging. In a primitive version [17] (Fig. 69.5c) of the subretinal array, a 2 mm-diameter silicon chip with approximately 5,000 small photodiode units was placed under the retina in 20 late stage RP patients with remaining central vision. These devices were located near the arcades, well away from the area of functional photoreceptors. The photodiodes converted incident light into small DC electrical currents and, while the precise mechanism of action of these currents remains to be elucidated, it appears that they may have caused secondary release of neurotrophic factors in the surrounding retina, which in turn exerted a beneficial effect on the remaining photoreceptors. This implant may therefore have preserved some remaining vision, but it did not substitute an image by stimulating the secondary neurons, as a prosthetic implant would.

A true prosthetic, photosensitive, subretinal implant does exist, however, by virtue of additional circuitry to provide signal amplification and pulse generation [18] (Fig. 69.5d). When

placed at the level of the missing photoreceptor/RPE layer, it collects a sharp image of the outside world, mediated by the eye's optics, and generates localized electrical impulses that stimulate nearby (bipolar) cells in the overlying retina. Such an integrated prosthesis has great simplicity and elegance, but its feasibility hinges on three important premises: that nutrients and oxygen from the inner retinal vasculature will suffice to nourish the retina overlying the implant; that external energy can be provided to drive the amplifier and pulse generation stages; and that the heat generated by the implant's electronics can be safely dissipated into the underlying choroid without appreciably heating the overlying retina. Developers of these systems have successfully demonstrated that solutions for these problems can be found, albeit that existing prototypes of the implant still use an external power supply. They have also designed surgical methods to safely insert large arrays of such units under the retina [19]. Clinical implantation for periods of up to a year have been carried out in several dozen patients, with positive functional outcomes reported [20]. A novel, integrated, subretinal prosthesis, developed by a consortium centered at Stanford University, circumvents the need for an external power supply by driving the implant with high intensity pulsed infrared light projecting a 'monochromatic' image of the scene onto the implant [21].

In addition to retinal stimulation, three other approaches to electrical stimulation of the visual system are being pursued. One of these is direct stimulation of optic nerve fibers, either through a set of electrodes mounted on the inside of a cuff placed around the optic nerve [22],

or through an array of penetrating electrodes placed on the inside of such a cuff [23]. Implantation around the optic nerve is surgically less invasive than placement of a device inside the eye, but it has the drawback that either large numbers of fibers are stimulated simultaneously (with the simple cuff), or correspondence between electrode location and retinal origin of the axon (and therefore location of the elicited phosphene in the visual field) cannot be predicted. Thus, selective stimulation of individual optic nerve fibers will require a sophisticated mapping system to establish the correspondence between visual field locations and individual electrodes. A second approach to an electronic visual prosthesis is through stimulation of cells in the lateral geniculate nucleus, an important relay station along the visual pathway. Access to the *lgn* is problematic, however, since in addition to the need for small openings in the skull, placement will have to be performed stereotaxically, similar to the placement of deep brain stimulating electrodes placed to reduce the effects of Parkinsonism [24]. Preliminary tests in rodents have shown the feasibility of this approach [25], but it is unlikely that major developments of this approach will occur in the near future.

The oldest attempts at vision restoration involved stimulation of the visual cortex through intracranial electrodes, controlled by external image acquisition and signal-conditioning circuitry. Several decades ago, Brindley and Lewin [26] took the first steps in this direction by implanting a set of electrodes over the visual cortex of a blind volunteer; the phosphenes described by this volunteer were similar to those elicited by intraocular stimulation. More recently, a team at the National Institute for Neurological Disorders and Stroke (NINDS) performed tests with over 30 electrodes penetrating the cortical surface [27], and scientists at the University of Utah experimented with implantation of denser intracortical electrode arrays in cat and monkey visual cortex [28] (Fig. 69.5e). The same group was also the first to perform simulation studies to establish minimum requirements for prosthetic vision [29], an approach followed by several other groups (for a review, see Dagnelie [30]). The cortical work that originated at NINDS is being continued through primate studies at the Illinois Institute of Technology [31] and through evaluation of unsuccessful previous attempts [32,33], in preparation for human implants in the near future.

The cortical prosthesis bypasses both retinal and optic nerve problems and might therefore be seen as a universal approach to vision restoration. Admittedly, it may be the only viable approach for patients whose inner retina and/or optic nerves have been destroyed by glaucoma or trauma. However, cortical stimulation requires complex surgery of an otherwise-healthy brain; moreover, the convoluted layout of the visual cortex complicates mapping of objects and locations in the outside world into a pixelized image that can be understood by the prosthesis wearer. Algorithms to establish such a map have been tested in primates [31] and through simulations in sighted volunteers [34], but thus far only for small sets of simulated phosphenes. Finding an efficient approach to mapping hundreds of phosphenes will be a crucial aspect of cortical implant research.

A final point of consideration for all visual prostheses for which the input image is acquired outside the eye is the altered role of eye movements. In natural vision, the intent of most eye movements is to bring an object of interest to the center of the retina, where it can be resolved with greater detail and receive directed attention. If a head-mounted or handheld camera is used for prosthetic image acquisition, movement of the camera rather than eye movements will recenter the image. To compensate for this difference, either the external portion of the visual prosthesis must be equipped with eye movement monitoring and processing capability to shift the image accordingly, or the prosthesis wearer must learn to suppress eye movements as a means to acquire visual information, and use camera (i.e., head or hand) movements instead.

Detailed reviews of visual prosthesis development and simulation studies can be found in Dagnelie [30,35,36].

Retinal cell transplantation

Cell transplantation in the neurosensory system can, in principle, restore function through two mechanisms: rescue of threatened cells (either by restoring a failing support system, or through trophic factors secreted by the transplanted cells) and replacement of degenerating cells and functional integration of the transplanted cells into the host tissue. Both mechanisms may play a role in retinal cell transplantation, and the distinction is not always obvious, as will become clear.

There are two important distinctions in the choice of transplant modality. First, there is the distinction between autologous cells — harvested from the same individual who is to receive them, typically following amplification and/or differentiation in tissue culture — and allografts — harvested from a different donor, who is typically unaffected and immunologically matched. Second, the developmental stage of the transplanted cells may range from pluripotent stem cells, to organ-specific undifferentiated cells, to postmitotic (e.g., photoreceptor precursor) cells. Since the range of possible approaches far exceeds the scope of this chapter, only major developments will be indicated; a recent review of stem cell approaches to retinal degeneration can be found in Tibbetts et al. [37].

Some important categories of retinal disease are mediated by loss of RPE function, and both transplantation of autologous pigment epithelium and allografts have shown success in rescuing photoreceptor function. In the Royal College of Surgeons (RCS) rat, rescue of photoreceptor function can be accomplished by replacement of the degenerating RPE with a wide range of transplants, from RPE xenografts (harvested in a different species) [38] to autologous iris pigment epithelium [39]. In human retinal disease, macular translocation surgery in AMD has demonstrated the feasibility of rescuing threatened vision by relocating the neural retina over a relatively healthy area of RPE [40], although visual outcomes of this surgical approach have been mixed and appear to be highly dependent on the surgeon's skill and experience. Immunologically mismatched RPE allografts and xenografts may not provide viable treatments in human retinal disease: Contrary to the neural retina, where immune response appears to be muted or absent, a slow inflammatory response to mismatched transplanted RPE tissue is commonly observed [41].

Such an inflammatory response is less likely to occur when the transplanted cells are grown *in vitro*. In the last few years, RPE replacement has shifted toward experimental procedures involving cultured RPE cells grown from pluripotent embryonic stem cells [42]. These cells, which can be grown in the laboratory under conditions meeting the standards of Good Manufacturing Practice, have now been awarded an Investigational Device Exemption (IDE) by the USFDA, and in 2011 entered clinical studies as a potential treatment for Stargardt macular dystrophy and dry AMD (http://www.clinicaltrials.gov: NCT01344993/ NCT01345006, date accessed July 10, 2013).

Retinal diseases that originate in a photoreceptor cell defect do not lend themselves to treatment with autologous cell transplantation, since the same defect is likely to plague the transplanted cells, unless these can be genetically modified prior to implantation. Since the mid-1990s, transplants with cell suspensions and organized sheets containing mature photoreceptors or photoreceptor precursors (with or without RPE) have been used therapeutically, with varying degrees of claimed efficacy. In a light-damaged rat model, morphological evidence of synapse formation [43] and behavioral evidence of regained function [44] were among the earliest indicators that transplanted photoreceptors may be capable of assuming visual function. More recent evidence in the same direction from other laboratories suggests that functional synapse formation is possible in some animal models, while in others a gliotic seal under the retina effectively inhibits integration of the transplanted tissue with the host retina [45]. The mechanisms responsible for such widely different results remain to be elucidated, but are most likely associated with varying

patterns of reorganization occurring in response to different retinal degeneration genotypes [46].

Fetal tissue has thus far proven more successful than fully developed retina or stem cells in forming synaptic connections and retinal morphology resembling that of intact retina, and it has become the tissue of choice in most transplantation attempts. This tissue also carries a lower risk of rejection by the host immune system, at least in photoreceptor grafts; indeed, rejection does not appear to occur in rat or mouse photoreceptor transplantation [47]. Admittedly, some caution in extrapolating this finding to other species is warranted, for immune reactions in rodents tend to be less severe than in humans. The use of fetal tissue for research and transplantation purposes is subject to legal and ethical concerns in a number of countries, and this is an important reason for continued efforts to develop transplantation techniques that use adult donor tissue.

Preliminary attempts at retinal cell transplantation in blind volunteers, performed primarily to demonstrate safety, have yielded mixed, and at best modest, results. Allografts of cultured RPE appear to provide protection to functional AMD through trophic factors, but in exudative AMD the graft is quickly overwhelmed by an inflammatory reaction [48]. Photoreceptor transplants appear to convey an improvement in vision in some cases [49], but whether this is mediated by graft-host synapse formation or trophic support to the few remaining photoreceptors cannot be distinguished [50].

The ciliary body in the human eye contains pluripotent stem cells that will, under appropriate conditions, differentiate into retinal neuron precursors [51]; hence, the potential for photoreceptor cell replacement from tissue culture does exist. At this time, however, any attempts to use bone marrow and retinal stem cells to replace degenerating photoreceptors in human patients through injection into the vitreous or subretinal space, as repeatedly claimed in the popular media, seem highly premature. Without thorough research in animal models of retinal degeneration, and until photoreceptor cells can be cultured with the same level of control as has been achieved for RPE cells, it is unlikely that such attempts will lead to effective and reliable vision restoration, or even to long-term survival of the remaining photoreceptors.

Optic nerve protection and regeneration

RGCs behave as central nervous system neurons in their inability to recover from severe injury: RGCs whose axons are damaged by cutting or crushing the optic nerve undergo apoptosis within days following injury, although this particular mechanism of cell death may be restricted to certain classes of RGC [52]. And while the axons of peripheral (motor or sensory) neurons can regenerate following surgical reconnection of nerve fascia, CNS neurons appear to lose such plasticity once their original outgrowth during the organism's development is completed, due to changes in both their internal makeup and their environment. Oligodendrocytes that form the protective myelin sheath around optic nerve axons and astrocytes appear to play a major role in preventing axon regeneration following injury [53]. It has been known since the 1980s, however, that this environment can be effectively modified. Cut optic nerve axons in the rat and cat will not form new neurites in their natural optic nerve environment, yet they can be made to regenerate into a peripheral nerve graft and reach the superior colliculus [54–56]. Two basic steps are thus necessary for therapeutic intervention in advanced optic nerve disease to become a reality: protection of RGCs from apoptosis following severe damage to the optic nerve, and axon regeneration, including formation of functional connections at the thalamus and other midbrain structures. In recent years, a third aspect, functional enhancement of remaining RGCs, has been added to the basic glaucoma research repertoire [57].

Studies in the last decade have provided encouraging indications in both areas. Intravitreal injections of anti-apoptotic drugs and neurotrophic factors can limit the loss of RGCs

and prolong the window for application of other therapeutic modalities [56]. Most of these therapies are aimed at preserving the RGC soma so that it can sustain a partially damaged axon, but there is still a need for targeted therapies that can either repair damaged axons or stimulate new axon growth [58]. Some progress is being made in stimulating axonal growth: Oncomodulin has been identified as a factor that is particularly effective in promoting growth following optic nerve crush [59]. In addition, there is increased interest among researchers in free radicals, immune response, and nerve growth factors in the retina remaining unbalanced even after the primary causes of glaucoma (such as increased intraocular pressure) have been treated [60].

Drug delivery

Since 1995, our understanding of photoreceptor and RGC death has changed dramatically. While it was previously thought that these cells die because a functional part — the photoreceptor outer segment and the axon, respectively — becomes dysfunctional, both events are now widely understood to trigger cell death through apoptosis and similar mechanisms. Better understanding of these mechanisms has led to the search for pharmacological interventions that may prevent cell death.

The process of RGC degeneration following transsection or crushing of the optic nerve can be halted, at least in animal models, with the use of neuroprotective agents such as neurotrophin-4/5 (NT-4/5) [61]. It turns out, however, that this protection has only a limited duration. Most RGCs die within two to four weeks, even with sustained administration of NT-4/5 [62]. Various other neuroprotective strategies have been attempted in animal models, but their long-term efficacy as well as the feasibility of long-term delivery near the threatened site remains to be demonstrated.

In the case of photoreceptor degenerations, a variety of nerve growth factors and neuroprotective agents have been used, both *in vitro* and in animal studies, and several of these have shown promise [63]. What remains to be worked out for most of these substances is the optimal delivery route. Systemic administration is not an option, since many of these agents do not easily pass the blood-retina barrier and/or have unwanted systemic side effects. Administration as an eye drop is not effective, because the active substance would need to diffuse through the cornea or sclera, and most of it would be washed away in the tear film. Repeated injection into the vitreous is unattractive to the patient, and it is not clear how long the active substance would persist in the eye and reach the outer retina.

Three relatively recent delivery techniques have all been successfully applied to ocular drugs in recent years: delivery by macromolecules, slow-release implants, and encapsulated-cell technology. The first of these approaches caused a revolution in the treatment of exudative AMD about 15 years ago, and is now widely known as photodynamic therapy (PDT). Liposomes with an embedded anti-angiogenic substance (verteporfin) are injected into the bloodstream, and irradiation of the retina with a low-energy laser beam is used to release verteporfin in the choroidal space under the retina. The resulting oxygen free radicals attack vascular endothelial cells and stop angiogenesis [64]. Unfortunately, this endothelial-cell cytotoxicity is not an effective long-term treatment, so, following the demonstrated safety of locally administered vascular endothelial growth factor (VEGF) inhibitors, PDT has now been replaced as the treatment of choice by intravitreal injections of such substances (notably Avastin, and Lucentis) [65], even though such injections have to be repeated, in most cases several times over a six month period. The longer-term outlook for these substances is very good. They can be embedded in poly(lactic-glycolic) acid (PLGA) microspheres to create slow-release implants that could be inserted into the eye through a small incision and attached to its inside wall, or they may even be effective when placed on the outside of the eyeball [66]. The third delivery method, encapsulated-cell technology (ECT), is elegantly exemplified by the NT-501-permeable-membrane delivery system developed by Neurotech

SA (Lincoln, RI). When loaded with a transgenic cell line producing ciliary neurotrophic factor (CNTF) and implanted in the vitreous cavity, it will release a flow of CNTF for many months [67]. Applications are sought in the area of photoreceptor protection in retinal degenerations; a Phase I trial in retinitis pigmentosa has been completed successfully [68], follow-up studies in RP and AMD have shown modest positive results, and several other clinical trials using NT-501 as a treatment for retinal diseases are planned or on-going.

In some diseases, even the simplest of drug delivery may be effective. In retinal ischemia, just as for other vascular blockages, 'clotbuster' drugs, such as tissue plasminogen activator, can be intravenously injected. If this is done soon (hours or even days) after the ischemic event, much of the damage may be prevented; experimental therapy with these drugs has had promising results [69].

Genetic interventions

Delivery issues also play a role in the introduction of new genes into the degenerating retina. Most retinal degenerations are genetic in nature, either inherited from one or both parents or caused by a new mutation. The premise of gene therapy is that intervention at an early stage may restore normal function to the cell and prevent the degeneration process that might otherwise ensue. Several strategies are needed to combat inherited retinal degenerations.

- In recessively inherited diseases, both copies of a gene are defective, and introduction of a third copy may be sufficient to achieve adequate production of a functional protein to replace the defective one encoded by the mutated gene. A virus is used to introduce a healthy copy of the gene. Following a number of demonstrations of successful gene transduction into RPE cells and photoreceptors *in vitro* and feasibility studies in rodents, a highly publicized study of vision rescue in a canine model of Leber congenital amaurosis (LCA) [70] provided proof that gene therapy for some human retinal degenerations may soon be a reality. Since then, several small trials in children with LCA have demonstrated some improvements in ambulatory vision, but limited long-term treatment effects; for a review, see [70a].
- In X-linked disease, males carry only one copy of the X-chromosome, including the defective gene; here, too, introduction of a healthy copy of the gene may be enough to achieve normal function.
- In dominant disease, a single bad copy of the gene suffices to 'poison' the delicate balance of the cellular machinery, or, at the very least, to prevent its proper function. To reduce or prevent this, a therapeutic intervention must block a step along the transcription pathway from the defective gene to its product protein but not inhibit expression of the good copy of the gene; a gene for such a blocking agent could, in principle, permanently neutralize the defect. This technique has been used in a transgenic rat model, using ribozymes to destroy mRNA produced by the P23H mutant gene defect responsible for one form of autosomal dominant RP [71]. In a rat model with a naturally occurring degeneration, a gene for ribozyme production was successfully introduced into photoreceptors and proved effective even when introduced at a time when many photoreceptors had already succumbed to the effect of the defective rhodopsin gene [72], which bodes well for therapeutic interventions in dominant RP. These forms of RP tend to preserve substantial levels of vision into middle age, and this remaining vision might thus be rescued.
- An entirely separate class of retinal degenerations, typically asymptomatic until middle age and often associated with multisystem disease, is caused by mutations of the maternally inherited mitochondrial DNA, responsible primarily for cellular energy supply. Mitochondrial DNA has multiple copies, and it remains unclear whether single or multiple copies are responsible for these disorders. Moreover, the mitochondrial DNA does

not lend itself to normal viral transduction techniques, which adds a level of complexity to potential gene therapeutic approaches. Recent reports suggest that proteins may be used to deliver expression-blocking factors or new functional genes into the mitochondrial milieu [73].

Vision-related gene therapy research is concentrated around RP, Stargardt macular dystrophy, LCA, and related diseases with known inheritance patterns. Due to the multiple genes that can lead to these disorders and the enormous number of specific mutations that have already been identified, many gene therapeutic variants will be needed to address a substantial proportion of these disorders. This is an extremely active area of research; recent reviews can be found in Farrar et al. [74] and Smith et al. [75].

Still, this means that a true cure may become available for these retinal degenerations. AMD and optic nerve diseases like glaucoma and ischemia, on the other hand, have no known genetic causes, though some genes associated with predisposition for such diseases have been identified. Genetic interventions may assist in preventing some forms of these diseases, but the prospects of other therapeutic approaches are more promising in the near term than those of gene therapy.

EMERGING APPLICATION AREAS FOR ENGINEERED CELLS AND TISSUES

Of the current approaches to vision enhancement considered earlier, strictly speaking only the use of stem and transgenic cells falls within the realm of tissue engineering. The complexity of ocular structures such as the retina and optic nerve poses daunting challenges to anyone seeking to recreate their function. While this may explain the lag in progress when compared to other organ systems, it should not keep the researchers who are working to restore vision from drawing on the remarkable progress of tissue-engineering approaches. We next briefly consider four application areas, corresponding to the aforementioned three processing stages in the early visual system where severe vision loss may occur and the supporting retinal infrastructure.

Photosensitive structures

Current efforts in the areas of retinal cell transplantation and intraocular prosthesis design, while promising, are in no way guaranteed to lead to reliable — i.e., long-term and stable — restoration of useful (let alone high-quality) vision. As was explained earlier, each of the approaches currently being explored has inherent drawbacks. Implanted electrode arrays require external image acquisition and preprocessing, which may necessitate real-time eye movement tracking and compensation. Integrated implants require signal amplification and thus external energy supply. Both implant types may be limited in resolution to ambulatory vision due to the 100 to 200 μm distance separating the electrodes from the target cells. As a rule of thumb, resolution in the underlying tissue will be no better than this distance. Retinal cell transplantation efforts are likely to be limited by the spotty record of transplanted cells in making functional contacts with the native inner retinal circuitry. And all three approaches are limited by microneuroma formation, destroying the functional diversity of the inner retina and limiting its resolution to 50–100 μm, i.e., at best 20/200 visual acuity — legal blindness.

To achieve improved retinal prosthetics, electrodes will have to make more intimate contact with the target cells. If successful, this would improve resolution to the limit imposed by the repatterned inner retinal neuronal circuitry. One can envisage such a penetrating array as the Normann microelectrode in Fig. 69.5e, but the damage such an array might do to the delicate microvasculature of the retina is a distinct disadvantage. As an alternative, one might envisage inserting or growing, *in situ*, an array of parallel 'neurites'. These might branch out of cells

grown on the surface of implanted stimulating chips, penetrating the retina until they reach a specific target environment, e.g., the inner nuclear layer, where they would make synaptic contacts with the native cell population; these neurites would act as 'tube electrodes', releasing either electrical charge or a neurotransmitter that would activate the target cells. An alternative approach would be an electrode structure that stimulates nearby retinal cells to form new neurites, spurred on by favorable growth conditions and a coating on the implant. Such coatings promoting cell growth, formed by microcontact printing, are under investigation [76].

The distance between implant and target cells could also be reduced by enticing native retinal cells to migrate toward the electrode surface, adding a new twist to the cell migration seen in naturally occurring retinal repatterning [46]. Such approaches are not as farfetched as they may sound. Several groups are experimenting with surface modifications on semiconductor chips that will allow cells to adhere to these surfaces and be activated by neurotransmitters [77], while researchers at Stanford University have reported the tendency of retinal neurons to migrate around pillar-shaped electrodes forming an array placed under the photoreceptor layer (Fig. 69.6) [78]. Combinations of such technologies may lead to improved implant-tissue interfaces.

A fundamentally different approach to improving (sub)retinal prostheses may be the use of high-yield photoconversion systems. Such high-yield conversions are known to be performed by Photosystem I (PSI), a macromolecule present in the membrane of thylakoids, which can be found inside the chloroplasts that give the green color to plant leaves and algae. Early experiments with thylakoids [79] showed that it is possible to anchor these structures onto a metal surface and use them as miniature photovoltaic elements. Lee et al. [80] also demonstrated that it is possible to chemically modify thylakoid surface membranes to create charge displacement in a specific direction. Kuritz et al. [81] demonstrated the ability

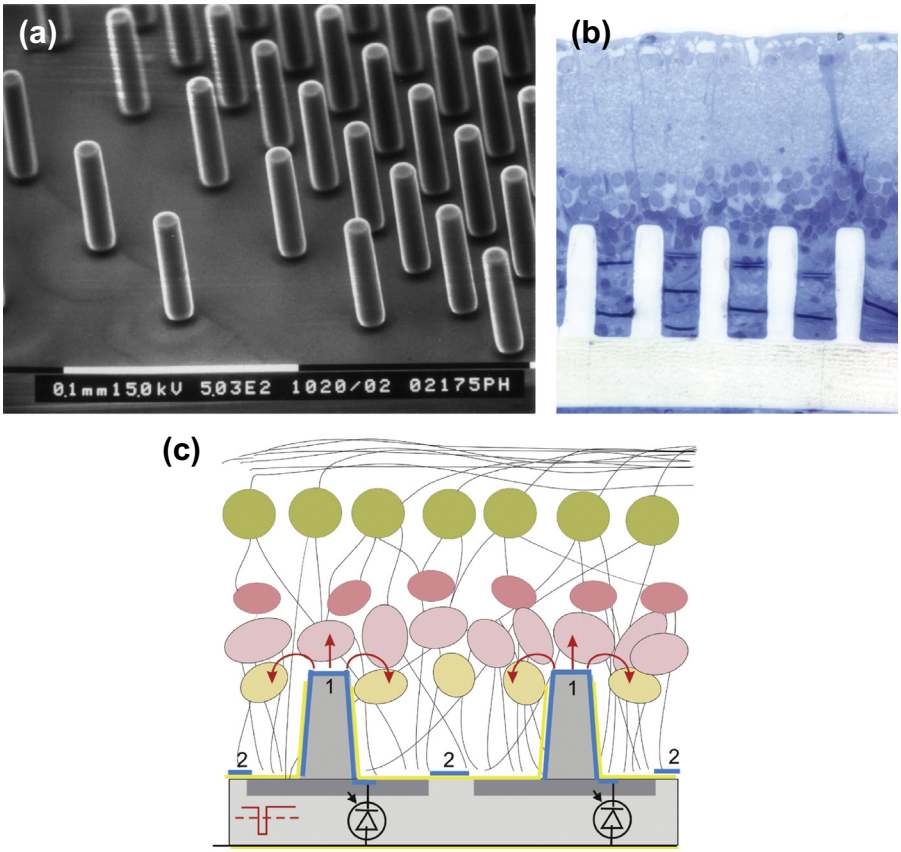

FIGURE 69.6
Pillar electrodes penetrating into the middle of the inner nuclear layer of degenerated retina. (a) Electron micrograph of an array having pillars of 10μm in diameter and 70μm in height. (b) Histology of the RCS rat retina with a pillar array six weeks after implantation. (c) Schematic of a retinal prosthetic: retinal cells in the inner nuclear layer stimulated by pulsed electric fields emanating from the exposed tops of the pillars. Images provided by Daniel Palanker. Ph.D., Stanford University.

of PSI to impart photosensitive polarization and Ca^{2+} ion movement to retinoblastoma cells in tissue culture, as a first example of cellular engineering that may eventually lead to artificial photoreceptors. The engineering successes of thylakoids and PSI open the opportunity to create cells that assume a dipole charge distribution or, with the help of some form of intracellular electronics, produce a biphasic pulse between the 'poles'; in a subsequent stage of development, automatic gain control could be incorporated, as a limited form of light/dark adaptation. If these cells can be made to attach to the outer retinal layers or to migrate into the inner nuclear layer, one could achieve microscopic local current sources with sufficient conversion efficiency to ensure vision at a broad range of (day)light levels. To achieve true night vision, an external device, such as a night vision scope, could be used.

Note that in this idealized situation, the synthetic 'photoreceptors' might be small and sensitive enough to provide good vision without external image preprocessing (e.g., magnification and contrast/edge enhancement). It is to be expected that preliminary forms of such light-sensing units will be neither small nor sensitive enough to provide the dynamic range and resolution required; at this intermediate solution level, external image processing with an advanced portable low vision visor would be a necessary complement to this intraocular light conversion array.

Optogenetics

Since 2006, research into sight restoration has been exploring the prospects of conveying artifical phototransduction to the cell membrane of retinal neurons [82,83]. These optogenetic approaches, as termed by Deisseroth et al. [84], introduce DNA to the target cells which codes for proteins reacting to certain wavelengths of light by depolarizing or hyperpolarizing the cell. The two primary proteins used in this research are channelrhodopsin-2 (ChR2) and halorhodopsin (NpHR), although melanopsin [85] is also considered a candidate for gene therapy.

Neuron depolarization is achieved by stimulating ChR2. This protein is a microbial-type rhodopsin from the green alga, *Chlamydomonas reinhardtii*. Nagel et al. [86] found ChR2 to be a plasma membrane channel that passively conducts both mono- and divalent cations upon capture of a photon by its attached chromophore. Similar to melanopsin ($\lambda_{max} = 480$ nm), ChR2 has an absorption peak at approximately 460 nm [86].

Conversely, neuron hyperpolarization can be achieved by stimulating NpHR. Originally thought to be an outward-directed cation pump, Schobert et al. [87] identified halorhodopsin as an inward-directed Cl^- pump. Although these experiments were performed on halorhodopsin from *Halobacterium halobium*, a variant (NpHR) from *Natronomonas pharaonis* is used for current experimentation because of its higher affinity for extracellular Cl^- [88,89]. Both forms of halorhodopsin absorb light at longer wavelengths than ChR2, with λ_{max} at approximately 580 nm. The two labs simultaneously reported the use of NpHR to optically hyperpolarize neurons.

These tools can be delivered to retinal cells by a variety of methods. The most widely used delivery system is that of adeno-associated virus type 2 (AAV2) vectors. These vectors were first reported for human preclinical gene therapy trials by Flotte et al. [90], applied to cystic fibrosis. Since then, the use of AAV2 for human gene therapy has expanded to cover a number of conditions [91]. Encouragingly, Simonelli et al. [92] reported the use of AAV2-based treatment for LCA with maintained single-dose efficacy and no serious adverse events as of 1.5 years post-treatment.

Bi et al. [82] injected AAV2, loaded with ChR2/GFP coding attached to a strong ubiquitous promoter, into the intra- and subvitreal spaces of mice. The authors found expression of the ChR2/GFP chimera in ganglion, amacrine, horizontal, and to a lesser extent, bipolar cells of the retina. Light responses were confirmed by whole-cell patch clamping in retina slices and

visually evoked potential (VEP) recordings from the visual cortex of otherwise blind mice. These authors further demonstrated that even non-specific transduction of ChR2 in degenerated retinae can produce light responses in the visual cortex. The quality of such information reaching cortex, however, may not be particularly meaningful. Specifically, the simultaneous activation of pathways that normally exhibit direction selectivity, lateral inhibition, and ON, OFF, or ON-OFF responses would likely generate a highly corrupted image of the original signal.

One way to avoid such signal corruption would be to limit the classes of cells that receive photic input. Busskamp et al. [93] reported transducing surviving cone cell bodies with eNpHR [94], a variant of NpHR with improved cell membrane localization. The target cones were in mouse models of RP and in human *ex vivo* retina explants. In mouse models, the authors demonstrated that such cone transduction could create light responses in the retinal network that display lateral inhibition, direction selectivity, and ON and OFF responses. Live mice with transduced cones also displayed visually guided behavior. In human retina explants, the authors showed that their AAV2 delivery method successfully transduces human cones, and results in the generation of photocurrents indicative of eNpHR activity. Although cone transduction would not be a viable treatment for patients with too few remaining cones, the authors identified an existing population of RP patients that had some remaining cone cell bodies, despite the apparent loss of their outer segments.

Another set of targets for cell-specific transduction in the retina are ON bipolar cells. While there is no promoter that is known to specify OFF bipolar cells [93], ON bipolar cells can be targeted using the promoter for the gene encoding the metabotropic glutamate receptor, mGluR6 [95,100]. Although not as advantageous as stimulating the retinal network from the level of the cones, specifying ON bipolar cells should allow for signals far less corrupted than one would expect from indiscriminate stimulation. Doroudchi et al. [95] used AAV2 to transduce ON bipolar cells in mouse models of blindness with ChR2. The authors observed ON-type retinal ganglion cell responses and visually guided behavior in the test animals. Unfortunately, Fradot et al. [96] performed a similar experiment in human retina explants, in which only a very small portion of ON bipolar cells was transduced. More efficient promoters and/or delivery methods will need to be explored before useful, selective transduction of ON bipolar cells can be realized [83,96].

While AAV2 delivery has been shown to be very productive, a number of researchers are doubtful of its practical use in the clinic. Specifically, the use viral vectors may introduce its own risk of immune responses, and it imposes limits on the size of DNA packages to be delivered [97]. Parallel to research using AAV2 vectors are experiments that generate pores in target cells through which desired genetic material can be absorbed. These pores can be generated using electric fields [98] or a femtosecond-pulsed laser beam [102].

In 2008, Lagali et al. [100] used electroporation to transfect ON bipolar cells of mouse models of retinal degeneration. Actually predating the analogous AAV2 experiments, these authors also observed expected ON ganglion cell responses and optomotor behavior, as well as center-surround organization and cortical responses. There is no indication, however, whether electroporation would have any more success than AAV2 at transfecting human ON bipolar cells. More recently, Gu et al. [101] also transfected ganglion cells with ChR2 in mouse models of retinal degeneration, generating visually guided behaviors.

Electroporation, by its nature, acts over a relatively wide area and does not offer more spatial specificity than AAV2 vector delivery. Should the treatment be aimed at specific parts of the retina, as in RP patients with remaining central vision, a more focal method of transfection may be desirable. By applying a 10^{12} W/cm 800 nm laser beam using femtosecond pulses, researchers can create transient perforations in specific cells through which DNA can enter [99].

Gu et al. [101] used this optoporation to transfect RGCs of goldfish with ChR2. Using multi-photon targeting, the authors were able to specify the 3D location of each pore, which had

radii of approximately 400 nm, and were laid out in 3 μm intervals over the targeted area. In a follow-up study, Villalobos et al. [102] transfected retinae of the same species using both optoporation and photothermal poration with carbon nanoparticles. Stimulation through ChR2 was observed by intracellular calcium imaging.

Separate from these experiments on targets and delivery methods, Nirenberg and Pandarinath [103] recently addressed the issue of optogenetic signal fidelity using a computational approach. Unlike other groups discussed here, these authors bypassed the typical issue of transfection by generating mouse lines that both were models of retinal degeneration and possessed ChR2-expressing RGCs. To determine proper stimulation parameters for these ganglion cells, the authors observed the spiking patterns of different classes of ganglion cells from normal retinae in response to movies with both natural and artificial scenes. Using these data, they constructed encoders, specific for each type of ganglion cell, which combined to model the signal processing performed by the normal retina. The models were data-driven, in that parameters for each model were chosen so the output for any given input would have the highest probability of matching actual retinal spike trains, as tested by cross-validation.

Nirenberg and Pandarinath stimulated the retinae of blind mice using either patterns generated by their encoder or the unprocessed spatial patterns of the stimuli. The authors demonstrated that cells stimulated by the encoder's patterns more closely matched the firing patterns of normal retinal neurons. Further, the authors used a drifting grating on an LCD screen to elicit optomotor tracking, which was only possible when the stimulus was presented though the stimulation encoder. No tracking was observed with the unprocessed stimulus or in control animals. These data imply that, although cerebral cortex is plastic, meaningful perception of visual information may depend on the preservation of the neural code normally exhibited by the retina.

For clinical purposes, Nirenberg and Pandarinath acknowledge that it may not be practical to target multiple classes of ganglion cells, each receiving its own coded version of a given stimulus. They do argue, however, that targeting a single ganglion cell class, with proper encoding, may be sufficient to provide more faithful percepts than those generated by conventional stimulation patterns. Their experiment inducing optomotor tracking, in fact, only utilized transient ON cell encoders.

Once applied to human subjects, optogenetic approaches to vision restoration may outpace less target-specific electrical retinal processes. Reactivation of cone remnants using NpHR could provide many benefits related to intrinsic retinal processing. For patients in whom such treatment would not be viable, stimulation of bipolar cells, or of ganglion cells in the fashion described by Nirenberg and Pandarinath, could provide similar benefits. To introduce light-sensitive properties into the target cells, electro- and optoporation may offer new avenues of treatment, should cases arise in which AAV2 vectors are insufficiently effective or specific to use as a delivery system.

Outer retinal cell transplantation

Despite almost two decades of careful investigation, reliable and widespread formation of synapses between transplanted photoreceptor precursors and native inner retinal cells — and thus full integration of the transplanted cells into the host retina — has remained elusive. Also, the effects of the host immune response on graft survival — especially of transplanted RPE — cannot be ignored, even if it appears to be mild, and this host reaction will have to be effectively controlled without long-term systemic immune suppression. Both areas can profit from tissue-engineering approaches. A complex set of conditions — cells in the proper stage of development, properly matched to the host retina, and spurred on by a proper combination of neuroprotective and neurotrophic modifications to the host environment — needs to be met for successful graft-host integration. Recent reports indicate that even

widely held beliefs regarding the proper developmental stage of the transplanted cells may need to be revisited. In a mouse model, early postnatal photoreceptors showed widespread synapse formation with native retinal cells [104], whereas most previous research has been directed at the use of postmitotic photoreceptor precursors in a much earlier stage of development.

Even if the cell population affected by the primary degeneration process is successfully replaced, secondary degeneration stages — of RPE cells in photoreceptor degenerative disease and of photoreceptors in RPE degeneration — may still prevent restoration of visual function. This problem can be addressed adequately only by performing a combined graft of RPE and photoreceptors, presumably prepared in a tissue culture environment and stimulated toward integration through a carefully tuned combination of neuroprotective and neurotrophic factors. Culturing stem cells or differentiated cell lines might allow the creation of heterogeneous structures such as RPE/photoreceptor double-sheets. Culture conditions and the growth stage of these sheets should be modulated to prepare the cells for integration with the host retina. In order to provide sufficient structural support to these fragile sheets during growth and transplantation, a resorbable polymer layer could be used as a substrate.

Cell matrices supporting axonal regrowth

Cell culture conditions and retinal integration alone will not be sufficient in the case of ganglion cell transplantation with the objective of repopulating the optic nerve with axons carrying visual information to the brain. As discussed earlier, this will require the (re)-creation of conditions favorable for axonal growth over distances of many centimeters and the ability of sprouting axons to contact target cells with the correct retinotopic mapping. This feat is accomplished effortlessly by RGC axons in the developing embryo, but to recreate the conditions for this to occur in an adult organism will be a considerable challenge.

As was noted earlier, an RGC axon damaged by glaucoma, optic nerve disease, or injury can only form new neurites under optimal environmental conditions, which essentially mimic those in a developing organism. At the same time, neuroprotective factors are required to sustain the RGC long enough for the axon to assume this support function. If the glaucoma diagnosis is made early and safe and effective neuroprotective agents become available, it may be possible to save most of the threatened axons and thus spare most RGCs and the patient's vision. In practice, however, many axons may have been lost by the time the diagnosis is made, and protection of the cell somata and stimulation of axon regrowth become the treatment objectives [105]. The experimental conditions employed thus far, using peripheral nerve sheaths to create a substrate for axonal regrowth, are less than ideal, because they do not provide an integrated environment in which regrowing axons combine with intact remaining axons and in which protection of the threatened RGCs is built into the environment. This is a very active field of research, offering great potential for tissue-engineering approaches, and one may expect such approaches to play a major role in achieving these objectives. Understanding the necessary conditions to create an integrated environment for axonal regrowth and creating novel synthetic materials to provide these conditions should provide wonderful challenges to tissue engineers.

One approach to such an integrated solution might be that engineered cells could be grown *in situ*, as a loose skeleton of supporting tissue, to follow the course of the optic nerve to the chiasm and optic tract; these cells would be programmed to exude the necessary factors promoting axon growth and RGC protection. Alternatively, it might be possible to modify the normal environment of the optic nerve (temporarily) to allow or even stimulate axonal growth. Assuming that it would be possible to guide outgrowing axons through the optic

chiasm toward the appropriate structures and retinotopic projections in the midbrain, RGCs may restore their connections to the target cells and resume functional visual processing.

Repopulating ischemic or diabetic retina

As mentioned earlier, new capillaries — formed under the influence of an angiogenic tissue response — tend to be poorly organized and fragile, causing leakage and thus a great deal of damage to the already stressed retinal tissue. Therefore, the prospects of restoring vision in such retinal areas are, at the present time, poor.

This may change, however, if cell populations can be grown *in vitro* and introduced into the retina under physiological conditions mimicking those during embryonal development. In that case the formation of new blood vessels could follow a more orderly pattern, and implanted cells would have a much better chance of forming functional connections. Whether and when it will be possible to recreate embryonal conditions and grow such integrated retinal tissue as is required to restore vision to an ischemic portion of the retina, from RPE to RGC axons, is difficult to predict. It is a challenge whose magnitude exceeds that of RPE/photoreceptor transplants, functional stimulation of inner retinal cells, and RGC protection/axonal regrowth combined.

Assessing the functional outcomes of novel retinal therapies

Electrophysiologic assessment of the functionality of a therapeutic intervention is considered a gold standard by many researchers and clinicians, but recording the responses in eyes that have undergone experimental treatments may not always be feasible. Retinal implants are in the unique position that they allow clinical functional evaluation directly from the implant provided the necessary signal collection hardware is available. This is exemplified by developments in cochlear implants. Cochlear implants have been clinically approved in the US since 1984 [106], and over the years advanced built-in electronics based on reverse telemetry [107] have been developed to record electrically evoked auditory nerve responses (electrically evoked compound action potentials, or eCAPs). eCAPs are recorded by stimulating the auditory nerve through a subset of electrodes in the implant array and recording the elicited neural activity at a more distant electrode. The recorded data is sent back through the same wireless radiofrequency link that is used to stimulate the implant. eCAP recordings are nowadays routinely applied intra-operatively [108], enabling the surgical team to assess functionality of the implanted device while the patient is still under general anesthesia. In addition, eCAPs are being used for rehabilitation purposes such as automated device fitting [109,110] and fitting of cochlear implants in young children [111,112].

The visual equivalent of the eCAP is the electrically elicited electroretinogram (eERG), which could fulfill similar purposes to the eCAP. However, none of the present retinal implant systems, such as the Argus® II device, has reverse telemetry capabilities sufficient for recording the eERG. Recording the eERG with standard Electroretinogram (ERG) methods such as corneal electrodes is difficult, due to the small signal amplitudes and the presence of electrical as well as physiological artifacts in the eERG signal [116]. Electrical artifacts generated by the implant can be effectively reduced by using filtering techniques such as stationary wavelet transformation [113–116]. Physiological artifacts are more difficult to deal with, because filtering techniques reducing these contaminations will inevitably also reduce the retinal responses of interest. In a recent conference presentation reporting on recordings from monocularly implanted Argus II recipients [116], it was demonstrated that a physiological artifact attributable to pupil innervation responses in both eyes can be largely eliminated through subtraction of the contralaterally recorded pupil response from the combined retinal+pupil response recorded at the implanted eye (Fig. 69.7). Although the decontaminated corneal responses have the predicted negative polarity, and show increasing amplitude with increasing stimulus level, their retinal origin remains to be definitively confirmed. It is likely

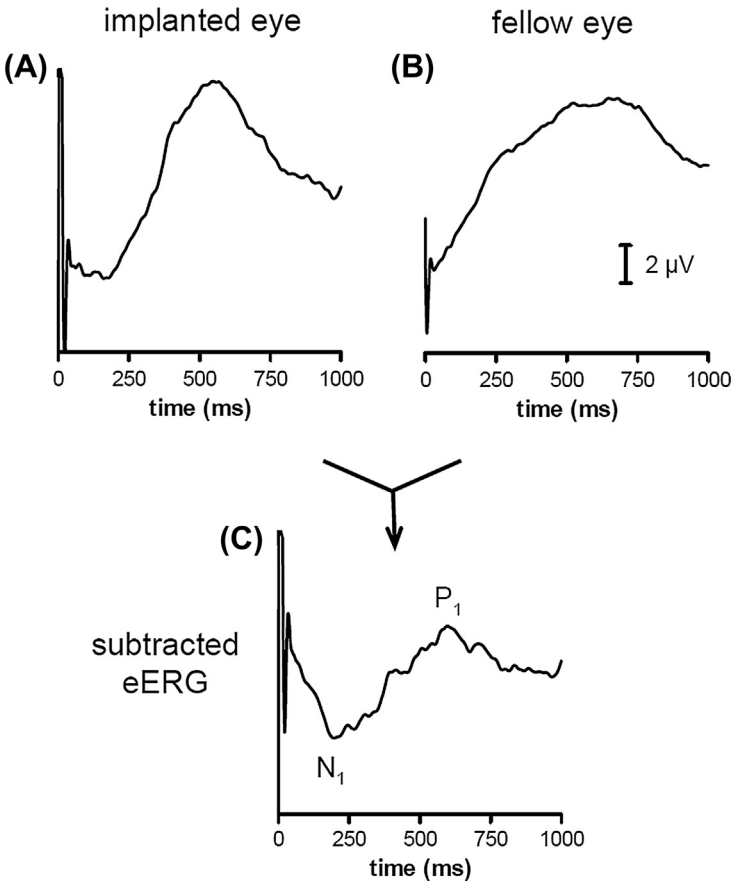

FIGURE 69.7
Electrically elicited electroretinograms (eERGs) evoked by unilateral stimulation of the implanted eye and recording the eERG bilaterally (a, b). The decontaminated eERG (c) was obtained by mathematically subtracting the physiological artifact recorded from the fellow eye.

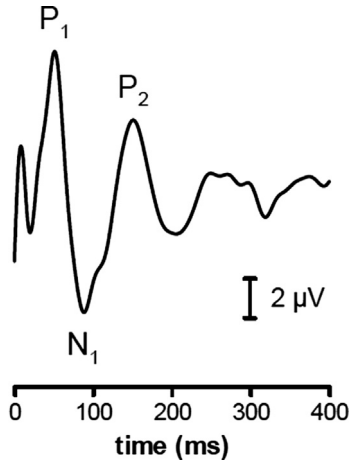

FIGURE 69.8
Cortical response of retinal implant stimulation: the electrically elicited visually evoked potential (eVEP).

that this confirmation will have to await direct recording, with high temporal and dynamic resolution, from implant electrodes through improved telemetry.

In the interim, cortical responses, i.e., electrically elicited VEPs (eVEPs) recorded from the scalp, can provide a promising alternative [117,117a] to retinal responses. Cortical [118] and brainstem [119] responses have been used to assess cochlear implant function, but eCAPs are applied more widely, due in no small measure to the availability of high-quality reverse

telemetry systems [120]. Nevertheless, advantages of cortical over peripheral potentials include the fact that cortical responses represent central nervous system activity (V1 in case of eVEPs), and may provide a more accurate indication of perception than eERGs. In addition, eVEPs can also be applied in case of visual prostheses implanted in the optic nerve [121] or central nervous system; are relatively easy to record; show the expected dependence on stimulus level; and accurately reflect subjective threshold [117a]. Unfortunately a single eERG or eVEP recording can take up to 15 minutes to complete, using current technology, thus limiting the usefulness of this approach at the present time. For the eERG and eVEP to be of clinical value, recording times will have to be substantially reduced; once this is accomplished, these recordings can be used in a similar fashion as is currently the case for eCAPs in cochlear implants.

CONCLUSION: TOWARD 2020 VISION

The potential applications of tissue engineering sketched in the previous sections pose enormous challenges, well exceeding the competency of any single group or institution. Concerted research efforts by multidisciplinary groups may allow the implementation of the complex systems required to restore and enhance vision. As researchers improve, on the one hand, their fundamental understanding of processes such as photoconversion, graft integration, immune regulation, and neuroprotection and, on the other, the engineering ability to control tissue properties and neurite growth, both *in vitro* and *in situ*, crude but functional vision restoration at the RPE/photoreceptor level and at the RGC level may advance to the level of experimental and even clinical therapy. Integration of all these areas to recreate the full range of retinal processing is a much more distant goal, for which the header of this section may well be too ambitious.

To accomplish any of these forms of vision restoration, however, funding mechanisms for multidisciplinary research and interest from the corporate sector will have to rise well beyond their current levels. While the number of severely visually impaired individuals and the economic impact of vision restoration alone may not justify that these approaches receive priority over treatment of life-threatening conditions, the investment required is relatively modest, and the improvement in quality of life for (nearly) blind patients can be very significant.

CHAPTER 70

Biological Tooth Replacement and Repair

Anthony J. (Tony) Smith[1] **and Paul T. Sharpe**[2]
[1] Deputy Head of School of Dentistry, University of Birmingham, Birmingham, UK
[2] Craniofacial Development and Stem Cell Biology, Dental Institute, Kings College London, London, UK

INTRODUCTION

Teeth might not at first seem an obvious organ for which to develop biological methods for replacement or repair. Teeth are non-essential organs, and modern dental treatments enable most dental problems to be treated using traditional non-biological approaches. Teeth do, however, offer unique opportunities to develop tissue-engineering-based approaches on an organ that is not only easily accessible and non-life-threatening but one where there are very large patient numbers and a significant clinical problem. The challenges of developing methods needed to restore and repair complex organs are immense, but the biggest challenge will be the testing of any such organs on patients. Patients requiring repair or replacement of major internal organs (heart, liver, lungs, pancreas, etc.) are by definition likely to have a serious illness. Access to these organs requires major surgery; should the treatment fail, the consequences will be severe and life threatening. Teeth do not present any such problems and thus provide an opportunity for the proof of concept to be tested safely, with little chance of danger to the patients.

Although there are an increasing number of alternative treatments in dentistry, most are non-biological and many are based on techniques that have been practiced for thousands of years. Dental implants, for example, involve the replacement of missing teeth with metal rods that are screwed into holes drilled into the jawbone. The practice of replacing missing teeth with metal implants can be traced back to the ancient Romans and Egyptians [1,2]. The number of dental implants installed is increasing each year, and thus there is a need to develop new biologically based approaches. Similarly, many tooth fillings still use mercury-based amalgams, and the possibility that repair of dental hard tissues (dentine and enamel) might involve the use of cells to remineralize the damage to teeth naturally is an exciting prospect. This chapter explores the current status of research directed toward whole tooth replacement and repair of dental disease.

TOOTH DEVELOPMENT

Teeth are ectodermal appendages (hair, sweat glands, salivary glands, etc.) that develop from an increasingly well-understood series of reciprocal epithelial mesenchymal interactions (Figs. 70.1 and 70.2). In mammals, these interactions take place in the developing oral cavity between the oral ectoderm (epithelium) and cranial neural crest-derived mesenchyme (ectomesenchyme). The cellular origins of the signals that initiate tooth development have

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00070-7

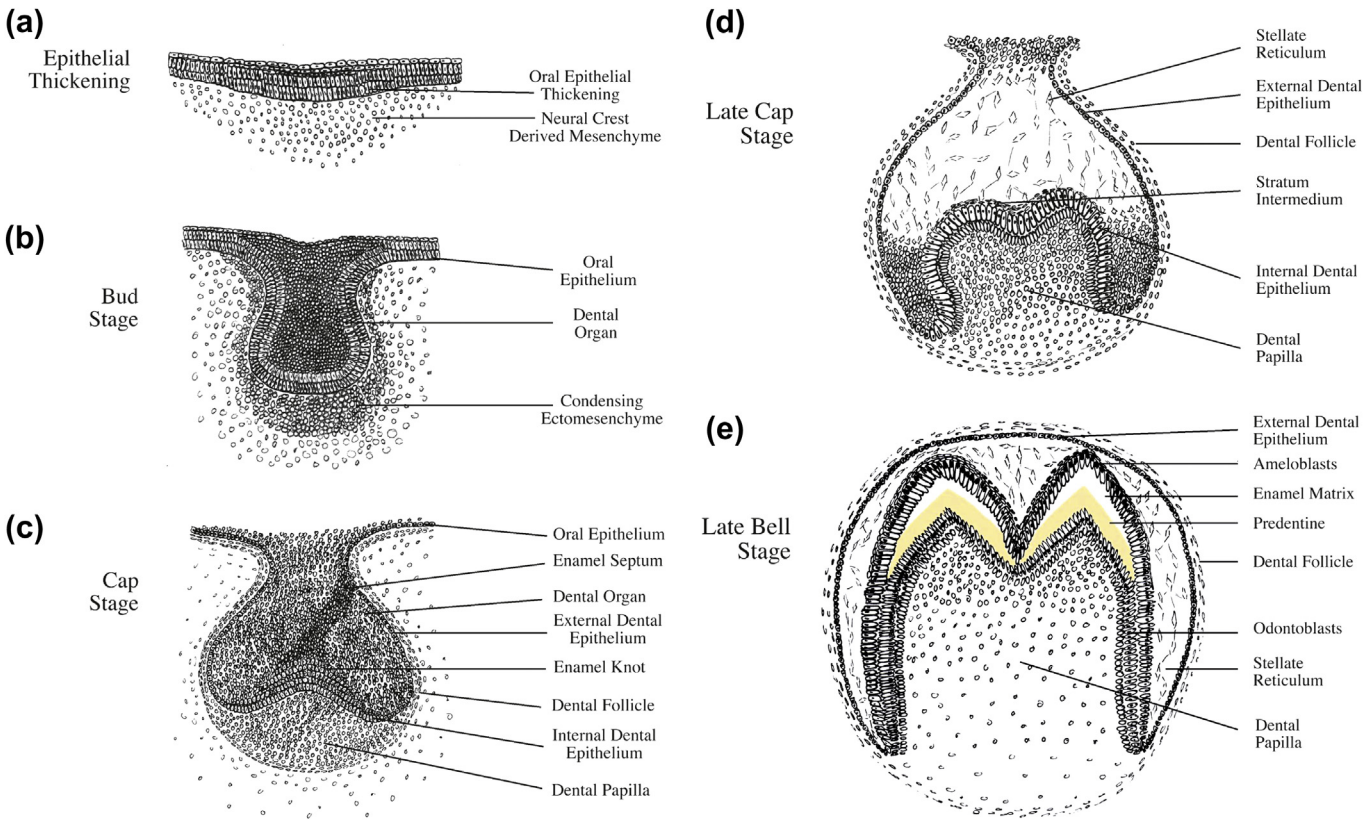

FIGURE 70.1
Drawings of histological sections of mammalian first-molar-tooth development.

been the subject of much controversy over the years, but modern molecular and animal techniques have confirmed that the oral (predental) epithelium is the source of the signals that initiate odontogenesis (reviewed in references [3,4]).

Recombination experiments between dental cells and non-dental cells have identified temporal changes in the direction of inductive signals. Following the initial epithelial-to-mesenchymal inductive signals, a long series of temporally and spatially controlled exchange of signals governs each step in the increasingly complex development of a tooth. With the exception of the nerve supply, all the cells of a mature tooth originate from the oral epithelium and ectomesenchyme. The epithelial cells form only one functional cell type, the ameloblasts which are responsible for enamel formation. All of the other cell types, including the odontoblasts that are responsible for dentine formation, periodontal ligament cells, the pulp cells, etc., are derived from ectomesenchyme. The ability of ectomes-enchyme to differentiate into these different cell types illustrates the stem cell-like properties of these cells. Classic recombination experiments in the 1980s established that non-neural crest cell populations of mesenchymal cells cannot respond to tooth-inductive signals, and, more recently, the requirement for dental mesenchymal cells to have stem cell properties has been established (see later). An understanding of the properties of predental epithelium, mesenchymal cells, and the interactions and molecules involved is the key to developing biological approaches for replacement and repair.

WHOLE TOOTH-TISSUE ENGINEERING

Stem cell-based tissue engineering of teeth

The aim of this approach is to reproduce an embryonic tooth primordium from cultured epithelium and mesenchymal cells. Since it is established that embryonic tooth primordia are

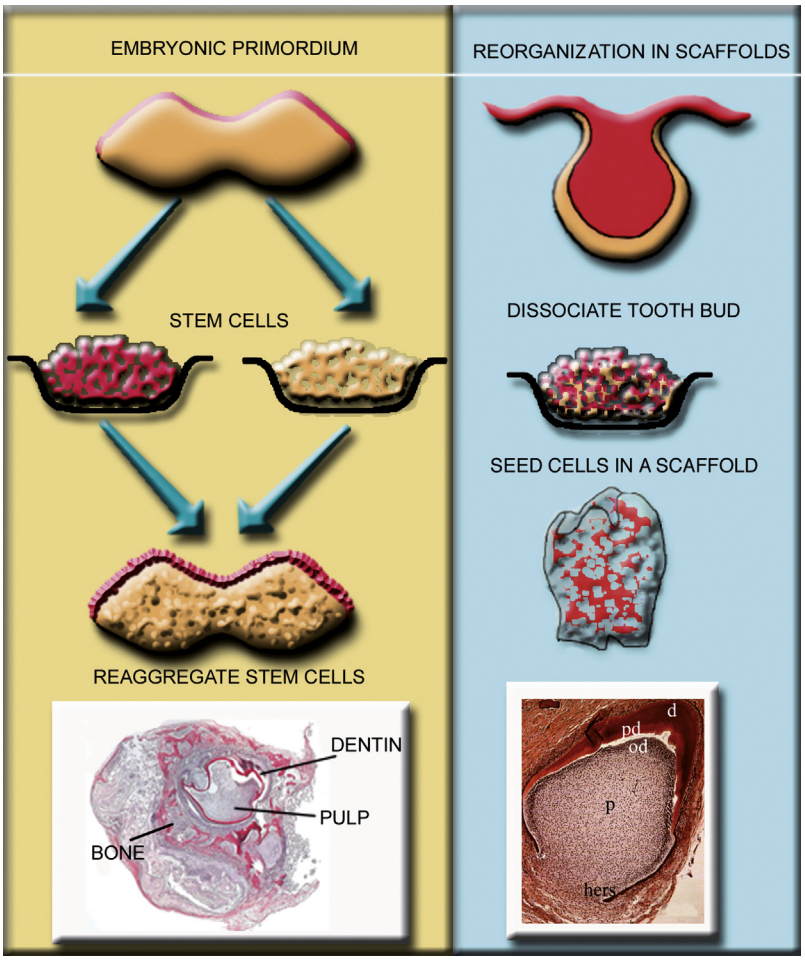

FIGURE 70.2
Diagrammatic representation of two methods currently being explored for producing biological tooth replacement. (*Figure kindly drawn by Rachel Sartaj.*)

able to continue their embryonic development in ectopic adult sites such as the kidney, the expectation is that the artificial primordia will develop into teeth following implantation as tooth rudiments into the adult mouth. Thus, rather than a metal dental implant, a cell-based biological implant will be transplanted. Since the ectomesenchymal cells of the tooth primordium form the majority of tooth cells and regulate tooth shape, it is finding replacements for these cells that has been the main initial focus of research. The early inductive interactions that take place *in vivo* show that the mesenchymal cells must have stem cell-like properties. Cultured populations of stem cells have thus been used to replace these ectomesenchymal cells in recombinant tooth explants. Cultures of mouse embryonic stem (ES) and neural and adult bone marrow cells were aggregated to form a semi-solid mass, on which embryonic oral epithelium was placed [5]. When cultured for two to three days, the initiation of an odontogeneic response in the stem cell 'mesenchyme' cells could be visualized with molecular markers. Transfer of the explants in the kidney capsules of adult mice was then used to assay for tooth formation. 'Bioteeth' explants made with mesenchyme derived from ES and neural stem cells proved difficult to transfer intact into kidneys. Explants made from adult bone marrow stromal cells, however, were substantially more robust and survived transfer. Following incubation of explants in kidneys for 10–14 days, clearly identifiable tooth crowns were formed, surrounded by bone. By using cells from genetically distinct transgenic mouse lines (GFP, LacZ), the stem cell origins of dental mesenchyme cells and bone cells could be confirmed. Cells derived from adult bone marrow stromal were thus capable of contributing to tooth formation is a way identical to ectomesencyme cells. Moreover, development of the tooth crowns appeared to follow the normal pathway of embryogenesis, with the formation of new bone completely surrounding the

tooth. New bone formation is an essential (but often overlooked) component of biotooth formation. A biotooth has to be able to anchor itself to the jawbone with roots and a periodontal ligament. Concomitant bone formation must therefore occur during tooth development.

The growth of tooth primordia following surgical transplantation into the adult jaw appears remarkably straightforward. Transplantation into ectopic sites or into tooth sockets following extraction provides a suitable environment to support continued development, postnatal growth, root formation and eruption [5–7].

Bioteeth from cell-seeded scaffolds

In the early 1950s, Shirley Glasstone-Hughes demonstrated that when early-stage embryonic tooth primordia are physically divided into two halves, each half develops into a normal-sized tooth [8]. This pioneering experiment demonstrated the developmental plasticity and regenerative capacity of embryonic tooth germs. This regenerative capacity has been exploited to devise a simple, biodegradable scaffold-based approach to biotooth generation. The early pioneering work of Vacanti and coworkers on the use of biodegradable scaffolds to act as supports for guided tissue regeneration has provided the basis for using the reorganizational properties of dental primordia cells to reform teeth *in vitro* [9]. The basic principle is to create scaffolds in the shape of the tooth required. These are then seeded with cells isolated following dissociation of third-molar-tooth germs. Third molars, or wisdom teeth, erupt late in human development and thus in young adults are present as dormant primordia. Both pig and rat third-molar primordia have been used with essentially the same procedure, utilizing biodegradable polymer scaffolds [10–12]. Cells from third molars at the late bud stage of development were dissociated by incubation with collagenase and dispase, and the cells were then either seeded directly into scaffolds or cultured for up to six days in Dulbeccos modified eagle medium (DMEM) plus 10% fetal bovine serum (FBS) before seeding. The scaffolds were composed of polyglycolate/ poly-L-lactate and poly-L-lactate-co-glycolide prepared using polyvinyl/siloxane and molded into the shape of human incisors and molars. For pig cells, scaffolds of $1 \times 0.5 \times 0.5$ cm were used; whereas for rat cells, rectangular scaffolds of $1 \times 5 \times 5$ mm were used. Scaffolds containing seeded cells were surgically implanted into the omentum of rats (athymic rats for pig cells) and left for 12–30 weeks. Histological sectioning of the explants revealed the formation of tiny tooth-like structures. The structures were between 1 and 2mm in size and showed many of the features of molar-tooth crowns, including differentiation of ameloblasts and odontoblasts. Experiments using pig cells detected the tooth-like structures after 20 weeks, whereas with rat cells these formed after 12 weeks. In all cases, the shapes of the toothlets formed were independent of the shape of the scaffold, and, unlike natural tooth formation, no bone was formed in association with the teeth. Based on the previous results of Glasstone-Hughes, the most likely explanation for these results is one of reorganization rather than *de novo* formation. The small size of the teeth indicates that small numbers of dental epithelium and mesenchyme cells reassociated to form tooth germs. The fact that cells could be cultured for up to six days indicates that either the epithelial and/or mesenchymal cells are able to retain their odontogenic properties, or the possibility exists that stem cells were present in the cell populations, but this remains to be demonstrated. A functional biotooth must be able to form roots; in order to do this, new bone must form at the same time as the tooth. In the scaffold approach, no new bone is formed. In order to address this, scaffold tooth-like structures have been generated together with bone implants produced from osteoblasts induced from bone marrow progenitor cells seeded onto polyglycolide-co-lactide-fused wafer scaffolds [13]. The codevelopment of bone and tooth-like structures permitted the early formation of roots and thus demonstrated the possibility of utilizing a form of hybrid tooth/bone-tissue-engineering approach.

The phenomenon of reorganization of dental primordia cells into teeth has been investigated in detail by Lesot and colleagues. Using cap-stage-tooth germs (E14 – mouse) (Fig. 70.1), they showed that following complete dissociation of both the epithelium and mesenchymal cell derivatives, teeth could be produced when the cells were reaggregated and reassociated [14,15]. Thus, as observed with third-molar-tooth primordial, the cells retained their odontogenic capacity following dissociation. This property was utilized as a method of investigating the potential of non-dental cells to participate in tooth development. The experiments of Ohazama et al. [16] showed that bone marrow stromal cells were able to replace all dental mesenchyme cells. Bone marrow cells were mixed with dissociated dental epithelial cells and reassociated with dental mesenchyme [17]. The bone marrow cells were found to contribute to ameloblast formation. In order to determine which cells within the crude marrow population might give rise to epithelial ameloblasts, cell sorting with c-kit was used to separate hematopoietic progenitor cells. When mixed with dental epithelial cells, these cells were observed to form both ameloblasts and odontoblasts. The ability of bone marrow mesenchymal progenitors (stem cells) to contribute to ameloblast formation was not assessed in these experiments. However, the principle, as originally proposed by Ohazama et al. [16], that bone marrow cells can be a potential source of cells for tissue-engineering bioteeth is further supported by these reaggregation experiments. In all the experiments reported by Lesot and colleagues, the ability of non-dental cells to contribute to tooth formation occurs only when the cells are mixed with dental cells from cap-stage tooth germs. The experiments reported by Ohazama et al. [5] did not require a mixed population. It remains to be seen therefore whether any commercial biotooth procedure could feature the use of dissociated embryonic third-molar dental cells. Since bone marrow can be used totally to replace dental mesenchyme in the absence of any dental mesenchyme cells, the prospect exists that if a source of epithelial cells can be identified that can replace dental epithelial cells in the absence of any epithelial cells, then bioteeth could be formed entirely from adult cells. Dental epithelial cells produce the signals that initiate the whole process of tooth formation, and, thus, a non-dental source of these cells must in part be capable of reproducing these signals.

One signal that has been identified is BMP4, which is specifically expressed in early predental epithelium before bud formation. When exogenous BMP4 is added to non-dental embryonic explants, odontoblast and ameloblast differentiation can be detected [16]. Although these cells are organized together in cell layers as they appear *in vivo*, they are not present in a recognizable tooth structure. Nevertheless, the fact that one molecule applied to cells early can stimulate the differentiation of non-dental cells into both epithelium and mesenchymal dental cells offers the possibility of engineering a dental epithelium from non-dental epithelial cells.

Root formation

In order to be functional, bioteeth must develop roots. Root formation is a complex and little-understood process. However, although little is known of the molecules that stimulate and coordinate root formation, the absolute requirement for bone is established. If teeth form in the absence of bone, they cannot form roots, as observed in the seeded scaffold tooth-like structures. When these scaffold teeth develop alongside new bone, root formation is stimulated [13]. Tooth formation is most often studied experimentally by transplantation of tooth primordia to ectopic sites in adult rodents. The anterior chamber of the eye, the kidney capsule, the omentum, and the ear have all been used as sites that permit tooth formation. Root formation can occur at all of these sites if accompanied by bone development [17]. A prerequisite of any method of biotooth formation therefore is that tooth primordia are able to form teeth and roots integrated into jaw bone in the mouth. The mouth is, however, not routinely used as an experimental ectopic site for tooth development because of the difficulty of the surgery involved. In order to determine whether the adult mouth can support tooth formation, embryonic tooth primordia have been surgically transplanted into the mouths

of adult mice. Not only do these develop into teeth in the mouth, but they also produce functional roots and erupt [5].

Cell sources

The biggest hurdle to a successful clinically-translatable protocol for whole tooth-tissue engineering is the issue of the source(s) of cells to be used. Both epithelial and mesenchymal cell sources need to be identified and with the exception of the use of bone marrow stromal cells, all other reports of whole tooth 'bioengineering' have employed cells dissociated from tooth primordia. A feature of the successful experiments using dissociated tooth germ cells is that the cells are not expanded *in vitro* before use. In order to obtain sufficient cells to generate one tooth, many tooth primoria need to be dissociated to produce at least 5 x 10^4 cells [17a]). For any viable clinical approach, the cells, whatever their source, will have to be expanded *in vitro*. However, when tooth primordia cells are expanded *in vitro* they rapidly lose their ability to re-participate in tooth formation [17b,18]. A major challenge therefore is to develop ways of maintaining tooth forming capacity following *in vitro* cell expansion.

Since tooth formation requires both epithelial and mesenchymal cells and these cells exhibit reciprocal signaling interactions, one of the cell types used must be able to induce odontogenic capacity in the other. In the bone marrow stromal cell experiments, embryonic tooth epithelium was used to induce this capacity in the bone marrow-derived cells [5]. Cells isolated from adult oral mucosa are capable of responding to odontogenic-inducing signals from embryonic tooth mesenchymal cells and forming tooth-like structures [19,20]. Potential adult cell sources are thus available but none have inherent odontogenic-inducing properties.

DENTAL-TISSUE REGENERATION

An important long-term goal for dental-tissue engineering is developing strategies for biotooth formation, thereby addressing many of the clinical problems arising from developmental anomalies and dental disease. However, in the shorter term there are many opportunities to be exploited for partial reconstruction of the tooth organ by tissue regeneration. Such approaches may be more readily achieved and still provide the potential for very significant impact on delivery of oral health care. Natural tissue regeneration, i.e., wound healing in the dental environment, is well recognized but represents a rather serendipitous event, and the approaches used to encourage such processes are somewhat empirical. A key factor in encouraging natural tissue regeneration is facilitating a conducive tissue environment in which the regenerative processes can take place, including moderation of chronic inflammatory events, control of bacterial infection, and minimizing tissue injury during any restorative surgical intervention. A good understanding of how to control these influences on tissue regeneration is fundamental to clinical success. There are also significant opportunities for the application of agents, whether directly through bioactive molecules or indirectly through agents that can release tissue-sequestered pools of these molecules locally, to promote regenerative processes and tip the balance between tissue degeneration and regeneration.

Natural tissue regeneration

Natural tissue regeneration implies a cellular basis to regeneration, and the non-vital nature of mature dental enamel provides major hurdles to its regeneration by any but physicochemical remineralization processes. However, the vitality of the dentin-pulp complex provides significant opportunities for regeneration. Regeneration in the dentin-pulp complex will only take place, however, if there is a conducive tissue environment. Early studies highlighted the causal link between bacteria and inflammatory events in the dental pulp, and the presence of pulpal inflammation provides an effective barrier to initiation of regeneration therein [21]. Thus, if natural tissue regeneration is to be facilitated, it is essential that bacterial infection and the consequent inflammation in the tooth are controlled. The inhibitory action of

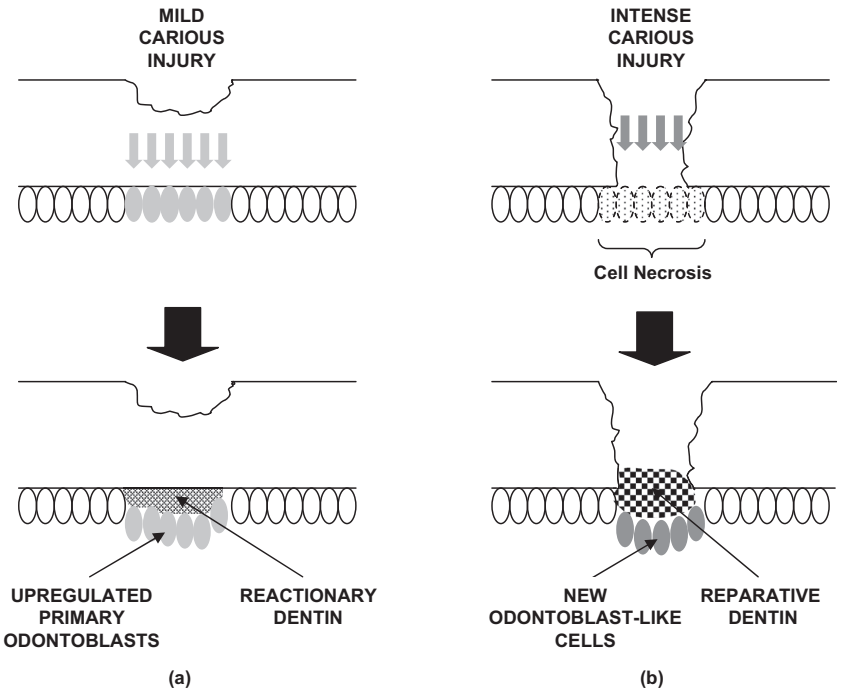

FIGURE 70.3
Schematic diagrams of reactionary (a) and reparative (b) dentinogenesis. (a) Mild carious or other injury signals upregulation of the primary odontoblasts underlying the injury site, leading to secretion of reactionary dentin. (b) More intense injury causes necrosis of the odontoblasts underlying the injury site, and progenitor cells are recruited from the pulp to differentiate into a new generation of odontoblast-like cells, which secrete reparative dentin. Dentin bridge formation at sites of pulpal exposure arises from reparative dentinogenesis.

inflammation on regeneration may represent an effect more on signaling events than stem/progenitor cell survival, since inflamed pulp tissue can allow isolation of cells with some stem cell properties [22,23]. The close interplay that is emerging between inflammation and tissue regeneration [24], however, emphasizes the complexity of events in the post-injury tissue environment where intervention should be carefully targeted. Traditionally, bacterial control has often been achieved through extensive surgical removal of infected dental hard tissues, although the trend toward minimal intervention therapy during tooth restoration potentially places the tooth at risk through incomplete bacterial control. Sealing or 'entombing' the bacteria within the restoration may help to compromise their viability, as may some of the chemical agents used in the placement of dental materials. Nevertheless, control of pulpal inflammation may be desirable in the context of tissue regeneration, and an improved understanding of the inflammatory mediators involved [25,26] may allow specific targeting with novel anti-inflammatory molecules.

The concept of tissue regeneration in the dentin-pulp complex has been recognized since the first report of tertiary dentinogenesis in response to injury from caries by Hunter in the 18th century, and dentistry has long been a pioneer in regenerative medicine through the use of calcium hydroxide to stimulate reparative dentinogenesis to bridge pulpal exposures in the dentin [26a]. Tertiary dentinogenesis (reactionary and reparative dentinogenesis are subvariants) represents the upregulation of the dentin-secreting cells, the odontoblasts, in teeth after completion of tooth formation to initiate tissue regeneration in response to injury. With mild injury, the odontoblasts underlying the injury survive and respond by upregulation of their secretory activity to form reactionary dentin, while with injury of greater intensity a number of these odontoblasts undergo necrosis and may be replaced by a new generation of odontoblast-like cells secreting a reparative dentin matrix [27] (Fig. 70.3).

Importance of the injury-regeneration balance

Dental caries is one of the most widespread infectious diseases globally and continues to be a major health care problem. Initially, colonization of bacteria on the tooth surface within the dental plaque biofilm leads to demineralization and proteolytic degradation of the dental

hard tissues following diffusion of bacterial acids and metabolites. As the disease progresses, both the hard and soft tissues of the tooth become infected, and a sustained bacterial challenge ensues, with consequent host inflammatory responses. The dynamics of the disease process determine the opportunities for tissue regeneration through tertiary dentinogenesis – with a rapidly progressing lesion, little tertiary dentinogenesis or regeneration is seen, but in a more slowly progressing lesion, induction of tertiary dentin secretion occurs immediately beneath the lesion [28]. Classically, this has been assumed to reflect the intensity of microbial challenge, but more recent data indicate that the response is in part due to local release of dentin matrix components. During intense carious injury, appreciable levels of dentin matrix components are released, and these compromise survival of the odontoblasts [29]. It is possible that growth factors contained within the dentin matrix, particularly those from the TGF-β family, contribute to this loss of odontoblast survival, since levels of TGF-β similar to those released from the dentin matrix have a comparable effect on odontoblast survival *in vitro* [30]. At lower doses, however, these dentin matrix components and the cocktail of growth factors contained therein can stimulate regenerative events.

It has long been recognized that particles of dentin displaced into the pulp during surgery can act as a nidus for regeneration. Implantation of solubilized dentin matrix components in the base of either unexposed [27] or exposed cavities [31] induces a regenerative response of tertiary dentinogenesis. Such responses mirror those seen beneath more slowly progressing carious lesions [28] and suggest that the natural regeneration seen during carious and other dental tissue injury is induced by local release of bioactive tissue matrix components. If such processes are to be successfully mimicked for development of novel regenerative therapies, it is important that we understand the nature of the signaling molecules involved.

Signaling events in dental regeneration

It seems probable that the signaling events during tertiary dentinogenesis and regeneration in the dentin-pulp complex recapitulate many of those occurring during embryonic development. During tooth development, the cells of the inner enamel epithelium of the enamel organ induce the ectomesenchymal cells at the periphery of the dental papilla to differentiate into odontoblasts through the mediation of the dental basement membrane, which may function in the immobilization and presentation of the signaling molecules [32]. Growth factors, especially those of the TGF-β family, may be key signaling molecules during induction of odontoblast differentiation [33,34]. While an epithelial source of these molecules is not available in the mature tooth for signaling regeneration, sequestration of these molecules in the dentin matrix [35,36] following secretion by the odontoblasts may provide such a source. Their release during carious demineralization [29] by lactic and other bacterial acid metabolites would allow their diffusion through the dentinal tubules to the odontoblasts and pulp cells, which express receptors for these growth factors. Application of recombinant members of the TGF-β family, either *in vitro* [37–39] or *in vivo* [40–42], has been demonstrated to induce a regenerative response of tertiary dentinogenesis.

However, while this mirrors some of the signaling events of embryonic development, there is likely to be much reduced control over the signaling, since the rate of release of these molecular signals from the dentin matrix will be of variable intensity and the spectrum of cells with which they can interact will differ from embryogenesis.

Control of specificity of dental-tissue regeneration

During wound healing in the dentin-pulp complex, a broad spectrum of tissue responses may be observed, ranging from regeneration of dentin tissue virtually indistinguishable from primary physiological dentin in terms of its tubularity and structure to secretion of atubular tissues with many of the structural features of bone. While terms such as tertiary dentin, reparative dentin, and irritant dentin have been used to encompass all of these responses, the

dentinogenic specificity of some of the responses remains to be demonstrated. It is unclear, though, as to what the determinants are of the specificity of the response during natural tissue regeneration. Is it control of the molecular signaling processes, is it heterogeneity in the types of cells participating in the regeneration, or is it some other factor? Answering these questions will be fundamental to future strategies for exploiting tissue regeneration in the tooth in a controlled manner. The ability to determine whether tissue regeneration gives rise to tubular or atubular dentin matrix could be of great value in developing designer regenerative clinical approaches. For example, there may be significant benefit in directing secretion of a tubular dentin matrix in the tooth crown during regeneration to restore the normal physiological tissue architecture and function. However, it could be advantageous in possible exploitation of tissue regeneration for endodontic applications, such as root canal therapy, to generate an atubular dentin matrix, thereby providing an effective seal to the periapical region of the tooth.

Dental postnatal stem cells

The cells of the dental pulp have traditionally been considered to be neural crest-derived ectomesenchymal cells, although it is clear that during embryogenesis the migrating neural crest cells will intermingle with mesenchyme in the first branchial arch [43]. Thus, cells of the pulp may not all share the same lineage, although those at the periphery, including the odontoblasts, appear to be of neural crest origin. In reparative situations, there are potentially a variety of possible progenitors in the pulp for differentiation of a new generation of odontoblast-like cells, including undifferentiated mesenchymal cells in the cell-rich layer of Höhl adjacent to the odontoblasts, perivascular cells, undifferentiated mesenchymal cells, and fibroblasts. This highlights the diversity in reparative response, which may occur after injury to the tooth. While the tissues that regenerate in such situations are all referred to as tertiary dentin (reactionary or reparative variants), in reality they represent a spectrum of tissue responses, dependent on the origin of the formative cells.

During normal tooth development, it has been suggested that cells destined to differentiate into odontoblasts have to achieve a level of competence before they can respond to an inductive signal for terminal differentiation [32]. If this is the case, then it may be a very restricted population of cells able specifically to give rise to odontoblasts during regeneration in the mature tooth. Just prior to terminal differentiation during tooth development, the pre-odontoblasts align perpendicular to the dental basement membrane, and after the final cell division, one daughter receives the inductive signal to differentiate into an odontoblast, while the other daughter shares a similar developmental history, with the exception of this final inductive step. It has been presumed that this latter group of cells resides in the cell-rich layer of Höhl just beneath the odontoblast layer in the mature tooth and as such, these cells would be prime candidates as progenitors for odontoblast-like cells during regeneration. Certainly, there is a decline in the numbers of cells in this subodontoblastic site with age [44], which mirrors anecdotal clinical reports of impaired tissue regeneration with age. Interestingly, many of the cells in the Höhl layer express the stem cell marker Thy-1 and those cells showing high expression of Thy-1 demonstrated enhanced potential to differentiate into hard tissue-forming cells [45]. Undifferentiated mesenchymal cells are also found within the central core of the pulp, which could contribute to regenerative processes. A specific population of postnatal dental pulp stem cells (DPSCs) has also been described [46], which show many characteristics of postnatal stem cells, although it is possible that this population of cells may be heterogeneous in its phenotype. Transplantation of these cells subcutaneously into immunocompromised mice in association with hydroxyapatite/tricalcium phosphate powder generated ectopic deposits of reparative dentin with expression of dentin sialoprotein [47]. These DPSCs appear to be distinct from the stem cells from human exfoliated deciduous teeth (SHED) [48] and stem cells from the apical part of the papilla (SCAPs), the latter of which have been isolated from apical areas of the tooth [49]. Despite this focus of looking for specific cell populations in pulp, it is unclear

whether these various populations simply represent mesenchymal stem cells (MSCs) recruited through the circulation from sites outside the tooth and if their exposure to the niche environment within the pulp provides their phenotypic characteristics. Genetic lineage tracing provides evidence to support such an origin for some cells involved in odontoblast-like cell differentiation [50], which has significant implications for regenerative strategies in dentin-pulp. Issues with phenotypic change of pulp cells during expansion culture [51] also highlight the opportunities to source stem/progenitor cells from non-pulp tissue, such as bone marrow and adipose tissue [52,53] for dentin-pulp regeneration.

As interest in dental regeneration increases, it is important that detailed characterization be performed of the progenitor cells involved. Primary cultures of dental pulp cells give rise to many cells with myofibroblastic characteristics, and similar results have been observed during extended serial expansion of such pulp cultures [29]. Whether this represents asymmetric growth of these cells or the myofibroblast phenotype represents a default phenotype is unclear, but it is probable that such cells are not true postnatal stem cells, and any attempt to label them as such should be resisted in the absence of fuller characterization. Clearly, there is potential for a spectrum of derivations for the cells potentially involved in regeneration of the dentin-pulp complex, and the consequences of this may be a variety of phenotypic responses. It seems probable that only some of these responses may involve true postnatal stem cells. However, the diversity of cellular responses highlights the potential benefits of achieving control over these regenerative processes and the opportunities for developing strategies for directed tissue regeneration.

Directed tissue regeneration

The concept of directing tissue regeneration will be successful only if it builds on the foundation of our knowledge of natural tissue regeneration, which in turn exploits our appreciation of the molecular cellular signaling events during normal tooth development. Focus on both cell- and signaling-based approaches has provided many interesting initial avenues for directed tissue regeneration in the tooth, but it is probable that the combination of these two approaches will prove the most effective in providing us with novel solutions for regenerating tooth structures. For example, seeding of SHED cells in a poly-lactic acid scaffold within a tooth slice has allowed regeneration of pulp tissue resembling that seen physiologically [54] and the acidic conditions created by the scaffold were hypothesized to be responsible for release of signaling molecules from the dentin matrix.

Signaling-based strategies

Signaling-based strategies have generally aimed to mimic those signaling events responsible for cell differentiation and secretion during embryonic tooth development and natural tissue regeneration. Thus, there has been a strong focus on application of growth factors, as well as various matrix-derived molecules, which also appear to stimulate regenerative events. Growth factor application has also been investigated for chemotaxis-induced cell homing in pulp regeneration [55], which lends support to the concept of MSC recruitment from non-dental locations [50]. Approaches have been used to upregulate secretion by existing cells (reactionary dentinogenesis) as well as to induce the differentiation of new odontoblast-like cells (reparative dentinogenesis) for tissue regeneration, although the former has been constrained by our lack of understanding about the physiological control of odontoblast secretion during primary dentinogenesis.

Both *in vitro* [37–39] and *in vivo* [40–42] application of growth factors, particularly of the TGF-β family, to the exposed pulp in pulp-capping situations induces regeneration, although the tissue formed has shown a range of appearances, from osteodentin to tubular dentin-like. There have also been several reports of the application of matrix molecules [56–59] promoting dentin regeneration, and a Phase II clinical trial with a synthetic peptide derived from

matrix extracellular phosphoglycoprotein (MEPE) is presently in progress. While all of these approaches provide the foundation for a new era of biologically based regenerative therapies for the teeth, there are a number of limitations. The half-life of free growth factors is generally short; for instance, that of free TGF-β1 is estimated to be of the order of 2−3min. In fact, when the growth factors are sequestered within the dentin matrix, they are remarkably well protected from degradation by association with extracellular matrix components. This protective mechanism can allow the growth factors to remain 'fossilized' for the life of the tooth, thereby providing an exquisite life-long potential for natural regeneration. Also, the consequences of short half-life of these molecules and the ubiquitous presence of proteolytic enzymes in the tissue milieu at sites of injury require high concentrations to be applied for regenerative signaling. As for all tissue regenerative and engineering strategies, the mode of delivery of signaling molecules is key to their effective action. To date, most signaling molecules have been simply applied as lyophilized powders or aqueous solutions, but considerable potential exists for development of novel delivery systems. An alginate hydrogel has shown encouraging results for delivery of TGF-βs for induction of *de novo* dentinogenesis on cut surfaces of pulp tissue [60], and innovative approaches are needed to deliver such molecules through the dentin matrix via the dentinal tubules. While passive diffusion through the tubules will have some effect, histomorphometry of restored human teeth suggests that natural regeneration occurs optimally when there is only a very limited residual dentin thickness, and a challenge will be to develop systems for delivery across greater distances in the dentin matrix. Gene therapy (see later) offers interesting opportunities for targeting signaling molecules to the regenerative site, although safe and suitable delivery systems are still required.

Calcium hydroxide has long been used to stimulate dentin bridge formation for dental regeneration, although its mechanism of action has remained largely elusive. Recent studies, however, have indicated that both calcium hydroxide, and the closely related material mineral trioxide aggregate (MTA), probably acts by release of stores of endogenous bioactive molecules and growth factors sequestered within the dentin matrix, which are responsible for the cellular signaling [61,62]. The limited control of growth factor dissolution from the dentin matrix by calcium hydroxide may in part help to account for its rather variable activity during regeneration. However, its action does point to an interesting approach for regeneration, whereby agents target release of endogenous signaling molecules from the tissue, thereby obviating some of the issues associated with the application of exogenous sources of these molecules. Such agents might also include some of the cavity etchants and irrigants commonly used in restorative dentistry [63,64].

Cell- and gene-based strategies

Cell- and gene-based strategies offer exciting opportunities for dentin-pulp regeneration, although many hurdles have to be overcome before these can become a clinical reality. Using electroporation, Gdf11 gene transfer to an exposed pulp *in vivo* failed to provide effective regeneration [65], although use of ultrasound for transfer of the Gdf11 plasmid provided an osteodentinogenic regenerative response [66]. *In vivo* gene transfer of a recombinant adenovirus containing a full-length cDNA encoding mouse bone morphogenetic protein (BMP)-7 failed to induce reparative dentinogenesis in inflamed ferret dental pulps, while *ex vivo* transduced dermal fibroblasts induced regeneration in the same model, although the dentinogenic specificity of this response requires further characterization [67]. These studies highlight the negative impact on regeneration of a non-conducive tissue environment, due to inflammation and, also, the limited numbers of stem/progenitor cells in the pulp for recruitment to participate in regeneration. The latter issue might be overcome by transplantation of suitable stem/progenitor cells for regeneration at sites of injury, especially if transduced with suitable signaling molecules. *Ex vivo* gene therapy by transplantation of Gdf11 [68] or Bmp2 − electrotransfected pulp stem/progenitor cells [69] − shows promise for induction of regeneration, although the tissue formed was osteodentin-like in appearance. It is

unclear whether the lack of dentinogenic specificity in these responses can be ascribed to the nature of the cells transplanted or to the inductive signaling molecules. However, the results highlight the importance of considering not only the cells and signaling molecules involved, but also the delivery mechanisms for effective therapies to be developed. Novel approaches may also include epigenetic modification of pulp cells with histone deacetylase inhibitors (HDACi) to stimulate regenerative events [70,71].

The anticipated low numbers of stem/progenitor cells for regeneration in the dental pulp indicate the need to optimize recruitment strategies for these cells, whether locally recruited from within the tissue or transplanted from without. The former approach avoids possible issues of immune reaction to non-autologous cellular material. However, local recruitment requires selection of those cells of appropriate lineage and phenotype. Cell markers for potential selection stem cells from embryonic first branchial arch tissue have been investigated [72], and low-affinity nerve growth factor (NGF) receptor is being targeted for selection of odontoblast-like cell progenitors from the mature dental pulp [29]. A combination of c-kit, CD34, and STR-1 has been reported for selection of stromal stem cells from human deciduous dental pulps, which can be induced to differentiate into osteoblasts for bone regeneration [73], while c-kit has been used for selection of odontoblast progenitor cells from bone marrow [17]. CD105 has been reported to allow for selection of pulp cells capable of regenerating pulp tissue including nerves and vasculature followed by new dentin formation [74]. Use of such cell selection approaches may overcome problems associated with recruitment of stem/progenitor cells for odontoblast differentiation from a relatively small niche within the pulp during dental regeneration. Future strategies might include *ex vivo* selection of these cells for transplantation or immobilization of antibodies or other capture molecules for selection at regenerative sites for recruitment of the cells. A combination of these approaches with novel delivery of signaling molecules may prove effective in optimizing the regenerative response.

CONCLUSIONS

Tissue-regenerative strategies offer exciting possibilities for development of novel clinical solutions for treatment of dental developmental anomalies and disease. The exquisite natural tissue-regenerative capacity of the dentin-pulp complex in the tooth provides an invaluable foundation on which to develop novel biologically based regenerative therapies. Particular attention will need to be focused on both the control and the specificity of the regenerative processes, and a combination of natural and directed tissue regeneration offers many exciting opportunities for the future.

Progress in the identification, isolation, and understanding of the differentiation of embryonic and adult stem cells, together with a continuing understanding of the control of tooth development, will undoubtedly aid the production and refinement of approaches for biotooth formation. Although there remain many potential problems and pitfalls, biological tooth replacement is now a realistic possibility.

INTRODUCTION

The oral and maxillofacial region is defined as the mouth and surrounding structures, bounded superiorly by the cranial base and inferiorly by the lower jaw. It is a highly complex area that includes morphologically intricate skeletal elements (Fig. 71.1), organs responsible for the special senses, lining and covering tissue (i.e., skin and subcutaneous fat), a rich neural and vascular network and teeth. The prominent position adopted by this area makes it particularly vulnerable to injury, while the complicated interplay of events during embryogenesis of the craniofacial skeleton increases the possibility of developmental aberrations. Regular exposure to various disease-inducing agents including complex carbohydrates (e.g., sugar), ultraviolet rays, thermal insults, and carcinogens (e.g., tobacco products) produces a variety of common pathological conditions such as dental caries, burns and malignant neoplasms. The loss of tissue integrity and continuity resulting from trauma, developmental deformities, and pathology imposes upon both physicians and dentists considerable

reconstructive challenges. Meeting these requirements in the twenty-first century will include strategies based upon tissue-engineering principles. While the discipline itself is several decades old, clinical applications for the reconstruction of the oral and maxillofacial region are currently absent. The purpose of this chapter is therefore to describe the special challenges posed by oral and maxillofacial reconstruction, outline existing reconstructive techniques, and review the available literature on tissue-engineering protocols that may be relevant. Providing tissue engineers with a description of current reconstructive modalities and in particular, their shortcomings, creates a reasonable starting point on which to base the development of revolutionary, new methods. We have specifically excluded descriptions of tissue engineering of teeth and special sensory organs, because these subjects have been covered elsewhere in this textbook.

SPECIAL CHALLENGES IN ORAL AND MAXILLOFACIAL RECONSTRUCTION

Virtually all tissue types of ectodermal, mesodermal and endodermal origin are candidates for tissue-engineering strategies and are present in the oral and maxillofacial region. However, certain structures are more commonly impacted by disease, trauma, and developmental failures and constitute the focus of our discussion, though the reconstructive methods described can be applied to more rare conditions. Common *pathological* entities include both benign and malignant cystic and neoplastic processes affecting the upper (maxilla) and lower (mandible) jaws, as well as degenerative conditions involving the mandibular articulation (temporomandibular joints). These diseases, or the subsequent removal of pathologically involved tissue, can produce continuity defects of the jaws requiring the replacement of bone, cartilage and lining epithelium (Fig. 71.2). Since many of these conditions are frequently silent and the dimensions of the structures involved relatively small, their initial presentation is usually associated with significant tissue involvement. In addition to disease, non-physiological loading of bone can also produce loss of skeletal tissue affecting the jaws and joints. *Edentulous bone loss* involves the resorption of the alveolar processes of the jaws (i.e., that portion of the jaw bone surrounding the tooth roots) following tooth removal (Fig. 71.3). This phenomenon is believed to be the result of direct loading of bone during mastication and the loss of physiological maintenance forces transmitted by the teeth. Over time, the loss of bone produces severely atrophied alveolar ridges, posing significant challenges to prosthetic reconstruction of the dentition and a predisposition to pathological fracture of the mandible [1].

Degenerative diseases of the temporomandibular joints (TMJs) are commonly the result of non-physiological mechanical forces produced by excessive ranges of motion of the joints or

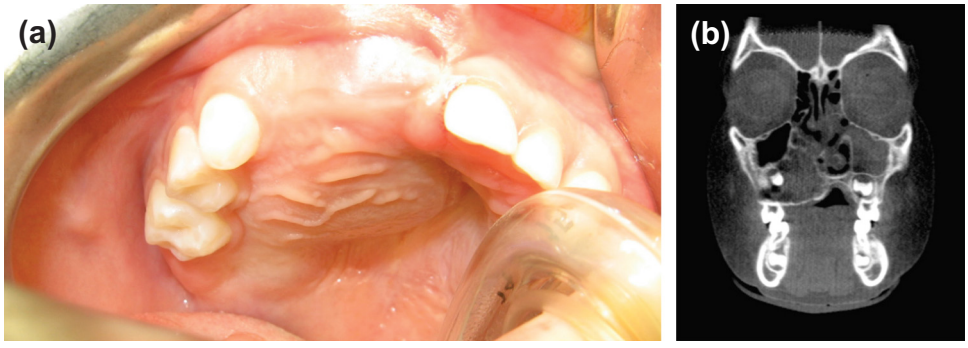

FIGURE 71.2

(b) Coronal computed tomography (CT) scan of the same patient with a giant cell lesion of the right maxilla which has produced marked bone destruction and displacement of developing teeth. Sinusitis of the left maxillary sinus is an incidental finding.

chronic micro-trauma from various parafunctional habits [2]. The habits in question include jaw clenching or tooth grinding (nocturnal bruxism) and repetitive motion habits such as nail biting and gum chewing. Injury to the TMJs commonly affects both the articulating surfaces of the condylar head and glenoid fossa as well as the interpositional disk, producing a spectrum of disease from chondromalacia to severe osteoarthritis. As a synovial joint, the TMJs can also fall victim to various immune-mediated disease processes, such as rheumatoid or psoriatic arthritis. The inflammatory component is responsible for progressive structural tissue loss leading to changes in skeletal relationships and malocclusion [3]. In advanced forms of disease, replacement of both cartilage and bone as a total joint reconstruction may be necessary to restore function or skeletal support to the mandible.

Maxillofacial trauma constitutes another group of conditions providing opportunities for tissue engineering reconstruction. Whereas most forms of blunt trauma result in fractures where tissue loss is minimal, penetrating injuries produced by high velocity missiles and projectiles often create significant loss of bone and overlying soft tissue (Fig. 71.4). Finally, consideration should be given to the various forms of congenital facial clefts that commonly affect the oral and maxillofacial region. In a limited form, failure of the maxillary processes to fuse unilaterally or bilaterally produces alveolar clefts (Fig. 71.5). When the upper lip, maxilla and palate are involved, a constellation of deformities associated with unilateral or bilateral cleft lip and palate patients is present.

In the reconstruction of anatomical defects, the causative events must be taken into account to ensure long-term success. Defects produced by traumatic, developmental and pathological conditions are associated with a defined end-point. Assuming that pathology has been completely eradicated or further traumatic insults do not occur, defects produced by these mechanisms can be fully characterized with respect to size and missing tissue types. In contrast, tissue loss as a result of parafunctional habits, non-physiological loading patterns and immunologically mediated degeneration often continue following reconstruction. This set of circumstances will adversely affect any biological constructs produced by tissue-engineering techniques and impose an important limitation on the clinical application of their usage. Before biological, rather than alloplastic materials can be employed, correction of the underlying etiology is of paramount importance.

A special concern in oral and maxillofacial reconstruction is the potential exposure of grafted tissue to the external environment. Constructs used to restore defects involving the jaws, orbits, nose and ears are potentially in direct contact with the mouth, sinuses (maxillary, ethmoidal and frontal), nasal passages and external environment. These areas are characterized by high moisture content, significant bacterial populations, and functional loads imposed by physiological activities such as chewing. If biological (i.e., tissue engineered) constructs are to survive under these conditions, modifications to account for the dilutional effects of moisture, presence of infective organisms, and mechanical loads must be provided by the engineered tissue. For example, when *in vivo* polymerization of materials is intended, the presence of fluid must be considered. Alternatively, pre-formed constructs can be used. Colonization of constructs with a mixed population of aerobic and anaerobic bacteria is expected with reconstructions involving oral, nasal and sinus-related structures. Porous constructs, capable of harboring potentially pathological organisms might be modified to reduce either bacterial attachment or replication until lining tissue develops over the implant, forming a barrier to the external environment. In addition to contaminated wound sites, tissue constructs may be exposed to complicated mechanical loads before anisotropy is restored with the regeneration of biological tissue. Both the mandible and TMJs are subject to a combination of compressive, shear and tensile loads depending on the type and degree of function [4,5].

Another special feature of the maxillofacial region is the number of tissue types within a relatively small region. As a result of this proximity, traumatic, pathological, and developmental events often lead to the creation of composite defects requiring reconstruction of multiple tissue types. This results in a special challenge not only to engineer composite tissues, but also to attach the various constructs to each other in their normal anatomical relationship.

Facial symmetry is an important consideration in oral and maxillofacial reconstruction. Since most structures are paired or contiguous (e.g., the orbits, zygomas, left and right maxillae and mandible), accurate reproduction of the external form is an important aspect to preserve facial esthetics. The paucity of overlying soft tissue as camouflage contributes to the exacting

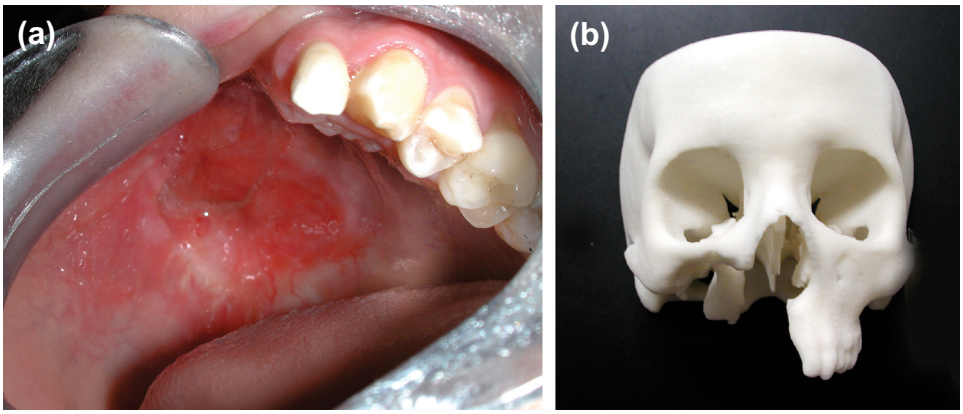

FIGURE 71.6

(b) Stereolithographic model of the same patient demonstrating the extent of the maxillary hard tissue defect.

nature of oral and maxillofacial reconstruction, and these requirements impose upon tissue engineering methods the ability to compose and maintain accurate morphology. The advent of new three-dimensional imaging techniques with the capacity to produce stereolithographic skeletal models that mirror both the normal anatomy and defect is a valuable adjunctive tool (Fig. 71.6). These models assist in the fabrication of scaffolds to support the reconstruction of missing tissue.

CURRENT METHODS OF ORAL AND MAXILLOFACIAL RECONSTRUCTION

There are several methods used for oral and maxillofacial reconstruction, and the selection of a particular modality takes into account a number of important issues. Major factors that guide this process include the presence (or absence) of associated soft tissue, the vascularity and vascular pattern present, a multi-dimensional characterization of the defect size, the types of missing tissue, availability of tissue for transfer, and both patient and surgeon preference. Most reconstructive techniques can be categorized into four categories:

1) Soft tissue pedicled flaps
2) Non-vascularized soft and hard tissue grafts (the graft establishes in a delayed fashion, a vascular network following implantation, relying upon tissue diffusion to preserve the viability of the transplant)
3) Soft and hard tissue vascularized grafts (the graft is immediately perfused through an existing arterial-venous system)
4) Alloplastic reconstructions with prosthetic appliances

On occasion, composite techniques can be used, such as the staged reconstruction of a defect where soft tissue is first added to a defect site followed by bone at a later time.

Mandibular defects

Reconstruction of the lower jaw is indicated following removal of tissue during surgical excision of a pathological lesion or following loss of tissue due to a traumatic injury. When malignant disease is present, not only is more radical removal of tissue required, but post-operative radiation therapy produces lasting compromise to both the cellularity and vascularity of the remaining tissue. Blast effects from missile injuries can also produce significant composite injuries with loss of bone soft tissue, and diminished vascularity of the tissue bed. Two techniques are commonly employed for the reconstruction of mandibular defects. Vascularized grafts are indicated when the vascularity of the tissue bed is compromised by radiation or excessive scarring. They are also valuable when there is a requirement to replace both hard and soft tissue at the same time [6]. Hard and soft tissue defects can also be reconstructed using non-vascularized grafts, but their success relies

upon an adequately vascularized tissue bed, which can be compromised in irradiated or traumatically injured tissue, to support the survival of transplanted cells before a new supply is established [7].

As composite structures, vascularized grafts contain either soft tissue alone (muscle, subcutaneous tissue with or without epithelium) or include hard and soft tissue components (bone and soft tissue). Since the vascular supply to bone is contained within a peri-osseous cuff of muscle and fibrous tissue, it is not possible to transplant only bone. The additional tissue transferred into the site of a bony defect often produces a bulky graft. While this can be easily excised once a new vascular network is established, a second procedure performed several months after the initial transplantation is required. Another potential limitation to the use of vascularized bone grafts for the reconstruction of mandibular defects is the amount of bone available, since the dimensions of the graft are determined by the morphology of the donor site and not the size of the defect. Special techniques such as osteotomizing the graft and folding it upon itself have been described, but this can compromise the blood supply to the graft. Vascularized grafts are harvested from a limited number of anatomical sites characterized by a dominant arterial supply or venous drainage system. In addition, the *en bloc* harvesting of the graft must not compromise either the function of the donor site or the vascular and neural supply of structures distal to the harvest. Commonly used donor sites that meet these requirements include the fibula, ilium, scapula, and distal radius. Vascularized grafts transplanted to mandibular defects are anastomosed to patent vessels adjacent to the mandible, such as the facial, lingual or superior thyroid arteries and veins. This reconstructive approach is highly technique sensitive, and, while experienced microvascular surgeons achieve successful outcomes in over 90% of cases, less experienced surgeons or patients with underlying vascular disease (e.g., diabetes) enjoy less success.

Mandibular defects can also be reconstructed using non-vascularized transplantations of autologous bone from various sites. Successful bone grafts rely upon adequate cellularity and a sufficiently cellular and vascular recipient bed. When the soft tissue bed is deficient or lacks a decent blood supply, addition of well-vascularized soft tissue is achieved by the rotation of a muscle flap (with or without skin) into the mandibular defect. The pectoralis major, latissimus dorsi and deltopectoral flaps have all been described for this purpose. The bony reconstruction is delayed for a period of three to six months until the soft tissue flap has healed. In patients whose soft tissue is adequate, but avascular as a result of radiation therapy, hyperbaric oxygen therapy can improve the quality of the vascular supply in a course of treatments lasting between four to six weeks where repeated exposures to pressurized room air promote tissue angiogenesis. This process adds both time and considerable expense to the reconstructive process, but has been shown to be effective in improving the quality of the recipient bed. Once the soft tissue in a mandibular defect has been optimized with respect to quantity, cellularity and vascularity, autologous bone is transferred from a donor site and molded to fit the dimensions of the defect. The bone graft can be retained with screws fixed to a rigid bone plate, or held in position with the aid of cribs fashioned either from processed allogeneic bone or alloplastic materials. Depending upon the size of the defect, bone can be harvested from the anterior ilium (suitable for defects up to 4 cm in length), the posterior ilium (defects up to 8 cm in length), and the tibia or mandibular symphysis and rami (defects of less than 2 cm in length). Non-vascularized grafts, especially those combined with allogeneic bone are susceptible to infection especially following exposure to the intra-oral environment, with a frequency of 43% in one case series [8]. When a non-vascularized graft is colonized by organisms, infection often ensues and the graft fails to survive or integrate with the host bone. Aside from the potential for infection, non-vascularized grafts are less technique sensitive, allow 'complete' reconstruction of a defect by customizing the volume of bone harvested, and are associated with less donor site morbidity [9].

Maxillary defects

Defects of the upper jaw pose difficult reconstructive challenges from several perspectives, but must be undertaken to preserve speech, prevent the escape of food and fluids during eating, and maintain esthetics. Unlike the mandible, which is related to the oral cavity alone, the maxilla is bounded both inferiorly by the mouth and superiorly by the nasal cavity and maxillary sinuses. Even when present, the thin lining epithelium does not provide a sufficiently cellular or vascular bed to support the transplantation of sufficient quantities of non-vascularized bone, and the potential for exposure of the graft to oral and nasal environments is high. Post-operative or post-traumatic scarring reduces the tissue envelope even more, further complicating reconstructive efforts. Staged reconstructions have been described involving the initial transfer of vascularized soft tissue with a pedicled flap, such as the temporalis muscle or temporo-parietal flap, followed by the addition of bone several months later [9]. As an alternative, vascularized flaps have been used because of their ability to transfer both hard and soft tissue at the same time [10]. However, the accompanying soft tissue and vascular pedicle may not be accommodated by the smaller dimensions of a maxillary defect and this has limited their use to hemi- or total maxillary reconstructions. The simultaneous transfer of a large bulk of overlying soft tissue also results in a post-operative recovery period of several months where the flap can prevent mouth closure and compromise eating.

As a result of these challenges, prosthetic appliances have become the most commonly used method to reconstruct maxillary defects. These devices incorporate teeth and a fitted base to separate the mouth from the superior defect [11]. Excellent restoration of both esthetics and function can be achieved, but the fact that they are not permanently fixed in place and in fact, require daily removal and cleaning, reduces their acceptability by patients. In addition, adjustments are required periodically to account for remodeling of the underlying tissue bed.

The reconstruction of maxillary alveolar clefts is one exception to the use of prosthetic appliances as a primary reconstruction technique, even though they can be used very effectively to restore missing teeth in the cleft site or obturate an oral-nasal communication. When teeth are present in a cleft site, provision of bone is essential for eruption and support [12]. Alveolar grafting is therefore timed according to the presence and stage of development of adjacent teeth and is usually performed between the ages of eight and eleven years. The procedure involves the development of soft tissue flaps to isolate the mouth from the nasal cavity and placing autogenous bone between the cleft segments to restore maxillary continuity. Loss of the graft from infection, insufficient vascularity or lack of functional stimulus is not an infrequent occurrence and opportunities for tissue-engineering alternatives exist. This would be especially true if new interventions minimized the extent of surgery, since post-surgical scarring has been associated with restricted growth and development of the maxilla.

RELEVANT STRATEGIES IN ORAL AND MAXILLOFACIAL TISSUE ENGINEERING

Driven by the limited supply and inherent shortcomings of various autogenous, allogeneic, and prosthetic materials currently used for the reconstruction of oral and maxillofacial tissues, the potential for tissue-engineered biomaterials as alternatives is under serious investigation with the hope that significantly improved therapies will result.

While a diverse number of strategies are presently under development, the fundamental tenets of tissue engineering (TE) remain the same. These include consideration of the biological and mechanical properties of the scaffold material and its interactions with relevant bioactive molecules and cell populations.

Although multiple tissue types exist in the oral and maxillofacial region, TE research in this field has focused primarily on the regeneration of single tissues: the bony craniofacial skeleton,

lining epithelium, the cartilages of the temporomandibular joint, auricle, and nose, and the teeth and surrounding periodontal tissue (please refer to Chapters 74 and 76 for teeth and periodontal regenerative initiatives, respectively).

Bone applications

An ideal biodegradable TE bone construct should combine the biocompatibility and osteoinductive potential of autologous bone, with the availability and structural characteristics of allogeneic bone. Additional scaffold design considerations include porosity, pore interconnectivity, surface chemistry, and the ability to reproduce complex three-dimensional defects.

Scaffolds are responsible for a construct's initial mechanical integrity and provide surface area for cell attachment. Several biocompatible scaffold materials are currently used in oral and maxillofacial surgery, including naturally derived materials like collagen, gelatin, or hyaluronic acid, synthetic polymers like poly(lactic acid) and poly(glycolic acid) and ceramics like calcium phosphate granules, blocks and cements [13]. In addition to those materials clinically used, several materials have been tested using *in vivo* models for craniofacial bone, including alginate, chitosan, poly(propylene fumarate), oligo(poly(ethylene glycol)-co-fumarate), poly(caprolactone), and polyurethanes [13]. These materials are typically processed as porous structures or hydrogels that guide the morphology of regenerated tissue, allow for tissue ingrowth, and control the release of bioactive molecules such as growth factors or nucleic acids.

Other approaches to tissue engineering use novel biomaterials capable of implantation through minimally invasive surgery. This can be achieved via *in situ* crosslinking or polymerization via chemical reactions initiated by mixing chemicals immediately before injection, transcutaneous photopolymerization or thermogelation [14–17]. Delivery of osteogenic factors or cells has been demonstrated with these techniques; however, parameters such as cell viability must be weighed against gel stiffness with such materials.

Growth factors act as mediators of cellular growth and differentiation during tissue regeneration and play an important role in extracellular matrix synthesis. Utilized as recombinant proteins in TE strategies, growth factors require a local population of target cells capable of effecting the desired response [18]. This constituency of cells may be naturally present at the wound site or added to the scaffold at the time of fabrication [19] prior to implantation.

Factors that have been used for the regeneration of *in vivo* TE craniofacial bone include the bone morphogenetic proteins (BMPs) [19,20], transforming growth factor-beta (TGF-β) [21], fibroblast growth factors (FGFs) [22], insulin-like growth factors (IGFs) [23], and platelet-derived growth factor (PDGF) [24]. The bulk of experience concerning the use of growth factors for bone repair has involved BMPs [25] and this popularity has been extended into clinical investigations using recombinant human BMP-2 (rhBMP-2) for alveolar ridge augmentation [26], maxillary sinus floor augmentation [27], mandibular reconstruction following tumor resection [28], and distraction-assisted alveolar cleft repair [29]. A review by Herford et al., covers several cases of BMPs used in mandibular reconstruction secondary to tumor excision, trauma, and infection, highlighting the versatility of growth factor mediated bone regeneration [30]. However, the review notes a relatively small number, 37, of documented clinical cases in the literature with a significant failure rate of 13.5%. This highlights the need for further investigation of these growth factor-based technologies in the craniofacial complex.

BMP-2 has found some definitive success in other aspects of oral and maxillofacial surgery, such as dental implants and sinus floor augmentation. Jung et al. [26] examined the effect of combining recombinant human BMP-2 with a xenogeneic bone substitute in order to improve membrane-guided bone regeneration therapy of osseous defects in areas of dental implant placement. Although there was not a statistically significant difference in percentage of newly

formed bone at the rhBMP-2 treated site versus the control site at six months, a larger fraction of mature lamellar bone (76% vs. 56%) was present in the experimental sites, as well as increased graft to bone contact (57% vs. 29.5%). In addition, Boyne et al. [27] completed a Phase II randomized controlled study investigating the safety and efficacy of rhBMP-2 combined with an absorbable collagen sponge (ACS) versus bone graft for staged maxillary sinus floor augmentation. It was concluded that rhBMP-2 had a similar safety profile to bone graft with the added benefit of lacking donor site morbidity. In addition, the rhBMP-2/ACS treatment induced similar amounts of bone to the bone graft group, allowing for the placement and long-term functional loading of dental implants in approximately 75–80% of the patients treated.

The clinical use of rhBMP-2 to regenerate much larger bone defects has also been reported in the literature. Carstens et al. [29] described the use of 'distraction-assisted *in situ* osteogenesis' (DISO) to treat a severe facial cleft, in which rhBMP-2/ACS implantation was combined with distraction osteogenesis to create the patient's ramus and condyle as part of the surgical reconstruction. A similarly spectacular application of rhBMP-7 has been described by Warnke et al. [31] for the reconstruction of a 7 cm mandibular continuity defect in a patient who had received ablative tumor surgery and subsequent radiation treatment. A bone-muscle-flap prefabrication technique was utilized, in which computed tomography and computer aided design techniques were used to fabricate a custom titanium mesh cage replicating the contours of the missing mandible. Within this cage, a combination of xenogeneic bone mineral blocks coated with rhBMP-7 and autologous bone marrow were placed, prior to implantation of the entire construct within the latissimus dorsi muscle of the patient. Following seven weeks of implantation within this '*in vivo* bioreactor', the viable mandibular replacement was harvested from the patient along with part of the muscle containing a major artery and vein which were subsequently anastomosed with vessels at the recipient site using microsurgical techniques. Four weeks after this transplantation surgery, the patient was able to undertake a small amount of mastication and enjoy more solid foods. In a similar case of prevascularization, Mesimaki et al. implanted a titanium mesh containing β-TCP granules seeded with adipose derived stem cells (ASCs) cultured in rhBMP-2 into the rectus abdominus muscle of a patient who had undergone hemimaxillectomy [32]. The mesh was harvested with a vascular pedicle eight months later and anastomosed to vasculature in the face replacing the resected bone. This patient went on to receive dental implants for complete dental rehabilitation.

A significant drawback to growth factor strategies in tissue engineering is the shortage of naturally derived factors isolated from biological tissue. This deficiency has been addressed with the development of techniques to produce biologically active proteins using recombinant engineering techniques. However, the use of recombinant proteins is not without concern [25]. Compared to animal models, bone regeneration in humans does not appear to be as robust. In order to overcome this species recalcitrance, administration of factors in excess of naturally occurring concentrations appears to be necessary. The augmented administration of exogenous factors may potentially stimulate harmful biological effects, such as malignant transformation of cells, and could also prove to be too expensive when compared to alternative techniques for tissue regeneration. In an effort to mitigate cost, potential for harmful stimulation or disease transmission, autologous supplies of growth factors have been investigated, primarily through the use of platelet rich plasma (PRP). As a natural source of growth factors, PRP has been applied to craniofacial bone tissue-engineering scaffolds, but with limited success, illustrating the inherent difference in the effect of therapies across species [33,34].

Attempts to address the shortcomings of recombinant protein-based strategies have spurred investigation into the use of gene delivery for tissue engineering. By delivering the gene for the expression of a protein with specific effects on a target cell population, successfully transfected cells will elaborate the protein constitutively. This results in higher and more constant levels

of protein production [35]. However, while both viral [36,37] and non-viral [38] gene delivery vectors have been utilized for bone regeneration in cranial defect animal models, compromises must be made with each. Adenoviral constructs have commonly been used as viral vectors to transfect craniofacial tissues and have the advantage of efficiently transfecting both replicating and quiescent cells [39]. In addition, adenoviruses are easily manipulated, can be produced in high titers, and large amounts of genetic information can be inserted into them. However, concerns related to viral vectors include *in vivo* homologous recombination and the possibility of an immune response from the expression of viral antigens on the surfaces of transfected cells. These concerns have led to the development of non-viral vector agents [35].

While numerous non-viral gene delivery systems exist, a common problem is their low *in vivo* transfer efficiency [39]. Nonetheless, such systems are able to deliver much larger genes with minimal immunogenicity. One promising modality of non-viral gene delivery for craniofacial applications is the use of cationic liposomes which have been used to regenerate cranial bone defects in rabbits by delivering BMP-2 plasmid cDNA [40]. The low transfection efficiency of uncondensed, naked plasmid DNA has also been addressed by the use of the cationic macromer poly(ethylene imine), which has been used to condense BMP-4 plasmid DNA and deliver it in a sustained and localized manner from poly(lactic-co-glycolic acid) scaffolds within critical size cranial defects [38].

Gene transfection can take place directly within the defect site by releasing the delivery vector *in vivo* from the TE scaffold [36,37]. Indirect delivery methods have also been described utilizing a target cell population harvested from the patient, performing *in vitro* transfection of the cells, and then re-implanting the transfected cells into the defect along with the TE scaffold material [41]. While the direct technique may be simpler, it has a lower transfection efficiency and targets cells in a non-specific manner [25]. The indirect *ex vivo* approach on the other hand, requires additional harvesting and culturing procedures, but avoids the risks associated with placing viral vectors directly into the patient and disturbing the host genome. *Ex vivo* transfected cells are not immunologically privileged and may still express viral antigens on their surface which can lead to a host response following implantation.

As a corollary to gold standard approaches where bone grafts and flaps include the donor site cells, some TE approaches to craniofacial reconstruction employ cell-seeded scaffolds as implants. These have potential benefits for regenerating tissues in large defects or those with compromised healing capacity, such as those affected by radiation therapy [7]. The majority of cell-seeded scaffolds have investigated mesenchymal stem cells (MSCs) or ASCs. Reviews have covered some of the work in these areas looking at various stem cell sources, delivery and other parameters such as *in vitro* expansion and differentiation [7,42]. To highlight a few studies, MSCs were applied to ceramic and polymer scaffolds with and without PRP in both cranial and alveolar defects of rats and minipigs, respectively [33,34]. In both studies, the addition of MSCs enhanced bone regeneration over all other groups irrespective of PRP presence. In another study, autologous, culture expanded MSCs were utilized in combination with alginate hydrogels for the treatment of large cranial bone defects in sheep [43]. Finally, pre-differentiated ASCs were applied to rabbit cranial defects on gelatin scaffolds showing enhanced bone regeneration within the defect [44]. However, in another rabbit cranial defect study, rhBMP-2 on collagen regenerated greater amounts of bone compared to ASCs or pre-differentiated ASCs, indicating that although cell delivery for bone regeneration in the craniofacial complex shows promise, issues of cell sourcing, purification and processing need to be investigated further [45].

Aside from the biological components of tissue-engineering constructs, scaffold properties are also extremely important to the overall success of any particular strategy. A common misconception is that bone TE scaffolds for craniofacial applications do not require substantial strength since the craniofacial skeleton is not subjected to heavy loading. However, *in vivo* studies demonstrate that many craniofacial bones undergo levels of strain similar to that

experienced by the appendicular skeleton [46], substantiating the need for mechanical strength of potential bone TE scaffolds. Ideal scaffold design must therefore reconcile the need for high porosity and interconnectivity which promotes tissue in-growth and scaffold degradability, with a requirement for mechanical strength. Computational methods for designing and fabricating scaffold architectures to optimize both pore interconnectivity and load bearing characteristics have been performed [47], and a proof of concept study has illustrated the effectiveness of scaffold design in fabricating a mandibular condyle for a minipig [48].

The surface characteristics of bone tissue-engineering scaffolds also determine their ability to regenerate tissue in the wound healing environment. Surface chemistry has a significant effect on the interactions between the cell populations present in the defect and the biomaterial. Hydrophilic synthetic polymers such as oligo(poly(ethylene glycol) fumarate) (OPF) have been shown to impede bone healing in extraction sockets as compared to the hydrophobic polymer poly(propylene fumarate), based on the OPF macromer's prevention of protein adsorption and hence cell adhesion [49]. Interestingly, the resistance of OPF hydrogels to generalized cell adhesion has been used to advantage in the fabrication of biomimetic scaffolds, which are able to selectively encourage the migration of osteoblasts *in vitro* through the addition of specific binding peptides to their surfaces such as osteopontin-derived peptide [50]. In addition to surface chemistry, surface topography can impact healing. In a series of studies, porous materials in the mandibles of New Zealand White rabbits were shown to enhance the healing of the overlying mucosal surface in a composite tissue defect model [51–53]. However, contrary to traditional tissue-engineering materials with high porosity led to an increased inflammatory response not seen with lower porosity materials [51]. Two of these studies, investigated porous poly(methyl methacrylate) (PMMA), a material currently part of many Food and Drug Administration (FDA) cleared products. By creating porous PMMA and enhancing soft tissue interaction with the implant, these materials show promise for rapid translation to clinical use in a staged approach, whereby the implants serves to temporarily maintain the bone space during soft tissue regeneration and is removed for the definitive therapy.

Cartilage applications

While there has been extensive research in bone tissue engineering in the craniofacial complex, there has been less research in cartilage tissue engineering. However, cartilage tissue engineering in the craniofacial complex remains a significant challenge due to the inherent lack of remodeling in cartilage due to decreased cellularity and vascularity and due to the various cartilaginous tissue types in the craniofacial complex. As in musculoskeletal tissue engineering, articulating cartilage is part of the TMJ on the mandibular condyle, while the TMJ disk has different morphology. Additionally, there is structural cartilage in the nose and ears, which supports the skin to create openings critical for the senses.

The earliest tissue-engineering study directed at reconstruction of the TMJ disk utilized a porous collagen scaffold seeded with articular cartilage cells. After two weeks, the construct appeared similar to a disk with regards to gross morphology and cell shape [54]. Later efforts tested fibers of poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) and concluded that both materials were able to support cell attachment, matrix production, and exhibited acceptable mechanical properties after 12 weeks [55]. Another study comparing PGA, polyamide filaments, expanded polytetrafluoroethylene (ePTFE) filaments, and bone blocks [56] demonstrated cell attachment and limited collagen production, but neochondrogenesis was not observed after four and eight weeks. While PGA is an acceptable scaffold substrate, the material degrades exceedingly rapidly, leaving constructs with limited mechanical integrity after only a few weeks. As an alternative, PLA non-woven mesh has been tried and initial results show promise with retention of tensile and compressive integrity over a similar timescale [57].

However, replacement of fibrocartilage to restore the articulative surfaces or interpositional disk of the TMJs constitutes a special challenge including identifying a suitable source of healthy fibrochondrocytes. In a review by Wang et al., cell sources for TMJ tissue engineering are discussed [58]. Primary cells such as chondrocytes from articular cartilage or the TMJ disk have enhanced phenotypic characteristics for tissue engineering, but require expansion which commonly results in dedifferentiation and loss of this phenotype [59,60]. Stem cells on the other hand proliferate extensively and can be induced into a chondrocyte-like cell through growth factors and other parameters. In a study by Bailey et al., condylar chondrocytes were compared to human umbilical cord cells on PGA scaffolds and were not only able to proliferate more but also produced more extracellular matrix with components similar to that of native articulating cartilage [61]. Beyond differences in cell type, chondrocytes from various anatomical regions have shown varied ability to proliferate or synthesize extracellular matrix components *in vitro*. Specifically, costal and ankle chondrocytes have shown greater synthesis of collagen and glycosaminoglycans (GAGs) compared to chondrocytes harvested from the TMJ disk [62,63]. Other studies have investigated paracrine and cell contact signaling by coculturing differentiated cells together or with undifferentiated cells [64,65]. In these studies, coculture of fibrochondrocytes with either chondrocytes or with embryonic stem cells resulted in greater extracellular matrix production.

In addition to cell types, growth factors have been utilized to enhance the regeneration of cartilage tissue for the craniofacial complex. This potential was first observed in an experiment comparing the effects of transforming growth factor-β_1 (TGF-β_1) with prostaglandin E_2 (PGE_2) on bovine TMJ disk cells in monolayer. TGF-β_1 increased cell proliferation 2.5-fold, while PGE_2 had no significant effect [66]. The effects of PDGF, IGF and basic fibroblast growth factor (bFGF) have also been assayed using monolayer cultures of porcine TMJ disk cells. The results of these studies suggest that lower concentrations favor biosynthesis, while higher concentrations favor proliferation [67]. The most beneficial growth factors appear to be IGF-I and bFGF, both of which produce significant increases in collagen synthesis and cell proliferation [63,67]. Since native tissue is exposed to a variety of growth factors, combination strategies are likely to prove more beneficial than single factor therapy. To explore this hypothesis, IGF-I and bFGF in low concentration were combined with bFGF and TGF-β_1. This cocktail successfully demonstrated increased collagen production when applied to porcine TMJ disk cells seeded on PGA scaffolds [68]. However, while constructs exposed to growth factor combinations improved structural integrity and overall cellularity, a statistically significant improvement in biochemical or mechanical properties was not demonstrated [69]. Finally, other combination strategies employed coculture with growth factor delivery, which were shown to increase matrix production and structural integrity of a gel construct over the individual strategies alone [64,65].

The TMJ is not the only cartilaginous tissue of the craniofacial complex, and research into cartilage tissue engineering of the ear has also been investigated. *In vitro* expansion and seeding of harvested chondrocytes into degradable polymer scaffolds is capable of producing cartilage following implantation in immunocompromised and immunocompetent animal models [70], but the clinical experience has been somewhat disappointing with resorption of tissue-engineered auricular cartilage after several months [71]. However, to enhance the structural aspects of engineered cartilage and to increase the viability and maintenance of overlying tissue, Lee et al. seeded porous polyethylene implants with chondrocytes in fibrin gels [72]. These implants showed dimensional stability unlike previous auricular tissue-engineered constructs.

Although growth factors have received the most attention, positive biochemical stimulation is also likely to come from culture conditions and cellular interactions as well. An ascorbic acid concentration of 25 μg/mL has been shown to produce constructs with higher total collagen content and higher aggregate modulus relative to concentrations of 0 μg/mL or

50 μg/mL [73]. This was likely associated with improved seeding observed for the constructs cultured in 25 μg/mL of ascorbic acid. Additionally, a concentration of 100 μg/mL of glucosamine sulfate was found to enhance condylar cell proliferation and matrix production as a media supplement [63]. Metabolic supplements have also been shown to impact cell proliferation and matrix synthesis. L-glutamine, sodium pyruvate and insulin increased cell proliferation, while L-proline at high concentrations decreased matrix production [74]. Initial cell seeding is another important consideration in any tissue-engineering construct due to cell-to-cell interactions and signaling. It has been shown that PGA scaffolds seeded at saturation increased cellularity and extracellular matrix (ECM) content relative to scaffolds seeded below saturation [75].

The native TMJ disk undergoes significant compression, tension, and shear [76]. While cells proliferate and produce ECM in static culture, mechanical stimuli may be required to produce an optimal tissue-engineered construct. A variety of mechanical stimuli may be beneficial including compression, tension, hydrostatic pressure, and fluid shear stress. An extensive review of the mechanical bioreactors that have been used in engineering cartilaginous tissues has been published on the subject [77].

Three recent studies have investigated the effects of mechanical stimulation on TMJ disk constructs. A low-shear fluid environment by means of a rotating wall bioreactor created constructs with dense matrix and cell composition [78]; however, when the biochemical content of these constructs was compared to those grown in static culture, no clear benefit of the bioreactor was observed. When disk cells were exposed to hydrostatic pressure in monolayer or PGA scaffolds, constant hydrostatic pressure at 10 MPa increased collagen production compared to static culture [79]. In contrast, intermittent hydrostatic pressure from 0 to 10 MPa at 1 Hz frequency was detrimental to the constructs, producing less collagen and GAGs than unloaded controls. These results were consistent in both two- and three-dimensional culture. In another recent study, dynamic tensile strain significantly reduced interleukin-1β induced up- regulation of matrix metalloproteinase [80]. This may have implications on future tissue-engineering studies since matrix metalloproteinases (MMPs) play an important role in ECM degradation and remodeling.

Oral mucosa applications

Oral mucosa regeneration has followed many of the strategies of skin tissue engineering, in that cultured epithelial sheets showed inadequate results due to fragility, contractility and failure due to lack of underlying supporting tissue. Thus many approaches have considered the use of thick cultured grafts containing single or multiple cell types. An extensive review by Moharamzadeh et al. covers scaffold materials, cell sources and culture medium [81]. Many of the same materials have been investigated for oral mucosal engineering as in bone and cartilage such as collagen, fibrin, gelatin, poly(lactic-co-glycolic acid (PLGA), and polycaprolactone (PCL). Additionally, various cell sources have been used, primarily keratinocytes and fibroblasts either from oral or skin origins. Finally, growth factors like epidermal growth factor have been employed to promote proliferation. In one study, fibroblasts and keratinocytes were cultured on a collagen composite scaffold [82]. The culture led not only to cell specific markers for a full thickness mucosa but structural components including a basement membrane and extracellular matrix. A similar study used gingival fibroblasts and keratinocytes harvested from patients on a clinically available collagen matrix, resulting in cell markers and tissue structures similar to mucosal tissue [83]. *In vivo*, mucosal grafts of collagen precultured with gingival fibroblasts and keratinocytes have maintained their phenotype as mucosal tissue after 60 days of implantation [84]. Finally, one group has shown translation of tissue-engineered mucosal graft. Creating a mucosal graft *in vitro* using canine cells cultured on AlloDerm, the group translated this technique by first using human cells *in vitro* [85,86]. Subsequently, in a 30 patient study comparing AlloDerm alone to AlloDerm precultured with autologous cells,

the precultured grafts show enhanced wound healing with earlier vascularization and maturation of the submucosal layer at 28 days after grafting [87].

In addition to oral mucosa, composite grafts for muco-cutaneous junctions such as the lips. Peramo et al. presents a novel approach to creating these junctions, in which oral mucosal cells and skin cells are cultured on AlloDerm *in vitro* with a separation barrier [88]. This barrier is lifted and the cells are allowed to migrate into the junction space and interact. The cell construct was then lifted to air-liquid interface for maturation of the construct and characterized for morphology and immunohistochemical staining for keratin content. Biochemical markers were consistent with spatial distribution in mucocutaneous tissues, illustrating the possibility of this strategy to be employed for tissue-engineering lips.

Composite tissue applications

Success with the regeneration of single tissue types such as bone and cartilage has encouraged investigators to attempt the reconstruction of structures composed of multiple tissue types. Such anatomic structures may exist as composites of hard and soft tissues, which differ in their cellular composition and mechanical properties, yet perform as a single functional unit [89].

The temporomandibular joint condyle serves as an example of a maxillofacial composite structure consisting of articular cartilage and subchondral bone and provides an excellent opportunity for composite osteochondral tissue engineering. A study performed by Alhadlaq et al. [90] used adult bone marrow MSCs, expanded in culture and induced to differentiate into separate osteogenic and chondrogenic lineages *in vitro*. The resultant cells were then encapsulated in poly(ethylene glycol) based hydrogels and the cell-polymer solutions cross-linked in a mold which provided the correct stratified organization of the osteogenic and chondrogenic layers. Finally, the osteochondral constructs were implanted into the dorsum of immunodeficient mice for up to eight weeks. Histological and immunohistological analysis revealed both structural and immunohistochemical differences between the osteogenic and chondrogenic layers, which served as a primitive proof of concept of the potential for composite tissue-engineered constructs in the craniofacial region. In a similar study trying to regenerate tissue within an osteochondral defect, a gradient scaffold releasing BMP-2 on the osteogenic side of the scaffold and TGF-β1 on the chondrogenic side was fabricated [91]. This construct showed increased osteo- and chondrogenesis on the respective sides.

Animal models

As tissue-engineering strategies become more sophisticated, the complex interactions between multiple cell populations, growth factors, and scaffold biomaterials require testing within clinically-relevant *in vivo* healing environments. While computational models and *in vitro* testing provide proof of concept verification of a particular tissue-engineering strategy, more challenging test beds utilizing animal models are ultimately required, to allow discrimination of the healing potential of different biomaterial constructs [92].

The ideal model for testing the validity of tissue-engineered bone constructs is the *critical size defect* (CSD): namely, an intraosseous defect which will not heal by bone formation during the lifetime of the animal [93]. Several CSD models have been described in the literature including the calvarial defect [21,41] and long bone segmental defect [94,95]. These models do not accurately describe the oral and maxillofacial environment, because they do not simulate the unique masticatory stresses and cell populations seen in mandibular or maxillary wound healing. Mandibular defects have been described in rats, but they have the disadvantages of poor surgical access and a tendency for implanted materials to fall into the fascial spaces [93]. Conversely, larger animals such as dogs [96], minipigs [97], goats [98], and non-human primates [99] offer the advantages of easy surgical access and the ability to create large defects, but are expensive to maintain. As such, a critical size mandibular defect in a rabbit was developed. This 10 mm, cylindrical, bicortical defect in the New Zealand White rabbit has been shown to

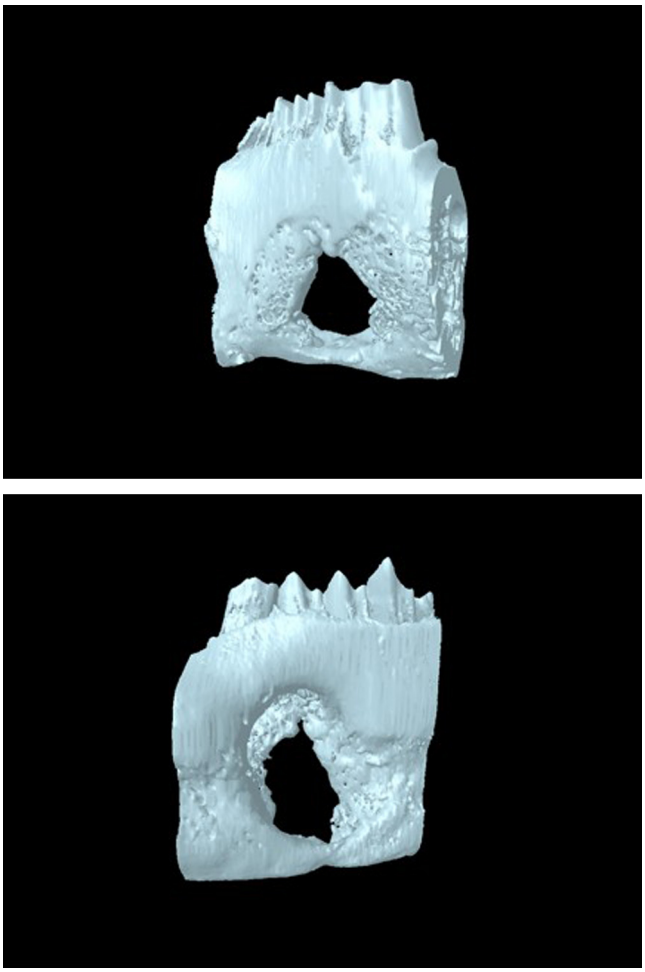

FIGURE 71.7
Micro-CT generated representative three-dimensional reconstructions. Note the buccal aspect of the specimen is shown on the top, with the lingual aspect on the bottom. The critical size defect at 16 weeks shows a 'through-and-though' defect and a lack of bony bridging across its center. *Reprinted from Young S, Bashoura AG, Borden T, Baggett LS, Jansen JA, Wong M, et al. Development and characterization of a rabbit alveolar bone non-healing defect model. J Biomed Mater Res A. 2008 Jul;86(1):182–94 with permission.*

be non-healing after 16 weeks (Fig. 71.7) [100]. Additionally, this model was expanded into a composite tissue defect model, whereby an overlying mucosal defect is created (Fig. 71.8) [51–53]. Composite tissue defect models represent an important direction for evaluation of tissue-engineered constructs. Defects resulting from trauma and resection of pathology frequently involve multiple tissue types and the combination of successful therapies for each individual may not suffice when both tissues need regeneration.

THE FUTURE OF ORAL AND MAXILLOFACIAL TISSUE ENGINEERING

While significant progress has been made towards our ability to fabricate tissue in the laboratory for the reconstruction of defects in the oral and maxillofacial skeleton, considerable challenges remain before these techniques can be embraced as a feasible clinical modality. Some of the issues pertain to tissue engineering itself, such as the ability to identify and harvest a suitable population of cells capable of fulfilling the functions of the desired tissue, supporting cellular differentiation and reproduction through physiological levels of growth and attachment factors, promotion of vasculogenesis, and the development of matrices that fulfill the physical requirements of a skeletal site. Since many of the structures in the oral and maxillofacial region are composed of multiple tissue types, the ability to engineer composite structures is also important, as is consideration of the unique environment that tissue-engineered constructs are exposed to. Even as these demands are met, other factors must be considered before TE tissue can be adopted as part of a reconstructive surgeon's armamentarium. Existing reconstructive techniques were originally based on macroscopic concerns for

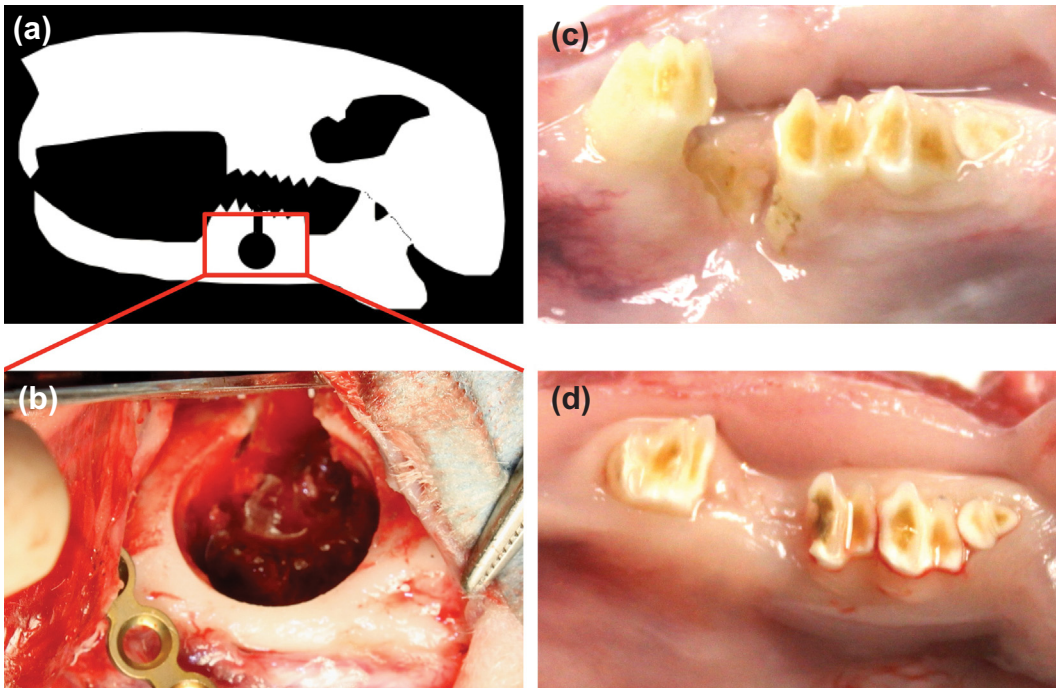

FIGURE 71.8

restoring the shape and size of a missing structure. Since TE is essentially based upon cells, a microscopic appreciation of the function of a particular tissue type must first be derived. At this time, characterization of the function and pathological degradation of many of the structures in the oral and maxillofacial region is unfortunately deficient. In other words, before the replacement for a structure can be appropriately engineered, a better understanding of the function and local environment must first be achieved. This is particularly true of defects produced by on-going pathological processes where correction of the condition must precede replacement with yet another biological substrate. The future of oral and maxillofacial TE therefore lies in the hands of close collaborations between engineers and clinicians together.

INTRODUCTION

Periodontitis is an infectious disease caused by pathogenic microorganisms in the subgingival biofilm, in combination with other risk factors, such as aging and cigarette smoking. Untreated periodontitis results in irreversible destruction of the tooth-supporting tissues, including periodontal ligament (PDL), alveolar bone and cementum, and may lead to early tooth loss [1]. It has also been linked to many systemic disorders, such as diabetes, rheumatoid arthritis and cardiovascular complications, and has been associated with adverse pregnancy outcomes [2]. Consequently, periodontal disease significantly impacts a patient's quality of life and financially impacts both patients and the public healthcare system. Blocking the progression of periodontitis has been achieved by mechanically removing bacterial biofilm with scaling and root planning procedures. Although the elimination of periodontal pathogens may improve clinical attachment levels of a tooth, reconstruction of the support and function of the affected tooth attachment apparatus represents an important therapeutic endpoint that has been an ongoing challenge in clinical periodontitis treatment [3]. Conventional treatment is generally unable to promote the regeneration of the damaged periodontal structures. Although numerous periodontal regenerative treatments have been established, such as techniques that use bone grafting, guided tissue/bone regeneration (GTR/GBR), enamel matrix derivative (EMD) and platelet-rich plasma (PRP), a positive outcome is difficult to predict, and in principle, these existing therapeutic paradigms fall short of reaching a consistent and complete regeneration of the periodontium, particularly in cases where the disease has caused large defects in the periodontal tissue [4].

The recognition that periodontal tissues possess the capacity, albeit in a very limited manner, to repair/regenerate has led to substantial efforts focused on understanding the biological basis for this activity and employing the accumulated knowledge to devise tissue-engineering technology that predictably promotes functional periodontal regeneration, i.e., the restoration of all components of the periodontium and the re-establishment of their appropriate connections [5]. Tissue engineering, which is a term often used interchangeably with regenerative medicine, merges the fields of life sciences and engineering biotechnologies and aims to orchestrate body regeneration by specifically controlling the biological environment or developing biological substitutes to restore, maintain or improve tissue function. The 'engineering' of irreversibly damaged tissues is progressing toward reality by improvements in our understanding of wound repair and recent advancements in mysenchymal stem cell

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00072-0

(MSC) biology and biomaterials science. Such advancements help to target molecules and pathways in an effort to restore the regenerative capacity of tissue, and the periodontium could be considered a prime candidate for such endeavors [6]. Applied to periodontal therapy, tissue engineering offers the opportunity to improve periodontal regeneration in a more predictable and qualitative, but possibly less invasive manner than currently available regenerative procedures [3,5].

It is an inherent belief in the current concept of periodontal tissue engineering that naturally occurring tissue regeneration can be reproduced *in vitro*. Clearly, a tissue-engineering approach to periodontal regeneration will need to utilize the regenerative capacity of stem cells residing within the periodontium (or other related tissues), and would involve the isolation of such cells and their subsequent proliferation/differentiation within a three-dimensional (3D) framework followed by implantation into the defect [6]. The *in vitro* design of such therapeutics primarily considers the delivery of appropriate cells in sufficient quantity, the sustained release of chemical and mechanical signals that are often popularly termed growth factors (GFs) in a near-physiological level, and the engineering of extracellular matrix (ECM)-mimicking biomaterials with such desirable properties as macrostructures and microstructures, biodegradability and biocompatibility [5]. The scaffold not only acts as a delivery vehicle for the cells to the site of regeneration, but it also plays an essential role in cell attachment, space retention, determination of morphological features and recruitment of oxygen and nutrients [7]. After *in vivo* transplantation, blood supply, mechanical loading and pathogen control will become the critical factors which influence the predictability of final outcome. New vascular networks promoted by angiogenic signals provide the nutritional base for periodontal tissue growth and homeostasis, while appropriate mechanical loading would be essential for the development of highly organized, functional PDL fibers [8]. Finally, because of the microbial load at the periodontal lesion, strategies to control infection and host response are required to optimize periodontal regeneration [3].

We must be aware that periodontal tissue engineering is now still in its early stage, with no current paradigm that takes all the aforementioned factors into proper consideration. If periodontal regeneration relies on the *in vitro* conditioning of a cell-seeded construct for implantation, then the transplants should be designed to incorporate biochemical and biophysical signals that recreate important *in vivo* stimuli, albeit in simplified form, to create a tissue functionally equivalent to native periodontal tissue in terms of composition, biomechanical properties and physiological performance [9,10]. Although *in vitro* periodontal tissue engineering has greatly increased our understanding of cellular behavior and cell-material interactions, this methodology is often unable to recreate tissue with the hierarchical organization and vascularization found within the native periodontium. Thus, most, if not all, efforts in this field are focusing on *in vivo* tissue-engineering strategies, in which the traditional triad (cells, regulatory signals and scaffolds), or a combination thereof, is directly implanted at the damaged tissue site, or within ectopic sites capable of supporting neotissue formation, instead of attempting to recreate tissue replacements/constructs *ex vivo* [6]. In the broader scope of tissue engineering, cell-free methods can also be considered; nonetheless, it is widely accepted that most of the developing and established strategies rely on the use of cells of different origin. *In vivo* tissue engineering via cell transplantation or biomaterials design may offer a preferential route for regeneration of periodontal tissue with distinct advantages over *in vitro* methods that are based on the specific location of endogenous cultivation, recruitment of autologous cells and patient-specific regenerated tissues [11]. In the future, these exciting developments are likely to help reconcile the clinical and commercial pressures on tissue engineering. However, even if *in vivo* tissue-engineering strategies are to be used, many issues still that need to be addressed before such strategies become routine in periodontal practice. In particular, the events following cell transplantation are poorly understood. Furthermore, the efficacy and safety of prospective tissue-engineering-based therapies have not been fully evaluated, and the risks have already been underscored by several clinicians and researchers [12].

Approaches to the regeneration of periodontal tissue have made some progress recently, and these paradigms provides useful experimental models for the evaluation of future strategies for treating other connective tissue diseases. This chapter explores the potential cell types, signaling molecules, biomaterials and various technologies based on the concept of tissue engineering for periodontal regeneration. In addition, possible new directions that need to be exploited to make periodontal tissue engineering a clinical success are highlighted.

STEM CELLS FOR PERIODONTAL BIOENGINEERING

Stem cells are the foundational cells for every organ and tissue, and they have a remarkable self-renewal ability, in that they can divide to replenish any other cell type, thus functioning as a part of a repaired tissue. The healthy PDL harbors stem cell niches throughout adulthood and exhibits a limited regenerative capacity. However, in a diseased periodontal environment, the lack of robust stem cells renders the use of *ex vivo* expanded/manipulated stem cells a necessity [5,13]. In this context, periodontal cell therapy involves the treatment of periodontitis by transferring new cells into a defect site with the goal of improving the regeneration process [14]. The transplanted cells may participate in the repair of damaged periodontium, serving as building blocks by differentiating into multiple cell types, or regulate repair via secretion of growth or cellular signals, instead of, or in addition to, directly participating in regeneration of the tissue [15]. Both intraoral and extraoral MSCs have been evaluated for the treatment of periodontal disease and for the regeneration of damaged periodontium [3,12].

Intraoral MSCs

Of note, several cell populations with stem cell properties have now been harvested from different tissues in and around a tooth and subjected to enrichment and expansion techniques (Fig. 72.1). These populations generally include dental pulp stem cells (DPSCs) [16], stem cells from exfoliated deciduous teeth (SHED) [17], PDL stem cells (PDLSCs) [18], stem cells from apical papilla (SCAP) [19,20], dental follicle stem cells (DFSCs) [21,22] and MSCs

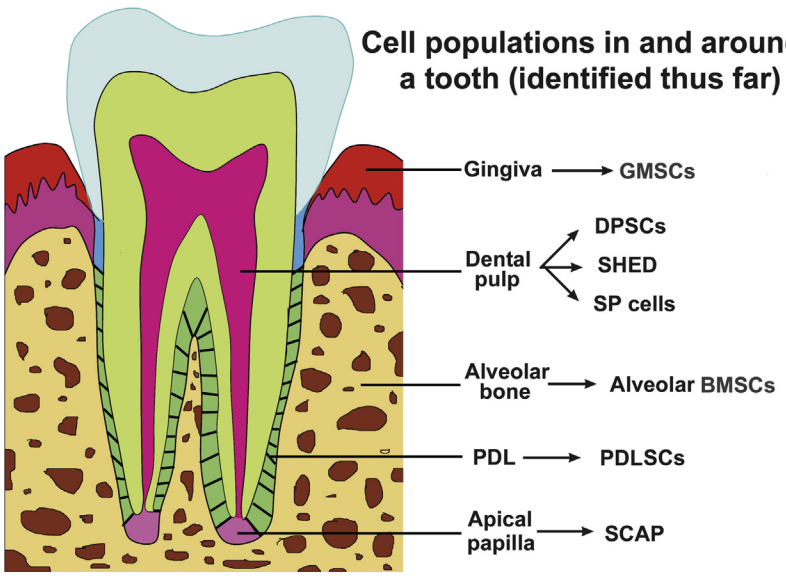

FIGURE 72.1

Selected stem/progenitor cells identified thus far in and around a tooth. PDLSCs: periodontal ligament stem cells [18]; DPSCs: dental pulp stem cells from pulp of permanent teeth [16]; SP cells: side population cells isolated from dental pulp tissue [61]; SHED: stem cells from human exfoliated deciduous teeth [17]; SCAP: stem/progenitor cells from apical papilla [19,20]; GMSCs: mesenchymal stem cells from gingiva [23,24,52]; alveolar BMSCs: bone marrow stromal cells isolated from alveolar bone marrow [25,26].

from gingival tissues [23,24] and alveolar bone [25,26]. These stem/progenitor cells can be obtained with ease from medical waste, such as teeth extracted for orthodontic, impaction or irreversible periodontitis reasons, exfoliated deciduous teeth or even gingiva that was removed for hyperplastic or aesthetic reasons. The ease of access makes them an important source of autologous stem cells for use in the regeneration of PDL and bone lost in periodontal disease. These stem cell populations have an advantage over other stem cells, such as bone marrow-derived MSCs (BMMSCs), because they can be obtained from patients in the dental clinic rather than requiring an invasive bone marrow aspiration procedure at a secondary clinic [7]. Because of their particular characteristics of proliferation, differentiation and plasticity, dental stem cells have also enabled significant progress towards clinical orthopedics and oral maxillofacial bone reconstruction [27–29]. Thus, while not largely exploited, it can be seen that the humble tooth has an important role to play in the development of future regenerative therapies [30].

Periodontal tissue-derived stem cells

When considering application to periodontal regeneration, stem cells derived from the tissues surrounding the teeth, i.e., the periodontium should be considered the first choice [12]. The PDL is a fibrous connective tissue that contains specialized cells located between the bone-like cementum and the inner wall of the alveolar bone socket. Just as PDL is essential for osteogenesis and cementogenesis during development and remodeling, cells derived from this tissue are supportive for the healing response to injury [31]. Early observations indicated that the PDL has a regenerative capacity and that a population of multipotent progenitor cells may exist within this tissue [32]. Transplantation of PDL-derived cells has shown the potential to regenerate bone and periodontal attachment apparatus *in vivo* [33–35]. PDLSCs were first isolated in 2004 and have been shown to give rise to adherent clonogenic clusters resembling fibroblasts [18]. They are positive for the stem cell markers STRO-1 and CD146, and they are capable of developing into adipocytes, osteoblast-like cells and cementoblast-like cells *in vitro* as well as producing cementum-like and PDL-like tissues *in vivo* [18,36]. In recent years, sources of stem cells from human [37], swine [38,39] and canine PDL tissues [40,41] are reported to be the most potent for periodontal tissue regeneration. Furthermore, *in vitro* studies have also found that PDLSCs were able to differentiate into mesodermal (i.e., adipocytes, osteoblasts, chondrocytes), ectodermal (i.e., neurons) and endodermal (i.e., hepatocytes) lineages [42]. Meanwhile, PDLSCs have also shown the capacity to differentiate into vascular cells, forming blood vessel-like structures in rats [43]. These findings suggest that the PDL constitutes an important stem cell source, not only for the regeneration of periodontal tissues, but also for the regeneration of other tissues and organs, making them highly amenable for use in periodontal regeneration. The PDL is under constant strain from the forces of mastication, and thus PDLSCs are likely to play an endogenous role in maintaining PDL cell numbers. This might explain why they are better than other dental stem cell populations at regenerating the complex structures of the periodontium [36,40,41]. Despite the considerable promise that the PDL holds for periodontal regenerative medicine, a need still exists for further characterization and validation of PDLSCs for clinical use [44].

The alveolar bone is a main part of the tooth-supporting apparatus, functioning as an anchorage of the tooth root to the alveoli and resorbing the forces generated by the function of mastication. Progenitor cells responsible for alveolar bone formation lay in the periosteal region, the PDL or around the blood vessels. Alveolar bone marrow is considered to be a useful and easily accessible source of bone-related progenitor cells; alveolar MSCs have an osteogenic potential that is similar to, or even more responsive than, cells derived from the iliac crest, although alveolar MSCs show poor chondrogenic or adipogenic potential [25]. Recently, putative stem cells from human PDL on the alveolar bone surface were isolated, characterized, and provisionally named as 'alveolar PDLSCs'. Interestingly, these 'alveolar PDLSCs' exhibited a strong proliferative capability, expressed high percentages of MSC markers, and were found

to have a higher osteogenic/adipogenic differentiation potential than those from the PDL of the root surface [26]. However, further studies need to be carried out to demonstrate that the reported 'alveolar PDLSCs' are PDL-derived.

The periosteum is also considered to be a suitable cell source for periodontal regeneration [45]. Mizuno et al. [46] grafted autologous cultured cell membrane that was derived from periosteum peeled from the mandibular body into a mechanically created class III furcation defect in dogs. Proper regeneration of multiple periodontal tissues was observed three months after the surgery. In addition, a treatment for human periodontal disease using periosteum-derived cells has already been conducted. It was shown that cultured periosteum combined with PRP and porous hydroxyapatite (HA) granules induced significantly more favorable clinical improvement in infrabony periodontal defects, when compared with the control group (PRP with HA) [47].

The cementum is a specialized calcified substance with ultrastructural similarity to bone that covers the root surface. It is excreted by cementoblast cells within the root of the tooth and is thickest at the root apex. These cementoblasts develop from undifferentiated mesenchymal cells in the connective tissue of the dental follicle at the interface between the dentinal tissue and the PDL, and they contribute to periodontal repair/regeneration after damage. The organic ECM of cementum contains proteins that selectively enhance the attachment and proliferation of cell populations residing within the PDL space [48]. In 1998, human cementum-derived cells were isolated, cloned and characterized *in vitro* and *in vivo*. These cells are capable of differentiating and forming mineralized tissue that exhibits several features identical to cementum when transplanted into immunodeficient mice, although different from the mineralized matrix produced by human BMMSCs [49]. In a proof-of-concept investigation, cementoblasts showed a marked ability to induce mineralization in periodontal wounds in a rodent periodontal fenestration model when delivered to the defects via biodegradable polymer sponges. However, the implanted dental follicle cells seemed to inhibit periodontal healing [50]. These results confirm the selective behaviors of different cell types *in vivo* and support the role of cementoblasts as a tool to better understand periodontal regeneration and cementogenesis.

The human gingiva is the oral mucosal tissue that surrounds the teeth and forms a mucoperiosteum covering the alveolar bone. Since the epithelial layer shows a unique fetal-like scarless healing process after wounding and has the capacity for continuous renewal, it is anticipated that this tissue could also be a source of stem cells. Recently, cells with MSC properties (GMSCs) have been isolated from gingival tissues and characterized [24,51,52]. GMSCs are easy to isolate and homogeneous, and they proliferate more quickly than BMMSCs in the absence of GFs. GMSCs display a stable morphology and do not lose MSC characteristics at higher passages. In addition, they maintain normal karyotype and telomerase activity in long-term cultures and are not tumorigenic, suggesting that they are superior to BMMSCs for cell therapy in regenerative medicine [23]. Very recently, the *in vivo* efficacy of utilizing GMSCs in bone regeneration was demonstrated in a mandibular defect as well as a critical-sized calvarial defect model in rats [53]. Furthermore, these cells gave rise to high-quality iPS cells, which suggests that gingival tissue is also a promising cell source for investigating the basis of cellular reprogramming and pluripotency for future clinical applications [54].

Stem cells from apical papilla

The apical papilla tissue is only present during root development before the tooth erupts into the oral cavity [55]. A unique population of dental stem cells known as SCAP is located at the tips of growing tooth roots. These cells form adherent clonogenic clusters and, similar to other MSC populations, they are capable of differentiating into adipocytes and odontoblasts/osteoblasts *in vitro* [20]. By co-transplanting SCAP cells, to form a root, and PDLSC, to form a PDL, into tooth sockets of mini pigs, dentine and PDL was formed [19]. These findings

provide support for the use of combined MSC populations in root and periodontal regeneration. Most human tissues from early in their development are not clinically available for stem cell isolation; however, because roots develop postnatally, the root apical papilla is accessible in dental clinical practice from extracted wisdom teeth. Thus, a very active source of stem cells with embryonic-like properties can be readily obtained. Further experiments on the properties of these cells obtained from human teeth following expansion in culture are needed.

Dental follicle stem cells

The dental follicle is a loose mesenchymal tissue surrounding the developing tooth germ which participates in the formation of periodontal progenitor cells. It is believed that this tissue contains stem cells and lineage-committed progenitor cells or precursor cells for cementoblasts, PDL cells and osteoblasts [56]. The presence of stem cells in the dental follicle (DFSCs) of human third molar teeth was demonstrated in 2005 [22], suggesting an alternative population of dental stem cells capable of differentiating into cells of the periodontium [57]. These fibroblast-like, colony-forming and plastic-adherent cells express stem cell markers (STRO-1 and nestin) and can be maintained in culture for at least 15 passages. STRO-1-positive dental follicular progenitors have been shown to differentiate into cementoblasts *in vitro* [57] and to form cementum *in vivo* [21]. Current evidence has shown that immortalized DFSCs were able to recreate PDL-like tissues that expressed periostin, Scx and type XII collagen, as well as the fibrillar assembly of type I collagen when transplanted into immunodeficient mice [58], while EMD [59] or dentin non-collagenous proteins (dNCPs) extracted from dentin [60] could stimulate DFSCs to differentiate into cementoblast lineages. Similar to SCAP, DFSCs represent cells from a developing tissue and might therefore exhibit a greater plasticity than other dental stem cells. However, further research is needed to explore the properties and potential uses of both SCAP and DFSCs.

Stem cells from dental pulp or exfoliated deciduous teeth (SHED)

The first human dental stem cells were isolated from dental pulp tissue of extracted third molar teeth (DPSCs) and were characterized relative to BMMSCs [16]. DPSCs were found to be highly proliferative, clonogenic cells capable of differentiating into odontoblast-like cells and forming dentin/pulp-like complex when implanted into immunocompromised mice. Subsequently, human MSCs were isolated from exfoliated deciduous teeth and were observed to induce bone and dentin formation *in vivo*. Furthermore, compared with DPSCs or BMMSCs, SHED grow and proliferate more rapidly and have a higher number of population doublings [17]. Further data demonstrate that pulp side population (SP) cells maintain self-renewal and multipotency for dentinogenesis, chondrogenesis, adipogenesis and neurogenesis [61]. Although there is no evidence that supports the use of DPSCs to regenerate PDL, they showed the highest osteogenic potential among BMMSCs, PDLSCs and periosteal cells, indicating that they may form a useful cell source for bone reconstruction around teeth and dental implants [62,63]. In 2009, the clinical trial of alveolar bone reconstruction using DPSCs was successfully carried out, and the data suggest that a DPSC/collagen sponge biocomplex can completely restore human mandible bone defects [27]. Taken together, these results suggest a potential role for DPSCs in bone and dentin regeneration; however, significant further work is required in this area.

Extraoral MSCs

Extraoral MSCs, i.e., non-dental stem cells, such as BMMSCs and adipose-derived stem cells (ASCs), have also been investigated as alternative cell sources for periodontal regeneration and bioengineering [64–67].

Bone marrow-derived MSCs

BMMSCs are the most widely investigated MSCs in tissue engineering and regenerative medicine because they are easily accessible, their isolation is straightforward, they can be biopreserved with minimal loss of potency, and they have shown no adverse reactions to allogenic versus autologous MSCs transplants. These cells are clonogenic and have demonstrated the ability to form bone and cartilage *in vivo*. Because of their differentiation potential, BMMSCs have been used in various phases of clinical application, particularly in orthopedics [68]. Indeed, BMMSCs can efficiently regenerate not only bone tissue, but also periodontal tissue in various animal models [69]. Recent data have shown that bone marrow progenitor cells can communicate with dental tissues and become tissue-specific mesenchymal progenitor cells to maintain tissue homeostasis [70]. Animal experiments have demonstrated that autotransplantation of BMMSCs induced periodontal regeneration in experimental class III furcation defects, and that the defects were regenerated with cementum, PDL and alveolar bone in the MSC-atelocollagen groups. Less periodontal tissue regeneration was observed in the control group than in the MSC-atelocollagen groups [64]. In addition, transplanted BMMSCs labeled with green fluorescent protein (GFP) were detectable by immunohistochemical analysis four weeks after transplantation. The periodontal defects were almost regenerated with periodontal tissue. Cementoblasts, osteoblasts, osteocytes and fibroblasts of the regenerated periodontal tissue were positive for GFP, which suggested that transplanted BMMSCs could survive and differentiate into periodontal tissue cells, resulting in an enhancement of periodontal tissue regeneration [71]. Moreover, clinical evidence indicated that periodontal tissue could be successfully regenerated using autologous BMMSCs combined with PRP [28]. Significantly, when evaluated in periodontal defects in dogs, cryopreserved MSCs showed no altered regenerative capacity compared with freshly isolated MSCs when applied to periodontal regeneration [72]. Notably, a few clinical cases showed the successful treatment of challenging periodontal defects with a novel cellular allograft that contains native MSCs and osteoprogenitor cells [73]. These data suggest that bone marrow is an excellent candidate source of MSCs for periodontal regeneration. Nonetheless, the established shortcomings in relation to the isolation of BMMSCs, i.e., pain and morbidity associated with bone marrow harvest, complicated procedures, as well as low harvested cell number, all mean that the use of this cell population in periodontal regeneration in the clinical setting will be a significant challenge in the future. Consequently, researchers have shifted their efforts on assessing alternative sources of MSCs for periodontal therapies [7].

Adipose-derived stem cells

Adipose tissue is an abundant source of MSCs. ASCs can be readily harvested in large quantities and can be obtained with relative ease with low donor site morbidity. ASCs have adipogenic, myogenic, osteogenic and chondrogenic potential, and they are very angiogenic in nature. These multipotent cells can be utilized in regenerating diseased or damaged tissue throughout the body, including the periodontium. More importantly, the safety and efficacy of ASCs have been demonstrated in numerous preclinical studies, supporting the use of these cells in curing human disease. Although ASCs originate from mesodermal lineages, recent preclinical studies have demonstrated that the use of ASCs in regenerative medicine is not limited to mesodermal tissue, but can also extend to both exodermal and endodermal tissues and organs [66]. Recently, ASCs were investigated for periodontal regeneration. For example, eight weeks after the transplantation of ASCs mixed with PRP into rat periodontal defects, new PDL-like and alveolar bone-like structures were formed, which implies that ASCs could promote periodontal regeneration *in situ* [67]. In a canine model of periodontal tissue regeneration, ASCs were transplanted with PRP into dental root bifurcation defects. ASC and PRP transplantation were found to prevent epithelial invasion into the defect area after four weeks, while newly induced bone was observed at the site of implantation after eight weeks [66]. Recently, freshly isolated, uncultured stromal vascular fraction of adipose tissue has been suggested as

a source of autologous progenitor/stem cells [74], offering a practical, promising candidate for future periodontal tissue engineering or cell-based periodontal therapy.

Selection of cell types

Although both dental and non-dental MSCs for periodontal regeneration are promising (Table 72.1), we must be aware that mesenchymal cell populations from different tissues display distinct biological properties [12]. Even if they carry common genetic markers, they are likely to be conditioned by their specific microenvironment and to be committed towards a specific differentiation pathway. Dental stem cells are isolated from specialized tissue with potent capacities to differentiate into odontogenic cells. However, they also have the ability to give rise to other cell lineages similar to, but different in potency from, that of BMMSCs [55]. When comparing different tissue-derived stem cell sheets for periodontal regeneration in a canine 1-wall defect model, PDLSCs resulted in more newly formed cementum and well-oriented PDL fibers than other cells (BMMSCs and alveolar periosteal cells). In addition, nerve filament was observed in the regenerated PDL tissue only in the periodontal ligament cell (PDLC) group. The amount of alveolar bone regeneration was highest in the PDLC group, although it did not reach statistical significance among the groups. These results indicate that PDLSCs combined with a β-tricalcium phosphate (β-TCP)/collagen scaffold serve as a promising tool for periodontal regeneration [41]. In another dog model with advanced periodontitis, PDLSCs were also demonstrated to be the most favorable candidate for cell therapy when compared to DPSCs and DFSCs. Autologous PDLSCs showed the best regenerative capacity of PDL, alveolar bone and cementum as well as peripheral nerve and blood vessel [40]. Except for PDLSCs, it remains to be determined which source of MSCs will be most suitable for regenerative periodontal therapy. The use of dental follicular cells is likely to be limited by the availability of tooth germs, and non-dental stem cells may require the transfer of genes to enhance their odontogenic potential. Although the best stem cell source is yet to be identified, the prospect of using these cells for regeneration represents a step forward in the development of more predictable biologically based therapies for the periodontium [69].

SIGNALING MOLECULES

GFs mediate crosstalk between cells and their microenvironment via their autocrine and paracrine effects [75]. They initiate their action by binding to specific receptors on the surface of target cells and their chemical identity, concentration, duration and context contain information that dictates cell fate for safe and effective regeneration of functional tissue. Hence, the importance of GFs in tissue engineering is unsurprising, considering their importance for tissue regeneration [76]. Accordingly, stimulation of osteogenesis, cementogenesis and connective tissue formation via presentation of various signaling molecules is necessary for periodontal tissue engineering. A number of recombinant human GFs, biological agents (e.g., EMD), and a patient's own biologically active products (e.g., PRP) are now used clinically, or are currently under extensive investigation and some of them have been examined by controlled clinical studies or randomized controlled clinical trials.

Types of signals

BONE MORPHOGENETIC PROTEINS

The bone healing process initiated by a single molecular species of bone morphogenetic proteins (BMPs), members of the transforming growth factor (TGF)-beta superfamily such as BMP-2 or BMP-7, sets in motion a cascade of cellular events resulting in differentiation of progenitor cells into phenotypes involved in periodontal regeneration [77]. Current data suggest that BMP-2, BMP-4, BMP-7 (i.e., osteogenic protein-1, OP-1) and BMP-12 are potent inducers of bone formation during mandibular reconstruction, with OP-1 (occasionally BMP-2) inducing substantial cementogenesis. In this context, BMP-12 supports the

reestablishment of the PDL, including regeneration of cementum and functionally oriented fibers, and prevents ankylosis and root resorption following replantation of teeth (reviewed in [77, 78]). There is mounting evidence that recombinant human BMPs stimulate periodontal regeneration if applied with suitable carriers [79,80]. However, the optimal effects are modulated by a range of factors that need careful evaluation in clinical studies. Furthermore, we must be aware that severe side effects, such as ankylosis and root resorption, have also been reported [81], although these were not always in accordance with outcomes obtained by other groups [82]. Considering the results of studies indicating that the application of recombinant human BMP-2 around a periodontal defect induces bone formation but not cementum formation [83], the combined use of BMP-2 and BMP-7 might be suitable for regenerating two hard tissues: bone and cementum [84]. In addition, BMP-2 has also been used in combination with other GFs, such as insulin-like growth factor (IGF)-1, to synergistically enhance differentiation of PDLCs [85,86] or recombinant human β-nerve growth factor [87] to improve the quality and quantity of regenerated bone. Of note, the absorbable collagen sponge (ACS) carrier containing recombinant human BMP-2 is now commercially available as InFuse® Bone Graft (Medtronic, Minneapolis, MN, USA) and has been applied for sinus floor augmentation and for localized alveolar ridge augmentation following tooth extraction in patients.

PLATELET-DERIVED GROWTH FACTORS

Platelet-derived growth factor (PDGF), as a serum GF for fibroblasts, has five isoforms (AA, AB, BB, CC and DD); of these, PDGF-BB was found to be more potent than the other isoforms in

promoting mitogenesis of PDL cells [88]. At concentrations of 10–20 ng/ml, *in vitro* studies suggested that PDGF-BB stimulated the proliferation of fibroblasts and osteoblasts [89,90], whereas a higher concentration (≥50 ng/ml) is required for the adhesion of PDL fibroblasts to diseased roots; concentrations of 5–20 ng/ml were not effective [91]. PDGF has also been shown to be effective when combined with either IGF, as shown by significant bone fill upon re-entry into the defects in animal models [92] and in patients with periodontal disease [93], or with dexamethasone [94], the latter being a well-known osteogenic differentiation factor. PDGF and IGF-1 had additive effects on calvarial DNA synthesis, but PDGF opposed the stimulatory effect of IGF-1 on collagen synthesis, and IGF-1 prevented the PDGF effect on collagen degradation [89]. In further research, IGF-1 alone at a dose of 10 μg did not significantly alter periodontal wound healing, while PDGF-BB alone at the same dose significantly stimulated new attachment, with trends of effect on other parameters. For example, the PDGF-BB/IGF-1 combination resulted in significant increases in new attachment and osseous defect fill above vehicle at both four and 12 weeks [95]. In humans, the use of purified rhPDGF-BB mixed with bone allograft resulted in robust periodontal regeneration in both class II furcations [96] and interproximal intrabony defects [97]. Based on those preclinical and clinical studies, recombinant human PDGF-BB homodimer in β-TCP is approved for the treatment of intrabony and furcation defects, as well as gingival recession in periodontal disease and is commercially available as Gem-21® (Osteohealth Co., Shirley, NY, USA). Furthermore, a large multicenter randomized controlled trial study of PDGF-BB homodimer, together with β-TCP, in the surgical treatment of a 4 mm or greater intrabony periodontal defect demonstrated significant increases in clinical attachment levels (CAL) reduced gingival recession at three months post-surgery, and improved bone fill when compared with those of β-TCP alone at six months [97]. The safety and effectiveness of this product was further demonstrated recently in a double-blind, prospective, parallel, active-controlled, randomized, multicenter clinical trial involving 54 patients with periodontal osseous defects [98]. Further longitudinal clinical data are still needed to confirm the long-term effect of this product [99]. Although far from ideal for meeting the needs of complex periodontal therapy, the road from basic research to clinical applications of PDGF-BB, or BMP-2 suggests a potential use of protein-based therapeutics for stimulating and accelerating periodontal tissue healing and bone regeneration [100].

FIBROBLAST GROWTH FACTOR-2

Fibroblast growth factor (FGF)-2 is a heparin-binding protein that regulates cellular functions including migration, proliferation and modulation of ECM production, in the wound healing cascade [101]. In periodontal regenerative therapies, the *in vivo* effectiveness of FGF-2 has been evaluated in beagle dogs as well as in non-human primates (reviewed in [102]). The results of these studies suggest that FGF-2 induces significant periodontal tissue regeneration with new cementum and new alveolar bone formation. Recently, a double-blind, placebo-controlled clinical trial (Phase II) was conducted in 253 adult patients at 30 Japanese dental facilities. The data obtained demonstrated that FGF-2 was efficacious in regenerating periodontal tissue without clinical safety problems [103]. Further clinical trials (Phase III) are still needed in order to establish the clinical efficiency and value of FGF-2 products [104].

GROWTH/DIFFERENTIATION FACTOR-5

Growth/differentiation factor (GDF)-5 is a member of the TGF-β superfamily, which shows a close structural relationship to BMPs and plays critical roles in skeletal, tendon and ligament morphogenesis [105]. In the periodontal field, it has been reported that cells involved in root- and PDL-forming stages exhibit significantly stronger signals of GDF-5 in comparison to those in more mature, well-established tissues [106]. *In vitro* studies have shown that recombinant human GDF-5 at concentrations of 10–1000 ng/ml inhibits alkaline phosphatase activity in human PDL cells [107]. Recently, the effect of recombinant human GDF-5 on periodontal repair was demonstrated in animal models by using various biomaterials as vehicles for delivery, such

as ACS, β-TCP or an injectable poly-lactide-co-glycolide-acid (PLGA) composite (reviewed in [108]). The combined results suggest that recombinant human GDF-5 appears to safely and effectively support periodontal wound healing/regeneration in intrabony periodontal defects without complications, while in a dose-dependent order. Recently, a Phase IIa randomized controlled clinical and histological pilot study evaluated recombinant human GDF-5/β-TCP for periodontal regeneration in twenty chronic periodontitis patients [109].

PLATELET-RICH PLASMA

The use of PRP, a platelet concentrate from autologous blood, is one of the strategies available for modulating and enhancing periodontal wound healing and regeneration [4]. PRP includes a pool of GFs such as TGF-β, vascular endothelial growth factor (VEGF), PDGF, IGF-1, epidermal growth factor and FGFs. For this reason, it has been suggested that the use of PRP might increase the rate of bone deposition and bone quality in such dental treatments as sinus lifts, placement of autogenous mandibular bone grafts, implants, and periodontal surgery. Both preclinical and clinical studies demonstrate the effectiveness of PRP in bone and periodontal augmentation when used in conjunction with bone graft materials (reviewed in [4]). Unfortunately, the literature on the topic is contradictory and the published data are difficult to sort and interpret. For example, in a series of clinical studies performed by Döri and co-workers on the healing of intrabony defects, the addition of PRP failed to improve the total outcomes in terms of probing depth reductions and CAL gains [110]. Furthermore, PRP may not provide any additional effect when associated with GBR around dental implants [111]. Although data published thus far suggest that PRP does not always exert additional effects, a systematic review of literature does find evidence for beneficial effects of PRP in the treatment of periodontal defects. Nonetheless, evidence for beneficial effects of PRP in sinus elevation appeared to be weak [112]. While PRP has been somewhat beneficial when used in periodontal or implant regeneration, it has fallen out of favor recently because of the lack of controlled clinical trials providing strong evidence of its efficiency [113]. However, the use of a patient's own biologically active proteins, GFs and biomaterial scaffolds for therapeutic purposes has opened a new way of understanding regenerative medicine. These simple and cost-effective procedures may have a potential impact in reducing the economic costs for standard medical treatments, soon achieving a 'golden age' by the development of user-friendly platelet concentrate procedures and the definition of new and efficient concepts and clinical protocols [4].

ENAMEL MATRIX DERIVATIVE

EMD, an extract of porcine immature enamel matrix, is regarded as a candidate protein mixture that is thought to be the induction of proliferation, migration, adhesion, mineralization and differentiation of cells in periodontal tissue [114]. EMD contains over 95% amelogenin with small amounts of enamelin and other proteins. In 2000, a randomized, double-blind, placebo-controlled, split-mouth study was designed to compare the clinical and radiographical effects of EMD treatment with that of placebo-controlled treatment for intrabony defects. The results demonstrated that treatment with flap surgery and EMD, compared to flap surgery with placebo, produced a significantly more favorable clinical improvement in intrabony periodontal defects [115]. A commercial EMD, marketed as Emdogain® (Institut Straumann AG, Basel, Switzerland), received US Food and Drug Administration (FDA) approval and has been available for clinical application for over 10 years, leading to a number of clinical trials performed to evaluate the clinical effects of Emdogain® (reviewed in [4]). In principle, EMD, which seems to be safe, was able to regenerate lost periodontal tissues in previously diseased sites based on clinical parameters and was better than open flap debridement (OFD) alone or GTR. Combined with allograft materials, EMD may be of additional benefit, but it needs to be further investigated [116]. Thus far, however, no evidence indicates that more teeth could be saved, and no evidence points to any

important differences between EMD and GTR [117]. Of interest, a ten-year investigation following treatment of intrabony defects with EMD, GTR, EMD plus GTR or OFD indicated that the three regenerative treatments showed a statistically significant higher CAL gain, compared with that of OFD at both one and 10 years [118]. However, another double-blind randomized clinical evaluation of EMD for the treatment of proximal class II furcation involvements showed that the use of EMD did not promote a superior reduction in probing pocket depths or a gain in clinical and osseous attachment levels, but only resulted in a higher rate of class II to class-I furcation conversion [119]. It seems that the clinical application of EMD for periodontal therapy still requires additional well-controlled clinical trials. EMD is applied not only for periodontal surgery, but also for tooth transplantation [120] and management of peri-implantitis [121]. However, the clinical predictability of such treatments remains to be determined.

Crucial delivery barriers to progress

The biological basis of using GFs in periodontal tissue engineering stems from their inherent property of inducing chemotaxis and/or mitogenesis of mesenchymal and somatic cell populations, initiating a cascade of events that ultimately lead to proliferation and differentiation of these cells. BMP-2/-7, GDF-5, FGF-2 and PDGF have been intensively investigated in preclinical and clinical trials and the results appear promising [77,78,100,102,108]. However, at this point in time, it appears very difficult, if not impossible, to translate knowledge about the functions of GFs in embryonic development, tissue formation/homeostasis and bone healing into clinically applicable solutions that address the loss of periodontal tissue. First, GF therapy is currently hampered by the lack of a safe and efficient delivery system that can provide a sustained therapeutic effect without cytotoxicity or unwanted side effects as a result of using very high doses of GFs [122]. Second, enormous costs are associated with recombinant human GFs in relation to the relatively small and non-life-threatening periodontal defects for which other treatment options (e.g., implants) exist. Of note, the delivery strategies commonly used today in periodontology are bolus injection or physical combination of GFs with prefabricated biomaterials. The rapid degradation, hence, low local availability of GFs suggests that these delivery strategies do not meet the physiological requirements of periodontal tissue repair processes [123]. Thus, in spite of the many recombinant GFs and cytokines now available for research purposes and the testing of some in humans, the clinical experience has, so far, been disappointing. Consequently, sophisticated approaches must be developed to deliver GFs that allow for the controlled, sustained and localized delivery of proteins [76]. New drug delivery systems that regulate the biological presentation of GFs represent an attractive new generation of therapeutic agents for the treatment of a wide variety of diseases. Such devices essentially allow the loaded GF(s) to be released at a desired rate and concentration and to remain at injury sites for a sufficient time to recruit progenitors and stimulate the tissue healing processes [123] (Fig. 72.2). In addition, drug delivery systems, termed cell scaffolds, can be formulated to have particular structures that facilitate cellular infiltration and growth. To improve their properties, many drug delivery systems serve dual purposes. In addition to providing cell support, cutting-edge scaffolds biologically interact with adhering and invading cells and effectively guide cellular growth and development by releasing bioactive proteins. To design controlled release systems for specific applications, it is important to understand the basic principles of protein delivery and the stability of each applied biomolecule [124].

Many biological and engineering challenges in the use of GFs for tissue regeneration remain to be solved. It is certain that these signaling molecules promote periodontal tissue and bone formation, but the ideal concentrations still need to be determined, and safety issues currently remain. In addition, understanding when to manipulate the cell's differentiation pathway with the application of single or multiple doses of GFs at the appropriate concentration is required to optimize the effect of these agents in periodontal wound healing. It also seems that

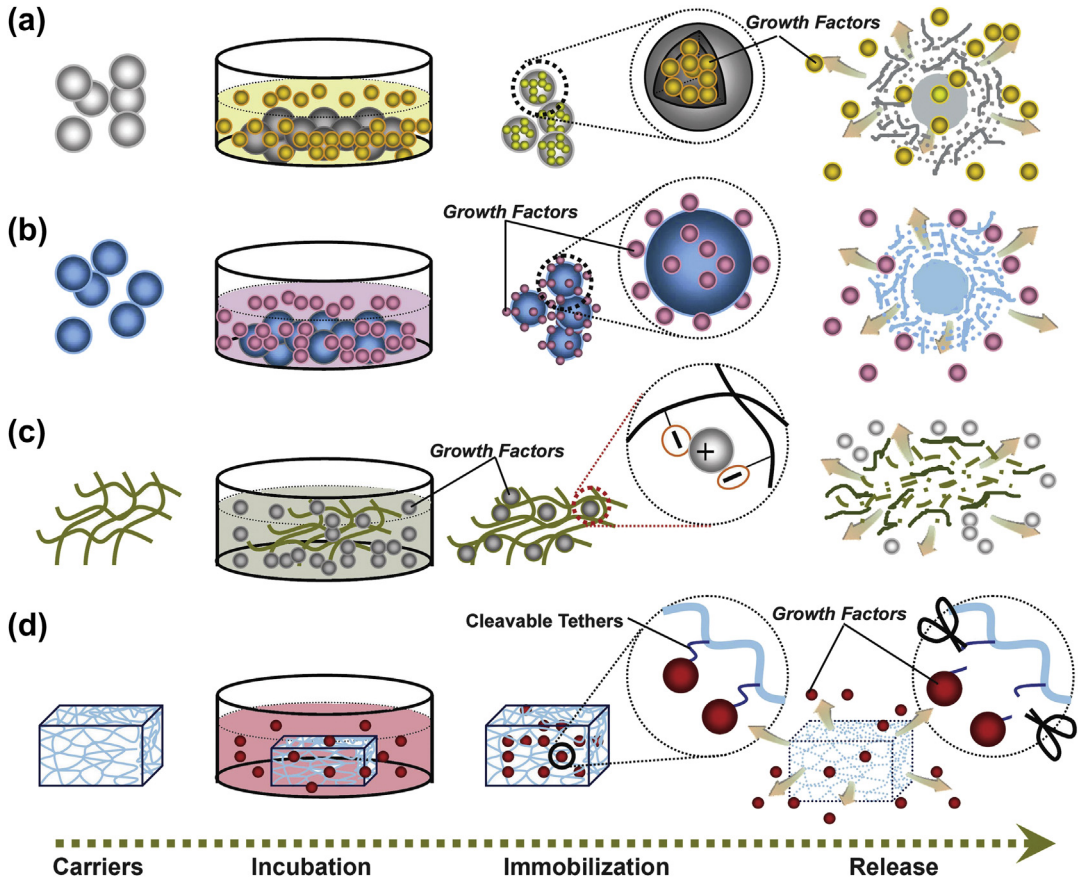

FIGURE 72.2

Schematic illustrations of the frequently investigated methods for immobilization of growth factors (GFs) and their primary release mechanisms (illustration is not to scale). (a-c) Non-covalent immobilization: GFs are directly entraped into (a) or adsorbed onto (b) the carriers, or immobilized via the formation of ionic complexes with polymer matrices (c). (d) Covalent immobilization: GFs are modified and thereafter covalently crosslinked to the hydrogels via crosslinkable and cleavable bonds that can be liberated once the tethers are degraded hydrolytically or enzymatically. *Reproduced from Chen et al. [167] with the permission of Elsevier Inc.*

any treatment aiming to mimic the natural tissue regeneration processes should not be limited to the provision of a single GF, but should deliver multiple agents at an optimized ratio in a specific spatiotemporal pattern [75]. Therefore, different release profiles from the same carrier may be particularly important in tissues with mixed cell populations, such as those found in the periodontium, where similar tissues, like bone and cementum, grow at different rates [124]. Furthermore, treatment of intrabony defects with GFs is likely to require both appropriate temporal release of the agents and a carrier that can serve as a template for new tissue formation, providing space maintenance and supporting the mucoperiosteal flap. Many of these issues have not been adequately addressed, at least from a periodontal standpoint; elucidation of these factors is essential prior to conducting expensive human clinical trials.

Gene delivery as an alternative to GF delivery

Because of the short half-life of topically administered GFs *in vivo*, usually ranging from several hours to several days, researchers have tried to extend protein activity using gene delivery strategies that involve converting cells into protein-producing factories. This is achieved by delivering plasmid DNA encoding the GF(s) of interest into cells/tissues either directly or via gene delivery vehicles or vectors [125]. This therapeutic concept has emerged as a promising

strategy for the modulation of the host response triggered by periodontal microbe and the regeneration of periodontium during disease progression [3].

Using viral vector transduction, cells can be manipulated *in vitro* and when transplanted into patients, these cells might restore normal tissue function. One of the most promising gene therapy approaches for periodontal regeneration, however, is based on the combination of naked DNA with a biodegradable carrier. Using this approach, collagen or other biomaterials are used to engineer a so-called 'gene-activated matrix' (GAM) that can carry and deliver naked DNA that directs an individual's own cells to produce a therapeutic effect [126]. A gene therapy product does not need to carry and deliver manipulated stem/progenitor cells, rather, it is able to signal the available cells to differentiate into a phenotype more favorable to the regenerative process [127].

Viral vector genes can be expressed *in vivo* from weeks to years, thereby having greater sustainability than that of a single protein or compound application. A unique advantage of gene therapy is the possibility of delivering more than one regenerative factor by employing two or more DNAs [128]. This combinatorial approach has shown significant regenerative potential compared to individual gene delivery, offering strong potential in regenerating tissues in three dimensions at the tooth-ligament-bone interface. In addition, gene therapy has also been investigated for the possibility of modulating periodontal disease progression via delivery of either antimicrobial or host modulators, considering that the host response against pathogenic bacteria is a major cause of periodontal tissue destruction [129]. Based on this concept, gene delivery, in combination with tissue engineering, is the only possible strategy that may mimic critical aspects of the natural biological processes occurring in periodontal development and repair [3,9,10,130–132]. The genes of interest in periodontal therapy include, but are not limited to, BMPs, PDGF, FGF-2, IGF-1 and TGF- β (reviewed in [125]). Of interest, the adenovirus encoding the PDGF-B gene delivered in a collagen matrix exhibits acceptable safety profiles for possible use in human clinical studies [133]. Although hundreds of gene therapy clinical trials have taken place in the past 20 years, much work still needs to be done to ensure an ideal safety profile for each gene and delivery method combination. With further efforts in this field, it is expected that gene therapy may augment current protein-based strategies and potentially allow for tissue-specific targeting and delivery of multiple signals in a spatially controlled and bioavailable fashion with the goal of regenerating natural tissue replacement in the craniofacial and periodontal region [127].

SCAFFOLDING AND BIOMATERIALS SCIENCE

The management of periodontal defects began with the introduction of a 'filler' material that aimed to induce bone regeneration. Various types of bone grafts, such as synthetic filler materials (alloplastic materials), autografts, allografts and xenografts, have been investigated for this purpose. Although utilization of such grafting materials for periodontal defects may result in some gain in CAL and radiographic evidence of bone fill, careful histological assessment usually reveals that these materials have little osteoinductive capacity and generally become encased in dense fibrous connective tissue [6]. Frequently, these treatments serve to ease the symptoms, not cure the disease. Tissue engineering offers clear merits over conventional replacement therapies that suffer from a host of drawbacks, such as scarcity of donor source, donor site morbidity, risk of lateral transmission of pathogens and graft-versus-host rejection. A major unmet challenge in tissue engineering today has been the synthesis of complex constructs that are principally comprised of biomaterials and multiple cell types.
This development is also true in periodontal tissue engineering. With the possibility of therapeutic cell cloning becoming a reality, there is an urgency to develop technologies that can precisely control the behavior of stem cells in culture. Central to these technologies would be the probable inclusion of biomaterials as an important component because the scaffold plays a vital role in converting isolated cells into functional tissues. Advances in biomaterial

research will undoubtedly facilitate the transformation of this concept into reality. Factors of great importance in the selection of a suitable scaffold material include such properties as porosity, tissue conductivity, biocompatibility and resorption rate. An appropriate scaffold has several design criteria that ensure not only the precise delivery of therapeutic cells to the site of injury, but also the rigorous control of their fates *in vitro* and *in vivo* toward regeneration.

Requirements of cell scaffolds

The implantation of cells in the afflicted area could be a direct approach in regenerative strategies, but the requirement for a support material to promote regeneration, especially in large sized defects, is a critical consideration. Periodontal tissue and bone are expected to grow into an adjacent defect only when the space is maintained and soft tissue ingrowth is prevented. Thus, the scaffold should act in a manner consistent with the established principles of GTR. To maintain the space for a sufficient time, the scaffold needs to feature such properties as ease of clinical handling and shaping and sufficient rigidity to withstand soft tissue collapse into the defect [6]. Additionally, the scaffold should be biocompatible with no biological hazards, and it should assist tissue functionality by promoting the easy diffusion of nutrients, GFs and cellular waste products. Furthermore, its biodegradability should be adjustable to the time required for tissue regeneration, thus avoiding interference with the physiological healing process. When considering the compatibility of internal structure with cell attachment and colonization and the compatibility of ingrowth tissues with those to be regenerated, the amount of porosity and the pore size of the supporting 3D structure are important features in the design of tissue-engineering scaffolds [134]. ECM components organized in the PDL not only reflect the functional requirements of this matrix, such as mechanical stress and storage of signaling molecules, but also regulate the tissue framework during development and regeneration. This idea is inspired in nature itself because most cells in the body subsist in a 3D world and are anchored onto a network of ECM, which the scaffolding design proposes to recreate. With this in mind, scaffold characteristics should mimic the complex and demanding environment to which cells are exposed and should be able to define a local biochemical and mechanical niche with complex and dynamic regulation that cells may sense, while, at the same time, not inducing an overexpression of inflammatory response [135]. Moreover, biosafety and bioactivity are of great importance. Although no guidelines have yet been established for assessing the safety and efficacy of a biological transplant, clearly the materials should be free from transmittable disease and immunologically inert [6].

Classes of biomaterials

For regeneration, biomaterials are intensively utilized, as a scaffold for cell delivery, a template for cell proliferation and differentiation, or as a capsule/filter to maintain the cell's viability and to deliver the synthesized biomolecules. The resorption, mechanical strength and efficacy of these materials can be manipulated through structural and chemical design parameters. Biomaterials used in periodontal tissue engineering include natural or synthetic polymers, ceramics and composites. Each material offers a unique chemistry, composition and structure, degradation profile and possibility for modification.

NATURALLY DERIVED POLYMERS

Natural biomaterials serve as a cornerstone in the development of matrix-based regenerative therapies that aim to accelerate clinical application due to their excellent biocompatibility, biodegradability, affinity for biomolecules and wound healing activity [136]. Collagen, hyaluronic acid, alginate and chitosan scaffolds have been used in periodontal regenerative research for more than two decades. The natural origin of these materials allows the design and engineering of biomaterial systems that function at the molecular level, often minimizing chronic inflammation. They can also be easily modified, both chemically and physically, to form desired structures, possess optimal properties and perform specific functions for various

applications. The use of natural polymers in the form of hydrogels allows for the incorporation of biological agents by promoting crosslinking when the GF is dispersed in the polymer solution. Because natural polymers are often soluble in water, the creation of hydrogels may occur under mild fabrication conditions that are relatively harmless to the bioactivity of the GFs. Normally, these hydrogels are degraded by enzymes and/or acid hydrolysis at a rate depending on the degree of crosslinking or the molecular weight [136]. In addition, natural polymers can also be modified to become 3D scaffolding materials, such as porous sponges, particles, films and rods, and for the formulation of stimuli-responsive biomaterials.

Purification of the major component of the ECM has been the subject of many potential tissue engineering strategies. Collagen is regarded as one of the most useful biomaterials owing to its excellent biocompatibility and safety associated with its biological characteristics, such as biodegradability and weak antigenicity. While collagen hydrogel fits well with injectable cell delivery, highly porous collagen lattice sponges with crosslinking provide mechanical stability that has been used to support the *in vitro* growth of many types of tissues and to deliver multiple GFs. Following the clinical use of collagen carriers delivering BMPs for tibial shaft fractures [137], spine fusions and long-bone nonunions [138], collagen is currently being evaluated for widespread clinical periodontal regeneration. Particularly, collagen is used clinically as a composite with ceramics [139]. Commercially available collagen composite scaffolds include Formagraft™ (Nuvasive, San Diego, CA, USA) and OssiMend™ (Collagen Matrix, Franklin lakes, NJ, USA). Apart from InFuse® Bone Graft, ACS has been used as a carrier and/or scaffold for periodontal regeneration in animal studies [140] and clinical trials [37].

As a deacetyled derivative of chitin, chitosan is structurally very similar to naturally occurring glycosaminoglycans and is biodegradable in mammals. Chitosan has several merits for use as a cell vehicle material, including its ability to be molded into various geometries (e.g., porous structures) and forms (e.g., gels), ease of chemical modification, high affinity for *in vivo* macromolecules and minimal foreign body reaction [141]. While chitosan can support cell attachment for cell delivery purposes, it is not strongly supportive of tissue regeneration, as demonstrated by its effect on the width of keratinized gingiva in dogs [142]. Accordingly, chitosan needs to be either modified chemically or conjugated with other molecules or peptides to enhance its biocompatibility for cell attachment and capability for tissue regrowth [6]. For example, the addition of HA beads to chitosan gels produced a novel scaffold in which the pore sizes and interconnectivity were preserved. When loaded with FGF-2, this scaffold may provide a suitable 3D environment supporting cellular structure, proliferation and mineralization [143]. Chitosan has also been widely used in combination with collagen [130,144], coral [132], HA [131] and β-TCP [145] to develop new scaffolds for periodontal tissue-engineering applications.

Alginate hydrogels bearing cell adhesion ligands have been used as scaffolds for cell encapsulation and transplantation, and they have yielded promising results in experiments aimed at engineering bone tissue capable of growth from small numbers of implanted precursor cells . An alternative to alginate hydrogels as a cell carrier is the incorporation of cells into beads of alginate to prevent immune cells and soluble complexes from killing the transplanted cells; this property negates the need for immunosuppressant use [146]. As a result of the semipermeable nature of the beads, the soluble factors made by the entrapped cells can be released at the implantation site to guide regenerated tissues [6]. However, these developments have not yet been used in periodontal bioengineering. Of interest, calcium alginate film was found to be more effective for GTR and GBR use than the collagen membrane [147].

SYNTHETIC POLYMERS

Numerous synthetic polymers have been widely used for scaffolding applications. Although synthetic matrices in their native forms lack cellular recognition sites, they have well-controlled and reproducible chemical and physical properties [148]. Synthetic polymers have many

advantages. For example, they offer the ability to provide controllable and reproducible structural properties, they are biocompatible, and their biodegradation rates can be tailored for the intended application through specific chemical manipulation. Synthetic scaffolds are produced by a variety of fabrication techniques, and these materials can be easily manufactured into preformed sizes and shapes according to clinical requirements. Synthetic matrices are typically processed into the form of solid scaffolds, small particles or hydrogels, depending on the mechanical and degradation properties for the particular application [148].

Hydrolytically degradable polymers are widely used materials for scaffold manufacture. The US FDA has approved the use of poly(α-hydroxyester)s, such as poly(glycolic acid) (PGA), poly(L-lactic acid) (PLA) and their copolymers, (PLGA) and polycaprolactone, for a variety of clinical applications. Solid scaffolds are typically porous matrices fabricated by techniques such as solvent casting, gas foaming, particulate leaching, and electrospinning [148]. Normally, these materials do not elicit a permanent foreign body response as they are gradually degraded into natural metabolites and eventually replaced by natural tissue. The physical properties of these polymers can be readily altered by varying the ratio of lactide/glycolide, the molecular weight and the crystallinity, or by combining them with other materials [134]. In some cases, synthetic polymers can be used as additions to natural biomaterials. For example, the rapid degradation of fibrin, a biopolymer critical to hemostasis and wound healing, can be decelerated by modification with poly(ethylene glycol) (PEG), thus creating a hybrid material for cell delivery [149].

PLA is one of the most promising biopolymers, because it is a naturally occurring organic acid, and the monomers may be produced from non-toxic renewable feedstocks [150]. Other degradable polymers include PEG [151], polylactide and polyglycolide [152], and polylactide acetyltributyl citrate and polydioxanon [153], and these polymers have also been explored and tested for guiding periodontal tissue regeneration. Amorphous poly(D,L-actic acid) (PDLLA) is one of the most popular materials considered for scaffold production, and it is used in combination with bioactive glasses because it can be combined with such biomolecules as GFs and antibiotics to establish a locally acting drug delivery system [134]. By this modification, the creation of a macroporous structure within the bioceramic materials is possible. For example, when PLGA microparticles are incorporated into calcium phosphates (CaP) cement, a macroporous CaP cement scaffold is formed after PLGA hydrolysis *in vivo* [154]. Although synthetic scaffolds have excellent mechanical properties and processing ability, their lack of natural biological cues can be a potential weakness. Furthermore, some polymers suffer from shortcomings, such as eliciting persistent inflammatory reactions and eroding or being incapable of integrating with host tissues [11]. These issues need to be addressed prior to clinical application.

CERAMIC-BASED MATERIALS

Ceramic-based materials have been widely used for bone and periodontal regeneration. Commercially available products include CaPs (e.g., HA and TCP), calcium sulfate and bioactive glass [155]. Clinically used forms of HA and β-TCP include injectable formulations that harden at body temperature, such as β-BSM™ (Etex, Cambridge, MA, USA) and BoneSource HA Cement (Stryker, Kalamazoo, MI, USA). These materials exhibit a range of degradation rates that span from weeks to years. Their biocompatibility and high protein-binding affinity make them good vehicles for drug delivery [98]. Recently, several porous ceramic scaffolds have also been examined for their utilization as cell delivery materials [6].

Both synthetic and coral-derived porous HA have been shown to support significant clinical improvements in periodontal measures following implantation in intrabony defects [13]. The porosity and degree of sintering of synthetic HA ceramics primarily determine the rate of biodegradation.

The degradation rate of β-TCP, a porous form of CaP, can be controlled by changing the Ca/P ratio. Because of its degradation characteristics and its similar proportions of calcium and phosphate to cancellous bone, β-TCP is regarded as an ideal material for bone substitutes for periodontal repair [108,156]. Owing to the rapid degradation of β-TCP and its associated poor mechanical properties, research has focused on mixed CaPs, such as mixtures of β-TCP and HA or β-TCP and polymers. These hybrid materials appear to be reliable vehicles for cell delivery, with studies showing good tissue formation associated with the implanted cells [6]. The treatment of periodontal intrabony defects with a combination of two ceramics (calcium sulfate in combination with β-TCP) led to a favorable clinical outcome after two years [157]. The alloplastic material Osteon (Genoss, Suwon, Korea) has an HA surface coated with β-TCP (70% HA and 30% β-TCP). The pore size of Osteon is 300−500 μm, and its volumetric porosity is approximately 77%. It has recently been reported that it is suitable for use in sinus graft applications [158]. For periodontal regeneration in periodontitis models, HA/TCP composite is demonstrated to be effective, both as vehicles for cell delivery [38] and as supporting biomaterials for cell sheet implantation [39].

Biomaterial redesign for periodontal application

The selection of the specific biomaterial is a key variable in the design and development of scaffolding systems. It has recently been proposed that a combination of several materials may offer the best opportunity for beneficial clinical outcomes [122]. For example, a porous chitosan/collagen scaffold [144] and a glycidyl methacrylate derivatized dextran (Dex-GMA)/gelatin scaffold prepared through a freeze-drying process were developed specifically for periodontal tissue engineering. Furthermore, natural polymers can be strengthened mechanically by combining them with ceramics, such as HA [131,143], β-TCP [145] or polylactide (blends, copolymers and interpenetrated networks) [159]. Thus, for periodontal regeneration, one promising direction is the formation of hybrid materials that take advantage of both natural and synthetic materials by combining excellent mechanical properties and an intrinsic structure highly compatible with tissue ingrowth. However, in nearly every case, these materials were adopted from other areas of science and technology without substantial redesign [11]. Although a number of biomaterials, such as ASC and β-TCP, have had a long history of clinical use in periodontal therapy, very few interact with their surrounding host environment or promote regeneration of functional periodontal tissue such that a seamless integration with host tissue is created in an intelligent and proactive fashion. Alongside the rapid advances in stem cell biology, progress in biomaterials design and engineering is now converging to enable a new generation of instructive materials to emerge as candidates for periodontal regenerative medicine.

In terms of shape and geometry, preformed scaffolds are suitable for defects requiring mechanical strength or a predefined shape, such as one-walled bone defects, whereas injectable scaffolds may facilitate clinical use in two- or three-walled intrabony defects. Injectable types of scaffolds are expected to form the shape of any cavity or repair site, but must solidify within a clinically acceptable timescale *in situ*. Of note, such devices will shorten surgical operation time, minimize damaging effects of large gingival retraction and lessen postoperative pain. One critical disadvantage of injectable biomaterials is their poor mechanical strength and porosity; however, pores can be generated in scaffolds with rapidly degrading particles or gaseous bubbles as porogens to promote cell attachment, migration, proliferation, mass transfer, vascularization and material resorption [160]. These modified hydrogels are promising delivery systems for therapeutic cells.

The functional significance of the ECM has generally been defined in terms of the provision of a structural support for cell adhesion and the establishment of tissue physical integrity. Recent evidence has, however, led to a paradigm shift where the ECM is increasingly recognized as exerting a profound influence on cell behavior. Therefore, biomaterials are required to act as

the temporary ECM in the regeneration of a new tissue. To this end, a scaffold is not simply a mechanical support and initial cell anchorage site, but it must be 'informative' to the cells. That is, the scaffold should be capable of stimulating specific cellular response at the molecular level [161]. It follows that the design of new cell seeding scaffolds must take into account microenvironment design features that induce the appropriate gene expression in cells forming new tissues [162]. The complexity of this design process is exemplified by the dynamic states of the cells and tissues, which are regulated by the spatial and temporal coordination of multiple cell processes, each of which is regulated by multiple reciprocal interactions between cells and their ECM [162]. Biomaterial modification can take on different levels of complexity to produce increasing levels of physiological 'mimicry' and functionality. Their interactions with cells and tissues may be improved or fine-tuned by adequate chemical modifications, such as grafting with cell adhesion peptide Arg-Gly-Asp (RGD) or by surface treatments (e.g., surface plasma modification or surface chemistry modification through grafting with other polymers) [136,163]. The incorporation of RGD peptides in hydrogel matrices has been found to significantly enhance the attachment, spreading, survival and mineralization of encapsulated dental follicle progenitors, suggesting that RGD additives may promote the use of hydrogels for periodontal mineralized tissue engineering. The incorporation of peptide motifs recognized by cell receptors and the use of recombinant DNA technology have enabled the creation of naturally derived tissue-engineering scaffolds with new levels of biofunctionality [15]. Typical surface modifications include, but are not limited to, changes in hydrophilicity, functionalization with charged groups, the incorporation of insoluble ligands and peptide cell recognition sequences (e.g., RGD), the attachment of larger proteins, supramolecular self-assembly and the development of materials that bind and release soluble factors [164]. The wettability of the material surface, particularly in synthetic polymers, can be effectively regulated by physical treatments, e.g., by irradiation with ions, plasma or ultraviolet (UV) light. The irradiation-activated material surface can be functionalized by various biomolecules and nanoparticles. This characteristic further enhances its attractiveness for cells and its effectiveness in regulating cell functions [165]. Strategies based on physical cues include the reproduction of nanoscale topology, superposition of mechanical cues and control of degradation. Designing biological recognition into a biomaterial may also obviate the need for therapies based on the delivery of cells or recombinant GFs, which are subject to regulatory constraints [162]. To this end, scientists are creating new materials, including those with improved biocompatibility, stealth properties, responsiveness (smart materials), specificity and other critical properties.

We must be aware that sites of injury or diseased organs are characterized by heightened immunological surveillance and a high concentration of inflammatory cytokines. As such, these sites often present environments hostile to healthy cells attempting to establish and repopulate. This is extremely important in the management of periodontal disease. Therefore, to eliminate the need to promote a harsh immunosuppressive regime, an additional role for scaffolds needs take into account the insulation of their cellular cargos from the host immune system to, in turn, promote the survival of transplants [3]. Finally, in order to engineer functional periodontal tissues, the correct mechanical stimuli will need to be conveyed to the developing tissues within the scaffold, although very few studies have addressed this issue [6]. To date, biomaterials are rapidly being developed to display and deliver stem cell regulatory signals in a precise and near-physiological fashion within the tissue defect, fostering the regeneration of the missing tissue [75]. The transplant must participate in the regenerative process, considering the specific properties of each tissue interface, which can only be achieved through the design of scaffold materials accommodating the specific characteristics of periodontal hard and soft tissues, and providing stem cells with the necessary cues to satisfy cellular needs of both tissue types. Further synergism of cell biological and biomaterials technologies promises to have a profound impact on stem cell biology and to provide insights that will advance stem cell-based clinical approaches to tissue regeneration [166].

PERIODONTAL BIOENGINEERING STRATEGIES

Periodontal tissue-engineering strategies typically involve harvesting of suitable autologous donor tissues (e.g., the PDL) from which cells are isolated and expanded in a good manufacturing practice (GMP) facility. Expanded cells are then seeded onto a matrix and surgically implanted into the host's periodontal defects. Alternatively, the cell/matrix may be further incubated in a bioreactor, or other such system prior to implantation, in which the cells may be exposed to biological, chemical or physical stimuli that promote the formation of the appropriate tissue [5]. Considerable preclinical data and some clinical successes support the applicability of these cell-based approaches [40,64,66]. However, the process is very complex and not cost-effective. Additionally, the scarcity of the cell source is an issue. Although allogenic cell transplantation has shown success [39], the potential risks associated with transplanting exogenous (foreign) cells remain to be addressed. Even without any therapeutic intervention, living periodontal tissues can have a staggering capacity for regeneration. As such, a biomaterials/protein-based strategy that avoids the use of *ex vivo* cultured stem cells to facilitate endogenous repair is a novel approach to periodontal tissue engineering. Based on current understanding of periodontal tissue engineering, both cell-free and cell-based approaches have their own advantages and disadvantages, and both warrant further investigation (Fig. 72.3).

Cell-free approaches

As noted in the Introduction section, recent advances in periodontal bioengineering have shifted the focus from the attempt to recreate tissue replacements *ex vivo* (*in vitro* paradigm) to the development of an *in vivo* paradigm to achieve *in situ* periodontal regeneration [5]. However, a daunting question for the *in vivo* paradigm involves the requirement for transplanted cells, as this has been viewed as a core component for *in vivo* tissue engineering. Interestingly, but not surprisingly, cell-free *in vivo* tissue engineering has shown that appropriate stimuli can activate local cellular populations and direct their trafficking, leading them to contribute to endogenous tissue formation [4] (Fig. 72.4). The design of cell-free approaches for periodontal regeneration is based on the concept that relies on harnessing the intrinsic regenerative potential of endogenous tissues using a conductive/inductive scaffold, either alone or in combination with such molecular stimuli as GF or genes, to initiate reparative processes *in situ* [167].

In carefully selected cases, upon implantation, a conductive scaffold may guide the regeneration of the periodontal tissue by passively allowing the attachment and growth of vascular elements and progenitor/stem cells that reside in the tissue defect. Nevertheless, its regenerative potential is limited by the lack of biologically active factors and sufficient progenitor cells within the defect site. On the other hand, an inductive scaffold may guide the regeneration of the periodontal tissue by carrying one or more biologically active factors, such as stromal cell-derived factor (SDF)-1, BMP-2, PDGF-BB and/or FGF-2, which recruit vascular events and progenitor/stem cells from the immediate vicinity to the tissue defect (reviewed in [11]). The regenerative potential of an inductive scaffold is higher than that of conductive biomaterial because more progenitor cells can repopulate the tissue defect [168]. Trafficking of stem/progenitor cells requires the complex processes of mobilization of MSCs from their niche, recruitment to the desired target tissue or site, and integration and maturation at the target site. For cell-free tissue engineering to be successful, identification of specific cues that steer stem cells to their niche and increase the efficiency of the homing process is of critical importance. For stem cells to be recruited by injured tissues, implanted biomaterials must initiate a sequence of coordinated interactions between the cells and their environment and provide the signals and signposts that guide the cells along their journey [167]. Therefore, artificial biomaterial niches would need to incorporate appropriate navigation cues that could attract endogenous stem cells and have ECM-mimicking components and structures that could localize and accommodate the cells within the destination [5].

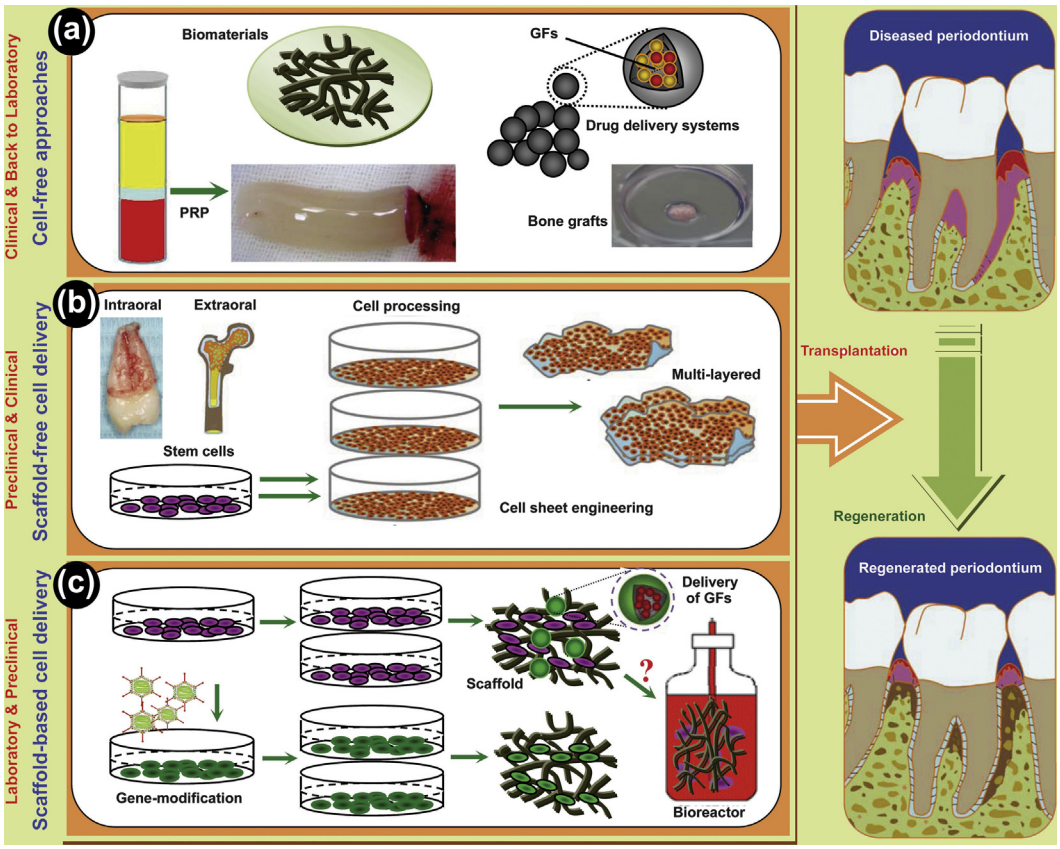

FIGURE 72.3

Cell-free (a) and cell-based (b & c) technologies for periodontal tissue engineering. (a) Cell-free approaches aim at achieving endogenous periodontal regeneration with the use of growth factors (GFs), well-designed biomaterials, platelet-rich plasma (PRP) and its associated formulations, and maybe other commercially available products, alone or in combination. In this regard, periodontal defects is likely to be restored by endogenously recruited cells and without the need of delivery of *ex vivo* manipulated cells. This concept has been employed in clinic for several decades and feedback based on clinical practice has led to new insights into and novel applications of such endogenous mechanisms for tissue regeneration [122,167]. Besides, both extraoral and intraoral stem cells represent a viable and accessible 'tool' for regeneration. Adequate cell density could be reached *in vitro* under a controlled environment and made readily available for reimplantation into a periodontal defect site via either scaffold-free (i.e., cell sheet engineering) (b) or scaffold-based delivery (c). Although the time is now ripe to move stem cell-therapy from preclinical studies to clinical trials, there are a number of biological, technical and translational hurdles that remain unresolved. For scaffold-based delivery, the expanded cells are seeded into a three-dimensional (3D) scaffold (normally containing GFs), and immediately implant into periodontal defects (*in vivo*); or to create tissue-like constructs in bioreactor before transplanting into patients (*in vitro*). In both cases, gene of interest may be incorporated into a therapeutic cell because a therapeutic gene has been shown to increase the regenerative potential and enhance the availability of therapeutic cells.

The use of PRP and EMD in periodontal reconstructive surgery provides evidence that cell-free approaches are useful in various experimental and clinical models, yet the outcomes have frequently been inconsistent or conflicting between studies [5]. If we just consider the current endogenous technique for routine clinical periodontal regeneration, it clearly needs to be improved and refined [169]. One pivotal aspect in the development of PRP technology, for example, has been the deep platelet characterization that has been developed to determine the most important GFs and cytokines contained within these cells, and the protocols that facilitate their safe manipulation and concentration [170]. Cell-free tissue engineering is still in its infancy. New insights from developmental biology and other biological disciplines are actively guiding the development of biofunctonalized materials that work with nature's own mechanisms of repair, where the scaffold should be considered as both a biochemical and biophysical signaling device, modulating and orchestrating cellular activity in the defective microenvironment to harness and direct a patient's own regenerative potential. To date, the cell-free approach offers a preferential route for tissue-engineering therapies to be utilized within clinical settings.

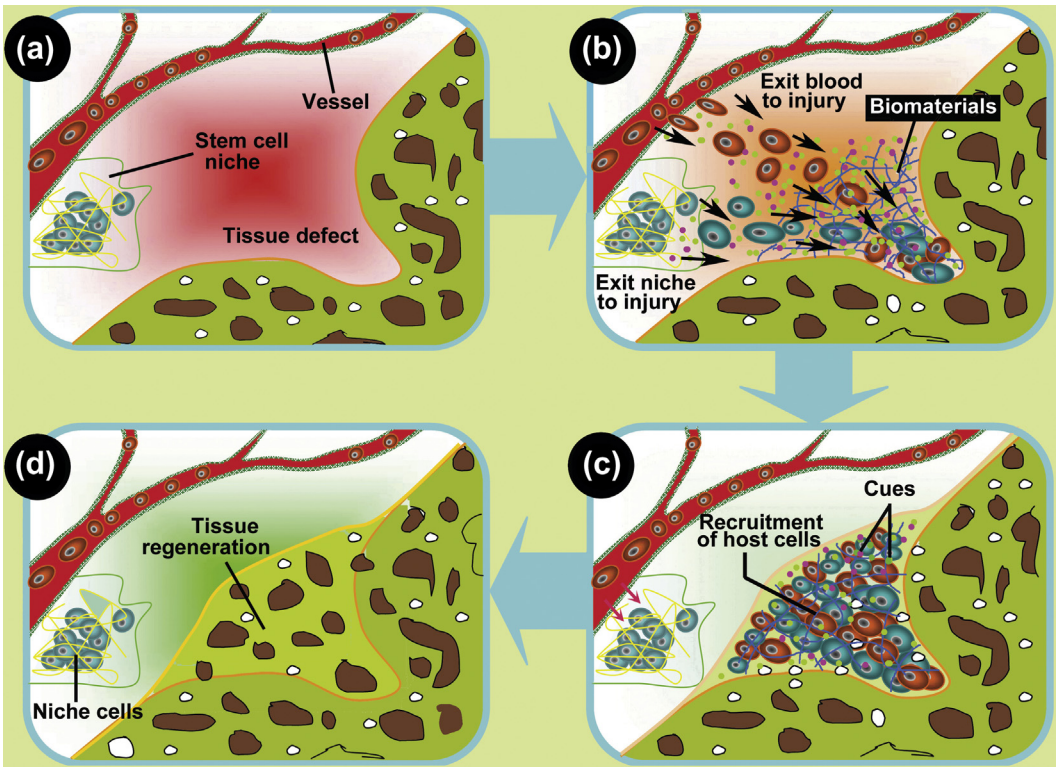

FIGURE 72.4
Schematic representation of the recruitment of host cells for endogenous tissue regeneration (a: tissue defect; (b: cell trafficking in response to implantated biomaterials and growth factors; (c: sufficient cell populations recruited to the defect; (d: defect restoration via endogenous tissue regeneration). The use of well-designed biomaterials in combination with molecular stimuli (growth factors or genes) may harness the body's innate ability to restore small or moderate tissue defects without the need of *ex vivo* cell delivery. This concept is generally termed cell-free tissue-engineering strategy (modified from Chen et al. [15].

Cell-based approaches

If an existing degree of periodontal dysfunction already exists and cannot be restored by endogenous mechanisms alone, stem cell implantation to enhance a regenerative outcome could be pursued as an alternative (Table 72.2). In addition to promoting tissue repair directly, MSCs have also been shown to modulate the immune system and attenuate tissue damage caused by excessive inflammation [5]. This immune modulation has been found to be an active process that renders stem cell therapy.

SCAFFOLD-FREE CELL DELIVERY

Without the use of scaffolds, cells can either be injected directly to the defect or form sheets/microtissues for surgical implantation (reviewed in Ref. [12]). The main drawback of single-cell injection is the high cell loss caused by washout and the low level of integration of the transplanted cells, in addition to the risk of unwanted neoplastic growth if the cells eventually settle in non-target sites. The development of advanced scaffold-free delivery systems is an emerging subdiscipline of regenerative medicine with broad applications and significant impact in orthopedics and reconstructive surgery. For example, cell sheets/microtissues allow for the generation of functional cell transplants in which cells can survive, grow and recapitulate native tissue characteristics. In this concept, fibroblasts, or other cell types that secrete significant amounts of ECM proteins, are cultured for a prolonged period to create sheet/tissue-like structures for therapeutic use [104]. Based on the presence of deposited ECM produced during *in vitro* incubation, the cell transplants can be easily transferred and attached to

TABLE 72.2 Delivery strategies in cell-based periodontal tissue engineering

Scaffold-free delivery

Design of Delivery	Therapeutic cells	Applications	References
Cell sheet engineering	Human PDL[a] cells	Dog — dehiscence defects on the buccal surface of the mesial roots of bilateral mandibular first molars	Akizuki et al. [35]
	Allogeneic PDLSCs[b]	Miniature pig — experimental periodontitis	Ding et al. [41]

other surfaces, such as tooth root and host bone tissues. The resulting cell sheets/pellets retain their original ECM and cell-cell contacts to facilitate cell integration and tissue formation.

Because cell sheet engineering can produce functional layers of cells, various types of cell sheet transplantations without scaffolds have been tested for periodontal regeneration, and these have shown significant potential to induce the reformation of the PDL and cementum

[35,39,41]. Thus, the application of cell sheets may be an effective clinical strategy, and the safety and efficacy were evaluated, both *in vitro* and *in vivo*, and presented no evidence of malignant transformation [44,171]. Very impressively, this concept has also been tested in a feasibility/pilot study in which autologous PDL cells were utilized in the treatment of human periodontitis [37].

Cell pellets or microtissues are groups of cells (cell re-aggregates) normally ranging in size between 100 and 500 μm in diameter. These cell aggregates gain structure and functionality resembling the native tissue when dispersed cells are grown under certain culture conditions [172]. Keeping this in mind, *ex vivo* expanded dental stem cells were grafted to the periodontal defect without the need of a scaffold, where the cellular pellets could cover the denuded root surface thoroughly and fill the defect [40]. Furthermore, bilayered cell pellet constructs comprising calcified bone-forming cell pellets (i.e., BMMSCs) and cementum/PDL-forming cell pellets (i.e., PDLSCs) can be fabricated *in vitro* via the intrinsic capacity of monodispersed cells to self-assemble into a microtissue (e.g., 3D spheroid). This strategy may provide an alternative to reconstruct extensive periodontal defects and achieve a predictable and complete regeneration of the periodontium. However, the possibility of microtissues turning into tumors based on their structural similarity is a great concern, especially when undifferentiated cell types are used [173].

SCAFFOLD-BASED CELL DELIVERY

From an engineering standpoint, current approaches to periodontal regeneration via scaffold-based cell transplants can be summarized into four possible strategies [12]:

- stem cells are amplified by *ex vivo* expansion and differentiated into the target cell type before being seeded into scaffolds to constitute the transplants;
- stem cells are amplified and differentiated directly in the scaffold before implantation, which is a strategy more suited to adult stem cells, but instructive signals need to be incorporated into the scaffolds to effect direct cell proliferation/differentiation *in situ* within the scaffolds;
- stem cells are partially differentiated into progenitor cells, either before or after seeding into scaffolds, to give rise to proto-tissues; following implantation, these constructs transiently release progenitors that migrate into surrounding regions where they undergo terminal differentiation, integrate and contribute to regeneration of the lesion areas (prolonged release of stem/progenitor cells may be achieved when a suitable scaffold is used to maintain them in a partially differentiated state;
- injectable transplants composed of pristine or stimulated stem cells encapsulated in biodegradable hydrogels; this strategy is attractive for soft tissue repair or treatment of solid tissues with critical size defects that are too fragile for surgical intervention.

All four strategies have been tested in periodontal tissue engineering. Injectable materials are considered to be the ideal delivery vehicles for cells and bioactive factors, because they can be delivered by a minimally invasive process and can fill irregular spaces of the defect. The injectable system can offer early mechanical stabilization by *in situ* polymerization, such as fibrin and alginate [174]. The rapid degradation of fibrin can be decelerated by modification with PEG, thus creating a hybrid material for robust cell delivery [149]. It is known that PRP may enhance new bone formation and accelerate existing wound healing process. Therefore, autologous injectable scaffold, was used to deliver BMMSCs to the periodontium [28]. Although cell transplantation via injectable matrices into sites of articular defects has been successful, it has not been tested in either preclinical or clinical studies to demonstrate whether injections of stem cells into periodontal defects can achieve significant improvement.

In contrast, hydrogel sponges as vehicles for cell and drug delivery for periodontal regeneration have been tested in various animal models and in clinical practice with success [136,175]. In terms of synthetic biomaterials, a pilot study has demonstrated that cementoblasts have

a marked ability to induce mineralization in periodontal wounds when delivered via PLGA polymer sponges [50]. Impressively, a collagen sponge scaffold has been shown to be an effective cell delivery vehicle for oro-maxillofacial bone tissue repair in patients [27].

Solid scaffold-cell transplants may stimulate the repair of damaged/diseased tissue while maintaining adequate integrity, where HA/TCP can be used directly as a cell delivery scaffold [38,39]. The requirements and design of scaffold systems for cell delivery have been discussed previously in this chapter. Many promising strategies for functional tissue engineering aim to replicate components of the natural cellular microenvironment by providing a synthetic ECM and by delivery of GFs [122]. A major clinical challenge in the reconstruction of large oral and craniofacial defects is the neogenesis of osseous and ligamentous interfacial structures where the natural 3D shape of the tissue needs to be recreated. In this regard, the multiscale computational design and fabrication of composite hybrid polymeric scaffolds (PCL-PGA) to carry genetically modified human cells to regenerate human tooth dentin-ligament-bone complexes have been tested *in vivo*. This approach offers potential for the clinical implementation of customized periodontal scaffolds that may enable regeneration of multi-tissue interfaces required for oral, dental and craniofacial engineering applications [9,10]. Recently, cell-based research has focused on the geometric design of scaffolds for tissue engineering. However, the orchestration of multiple tissue formation, spatial fibrous tissue organization, and endpoint functional restoration using a single *in vivo* scaffold system remains a significant challenge.

Stem cells can potentially be expanded on microcarrier beads in spin culture for direct transplantation into tissue defects. The process of encapsulation physically isolates cells from the outside environment and aims to maintain cellular physiology within a selectively permeable membrane [176,177]. By mechanically blocking the cells from immune attack, this technology significantly reduces post-transplantation cell apoptosis and offers a solution to the shortage of donors for functional cell transplantation, particularly since it allows xenobiotic or allogenic cells to be used. However, this therapy has not yet been introduced to periodontics, and it still faces many challenges, such as materials choice and design, before it can be moved into clinical reality [178].

In prospect, shape memory materials are potentially useful for periodontal regeneration, although they remain to be tested. These materials can deliver bulky scaffolds via minimally invasive surgery to the periodontal defects. Using these smart materials, future scaffolds may be fabricated in a condensed state before transplantation and then later acquire the desired shape *in vivo* [172]. Self-shaped hydrogels can be structurally collapsed into smaller, temporary shapes that permit their minimally invasive delivery *in vivo*. Scaffolds are rehydrated *in situ* with a suspension of cells or cell-free medium and delivered through the same catheter. The rapid recovery of the scaffold properties facilitates efficient cell seeding *in vivo* and permits neotissue formation in the desired geometries [178]. Improved delivery platforms coupled with enhanced understanding of the mechanistic/biological regulators of tissue formation should lead to better and more predictable therapeutics within the next decades [132].

CHALLENGES AND FUTURE DIRECTIONS

The currently available treatments, which are based on the 'damage to heal approaches', have had only limited success in periodontal medicine. With an increasing aging population, tissue-engineering strategies provide important cures and hope for the treatment of periodontal disease, and they have set the stage for successful regeneration of many other tissues. The development of biological transplants for reconstructive therapies has considerably improved the currently available treatment options for periodontal repair. Particularly, the accelerated pace of research in the stem cell field and the accumulated body of knowledge has spurred interest in the potential clinical use of stem cells [15]. This developing area is attracting

increasing attention from both the private and government sectors because of its considerable economic and therapeutic potential. However, there are critical steps in moving the field towards human clinical utility [179]. In particular, the events following cell transplantation are poorly understood, underscoring the considerable need for robust preclinical modeling for the evaluation of the safety and efficacy of stem cells. Although the clinical application of stem cells to the regeneration of periodontal tissue has begun, the risks of stem cell therapies should not be ignored or underestimated by clinicians and researchers [12].

There are two main criteria for successful tissue engineering [6]. First, there are the engineering principles, which relate to biomechanical properties of the scaffold, architectural geometry and space maintenance. In this regard, biomaterials are increasingly being developed as *in vitro* microenvironments mimicking *in vivo* stem cell niches. Future successful periodontal bioengineering may very well rest on the ability to effectively utilize these biomaterials as delivery platforms for appropriate cells and/or factors [132]. However, current macroscale methodologies to produce these niche models fail to capture the spatial and temporal characteristics of the complex native stem cell regulatory systems. The second criterion relates to the biological functions of the engineered construct, including cell recruitment, proliferation and survival in culture and at the site of implantation, neovascularization and delivery of GFs necessary for successful differentiation and tissue regeneration. However, control over stem cell fates within a complex *in vivo* milieu is extremely difficult and represents the most challenging issue faced by current periodontal bioengineering.

Tissue engineering is making an important impact on the concept of periodontal therapy, and several clinical trials involving transplantation of stem cells into human patients have already begun or are in preparation (reviewed in Ref. [12,179]). The use of protein- or cell-based therapy to enhance and direct periodontal wound healing into a more predictable regenerative path is being exploited in bioengineering efforts that aim at developing a new therapeutic paradigm for clinical application. As tissue engineering becomes more of a clinical reality through the ongoing bench-to-bedside transition, research in this field must focus on addressing relevant clinical situations [179]. Acknowledging that tissue regeneration alone is not the only answer to predictably securing a long-term stable treatment for the patient with a history of periodontal disease, host modulation therapies are therefore rising as an important aspect in the control of periodontal diseases and tissue reengineering [3]. Although most *in vivo* work in the area of periodontal tissue engineering focuses on tissue regeneration within sterile, surgically created defects, there is a growing need for the investigation of engineering approaches within contaminated or infectious wound beds, such as those that may be encountered following tissue damage by periodontitis. As discussed within the context of this chapter, there are a number of developing systems that have the potential to optimize tissue healing biology. A major obstacle that remains today is how to maximize the utility of therapeutics delivered to a passive or permissive environment where there is a context for the type of cell needed, but in which very few biological signals are given to encourage normal cell function [3]. In addition, the tissue-engineering field still needs to confront other hurdles, such as identifying the best cell sources, clinically relevant cell numbers, an effective mode of administration, the integration of new cells into existing tissue matrices, and the achievement of functional properties of tissue equivalents using an expanded repertoire of biomaterials. Finally, major constraints to the tissue-engineering fields remain in the context of practical, safety and regulatory concerns related to the application of these technologies in the clinical arena [3].

CLOSING REMARKS

Regenerative therapies for periodontal disease that use patients' cells to repair the periodontal defect have been proposed in a number of preclinical and clinical studies. Periodontal tissue-derived stem cells, such as PDLSCs, are committed toward all of the periodontal developmental lineages that contribute to cell turnover in the steady-state and would thus

be useful cell sources for treating periodontally destructive diseases, such as periodontitis. Treatments that partially regenerate damaged periodontal tissue through the localized administration of GFs have now been established. Although the clinical practice is not very successful, such regenerative therapies have provided very useful and feasible clinical study models for the future design of tissue engineering and stem cell therapies. Using currently available clinical strategies, partial regeneration of the periodontal tissue is becoming possible; however, methods to achieve the functional regeneration of large defects caused by severe periodontal disease are still lacking. To address this, it is essential to better understand the cellular and molecular mechanisms underlying periodontal development and, thereby, identify the appropriate functional molecules that induce the differentiation of stem cells into periodontal lineage cells for the successful reconstruction of periodontal tissue. The field of periodontal bioengineering has entered an exciting new developmental phase that will make increasingly important contributions to the patient. Particularly, a number of biological technologies are being aggressively explored for clinical translation, signifying a veritable "coming of age" of the field. However, such issues as appropriate delivery devices, immunogenicity, autologous cells *vs.* allogenic cells, identifying tissues that provide the most appropriate donor source, control of the whole process, and cost-effectiveness are all important considerations that should not be overlooked. The future of periodontal bioengineering is undoubtedly driven by technology. New applications and improvement upon current designs will depend heavily on innovations in biomaterials engineering. Progress in stem cell biology will be imperative in dictating advances in stem cell-based regeneration. A better understanding of the molecular mechanisms by which substrate interactions impact stem cell self-renewal and differentiation is of paramount importance for targeted design of biomaterials. Discoveries in the fields of developmental biology and functional genomics should also be exploited for broadening the repertoire of biological molecules that can be incorporated into biomaterials for fine-tuning stem cell activities. With the merger between the two powerful disciplines—biomaterials engineering and stem cell biology—a new drawing board now lies before us to develop therapies that promise to revolutionize periodontal tissue engineering.

CHAPTER 73

Tissue Engineering for the Respiratory Epithelium: Cell-Based Therapies for Treatment of Lung Disease

Valérie Besnard[1] **and Jeffrey A. Whitsett**[2]
[1] Inserm U700-Faculté de Médecine Xavier Bichat, Paris, France
[2] Perinatal Institute, Division of Neonatology, Perinatal and Pulmonary Biology, Cincinnati Children's Hospital Medical Center and University of Cincinnati College of Medicine, Cincinnati, Ohio

INTRODUCTION: THE CHALLENGES FACING CELL-BASED THERAPY FOR TREATMENT OF LUNG DISEASE

The lung is a remarkably complex organ that evolved for the adaptation of vertebrates to terrestrial life. While embryonic development proceeds normally in the absence of lung tissue, life after birth is entirely dependent upon respiration, a process that, in turn, is dependent upon the structure and function of the lung. The respiratory tract consists of distinct anatomic regions from the nasal passages, pharynx, larynx, trachea, bronchi, lobar bronchi, bronchioles and peripheral airways that direct inhaled gases to the alveoli. Gas exchange occurs across alveolar epithelial and capillary endothelial cells. Ventilation is driven by mechanical forces dependent upon neuromuscular activity that is precisely controlled by neurosensory inputs to maintain normal pCO_2, pO_2, and pH. There is little evidence that the lung serves critical physiological roles other than gas exchange. Lung function is entirely dependent on its remarkable structure that exchanges millions of liters of environmental gases throughout our lifetime. Unlike other organs, for example endocrine organs that synthesize and secrete hormones critical for growth and metabolism of many target organs, respiration is an intrinsic property defined by lung structure and mechanics. Regeneration or replacement of functional respiratory tissues will depend upon creating and protecting the structures of the lung that bring environmental gases to an extensive alveolar surface across which oxygen and carbon dioxide are exchanged with the pulmonary vascular bed. Achieving these goals presents formidable technical challenges for regenerative medicine (Fig. 73.1). Repair/regeneration of tissues in conducting airways (for example, the repair or replacement of the larynx, trachea or bronchial cartilage), or the delivery of therapeutic cells to the lung parenchyma may represent a more achievable target for the application of regenerative medicine for the respiratory tract. Significant progress has been achieved recently in developing re-cellularized matrices for tracheal-bronchial engraftment. This chapter will consider issues regarding the application of cell-based therapy for prevention and/or treatment of lung diseases, as well as the role of

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00073-2

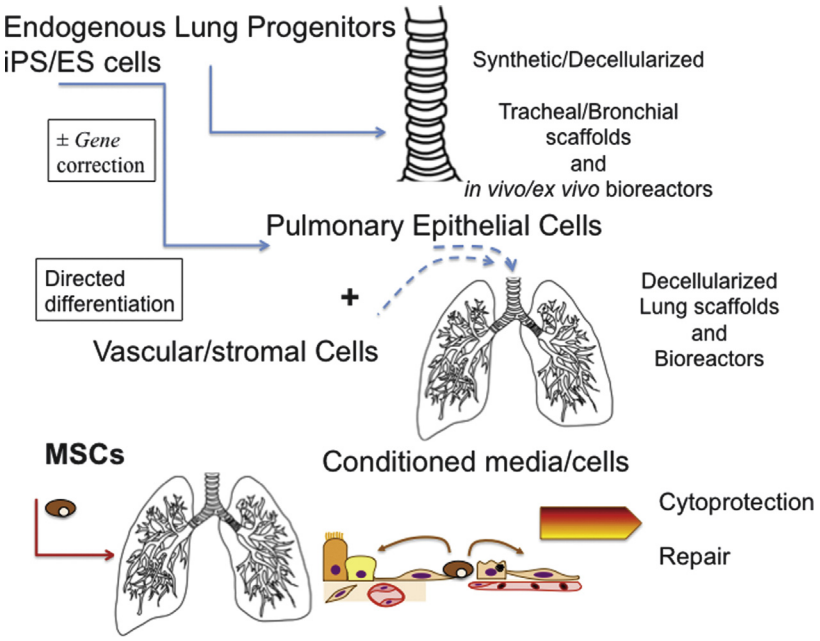

FIGURE 73.1

Strategies for cell-based therapies for the lung. Cell-based therapies for treatment of lung disease using distinct strategies are in active experimental stages. Embryonic stem cells (ES) and induced pluripotent cells (iPS cells) can be genetically modified and differentiated to specific lung cell types *in vitro*, producing respiratory epithelial or pulmonary vascular cells. Resident pulmonary stem/progenitor, ES or iPS cells have been identified, isolated, cultured on acellular or decellularized matrices and engrafted to create airway and alveolar-like tissue. Bone marrow tissue derived stem cells or cell conditioned media from progenitor cells are administered systematically or intratracheally to participate in cytoprotection after acute injury or for correction of pulmonary disease.

mesenchymal stem cells for treatment of lung disorders. The development of new therapeutic strategies, for example the use of endogenous lung stem cells, mesenchymal stem cells (MSCs), embryonic stem (ESs) or iPS cell-based treatments using tissue engineering will depend upon knowledge of pulmonary morphogenesis and repair. Understanding these processes will be useful in guiding studies in which the principles of lung cell biology can be applied to enhance the treatment of life-threatening pulmonary disorders.

LUNG MORPHOGENESIS

The lung is a highly complex organ that contains multiple cell types which are derived from the three layers of the early embryo, including the ectoderm, mesoderm, and endoderm. All germ layers contribute to the diverse cell types that form the respiratory tract. Lung morphogenesis begins as evagination of foregut endodermally derived cells along the anterior foregut. Epithelial cells of the lung primordia proliferate and migrate into the splanchnic mesenchyme influenced by paracrine and cell-cell signaling between the epithelium and mesenchyme. These interactions are regulated by numerous signaling and transcriptional pathways that instruct cell proliferation, migration, and differentiation (see reference [1] for review). Rapid progress is being made regarding the genes and processes by which the trachea, bronchi and peripheral airways are formed during lung morphogenesis, knowledge that has been useful in programming of ES cells or induced pluripotent stem (iPS) cells into lung epithelial cell lineages *in vitro*.

Understanding the early events directing the normal embryonic development are highly relevant to methods to program ES or iPS cells to produce progenitor cells that can be expanded for cell-based therapies. During early embryonic development, pluripotent cells are

sequentially programmed to produce endoderm, anterior foregut endoderm, further restricted to respiratory epithelial progenitor cells that produce a diversity of respiratory epithelial cells that line the conducting airways and the alveoli, (Fig. 73.2). High levels of Fibroblast Growth Factor (FGF) signaling from the cardiac mesoderm induce the commitment of foregut endodermal cells to produce lung epithelial cell progenitors. Suppression of Bone Morphogenetic Protein (BMP) signaling, receipt of high levels of FGF, and expression of specific Wnt ligands (Wnt2A/B) serve to specify lung epithelial cell progenitors from those destined to form other organs along the gut tube, e.g., thymus, thyroid, the gastrointestinal tract, liver, and pancreas [1–3]. The commitment, restriction, and differentiation of endodermal cells to form the lung buds, are first marked by the expression of the thyroid transcription factor-1 (also termed NKX2.1) [4]. While the trachea and main bronchi are found in TTF-1 gene deleted mice, branching morphogenesis and differentiation of pulmonary epithelial cell types fails to occur. Complete separation of the trachea and esophagus requires TTF-1, as dose formation of

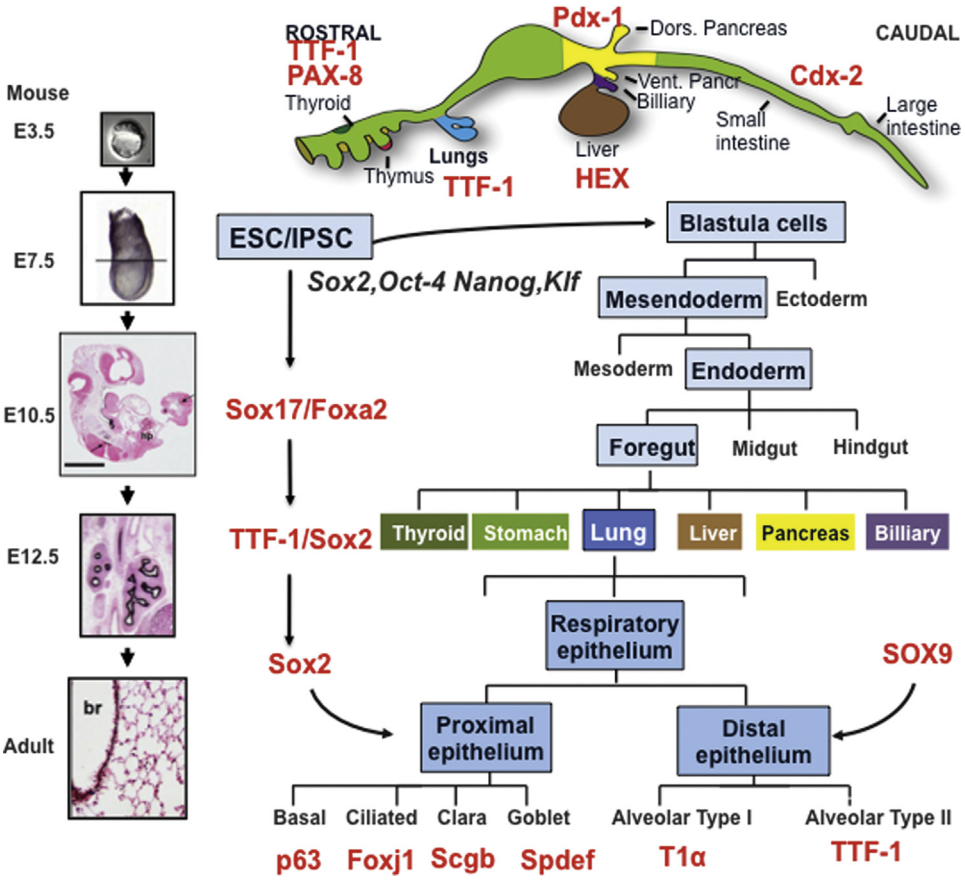

FIGURE 73.2

Stage-specific specification and differentiation of the foregut endoderm during lung formation. The tracheal-bronchial tree and alveolar regions of the lung are derived from progenitor cells located in the anterior (rostral) foregut endoderm. Shown (left) is staining of FOXA2 in respiratory epithelial cells during mouse embryonic lung development from E10.5-adulthood. Cells along the embryonic gut tube are sequentially programmed by inductive signaling between mesenchyme and endoderm to initiate organ formation at specific sites along its rostral-caudal axis. Endodermal cell commitment is marked by expression of SOX17 and FOXA2, as the A-P axis of the embryo is initially formed near the time of implantation. Lung cell specification (blue) from the esophagus (green) is marked by differential expression of TTF-1 (Nkx2.1) and SOX2. Conducting airways express SOX2 and are distinguished from progenitor cells that form the distal epithelium, the latter marked by expression of SOX9. Later in fetal lung morphogenesis, basal (Trp63), ciliated (Foxj1), serous/Clara cells (Scgb) and goblet cells (Spdef) differentiate from airway progenitors. Cells in the distal epithelium differentiate into type I and type II epithelial cells that form the alveolar, gas exchange region critical for respiration after birth. Sequential specification and differentiation of lung progenitor cells during normal lung morphogenesis provides the molecular pathways by which ES or iPS cells are being reprogrammed to differentiate into pulmonary cells *in vitro*. Lung epithelial selective markers are shown in red. Neuroepithelial cells are not shown. (E) represents embryonic day of mouse development.

conducting airways and the lung periphery. In the mouse, lung tubules, stromal, and vascular components typical of the normal lung are lacking in the absence of TTF-1 [5]. The activity of TTF-1 is influenced by its interactions with other transcription factors and co-factors that regulate gene expression and differentiation in the various cell types that line the respiratory tract. TTF-1 is co-expressed with a number of transcription factors, including FOXA2, FOXA1, GATA-6, NFATc3, NF-1, SOX and ETS family members (to name only a few) to regulate gene expression and cell differentiation during formation of the respiratory epithelium [6]. The proximal-peripheral patterning of the embryonic lung is established early in lung morphogenesis [7], SOX2 directing differentiation of conducting airway epithelial cells while SOX9 identifies cells that form the alveolar regions of the lung [1]. Signaling between the lung mesenchyme and respiratory epithelial cells, and between subsets of cells establishes the number and sites of distinct cell types that line conducting and alveolar regions along the cephalo-caudal and ventral-dorsal axes of the lung.

Integration of signaling and transcriptional pathways during lung formation

A number of signaling molecules mediate the autocrine and paracrine signals that are precisely regulated during lung formation. Wnt-β-catenin [8,9], FGF [10–12], SHH [13,14], BMP4 [15], Notch [16] and retinoic acid [17] pathways play critical roles during formation of the lung. The sites and functions of ligands and receptors that determine the multiple signaling centers required for precise temporal-spatial control of cellular behaviors during lung morphogenesis are complex and are in active study at present. Elucidation of these pathways will be relevant to understanding the control of proliferation and differentiation of embryonic stem cells, iPS, and ES and endogenous lung 'stem' or 'progenitor' cells that can be programmed to generate the pulmonary cells and tissue used for development of cell-based therapies for repair or regeneration of the lung.

The mature lung consists of diverse cell types

The respiratory epithelium itself consists of many distinct cell types that are characteristic of the proximal (conducting or cartilaginous) airways, as compared to peripheral airways and alveolar (gas exchange) regions of the lung, (Fig. 73.3) ([1,18] for review). The extent of the respiratory tract covered by distinct cell types varies greatly among species and during development. There are considerable species differences in the number of branches, extent of cartilaginous airways and submucosal glands, and the numbers and types of epithelial cells lining the airways. In general, similar types of respiratory epithelial cells are found in all vertebrate lungs. In human and mouse lung, cartilaginous, conducting airways are lined predominantly by a pseudo-stratified epithelium primarily consisting of ciliated, basal, goblet and other secretory cells, including Clara cells. Cartilaginous airways contain an abundance of submucosal glands consisting of multiple epithelial cell types, including myoepithelial cells and those secreting fluid, electrolytes, mucins, and host defense proteins. Conducting airways and the ducts of submucosal glands contain progenitor cells capable of rapid migration, proliferation, and differentiation to repair the airway epithelium after injury. Neuroendocrine cells are a relatively less abundant cell type and are found either as isolated cells, or as organized clusters termed neuroepithelial bodies (NEBs) found in precise anatomic regions of the conducting airways. NEBs are found in close apposition to a subset of non-ciliated airway epithelial cells that together may provide a cellular niche with unique repair capacity. Smaller, non-cartilaginous airways are lined primarily by a more simple columnar epithelium consisting of ciliated, serous and 'Clara cells,' and less abundant neuroepithelial cells. Squamous type I and cuboidal type II cells line alveolar surfaces in the peripheral lung. Type II cells synthesize and secrete pulmonary surfactant necessary to maintain lung inflation during the respiratory cycle. Squamous type I cells derived primarily from type II epithelial cells or other progenitors, are found in close apposition to alveolar capillaries to facilitate gas exchange.

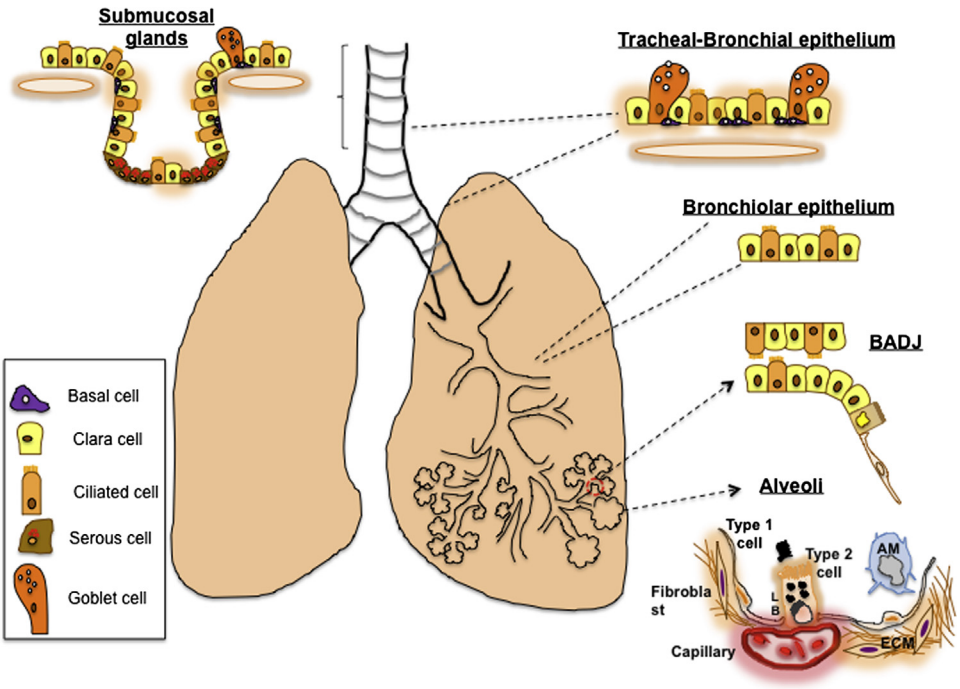

FIGURE 73.3

The complexity of the respiratory epithelium. Epithelial surfaces of the larger cartilaginous airways are generally lined by a pseudo-stratified columnar epithelium consisting of basal, ciliated, goblet, Clara (non-ciliated secretory cells) and less abundant neuroepithelial cells (not shown). Submucosal glands are present along the tracheal-bronchial tree and consist of numerous cell types including basal, ciliated, and various secretory cells. Smaller airways, including bronchioles and respiratory acinar ducts, are lined by a single columnar or cuboidal epithelium that consists primarily of ciliated and non-ciliated secretory cells. In the alveoli, peripheral lung epithelial cells become cuboidal (type II) or squamous (type I) as the peripheral saccules form.

Respiratory epithelial cells create a tight alveolar-capillary barrier that restricts fluid from the alveolar surface, a barrier critical for lung formation that is lost following severe lung injury. After birth, the diversity of cells lining the respiratory tract is strongly influenced by acute and chronic injury. For example, goblet cell and squamous metaplasia are associated with asthma, chronic obstructive pulmonary disease (COPD) and other pulmonary disorders. The pattern of stromal tissue and the pulmonary vasculature also varies greatly along the proximal-distal axis of the lung. Proximal regions of the lung are supported by cartilage, nerves, larger pulmonary arteries, veins, and lymphatics, as well as tracheal-bronchial glands. Pulmonary vessels (arteries, veins, capillaries and lymphatics) are precisely aligned with the lung tubules and are supported by smooth muscle and a diversity of lung fibroblasts or 'stromal' cells. In alveolar regions, mesenchymal cells are less abundant and endothelial cells within the microvascular network come in close contact with type I epithelial cells. The alveoli are supported by a network of elastin. Autocrine-paracrine and direct cell-cell interactions among the various cell types control proliferation and differentiation during lung formation. Mitotic activity of the lung parenchyma is generally high during embryonic and postnatal development of the lung. In contrast, proliferative rates in the mature lung are remarkably low, cell turnover of lung parenchymal cells occurring over many months in the absence of lung injury.

Evidence supporting lung regeneration

In general, cell proliferation in the mature lung is remarkably quiescent. Proliferative rates of all types of pulmonary cells are remarkably slow in stark contrast to the rapid and ongoing turnover of cells lining the gastrointestinal tract or skin, wherein stem cells proliferate, differentiate, migrate and senesce within days. Rates of cell proliferation in the lung are low unless subjected to injury, chronic disease or resection, after which the lung is capable of remarkable proliferative

responses. Perhaps the most dramatic of these is the post-pneumonectomy response after ipsilateral lung resection that is followed by rapid proliferation of many cell types in the remaining lung tissue, serving to regenerate lung volume and function within several weeks after resection (see [19] for review). Regeneration of well-perfused, functional respiratory units occurs in rodent models and is most efficient in younger animals. Lung regeneration depends on available space (chest volume), likely indicating that tissue stretch is an important component of the growth response. Although evidence of lung regeneration in human is less well documented, there is some evidence that the mature human lung is capable of regeneration [20]. Animal studies support the concept that retinoids and growth factor signaling can enhance or are required for efficient lung regeneration, respectively, providing the scientific framework for development of new therapies for lung disease [19].

The diversity of lung epithelial progenitor/stem cells

Reagents useful for immunohistochemistry, cell sorting, and *in situ* hybridization are being utilized to identify specific lung epithelial cell types and to identify progenitor cells useful for tissue-based therapy. Cell survival, proliferation, and capacity for self-renewal and differentiation differ amongst various cell types and regions within the lung [18,21,22]. In conducting airways, the epithelium is repaired primarily by proliferation of basal cells and other non-ciliated epithelial cells. Basal cells express p63 (Trp63); variably express cytokeratins (e.g., CK5, CK14). Basal cells are capable of self-renewal and differentiating into ciliated, goblet, and other secretory cells in the airways *in vivo* and *in vitro* [18,23,24]. After severe lung injury, basal cells lining the airways and within the ducts of tracheal-bronchial glands migrate along the airway surfaces, proliferate and differentiate to contribute to repair the respiratory epithelium [18,25,26]. 'Label-retaining cells' or LRCs are present in distinct anatomic regions where they are relatively protected, perhaps providing slow cycling progenitor cells for repair of the respiratory epithelium. Basal cells and various subsets of non-ciliated epithelial cells are capable of rapid migration, proliferation and differentiation during repair of the conducting airways and are likely to form a hierarchy of cells with varying stem/progenitor cell capabilities. In conducting airways, regional differences in proliferation and progenitor cell behavior occur in NEBs near bifurcations of airways, in bronchoalveolar ducts, and along vessels and stroma. Mitotic activity is induced throughout the airways following injury, although selective anatomic regions of cytoprotection or enhanced proliferative capacity may serve unique functions during lung repair and depend upon the nature and severity of injury [27]. Evidence indicating that many endogenous cells play a role in lung repair is derived from experiments in animals models exposed to toxicants (naphthalene, SO_2) [18]. Purified basal cells and/or Clara cells re-establish a complex respiratory epithelium consisting of numerous cell types *in vitro* [28] including ciliated, non-ciliated epithelial cells, and goblet cells. In the peripheral lung, type II alveolar cells express surfactant proteins, e.g., proSP-C, proSP-B, and other surfactant proteins, and are capable of rapid proliferation and differentiation into type I cells after alveolar injury. A distinct subset of $\alpha 6\beta 4$ integrin expressing airway and alveolar epithelial progenitor cells was identified recently in the mouse lung [29]. In the alveoli, there is evidence that both type II epithelial cells and $\alpha 6\beta 4$ integrin positive cells are recruited into the cell cycle following injury. Self-renewal and differentiation of airway basal cells is influenced by Notch signaling [18,30]. High levels of Notch activity induce secretory cell differentiation producing goblet and serous cells, while ciliated cells are produced in the absence or paucity of Notch activity.

In conducting airways, other subsets of 'stem cells' have been described in the lung including side population cells, LRCs and bronchoalveolar stem cells. 'Side population' (SP) cells are defined by their ability to actively efflux DNA-binding dye, Hoechst 33342. SP cells were identified in the embryonic and adult lung in distinct anatomic regions including the trachea and the alveolar epithelium [31–34]. SP cells are CD45 negative (non-hematopoietic), have

Hoechst efflux capacity, verapamil-sensitivity, low auto-fluorescence and are enriched in vimentin mRNA [35]. Analysis of the stem cell-like subpopulations demonstrated that SP cells present in the tracheal compartment represent a heterogeneous cell population that varies in clonogenicity, whereas alveolar SP cells are more homogenous. Some subsets of 'stem cells' in various organs have been defined by their low rate of proliferation and termed label-retaining cells (LRCs) because of their prolonged retention of BrdU or 3H thymidine after labeling. LRCs turn over slowly, are capable of self-renewal and may be an important source of progenitor cells that can further proliferate and differentiate during repair of the lung. LRCs populations are enriched in the necks of submucosal glands and in tracheal/bronchial folds in non-cartilaginous regions of the conducting airways [26,36–38]. Other potential populations of stem cells with label-retaining capacity are located near NEBs at branch points of conducting airways [39]. Stem cells within terminal bronchioles adjacent to the bronchoalveolar duct junction, termed bronchoalveolar stem cells (BASCs) may represent another subset of cells with unique proliferative and differentiation capacities [40,41]. BASCs were defined as CCSP- and pro-SPC-co-expressing cells that resist naphthalene injury and repopulate terminal bronchioles. These cells are not abundant and it is not clear at present whether the properties of self-renewal and production of daughter cells of BASCs are distinct from more abundant cells (e.g., Clara cells, alveolar type II cells) that are known to contribute substantially to repair of terminal airways and the alveoli. Lineage tracing experiments will be useful in defining the ability of these 'stem cells' to renew and differentiate into various cell populations.

In the peripheral lung, type I cells are sensitive to injury and do not proliferate. Repair of the peripheral lung depends upon alveolar epithelial type II cells. Proliferation of alveolar type II epithelial cells occurs two to three days following hyperoxia-induced injury. Subsets of these cells differentiate into type I cells to complete repair [42,43]. Recent studies support the presence of a distinct subset of alveolar cells, $\alpha 6\beta 4$ integrin positive cells, which do not express surfactant markers typical of type II alveolar cells and are capable of proliferation, self-renewal and differentiation into type II alveolar cells [29].

Thus, under physiologic conditions, repair is accomplished primarily by the proliferation of endogenous progenitor cells present in the various compartments/niches of the respiratory epithelium. There is increasing evidence that there exists a hierarchy of lung epithelial stem/progenitor cells. Identification of endogenous lung 'stem' or 'progenitor' cells, characterization of their proliferation and differentiation potentials and the development of processes to genetically repair progenitor cells capable of permanent engraftment and proliferation represent important scientific goals that will enable stem cell therapies for pulmonary diseases.

Since the respiratory tract is continuously exposed to pathogens, including viruses, bacteria, fungus, toxic particles, and toxicants, a remarkable system of innate defense has evolved to maintain pulmonary homeostasis throughout life. This is accomplished by the intrinsic integrity of the epithelial lining, mucocillary clearance, production of innate host defense molecules, and the instruction of acquired immune defenses that serve to maintain lung sterility after birth. Since many viruses and pathogens have developed strategies for targeting specific cells, vertebrates have also developed strategies to maintain cells capable of regeneration. Variation of surface molecules and distinct capacities for proliferation and differentiation of cells in protected anatomic regions provides multiple progenitor cells capable of repairing the lung. Under most circumstances, lung injury is followed by rapid repair with maintenance and restoration of normal lung structure and function. Repair of the respiratory epithelium occurs rapidly to maintain alveolar-capillary permeability and pulmonary homeostasis. Failure to repair is associated with loss of alveolar capillary integrity that can cause acute respiratory failure, as seen in adult respiratory distress (ARDS) or acute ling injury (ALI) syndromes. Repair of the respiratory epithelium primarily is dependent upon endogenous cells that line distinct regions of conducting and peripheral airways rather than bone marrow or EMT-derived progenitor cells. Epithelial cells that survive injury rapidly spread and migrate

to cover the epithelium surfaces. While the mature respiratory epithelium does not undergo rapid turnover, the respiratory epithelium responds rapidly to acute injury and many cell types are capable of re-entering the cell cycle during the repair process. While rare subsets of progenitor cells have been identified in the lung, rapid repair of the respiratory epithelium that occurs following the infection or other injury is likely mediated by the proliferation and re-differentiation of relatively abundant progenitor cells.

Selected anatomic regions of the lung likely serve as potential reservoirs of progenitor cells that are located along the airways and in the alveoli with important roles in regeneration of tissue following acute and chronic lung injury. In conducting airways, *in vitro* and *in vivo* experiments have demonstrated the ability of basal cells, Clara cells or other secretory cells to proliferate and differentiate into other respiratory epithelial cell types [18,24,37–40,44–47]. Ciliated cells contribute to repair by undergoing squamous metaplasia. Lineage tracing experiment indicate that ciliated cells are not proliferative and do not serve a role as progenitor cells after injury to airway epithelium [48]. There is evidence that both type II epithelial cells and α6β4 integrin positive cells are recruited into the cell cycle following injury [29,42]. While Trp63 positive basal cells were considered to be confined to conducting airways and ducts of submucosal glands, recent studies demonstrated expression of Trp63 in regenerating pods of epithelial cells that contributed to repair of alveoli following influenza pneumonia in the mouse [49]. Thus, there is increasing evidence of a diversity of lung progenitor/stem cells that variably contribute to repair at distinct anatomic sites following injuries of varying types and extent. Whether distinct activities of subsets of respiratory epithelial cells contribute uniquely to normal or pathological repair processes to cause chronic lung disease remain to be clarified. Understanding these normal repair processes will serve to inform the scarring and hyperproliferative responses seen following catastrophic or chronic injury that lead to airway epithelial metaplasia, dysplasia, and hyperplasia that are associated with lung fibrosis, remodeling, and cancer.

Cell plasticity and reprogramming

Studies in mouse models and recent major advances in ES and iPS cell technology have revolutionized our understanding of cell plasticity and reprogramming, concepts that are creating the foundations for regenerative medicine applicable to many organs including the lung [50]. Early in foregut endoderm differentiation, there is considerable cell plasticity among foregut epithelial cells. The anterior-posterior axis of the early endoderm is strongly influenced by BMP/Activin and Wnt signaling. Expression of β-catenin-LEF caused differentiation of embryonic pulmonary epithelial cells into cells with gastrointestinal tract selective markers [51]. Later in lung development, mesenchyme obtained from the peripheral lung can reprogram epithelial cells from the trachea to differentiate with peripheral alveolar cell types [52]. Likewise, expression of SOX2 in alveolar cells of the adult mouse reprograms cells in the peripheral lung to proximal epithelial subtypes, demonstrating remarkable cellular plasticity even in the mature lung [53]. While normal differentiation processes occur during defined developmental stages, foregut endodermal cells display remarkable plasticity during the embryonic period and *in vitro*. Recent findings, that embryonic stem cells (ESCs) and iPS cells can be directed to differentiate into respiratory, epithelial cell-like cells demonstrate the potential to produce lung progenitor cells by recapitulating some of the processes that direct normal differentiation of respiratory epithelial cells during lung formation [50]. Culture conditions including nutrients, hormones, matrices, transplantation, or co-culture with mesenchymal cells provide instructive signals that recapitulate aspects of normal lung development. Understanding these developmental programs has been useful in engineering iPS and ES cells capable of differentiation into lung epithelial cell lineages, see Fig. 73.3.

EXOGENOUS SOURCES OF STEM CELLS: ES, iPS, HSC, and Mscs

'Stem cell' is a term used to define cells that are capable of both self-renewal and production of daughter cells with capacity to differentiate and contribute to tissue formation and repair. ESCs retain the potential to differentiate into cells forming all germ layers, e.g., ectoderm, mesoderm and endoderm. Pluripotent stem cells, exemplified by ESCs, are derived from the inner cell mass of the embryo, and are capable of proliferation and contribution to the formation of multiple tissue types. The term 'stem cell' is used with varying precision amongst fields of study, for example, being more precisely defined for embryonic, bone marrow stem cells but perhaps more loosely in tissues in which precise cell types and lineage relationships are not known. Hematopoietic stem cells (HSCs) in the bone marrow are considered stem cells, when a single cell regenerates the entire hematopoietic system after transplantation. Bone marrow-derived MSCs are considered 'multipotent' when exhibiting capacity for differentiation into two of the germ layers. Distinct stem cell properties have been described for HSCs, MSCs, tissue-derived stem cells, circulating endothelial progenitor cells (EPCs) that are capable of differentiating into endothelial-like cells *in vitro* [54], SP cells, and multipotent adult progenitor cells (MAPCs) (see [55] for review, and various contributors in this book). Capacities of various stem/progenitor cells to contribute to the diverse cell types present in the lung are not well defined at present but are under intense investigation.

Embryonic and induced pluripotent (iPS) stem cells

Embryonic stem cells (ES cells) provide a remarkable source of cells that can be programmed by various *in vitro* cell culture conditions to differentiate to organ-specific cell types, including those with respiratory epithelial cell characteristics [50,56–58]. While ES cells are subject to clinical and ethical constraints and are extremely limited for investigative and clinical applications, recent advances in cellular reprogramming have revolutionized our concepts regarding cell plasticity, enabling generation of patient-specific, non-immunogenic cells for the study and treatment of human disease, Figs. 73.1 and 73.4. Differentiation of respiratory epithelial cells requires that iPS/ES cells acquire endodermal, foregut, then pulmonary specific characteristics following the normal developmental patterning of the foregut endoderm. For example, TTF-1 is useful cell markers for early differentiation of lung epithelial cells. ProSP-C selectively stains type II alveolar cells in the lung. Foxj1 and β-tubulin are useful in identifying ciliated cells. Serotonin, CGRP (Calcitonin gene related peptide), and bombesin are used as markers of neuroepithelial cells. Non-ciliated secretory cells express Secretoglobin1a1 and Secretaglobin3ac. Increasing numbers of cell markers are used to identify and sort lung tissue-specific progenitor cells and for study of differentiation of iPS/ES cells into pulmonary cell types. iPS/ES cells are cultured under various conditions to enhance respiratory epithelial cell differentiation. Cultures of iPS/ES cells in defined media, at air/liquid interfaces or in organoids are being used to produce a complex, highly differentiated epithelium with properties of conducting and peripheral airways that contain ciliated, basal, and secretory and alveolar-like cells [58]. Co-culture of ES cells with embryonic lung mesenchyme enhanced the differentiation into cells with respiratory epithelial cell characteristics [59]. Nuclear extracts obtained from A549 adenocarcinoma cells, and mouse lung epithelial (MLE)-12 cells (an SV40 large T-antigen immortalized cell line) increased pulmonary differentiation of ESCs *in vitro* [60]. Differentiated alveolar type II-like cells were produced after genetically modified ES cells were selected on the basis of expression of TTF-1 or grown under conditions that selected for the survival of respiratory epithelial cell phenotype [61]. Differentiation of ES cells into respiratory epithelial-like cells has been associated with the expression of pro-SP-C, CFTR, α1AT, cytokeratin, ZO-1 and others [59,61–63]. It remains unknown whether stem cells or 'differentiated' respiratory epithelial cells can be re-introduced into the lung to contribute to normal lung function or repair. Initial experiments in which ES/iPS derived cells are administered to mice following severe lung injury caused by bleomycin, supports their ability to engraft and ameliorate lung injury and fibrosis. While ES/iPS cells expressing markers

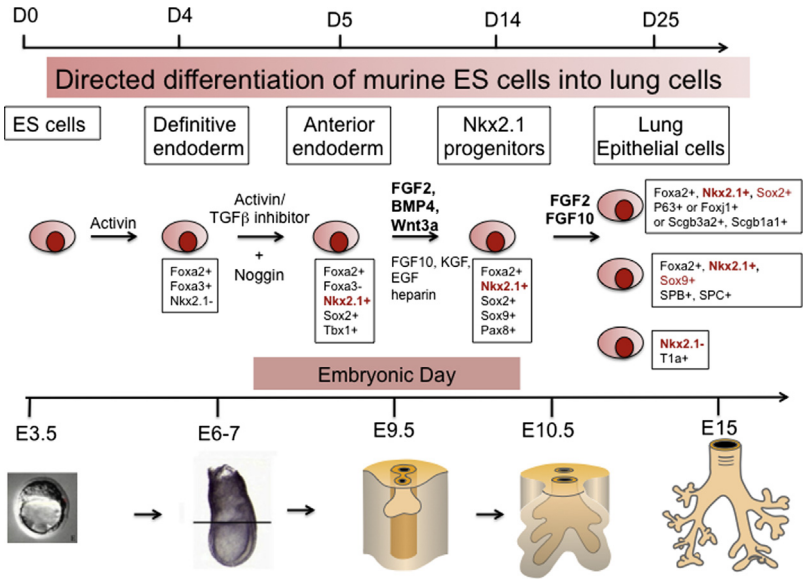

FIGURE 73.4

iPS/ES cells are reprogrammed into respiratory epithelial-like progenitors. Schematic representation of murine ES cells reprogramming adapted from the study by Mou et al. [57]. Directed differentiation of murine ES cells into lung epithelial cells was achieved by activation/inhibition of signaling and transcriptional pathways occurring during normal lung development. In general, the normal pattern of endoderm, foregut endoderm to lung formation is recapitulated during the *in vitro* differentiation of iPS/ES cells. Sequential expression of transcription factors marking and regulating specific stages of differentiation are indicated in association with the signaling molecules used in culture. Development stages of mouse embryogenesis are shown below each phase of differentiation. (E) is embryonic day. (D) represents day in culture.

specific for respiratory cell types have been produced, it is unclear whether these cells recapitulate gene expression or other biological functions comparable to endogenous lung epithelial cells. Engineering ES/iPS cells capable of engrafting, proliferating, differentiating and repopulating the respiratory epithelium represents a considerable technical challenge.

Advances in reprogramming of somatic cells into induced pluripotent stem (iPS) cells are transforming biology and medicine [64–67], enabling production of patient-specific iPS cells useful for study of the pathogenesis of disease and for cell-based therapies for many disorders. The success of exogenous stem cell-based therapies for the lung and other organs will depend on the ability to isolate, culture, and genetically modify cells capable of influencing tissue repair or directly engrafting, proliferating and differentiating into cells that can contribute to organ function. Because of their capacity for self-renewal and pluripotency, it may be possible to generate large numbers of iPS cells for cell-based therapy. Patient-specific stem cells will be non-immunogenic and therefore uniquely applicable for cell-based therapies. Reprogramming somatic cells into pluripotent stem cells overcomes social and religious barriers to the use of ES cells. The ability to reprogram iPS cells capable of safely contributing to organ function *in vivo* remains a considerable scientific challenge. Nevertheless, patient-specific stem cells can be genetically modified for cell-based therapy that will substantially bypass the immunologic barriers intrinsic to organ transplantation. iPS cells are now readily generated from patients' skin, blood or other cells, and can be differentiated into multiple cell types *in vitro*. Gene transfer or genomic modification, e.g., utilizing non-viral and viral vectors, TALENS or Zn-finger nucleases, provides the technology to repair genetic disorders in the future.

Application of mesenchymal stem cells (MSCs) for treatment of lung disease

MSCs have been derived from bone marrow stroma, umbilical cord blood (UCB) [68], whole blood and other organs (see also other chapters in this book) [68–74]. Adult bone

marrow-derived MSCs have limited capacity to proliferate *in vitro* but are able to grow and differentiate into bone, cartilage, fibrocytes and other cell types [68]. MSCs and HSCs isolated from umbilical cord blood (UCB) contain pluripotent hematopoietic stem cells that are readily isolated at birth. UCB stem cells have clinical and logistical advantages for cell-based therapy and are routinely used for bone marrow transplantation [71]. UCB cells are collected without risk to the donor and can be readily stored. UCB cells are amenable to Human Leukocyte Antigen (HLA) matching for allogeneic transplantation. MSCs are present in UCB and are relatively abundant (0.1%) compared to adult bone marrow, wherein the frequency of the MSCs ranges from 0.01% to 0.001% of total nucleated cells [70]. UCB-derived MSCs produce multipotent colony, and have longer telomeres than adult BM-derived MSCs perhaps providing an advantage for longevity as progenitor cells [71,72]. MSC derived from UCB are expanded *in vitro* and differentiate into multiple cell types (e.g., chondrocyte, osteocyte, myocyte and adipocyte lineages) [69,73,74]. 'Fibrocytes' are bone marrow-derived mesenchymal progenitors that express cell surface markers indicating hematopoietic origin but express collagen and other matrix proteins characteristics of fibroblasts [75,76]. Circulating fibrocytes migrate to wounds where they contribute to populations of fibroblasts, lipocytes and myofibroblasts [77]. Circulating epithelial progenitor cells (CEPCs) have been identified in bone marrow and blood by expression of CD45, cytokeratin-5 and CXCR4 [78]. CEPCs are recruited to the airways in response to a gradient of CXCL12 following lung injury. CEPCs enhanced re-epithelialization of tracheal transplants *in vitro*, inhibiting squamous metaplasia resulting from the excessive proliferation of the resident epithelial progenitor cells during repair of the airway epithelium [78]. FGF-7 enhanced the migration of CEPCs to proximal airways following injury [79].

DO BONE MARROW-DERIVED CELLS DIRECTLY CONTRIBUTE TO REPAIR AND PROVIDE PROTECTIVE FACTORS?

Stem cell-based therapies may be designed to provide cytoprotective factors to enhance repair by endogenous cells or alternatively to provide progenitor cells (or genetically altered progenitor cells) capable of engraftment and permanently contributing to the lung ([80] for review). Long-term engraftment and proliferation of stem cells for repair following injury has not been accomplished in the laboratory. Evaluation for Y-chromosome-containing type II pneumocytes using Fluorescence *In Situ* Hybridization (FISH) technology indicated that repopulation by bone marrow-derived stem cells or their progeny may occur at a low frequency in the lungs [81,82]. Early studies of potential bone marrow contribution to lung repair reported that bone marrow-derived cells from male donors readily engrafted, forming alveolar and bronchiolar epithelial cells into female lung [83]. In a model of bleomycin-induced lung injury, MSCs were proposed to differentiate into alveolar type I cells. However, later studies have not supported these initial concepts. Engrafted MSCs fail to proliferate and differentiate into pulmonary epithelial cells. Cell fusion between the MSCs and endogenous epithelial cells or aberrant co-localization of cell markers perhaps related to insufficient technical resolution may have accounted for these earlier findings [84–86]. While it is well known that hematopoietic cells migrate to the lung and repopulate alveolar macrophages following bone marrow transplantation, definitive data supporting engraftment of bone marrow-derived cells capable of proliferation and differentiation in the lung has not been provided.

Systemic or tissue directed infusion of MSCs has been proposed for therapies that do not depend on long-term engraftment but influenced by provision of MSCs or their products. MSC conditioned media ameliorated cell injury from cigarette smoke [87]. In the kidney, in a rat model of ischemia/reperfusion, MSCs infusion enhances the restoration of renal function [88]. Recovery after MSCs infusion was mediated via paracrine actions with decreased expression of proinflammatory cytokines, and increased anti-inflammatory cytokines [89]. Pulmonary hypertension and endothelial function improved after engraftment of MSCs

into the injured lung in a process likely related to transient paracrine effects rather than replacement of endothelial cells [90,91]. Recent studies suggest that epithelial cell survival following severe lung injury may be initiated by mitochondrial transfer from MSCs to lung cells [92]. The utility of MSCs for therapy of pulmonary injury, bronchopulmonary dysplasia and pulmonary hypertension is being actively studied in animal models and in the clinic at present [93].

Delivery of stem cells into the lung

The efficient recruitment or delivery of stem cells into the lung represents another challenge for the application of stem cell therapy to the lung. There is at present little evidence that exogenous cells readily engraft and permanently contribute to normal lung function. While normal and tumor cells readily enter the pulmonary vasculature and can embolize or metastasize to the lung, engraftment appears to occur with very low frequencies. Previous studies with MSCs or marrow-derived cells demonstrated extremely low efficiency of integration into the normal lung epithelium or vasculature after intravenous injection. In most studies, engraftment of bone marrow and MSCs into the lung does not occur unless the lung was severely injured. The mechanisms underlying this observation are unclear. Secretion of growth factors and cytokines may enhance recruitment of MSCs to sites of injury. *In vitro* experiments demonstrated that cell suspensions from the injured lung contain chemoattractants and growth-stimulating factors including hyaluronan (CD44), osteopontin and SDF-1α [94]. Repair of the lung after bleomycin injury was enhanced after intravenous administration of bone marrow-derived cells and was associated with an increased expression of anti-inflammatory cytokines (IL-10, IL-1ra, IL-13), G-CSF and GM-CSF [95].

Intratracheal delivery of stem cells

Since the surface of the lung is directly accessible via the trachea, stem cells may be directly injected intratracheally. Intratracheal injection of bone marrow-derived mesenchymal cells decreased bacterial and bleomycin-induced lung injury [96,97]. The beneficial effects of MSC were independent of the ability of the cells to engraft in the lung and were proposed to be mediated by paracrine effects modulating inflammation. Intratracheal injection of alveolar type II cells decreased fibrosis after induction by bleomycin [98]. Engrafted alveolar type II cells did not contribute to alveolar epithelium repopulation but reduced collagen deposition and fibrosis development. The remarkable structural integrity of the respiratory epithelium is likely to limit the ability to introduce exogenous cells and may require depletion of endogenous cells to provide 'space' for engraftment. The success of bone marrow transplant depends on marrow ablation creating space for engraftment. Inhibition of c-kit, the receptor for the stem cell factor, by ACK2 antibody treatment depleted 99% of the host HSCs enhancing the engraftment of donor HSCs in the host stem cell niches [99]. Development of safe methodologies for providing the cellular space required for the engraftment of stem cells into the lung will likely be required for success of cell-based therapies dependent upon engraftment of cells into the respiratory epithelium.

Recruitment of MSCs to tumors

The use of genetically modified mesenchymal cells has been proposed for treatment of pulmonary tumors [100–102]. 'Umbilical cord matrix stem cells' (UCMS) transplanted into Severe Combined Immunodeficiency (SCID) mice bearing lung tumors, migrated to pulmonary carcinomas [102], indicating that mesenchymal cells may represent a vehicle for delivery of therapeutic molecules to the lung. Mesenchymal cells expressing therapeutic proteins (IFN-γ, NK4, CX3CL1) decreased the growth of pulmonary tumors [103–107]. The enhancement of recruitment of MSCs to pulmonary tumors represents a promising application of cell-based therapies for the lung.

BIOENGINEERING OF LUNG TISSUES

Acellular Matrix, Bioreactors and Synthetic Biomatrices for Study of Lung Biology

Advances in the identification and purification of endogenous lung progenitor cells and the ability to reprogram iPS or ES cells into respiratory epithelial-like progenitors enable experiments designed to seed these cells into organ-like scaffolds prepared from decellularized lung tissue or on synthetic matrices. The relative simplicity of the conducting airways has enabled the clinical use of both decellularized and synthetic tracheal-bronchial scaffolds capable of supporting the airways. Macchiarini et al. seeded the grafts with MSCs and applied growth factors and chemokines to enhance cell recruitment and proliferation to both bioengineered or decellularized tissue grafts that have been used to replace diseased airways in selected patients [108]. These airway grafts are rapidly vascularized and less rapidly epithelialized. Though considerably more complex in cellularity and architecture, similar procedures are being utilized to create acellular lung scaffolds that are seeded with lung cells, reperfused and ventilated in bioreactors or transplanted to sites compatible with continued growth and differentiation [29,109–113]. Lung epithelial progenitor cells bind to the de-cellularized lung scaffolds produced from cadaveric human or animal lung tissues. Endothelial cells are instilled into the vascular compartment and perfused to generate a capillary bed. Diverse epithelial cell types bind to and proliferate on the scaffolds. Conducting airways and alveolar surfaces become populated with the appropriate cell types characteristic of each region of the lung. Short-term physiological activity was demonstrated after orthotopic transplantation of lung tissue prepared on decellularized matrices, providing a model system with which to study lung cell biology and to test the feasibility of using various lung cell preparations ES/iPS cells as precursors [112]. Such experimental approaches seek to generate functional lung tissue on the decellularized lung matrices. Completely synthetic scaffolds and microfluidic chambers in which pulmonary cells are subjected to shear forces consistent with both ventilation and perfusion also hold promise for study of lung regeneration and repair.

Differentiation of iPS and ES cells to pulmonary epithelial cell lineages

Successful cell-based therapy for many genetic diseases affecting epithelial cell function (e.g., cystic fibrosis, genetic defects in genes controlling surfactant homeostasis and others) may require the permanent introduction of cells capable of maintaining stem cell activity as well as the ability to contribute to highly differentiated lung cell function. Differentiated respiratory epithelial cells have been produced from iPS, ES, and endogenous lung cells on various biomatrices, decellularized lung and tracheal-bronchial grafts, in air-liquid interface cultures and after transplantation under the renal or testicular capsules of SCID mice [57,110–113] supporting the feasibility of directing both lung epithelial cell differentiation and organ-like structure. Cell sorting or selectable markers may be used to enrich differentiating iPS cells with lung epithelial cell characteristics during preparation. For example, ES cells transfected with a Surfactant Protein C (SFTPC) promoter/NEOr fusion gene were selected with gancyclovir, enhancing the numbers of cells with respiratory epithelial cell characteristics [61]. Insertion of selectable markers directed by lung epithelial specific gene promoters, from the *TTF-1* or *SFTPC* gene loci have been used to search for lung cell differentiation [56,114]. Use of cell selection strategies and the expression of genes known to regulate differentiation of stem/progenitor cells into specific lung epithelial cell types may be used to search for specific cell types needed for treatment of pulmonary disorders. Thus, the elucidation of the signaling and transcriptional networks controlling lung epithelial cell differentiation will be useful in guiding the production of stem cells for therapy of lung diseases in the future.

CONCLUSION

Knowledge regarding the depth of physiology, genetics and cell biology of life-threatening diseases of the lung is expanding rapidly. Likewise, our understanding of development, lung morphogenesis and stem cell biology has accelerated. Together, these technical and scientific advances raise the hopes that novel therapies may be developed for life-threatening disorders in many organs including the lung. Major barriers to successful application of cell-based therapies for the lung remain. The ability to engineer lung tissue capable of enhancing respiratory function remains conceptual rather than actual, see Fig. 73.1. Nevertheless, isolation, culture and genetic manipulation of cells able to differentiate into pulmonary cell types have been achieved *in vitro*. A multiplicity of lung stem and progenitor cells has been identified and introduced into the various tissue compartments and bioreactors, providing the scientific basis for cell-based therapies for pulmonary diseases in the future.

INTRODUCTION

Pediatric and adult lung diseases are on the increase globally and represent one of the major challenges facing healthcare systems in the 21st century. In the pediatric realm, significant advances in preterm clinical care have increased the population of premature infants at risk of defective postnatal lung development due to 'chronic lung diseases of prematurity' [1], such as bronchopulmonary and alveolar capillary dysplasia [2]. In the adult realm, chronic obstructive pulmonary disease (COPD), which includes emphysema and chronic obstructive bronchitis, was responsible for more than 120,000 deaths in the US alone in 2008 [3].

Pharmacological intervention treats symptoms at the various disease stages; however, the only current viable option for patients with end stage diseases is lung transplantation. Unfortunately many patients on the transplant list die while waiting for a suitable donor organ, and those that are fortunate enough to receive a transplant have a life-long need for immunosuppression. Providing life-saving solutions for these daunting clinical challenges with cell therapies and implantable tissue constructs is the long-term goal of pulmonary regenerative medicine and tissue engineering. For the sake of simplicity, a regenerative medicine or tissue-engineering strategy can be thought of as any combination of four core elements: cells, matrices and scaffolds, growth factors or other signaling molecules, and 3D cell culture systems, aka bioreactors. In this chapter we will briefly introduce key elements of lung biology, and then address all four of these core elements, with particular emphasis on integrated strategies toward the generation of three-dimensional pulmonary tissue constructs.

LUNG FUNCTION AND ANATOMY

The lungs facilitate oxygenation of the blood by respiration, and therefore sustain life. The focus of this chapter is on the distal gas exchange units; however the lung is also an immunological interface under constant assault by inhaled particulates and pathogens [4]. The airways are the central component of the lung, organized in a branched network of conduits which decreases in diameter with each generation until reaching the terminal alveoli in the distal lung (Fig. 74.1), which have an average diameter of 200 micrometers in humans, while mice alveoli are ~50–70 micrometers in diameter [5]. Region-specific epithelial

differentiation occurs along the proximal-distal axis, resulting in distinct local phenotypes that facilitate required physiological functions (Fig. 74.2a). Tracheal and upper airway epithelium is composed of columnar ciliated and mucous secretory cells, which function in concert to entrap inhaled particles in mucus that is then removed by upward beating of cilia. Pulmonary neuroendocrine cells (PNECs), comprising neuroepithelial bodies, are found throughout the upper airways, sense gas content of the air and are believed to play a potential role in mediating developmental and regenerative processes through paracrine activity of molecules such as calcitonin gene related peptide (CGRP) and gastric releasing peptide (GRP), both of which are classic markers of PNECs [6]. Clara cells are cuboidal secretory cells that reside in the bronchioles, functioning to protect the bronchiolar epithelium via secreted substances including Clara cell secretory protein (CCSP). Terminal bronchioles transition into the alveoli, marking the beginning of the distal respiratory zone (Fig. 74.2a).

In the alveoli, there are type I (AE1) and type II (AE2) alveolar epithelial cells. AE1 cells constitute the squamous, attenuated epithelium that forms the blood-air barrier interfacing

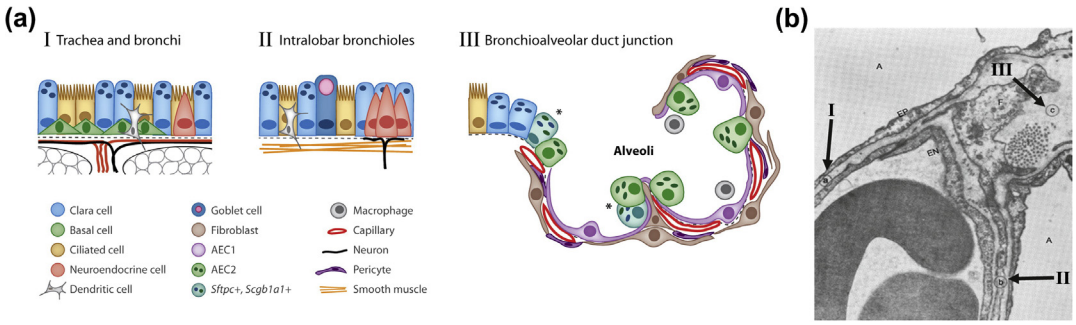

FIGURE 74.2
Cellular composition of the lung epithelium and surrounding mesenchyme at various depths in the respiratory tree. (a) Illustration of the trachea/bronchi, intralobular bronchioles, and the bronchioalveolar duct junction transition into the alveoli with all epithelial and mesenchymal phenotypes indicated. Note the transition in epithelial phenotypes as well as the tight association of capillaries with alveolar type I (AEC1) cells. *(Reproduced with permission from Rock and Hogan [9].)* (b) Transmission electron micrograph of the alveolar-capillary barrier illustrating ultrastructure that facilitates efficient gas exchange, i.e., O2 and CO_2 transport. Type I epithelial cells (EP) are seen in direct contact with a red blood cell-containing capillary lined by an endothelial cell (EN). Note the intervening basement membrane at 'i', the presence of a fibroblast 'F' with extension at 'ii', and collagen fibers in the alveolar septum at 'iii'. *(Reproduced with permission from Weibel, E.R. 1969 [10].)*

with the alveolar capillary bed. Aquaporin-5 and T1-alpha are commonly used markers of AE1 cells. AE2 cells, cuboidal and far fewer in number, produce and secrete lung surfactants, a lubricant mixture of phospholipids and proteins that regulates alveolar surface tension during inflation and deflation. Anatomically, the key functional feature of the pulmonary vasculature is its close association with the airways throughout the proximal-distal axis [7]. The vasculature accompanying the upper airways is smooth muscle-enrobed, while the alveolar capillary bed, the densest in the entire body, is comprised of attenuated capillary endothelial cells with occluding junctions and no fenestrations — conferring tissue-specific regulation of fluid transport [8]. The specialized gas exchange function of the distal lung is facilitated by seamless interfacing of the alveolar epithelium and capillaries (Fig. 74.2b).

During the process of epithelial branching morphogenesis and cytodifferentiation, the surrounding mesenchyme also differentiates in a region-specific manner. Sub-tracheal mesenchyme gives rise to cartilage, while the mesenchyme beneath the bronchi gives rise to smooth muscle and hyaline cartilage [8]. Mesenchymal cells surrounding the bronchioles are comprised of subsets of myofibroblasts and connective tissue fibroblasts that synthesize the collagenous and elastic interstitial matrix [11].

Lung mechanical properties

The lung possesses unique mechanical properties associated with respiration. Lung compliance and elastance[1] are conferred by collagenous and elastic fibers of the interstitial extracellular matrix (ECM) and are altered in various pulmonary diseases [12]. Fibrotic diseases are characterized by increased deposition of collagenous ECM, resulting in decreased compliance, i.e., a stiffer lung; thus increasing the amount of work required inflating the alveoli [11]. In emphysema there is a loss of elastin protein in the alveolar walls, decreasing lung elastance [13]. This results in a higher compliance and therefore increased difficulty exhaling. The elastic modulus of the tissue, i.e., the stiffness sensed by parenchymal lung cells, is of interest for the selection of suitable materials for three-dimensional culture of lung cells *in vitro*. The generally accepted range for elastic moduli of healthy mammalian lung tissue at rest is 5—30 kPa [14,15], a range of elastic moduli that can easily be achieved using 'soft' hydrogels. Elastic moduli for acellular collagen gels across a broad concentration range is 0.5—12 kPa [16], while that of Matrigel™ is approximately 450 Pa [17]. Other natural polymers such as alginate have been used to create hydrogels with Young's moduli on the order of 20 kPa [18]. For comparison the elastic moduli of synthetic polymer matrices, such as polylactide-co-glycolides, are about three orders of magnitude higher (in the MPa range) [19], which is less suitable for lung tissue-engineering applications. To date, no focused studies have been reported that test the effect of matrix stiffness on lung tissue formation *in vitro*.

LUNG DEVELOPMENTAL BIOLOGY 101: PRIMER FOR TISSUE ENGINEERS

Our increasing knowledge of the intricacies of embryonic development provides a sound basis for tissue-engineering strategies. Lung development begins with specification of a field within the ventral foregut endoderm. Among other early signals, cardiac mesoderm-derived FGF-2 is a key factor driving the commitment of the anterior foregut endoderm to the lung epithelial lineage, which will eventually give rise to all the diverse cell types comprising the pulmonary epithelium (Fig. 74.2a; Fig. 74.3) [20]. Thyroid transcription factor-1 (TTF-1), also known as Nkx2.1, is a definitive marker of commitment to the lung epithelial lineage. Following specification, the epithelium buds into the surrounding splanchnic mesenchyme,

[1] Lung compliance impacts how much work is required to inhale air. Lung elastance is a measure of how easily the lung recoils to its resting position after inflation, and is conferred primarily through elastin present in the alveolar walls.

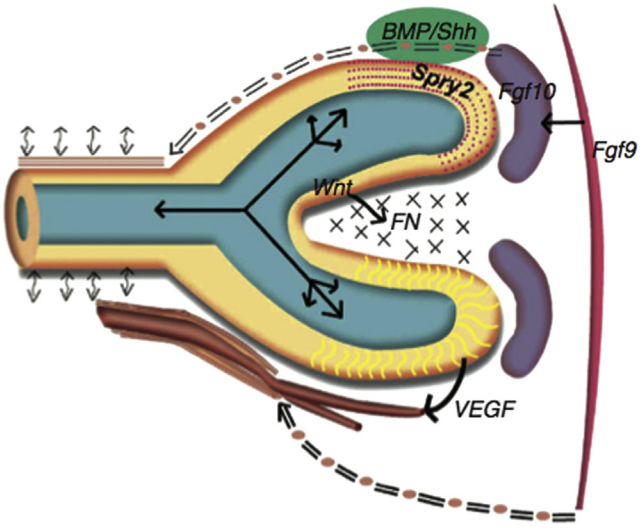
FIGURE 74.4
Molecular regulation of epithelial branching morphogenesis and capillary network interfacing. Fibronectin (FN) deposition occurs in epithelial clefts, the regulation of which is known to involve Wnt signaling. FGF10 expression in the distal mesenchyme guides the pattern of lung budding and is known to be regulated by mesothelial-derived FGF9. Bone morphogenetic protein (BMP) and Sonic hedgehog (Shh) signaling, as well as transcriptional activity of Sprouty-2 (Spry2) in the distal epithelium are all known to contribute to refinement of epithelial-mesenchymal interactions. VEGF released from the distal epithelium patterns interfacing with capillaries. *(Reproduced with permission from Warburton 2010 [45].)*



giving rise to the airway tree through the highly choreographed process of epithelial branching morphogenesis [7], the pattern of which is known to be regulated by mesenchymal FGF10 expression [21][2]. The upper airways undergo a series of fractal bifurcations that occurs in parallel with branching of the proximal vasculature; decreasing in diameter with each generation (altogether there are some 23–25 generations of branching) through the pseudoglandular and canilicular stages until the saccular stage after which sacculation of the terminal epithelial buds gives rise to the alveoli. The alveoli are refined and further increased in surface area through the process of secondary septation during the alveolar stage (Fig. 74.1).

[2] The lung developmental biology literature is almost entirely based on animal models, primarily mice. The precise timing and spatial patterning of the signals involved in specification and subsequent lineage commitments in humans is not known due to the inability to perform exhaustive time course embryological studies. It isn't clear whether all of the signals discovered in mice will have direct functional translation in human lung development, but the importance of some of the major players discussed here has been confirmed.

In addition to secreting morphogens that pattern epithelial branching morphogenesis, the mesenchymal compartment gives rise to fibroblasts which synthesize and deposit the fibrous interstitial matrix, smooth muscle cells of the upper airways and proximal vasculature, pericytes, and endothelial cells. The development of the proximal vasculature occurs by sprouting angiogenesis and coordinated fractal branching in parallel with the airway epithelium [23,24]. By contrast, the distal vascular plexus forms by vasculogenesis from differentiating resident endothelial progenitor cells and subsequently anastomoses with the expanding pulmonary circulation [25–27]. Also found within the interstitium are the pulmonary veins, nerves, and lymphatics. The lungs are innervated by extrinsic parasympathetic (Vagus nerve) and sympathetic (pulmonary nerve root) sources, as well as intrinsic neural crest cells during development [28,29]. The pulmonary lymphatics are believed to emerge exclusively from sprouting of pre-existing extrapulmonary sources [30]. While nerves and lymph vessels are largely absent in the distal airways, pulmonary nerves are required for autonomic control of the upper airways and relay of sensory information to the central nervous system, while the lymphatics perform essential fluid clearance functions. Re-innervation and lymphangiogenesis in tissue-engineered lungs are uncharted areas which should be of keen interest going forward.

Epithelial-mesenchymal interactions are known to guide lung morphogenesis and cytodifferentiation [31]. Members of the FGF family of cytokines are amongst the key molecular regulators of these interactions [32–34], along with bone morphogenetic proteins [35], Wnts [36], Sonic hedgehog (Shh) [37,38], and ECM molecules such as fibronectin [39], tenascin-C (TN-C) [40], and chondroitin sulfate proteoglycans. Some key signals are summarized in Figures 74.3 and 74.4. SHH-FGF crosstalk regulates VEGF-A expression [41], a key factor in patterning vascular development. Whole organ explants studies using rat lungs demonstrated increased branching morphogenesis and TN-C deposition in hypoxia (3% O2) compared to normoxia (21% O2) [40]. In a similar experimental system Van Tuyl et al. [42] reported increased VEGF expression and vascular development in explants cultured in hypoxia. Alveolarization occurs postnatally, i.e., in normoxia, however hypoxia can be a powerful driving force for the differentiation and morphogenesis of fetal lung cells and embryonic stem cell-derived progenitors. An exhaustive discussion of these developmentally relevant factors is beyond the scope of this chapter, therefore the reader is referred to the numerous textbooks and excellent literature reviews on the subject [43–46].

CELL SOURCES FOR LUNG REGENERATIVE MEDICINE AND TISSUE ENGINEERING

The field of pulmonary regenerative medicine and tissue engineering has focused heavily on identification, characterization, and application of stem and progenitor cell populations for clinical application. Some candidate stem/progenitor cell types that have been used to generate pulmonary tissue constructs are: embryonic stem cells, tissue-specific lung stem cells (fetal and adult), circulating endothelial progenitor cells, and mesenchymal stem cells derived from sources such as bone marrow and adipose tissue.

The earliest reports of differentiating rodent embryonic stem (ES) cells into pulmonary epithelium date back to 2002 [47]. Several approaches have been successfully applied to generate pulmonary epithelial cells from ES cells, such as: co-culture with mesenchyme [48], ES permeabilization and exposure to mature type II cell extracts [49], and culture with medium conditioned by A549 cells, a human pulmonary adenocarcinoma cell line, or in defined medium in with high dosages of FGF-2 [50]. More recently, researchers focused on defining culture conditions for optimal generation of definitive endoderm [51], in order to enrich the amount of cells competent to become lung. For example, in extending previous studies that emulate paracrine signaling during embryonic development, Longmire et al. [52] and Mou et al. [53] developed stepwise differentiation protocols that mimic the temporal progression of key signaling factors during lung development *in vivo*. With all of the incremental progress

many challenges still remain: The efficiency of differentiation protocols needs to be improved, functional efficacy and, more importantly, safety of derived populations needs to be assessed. The vast majority of work has focused on lung epithelium; however, directed, efficient differentiation of the pulmonary vasculature and connective tissue cells will also be required [54]. Furthermore, the entire repertoire of proximal-distal cytodifferentiation in the various tissue compartments and up to 40 different cell types of the lung may ultimately have to be accounted for.

The existence of peripheral airway stem cells, both bronchioalveolar stem cells (BASC) and AE2 progenitor cells, in rodents and humans has been extensively documented and reviewed [55–58]. A recent report of the existence of a subset of multipotent human lung stem cells, described as $CD117^{+}/CD90^{-}$ interstitial cells, that are putatively capable of generating all cell types and tissues in the lung remains highly controversial [59,60]. When injected into the cryo-injured lungs of recipient mice, these cells reportedly give rise to human airway and vascular structures integrated within the host tissue. If confirmed this finding might have tremendous therapeutic implications, representing an autologous source of cells, which could potentially be harvested from small biopsies, expanded, and used to reconstitute diseased or damaged tissue. In an exciting recent report, human iPS cells differentiated into proSpC+ alveolar type II lineage cells were shown to engraft in a murine model of acute lung injury [61].

Bone marrow-derived mesenchymal stem cells (MSCs) are the only class of stem cells, to date, that have been investigated as candidates for pulmonary regenerative medicine in humans. Osiris Therapeutics recently completed a phase II clinical trial testing the safety and efficacy of intravenous infusion of *ex vivo* cultured adult human MSCs (Prochymal™) for the treatment of moderate to severe chronic obstructive pulmonary disease (COPD) (http://clinicaltrials.gov/ct2/show/NCT00683722). MSCs are believed to function primarily as support cells, secreting paracrine factors that may stimulate both epithelial regeneration [62] and angiogenesis [63]; as well as playing an immunomodulatory role, acting to reduce inflammation and promote tissue healing [64,65]. Major advantages of MSCs include: relative ease of autologous sourcing [66], documented immune tolerance of allogeneic sources, and lack of tumorigenecity. An additional class of potentially relevant marrow-derived progenitor cells is the so-called 'circulating endothelial progenitor cells' [67], though contributions of these cells to lung vascular development and regeneration are not well-defined.

SCAFFOLDS AND THREE-DIMENSIONAL PULMONARY TISSUE CONSTRUCTS

In addition to development of cell therapies based on infusion of stem and progenitor cells, there has been significant progress toward the generation of three-dimensional pulmonary tissue constructs. Tracheal and upper airway tissue engineering have enjoyed major translational successes. For example, there have been several reports of creating bronchial tissue equivalents *in vitro* as models for studying topics such as stem cell differentiation and asthma [68,69]. The first tissue-engineered tracheal replacement in human was performed in 2008 utilizing allogeneic decellularized trachea seeded with the patient's own epithelial cells and mesenchymal stem cell-derived chondrocytes [70]. As the next consequential step, Macchiarini et al. have also performed a successful transplant of tissue-engineered trachea generated using an elastic nanocomposite scaffold [71]. This year (2012), Elliot et al. reported a two year follow-up study on a 12 year old boy that received a tissue-engineered trachea comprised of decellularized donor trachea seeded with autologous MSCs and patches of bronchial epithelium [72]. Trachea and the primary bronchus are among the few examples of engineered tissues successfully implanted into humans; however, the remainder of this chapter will focus on the ongoing efforts to engineer the lung as a whole, with particular emphasis on the alveolar compartment.

Naturally-derived scaffolds

The earliest reports of three-dimensional culture of lung cells were published by Douglas et al. in the 1970s [73]. These seminal experiments demonstrated that quasi 3-D culture of rat fetal lung cells on a collagen matrix with appropriate growth factor supplementation drove formation of alveolar-like cystic structures with extended maintenance of epithelial cell differentiation *in vitro*. The goal of the work was to develop models for studying pulmonary epithelial cell biology; however, these systems were largely overlooked in favor of considerably less complex 2D culture models.

Some 30 years later, Andrade et al. utilized Gelfoam™, a gelatin-based porous sponge as a model matrix for engraftment of rat fetal lung cells into the lung parenchyma of adult rats [74]. Survival and continued proliferation of pre-labeled fetal lung cells was maintained for up to 35 days *in vivo*, both within the Gelfoam™ sponge and at the interface with host lung parenchyma. The authors reported low levels of local inflammatory response and the presence of graft-derived epithelial and endothelial cells, as well as neovascularization within the Gelfoam™ construct. In a related set of experiments, Chen et al. showed that porous collagen type I-chondroitin-6-sulfate scaffolds supported the formation of alveolar-like structures by disaggregated rat fetal lung cells *in vitro* [75]. In line with the known role of chondroitin sulfate proteoglycans (CSPGs) in lung development [76], these *in vitro* findings suggest that incorporation of CSPGs into biomimetic matrices might be beneficial for driving lung epithelial morphogenesis.

Compliant natural ECM hydrogels such as Matrigel™ and collagen type I gels possess biochemical cues and mechanical properties that are permissive to three-dimensional organotypic morphogenesis of lung cells and maintenance of epithelial cytodifferentiation. Mondrinos et al. demonstrated that growth factor depleted Matrigel™ in combination with basal serum-free medium devoid of exogenous growth factors supported the formation of lumen-containing spherical cystic epithelial structures by mouse fetal lung cells, while addition of FGFs 10, 7, and 2 to the serum-free culture medium stimulated budding and sacculation of epithelial structures, a process akin to the early saccular stage of lung development [77]. Subsequently, Mondrinos et al. went on to show that simple collagen type I hydrogels in conjunction with the above mentioned combination of growth factors of the FGF family supported extensive epithelial budding and sacculation and robust endothelial network formation [78]. As an important step toward recreating the respiratory unit *in vitro*, this combination of matrix and growth factors also facilitated the interfacing between epithelial alveolar forming units and capillary-like tubes with continuous lumens (Fig. 74.5). Utilizing a subcutaneous implantation model, these authors further demonstrated that graft-derived endothelial cells contributed to the formation of perfused vessels that had anastamosed with the host vasculature *in vivo* [79].

Synthetic (polymer) scaffolds

Degradable polymeric biomaterials, such as poly(lactic-co-glycolic acid) (PLGA) can easily be engineered into scaffolds with fibrous or porous geometries. Lin et al. demonstrated that coating the surface of synthetic polymers with natural ECM proteins facilitates enhanced initial attachment [80] but might not suffice to overcome the inherent stiffness-driven dedifferentiation of the seeded (epithelial) cells towards the mesenchymal phenotype [77]. Utilizing surface modification strategies, such as integrating adhesive or instructive peptide domains, could enhance the differentiative properties of synthetic materials. In addition, elastomeric polymer chemistry could facilitate the design of materials that satisfy the mechanical requirements for organotypic cell growth and differentiation, as well as the need to support cyclic strain of respiration.

An additional limitation of synthetic materials is that they often induce foreign body reactions, limiting tissue development and integration *in vivo*. For example, Cortiella et al. tested the

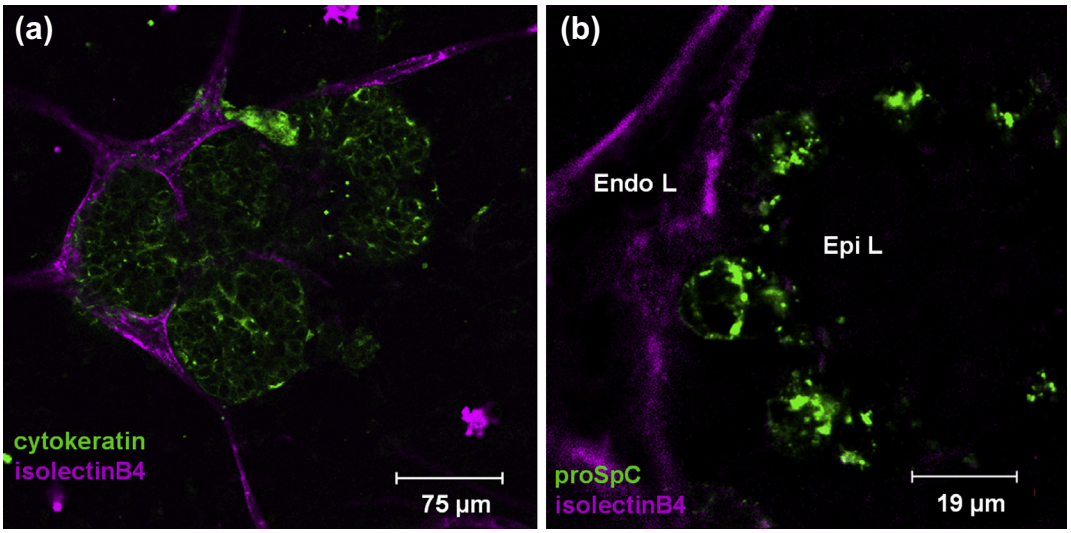


FIGURE 74.5
Interfacing of epithelial and endothelial tissue components in three-dimensional pulmonary tissue constructs. (a) A sacculated epithelial alveolar forming unit (AFU), shown with cytokeratin staining (green), enrobed by a developing capillary-like endothelial network, shown with isolectinB4 staining (magenta). (b) A single epithelial saccule of a developing alveolar forming unit (AFU) with a defined lumen (Epi L), comprised of proSpC-positive alveolar type 2 lineage cells (green) directly contacting an endothelial capillary-like tubule (isolectinB4 labeling, magenta) with a defined lumen (Endo L). Embryonic day 17 murine fetal pulmonary cells were admixed into collagen type I hydrogels and cultured for 1 week in a serum-free defined medium containing FGFs 10, 7, and 2. *(Reproduced with permission from Mondrinos et al. 2007 [78].)*

ability of polyglycolic acid (PGA) scaffolds and pluronic F-127 hydrogels to support *in vivo* lung tissue formation by ovine 'somatic lung progenitor cells' [81]. While these lung progenitor cells proliferated on PGA scaffolds *in vitro* and continued to express lung-specific markers, the scaffolds induced a foreign body response *in vivo*, limiting tissue development and integration. This limitation was partially overcome through the use of pluronic F-127. Shigamura et al. used a lung volume reduction surgery (LVRS) model in rats to test the efficacy of PGA felt sheets seeded with adipose-derived stem cells (ASCs) as a sealant graft construct [82]. The ASC-containing PGA grafts significantly improved compensatory growth following surgical resection, as evidenced by both alveolar and vascular regeneration. This improvement in tissue restoration resulted in enhanced as exchange and exercise tolerance when compared to control animals, which had undergone LVRS without any further treatment.

Decellularized lung tissue scaffolds

A potential paradigm for whole organ engineering has emerged recently in the form of decellularized cadaveric donor tissue. Paradigms of decellularized organs are heart, lung and liver [83]. Decellularized lungs are typically prepared using combinations of hypotonic lysis, detergent solutions – by diffusion or perfusion, and DNAse [84]. Petersen et al. were the first to demonstrate the ability of decellularized rat lungs subsequently repopulated with fetal lung cells to participate in gas exchange upon *in vivo* implantation for short periods (<120 minutes) [85]. The feasibility of this concept was confirmed by Ott et al., with slightly longer periods (up to six hours) of gas exchange *in vivo* [86], followed by a paper by Song et al., who described enhanced *in vivo* function of these decellularized/recellularized lungs [87]. In the latter study, decellularized rat lungs were recellularized with rat fetal lung cells and human endothelial cells, cultured for seven days in biomimetic bioreactor culture under dynamic conditions, then implanted following left pneumonectomy and maintained *in vivo* for up to 14 days. Gas exchange function was comparable to transplanted lung allograft controls up to day 7, however, the function of engrafted bioartificial lungs declined over the subsequent seven days due to graft immune rejection. The key component in the preparation of these

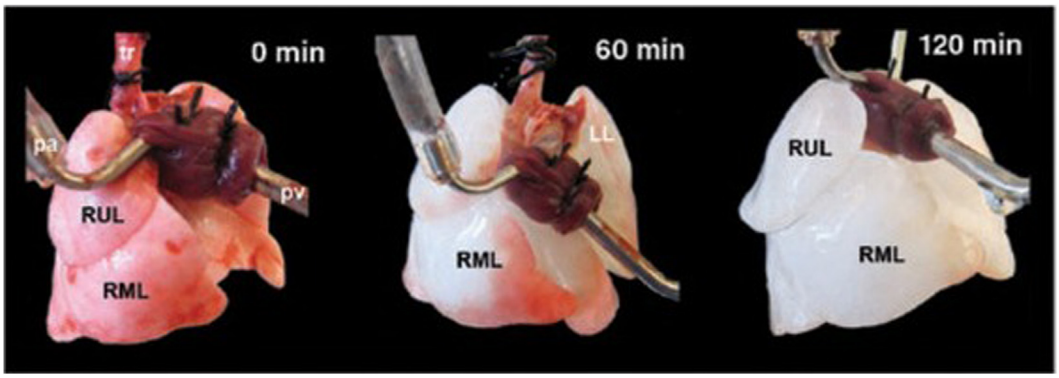

FIGURE 74.6

Rapid decellularization of whole rat lungs using a perfusion bioreactor and detergent solutions. Removal of the cellular contents is visible as the tissue loses its color and becomes more translucent. Decellularized lungs may then be re-seeded using the same perfusion approach, and subsequently mechanically conditioned with both ventilation of the tracheal conduit and perfusion of the reconstituted vascular tree at appropriate pressures. RUL = right upper lobe; RML = right middle lobe. *(Reproduced with permission from Ott et al. [86].)*

engineered whole organ systems is the independent perfusion of both the airways and vasculature, which allows for perfusion decellularization, seeding, and culture for mechanical conditioning of both these compartments *in vitro* (Fig. 74.6).

Some investigators have looked into re-seeding decellularized lungs with stem cells derived from various sources. Jensen et al. seeded mouse ES cells which were pre-differentiated into prosurfactant protein C-expressing alveolar type II-like cells into decellularized mouse lungs [88]. Inoculated cells maintain differentiation both *in vitro*, and *in vivo* – where vascularization of subcutaneous allografts was observed. Longmire et al., seeded murine ES cells that were pre-differentiated in a multi-step process first toward the definitive endodermal lineage and then into immature lung epithelial cells. Upon seeding into decellularized lung matrices, structures reconstituted by these cells demonstrate morphologies and expression of proteins indicative of both type I and type II alveolar epithelial cell differentiation [52]. This latter study suggests that a decellularized ECM may serve as a natural bioreactor that can enhance directed tissue-specific differentiation of competent progenitor cells.

Daly et al. reported preservation of ECM components following decellularization, along with the ability to support attachment and survival of MSCs for up to one month *in vitro* without, however, expressing any alveolar or vascular genes [89]. The re-seeding of decellularized mouse lungs with ES-derived lung cells [52], taken together with ability to generate patient-specific lung cells with iPS technology [53], provides the proof of concept for potentially utilizing autologous cells for the recellularization of whole decellularized lungs, although at this time this has only been accomplished in small animal models. As a next step forward towards clinical feasibility, Bonvillain et al. demonstrated effective decellularization of rhesus macaque monkey lungs using protocols developed with rodent lungs [90]. Importantly, this study demonstrated for the first time in a larger animal model, that ECM structure and composition were largely preserved, including the proteins collagens type I and IV, laminin, fibronectin, and sulfated glyosaminoglycans. As an additional proof of concept, decellularized primate lungs supported the adhesion, integration, and *in vitro* proliferation of allogeneic rhesus MSCs derived from adipose tissue and bone marrow.

The paradigm of combining decellularized lung scaffolds with stem cell-derived populations of lung cells represents the current 'state of the art' in the field. However, many practical challenges facing clinical translation remain. First, it is known that decellularized lung scaffolds retain cytoplasmic and nuclear contents, up to 8% of the original total DNA in the lung according to one report [90], which may potentially elicit immune rejection. Once

short-term functional integration of tissue-engineered lungs using autologous or otherwise known to be non-immunogenic cells is achieved (e.g., avoiding leakage of the vasculature), it will be possible to assess the long-term immune response specific to the allogeneic lung matrix and the seeded cells. In addition to determining the safety, immunogenicity, and long-term functionality of decellularized/recellularized matrices, the availability of healthy cadaveric human lungs will remain a problem.

Bioreactors and cell culture systems

Bioreactors are cell culture systems for the three-dimensional assembly, growth and differentiation of cells and tissues under tight control of key physicochemical factors such as pH, oxygen tension, nutrients and metabolite levels, as well as growth factors and hormones [91]. Importantly, these physicochemical parameters can be measured and controlled in real time [92], providing a level of complexity that could potentially facilitate more suitable bioprocesses to mimic the pulmonary microenvironment. Currently available real-time monitoring systems include: sensors for measuring pH, pO_2, and pCO_2 [93], protein quantification sensors [94], as well as *in situ* microscopy capable of measuring cell size, aggregation, and differentiation state [95].

The lung presents a uniquely challenging bioreactor design problem due to the need for independent perfusion of the airway and vascular trees, concomitant with the ability to ventilate tissue-engineered lungs for mechanical testing and conditioning. In their seminal work, Price et al. developed a simple bioreactor based on these principles that facilitated ventilation of decellularized mouse lungs suspended in culture medium [96]. The trachea was cannulated and tied off with sutures, serving as a path for delivery of fetal lung cells, and also allowing for mechanical ventilation. Subsequent designs include separate perfusion loops for the airways and vasculature [85–87] (Fig. 74.6). A similar but more sophisticated design, which is now being offered commercially (Harvard Instruments), satisfies the need to mechanically condition both compartments independently; the airways through ventilation, and the vasculature with constant perfusion recreating physiological flow rates, shear stresses and pressures. A major challenge will be to scale-up these bioreactors to the size of human lungs and make them a broadly applicable technology in a clinical setting.

In a different approach, perfused rotating wall vessel (RWV) bioreactors have been used as a venue for efficient expansion and differentiation of mouse ES cells into pulmonary alveolar cells [97] (Fig. 74.7a). When murine and human ES cells were encapsulated in alginate and cultured for 11 days in high aspect ratio vessel (HARV) bioreactors with A549 cell-conditioned medium, which has been previously shown to promote efficient pulmonary differentiation of mES cells [50]. Approximately 50% of the resulting cells were SPC-positive type II alveolar cells following removal from the RWV environment and de-capsulation. The system described by Siti et al. [97] is amenable to stringent process design/control, automation, scale-up, and adaptation to GMP manufacture, thus opening the prospect for generating larger reproducible batches of ES derivatives that might be used in future clinical applications. Recently, Botta et al. [98] developed an optical monitoring system capable of visualizing individual fluorescent-labeled cells and cell aggregates in real time in HARV bioreactors (Fig. 74.7b). Thus, using ES cell lines with GFP reporter genes [52] that indicate expression lineage-specific markers, this system could be applied to monitor stem cell differentiation in real time, all this within the context of a system that is scalable to larger batch processing.

Biohybrid mechanical devices

The highly complex alveolar architecture is a product of biological evolution; however a functional respiratory analog does not necessarily need to reproduce this complexity of structure. Extracorporeal membrane oxygenators are used for short-term support of patients with respiratory failure; however they do not offer a long-term solution. Paracorporeal artificial

lungs (PALs) have been in development for decades [99], with design features such as rotating microporous fibers that simultaneously drive blood blow and facilitate gas exchange. Polk et al. created a biohybrid version of traditional PALs which incorporated endothelialized microporous fibers, reporting improved blood biocompatibility and enhanced gas transfer [100]. Fritsche et al. employed microfabrication techniques using polydimethylsiloxane to create dual compartment scaffolds mimicking the interfaced airway and vascular trees [101]. Hoganson et al. developed a prototype implantable ambulatory lung assist device based on tissue-engineering scaffold platform technology [102], demonstrating physiological blood flow in terms of pressures, flow rates and shear stresses, with gas exchange rates comparable to the traditional hollow fiber devices. A more compact device (NOVALUNG iLA) is in clinical use and has been tested successfully [103].

Current bioengineering efforts are aimed at miniaturizing these devices and enhancing their functionality by incorporating tissue-engineering approaches that enhance the gas exchange across the epithelial/endothelial permeability barrier. Beyond the realm of clinical applications, similar technologies are being used on the microscale to develop miniaturized analogs of a respiratory unit for pharmacological and toxicological studies. Huh et al. created a prototype of a 'lung on a chip', demonstrating the utility of a microfluidic respiratory analog for modeling lung clearance of inhaled toxic particles [104] (Fig. 74.8). This system can, for example, be used to test the effects of cyclic strain on transport of silica nanoparticles *in vitro* from the 'alveolar' space of the device – across an epithelial layer, an interfacial membrane, and an endothelial layer – into the 'capillary' space, demonstrating similar biological responses to macro-scale experiments using whole mouse lungs. Currently (2012) a multi-institutional effort have been launched to expand the 'lung-on-a chip' into a more complex microfluidics-based 'human-on-a-chip' that is slated to model complex interactions between up to 10 vital organs, such as lung-heart-liver-kidney and the brain.

CONCLUSIONS AND CHALLENGES

Over the last decade the field of pulmonary regenerative medicine has advanced out of the realm of science fiction. In parallel with significant advances in human stem biology, the use decellularized cadaveric lung tissues as scaffolds in combination with bioreactor systems that facilitate ventilation of the airways and perfusion of vascular components in animal models

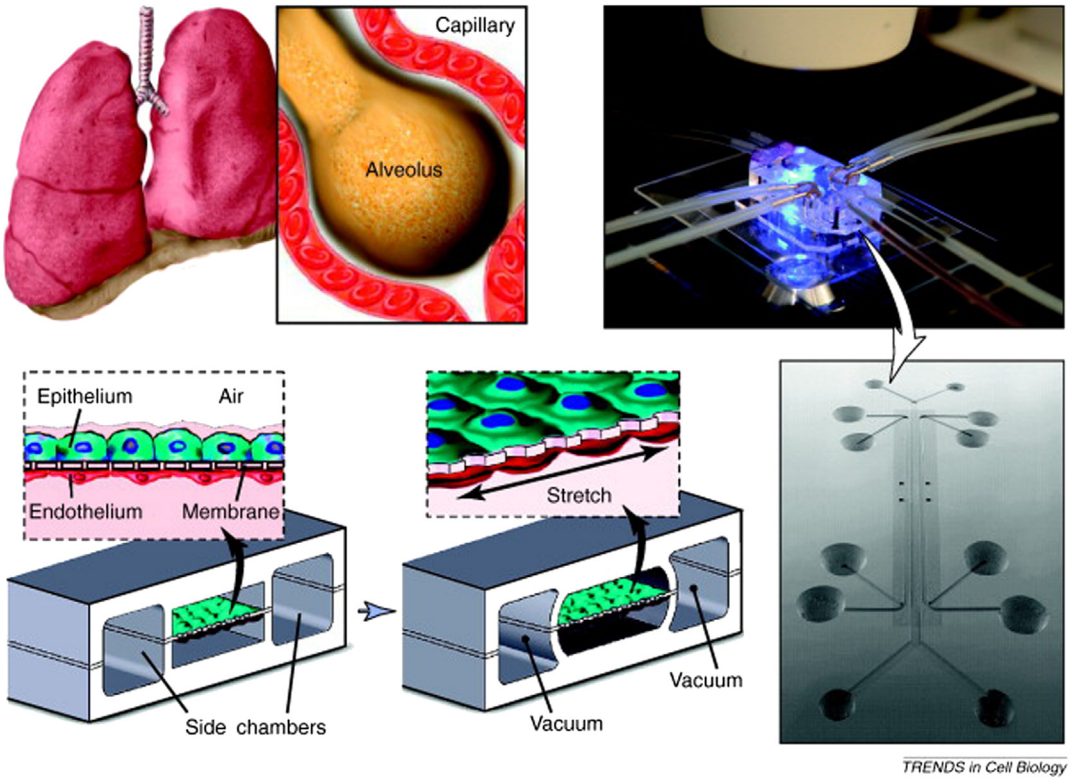

FIGURE 74.8

Microfluidic 'lung on a chip' device. Recreating the alveolar-capillary interface on a single sub-unit microscale allows for separately perfusable alveolar and capillary spaces on either side of the interface, as well as the ability to stretch the cell layers by applying vacuum to parallel side chambers. *(Reproduced with permission from Huh et al. [105].)*

has provided a functional paradigm for the field. Tissue-engineered lungs generated *in vitro* demonstrated short-term life-sustaining efficacy *in vivo* in small animal models. These landmark steps set the stage for a productive future in pulmonary regenerative medicine and tissue engineering, however there are several challenges remaining in each of these core areas.

In regards to stem cell differentiation, multiple protocols have been established for derivation of pulmonary epithelial cell lineages from human ES cells. The efficiency of these protocols can be improved, as well as expanded to more clearly define the conditions required to generate the milieu of epithelial cell types – as well as the as of yet largely ignored pulmonary-specific endothelial and mesenchymal lineages. Tissue-specific adult lung stem cells capable of forming cells from multiple germ layers have been described, but the *in vitro* differentiation repertoire and therapeutic efficacy of these cells *in vivo* needs to be more extensively validated. Once the optimal cell source has been established, the scalability of protocols for economically feasible generation of the numbers of cells required for therapies in humans (both infusion/injection and seeding of sufficiently large scaffolds), on clinically relevant time scales, is a challenge for the development of cell culture systems aimed at both expansion and multi-lineage differentiation. Along with progress in all of these areas, testing the efficacy of cell-based therapies for the treatment of lung disease in animal models and eventually clinical trials in humans will provide the ultimate measuring stick.

Decellularized lung tissue scaffolds are the current 'state of the art', providing nature's own matrix for rebuilding this highly complex organ. Once optimal preservation of ECM components and tissue-mechanical properties are attained, and methods for re-seeding of the epithelial, vascular, and interstitial compartments are established, the challenges of available

donor tissue and potential immunogenicity will need to be tackled. After resolving these core issues, further refinement of bioreactor systems for *in vitro* conditioning, and demonstration of the long-term efficacy of implanted tissue-engineered lungs in large animal models, will be required to move the field forward. Natural ECM hydrogels remain promising as *in vitro* models, and as a basis for the design of bioengineered matrices or injectable therapeutics – which may or may not contain cells – aimed at facilitating regeneration of pulmonary tissue *in situ*. Methods for engineering natural and synthetic materials into architectures that facilitate creation of the global interconnectivity of the airway and vascular systems, as well as the interstitial tissues, will be required to move beyond the use of decellularized lung tissue. The road to clinical translation will be long and arduous, however the numerous advances discussed herein lay the foundation for pulmonary regenerative medicine to grow and make an impact on the treatment of human lung disease in the coming decades.

INTRODUCTION

The epidermis consists of multiple cell types and layers. The outermost layer, called the stratum corneum is composed of dead 'corneocytes' that adhere tightly to each other to form a hydrophobic barrier that protects us from the environment and prevents water loss. The innermost layer at the base of the epidermis generates new cells that migrate to the surface while terminally differentiating and eventually forming the stratum corneum. In addition to keratinocytes, which produce intermediate filament proteins called keratins and constitute the majority of the cells, the epidermis also houses melanocytes, fabricators of pigment, and Langerhans cells, sentinels against invaders, whose primary job is that to present foreign antigen to roaming T cells.

The epidermal surface is interrupted by orifices arising from adnexal structures, such as the hair follicles and sweat glands. The epidermal basal layer constitutes the outer cell layer of these structures and it has been shown that such basal cells from hair follicles and sweat ducts can move out and repopulate the epidermis after wounding. The adnexal structures possess a greater degree of tissue complexity compared to the epidermis. For example, in contrast to the stratified squamous epithelium of the epidermis, the hair follicle consists of at least eight different concentric layers of epithelia, which undergo degeneration and regeneration with each hair follicle cycle.

Because the epidermis and hair follicles continuously generate new cells to replenish dead corneocytes and hairs, which are sloughed into the environment, their homeostasis and repair were thought to depend on epithelial stem cells. Work by many investigators has proved the existence of such cells, and indeed provided a leading example for discovery of stem cells in other regenerative tissues. Epithelial stem cells, found in interfollicular epidermis and the hair follicle, fit a broader definition of adult stem cells, as they are quiescent in nature, with the unique capacity for self-renewal as well as differentiation. In recent years, the concept of interfollicular epithelial stem cells to replenish skin has come into conflict with a new theory. Hair follicle stem cells, once thought to be a single population arising from the bulge region, are now competing with several newly described follicular populations. In this chapter, we will review old and new evidence to integrate historical dogma with newly emerging concepts in the evolving tale of skin regeneration.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00075-6

INTERFOLLICULAR STEM CELLS

Physiological renewal of epidermis is supported by proliferation of cells in the basal layer. Since epidermal renewal continues throughout a person's lifetime, it has been postulated that at least a portion of epidermal basal cells behave like stem cells (Fig. 75.1a for location of putative stem cells in interfollicular and follicular epidermis).

Bickenbach and Mackenzie, in pioneering work, devised 'label-retaining cell' methods for detecting quiescent cells in the epidermis [1]. Further, Morris and Potten showed that these cells retained carcinogen and possessed the quiescent characteristic of stem cells (reviewed in [2]). To test the concept that these cells give rise to all skin layers, a replication-deficient retroviral vector carrying the beta galactosidase gene was transduced with low frequency into the skin basal layer *in vivo* [2a]. Over a period of one month, discreet blue columns of cells could be visualized arising from the basal layer and progressing to the skin surface, thus supporting the existence of clonal epidermal proliferative units (EPUs), at least in the mouse epidermis. To further support this hypothesis, bromodeoxyuridine (BrDU) pulse labeling of the basal layer revealed the presence of a small number of quiescent (label-retaining) cells. Taken together, these data suggested that quiescent stem cells in the basal layer serve to replenish the upper layers during homeostasis and following wounding.

Two models for skin renewal (EPU vs. Committed Progenitor (CP) model)

Historically, the favored model has been that basal layer stem cells provide 'transit amplifying' progeny which undergo a limited number of divisions to generate the upper strata of the

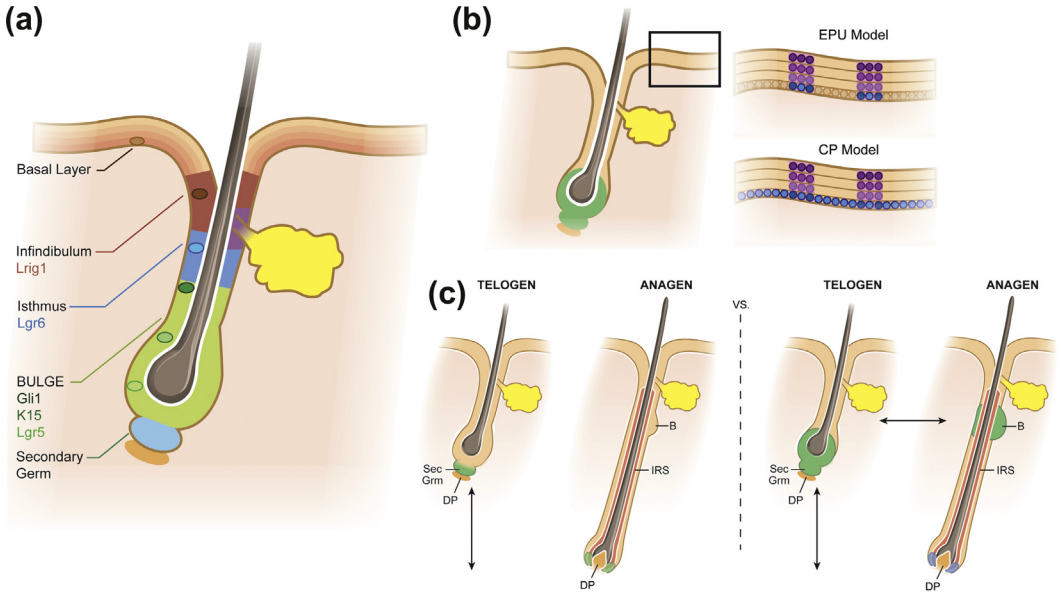

FIGURE 75.1

(a) Location of putative epidermal stem cells in the hair follicle and interfollicular epidermis. (b) Two models for interfollicular epidermal homeostasis. EPU model: In this model, rare stem cells (light blue) in the basal layer of the skin give rise to new progeny identical to itself (adjacent dark blue cells) or more differentiated progeny (pink and purple cells in upper layers). Each unit with a single central stem cell is termed an Epithelial Proliferative Unit (EPU). CP model: In this model, all cells in the basal layer have the same potential to make new identical progeny or more differentiated progeny. Therefore all cells in the basal layer are the same color. (c) Two models for hair follicle regeneration during cycling. Historic model (left panel): 'secondary germ cells,' (named for their similarity to primary germ cells present during development) were thought to contain the stem cells for the follicle. It was thought that these cells migrate from the base of the telogen follicle to the bulb during anagen onset, and then migrate back up during catagen. Current model (right panel): The secondary germ cells found at the base of the telogen follicle arise from the lowermost portion of the bulge at the end of catagen [15]. These cells migrate down into the secondary germ from their niche region where they alter their gene expression profile, proliferate and ultimately provide all the cells for the new lower half of the anagen follicle [49].

epidermis [2b,2c]. According to this model, a slower cycling central cell and more rapidly proliferating surrounding cells constitute approximately 10 basal cells and are roughly organized into a hexagonal unit, which lies beneath a single keratinocyte (reviewed in [3], Fig. 75.1b). Based on these proliferative and morphological characteristics, the term 'epidermal proliferative unit' (EPU) was coined to describe this architecture [2,3]. Without the benefit of direct lineage analysis, it was assumed that the central cell within the EPU generates the rapidly proliferating cells, termed transient or transit amplifying (TA) cells, which move laterally and then differentiate and move upward. Thus, within the epidermis, the main source of cells, i.e., the stem cells, responsible for continual epidermal renewal appear to reside in the center of the EPU.

The size of any EPU would be dependent on the total number of mitotic cycles that transiently amplifying progenitors derived from a single stem cell are able to undergo prior to terminal differentiation. The entire epidermal sheet would thus be maintained by a collection of co-existing stable EPUs with one stem cell at the center of each.

In recent years, the EPU-based model of epidermal regeneration has been challenged. Using a low frequency cre-inducible genetic model, individual proliferating basal cells were marked and followed for one year in a long-term fate mapping study [4,5]. In contradiction to the canonical EPU model, which predicts the size of each EPU to be finite, it was shown that some epidermal clones continuously expand in size over a period of one year, while others shrink and disappear, and yet others behave like typical EPUs. Mathematical modeling of these clone patterns suggested a stochastic model for epidermal renewal, in which each proliferating basal cell can give rise to two new proliferating basal cells, two differentiated progeny or both [4]. According to this CP model, epidermis is maintained by a uniform population of basal progenitors via stochastically distributed symmetric divisions to maintain the basal layer and asymmetric divisions to generate more differentiated progeny [6]. In support of this model, data showed that a single basal epidermal cell could indeed divide both symmetrically to produce two new basal cells and asymmetrically to generate more differentiated progeny [7].

New data challenge the CP model and reconfirm the existence of at least two populations within interfollicular epidermis; a slow cycling 'stem cell' and a rapid cycling 'progenitor' pool [8]. It has long been known that heterogeneity in marker expression defines multiple populations within epidermis. Indeed, this has provided a compelling argument against the possibility of a uniform basal population as proposed by the CP model. Mascre et al. [8] have capitalized upon this knowledge to follow the fate of two distinct basal populations, as defined by expression of involucrin. Their work conclusively demonstrates that involucrin-expressing cells divide rapidly (once per week) and quickly contribute to all layers of the epidermis. Thus, these cells are comparable to those described by Jones et al. as 'committed progenitors' [6]. However, some cells within the involucrin-negative population divide infrequently (4–6 times/year), have a distinct gene expression profile and can also contribute to skin homeostasis. In contrast to 'progenitors', these 'stem cells' are the primary contributors to re-epithelialization following wound repair (see below).

In reconciling the EPU and CP models, it thus appears that two populations maintain skin homeostasis, a rapid cycling progenitor and a slow cycling stem cell. Tissue damage invokes the aid of the stem cell population *only* for re-epithelialization. A similar phenomenon has been observed in hematopoiesis in which distinct rapid cycling and slow cycling cells contribute to homeostasis of immune cell lineages but only slow cycling cells are called upon for rapid repair as a stress response [9].

HAIR FOLLICLE STEM CELLS

Similar to the epidermis, the hair follicle generates a terminally differentiated keratinized end product, the hair shaft, which is eventually shed. Tracing back a hair shaft cell to its origin in

adult skin is not straightforward. In contrast to epidermis, the follicle undergoes cyclical regeneration, and has a more complicated proliferative profile and architecture with at least eight different epithelial lineages (Fig. 75.2). Hair is formed by rapidly proliferating matrix keratinocytes in the bulb located at the base of the growing (anagen) follicle. The duration of anagen varies drastically between hairs of differing lengths. For example, mouse hair and human eyebrow hair follicles stay in anagen for only 2–4 weeks while human scalp follicles can remain in anagen for many years. Nevertheless, matrix cells eventually stop proliferating, and hair growth ceases at catagen when the lower follicle regresses to reach a stage of rest (telogen). After telogen, the lower hair-producing portion of the follicle regenerates, marking the new anagen phase (Fig. 75.2).

Because the lower portion of the follicle cyclically regenerates, hair follicle stem cells were thought to govern this growth. Historically, hair follicle stem cells were assumed to reside exclusively in the 'secondary germ', which is located at the base of the telogen hair follicle (Fig. 75.1c). It was felt that the secondary germ moved downward to the hair bulb during

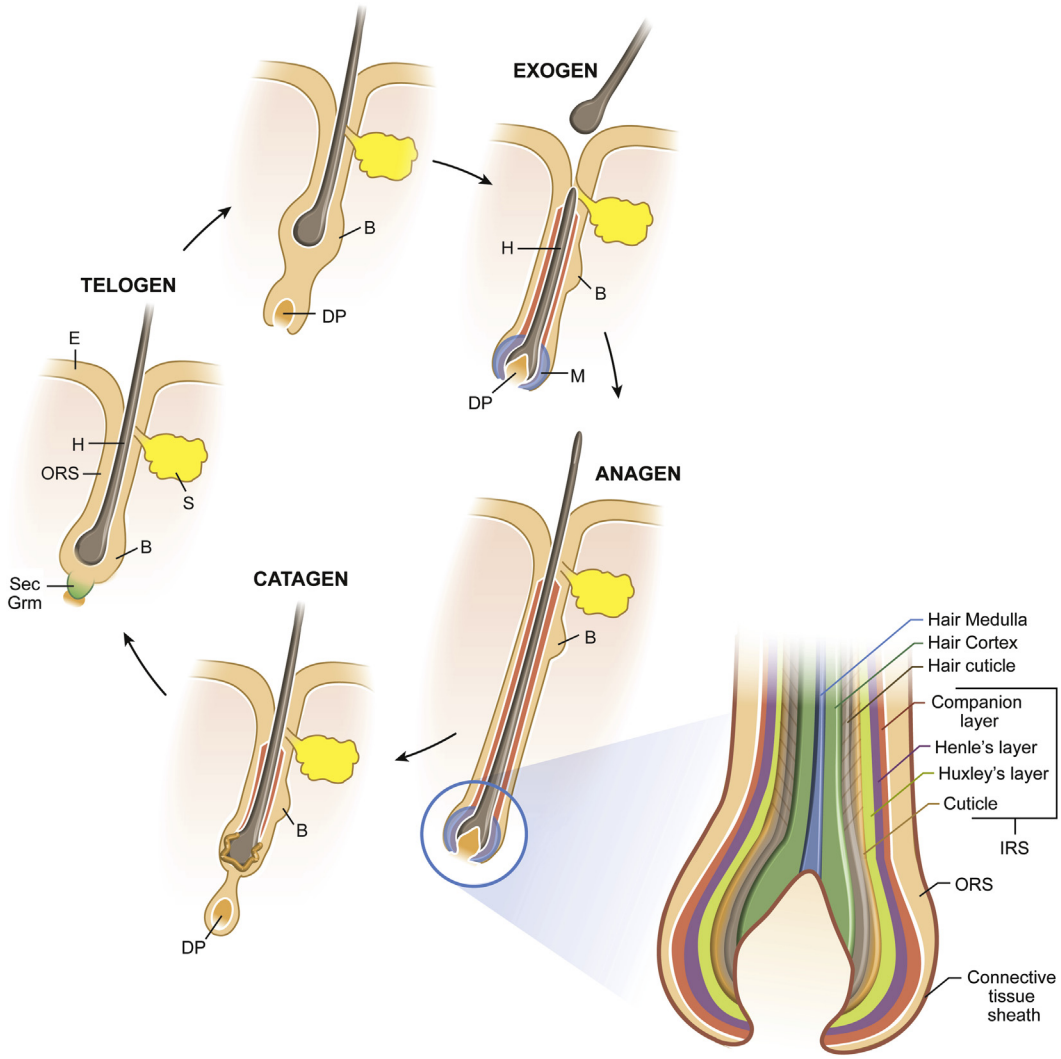

FIGURE 75.2

Hair cycle and anatomy. The hair follicle cycle consists of stages of rest (telogen), hair growth (anagen), follicle regression (catagen) and hair shedding (exogen). The entire lower epithelial structure is formed during anagen, and regresses during catagen. The transient portion of the follicle consists of matrix cells in the bulb that generate seven different cell lineages, three in the hair shaft and four in the inner root sheath (IRS).

anagen and provided new cells for production of the hair. At the end of anagen, the secondary germ was thought to move upward with the dermal papilla during catagen to come to rest at the base of the telogen follicle.

This scenario of stem cell movement during follicle cycling was brought into question when a population of long-lived presumptive stem cells was identified using label-retaining cell methods in an area of the follicle surrounding the telogen club hair, and not in the hair bulb [10]. That the presumptive stem cells localized to a previously defined area called the bulge was not appreciated until this description of the human embryonic follicle by Hermann Pinkus, [11] was rediscovered.

> 'This *bulge*, often the most conspicuous detail of the young germ, is as large as the bulb… The function of the bulge is obscure. While it serves as the point of insertion of the arrector muscle later in life, it develops much earlier than the muscle and the latter seems to originate quite independently in the skin near the sebaceous gland, and in many instances streaks by the bulge before approaching the lower follicle below it. Unna (1876) named the bulge area of the adult follicle the *hair bed* (Haarbett) believing that the club hair became implanted there and derived additional growth from it. Stöhr gave it the neutral name 'Wulst' (bulge or swelling). Some texts state that this is an area of marked proliferative activity, but no mitotic figures were observed in the bulge even if other parts of the follicle contained them. Whatever its function, the bulge marks the lower end of the 'permanent follicle' later in life. Everything below it is expendable during the hair change [cycle].'

This remarkable description, based purely on morphological observations, portended the characterization of the bulge cells in both human and mouse follicles as an area containing quiescent cells important for hair follicle cycling [10,12,13]. In the mouse pelage follicle, the area analogous to the human bulge becomes morphologically apparent in the postnatal period during the first telogen stage at the site of arrector pili muscle attachment. The shape of the bulge in the mouse follicle results from displacement of the outer root sheath (ORS) by the club hair. In the human follicle, the bulge appears as a true thickening of the ORS, but generally becomes much less apparent with age (Fig. 75.3).

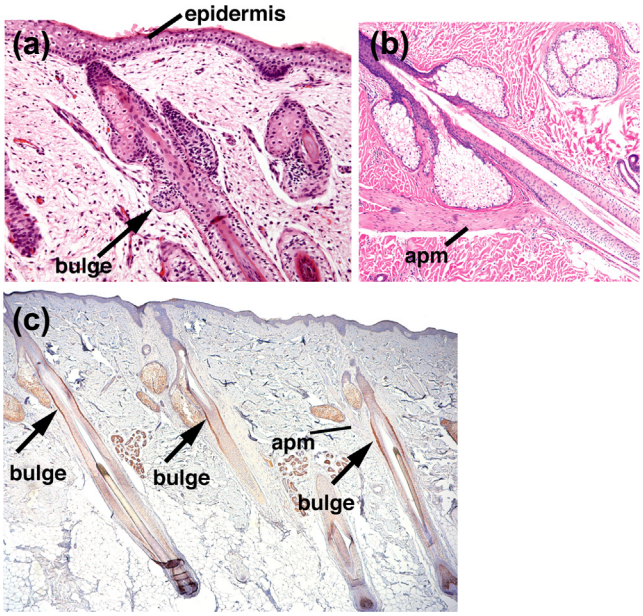

FIGURE 75.3
The bulge is a prominent structure in fetal skin (a), but generally is not morphologically distinct in the adult (b). Immunostaining for keratin 15 in scalp preferentially detects bulge cells (c). apm, arrector pili muscle.

THE BULGE AS STEM CELL SOURCE

Multiple criteria define the bulge as the true stem cell source for hair follicle regrowth. These include quiescence, gene signature and the ability of single cells to regenerate the entire hair follicle in skin reconstitution assays.

Quiescence: A salient feature of bulge cells in general is their quiescence. In both adult mouse and human skin grafted onto immunodeficient mice, the administration of nucleoside analogs, such as tritiated thymidine or BrdU, which are taken up by cells in S-phase, does not result in labeling of the bulge cells except at anagen onset [14,15]. Once labeled as either neonates or during anagen onset, when stem cells are proliferating, bulge cells can remain labeled for 14 months in the mouse and at least four months (the longest period examined) in the human [12]. This prolonged quiescence is remarkable given that the surrounding cells proliferate at a much higher rate. These results suggest that bulge cells persist for the lifetime of the organism.

Molecular signature: Understanding the genes that distinguish bulge cells from proliferating TA cells, as well as the genes that convert resting bulge cells to differentiating cells, provides insights into the precisely orchestrated events of hair follicle formation at anagen onset. With the advent of microarrays, large-scale comparisons of gene expression in bulge cells versus non-bulge basal keratinocytes could be performed [13,49]. These studies found that genes involved in activation of the WNT pathway were generally decreased in the bulge, in line with evidence that WNT activation induces proliferation and cell differentiation and is a hallmark of anagen onset [16]. Microarray analyses of the human hair follicle bulge showed many similarities to the mouse studies, including expression of Keratin15 (K15), thus validating the mouse as a useful model for studying human hair growth [17]. However, one important difference was that CD34, a mouse bulge cell marker, is not expressed by human hair follicle bulge cells.

Among other gene candidates important for the stem cell phenotype, functional studies demonstrate that Rac-1 plays an important role in the self-renewal of the epidermis and hair follicle [18,19]. Loss of Rac-1 causes a burst of proliferation in epidermal keratinocytes and then synchronized differentiation and loss of proliferative capability resulting in thinning of the cutaneous epithelium. Thus, this gene suppresses proliferation and differentiation, and seems important for the switch from stem cell to TA cell.

Multipotence: If hair follicle stem cells are located in the bulge, then these cells should give rise to all of the epithelial cells in the lower hair follicle. Early evidence supporting the concept that bulge cells generate the lower follicle includes proliferation studies showing that bulge cells preferentially proliferate at anagen onset [15,20]. More convincing evidence suggesting that the lower follicle originates from bulge cells came from *in vivo* labeling studies and transplantation studies. Taylor used a double-labeling technique to trace the progeny of bulge cells in intact pelage follicles [21]. Faint labeling in a speckled pattern was observed in some cells of the lower follicle suggesting that these cells had indeed originated in the bulge. Similarly, Tumbar et al. used persistence of green fluorescent protein (GFP) label as an indication that lower epithelial cells were progeny of the bulge cells [49]. Neither study provided convincing evidence that all hair matrix keratinocytes in the bulb originated from bulge cells, and both suffered from an inability to permanently mark bulge cells and their progeny.

Oshima et al. took a different approach and transplanted bulge regions from vibrissa follicles isolated by dissection from ROSA26 mice into non-ROSA follicles that were then grafted under the kidney capsule of an immunocompromised mouse. ROSA 26 mice express *lacZ* under the control of the ubiquitous ROSA promoter, thus the fate of the transplanted cells could be followed. After several weeks, they found labeled cells in the lower follicle indicating that bulge cells or their progeny had migrated down the vibrissa follicle. At later time points, some follicles expressed *lacZ* in all epithelial cell layers of the lower follicle suggesting that bulge

cells do generate all of the cells of the lower follicle. These elegant studies were limited by several caveats including unclear origin of the marked cell population, the manipulation required for grafting, and the use of vibrissa follicles, which are markedly different than other mouse and human follicles.

More definitive evidence for bulge cell multipotency *in vivo* was reported using the K15 promoter to target these cells with an inducible Cre (CrePR1) construct [13]. CrePR1 is a fusion protein consisting of Cre-recombinase and a truncated progesterone receptor that binds the progesterone antagonist, RU486 [22]. In *K15-CrePR1* transgenic mice, CrePR1 remains inactive in the cytoplasm of the K15-positive cells except during RU486 treatment, which permits CrePR1 to enter the nucleus and catalyze recombination. We crossed the *K15-CrePR1* mice with *Rosa26R (R26R)* reporter mice [22] that express *LacZ* under the control of a ubiquitous promoter after Cre-mediated removal of an inactivating sequence. Transient treatment of adult *K15-CrePR1;R26R* mice with RU486 results in permanent expression of *LacZ* in the bulge cells and in all progeny of the labeled bulge cells. Immediately following RU486 induction, only bulge cells showed lacZ expression but after anagen onset, the entire growing lower follicle became lacZ$^+$ proving the bulge as the origin of all epithelial cell types in the lower hair follicle.

Multiple bulge populations, some with surprising features

Recent data suggest that the bulge contains at least three distinct subpopulations as defined by marker expression. All have been implicated as true hair follicle stem cells (Fig. 75.1a).

Keratin 15 (K15) expression in human bulge cells was first described by Lyle et al. [12], (Fig. 75.3). K15 mRNA and protein are reliably expressed at high levels in the bulge, but lower levels of expression can be present in the basal layers of the lower follicle ORS and interfollicular epidermis. A K15 promoter used for generation of transgenic mice possesses a pattern of activity restricted to the bulge in the adult mouse [23]. This proved to be a powerful tool for studying bulge cells, establishing K15$^+$ bulge cells as stem cells responsible for hair follicle growth and cycling (see above).

Gli1 expression defines a new population of stem cells in the upper bulge adjacent to perifollicular sensory nerve endings [24]. Remarkably, these nerve endings provide a niche environment by secreting Sonic hedgehog protein (Shh), an essential component for the maintenance of the gli1$^+$ stem cell fate. Gli1$^+$ cells can reestablish the anagen follicle and they appear to contribute to long-term epidermal wound repair which does not appear to be dependent upon Shh signaling (see below [24]).

Lgr5, an R-spondin receptor implicated in facilitation of canonical WNT signaling [24a], marks a population of hair follicle progenitors in the lower bulge and secondary hair germ during telogen, and in the lower bulge during anagen [25]. Lgr5 expression is strongest in the secondary germ but overlaps with that of K15. Lineage tracing analyses showed that Lgr5--expressing cells contribute to all lineages during hair follicle cycling. Lgr5+ cells can also reconstitute entire new follicles when injected with dermal cells under the skin of nude mice [25]. The majority of the evidence indicates that Lgr5$^+$ cells derive from a quiescent stem cell pool and thus represent progenitors rather than true stem cells (see below).

OTHER NEWLY DISCOVERED HAIR FOLLICLE STEM CELLS

Isthmus: Recently, the junctional zone between infundibulum, sebaceous gland, and bulge, also known as the isthmus, was shown to harbor unexpectedly diverse populations of epithelial cells with stem cell qualities (reviewed in Gordon and Andersen [26]). The top of the isthmus contains stem cells co-expressing transmembrane proteins Lrig1 and Plet1 [27]. These authors place Lrig$^+$ cells in the junctional zone just above the bulge and next to the

sebaceous gland. Lineage tracing experiments have shown that Lrig1$^+$ stem cells tend to be bipotent, physiologically contributing predominantly to infundibulum and sebaceous gland lineages and only occasionally to the interfollicular epidermis. Interestingly, mice lacking Lrig1 develop spontaneous epidermal hyperplasia and exhibit elevated levels of the pro-proliferative cMyc protein. Further analyses indicate that Lrig1 is a downstream target of cMyc and may act to regulate cMyc expression in epidermis in a feedback loop [27].

Lgr6$^+$ stem cells localize immediately below the Lrig1+ compartment [28]. While multipotent during embryonic development, Lgr6$^+$ stem cells undergo progressive developmental fate restriction, and in the adult they participate mainly in epidermal and sebaceous gland maintenance [28]. Interestingly, despite very close physical proximity, Gli1$^+$ stem cells in the upper bulge only marginally overlap with Lgr6$^+$ cells.

Conclusions

All of the above described 'stem cell' populations have been shown capable of reconstituting hair follicles in cell reconstitution experiments. The lower three populations (Gli1$^+$, K15$^+$ and Lgr5$^+$) contribute normally to hair follicle regrowth during cycling. The upper populations (including Gli1$^+$) generate long-lasting epidermal progeny in the wound epidermis, making their contributions a contrasting feature to that observed by K15$^+$ bulge stem cells [29].

The obvious question arises: Why are so many different stem cell populations involved in hair follicle cycling? In other well-defined systems, such as hematopoiesis, a single unique stem cell population gives rise to multiple progenitors for establishment of many types of differentiated progeny. Recent work from Petersson et al. [30] and Francis and Niemann [31] suggests this may also be true in the hair follicle. Using lineage tracing to follow K15$^+$ bulge cells, they found that K15$^+$ progeny actually transit through all other putative stem cell compartments, ultimately giving rise to all differentiated hair follicle cell types including sebaceous gland. This implicates the bulge as the true stem cell location and all other regions as harboring more differentiated progenitors (see Horsley review [32]) leaving the K15 high expressing cell as the true stem cell.

STEM CELLS OF OTHER ECTODERMAL APPENDAGES

Sebaceous glands

Each hair follicle is closely associated with the sebaceous gland and, together, they constitute what is known as the pilosebaceous unit. The predominant cells in the sebaceous gland, sebocytes, secrete lipid-rich products into the infundibular opening of the adjacent hair follicle. Cells expressing the transcriptional repressor Blimp1 comprise unipotent sebocyte progenitors [33]. Horsley et al. [33] found that Blimp1$^+$ progenitors give rise to terminally differentiated Pparγ^+ sebocytes via transient amplifying progenitors, yet they do not contribute progeny toward interfollicular epidermis or hair follicles. Mechanistically, Blimp1 represses cMyc transcription, likely limiting the input of proliferative progenitors towards the gland from the multipotent stem cell populations of the isthmus [28,31] and the bulge [13,30]. The key rate-limiting role of Blimp1 in sebaceous gland homeostasis was revealed following epithelial *Blimp1* deletion, which led to sebaceous gland hypertrophy and oily hair coat phenotype [33].

Sweat glands

Acral skin (palms and soles in human and ventral paw in mouse) is hairless, but contains sweat glands, a secretory type of ectodermal appendage. Unlike hair follicles, sweat glands are relatively quiescent and, until recently, very little was known about their regenerative potential. A recent study by Lu C et al. [34] revealed that despite homeostatic quiescence, sweat glands feature several distinct progenitor types, whose regenerative potential can be stimulated by

injury. Sweat glands have relatively simple organization, consisting of a secretory glandular portion and duct leading to the skin surface. Basal myoepithelial cells and suprabasal luminal cells comprise the glandular portion of the sweat gland. Curiously, sweat-producing luminal cells are maintained by suprabasal unipotent progenitors, largely independent of the basal myoepithelial cells. Neither myoepithelial nor luminal glandular cells contribute progeny toward the duct which, in turn, is maintained by its own basal unipotent progenitors. Unlike glandular cells, ductal progenitor cells become activated upon wounding and help to restore ductal openings onto the skin surface. While ductal progenitors preferentially regenerate the duct itself, they can also regenerate interfollicular epidermis immediately surrounding the sweat gland opening [34]. In this respect, ductal progenitors of the sweat gland share characteristics with the hair follicle isthmus stem cells, which can also generate permanent epidermal progeny following injury [24,27,28]. Rittie recently showed that eccrine ductal cells also contribute to wound healing in human skin [35].

HAIR FOLLICLE STEM CELLS IN SKIN HOMEOSTASIS, WOUND HEALING AND HAIR REGENERATION

Homeostasis

In addition to the role of bulge cells in hair follicle cycling, their contribution to the maintenance of interfollicular epidermis and sebaceous glands has also been considered. Historically, one view was that bulge cells continuously provide progeny for repopulation of these skin regions [21,36]. Tracking of injected bulge keratinocytes *in vivo* showed only transient contribution to the interfollicular epidermi [37]. More direct fate mapping studies have shown that $K15^+$ cells do not contribute to homoeostatic maintenance of the epidermis. Using the K15CrePR;R26R transgenic mouse model, bulge cells labeled in three week old mice and followed for 6 months to determine their potential movements out of the hair follicle were never observed in interfollicular epidermis [13]. Furthermore, genetic ablation of $K15^+$ bulge cells does not result in interfollicular epidermal deficiency. Thus, $K15^+$ bulge stem cells can shift their fate towards the epidermal lineage, but only in response to wound-induced signaling (see below [29]). The other bulge populations ($Gli1^+$ and $Lgr5^+$) also appear to have no role in skin homeostasis [24,25].

Early evidence suggested that follicular cells from the infundibulum (upper follicle) might move into the epidermis. Recent work showed that both $Lgr6^+$ and $Lrig^+$ cells in the hair follicle can migrate into interfollicular epidermis and contribute to all epidermal strata during homeostasis [27,28]. However, their relative importance to skin maintenance compared with that of interfollicular basal cells remains unknown and is likely insignificant.

Wound healing

The contribution of the hair follicle to wound healing of the epidermis has been noted for decades by investigators working with mice and rabbits [38]. Clinicians are also well aware that keratinocytes emerge from the follicle to repopulate wounds. However, the role of bulge cells in wound healing has only recently been characterized.

Bulge $K15^+$ cell progeny migrate into the epidermis after different types of wounding. Using the K15CrePR;R26R transgenic mouse, $K15^+$ bulge cells were labeled in adult mice [29]. Excisional wounding with a 4 mm (punch) trephine, resulted in the migration of $K15^+$cell progeny into the healing epidermis. At least 25% of the newly formed epidermis originated from these $K15^+$ cells. They were also stimulated to move into the epidermis following incisional wounds and after tape stripping, indicating that $K15^+$ bulge cell activation plays a role in replenishing lost cells from the epidermis after wounding. Surprisingly, however, despite the presence of these cells in the basal layer of the re-epithelialized epidermis, the majority do not persist in the regenerated epidermis (Fig. 75.4).

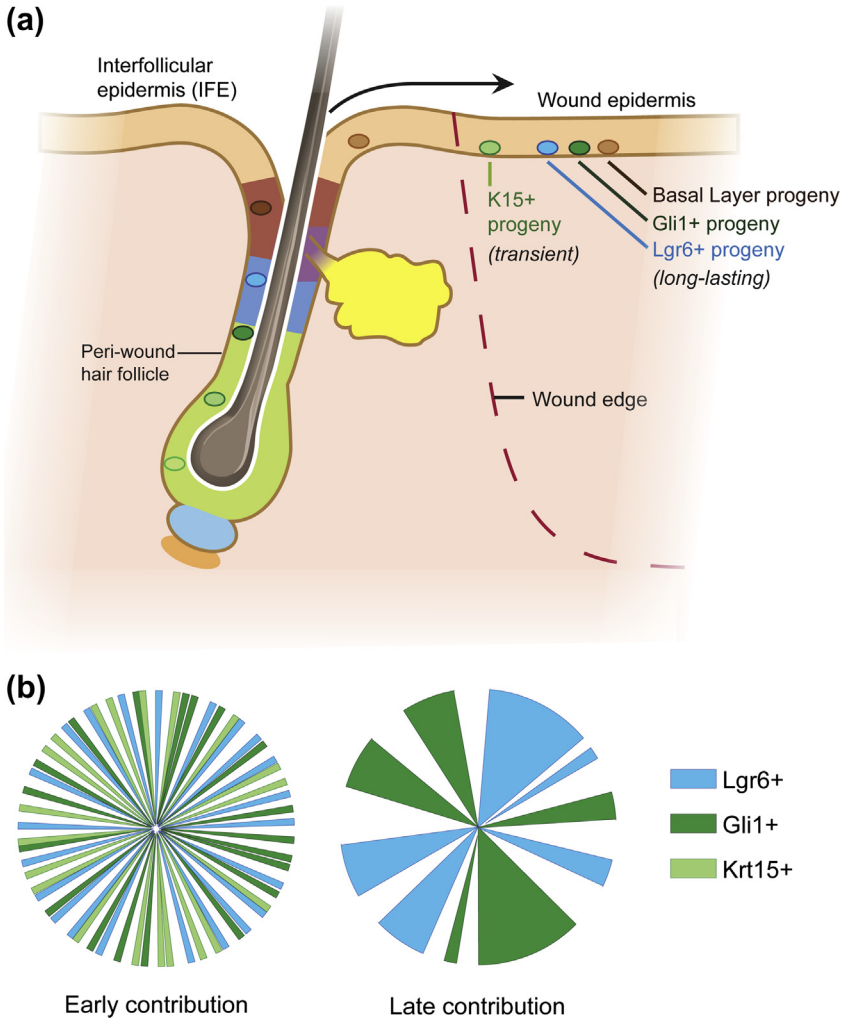

FIGURE 75.4
Contribution of epithelial stem cells to wound repair. (a) Various hair follicle and interfollicular stem cells migrate into the new epidermis for apparent contribution to re-epithelialization. (b) Although all three follicular populations are found in new epithelium during early time points, only Gli1$^+$ and Lgr6$^+$ cells exhibit permanent contribution.

Fate mapping studies of Gli1$^+$ and Lgr6$^+$ populations after wounding show that both can make long-term contributions to new epidermis [27,28]. Results suggest however that neither Gli1 nor Lgr6 progeny contributes significantly to re-epithelialization, as labeling studies indicate they make up 16% and 10% respectively of new epidermis. In contrast, interfollicular stem cells contribute substantially to skin regeneration [39]. These combined results challenge the notion that hair follicle stem cells make any significant long-term contribution to re-epithelialization following wounding.

Hair follicle neogenesis

Recently we discovered that completely new hair follicles can form in the center of large wounds via a process resembling embryonic development [40]. This hair follicle neogenesis is a relatively late event, contingent upon completion of wound re-epithelialization. Neogenic hair follicles start as bud-like invaginations of the basal layer (*aka* hair germs or placodes) and soon develop into elongated hair pegs that mature into hair shaft-producing anagen hair follicles within just a few days. Importantly, like normal hair follicles at the wound edge, neogenic hair follicles in the wound center have a prominent K15$^+$ bulge stem cell compartment and are able to undergo multiple hair follicle cycles.

Surprisingly, fate mapping approaches have shown that new hair follicles do not arise from existing bulge stem cells which have migrated into the wound during healing [40]. While currently it remains unknown what specific epidermal or isthmus stem cell types, or combination of stem cells, generate neogenic hair follicles, Snippert et al. [28] showed that

Lgr6$^+$ isthmus stem cells may be involved. Interestingly, new research suggests that neogenic hair follicles may arise from interfollicular epidermis created during wound re-epithelialization and that induction of these cells to a hair follicle fate depends upon both wound dermal and epidermal WNT activation [28a]. Thus, regenerated hair follicles may have multiple origins.

STEM CELLS AND ALOPECIA

Alopecias can be classified into scarring and non-scarring types [41]. The localization of hair follicle stem cells in the bulge may explain why some types of inflammatory alopecias cause permanent follicle loss (such as lichen planopilaris and discoid lupus erythematosis), while others (such as alopecia areata) are reversible [42]. In cicatricial alopecias, inflammation involves the superficial portion of the follicle, including the bulge area, suggesting that the stem cells necessary for follicle regeneration are damaged. The inflammatory injury of alopecia areata, however, especially in early lesions, involves the bulbar region of the hair follicle that is composed of bulge cell progeny. Because this area is immediately responsible for hair shaft production, its destruction leads to hair loss. However, the bulge area remains intact, and a new lower anagen follicle and subsequent hair shaft can be produced. Even patients with alopecia areata for many years can re-grow their hair either spontaneously or in response to immunomodulation.

The bulge may be targeted for inflammation in androgenetic alopecia (AGA, common baldness) as well. Jaworsky et al. [43] showed that in patients with early androgenetic alopecia, inflammatory cells localize to the bulge. Over time, this damage could contribute to the irreversible nature of androgenetic alopecia. To examine whether stem or progenitor cells were affected by this disease, we analyzed bald and non-bald regions from AGA patients for the presence of these cells. Facs analyses showed that true non-cycling K15$^+$ stem cells were retained in AGA bald regions. In contrast, larger, proliferative Cd200$^+$ progenitors residing in the lower bulge and secondary germ were markedly depleted. This suggested the lack of stem cell activation in balding scalp [44]. Further studies identified Prostaglandin D2 as an inhibitor of hair growth in bald scalp and a potential inhibitor of hair follicle stem cells [45].

TISSUE ENGINEERING WITH EPIDERMAL STEM CELLS

An exciting approach for the use of hair follicle stem cells in the treatment of alopecia includes tissue engineering [46]. In one scenario, isolated hair follicle stem cells could be used for generating new follicles in bald scalp. At least two groups have shown that freshly isolated bulge cells from adult mice, when combined with neonatal dermal cells, form hair follicles after injection into immunodeficient mice [13,39]. These studies provide proof of concept that isolated stem cells may be a part of tissue-engineering approaches for treating alopecia.

A goal for treating alopecia with cell-therapy approaches includes increasing the number of follicles, for example, by amplifying the number of stem cells *in vitro* prior to transplantation. Cultured keratinocytes from neonatal epidermis have been used for many years to generate hair follicles in reconstitution assays. Freshly isolated bulge cells from adult mice were shown to form hair follicles in skin reconstitution assays [13]. Importantly, cultured, individually cloned bulge cells from adult mice also formed hair follicles in skin reconstitution assays [39]. However, the ratio of new follicles formed from the number of donor follicles, and whether non-bulge keratinocytes also possessed these properties, were not analyzed.

The use of hair follicle stem cells for tissue-engineering approaches depends on isolation and characterization of human hair follicle stem cells. A major advance in this direction was reported by Ohyama et al. [17] In this work, cell surface markers, including Cd200 were identified on human bulge cells by using laser capture microdissection and microarray analysis for gene expression. A cocktail of antibodies against cell surface proteins was devised allowing for isolation of living hair follicle bulge stem cells, thus setting the stage for isolating human hair follicle stem cells for hair regeneration.

Human hair regeneration has recently been accomplished [47]. Single cell suspensions of hair bulge stem cells and dermal papilla cells have been layered into 'organ germs' *in vitro* and then transferred onto the backs of nude mice. Such germs create fully functional and pigmented human hair follicles. Analyses of comparable murine bioengineered follicles show that they cycle and maintain appropriate connections with muscle and nerve fibers. These experiments represent the first demonstration of bioengineered human hair and pave the way for exciting new advances in tissue regeneration.

Because hair follicle stem and dermal papilla cells exhibit multipotent behavior, ie the capacity to make several different cell types, they are now being exploited for use as pluripotent cells, ie those capable of generating *all* cell types (Jahoda). Elegant experiments have shown that addition of four defined transcription regulator genes (typically including oct4, nanog, cMyc) can transform fully differentiated fibroblasts into pluripotent cells, however numerous technical difficulties including the length of time required for appropriate dedifferentiation make this technology unfeasible for tissue engineering [48]. In an effort to shorten this time and to reduce the number of introduced genes, investigators have turned to multipotent stem cells for gene transfers, reasoning that these cells are closer in gene expression to pluripotent cells. Recent experiments with dermal papilla cells show that they can indeed undergo dedifferentiation but the timing and the number of transcription factors required remains the same as for fibroblasts [48a]. It remains unknown whether bulge stem cells may prove more useful for this approach.

CONCLUSION

Epithelial stem cells make essential contributions to skin and hair maintenance and repair. Balanced contributions by both interfollicular stem cells and more differentiated progenitors provide a constant supply of new cells during normal skin turnover. Interfollicular stem cells are also the primary source for new epidermis in wound healing. The hair follicle cycles throughout the life of the individual. New work suggests that the bulge is the likely source of true stem cells, giving rise to numerous progenitors throughout the follicle, each with distinct roles in hair and skin maintenance and repair. Engineered human hair can now be regenerated *in vivo* from bulge-derived stem cells, leading the way to future advances for therapeutic treatment of alopecia, chronic wound repair and with important implications for the regeneration of all tissues.

CHAPTER 76

Wound Repair: Basic Biology to Tissue Engineering

Richard A.F. Clark
Departments of Biomedical Engineering, Dermatology and Medicine,
Stony Brook University, Stony Brook, New York

INTRODUCTION

The skin is the largest organ in the body whose primary function is to serve as a protective barrier against the environment. Other important functions of the skin include fluid homeostasis, thermoregulation, immune surveillance, sensory detection, and self-healing. Loss of the integrity the skin due to injury or illness compromises its protective function and when the loss is extensive may result in significant disability or even death. It is estimated that in 1996, there were 35.2 million cases of significant skin loss (US figures) that required major therapeutic intervention [1]. Of these approximately 5 million wounds become chronic.

The most common single cause of significant skin loss is thermal injury, which accounts for an estimated 1 million emergency department visits per year [2]. Other causes of skin loss include trauma and chronic ulcerations secondary to diabetes mellitus, pressure and venous stasis. Every year in the US there are approximately 2 million cases of chronic diabetic ulcers, many of which eventually necessitate amputation. Pressure ulcers and leg ulcers, including venous ulcers, affect another 3 million people in the US with treatment costs as high as $8 billion annually [3]. In 2011, a survey estimated the US market for advanced wound care products, including biological and synthetic dressings, approximately $3 billion and expected to increase significantly as the population ages, becoming more susceptible to underlying causes of chronic wounds [4]. The quality of life tolls of chronic wounds are extremely high.

Over the past two decades, extraordinary advances in cellular and molecular biology have greatly expanded our comprehension of the basic biological processes involved in acute wound healing and the pathobiology of chronic wounds [5,6]. One recombinant growth factor, platelet-derived growth factor-BB (rPDGF-BB)(Regranex, Ortho-McNeil), and several skin substitutes (e.g., dermal substitutes: Integra Matrix Wound Dressings, Integra LifeSciences; AlloDerm, LifeCell; OASIS Wound Matrix, Healthpoint; Dermagraft and TransCyte, Advanced BioHealing; and Epidermal/dermal substitutes: Apligraf, Organogenesis; Orcel, Forticell Bioscience; Tissuetech, Fidia Advanced Biopolymers) have reached the market place for second-line therapy of recalcitrant ulcers [7]. These therapeutic interventions have added to the clinicians ability to induce skin healing but they have not had the impact that was predicted. Regardless of the advanced wound care product, the ideal goal would be to regenerate tissues where both the structural and functional properties of the wounded tissue are restored to the levels prior to injury.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00076-8

In contrast to adult wounds, embryonic wounds undergo complete regeneration, terminating in a scarless repair [8,9]. Thus, investigators are now using morphogenetic cues including hair development [10,11] to develop engineered constructs capable of tissue regeneration [12,13]. Cellular response to biological stimuli depends on the mechanical strength of the extracellular matrix (ECM) [14,15]. Therefore, the therapeutic successes of tissue-engineered constructs will depend not only on their molecular and cellular activity but also on their optimal mechanical properties [16]. This chapter will begin with an overview of the basic biology of wound repair, followed by a discussion of established practices and novel approaches to engineer tissue constructs for effective wound repair.

BASIC BIOLOGY OF WOUND REPAIR

Wound repair is not a simple linear process in which growth factors released by phylogistic events activate parenchymal cell proliferation and migration, but is rather an integration of dynamic interactive processes involving soluble mediators, formed blood elements, ECM, and parenchymal cells. Unencumbered, these wound repair processes follow a specific time sequence and can be temporally categorized into three major groups: inflammation, tissue formation, and tissue remodeling. The three phases of wound repair, however, are not mutually exclusive but rather overlapping in time. The reader is referred to the text 'The Molecular and Cellular Biology of Wound Repair' [17] for a more detailed discussion of the many processes involved in wound healing.

Inflammation

Severe tissue injury causes blood vessel disruption with concomitant extravasation of blood constituents. Blood coagulation and platelet aggregation generate a fibrin-rich clot that plugs severed vessels and fills any discontinuity in the wounded tissue. While the blood clot within vessel lumen reestablishes homeostasis, the clot within wound space acts as a growth factor reservoir and provides a provisional matrix for cell migration.

The primary cell types involved in the overall process of inflammation are platelets, neutrophils and monocytes. Upon injury, successful re-establishment of homeostasis depends on platelet adhesion to interstitial connective tissue, which leads to their aggregation, coagulation and activation. Activated platelets release several adhesive proteins to facilitate their aggregation, chemotactic factors for blood leukocytes, and multiple growth factors [5,6], to promote new tissue formation.

Of the two primary phagocytotic leukocytes viz. neutrophils and monocytes, neutrophils arrive first in large numbers due to their abundance in circulation. Infiltrating neutrophils cleanse the wounded area of foreign particles, including bacteria. If excessive microorganisms or indigestible particles have lodged in the wound site, neutrophils will probably cause further tissue damage as they attempt to clear these contaminants through the release of enzymes and toxic oxygen products. When particle clearance has been completed, generation of granulocyte chemoattractants ceases and the remaining neutrophils become effete.

Transition between inflammation and repair

Whether neutrophil infiltrates resolve or persist, monocyte accumulation continues, stimulated by selective monocyte chemoattractants [17]. Besides promoting phagocytosis and debridement, adherence to ECM also stimulates monocytes to undergo metamorphosis into inflammatory or reparative macrophages. Since cultured macrophages produce and secrete the peptide growth factors interleukin-1 (IL-1), platelet-derived growth factor-BB (PDGF-BB), transforming growth factor alpha (TGF-α), transforming growth factor beta (TGF-β) and fibroblast growth factor (FGF), presumably wound macrophages also synthesize

these protein products [18]. Although neutrophils and macrophages have a critical role in fighting infection and macrophages can contribute growth factors to the wound, it has become increasingly clear that too much of a good thing can be bad [19]. In fact, from knockout and knockdown experiments, it is evident that wounds in some situations heal faster with less inflammatory cells, especially if microorganism invasion is avoided by some other means [20].

Re-epithelialization

Re-epithelialization of a wound begins within hours after injury by the movement of epithelial cells from the surrounding epidermis over the denuded surface. Rapid re-establishment of the epidermal surface and its permeability barrier prevents excessive water loss and time of exposure to bacterial infections, which decreases the morbidity and mortality of patients who have lost a substantial amount of skin surface. If a wide expanse of the epidermis is lost, epidermal cells regenerate from stem cells in pilosebaceous follicles [21]. Migrating epithelial cells markedly alter their phenotype by retracting their intracellular filaments, dissolving most of their desmosomes, and forming peripheral actin filaments (which facilitate cell movement) [17]. These migrating cells also undergo dissolution of their hemidesmosomal links between the epidermis and the dermis. All these phenotypic alterations provide epithelial cells with the needed lateral mobility for migration over the wound site. Migrating epidermal cells possess a unique phenotype that is distinct from both, the terminally differentiated keratinocytes of normal (stratified) epidermis and the basal cells of stratified epidermis. It is now appreciated that the signals that control wound healing in the adult animal are similar to those that control epithelial fusion during embryogenesis [22].

If the basement membrane is destroyed by injury, epidermal cells migrate over a provisional matrix of fibrin(ogen), fibronectin, tenascin, and vitronectin as well as stromal type I collagen [23]. Wound keratinocytes express cell surface receptors for fibronectin, tenasin and vitronectin, which belong to the integrin superfamily (Table 76.1) [24]. In addition, α2β1 collagen receptors, which are normally disposed along the lateral sides of basal keratinocytes, redistribute to the basal membrane of wound keratinocytes as they come in contact with type 1 collagen fibers of the dermis. Whereas β1 integrins are clearly essential for normal

TABLE 76.1 Integrin superfamily

Integrins	Ligand	Integrins	Ligand
β1 Integrins		αv Integrins	
α1β1	Fibrillar collagen, laminin-1	αvβ1	Fibronectin (RGD), vitronectin
α2β1	Fibrillar collagen, laminin-1	αvβ3	Vitronectin (RGD), fibronectin, fibrinogen, von Willebrand factor, thrombospondin, denatured collagen
α3β1	Fibronectin (RGD), laminin-5, entactin, denatured collagens		
α4β1	Fibronectin (LEDV), VCAM-1	αvβ5	Fibronectin (RGD), vitronectin
α5β1	Fibronectin (RGD+PHSRN, the synergy site)	αvβ6	Fibronectin, tenascin
α6β1	Laminin		
α7β1	Laminin	β2 Integrins	
α8β1	Fibronectin, vitronectin	αMβ2	ICAM-1, iC3b, fibronogen, factor X
α9β1	Tenasin	αLβ2	ICAM-1, -2, and -3
		αXβ2	IC3b, fibrinogen
Other ECM Integrins

α6β4	Laminin		

re-epithelialization [25], it is not clear which subtype is essential. It is most likely that there is a redundancy in the requirement for α5β1 and α2β1 in re-epithelialization.

The migrating wound epidermis does not simply transit over a wound eschar but rather dissects through the wound, separating the fibrin/fibronectin-rich eschar and desiccated dermis containing denatured collagen from underlying viable tissue [26]. The path of dissection appears to be determined by the array of integrins expressed on the migrating epidermal cells. Keratinocytes do not express αvβ3, the integrin receptor for fibrinogen/fibrin and denatured collagen, *in vitro* or *in vivo* [26]. Thus, keratinocytes do not have the capacity to interact with these matrix proteins. Furthermore, fibrinogen or fibrin appears to inhibit epidermal cell interactions with fibronectin, hence migrating wound epidermis avoids the fibrin/fibronectin-rich clot but rather migrates along the type 1 collagen-rich wound edge via the α2β1 collegen receptor until it meets the fibronectin-rich granulation tissue and then proceeds to migrate over this newly forming tissue via the α5β1 receptor (Fig. 76.1).

ECM degradation is clearly required for the dissection of migrating wound epidermis between the collagenous dermis and the fibrin eschar and probably depends on epidermal cell production of collagenase, plasminogen activator, and stromelysin. Plasminogen activator activates collagenase (MMP-1) as well as plasminogen and therefore facilitates the degradation of interstitial collagen as well as provisional matrix proteins. Interestingly, keratinocytes in direct contact with collagen greatly increase the amount of MMP-1 they produce compared to that produced when they reside on laminin-rich basement membrane or purified laminin [27]. The migrating epidermis of superficial skin ulcers and burn wounds, in fact, express high levels of MMP-1 mRNA in areas where it presumably comes in direct contact with dermal collagen [28].

One to two days after injury, epithelial cells at the wound margin begin to proliferate. Although the exact mechanism is still not clear, both proliferation and migration of epithelial cells may be triggered by the absence of neighboring cells at the wound margin (the 'free edge effect'). The 'free edge effect' in the wound epidermis may be secondary to modulation of cadherins junctions as described for V-cadherins during angiogenesis [29]. In fact, studies indicate that epidermal desmosomes loose their hyperadhesiveness and cadherins switch from E-cadherins to P-cadherins at the wound edge [30]. Other possibilities, not exclusive of the former, are release of autocrine or paracrine growth factors that induce epidermal migration and proliferation and/or increased expression of growth factor receptors. Although some growth factors, such as insulin-like growth factor (IGF), may come from the circulation and thereby act as a hormone, other growth factors, such as heparin-binding epidermal growth factor (HB-EGF) and fibroblast growth factor 7 (FGF7, also called keratinocyte growth factor,

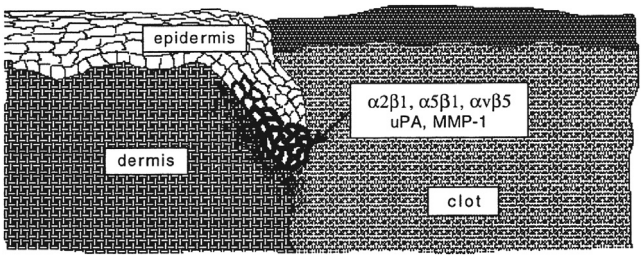

FIGURE 76.1
Integrins in early (three-dimensional) re-epithelialization. The migrating epidermis in contact with type I dermal collagen expresses a gene set including the collagen receptor α2β1, urokinase plasminogen activator (uPA), and interstitial collagenase (MMP-1). With this armamentarium, the epidermis can dissect a path between viable dermis and nonviable clot and denature stroma, ultimately leading to slough of the eschar.

KGF), are secreted from macrophages and dermal parenchymal cells, respectively, and act on epidermal cells through a paracrine pathway [31]. In contrast, transforming growth factor (TGF)-α and -β originate from keratinocytes themselves and act directly on the producer cell or adjacent epidermal cells in an autocrine or juxtacrine fashion. Many of these growth factors have been shown to stimulate re-epithelialization in animal models [5]. Furthermore, lack of growth factors or their receptors in knockout mice support the hypothesis that growth factor activation of keratinocytes is required for optimal epidermal migration and/or proliferation during normal wound healing [32]. In fact, it has been demonstrated that C-Jun N-terminal kinase (JNK) is a key signal transduction factor responsible for 're-setting' the epidermal program from differentiation to proliferation, and possibly migration [33].

As re-epithelialization progresses, basement membrane proteins reappear in a very ordered sequence from the margin of the wound inward in a zipper-like fashion [5]. Epidermal cells revert to their normal phenotype, once again firmly attaching to reestablished basement membrane through hemidesmosomal proteins, α6β4 integrin and 180 kDa bullous pemphigoid antigen [34], and to the underlying neodermis through type VII collagen fibrils [35].

Granulation tissue

New stroma, often called granulation tissue, begins to form approximately four days after injury. The name derives from the granular appearance of newly forming tissue when it is incized and visually examined. Numerous new capillaries endow the neostroma with its granular appearance. Macrophages, fibroblasts and blood vessels move into the wound space as a unit that correlates well with the biologic interdependence of these cells during tissue repair. Macrophages and ingrowing parenchymal cells provide a continuing source of cytokines necessary to stimulate fibroplasia and angiogenesis, fibroblasts construct new ECM necessary to support cell ingrowth, and blood vessels carry oxygen and nutrients necessary to sustain cell metabolism. Recently the importance of oxygenation has been reemphasized [36]. The quantity and quality of granulation tissue depends on biologic modifiers present, the activity level of target cells, and the ECM environment. As mentioned in the section on Inflammation the arrival of peripheral blood monocytes and their activation to macrophages, establish conditions for continual synthesis and release of growth factors. In addition and perhaps more importantly, injured and activated parenchymal cells can synthesize and secrete growth factors. For example, migrating wound epidermal cells produce vascular endothelial cell growth factor (VEGF), TGF-β and PDGF-BB, to which endothelial cells and fibroblasts respond, respectively. The provisional ECM also promotes granulation tissue formation by positive feedback regulation of integrin ECM receptor expression [37]. Once fibroblasts and endothelial express the appropriate integrin receptors, they invade the fibrin/fibronectin-rich wound space (Fig. 76.2). Although it has been recognized for many years that ECM modulates cell differentiation by signal transduction from ligation of ECM receptors, more recently it has become evident that the force and geometry of the ECM influences cell behavior and differentiation [15,38,39].

FIBROPLASIA

Components of granulation tissue derived from fibroblasts including the cells themselves and the ECM are collectively known as fibroplasia. Growth factors, especially PDGF and TGF-β, in concert with the provisional matrix molecules [37], presumably stimulate fibroblasts of the periwound tissue to proliferate, express appropriate integrin receptors and migrate into the wound space. Many of these growth factors are released from macrophages or other tissue cells [5,6]; however, fibroblasts themselves can produce growth factors to which they respond in an autocrine fashion [40]. Multiple complex interactive biologic phenomena occur within fibroblasts as they respond to wound cytokines including the induction of additional cytokines and modulation of cytokine receptor number or affinity. *In vivo* studies support the

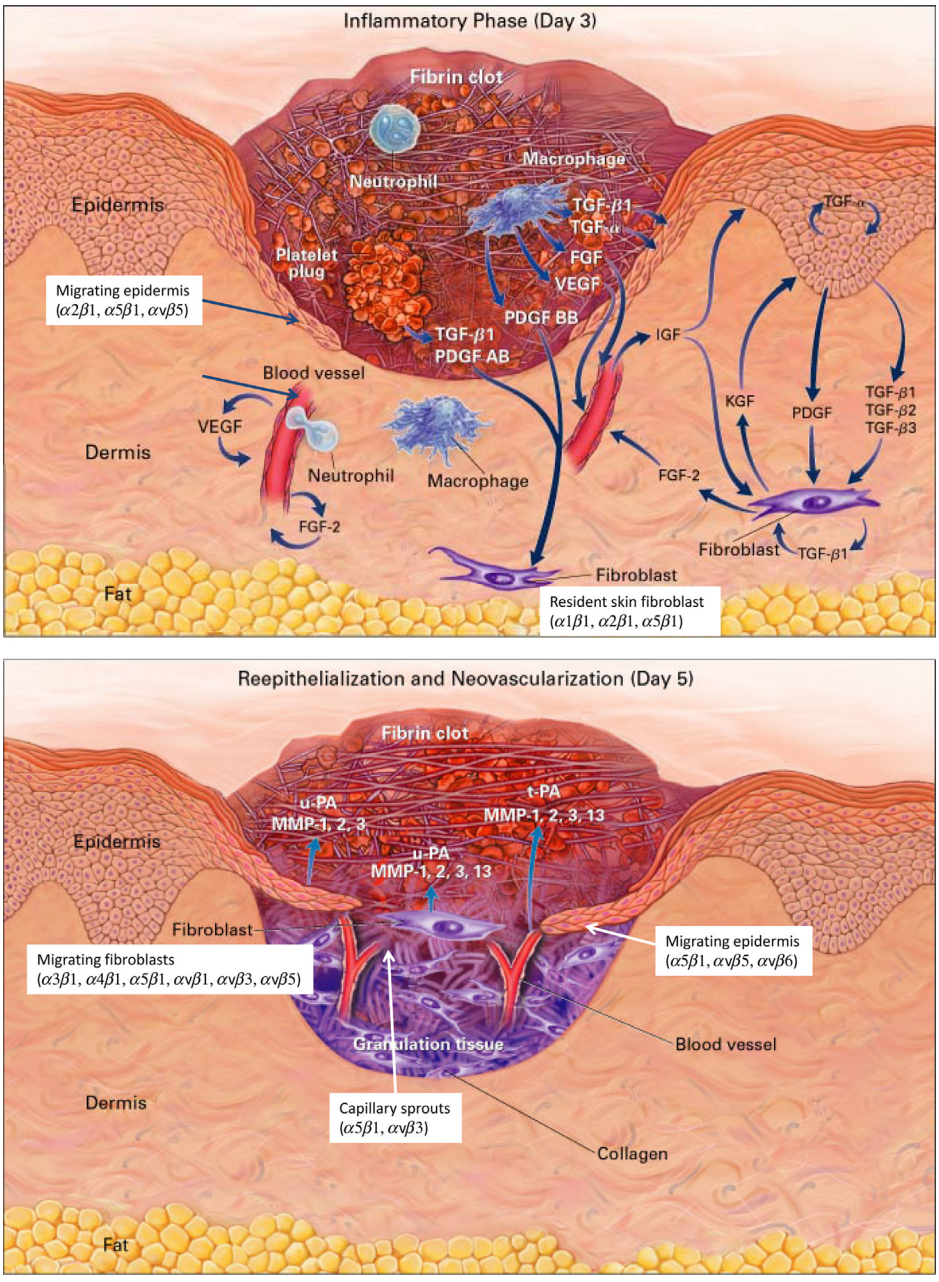

FIGURE 76.2
After injury, the platelets, inflammatory cells and the tissue cells (viz. fibroblasts, endothelial and epidermal cells) secrete abundant quantities of multiple growth factors thought to be necessary for cell movement into the wound. However, it is the provisional matrix integrin expression that acts as the rate-limiting step in granulation tissue induction. Once the appropriate integrins are expressed on periwound endothelial cells and fibroblasts on day 3, the cells invade the wound space shortly thereafter (on days 4 and 5). Fibroblasts and endothelial cells express the fibrinogen/fibrin receptor avb3 and therefore are able to invade the fibrin clot; the epidermis, however, does not express avb3 and therefore dissects under the clot. Proteinases play an important role during granulation tissue formation by clearing the path for migrating tissue cells. Ultimately, the clot that has not been transformed into granulation tissue by invading fibroblasts and endothelial cells is dissected free of the wound and sloughed as eschar. *(Modified from Singer, A.J. and Clark, R.A.F. (1999) Mechanisms of disease: cutaneous wound healing. New Eng. J. Med 341:738–46, with permission.)*

hypothesis that growth factors are active in wound repair fibroplasia. Several studies have demonstrated that PDGF, connective tissue factor (CTGF), TGF-α, TGF-β, HB-EGF and FGF family members are present at sites of tissue repair [41–44]. Furthermore, purified and recombinant-derived growth factors have been shown to stimulate wound granulation tissue in normal and compromised animals [5] and a single growth factor may work both directly, and indirectly by inducing the production of other growth factors *in situ* [45].

Structural molecules of the early ECM, coined provisional matrix [46], contribute to tissue formation by providing a scaffold or conduit for cell migration (fibronectin) [47], low impedance for cell mobility (hyaluronic acid) [48], a reservoir for cytokines [49] and direct signals to the cells through integrin receptors [24]. Fibronectin appearance in the periwound environment as well as the expression of fibronectin receptors appear to be critical rate-limiting steps in granulation tissue formation [50]. In addition, a dynamic reciprocity between fibroblasts and their surrounding ECM creates further complexity [51]. That is, fibroblasts affect the ECM through new synthesis, deposition, and remodeling of the ECM [52] while the ECM affects fibroblasts by regulating their function including their ability to synthesize, deposit, remodel and generally interact with the ECM [37,53]. Thus, the reciprocal interactions between ECM and fibroblasts dynamically evolve during granulation tissue development.

As fibroblasts migrate into the wound space, they initially penetrate the blood clot composed of fibrin and lesser amounts of fibronectin and vitronectin. Fibroblasts presumably require fibronectin *in vivo* for movement from the periwound collagenous matrix into the fibrin/fibronectin-laden wound space as they do *in vitro* for migration from a 3-dimensional collagen gel into a fibrin gel [47]. Fibroblasts bind to fibronectin through receptors of the integrin superfamily (Table 76.1). The Arg-Gly-Asp-Ser (RGDS) tetrapeptide within the cell-binding domain of these proteins is critical for binding to the integrin receptors α3β1, α5β1 αvβ1, αvβ3 and αvβ5. In addition, the CSIII domain of fibronectin provides a second binding site for human dermal fibroblasts via the α4β1 integrin receptor [54]. *In vivo* studies have shown that the RGD-dependent, fibronectin receptors α5β1 and αvβ3 are upregulated on periwound fibroblasts the day prior to granulation tissue formation and on early granulation tissue fibroblasts as they infiltrate the provisional matrix-laden wound [37]. In contrast, the non-RGD-binding α1β1 and α2β1 collagen receptors on these fibroblasts were either suppressed or did not appear to change appreciably [37,55].

Both PDGF and TGF-β can stimulate fibroblasts to migrate and can upregulate integrin receptors. Therefore, these growth factors appear to be responsible for inducing a migrating fibroblast phenotype. However, PDGF increases α5β1 and α3β1 while decreasing α1β1 in cultured human dermal fibroblasts surrounded by fibronectin [55]. Furthermore, fibronectin or fibrin-rich environments promote the ability of PDGF to increase α5β1 and α3β1, but not α2β1 by increasing mRNA stability and steady-state levels [37]. These data strongly suggest that the type of integrin increased by PDGF stimulation appears to depend on the ECM context and suggests a positive feedback between ECM and ECM receptors.

Movement into a crosslinked fibrin blood clot or any tightly woven ECM may also necessitate active proteolysis to cleave a path for migration. A variety of fibroblast-derived enzymes in conjunction with serum-derived plasmin are potential candidates for this task, including plasminogen activator, interstitial collagenase-1 and -3 (MMP-1 and MMP-13, respectively), the 72 kDa gelatinase A (MMP-2), and stromelysin (MMP-3). In fact, high levels of immunoreactive MMP-1 has been localized to fibroblasts at the interface of granulation tissue with eschar in burn wounds [28] and many stromal cells stain for MMP-1 and MMP-13 in chronic ulcers [56]. While TGF-β downregulates proteinase activity, PDGF stimulates the production and secretion of these proteinases [57]. From elegant knockout mouse studies it is clear that the plasminogen activating system is critical for clearing the wound clot [58]. While MMP-9 deficient mice demonstrate altered fracture repair [59], only single knockout MMP-8 (also called collagenase-2) adversely effected cutaneous wound repair [60]. However, double

knockout of MMP-13 (also called collagenase-3) and the plasminogen activating system in mice created more delay of healing compared to knockout of only the plasminogen activating system [61]. It was also shown that Galardin, a broad-spectrum MMP inhibitor, slowed cutaneous healing. Thus, although there is great overlap in MMP function in tissue repair, their activity is clearly necessary for proper healing of cutaneous wounds.

When fibroblasts have completed their migration into the wound site, they switch their major function to protein synthesis [52]. Thus, the migratory phenotype is completely supplanted by a profibrotic phenotype characterized by decreased α3β1 and α5β1 provisional matrix receptor expression, increased α2β1 collagen receptor expression, and abundant rough endoplasmic recticulum and Golgi apparatus filled with new collagen protein [37,52]. The fibronectin-rich provisional matrix is gradually supplanted with a collagenous matrix [52,53]. Under these conditions, PDGF, which is still abundant in these wounds [62], stimulates extremely high levels of α2β1 collagen receptor, but not α3β1 or α5β1 provisional matrix receptors, supporting the contention that the ECM provides a positive feedback for integrin expression [37]. TGF-β observed in wound fibroblasts at this time [53] can induce fibroblasts to produce great quantities of collagen [63]. IL-4 also can induce a modest increase in types I and III collagen production [64]. Since IL-4 producing mast cells are present in healing wounds, as well as fibrotic tissue, these cells may contribute to collagen matrix accumulation at these sites.

Once an abundant collagen matrix is deposited in the wound, fibroblasts cease collagen production despite the continuing presence of TGF-β [53]. The stimuli responsible for fibroblast proliferation and matrix synthesis during wound repair were originally extrapolated from many *in vitro* investigations and then confirmed by *in vivo* manipulation of wounds [17]. Less attention was directed toward elucidating the signals responsible for downregulating fibroblast proliferation and matrix synthesis until more recently. Both *in vitro* and *in vivo* studies suggest that gamma-interferon may be one such factor [65]. In addition, collagen matrix can suppress both fibroblast proliferation and fibroblast collagen synthesis [53,66]. In contrast, a fibrin or fibronectin matrix has little or no suppressive effect on the mitogenic or synthetic potential of fibroblasts [53,67].

Although the attenuated fibroblast activity in collagen gels is not associated with cell death, many fibroblasts in day 10 healing wounds develop pyknotic nuclei [68], a cytological marker for apoptosis or programmed cell death, as well as other signs of apoptosis. These results in cutaneous wounds and other results in lungs and kidney suggest that apoptosis is the mechanism responsible for the transition from a fibroblast-rich granulation tissue to a relatively acellular scar [69]. The signal(s) for wound fibroblast apoptosis have not been elucidated. Thus fibroplasia in wound repair is tightly regulated, whereas, in fibrotic diseases such as keloid formation, morphea, and scleroderma these processes become dysregulated. Recent evidence suggests that the fibroblast apoptotic signals in keloids are disrupted either directly or indirectly [70].

NEOVASCULARIZATION

Fibroplasia would halt if neovascularization failed to accompany the newly forming complex of fibroblasts and extracellular matrix. The process of new blood vessel formation is called angiogenesis [71]. Many soluble factors that stimulate angiogenesis in wound repair have been elucidated [72]. Angiogenic activity can be recovered from activated macrophages as well as epidermal cells, fibroblast, endothelial cells and numerous tumor cells [73]. Most biologically important angiogenic molecules have probably been identified and include VEGF, FGF-1 and FGF-2, TGF-α, TGF-β, TNF-α, platelet factor-4 (PF-4), angiogenin, angiotropin, angiopoietin, interleukin-8, PDGF, and low molecular weight substances including bioactive peptides, low oxygen tension, biogenic amines, lactic acid, and nitric oxide (NO) [5,6]. Some of these factors, however, are intermediaries in a single angiogenesis pathway, for example TNF-α induces PF-4 that stimulated angiogenesis through NO [74]. Even more important, low oxygen tension stabilizes hypoxia inducible factor-1α (HIF-1α) that induces increased expression of

VEGF [75]. To further complicate matters, not all growth factors within a family stimulate angiogenesis equally. For example, of four VEGF isoforms (VEGF-A, -B, -C, and -D) and three receptors (VEGFR1/Flt-1, VEGFR2/KDR/Flk-1, and VEGFR3), VEGF-A does not interact with VEGFR1 and VEGFR2 equally and the signal transduction stimulated in not the same [76]. Furthermore, VEGF-C and -D stimulate lymphangiogenesis, rather than angiogenesis, through VEGFR3. Another complexity is that different growth factors effect blood vessel development at different stages. For example, VEGF-A stimulates nascent sprout angiogenesis, while angiopoietin induces blood vessel maturation [77].

Angiogenesis cannot be directly related to proliferation of cultured endothelial cells since endothelial cell migration is also required. In fact, Folkman [78] postulated that endothelial cell migration can induce proliferation. If true, endothelial cell chemotactic factors may be critical for angiogenesis. Some factors, however, have both proliferative (mitogenic) and chemotactic (motogenic) activities, e.g., PDGF [79] and EGF [80] are both motogenic and mitogenic for dermal fibroblasts while VEGF is both motogenic and mitogenic for endothelial cells [81].

Besides growth factors and chemotactic factors, an appropriate ECM is also necessary for angiogenesis. Three-dimensional ECM proteins gels provide a more natural environment for cultured endothelial cells than monolayer protein coats [72] as is true for many other cultured cells [82]. Not surprisingly, different ECM proteins induce differential cell responses. For example, rat epididymal microvascular cells cultured in type I collagen gels with TGF-β produce capillary-like structures within one week [71]. Omission of TGF-β markedly reduces the effect. In contrast, laminin-containing gels in the absence of growth factors induce human umbilical vein and dermal microvascular cells to produce capillary-like structures within 24 hours of plating [83]. Matrix bound thrombospondin also promotes angiogenesis [84] possibly through its ability to activate TGF-β [85]. Although type 1 collagen does not induce angiogenesis without other contributing factors, it can protect newly formed blood vessels from apoptotic effects of angiostatic agents [86]. Together, these studies support the hypothesis that the ECM plays an important role in angiogenesis. Consonant with this hypothesis, angiogenesis in the chick chorioallantoic membrane is dependent on the expression of αvβ3, an integrin that recognizes fibrin and fibronectin, as well as vitronectin [87]. Furthermore, in porcine cutaneous wounds αvβ3 is only expressed on capillary sprouts as they invade the fibrin clot [18]. *In vitro* studies in fact demonstrate that v can promote endothelial cell migration on provisional matrix proteins [88].

Given the information outlined above, a series of events leading to angiogenesis can be hypothesized. Substantial injury causes tissue-cell destruction and hypoxia. Potent angiogenesis factors such as FGF-1 and FGF-2 are released secondary to cell disruption [89] while VEGF is induced by hypoxia. Proteolytic enzymes released into the connective tissue degrade extracellular matrix proteins. Specific fragments from collagen, fibronectin and elastin, as well as many phylogistic agents, recruit peripheral blood monocytes to the injured site where these cells become activated macrophages that release more angiogenesis factors. Certain angiogenic factors, such as FGF-2, stimulate endothelial cells to release plasminogen activator and procollagenase. Plasminogen activator converts plasminogen to plasmin and procollagenase to active collagenase and in concert these two proteases digest basement membrane constituents.

The fragmentation of the basement membrane allows endothelial cells to migrate into the injured site in response to FGF, fibronectin fragments, heparin released from disrupted mast cells, and other endothelial cell chemoattractants. To migrate into the fibrin/fibronectin-rich wound, endothelial cells express αvβ3 [87], as well as αvβ5 integrin [90]. Newly forming blood vessels first deposit a provisional matrix containing fibronectin and proteoglycans but ultimately form basement membrane. TGF-β may induce endothelial cells to produce the fibronectin and proteoglycan provisional matrix as well as assume the correct phenotype for

capillary tube formation. FGF, and other mitogens such as VEGF, stimulate endothelial cell proliferation, resulting in a continual supply of endothelial cells for capillary extension. Capillary sprouts eventually branch at their tips and join to form capillary loops through which blood flow begins. New sprouts then extend from these loops to form a capillary plexus. Angiopoientin [91] and the recruitment of perienodthelial cells (pericytes) [92] are important for maturation and stabilization of the newly formed capillaries and pericytes are possibly important in providing a stem cell niche or being stem cells themselves [93].

Within a day or two after removal of angiogenic stimuli, capillaries undergo regression as characterized by: mitochondria swelling in the endothelial cells at the distal tips of the capillaries; platelet adherence to degenerating endothelial cells; vascular stasis; endothelial cell necrosis; and ingestion of the effete capillaries by macrophages. Although αvβ3 can regulate apoptosis of endothelial cells in culture and in tumors [87], αvβ3 is not present on wound endothelial cells as they undergo programmed cell death indicating that their absence may be critical or that other integrins are involved. It is fairly clear that thrombospondin [94] or other ECM molecules are good candidate ligands for controlling endothelial cell apoptosis [95].

Wound contraction and extracellular matrix organization

During the second and third week of healing, fibroblasts begin to assume a myofibroblast phenotype characterized by large bundles of actin-containing microfilaments disposed along the cytoplasmic face of the plasma membrane and the establishment of cell-cell and cell-matrix linkages [52,96]. In some [68], but not all [52], wound situations myofibroblasts express smooth muscle actin. Importantly, TGF-β can induce cultured human fibroblasts to express smooth muscle actin and may also be responsible for its expression *in vivo* [97].

The appearance of the myofibroblasts corresponds to the commencement of connective tissue compaction and the contraction of the wound. Fibroblasts link to the extracellular fibronectin matrix through α5β1 [52]; to collagen matrix through α1β1 and α2β1 collagen receptors [98]; and to each other through direct adherens junctions [52]. Fibroblast α2β1 receptors are markedly upregulated in seven day wounds [37], a time when new collagenous matrix is accumulating and fibroblasts are beginning to align with collagenous fibrils through cell-matrix connections [52]. New collagen bundles in turn have the capacity to join end-to-end with collagen bundles at the wound edge and to ultimately form covalent crosslinks among themselves and with the collagen bundles of the adjacent dermis [99]. These cell-cell, cell-matrix, and matrix-matrix links provide a network across the wound whereby the traction of myofibroblasts on their pericellular matrix can be transmitted across the wound [100].

Cultured fibroblasts dispersed within a hydrated collagen gel provide a reasonable functional *in vitro* model of wound contraction [101]. When serum is added to the admixture, contraction of the collagen matrix occurs over the course of a few days. When observed with time-lapse microphotography, collagen condensation appears to result from a 'collection of collagen bundles' executed by fibroblasts as they extend and retract pseudopodia attached to collagen fibers [102]. More recent elegant studies have further defined fibroblast-collagen interactions [103]. The transmission of these traction forces across the *in vitro* collagen matrix depends on two linkage events: fibroblast attachment to the collagen matrix through the α2β1 integrin receptors [104] and crosslinks between the individual collagen bundles [105]. This linkage system probably plays a significant role in the *in vivo* situation of wound contraction as well. In addition, cell-cell adhesions appear to provide an additional means by which the traction forces of the myofibroblast may be transmitted across the wound matrix [96]. In addition, gap junctions between wound fibroblasts probably provide the mechanism for contraction control across the cell population [106].

F-actin bundle arrays, cell-cell and cell-matrix linkages, and collagen crosslinks are all facets of the biomechanics of extracellular matrix contraction. The contraction process, however, needs

a cytokine signal. For example, cultured fibroblasts mixed in a collagen gel contract the collagen matrix in the presence of serum, PDGF, or TGF-β. Since TGF-β factor, but not PDGF, persists in dermal wounds during the time of tissue contraction, it is the most likely candidate for the stimulus of contraction [5]. Nevertheless, it is possible that both PDGF and TGF-β signal wound contraction: one more example of the many redundancies observed in the critical processes of wound healing. In summary, wound contraction represents a complex and masterfully orchestrated interaction of cells, ECM and cytokines.

Collagen remodeling during the transition from granulation tissue to scar is dependent on continued collagen synthesis and collagen catabolism. The degradation of wound collagen is controlled by a variety of collagenase enzymes from macrophages, epidermal cells, and fibroblasts. These collagenases are specific for particular types of collagens but most cells probably contain two or more different types of these enzymes [107]. Three MMPs have been described that have the ability to cleave native collagen: MMP-1 or classic interstitial collagenase which cleaves types I, II, III, XIII, and X collagens; neutrophil collagenase (MMP-8); and a novel collagenase produced by breast carcinomas that is prominent in chronic wounds (MMP-13) [56]. Currently it is not clear which interstitial collagenases are critical in the remodeling stage of human wound repair. For example, no wound healing defect was observed in mice deficient of MMP-13 [108], however, a double knockout of MMP-13 and the plasminogen activating system created an additional delay of healing compared to knockout of only the plasminogen activating system [61]. These findings are likely attributable to the redundancy of nature.

Cytokines such as TGF-β, PDGF, and IL-1 and the ECM itself clearly play an important role in the modulation of collagenase and Tissue Inhibitor of Metalloproteinase (TIMP) expression *in vivo*. Interestingly, type 1 collagen induces MMP-1 expression through the α2β1 collagen receptor while suppressing collagen synthesis through the α1β1 collagen receptor [109]. Type 1 collagen also induces expression of α2β1 receptors [37], thus collagen can induce the receptor that signals a collagen degradation-remodeling phenotype. Such dynamic, reciprocal cell-matrix interactions appears to occur generally during tissue formation and remodeling processes such as morphogenesis, tumor growth, and wound healing to name a few [82].

Wounds gain only about 20% of their final strength by the third week, during which time fibrillar collagen has accumulated relatively rapidly and has been remodeled by myofibroblast contraction of the wound. Thereafter the rate at which wounds gain tensile strength is slow, reflecting a much slower rate of collagen accumulation. In fact, the gradual gain in tensile strength has less to do with new collagen deposition than further collagen remodeling with formation of larger collagen bundles and an accumulation of intermolecular crosslinks. Nevertheless, wounds fail to attain the same breaking strength as uninjured skin. At maximum strength, a scar is only 70% as strong as intact skin.

CHRONIC WOUNDS

Acute wounds are those that heal through the routine processes of inflammation, tissue formation and remodeling, which occur in a timely fashion. As discussed earlier, these processes may overlap temporally. However, prolonged continuance of any of these reparative processes may result in the formation of a chronic wound. Chronic wounds are often associated with underlying pathological conditions that contribute to an impaired healing. Venous leg ulcers and diabetic foot ulcers are common examples of chronic wounds caused or accentuated by an underlying disorder. While the former is being induced by insufficient venous flow that results in increased blood pressure in the lower limb and, therefore, increased vascular permeability, the latter is caused by peripheral neuropathy that leads to abnormal load distribution on the foot surface and decreased sensation [110]. Subsequently, these

abnormalities cause a loss of tissue viability, sub-optimal local tissue permeability and an elevated and sustained inflammatory response.

TISSUE-ENGINEERED THERAPY: ESTABLISHED PRACTICE

Initial attempts to speed up wound repair and improve the quality of healing in chronic or burn wounds involved the use of synthetic, composite synthetic or biological dressings [111]. Although temporarily effective, these dressings did not offer any permanent treatment since eventually, an autograft had to be implanted to achieve complete healing. The advent of tissue-engineered constructs has, however, benefited the wound healing care [112]. These constructs could be classified into two main categories: cellular and acellular. In both cases, the basic building blocks are a biomimetic and a scaffolding material. While the biomimetic functions to stimulate cell recruitment and the desired cellular functions, the scaffold typically provides a mechanical support for the cells. Scaffolds prepared from naturally occurring biopolymers tend to provide the correct biological stimuli to support cell function and tissue formation [113]. Nevertheless, whether the scaffold is natural or synthetic, the goal is to promote faster healing which results in the development of a new tissue that bears structural and functional resemblance to the uninjured, host tissue. A comprehesive list of current cell therapeutics, biologic dressings, and skin substitutes for acute and chronic skin wounds has been recently published [7].

Engineered epidermal constructs

Immediate wound coverage, whether permanent or temporary, is one of the cornerstones of wound management. Engineered epidermal constructs with attributes similar to those of autologous epidermis have been used to facilitate repair of partial-thickness wounds where the major damage is to the epidermis.

Cultured autologous keratinocyte grafts were first used in humans by O'Conner et al [114]. Subsequently there has been extensive experience with cultured epidermal grafts for the treatment of burns as well as other acute and chronic wounds [115,116]. Epicel™ (Genzyme Tissue Repair) is an example of an engineered epidermal autograft. The potential advantage of this technique is the ability to provide autologous grafts capable of covering large areas with reasonable cosmetic results. Another significant advantage of autologous grafts is their ability to serve as permanent wound coverage since the host does not reject them. However, major disadvantages are the several week lag between host skin harvest and the availability of sufficient quantities of keratinocytes, the need for an invasive procedure to obtain autologous donor cells, and the large costs incurred. Furthermore, graft take is widely variable based on wound status, patient age, general host status, and operator experience.

Cultured keratinocyte allografts were developed to help overcome the need for biopsy and separate cultivation for each patient to produce autologous grafts and the long lag period between epidermal harvest and graft product. Cultured epidermal cells from both cadavers and unrelated adult donors have been used for the treatment of burns [117] and chronic leg ulcers [118]. Although allografts made from neonatal foreskin keratinocytes were more responsive to mitogens than adult (cadaver) cells and, therefore, initially preferred for cultured allografts, a later investigation revealed that such allografts were more immunogenic than the regular culture skin substitutes and thus potentially problematic [119].

To facilitate mass allograft production and wide availability, cryopreserved allografts have been developed and were fairly comparable to fresh allografts [120]. In spite of these advances, the culture epidermal grafts have failed to produce satisfactory response. The primary reasons include the lack of mechanical strength and graft site susceptibility to wound contractures. As an alternative, keratinocyte delivery systems were developed where the cells were delivered to the injury site via a biodegradable scaffold. For example, Laser skin, produced by FIDIA

Advanced Biopolymer, Italy, is used to deliver keratinocytes via a chemically modified hyaluronan membrane, which is perforated with micron-sized holes that allow cells to grow to confluence. Another approach has been to isolate fresh keratinocytes from the patients and then spray them onto the wound site [121,122]. Spray therapy of cultured keratinocytes is currently approved for use for partial-thickness burns in Australia and undergoing clinical trials in the US (Recell, Avita Medical, Australia). In addition, spray therapy of freshly isolated keratinocytes is being commercialized by the Gown Institute at the University of Pittsburgh.

Engineered dermal constructs

While the use of cultured keratinocytes to enhance wound healing has met with modest success, it lacks a dermal component that, if present, would provide greater mechanical stability and possibly prevent wound contraction. Allografts containing dermis, e.g., pig skin or cadaver skin, have been used for many years as temporary coverage but they tend to induce an inflammatory response [123]. However, such skin can be chemically treated to remove the antigenic cellular elements (Alloderm, Life Cell Corporation, Woodlans, TX) and used alone or in combination with cultured autologous keratinocytes for closure of various chronic wounds and burns [124]. In spite of these modifications, allogenic grafts, when compared with autologous grafts, have been shown to promote lower percent re-epithelialization and excessive wound contraction [125]. Furthermore, the overall therapeutic outcome of a skin graft depends also on the site from which the cells were isolated (during biopsy) [126].

In 1981, Burke et al. [127] developed an acellular composite skin graft made of a collagen-based dermal lattice (containing bovine collagen and chondroitin-6-sulfate) with an outer silicone covering. After placement on the wound, the acellular dermal component recruits the host dermal fibroblasts while simultaneously undergoing degradation. About 2−3 weeks later, the silicone sheet is removed and covered with an autograft. This composite graft has been used successfully to treat burns [128] and has received Federal Drug Administration (FDA) approval for this indication as well as for reconstructive surgery (Integra, Integra Life Sciences Corporation, Plainsboro, NJ) [129]. However, these constructs cannot be used in patients who are allergic to bovine products.

Another rendition of a dermal substitute is TransCyte (Dermagraft-TC) (Advanced BioHealing, LaJolla, CA). This product consists of an inner nylon mesh in which human fibroblasts are embedded together with an outer silicone layer to limit evaporation. The fibroblasts are lysed in the final product by freeze-thawing. Prior to that time, the fibroblasts had manufactured collagen, matrix proteins and cytokines all of which promote wound healing by the host. TransCyte has been used successfully as a temporary wound coverage after excision of burn wounds [130], and has been approved by the FDA for this indication. Dermagraft is a modification of this product in which a biodegradable polyglactin mesh is used instead of a silicone layer and the fibroblast remain viable [131].

Engineered skin substitutes

Full thickness wounds involve the loss of both the epidermal and dermal layers of the skin. To treat such extensive wounds, Bell et al. first described a bilayered skin composite consisting of a collagen lattice with dermal fibroblasts that was covered with epidermal cells [132]. Modification of this composite consisting of type I bovine collagen and live allogeneic human skin fibroblasts and keratinocytes has been developed (Apligraf, Organogenesis, Canton, MA). It has been used successfully in surgical wounds, venous leg ulcers, and diabetic foot ulcers [133], despite the fact that it is not a permanent skin replacement [134]. In a large multicenter trial this product resulted in accelerated healing of chronic non-healing venous stasis ulcers when compared to standard compressive therapy [135], Both Apligraf (for venous stasis ulcers) and Dermagraft (for diabetic neurotrophic ulcerations) have been available in Canada since 1997 and more recently in the US. Several other composite skin substitutes combining

dermal and epidermal elements have been developed. Composite cultured skin (CCS, Ortec International Inc, New York, NY) is composed of both neonatal keratinocytes and fibroblasts embedded in distinct layers of bovine type I collagen. This product is currently being evaluated in clinical trials for the treatment of burns and in patients with epidermolysis bullosa. More extensive comparative data on the various biologic dressings and available tissue-engineered products has been published elsewhere [7,136].

TISSUE-ENGINEERED THERAPY: NEW APPROACHES

Although the increased healing rates observed with the use of these engineered constructs show promise for the treatment of burn and/or chronic wounds, they have several intrinsic disadvantages that limit their use:

1) The epidermal grafts are very fragile and therefore difficult to handle,
2) It is difficult to quality control the large scale production of any cell-populated matrix, and
3) While autografts require skin biopsy, allografts may experience early rejection.

Moreover, these constructs in general are only about 25% efficient, implying that they must be applied on at least four patients before their effect can be seen. These limitations suggest that further improvements be made so that tissue-engineered constructs are not only more effective but also less complex.

Two approaches emerge from the foregoing discussions. The first tissue-engineering design utilizes cells that resist rejection and/or provide a more robust clinical outcome that makes their use cost-effective despite the absolute costs required to produce them. Alternatively, second-generation, acellular tissue-engineered products are being developed that more effectively recruit host tissue cells into the wound and then provide biological signals for the accumulated tissue cells to induce tissue regeneration rather than scar.

To address the first approach many groups are trying to isolate the 'right' stem cells to stimulate wound repair or preferably tissue regeneration. For the skin, both epidermal stem cells [137,138] and bone marrow- or adipose-derived meschencymal stem cells (MSCs) have been isolated by numerous methods and delivered by many different methods [139,140]. New and better methods for isolating and standarding MSCs are greatly needed and several investigators are assiduously tackling this problem. Better understanding of the niche where stem cells normally reside will help elucidate the microenvironment that the cells need to self-renew versus differentiate along the appropriate path [141,142].

For the acellular 'smart' matrix tissue-engineering approach, clues learned from embryogenesis, morphogenesis and wound repair should be implemented to engineer revolutionary constructs that facilitate and synchronize tissue repair. The transformative acellular product must be conductive to rapidly recruit the host tissue cells and inductive to stimulate the invading cells to proliferate, synthesize new ECM and then differentiate appropriately to regenerate the lost tissue.

Various engineered skin constructs have used collagen as the preferred scaffolding material for cell seeding [143]. The huge popularity of collagen can be attributed to its abundance in skin and, therefore, its recognition by cell surface receptors, its multiple biological roles during both cutaneous homeostasis and wound repair, and its ability to crosslink and thereby impart mechanical strength to the final construct [136]. However, during wound repair, collagen appears only during the later stages after the invading and proliferating fibroblasts have filled the wound space. Therefore, collagen may not be optimal for initial cell migration. Since fibronectin and hyaluronan are present during early stages of embryogenesis, morphogenesis and wound healing [17], we have favored using these biomaterials or their derivatives to design 'smart' matrix for cutaneous wound repair.

Hyaluronan is a non-sulfated glycosaminoglycan that is present in most human tissues. During wound repair, it serves multiple important functions, ranging from regulating inflammation to promoting fibroblast migration and proliferation [144]. Interestingly, hyaluronan has been implicated in the scarless or minimally scarred repair of fetal wounds, perhaps owing to its role in regulating the inflammatory response [145] and collagen deposition [146]. Furthermore, similar to synthetic polymers, hyaluronan can be chemically modified to obtain a variety of stable derivatives [147]. Therefore, by offering the advantages of both natural and synthetic materials, hyaluronan promises to be a more suitable scaffolding material for acellular matrices as compared to collagen. Indeed, chemically modified hyaluronan scaffolds have been successfully used for various tissue-engineering applications, including wound repair [148].

Since fibroblast migration is the rate-limiting step in granulation tissue formation [50], a biomaterial ± biomimetic must support maximal fibroblast migration. Fibronectin is a favorable candidate since:

1) It appears together with hyaluronan at times of cell migration during embryogenesis, morphogenesis and wound repair [17,48],
2) Fibroblast migration on hyaluronan/fibronectin gels is far greater (~four-fold) when compared to that on fibrin/fibronectin gels (Greiling and Clark, unpublished observation),
3) Fibronectin has been shown to be required for fibroblast transmigration from a collagen gel to a fibrin gel [47], and
4) Fibronectin is absent in chronic wounds, where it is produced normally [149] but eliminated rapidly by the abundant proteases present in chronic wound fluid [150,151].

Although fibronectin appears to be an ideal biomimetic for use in hyaluronan scaffolds, its stability in the proteolytic environment of chronic wounds is a major concern.

Alternatively, the proteolytically stable arginine-glycine-asparatic acid (RGD) peptide sequence, the smallest cell recognition sequence in the tenth module of type III repeat of fibronectin, can be used to support key cell functions [152]. RGD has been widely used to promote cell attachment and spreading in various tissue engineering applications in general [153], and wound healing applications in particular [154]. This is perhaps because the RGD sequence is found in a variety of ECM molecules and, therefore, recognized by the transmembrane integrin receptors of multiple cell types, including dermal and epidermal tissue cells [155]. Our previous study has shown that hyaluronan hydrogels decorated with RGDS (arg-gly-asp-ser) support NIH 3T3 fibroblast functions *in vitro* [156] and when seeded with 3T3 fibroblasts and implanted in nude mice, produce granulation-like tissue in four weeks. Therefore, RGD-modified hyaluronan hydrogels appeared to possess great inductive properties. However, these hydrogels neither supported optimal human adult dermal fibroblast functions nor demonstrate conductive properties required of any acellular scaffold [156].

To impart our construct with both inductive and conductive properties, we selected, as the biomimetics, three fibronectin (FN) functional domains viz. $FNIII_{(8–11)}$, $FNIII_{(12–15)}$, and $FNIII_{(12\text{-}V\text{-}15)}$, that are necessary and sufficient for optimal dermal fibroblast migration *in vitro* [157]. Indeed, these hydrogels were successful in supporting dermal fibroblast functions *in vitro* and promoting wound repair *in vivo* [158]. Since these hydrogels can be formulated at room temperature and physiological pH, they are compatible with both cells and the incorporated biological molecules. In addition, their rapid gelation (<10 min) advocates their possible injectable use. However, manufacturing an tissue-engineered implant containing three recombinant proteins raises concerns related to cost, quality control, sterilization and shelf-like of the product. To solve this issue we are currently working to develop fibronectin-derived peptides that substitute for the three domains previously used.

With a similar objective, several other groups have also developed 'intelligent' scaffolds for tissue repair [159]. These approaches commonly employ synthetic materials to build scaffolds since they allow great flexibility during formulation. To impart bioactivity, these scaffolds contain potent biomimetics that can be recognized by tissue cells. However, as discussed earlier, cell invasion during granulation tissue formation occurs concurrently with matrix degradation, which can be typically observed when using naturally-derived materials. To elicit a similar response in synthetic materials, protease-sensitive sequences are incorporated within the scaffold, which are cleaved upon contact with the cell-secreted proteolytic enzymes [160,161]. Therefore, these scaffolds combine the advantages of both natural and synthetic biomaterials to facilitate wound repair.

Traditionally, the structural component of the tissue-engineered constructs has been viewed as providing only a passive mechanical structure. This design reflects our common understanding that cells primarily respond to biological signals. However, over the past decade it has become increasing clear that mechanical forces alone can govern cell and tissue phenotype in ways similar to biological stimuli [162]. Further studies have revealed that cells use an active tactile sensing mechanism to feel and respond to substrate mechanics [15,38] and that stem cells use clues from this mechanical sensing to select pathways for differentiation [163]. The latter observation was not too surprising since it had already been demonstrated that dermal fibroblasts respond to substrate mechanics by regulating levels of gene transcription that eventually lead to differential ECM synthesis and their transformation into myofibroblasts [100]. Since these processes are critical during wound repair, effective tissue-engineering approaches for wound repair would require optimization of both biological and mechanical effectors.

The acellular tissue-engineered constructs discussed so far utilize scaffolding materials to provide mechanical support for tissue ingrowth and biomimetics to induce key cell functions. The primary goal of these novel approaches is to mimic the attributes of fibrin clot for parenchymal cell migration. However, a fibrin clot is not only composed of a fibrin/fibronectin scaffold and an array of clotting and fibrinolytic enzymes, but also a plethora of growth factors that had been released during platelet aggregation [164]. Growth factors play a crucial role in the overall healing response where they function to stimulate cell migration, proliferation, differentiation and angiogenesis. Furthermore, growth factor deficiency often leads to impaired wound repair [165]. As a result, several groups have investigated the use of tissue engineered constructs for local growth factor delivery, where the release of appropriate growth factors produced an increase in angiogenic activity [166,167].

It is interesting to note that in spite of the release of growth factors immediately after wounding, there remains a three day lag before granulation tissue is formed. This suggests that the growth factors may be retained and functional within the clot. This form of 'solid-state' biochemistry may be unconventional but is backed by data from recent studies, which have shown that IGF and VEGF bound to specific molecular domains of FN retain or accentuate their bioactivity [168,169]. In fact, we have recently demonstrated that two FN domains used in our hyaluronan gel PDGF-BB [170] as well as other growth factors important in soft tissue healing. Therefore, by incorporating the appropriate growth factor-binding sequences/domains, tissue-engineered construct can be used as a growth factor repository, causing an increase in local concentration that may ultimately accentuate cell functions.

In conclusion, wound healing is a dynamic and fine-tuned cellular response aimed at reinstating tissue homeostasis after an insult. Vigorous cellular activities observed during wound repair are similar to those occurring during embryogenesis and morphogenesis, which indicates the enormous complexity of this physiological reparative process. That may also explain why despite over two decades of intense research and development, we have still not identified an 'ideal' therapy. However, novel tissue-engineering approaches are showing tremendous promise and aiming to push the limits of human expectations of wound therapy.

[2] Organogenesis Inc., Canton, Massachusetts

INTRODUCTION

Cutaneous wounds normally heal by formation of epithelialized scar tissue rather than regeneration of full-thickness skin. Consequently, strategies for the clinical management of wound healing have depended historically on providing a passive cover to the site of the wound while allowing the reparative mechanisms of wound healing, including re-epithelialization, remodeling of granulation tissue, and formation of scar tissue, to occur, and therapy could do little more than facilitate these processes. However, advances in our understanding of wound healing, wound assessment, the concerted action of several growth factors, the role of the extracellular matrix in regulating the healing process, and the demonstrated ability of bioengineered constructs to promote wound healing highlights the potential for intervening therapeutically in tissue repair by providing lost epithelium, stimulating dermal regeneration, and reconstituting full-thickness skin.

Bioengineered skin substitutes can be classified as both cell-based constructs that actively stimulate wound healing, and acellular constructs that provide a substrate or covering to facilitate wound healing. Cell-based constructs include autologous epidermal cell sheets (Epicel®, Genzyme, Cambridge, MA), allogeneic dermal substrates (Dermagraft™, Shire Regenerative Medicine, San Diego, CA), and human skin equivalents (HSE) composed of both dermal and epidermal components (Apligraf® [1], Organogenesis Inc., Canton, MA; Orcel®, Forticell Bioscience Inc., Englewood Cliffs, NJ; StrataGraft®, Stratatech, Madison, WI) and acellular products (Transcyte®, Shire Regenerative Medicine, San Diego, CA; Integra® Dermal Regeneration Template, Integra Life Sciences, Plainsboro, NJ; Biobrane®, UDL, Rockford, IL). Another construct, comprising cultured keratinocytes and fibroblasts in bovine collagen, is the living cellular sheet, GINTUIT™ (Organogenesis Inc., Canton, MA), indicated for topical application to a surgically created vascular wound bed in the treatment of mucogingival conditions. Although not all of these products are still commercially available, they represented the first of their kind, and are the result of basic research in the biology of skin and wound healing and clinical experience with skin grafts, cultured keratinocyte grafts, acellular collagen matrices, cellular matrices, and cultured composite grafts [1–4].

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00077-X

SKIN STRUCTURE AND FUNCTION

Skin has several distinct functions. As the interface between the environment and the body, skin provides a protective barrier from microbes, toxins, ultraviolet radiation and abrasion while also preventing water loss. Additionally, skin enables the body's ability to sense heat and cold, pressure, vibration and pain and regulate body temperature through perspiration and blood flow. The passive and active functions of skin are carried out by specialized cells and structures located in its two main layers: the epidermis and the dermis (Fig. 77.1). Complex functional relationships between these two anatomic structures of skin maintain its normal properties. Tissue-engineering applications in skin depend upon an understanding of the structural components of skin, their spatial organization, and their functional relationships.

The epidermis

As stated above, skin is a physical barrier between the body and the external environment. The outermost layer of skin, the epidermis, is the layer that is impermeable to toxic substances and harmful organisms. It is also the layer that controls the loss of water from the body to the relatively drier external environment.

The epidermis is composed primarily of keratinocytes, which form a stratified squamous epithelium (Fig. 77.1). Proliferating cells in the basal layer of the epidermis anchor the epidermis to the dermis and replenish the terminally differentiated epithelial cells lost through normal sloughing from the surface of the skin. These basal cells stop proliferating and terminally differentiate into squamous keratinocytes as they move from the basal layer through the suprabasal layers to the surface of the epidermis. Keratin filaments and desmosomes contribute physical strength in the living layers and maintain the integrity of the epidermis. The cornified envelopes serve as the bricks and the lipids as mortar.

The most superficial keratinocytes in the epidermis form the stratum corneum, the dead outermost structure that provides the physical barrier of the skin. In the last stages of differentiation, epithelial cells extrude lipids into the intercellular space to form the permeability barrier. The cells break down their nuclei and other organelles and form a highly crosslinked protein envelope immediately beneath their cell membranes. The physically- and chemically-resilient protein envelope connects to a dense network of intracellular keratin filaments to provide further physical strength to the epidermis.

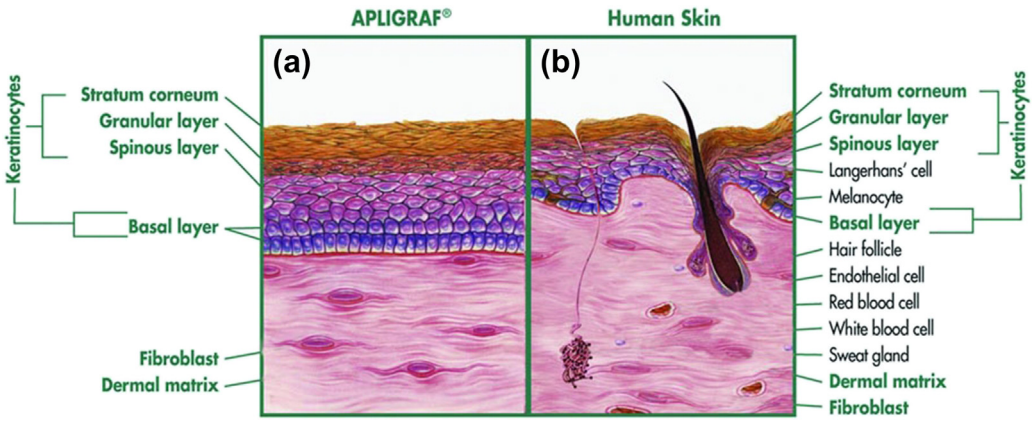

FIGURE 77.1

The basic components of skin and engineered skin equivalent. (a) Diagram showing the major cell types of skin and their organization. Note that stratified keratinocytes make up the epidermis and display distinct morphological phenotypes. (b) A histological section of Apligraf HSE, (hematoxylin and eosin,142 X). Italics indicate cell types present in real skin but not in the engineered skin equivalent.

Additional cells and structures in the epidermis perform specialized functions (Fig.77.1). Skin plays a major role in alerting the immune system to potential environmental dangers. The interacting cells in skin comprise a dynamic network capable of sensing a variety of perturbations (trauma, ultraviolet radiation, toxic chemicals, and pathogenic organisms) in the cutaneous environment, and rapidly sending appropriate signals that alert and recruit other branches of the immune system [5,6]. To restore homeostasis in the skin immune system, the multiple proinflammatory signals generated by skin cells must eventually be counterbalanced by mechanisms capable of promoting resolution of a cutaneous inflammatory response. Dendritic cells of the immune system (Langerhans cells) reside in the epidermis and form a network of dendrites through which they interact with adjacent keratinocytes and nerves [7]. Melanocytes distribute melanin to keratinocytes in the form of melanosomes. Melanin protects the epidermis and underlying dermis from ultraviolet radiation. Sweat glands help to regulate body temperature through evaporation of sweat secreted onto the skin surface. Sebaceous glands associated with hair follicles secrete sebum, an oily substance that lubricates and moisturizes hair and epidermis. Hair keeps the body warm in many mammals, although maintaining body temperature is not an important role for hair in humans. Hair follicles, however, are an important source of proliferating keratinocytes during re-epithelialization after wounding.

The dermis

The dermis underlies the epidermis (Fig. 77.1). The dermis is divided into two regions: the papillary dermis, which lies immediately beneath the epidermis, and the deeper reticular dermis. The papillary dermis is composed of loose connective tissue and form papillae that intertwine with the rete ridges of the epidermis. The reticular dermis is more acellular and has a denser meshwork of thicker collagen and elastic fibers than the papillary dermis. The reticular dermis provides skin with most of its strength, flexibility, and elasticity. Loss of reticular dermis can often lead to excessive scarring and wound contraction.

The dermis provides physical strength and flexibility to skin as well as the connective tissue scaffolding that supports the extensive vasculature, lymphatic system, and nerve bundles. The dermis is relatively acellular, being composed predominantly of an extracellular matrix of interwoven collagen fibrils. Interspersed among the collagen fibrils are elastic fibers, proteoglycans, and glycoproteins.

Fibroblasts, the major cell type of the dermis, produce and maintain most of the extracellular matrix (Fig. 77.1). Endothelial cells line the blood vessels and play a critical role in the skin immune system by controlling the extravasation of leukocytes. Cells of hematopoietic origin in the dermis (e.g., macrophages, lymphocytes) contribute to a surveillance function. A network of nerve fibers extends throughout the dermis, which serves the sensory role in the skin (and, to a more limited extent, a motor function). These nerve fibers also secrete neuropeptides that influence immune and inflammatory responses in skin through their effects on endothelial cells, leukocytes, and keratinocytes [8].

The process of wound healing

Wound healing progresses through three distinct phases, namely inflammation, proliferation, and remodeling. The immediate tissue response to wounding is clot formation to stop bleeding. Simultaneously, there is a release of inflammatory cytokines that regulate blood flow to the area, and recruitment of lymphocytes and macrophages to fight infection. This initial inflammatory phase stimulates angiogenesis, fibroblast proliferation, and collagen deposition [8], which marks the proliferation phase. Fibroblasts rich in smooth muscle actin, called myofibroblasts [9], are recruited through the action of factors such as platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β). These latter processes result in the formation of granulation tissue, a highly vascularized and cellular wound

connective tissue. In the remodeling phase of healing, granulation tissue is gradually replaced by scar tissue through the action of the myofibroblasts and factors such as TGF-β. Keratinocytes are stimulated to proliferate and to migrate into the wound bed to restore epidermal coverage.

Impaired healing and its mechanisms

Although there have been many recent advances in our understanding of the scientific basis of tissue repair, the treatment of chronic wounds and intervening in situations associated with impaired healing have been very challenging. The healing of chronic wounds is impaired for a number of reasons, and in general these types of wounds remain challenging because of our inability to completely correct their fundamental pathophysiological abnormalities [10]. Preparatory steps before the use of advanced treatments seem to be required; this preparatory phase may not have received proper attention in the past. This situation is slowly being corrected, but much more needs to be implemented in preparing the wound for the optimal success of advanced wound healing factors and bioengineered constructs. Several years ago, we proposed the notion of 'wound bed preparation' as a series of steps to improve the wound before advanced products are used [11]. This concept has gained acceptance (see below).

ACUTE VERSUS CHRONIC WOUND HEALING

One of the basic differences between acute and chronic wounds is that in the former the sequence of steps and phases involved (clot formation, inflammation, migration and proliferation, and remodeling) occur in a very orderly and linear fashion. Such is not the case in chronic wounds, where there is a fundamental asynchrony of the healing process. Within the chronic wound, the various phases of wound repair may be occurring at the same time, or not in the appropriate sequence. Wound bed preparation is a way to get the chronic wound to behave more like an acute wound. Often, surgical debridement is all that is required. At other times, treatment of bacterial infection, removal of edema, etc., are essential additional steps [11].

BACTERIAL COLONIZATION

Bacterial and, in some cases, fungal colonization or infection is a fundamental problem with non-healing wounds. Some of the causes that foster this colonization and the development of occult infection have already been addressed. These factors include absent epithelium and its barrier properties, the constant wound exudate resulting from bacterial products and inflammation, and poor blood flow and hypoxia [10]. It is well established that wounds have a 'bacterial burden' that interferes with healing. Thus, there is evidence that, regardless of the type of bacteria present, a level greater than or equal to 10^6 organisms per gram of tissue is associated with serious healing impairment [12]. The configuration of the bacterial sheets or colonies is also important. Therefore, there is a great deal of interest at this time in the role played by biofilms, which represent bacterial colonies surrounded by a protective coat of polysaccharides. Biofilms develop mechanisms for antibiotic resistance [13].

GROWTH FACTOR IMBALANCES

The poor healing response in chronic wounds has also been attributed to an imbalance of one or more growth factors [14]. Identification of putative wound healing factors has led to several attempts to speed wound healing by local application of one or more factors that promote cell attachment and migration. However, most if not all, factor-based approaches have had marginal success. TGF-β, epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), and PDGF have been candidates for this purpose [15–19]. Of these, only Platelet-Derived Growth Factor (PDGF) has shown efficacy in clinical trials and has FDA approval for clinical use (Regranex®, HealthPoint Biotherapeutics Ltd., Ft. Worth, TX).

The arginine-glycine-aspartic acid (RGD) matrix peptide sequence has been found to promote the migration of connective tissue cells, and thus stimulate production of a dermal scaffold within

the wound bed. This approach has been shown to accelerate healing of sickle-cell leg ulcers [20] and diabetic ulcers [21], compared with placebo, but not when compared with standard care.

Complex cell extracts have been used in hopes of providing the appropriate mixture of elements. These include the use of platelet extract to provide primarily PDGF [22], and the use of conditioned growth medium to provide a complex mixture of elements derived from rapidly-growing keratinocytes [23] again, with marginal effect, in part due to the complex nature of the wound healing response [24]. In addition, the use of factors is not a sufficient approach, in and of itself, in situations where there is severe or massive loss of skin tissue.

MATRIX METALLOPROTEASE ACTIVITY

The non-healing wound microenvironment can best be described as hostile. Wound exudate in general, the vast abnormalities in the release, activation, and persistence of matrix metalloproteases (MMPs), lack of cell adhesion to substrates within the wound bed, all may render the growth factors and cytokines unavailable to the healing process. A concept that takes into account these various components has been called the 'trap hypothesis' [25]. It has been hypothesized that non-healing wounds, particularly in response to bacterial antigens, are characterized by chronic leakage of macromolecules into the wound. These macromolecules may impair healing by 'trapping' cytokines and growth factors. The trap hypothesis suggests that, in spite of achieving adequate levels and even the orchestrated release of these growth factors, the polypeptides are quickly bound and unavailable to the healing process. Common macromolecules that might be involved in trapping include albumin, fibrinogen, and α-2-macroglobulin. The latter is particularly important because it is an established scavenger for growth factors. Fibrinogen can bind to fibronectin, providing a mechanism for the trapping of TGF-β1 [26].

MOIST WOUND HEALING IN CHRONIC WOUNDS

Moist wound healing has been shown experimentally to accelerate re-epithelialization of acute wounds [27], and these observations have led to a number of moisture retentive dressings [28]. For chronic wounds, moist wound healing has not been clearly shown to improve epidermal healing, but we do know that moist wound healing helps in the formation of granulation tissue and in relieving pain. Painless debridement, too, is another important property of moisture retentive dressings [28]. The properties of moist wound healing are important in the field of bioengineered skin constructs, because such constructs lead to increased moisture in the wound bed. Proposed advantages of moist wound healing include retention of cytokines within the wound, facilitation of keratinocyte migration, prevention of bacterial entry, and even poorly understood but favorable electrical gradients. For example, acute wound fluid stimulates the *in vitro* proliferation of fibroblasts, keratinocytes, and endothelial cells. However, fluid and exudate from chronic wounds appear to have a definite adverse effect on cellular proliferation, and contain excessive amounts of matrix metalloproteinases (MMPs), which can break down key matrix proteins critical to cell migration, such as fibronectin and vitronectin [10]. There is a great deal of information we still need about MMPs and their inappropriate activation in chronic wounds. Some of the information is often contradictory. For example, interstitial collagenase (MMP-1) is essential for keratinocyte migration. However, other enzymes (MMP-2, MMP-9) may prevent or interfere with healing [10].

ISCHEMIA

An ultimate goal for tissue-engineering constructs would be to offset very fundamental abnormalities that lead to impaired or slow healing. We have been discussing components of impaired healing that in some way or another can be approached or at least partially corrected by already available means. However, one important component of impaired healing is ischemia, due to poor arterial supply because of narrowing of blood vessels (i.e., atherosclerosis) or, indirectly, because of pressure upon those blood vessels (i.e., pressure ulcers, diabetic neuropathic ulcers). The ischemia, of course, has important consequences for the other

components of impaired healing we have discussed, such as bacterial colonization and infection. A challenge is how to use available tissue-engineering products or modify and develop new ones to correct the problem of ischemia. There are some interesting possibilities that one can use as proof of principle. An example is the role of oxygen tension. Thus, there is no debate over the fact that long-term hypoxia is detrimental to the healing process. This has been readily shown with diabetic ulcers, where low levels of transcutaneous oxygen tension ($TcPO_2$) correlate with inability to heal [29]. However, and this makes sense even from a teleological point of view, short-term hypoxia actually stimulates healing. It has been shown that hypoxia can increase fibroblast proliferation, fibroblast clonal growth, and the synthesis of several growth factors, including PDGF, TGF-β, and VEGF, among others [10]. Therefore, modulation of the oxygen environment within the wound may offer the possibility of accelerating the healing process.

ABNORMALITIES AT THE CELLULAR LEVEL

A very important mechanism for impaired healing is the phenotypic make-up of wound cells. This has critical implications for the use of bioengineered skin constructs, in that these constructs may offset cellular phenotypic abnormalities. There is increasing evidence that the resident cells of chronic wounds have developed phenotypic changes that interfere with their response to growth factors and cytokines. Such abnormalities may affect cellular proliferation, locomotion, and the overall capacity to heal [10]. Also, the signaling mechanisms, which are so critical to the action of cytokines, may be impaired. For example, at least in venous ulcers, there is decreased phosphorylation of Smad2/3 and MAPK p44/42 [30], and a complete deregulation of keratinocyte differentiation and activation and therefore wound closure [31], a result of impaired TGF-β signaling [32].

ENGINEERING SKIN TISSUE

Although the epidermis has an enormous capacity to heal, there are situations in which it is necessary to replace large areas of epidermis, or in which normal regeneration is deficient. The dermis has very little capacity to regenerate. The scar tissue that forms in the absence of dermis lacks the elasticity, flexibility, and strength of normal dermis. Consequently, scar tissue limits movement, causes pain, and is cosmetically undesirable. Engineered tissues that not only close wounds but also stimulate the regeneration of dermis would provide a significant benefit in wound healing.

Bioengineered skin equivalents should incorporate as many of these factors as possible:

1) An extracellular matrix,
2) Dermal fibroblasts,
3) An epidermis containing keratinocytes, and
4) A naturally occurring semi-permeable membrane, the stratum corneum to provide barrier function (Fig. 77.2).

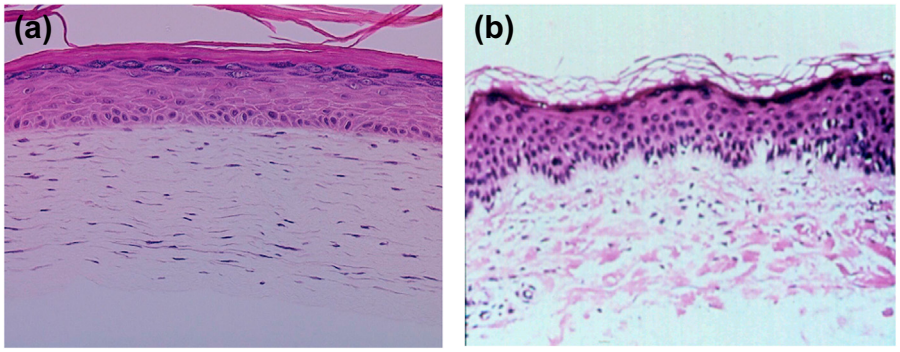

FIGURE 77.2
Histological appearance of Apligraf.
(a) compared to normal human skin. (b) A well-defined epidermal and dermal layer is observed in both. *(Copyright V. Falanga, 2006.)*

These components may act alone, but more importantly, they act in concert as part of a fully integrated tissue to protect the underlying tissues of a wound bed and to direct healing of the wound [33]. Dermis containing fibroblasts may be necessary for the maintenance of the epidermal cell population [34]. In turn, the epidermis is necessary for the formation of the so-called neodermis, in the absence of a dermal layer [35] and can dramatically influence underlying connective tissue response. The formation of the epidermal barrier also likely influences these processes through control of water loss and its influence on epidermal physiology [36].

Design considerations

Tissue engineering has not focused on regenerating certain skin structures, like hair follicles or sebaceous glands, whose loss is clinically less significant than the loss of dermis and epidermis needed to cover and protect the underlying tissues. Despite some early evidence for rudimentary eccrine tubules within the HSE [37], the development of functioning adnexal structures is likely to be years away. There has also been little need to extraneously stimulate regeneration of other dermal components (e.g., blood vessels and cells of the immune system) through tissue-engineering methods because these components have the ability to repopulate quickly and to normalize the area of a wound. Langerhans cells, for example, have been shown to migrate and repopulate effectively within months [9]. Control of vascularization is dependent on the make-up of the extracellular matrix and the degree of inflammation present in the wound. Whether modification of vascularization through the use of exogenous factors will be of additional benefit for certain wounds remains to be determined. While pigmentation is not critical for wound healing, clinical studies using Apligraf, which lacks melanocytes, have shown repigmentation of the grafted areas through repopulation of the area with host melanocytes, resulting in normal skin color for each individual. The constructs should have sufficient mechanical strength to allow for clinical manipulations (Fig. 77.3). The approach skin tissue engineering has taken has been to focus primarily on providing or imitating structural and biological characteristics of dermis, epidermis, or both.

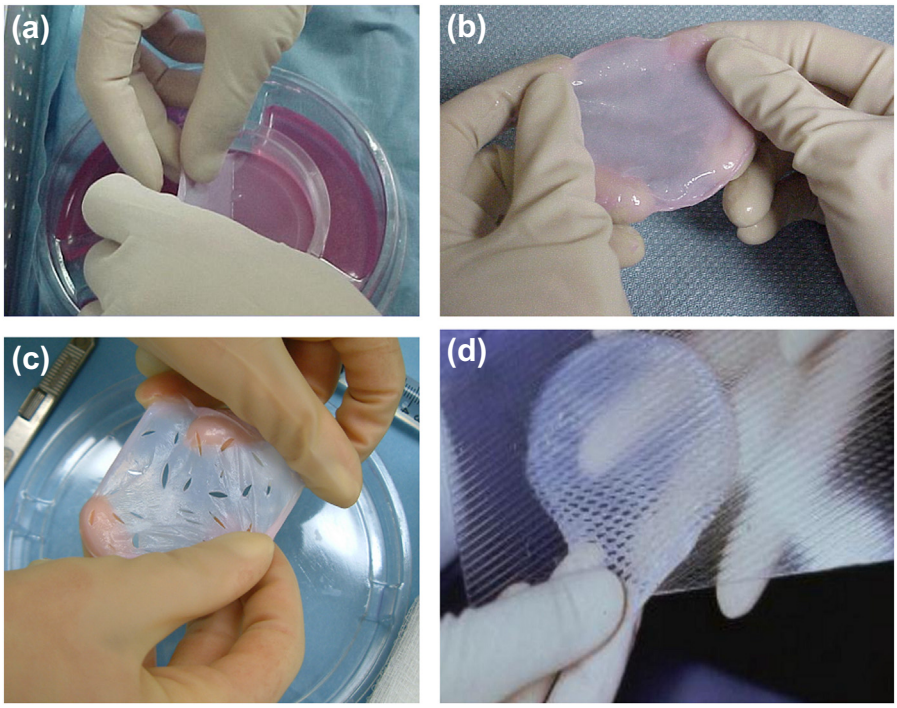

FIGURE 77.3
Appearance of Apligraf. (a) Being removed from its pink nutrient agar. (b) Being held just prior to fenestration or meshing. (c) After fenestration with a scalpel. (d) After meshing at a 1.5:1 ratio. *(Copyright V. Falanga, 2006.)*

The key features to be replicated in an engineered skin construct are:

- A dermal element capable of aiding appropriate dermal repair and epidermal support.
- An epidermis capable of easily achieving biologic wound closure.
- An epidermis capable of rapid re-establishment of barrier properties.
- A permissive milieu for the components of the immune system, nervous system, and vasculature.
- A tissue capable of achieving normalization of structure and additional functions such as reduction of long-term scarring and re-establishment of pigmentation.
- Active cellular component(s) capable of responding to different wound types and conditions.
- Sufficient mechanical strength to allow for clinical manipulation.
- Persistence of cells in the wound for multiple weeks to stimulate the healing process through delivery of cytokines and matrix proteins.

Commercial considerations

Engineered skin constructs, by virtue of being the first bioengineered products to be commercialized, have been at the forefront of science, industry, and regulation. In recent years more attention has been given to the subject of commercialization. In 2012 Jaklenec et al., published a review of the tissue engineering and stem cell industry [38]. The authors reported that there was approximately a three-fold increase in commercial sales, generating $3.5 billion from 2008 to 2011. During that time, the number of tissue-engineering companies increased from 171 in 2007 to 202 in 2011, with 62% of them based in the United States. These companies are spending $3.6 billion and employ 13,810 people. The findings indicate that the tissue engineering and stem cell industries are stabilizing.

Early industry leaders, Organogenesis, Advanced BioHealing (now Shire Regenerative Medicine) and Forticell Biosciences, initially struggled with the task of commercializing their technologies. The focus at Organogenesis, in the case of Apligraf, has been on understanding the cost of manufacturing and working to reduce those costs while increasing efficiency and maintaining high quality. Organogenesis has also built robust sales and marketing, customer service, reimbursement, and distribution functions to drive Apligraf sales. Having all of these functions within the same organization is proving to be of benefit by allowing for a more integrated, strategic company.

Process considerations

Consideration should be given to the design of the manufacturing process early in the product concept stage. Elements such as critical process parameters, quality control assays, production components and materials, process equipment, production facility requirements, product shelf life and distribution methods need to be developed in detail. From this design the cost of manufacturing and strategies for scale-up and automation can be developed. The requirements for the manufacturing facility are directly related to the design of the manufacturing process. For example, a manual process generally requires a large highly-specialized staff and a relatively large manufacturing floor space, whereas an automated process requires less specialized staff and potentially less manufacturing floor space. An aseptic process where the culture vessels are periodically opened to facilitate feeding and other manipulations requires tighter environmental controls to mitigate risk from contaminants on work surfaces or in the air, whereas developing a closed process that eliminates aseptic manipulations reduces the need for tight environmental controls, thus reducing facility costs. All of these elements impact the cost of manufacturing and the potential for scale-up.

Process components that will pose significant barriers to scale-up or automation can be identified and addressed while the product is still in research and development. This is critical when you consider that the further you advance in the development process the more

committed you become to the process design. The cost of making a significant process change increases the closer you get to manufacturing, and becomes exponentially more expensive and time consuming post product launch. Along these same lines, materials used in the process that are ill-defined, cell-based, single sources or of limited supply can contribute to a manufacturing process that is difficult to scale-up and control from a quality standpoint. These factors will influence the yield from the manufacturing process or, stated another way, the scrap rate for the product. High scrap rates increase manufacturing costs and create issues for inventory management. The pioneering lessons learned by early industry leaders in process scale-up apply to the broader field of tissue engineering. Ultimately, strategies for scale-up and automation can be evaluated and planned for.

Regulatory considerations

The Center for Devices and Radiological Health (CDRH) at FDA requires products to be developed following design control procedures (21 CFR 820.30). These design guidelines are in place to ensure that the products that are developed will be safe, effective and have a market research based justification for the product design. Establishing a Design Control system early will help refine the business model throughout the development life cycle. Design Control is not only a regulatory requirement, but it makes good business sense. HSEs have historically been classified and regulated as medical devices, though the trend at FDA is to regulate products having a cellular component as biologics. A case in point is the recent approval of GINTUIT™, a fibroblast and keratinocyte-containing construct, as a combination product (containing biologic and devices components) by the Center for Biologics Evaluation and Research (CBER) [39]. Finally, agencies like the US Center for Medicare and Medicaid Services (CMS) and foreign government reimbursement agencies (e.g., U.K National Institute for Health & Clinical Excellence, NICE) are increasingly requiring convincing data on the value and effectiveness of therapy as compared to standard of care or competing technologies [40].

Immunological considerations

The ability to utilize allogeneic cells rather than autologous cells facilitates the reproducible, large-scale commercial manufacture of an HSE [37], because large cell banks can be created, allowing manufacture of thousands of units of product from one cell strain and enabling a more accurate forecast of manufacturing demands. However, the problem of rejection needs to be taken into consideration when using living allogeneic cells in wound healing applications.

The first stage in the induction of a primary immune response after skin allografting is the presentation of antigen by donor dendritic cells (Langerhans cells with dermal dendritic cells), the professional antigen-presenting cells (APCs) in skin. These cells migrate out of the skin to the draining lymph node, where they can activate T cells directly through the presentation of MHC-class II antigens and co-stimulatory molecules, thereby eliciting both cell-mediated and humoral (antibody-mediated) immune responses to the grafted skin. Although cell-mediated cytotoxicity is a component of rejection, the primary mode of skin rejection is likely mediated via an attack on the vasculature present in a normal skin graft by recipient antibodies [41,42].

Bioengineered skin constructs are fabricated from highly purified banks of fibroblasts, keratinocytes or both, that are either poor or deficient in dendritic and other APCs found in skin. This has important implications for the use of allogeneic cells in the treatment of acute and chronic wounds. In the absence of APCs, fibroblasts and keratinocytes are the only cells capable of presenting donor antigen to the recipient. Under normal conditions, keratinocytes and fibroblasts do not express MHC-class II antigens. They can be induced by interferon-γ to express MHC-class II molecules and thereby acquire the ability to present antigen to T cells, however keratinocytes and fibroblasts do not express co-stimulatory molecules [43,44], so antigen presentation by keratinocytes and fibroblasts does not result in T cell activation. Instead, this antigen presentation can result in T cell non-responsiveness [45,46] or T cell anergy [47].

Autologous HSEs would avoid issues of immunogenicity, of course, but autologous grafts have significant limitations. Growing graft tissues from biopsy takes several weeks, the donor site creates another wound, and in some patients (e.g., severe burn patients) there may be no appropriate donor site. Reproducibly making complex HSE constructs to order from autologous cells would be time consuming, and very costly. Therefore, the ability to effectively use allogeneic human cells is a key element in the commercial success of engineered skin therapies.

Summary: engineering skin tissue

In summary, good science alone is not enough to ensure success. There are critical considerations to commercialization along the entire continuum from product concept, development, clinical evaluation, FDA and other regulatory agency approval, product launch, reimbursement and commercial scale manufacturing. Developing a comprehensive business model that takes all of these factors into account will increase the likelihood for a profit-generating product. Understanding the challenges and working to incorporate process designs that are forward-looking, will be amenable to scale-up, address regulatory hurdles and are supported by a viable business model are necessary for companies to be successful and the industry to grow.

EPIDERMAL REGENERATION

Re-epithelialization of the wound is a paramount concern. Without epithelial coverage, no defense exists against contamination of the exposed underlying tissue or loss of fluid. The approaches to re-establishing epidermis are numerous, ranging from the use of cell suspensions to full-thickness skin equivalents possessing a differentiated epidermis. Silicone membranes have been used as temporary coverings in conjunction with dermal templates [48], Regardless of approach, living epidermal keratinocytes are necessary to achieve permanent, biological wound closure.

Green et al., [49,50] developed techniques for growing human epidermal keratinocytes from small patient biopsy samples using co-culture methods [51]. The mouse 3T3 fibroblast feeder cell system allows substantial expansion of epidermal keratinocytes and can be used to generate enough thin, multi-layered epidermal sheets to resurface the body of a severely burned patient [52]. Once transplanted, the epidermal sheets quickly form epidermis and re-establish epidermal coverage [35]. With time, the cultured epithelial autograft (CEA) stimulates formation of new connective tissue ('neodermis') immediately beneath the epidermis [53], but scarring and wound contraction remain significant problems [54]. Studies have shown that grafting of a CEA onto pre-grafted cadaver dermis greatly improves graft take [55]. CEAs (Epicel®, Genzyme, Cambridge, MA) have been available since the late 1980s.

DERMAL REPLACEMENT

Dermal replacement is an essential first step in restoring normal skin structure following injury and leads to better cosmesis in full-thickness soft tissue defects. In one of the earliest tissue-engineering approaches to improving dermal healing, Yannas et al. [56] designed a collagen-glycosaminoglycan sponge to serve as a scaffold or template for dermal extracellular matrix. The goal was to promote fibroblast repopulation in a controlled way that would decrease scarring and wound contraction. A commercial version of this material composed of bovine collagen and chondroitin sulfate, with a silicone membrane covering (Integra™, Integra Life Sciences, Plainsboro, NJ) is currently approved for use in burns [48,57]. The dermal layer is slowly resorbed, and the silicone membrane is eventually removed, to be replaced by a thin autograft [58].

Biobrane® (UDL, Rockford, IL) is a non-viable temporary covering for burns, in which a nylon mesh, coated with porcine collagen-derived peptides and layered with a non-permeable

silicone membrane serves as a platform for deposition of human matrix proteins and associated factors by host wound-derived dermal fibroblasts. After epidermalization, the construct becomes non-adherent and is removed from the wound bed. A similar product, Transcyte (Advanced BioHealing, Westport, CT) [59], consists of a porcine collagen-coated nylon mesh that is incubated with human neonatal fibroblasts, which secrete extracellular matrix proteins and growth factors. The material is then frozen to preserve the matrix and factors produced by the fibroblasts, although the fibroblasts themselves are non-viable when the construct is applied to the wound. The temporary silicone covering is removed to allow epidermalization or prior to application of an autograft.

Although matrix scaffolds have shown some improvement in scar morphology, no acellular matrix has yet been shown to lead to true dermal regeneration. This may be due in part to limits in cell repopulation, the type of fibroblast repopulating the graft, and control of the inflammatory and remodeling processes (i.e., the ability of the cells to degrade old matrix while synthesizing new matrix).

The inflammatory response must be controlled in dermal repair in order to avoid the formation of scar tissue. Therefore, dermal scaffolds must not be inflammatory and must not stimulate a foreign body reaction. This has been a problem in the past for some glutaraldehyde cross-linked collagen substrates [60]. The ability of the matrix to persist long enough to redirect tissue formation must be balanced with effects of the matrix on inflammatory processes. One way to achieve this is to form a biological tissue that is recognized as living tissue, not a foreign substance.

There have been advances in the design of *in vitro* grown dermal tissues using living human neonatal fibroblasts grown on rectangular sheets of biodegradable vicryl mesh (Dermagraft, Shire Regenerative Medicine, San Diego, CA). The fibroblasts propagate among the fibers of the mesh, producing extracellular matrix in its interstices [61]. Like Transcyte, the final Dermagraft construct is then frozen, but in a manner that preserves approximately 60% fibroblast viability upon thawing and placement on the wound [62].

BIOENGINEERED LIVING SKIN EQUIVALENTS

HSEs have been generated by seeding cultured keratinocytes onto the surface of a variety of scaffolds, including artificial membranes, de-epidermalized dermis, collagen gels, chitosan-GAG sponges or fibroblast-populated nylon meshes [63]. One of the first attempts to replicate a full-thickness skin graft was by Bell et al. [64] who described a bilayered skin equivalent, which was the predecessor to Apligraf. The dermal component consisted of a lattice of type I collagen contracted by tractional forces of rat dermal fibroblasts trapped within the gelled collagen. This contracted lattice was then used alone or as a substrate for rat epidermal keratinocytes. These primitive skin equivalents were further demonstrated to take as skin grafts in rats. This technology has now advanced to enable the production of large amounts of Apligraf from a single donor [37].

Boyce et al. modified the approach first proposed by Yannas et al. to form a bilayered composite skin made using a modified collagen-glycosaminoglycan substrate seeded with fibroblasts and overlaid with epidermal keratinocytes [65]. An autologous form of this composite skin construct was used to treat severe burns with some success [66]. An allogeneic form of the construct showed improved healing in a pilot study in chronic wounds [67]. A similar technology has been studied in the treatment of patients with genetic blistering diseases [68]. Using methods of organotypic culture that provides a three-dimensional culture environment that is permissive for proper tissue differentiation, the resulting HSE develops many of the structural, biochemical, and functional properties of human skin [65,69–71], apart from the aforementioned lack of adnexal structures.

The process for formation of HSEs has been covered in detail many times [37,65,72] and will not be detailed here. However, there are points to be made about the approach to these procedures. The culture of an HSE proceeds best with minimal intervention. Normal keratinocyte populations seem to have an intrinsic ability to re-express their differentiation program *in vitro*. A medium that supplies adequate amounts of nutrients, lipid precursors, vitamins, and minerals may be all that is required [37]. This has now been achieved with both normal human keratinocytes (Apligraf, Orcel) and with immortalized human keratinocytes (StrataGraft) [73]. Another element is the environmental stimulus provided by culture at the air-liquid interface which promotes differentiation and formation of the epidermal barrier [65,69]. In the case of StrataGraft, the trisomy that caused immortalization of the cell line has apparently not affected the capacity of the cells to undergo differentiation in organotypic culture [73].

Recently, L'Heureux et al. were able to take advantage of the fact that mesenchymal cells secrete their own extracellular matrix (ECM) when cultured in the presence of ascorbic acid, to generate sheets of ECM, in the absence of a bovine collagen scaffold, from cultured fibroblasts and smooth muscle cells (SMCs). Initially, these ECM tissues were used to generate the first tissue engineered blood vessels [74]. Subsequently, the same technology was used to generate a scaffold-free HSE [75], in which the dermal layer normally constructed with bovine collagen was replaced with a completely fibroblast-derived ECM. The epidermis of the HSE was generated by seeding keratinocytes onto the self-assembled ECM and incubating at the air-liquid interface to promote stratification and differentiation. After 4 weeks of culture, a fully stratified and differentiated epithelium developed, which expressed the normal markers of differentiation. The tissue also included an organized basement membrane, including laminin and collagens IV and VII. Since this early work, a few groups have investigated the physical and biochemical properties of self-assembled ECMs [75,77,78] and have used these self-assembled constructs as *in vitro* models of percutaneous absorption [75] and hypertrophic scarrin [79,80]. However, self-assembled HSEs have yet to become a clinical and commercial reality.

BIOENGINEERED SKIN: FDA APPROVED INDICATIONS

Cutaneous indications

As discussed above, the rather formidable obstacles to healing chronic wounds have made it difficult for the simple topical application of growth factors and cytokines to have a successful outcome. It can be argued that tissue engineering, particularly with living cells, has an advantage in that cells may be capable of responding to the microenvironment and thus behave in a 'smart' way from an engineering point of view. Because of these considerations, cell therapy with bioengineered skin has been tested in difficult to heal wounds. Figs. 77.2 and 77.3 show Apligraf before and after meshing and fenestration, as well as its histological appearance. Venous leg ulcers and neuropathic diabetic foot ulcers have received the greatest attention. Two main types of living bioengineered skin have been proven to be effective in diabetic neuropathic foot ulcers and have received regulatory approval from the FDA. In a randomized 12 week trial of 208 patients with neuropathic ulcers, Apligraf led to complete wound closure in 56% of patients, compared to 38% in the control group [81]. The Kaplan-Meier median time to complete wound closure was 65 days for Apligraf and 90 days for control. Fig. 77.4 shows a diabetic neuropathic foot ulcer successfully treated with Apligraf. In an evaluation of the clinical trial adverse events, Apligraf treated patients had significantly fewer amputations/resections of the study limb and less incidence of osteomyelitis. These results on key complications of diabetic foot ulcers may have been due to faster healing. Another living cell product, Dermagraft, was shown in a 12 week randomized study to heal neuropathic foot ulcers, with an incidence of closure of 30% and 18% for the active and control arm, respectively [82].

In addition to its indication for diabetic ulcers, Apligraf also remains the only approved bioengineered product for venous ulcers. In a pivotal multicenter randomized study of 293

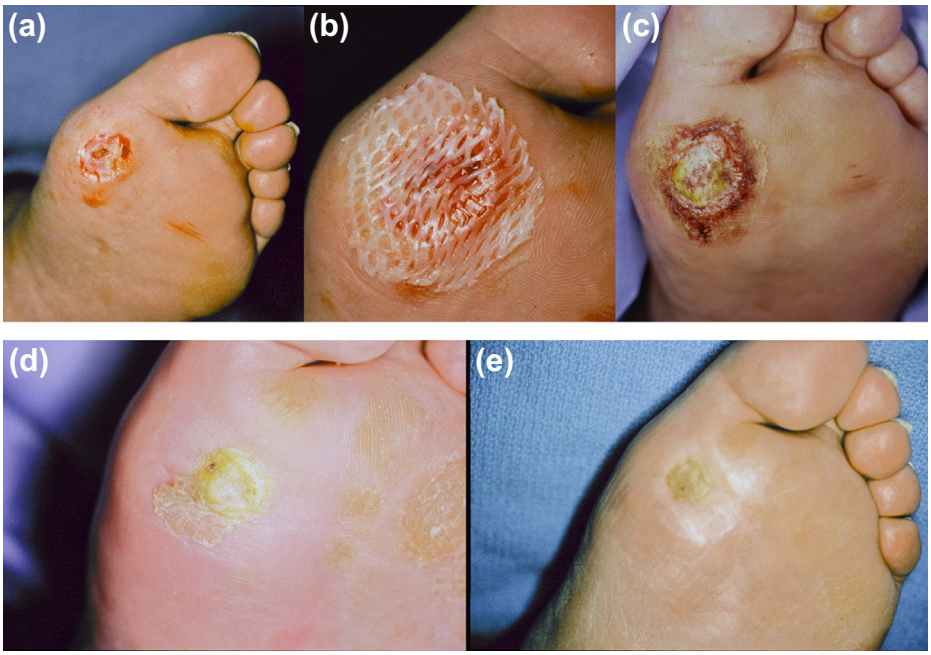

FIGURE 77.4

(b) Wound covered with meshed Apligraf. (c) Appearance of construct a week later. (d) At 3 weeks. (e) Complete wound closure at 5 weeks. *(Copyright V. Falanga, 2006.)*

patients with venous leg ulcers, Apligraf was more effective than leg compression alone (control) in the percentage of patients who healed by six months (63% vs. 49%) [83]. That study also showed that Apligraf healed ulcers that were larger and deeper than those in the control group. No evidence of sensitization was observed with the bioengineered skin product. Interestingly, a subsequent re-analysis of the data from this pivotal trial, limited to 120 patients having venous ulcers for over one year, showed that Apligraf healed 47% of patients, compared to 19% in the control group [84]. This observation, taken together with the mechanisms underlying impaired healing, suggests that cell therapy might have a greater effect when there are more substantial abnormalities leading to a prolonged failure to heal.

Oral indications

Like skin, soft tissues in the oral cavity need to be replaced or repaired due to trauma, disease or congenital defects. Treatment of soft tissue defects in the oral cavity has been done by either secondary intention healing (removing the diseased tissue and allowing it to heal on its own), by the use of flaps (a graft that is advanced over a defect and contains its own blood supply), or by the use of free grafts (tissue that lacks its own blood supply). Depending on the procedure, auto- or allografts may be used. Autografts are generally harvested from the palate, and are associated with significant donor site morbidity. However, some groups have had success with autologous epithelial cells, and with injected autologous mucosal fibroblasts [85].

Two types of allogeneic, tissue-engineered constructs have been used in the oral cavity. Dermagraft has been used in the oral cavity to treat gingival recessions, in which the amount of attached gingiva was insufficient. As with its Diabetic Foot Ulcer (DFU) indication, it is thought that the Dermagraft construct provides a scaffold for mucosal keratinocyte migration, and that it secretes growth factors and cytokines that promote secondary intention healing. Dermagraft has been the subject of a controlled within-patient clinical trial in the oral cavity, in which its efficacy was compared to that of a gingival autograft for the treatment of gingival recessions [86,87]. Treatment with Dermagraft resulted in an increase in the amount of attached gingiva, although the amount of keratinized tissue was inferior to that generated by the autograft, as expected from a construct that promotes secondary intention healing rather than immediate coverage. At the time of publication, Shire Regenerative Medicine is no longer pursuing an oral indication for Dermagraft.

GINTUIT, a product derived using a similar technology platform as Apligraf, has also been evaluated for its ability to replace a connective tissue autograft in the treatment of gingival recessions in a free gingival graft procedure [88]. Like Apligraf in the DFU and Venous Leg Ulcer (VLU) indications, GINTUIT did not persist long-term in the oral cavity. Like Dermagraft, GINTUIT was found to be superior to a gingival autograft in terms of color and texture match to surrounding tissue. In the pilot and pivotal studies, treatment with GINTUIT resulted in regeneration of ≥ 2 mm of keratinized gingiva in 81.8% and 95.3% of patients, respectively, which is clinically accepted as a level important for periodontal health. As of 2012, GINTUIT, is the first living cell-based therapy that has FDA approval for the treatment of oral soft tissue defects [39]. Although derived from the same technology platform as Apligraf, GINTUIT was approved as a combination product (containing biologic and devices components) by the Center for Biologics Evaluation and Research (CBER) [39] and is therefore subjected to additional product release criteria compared to Apligraf. Interestingly, the platform that gives rise to Apligraf and GINTUIT is able to regenerate tissue in a site-appropriate manner, in that it promotes secondary intention healing of difficult to heal cutaneous soft tissue defects, and also promotes regeneration of keratinized gingiva site-appropriately in the oral cavity.

APLIGRAF AND DERMAGRAFT: OFF-LABEL USES

Off-label use is the practice of using products for purposes not approved by the FDA. Physicians can prescribe and use products as they see fit because they are not regulated and are recognized as experts in their fields. Manufacturers of the products are not permitted to promote off-label use; however, data generated by off-label use can be very valuable and lead to new insights into product function and potentially to clinical trials for new indications, therefore the following discussion has been included in this chapter. It must be emphasized, however, that the determination of off-label use is not always clear-cut when it comes to chronic wound etiology. In some cases applicable to Apligraf, for example a scalp or hand wound, one is clearly using the product off-label. However, for many lower extremity wounds, the situation is much more complex. Thus, a patient may have a mixed etiology for the ulcer (for example, lymphatic and venous insufficiency) and will therefore not heal until the venous component is properly addressed. In addition to the use of standard care for venous insufficiency, such as compression bandages and wound dressings, one could make the argument that Apligraf is indicated in that clinical setting because the construct has indeed been proven to improve venous ulcers. It would be difficult, perhaps impossible, to conduct clinical studies that address ulcers of mixed etiology in a scientifically sound way. An even more complex clinical setting is when one treats patients who appear to have inflammatory ulcers (i.e., pyoderma gangrenosum, ulcers involving vasculitis, ulcers associated with cryoprotenemias, etc.) on a lower extremity that also exhibits definite signs and findings of venous insufficiency. The question then centers upon the predominant etiology of the ulceration. From a clinical standpoint, it can become very difficult to make that determination. Yet, treatment of that ulcer with Apligraf to improve the venous component can lead to complete wound closure (V. Falanga., personal observation as of 2012). These are challenging situations but, in our experience and exchanges with colleagues, these types of ulcers are probably not uncommon. Still, while being able to use certain constructs off-label, the clinician must keep in mind the appropriate approved indications for that product and not be swayed in his or her clinical judgment as to what is indeed the primary cause of the ulcer.

From both a therapeutic and purely scientific standpoint, of critical importance in the context of the clinical trials for venous leg and diabetic foot ulcers detailed is that, for the very first time, one has been able to show a beneficial effect of bioengineered products in situations of impaired healing. Understandably, clinicians have also used Apligraf off-label to accelerate healing in wounds not due to venous disease or diabetes [89]. Wounds that have been treated off-label with Apligraf include acute wounds after extensive skin surgery, donor sites after split-thickness skin

harvesting, traumatic wounds, burns, inflammatory ulcers such as pyoderma gangrenosum and vasculitis, scleroderma digital ulcers, wounds after keloid removal, genetic conditions such as epidermolysis bullosa, and a variety of situations that defy proper diagnosis because of their complexity. In these cases, bioengineered skin treatment with Apligraf seems to offer a viable alternative to stimulate wound healing and relieve unacceptable pain and suffering. For example, pyoderma gangrenosum is an inflammatory ulcer often associated with rheumatoid arthritis, inflammatory bowel disease, IgA gammopathy, among other predisposing factors. A peculiar feature of pyoderma gangrenosum is that it worsens with surgical manipulation and even develops at distant sites that are traumatized; thus, autologous grafting is a contraindication and bioengineered skin is an attractive therapeutic modality [90]. In a patient with multiple myeloma undergoing conditioning for bone marrow transplantation, extravasation of the chemotherapeutic drug adriamycin, occurred in his chest and created a very large, deep and painful wound. Apligraf played a major role in healing the full-thickness wound (Fig. 77.5), and led to a dramatic relief in pain. Pressure ulcers, too, have been treated with Apligraf. This is of particular interest because, based on the engineering aspects of the construct, one would have expected that very deep wounds with loss of a great deal of tissue would not respond to Apligraf. Yet, it appears that in such cases Apligraf is able to stimulate tissue re-growth in deep ulcers, and not just re-epithelialization from the edges of the wound (Fig. 77.6). Scleroderma digital ulcers are ischemic in nature, and have no known accepted treatment. Yet, Apligraf appears promising in those wounds (Fig. 77.7). There is no evidence that Apligraf stimulates malignancy within the wound bed, possibly due to its stimulatory action. An interesting case in point is shown in Fig. 77.8, where multiple and ulcerated basal cell carcinomas in the foot of a patient with the hereditary form of basal cell nevus syndrome were treated with Apligraf.

Epidermolysis Bullosa (EB) is a genetic skin disorder characterized by blistering of the skin and mucosae following mild mechanical trauma [91,92]. Falabella et al. performed an open-label uncontrolled study of 15 patents with EB treated with Apligraf [92]. The conclusion was that Apligraf induced rapid healing; the wounds remained healed for some weeks and there was no acute rejection reaction or other adverse effects related to the treatment. Currently there is no specific treatment for EB, and the nature of the condition is that these wounds tend

to heal slowly and in some instances fail to heal, becoming chronic wounds. Fig. 77.9 shows an example of a pediatric EB patient that was treated with Apligraf.

A case of vasculitis treated with Dermagraft is another good example of the use of a tissue-engineered construct to promote closure of a difficult to heal wound (Fig. 77.10). The patient (48 years old) had a severe course of cutaneous polyarteritis nodosa, which did not involve her kidneys. She was always in severe pain and could not be healed by conventional means. Dermagraft proved useful in terms of alleviating pain and promoting epidermalization. Stimulation of epidermal migration was observed by Day 14 after application of the construct. After the wound healed, the patient was placed on an anti-TNF-α biological agent to prevent recurrence and she remains healed.

THE IMPORTANCE OF WOUND BED PREPARATION (WBP)

Shortly after the FDA approval of two major products for the treatment of non-healing chronic wounds (topical PDGF for diabetic neuropathic foot ulcers and Apligraf for venous ulcers) it became apparent that many clinicians were either not well-versed in the treatment of chronic wounds, or could not easily incorporate these novel and advanced therapeutic technologies into their management strategies. The initial clues to this problem came from obviously sub-optimal results when compared to those obtained in the clinical trials, or the apparent use of these technologies at inappropriate times during the healing or non-healing trajectory of the wounds. In an editorial we published at that time [11] we laid down what we thought to be the reasons for these observations, and focused on a new term; Wound Bed Preparation (WBP), which we described as a global approach to the wound to improve its wound bed at multiple levels (optimizing the granulation tissue, decreasing the bacterial burden, removing phenotypically abnormal cells, enhancing epidermal migration) and which would then lead to a better outcome upon treatment with Apligraf and other advanced therapeutic agents. Since then, WBP has dominated the chronic wound field and has provided a more consistent way of approaching chronic wounds. Other publications on this subject have followed [93,94].

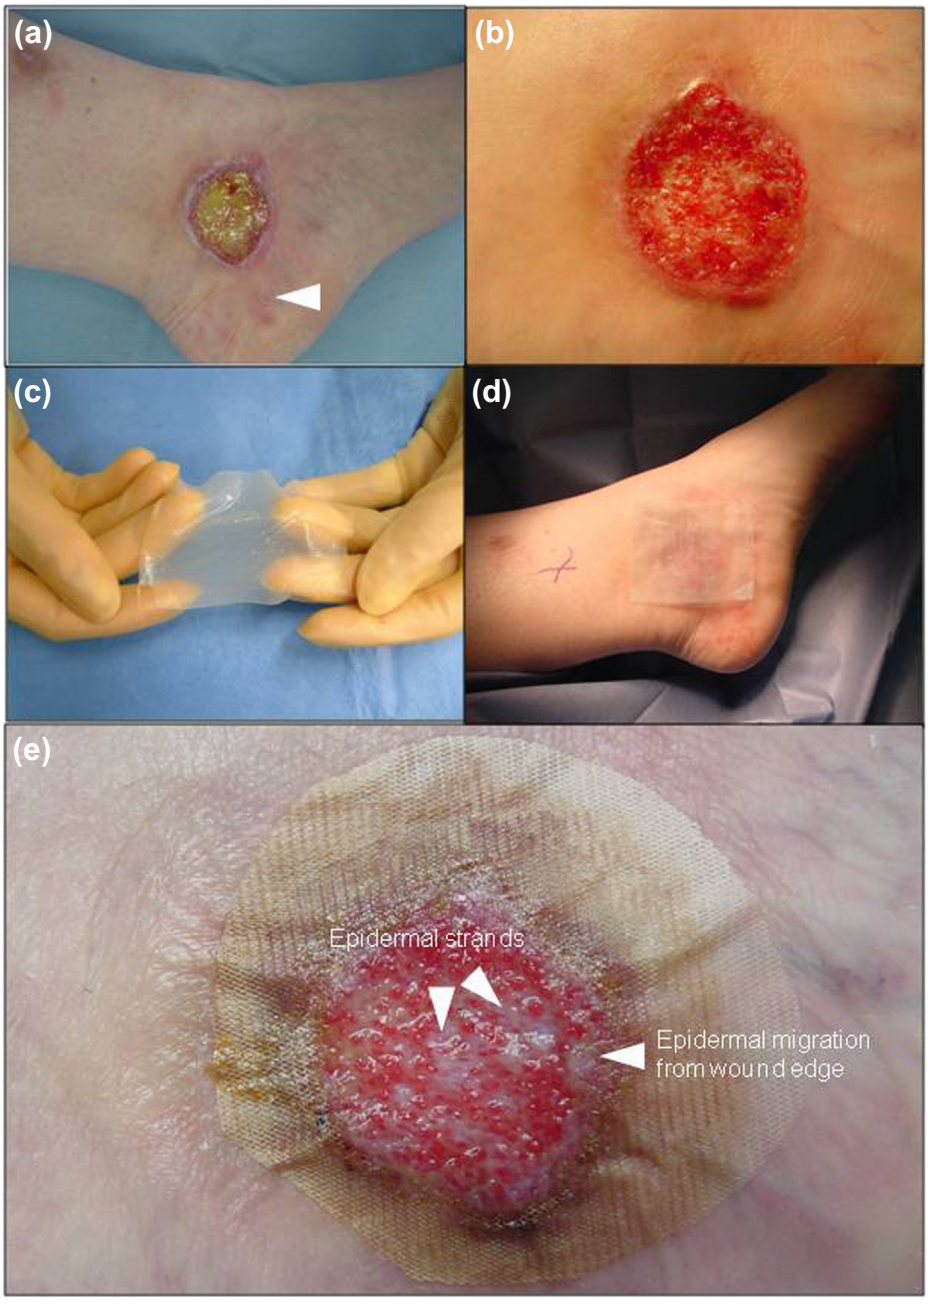

FIGURE 77.10
Treatment of vasculitis with Dermagraft. (a) Vasculitis at baseline. Arrowhead indicates livido pattern suggestive of vasculitis. (b) Appearance of wound after surgical debridement. (c) Dermagraft prepared for application. (d) Dermagraft applied to wound. (e) Wound appearance 14 days after applying Dermagraft. Granulation tissue has developed and there is evidence of epidermal migration (arrowheads). *(Copyright V. Falanga, 2012.)*

There has been some struggle to define exactly what constitutes optimal wound bed preparation but we have prepared a working scoring system to begin to investigate this issue [95]. Figure 77.11, taken from that publication, summarizes the scoring system. The Wound Bed Score (WBS) gives each of eight clinical parameters, assessable at the bedside) a score of 0, or 1, or 2. The maximum and best score is 16. Our experience with the WBS indicates that it is a useful starting point for deciding when to use a complex and advanced biological therapy.

PROPOSED MECHANISMS OF ACTION (MOA) OF BIOENGINEERED SKIN

As stated in the previous section, there are a number of bioengineered skin products that have been designed and in all cases, the mechanisms of action by which these bioengineered skin

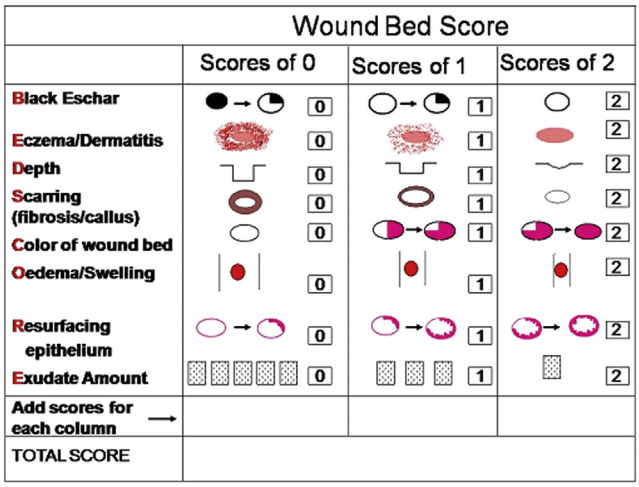

FIGURE 77.11
Wound bed scoring scheme. *(Copyright V. Falanga, 2007.)*

remains unknown. However, despite this, there is some strong evidence that supports plausible explanations of MOA. It has been stated that the delivery of living cells is associated with the release of growth factors and cytokines [62,96]. For example, it has previously been shown that, when wounded *in vitro*, Apligraf undergoes a staged expression of inflammatory cytokines and, later, growth factors, that is very much reminiscent of the normal process of wound healing [96]. Furthermore, a host of cytokines are produced by Apligraf, and there is evidence that its epidermal and dermal components work in concert to produce these mediators that would not normally be detected with the epidermal and dermal component alone [95].

Another interesting property of Apligraf, which is due to its unique bilayered configuration, is that it undergoes epiboly *in vitro* [97]. This ability to migrate over its own dermis suggests a very viable epidermal component, capable of allowing the construct to heal itself after injury [96].

The available evidence indicates that the cells from allogeneic constructs, including Apligraf, do not persist in wounds [98,99]. This has been shown in acute wounds as well as in venous ulcers, where the DNA from donor allogeneic cells is not detectable at 4–6 weeks, based on PCR-based detection of donor cells. Thus, there is strong evidence that true engraftment or prolonged persistence of cells from these allogeneic constructs does not occur. Apligraf may possibly persist longer when applied to patients with certain genetic conditions, as suggested by reports that Apligraf specific DNA may be detectable many more weeks or even months when the construct is applied in the wounds of young patients with EB, a condition characterized by a variety of genetic defects in molecules responsible for anchoring the epidermis to the dermis (i.e., laminin 5, type VII collagen) [100,101]. Still, in spite of lack of longevity of the construct, the clinical trial results indicate that even a few days or weeks of exposure of the wound to Apligraf have beneficial effects. Possible mechanisms include a more orderly and orchestrated release of cytokines, deposition of extracellular matrix material important for early migration of mesenchymal cells and keratinocytes, and even in the attraction of progenitor or stem cells from deep in the tissue or from the circulation [10].

Although it is tempting to think of Apligraf as a 'graft', available evidence indicates that this construct promotes secondary intention healing in an otherwise stalled wound. We have already discussed the issue of allogeneic cell longevity, which in itself speaks against the idea of Apligraf being a graft. Moreover, there is no evidence that wound bed blood vessels grow into Apligraf, as is commonly observed with autologous grafts. Perhaps most telling is the fact that, uniformly, Apligraf seems to stimulate the edges of this wound to migrate toward the center. This 'edge effect', which has also been reported with the application of living keratinocyte sheets, is the predominant observation with successful Apligraf treatment (Fig. 77.12). The edge effect strongly suggests that Apligraf does not act as a tissue replacement but,

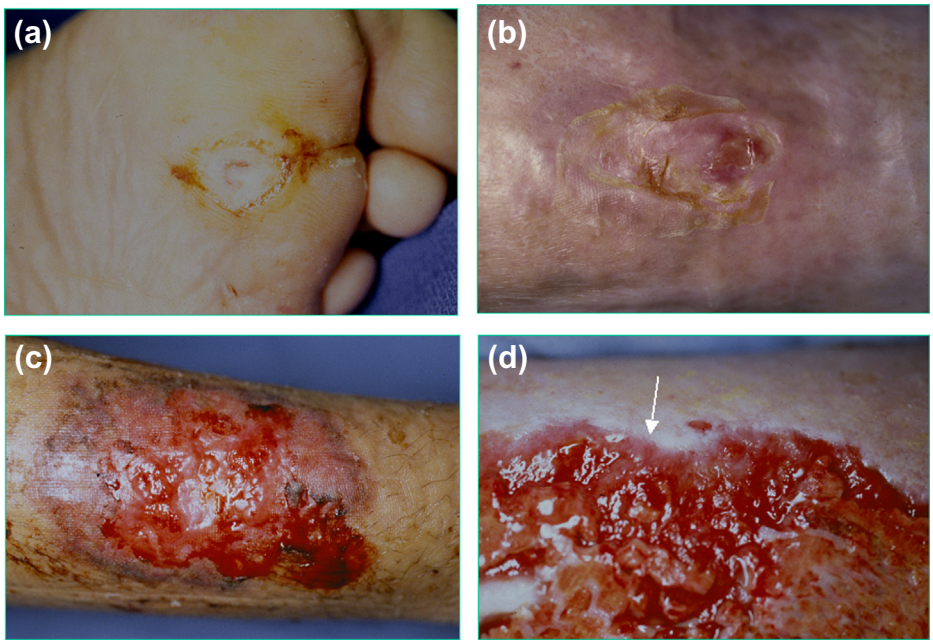

FIGURE 77.12
Different clinical appearances of wounds after Apligraf application. (a) Diabetic foot ulcer with white center representing degraded Apligraf remnants three week after application. (b) Venous ulcer six weeks post application. (c) Pyoderma gangrenosum only two weeks after Apligraf application and with thin layer of epidermis completely covering the wound bed. (d) Classical 'edge effect' (arrow) at the margins of a venous ulcer treated with Apligraf. The yellow material at the bottom of the pictures represent what is left of meshed Apligraf applied three weeks earlier. *(Copyright V. Falanga, 2006.)*

rather, stimulates secondary intention healing. Indeed, the rate at which the edges of a wound migrate toward the center has been used to determine whether eventual wound closure will occur, and Apligraf appears to accelerate wound edge migration [102].

CONSTRUCT PRIMING AND A NEW DIDACTIC PARADIGM FOR CONSTRUCTS

Two new concepts, priming and use of the construct in conjunction with stem cells, have emerged in our understanding of how constructs could potentially be used in different ways, even without modifying the initial manufacturing process of the product. These concepts are also mentioned by one of the authors (V. Falanga) in one of his recent publications on

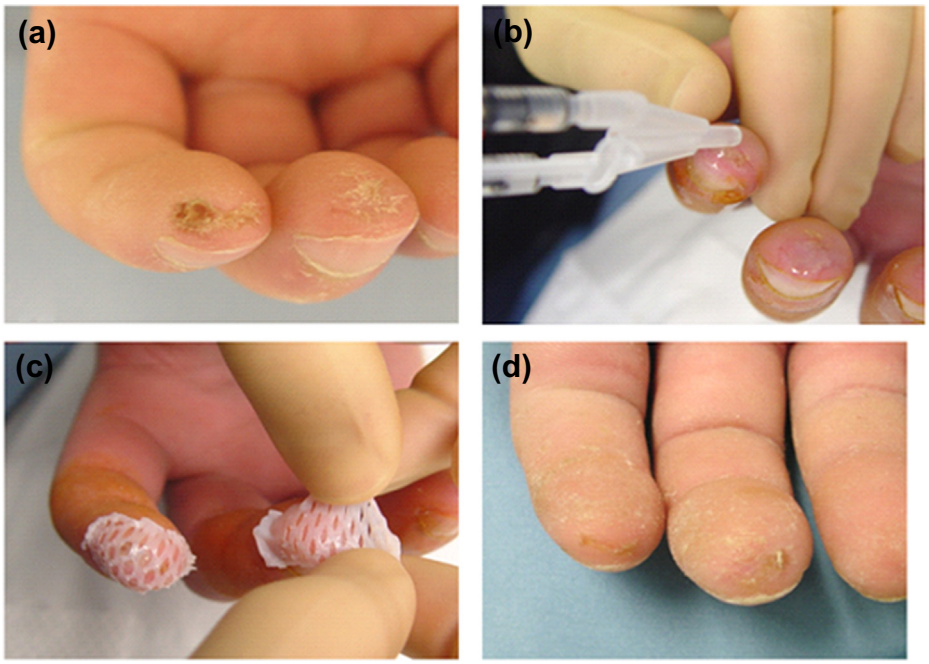

FIGURE 77.13
(a) Digital ulcers in a patient with systemic sclerosis (scleroderma). (b) autologous cultured bone marrow-derived mesenchymal stem cells being applied within a fibrin delivery system. (c) The digital ulcer was dressed with bioengineered skin (Apligraf). (d) Results observed one month later. *(Copyright V. Falanga, 2011.)*

bioengineered skin [102]. If priming proves to be clinically feasible, it would lead to a construct containing a richer and augmented repertoire of activated genes and proteins before it is applied to the wound. It has been demonstrated that this is possible using Apligraf as proof of principle *in vitro* and *in vivo* [103]. Indeed simple incubation of the construct for 24 hours in Dulbecco's Modified Eagle Medium (DMEM) plus 10% FBS leads to increased transcription (up to 200-fold) of hundreds of genes related to cellular proliferation and migration (V. Falanga, unpublished). The results obtained by microarray suggest that IL-6 is the most stimulated gene after using this priming step, and the results have been confirmed by western blot and by immunohistochemistry.

Another potentially useful concept, especially with the current interest in stem cells, is that bioengineered skin could be used in conjunction with stem cells to provide them with a didactic component and guidance for their differentiation. The wound bed can be treated with autologous bone marrow-derived cultured mesenchymal stem cells, and bioengineered skin can then be placed over the stem cells. We have successfully used this approach with scleroderma digital ulcers (V. Falanga, unpublished), and by delivering the stem cells with a modified fibrin spray. However, more work needs to be done to confirm these findings and to conduct appropriate clinical studies. Fig. 77.13 illustrates this type of approach [103].

CONCLUSION

Bioengineered skin constructs have played a lead role in the tissue-engineering field, particularly in terms of commercial successes. Like the natural tissue these constructs are designed to mimic, the engineered tissues are proving to be dynamic in the way they respond to environmental stimuli. The understanding of how these products induce healing is evolving. Greater understanding into how engineered tissues promote wound healing is being achieved through the clinical research, presented above, being done with Apligraf in different wound types. Initially the action was believed to be similar to skin grafts where the patient's native tissue was replaced with the graft tissue. It is now believed that the mode of action is more complex. Stimulation of healing by secondary intention appears to be the primary mode of action however there may be other mechanisms at work as well. The work being done in this area is very exciting and researchers have only begun to scratch the surface in terms of understanding the mechanisms and environmental stimuli involved.

Tissue-Engineered Food

This page intentionally left blank

CHAPTER 78

Principles of Tissue Engineering for Food

Mark Post[1] **and Cor van der Weele**[2]
[1] Department of Physiology, Maastricht University, The Netherlands
[2] Department of Social Sciences, Wageningen University, The Netherlands

INTRODUCTION

Most techniques in tissue engineering were developed for medical applications. The potential benefits of tissue engineering and regenerative medicine for the repair of non-regenerative organs in the human body have not really been questioned. It is generally accepted that these technologies offer therapeutic opportunities where very limited alternatives are at hand to improve quality of life. Therefore, a tremendous amount of government funded research and business R&D has been and continues to be devoted to tissue engineering. Still, 25 years after its introduction, regenerative medicine by tissue engineering is not yet part of mainstream medical therapy [1]. This suggests that the technical challenges to generate tissues that are fully functional and can immediately replace damaged tissue are substantial.

As a spin off from this research activity, techniques in tissue engineering and regenerative medicine may be used to produce organs to produce food. This idea is not new and had in fact been proposed by Winston Churchill in his 1932 book 'Thoughts and adventures' [2] and by Alexis Carrel [3]. Although the biological principles of tissue engineering of food are very similar to the medical application there are also differences in goals, scale of production, cost-benefit ratio, ethical-psychological considerations and regulatory requirements.

In this chapter the distinctions between the challenges of tissue engineering for food production are highlighted and discussed. The focus will be mainly on tissue engineering of meat as a particularly attractive and suitable example.

WHY TISSUE ENGINEERING OF FOOD?

Growing food through domestication of grasses, followed by other crops and livestock has a 13,000 years head start. The success of economical food production likely determined the growth and sophistication of our civilization [4]. Why would we try to replace the relatively low-tech, cheap and easy natural production of food by a high-tech complicated engineering technology that is likely to be more expensive? There are two main reasons why current ways of food production need to be reconsidered.

First, with growth of the world population to 9.5 billion and an even faster growth in global economy, traditional ways of producing food, and in particular meat, may no longer suffice to feed the world [5]. Food security is already an issue for some populations, but absence of this security may spread across all civilizations due to generalized scarcity of food. Meat production through livestock for example already seems maximized by the occupation of 70% of current

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00078-1

arable land surface, yet the demand for meat will double over the next four decades [6]. Without change, this will lead to scarcity and high prices. Likely, the high prices will be an incentive for intensification of meat production, which will increase the pressure of using crops for feed for livestock instead of feeding people. The arable land surface could be increased but this would occur at the expense of forests with predictable unfavorable climate consequences. Lifestyle changes that include the reduction of meat consumption per capita would also solve the problem, but historically this seems unlikely to happen. A technological alternative such as tissue engineering of meat might offer a solution. In fact, the production of meat is a good target for tissue engineering. Pigs and cows are the major sources of the meat we consume, and these animals are very inefficient in transforming vegetable proteins into edible animal proteins, with an average bioconversion rate of 15% [7]. If this efficiency can be improved through tissue engineering, this will predictably lead to less land, water and energy use for the production of meat [8], which introduces the second major reason why alternatives and more efficient meat production should be considered.

Livestock accounts for approximately 20% of total greenhouse emission [9]. Economizing meat production may therefore be an ecological imperative, improving the condition of the energy, water and food nexus.

In addition to these major issues with industrial dimensions of livestock breeding and feeding, there is an increasing public pressure to improve animal welfare and to reduce the risk of zoonoses.

Although there are other alternatives to avert an imminent meat and food scarcity, a technological solution might include tissue engineering of skeletal muscle and other tissues. It could be an excellent example of valorization of medical technologies that goes well beyond the traditional medical need and market.

SPECIFICS OF TISSUE ENGINEERING FOR MEDICAL APPLICATION

The general outline of tissue engineering (TE) for food is exactly the same as for tissues constructed for medical purposes. Somatic cells are seeded onto or printed with a temporary scaffold made of biocompatible natural or synthetic polymer. Subsequently, the cell scaffold combination is cultured under tissue specific biochemical and physical conditions to mature into the target tissue until it reaches maximum resemblance with the targeted tissue in the recipient.

However, there are differences as well that could have major implications for the technologies that need to be developed and used.

Uniqueness

To avoid immunologic or physiologic host versus graft reactions, medical tissue engineering aims to create a tissue construct that is mostly personalized and produced as a unique sample or at best in a limited volume [10]. Its uniqueness is determined by its shape and form and by its cellular components. The shape and form is adapted to the particular environment in the recipient by for instance rapid prototyping, molding or casting [11]. In some applications this might be achieved by computer assisted design linked to printing or molding equipment so that it can be automated. In other applications however, molds and casts are hand-made and therefore labor intensive and expensive.

In many examples of medical tissue engineering, cells producing the construct are of homologous origin, thus patient derived [12]. The number of tissue specific cells or even progenitor cells that can be harvested from patients is typically small and needs to be expanded before they can be used to populate a construct. The amount of cell culture that is required to reach sufficient cell numbers is a time and labor intensive process, especially when performed

for one sample of a personalized product. In many cases, the tissue still needs to undergo some form of conditioning, which again is time and labor intensive.

Thus, the production of patient-specific products is labor and time intensive and therefore extremely costly. In a medical application the cost of production is weighed against the benefit for the patient, which is usually expressed in quality adjusted life years (QALYs) that are gained through therapy. The value of a single QALY is set at approximately 40,000 USD [13], which sets the economic boundary condition of producing tissue-engineered constructs for medical application. The cost-benefit analysis will be very different between medical application and food production.

Function

Once implanted, the tissue-engineered products need to be functional and metabolically active, which means that they need to integrate with the circulation, the nervous system and the endocrine regulation. The integration is not only important to sustain and coordinate function (12); it is also crucial for homeostatic control by the recipient body. A good example is tissue-engineered myocardium to replace scar tissue in the heart that has developed after myocardial infarction. Myocardial tissue is continuously active in a highly coordinated and internally as well as external regulated. Implanted tissue-engineered constructs need to be fully integrated to maximize efficacy and minimize the risk of adverse effects (see Box 78.1).

BOX 78.1

Myocardial tissue has an extremely high metabolism to support the arduous labor of continuously alternating contraction and relaxation. To supply the tissue with sufficient nutrients and oxygen and to remove waste, the heart is highly vascularized with a microvascular density of one capillary per cardiomyocyte [14]. Without sufficient blood supply, tissue-engineered myocardial constructs would die within 30 min. The newly implanted myocardium also needs to integrate electrically with its neighboring myocardial cells. The heart shows continuous and highly integrated electrical activity as illustrated by the typical monomorphic and regular electro cardiogram (ECG). Failure to integrate through dyssynchronous electrical activation or through regional changes in conduction velocity can lead to lethal arrhythmias. Indeed in early trials using skeletal myoblasts to replace myocardial tissue, arrhythmias constituted the principle risk [15]. In addition to these already challenging forms of integration, the heart is a key effector in the homeostatic control of the body for instance during exercise, meals or abrupt changes in temperature. The heart is therefore under tight control of the autonomic nervous system, which regulates heart rate, contractility and coronary flow according to requirements imposed by the body. The implanted tissue needs to respond to these stimuli in concert with the native tissue to avoid dyssynchrony in electrical and mechanical activity during exercise for instance. An even more sensitive homeostatic mechanism that is essential to coronary flow regulation is the autoregulatory control of blood vessel diameter through organ specific myogenic responses of the vascular smooth muscle cells [16]. Organs such as the brain, heart and kidney have an important autoregulatory blood flow control that is partly dependent on these myogenic responses. At present it cannot be predicted how lack of this response would affect the function of the implanted tissue engineered myocardium, but it would be safe to optimize engineered tissues for all anatomic, histologic and physiologic characteristics.

The example of the heart illustrates the immense challenge for engineers and biologists to create a fully integrate tissue from cells of defined stages of differentiation and from biomaterials. Some of these challenges might be theoretical and will be resolved by remodeling of the construct after its implantation, but others might prove essential for safety and function.

SKELETAL MUSCLE AND FAT TISSUE ENGINEERING

To understand the specific requirements of tissue engineering of consumption meat a brief summary of the state of the art techniques to tissue-engineer skeletal muscle and fat is necessary. It is envisaged that the first tissue-engineered meat will be some form of processed meat such as in hamburgers or sausages. Producing processed meat is in that scenario translated into tissue engineering a large number of separate pieces of tissue that are later combined into a patty or a sausage.

Cells

The satellite cell is considered to be the tissue specific stem cell, responsible for *in situ* regeneration of damaged muscle although more pluripotent skeletal muscle derived stem cells have been described as well [17]. Culturing of skeletal muscle cells from satellite cells includes a proliferation phase followed by differentiation (Fig 78.1).

The goal of the proliferation phase the goal is to maximize the number of doublings. With the current isolation and culturing methods for satellite cells 30 doublings can be achieved. With proper conditions this can probably be improved to 50–70 doublings. A major improvement to keep the satellite cells in the replication phase comes from harvesting them through a combination of mild enzymatic treatment and trituration of remaining skeletal muscle fibrils according to Collins et al. [18]. Once harvested, the stem cell behavior is maintained in a niche environment [19]. The elasticity of the substrate for instance, seems important to maintain the stem-cell-ness of the satellite cells being cultured [20]. In our hands,

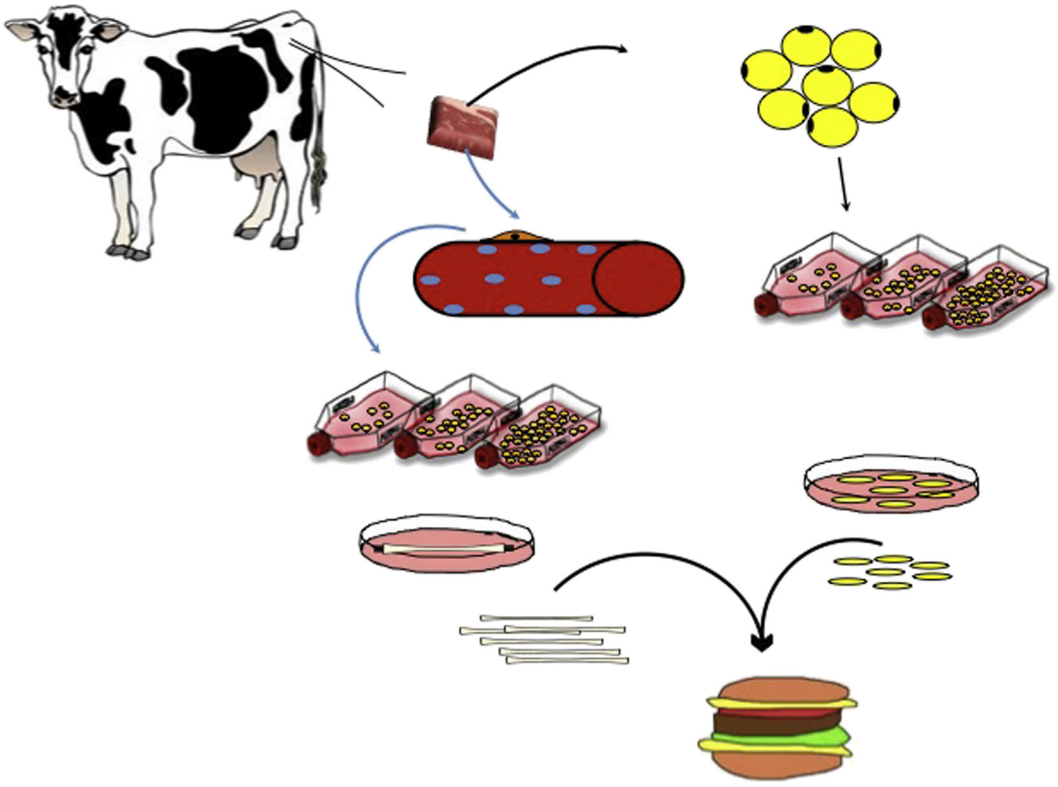

FIGURE 78.1

Tissue engineering of meat. From a biopsy of a cow, adipose tissue derived stem cells (ASCs) and satellite cells are harvested and cultured separately. The satellite cells are seeded in a gel onto a culture plate with anchor points (black pentagonal shapes). They self-organize into a bioartificial muscle. The ASCs are differentiated into adipocytes and cultured in a gel or scaffold, without the need for anchors. Minced meat, a hamburger for example, will be constructed from a mixture of bioartificial muscles and fat tissue.

the effect of physiologic substrate stiffness on myoblast cell proliferation was mild, higher than on very flaccid substrates (3kPa range) but not significantly different from stiff, plastic, surfaces [21]. Coating the culture surface with laminin and collagen IV, two major basal membrane proteins, has also some impact on the proliferation rate of satellite cells [22]. In addition, there are many biochemical stimuli for such as TGFβ1, Pax7, Notch and Wnt [23]. These mechanisms can be targeted with specifically designed agonists or with known biological modulators in order to delay differentiation.

Scaffold and seeding

Differentiation is primarily initiated by reducing the serum concentration in the medium. Cells are typically cast in a collagen gel with or without Matrigel™ supplement or they are seeded into a biodegradable polymer structure. In case of the casting in the gel it is important to provide anchor points in the culture dish. Typical for mesenchymal cells, differentiating satellite cells will organize the gel to the smallest structure possible. With the anchors provided the smallest configuration is a thin tissue strip in between the anchors. This will later form the myooid or bioartificial muscle (BAM, Fig 78.2) [24]. Differentiation leads to merging of satellite cells into primitive skeletal muscle cells, called myotubes. At this time, the cells will start to express early stage skeletal muscle markers such as MyoD, myogenin and embryonic isoforms of muscle myosin heavy chain [24a]. The cues for subsequent hypertrophy are of metabolic, biochemical and mechanical nature. After organization into a BAM and with subsequent differentiation, the muscle will develop increasing tension between the anchor points. This tension development is major trigger for protein production [25], the optimization of which is the final goal of tissue engineering of food. Several other mechanical stimuli such as passive cyclic stretch and electrical stimulation have been investigated. Interestingly, cyclic stretch did not further improve protein synthesis but had in fact a slight negative effect [26,27]. This result is somewhat controversial, as others have observed positive effects of cyclic stretch on muscle maturation [28]. In addition to passive stretch and tension, we and others have investigated the effect of electrical stimulation to further stimulate protein production and force generation [29]. In combination with specific coatings, electrical stimulation did lead to earlier maturation of the skeletal muscle fibers and more protein production. A more extensive review on the modes and efficacy of mechanical stimulation for muscle differentiation can be found at [30].

With the above described techniques it is feasible to generate BAMs of small dimensions, limited by the dependence on an adequate nutrient and oxygen supply through diffusion. No attempts

FIGURE 78.2
A bioartificial muscle from bovine satellite cells, three weeks after loading the gel onto the culture dish with anchors (black).

have been made yet to create large BAMs with a built-in blood vessel or channel system conducting a continuous flow of oxygenized, nutrient-rich medium. However, printing and biomaterial technologies have been described that would make this possible and certainly testable [31,32].

Although contractile proteins comprise the bulk of protein content and quality of muscle tissue, there are other proteins that are important for texture, color and taste of the muscle tissue. One particularly important protein is myoglobin. As a heme-carrying protein it is in part responsible for the pink color of meat and since it is a major carrier of iron, its presence will likely determine taste as well. The transcriptional regulation of myoglobin is reasonably well understood and involves the transcriptional activators MEF2 and NFAT/calcineurin [33] and co-activator PGC-1α. It appears that contractile activation of muscle in the setting of hypoxia will stimulate myoglobin maximally. It seems therefore feasible to increase the myoglobin content using stimuli that are compatible with tissue engineering of products that eventually should be consumed.

In summary, the effective culture of skeletal muscle is possible with current technology. There are numerous options for refinement and extension suggesting that it will take time and effort to optimize the product. Current progress however suggests that an acceptable mimic of meat tissue can eventually be generated.

Tissue engineering of fat

CELLS

The tissue engineering of fat tissue is less advanced than that of skeletal muscle because the medical need seemed less pressing. Indeed for the purpose of plastic surgery, tissue engineering of fat might be applicable in the clinic and scant efforts have therefore been made to create adipose tissue constructs [33a]. Also, differentiation of mesenchymal stem cells (MSCs) into adipocytes is one of the hallmarks of MSC phenotyping and as a result the various steps towards differentiation have been described in great detail.

BIOCHEMISTRY OF ADIPOCYTE DIFFERENTIATION

Pre-adipocytes are precursors of fat cells and determined by the expression of PREF-1 (pre-adipocyte factor 1 aka Dlk-1 or delta-like 1 homologue), CD105 (endoglin) and the absence of CD45 and CD31. These cells are typically fat tissue derived and therefore often referred to as Adipose tissue derived Stem Cells (ASCs). These collagenase-extracted, plastic, adherent cells initially comprise a heterogeneous population [34] that can differentiate into adipocytes, chondrocytes, and osteocytes. Unfortunately, these cells undergo limited proliferation and after a couple of passages they lose their capacity to differentiate [35] and are therefore not suitable for the tissue engineering of food. In contrast, human multipotent adipose derived stem cells (hMADS) that are derived from infants continue to proliferate and retain their differentiation capacity [35]. It remains to be shown if this is a consistent finding across species. If so, MADS can be harvested from young animals and these cells can then be used for tissue engineering of edible fat. An alternative cell source for production of fat tissue has been obtained by so-called ceiling culture of digested human adipose tissue [36]. In this technique two types of fibroblast like cells can be distinguished that both have a strong capacity to proliferate while retaining their ability to differentiate into adipocytes. It is likely that these cells can be harvested from bovine adipose tissue, as it has already been successful in humans, rats and sheep [36]. Differentiation of pre-adipocytes is typically initiated by starvation and a temporary cocktail of isobutylmethylxanthine (IBMX), dexamethasone and insulin. In some protocols, triiodothyronine [37] and or the PPARγ ligand Rosiglitazone [38] are added to the differentiation stimulus. It remains to be shown how much and if any of these stimulators are still present upon harvesting of the tissue after 3–4 weeks of differentiation, replacement of these agents by approved food additives is advisable.

IBMX is a very potent methyl-xanthine and a non-selective phosphodiesterase inhibitor that is not approved as a drug. IBMX induces the activation of PPAR$_\gamma$, which is a critical transcription factor required for adipocyte differentiation [39]. It probably acts through induction of intracellular cAMP. If so, other agents that act through induction of that second messenger and that are approved for drug or food purposes can replace IBMX. Dexamethasone is a glucocorticosteroid that acts through the intracellular glucocorticosteroid receptor (GR) through a number of intermediate products that eventually upregulate another major transcription factor, which in turn promotes adipocyte differentiation: C/EBPα (CCAAT enhancer binding protein). The steroid stimulated GR interaction with promotor elements in the intermediate products is required for its function; therefore it will be difficult to find a suitable substitute. The third component is insulin, which is typically short-lived and is therefore less likely to be a regulatory issue.

SCAFFOLD AND CELL SEEDING

The fat cells can be captured in a scaffold to form fat tissue. The same considerations apply that were presented for skeletal muscle tissue engineering, yet the specific biochemical and physical cues needed to mature and maintain fat cells are likely to be different from satellite cells. It is evident from the experience from many investigators that mature fat cells are fragile, prone to apoptosis and are terminally differentiated so they no longer can expand. For that reason, most cell seeding on scaffolds is performed in the pre-adipocyte stage [40–43], or is even performed with cell lines such as the mouse 3T3L1. In the vast majority of studies the constructs were implanted at an early stage and *in vivo* adipogenesis was allowed to develop for a couple of weeks after which the state of differentiation was assessed. This suggests that it is difficult or time consuming to reach full adipocyte differentiation and mature fat tissue by *in vitro* conditioning alone. A good summary of material and cell combinations that have been studied can be found at [43]. The specific requirements for the biomaterial component of fat tissue-engineered constructs for food purposes are:

1) Non-toxic biomaterial, degradation products or biochemical additives
2) Non-allergenic biomaterial, degradation products or biochemical additives
3) Residual biomaterial should be digestible
4) The scaffold should support full maturation of fat tissue *in vitro*

Any of these characteristics is unchartered territory and the present information on scaffold-adipocyte combinations should be re-evaluated in light of these requirements.

It is likely that non-toxicity of ingested material correlates with biocompatibility in current cell-based assays. If a particular biomaterial is not cytotoxic in direct exposure to cells it probably is not toxic after ingestion either. This reasonable hypothesis however, should be formally tested for each biomaterial as it is conceivable that rapid mechanic and enzymatic degradation by the gastrointestinal system release other or highly concentrated cytotoxic metabolites. The biomaterials that have been tested with adipocytes all conform to the requirement of being non-cytotoxic.

Non-allergenicity is less obvious. Most proteins and ingestible materials do not lead to an allergic reaction, but some foods, such as eggs, milk, shellfish and peanuts are particularly allergenic [44]. Bio-based materials that have been used for engineering adipose tissue include collagen [45], hyaluronic acid [46], fibrin [47], and chitosan [48]. Except for the latter, we already have bio-based materials in our present diet, so it is not to be expected that tissue-engineered food with these material will augment the risk of food allergy.

Of the synthetic or semi-synthetic biomaterials, poly(lactid-co-glycolic acid) (PLGA) [49] and esterified hyaluronic acid [46,50] are the most promising in terms of *in vivo* differentiation of adipocytes. In some studies, the addition of FGF-2 seemed to facilitate adipose differentiation. Confirming the results of others, but using bovine ASCs, we observed little development of fat tissue in electrospun PLGA scaffolds and fibrin sheets (preliminary data).

As for skeletal muscle engineering and mesenchymal stem cell differentiation, the stiffness of the matrix may be a particularly interesting parameter to affect specification and maturation of ASCs *in vitro* [51]. Human bone marrow derived MSCs assume quiescence when placed on a 250 Pa surface, which represents the natural elasticity of fat tissue. In this quiescent state they cease to proliferate, enter differentiation and develop into adipocytes that adipose tissue [52].

Recently the use of decellularized extracellular matrix has been gaining attention in regenerative medicine [53]. It is obvious that this technology will not be applicable in tissue engineering of food, since you first need to harvest the original tissues and the animals would still have to be bred as donors of these tissues. While the volume of tissue generated during culture cannot be drastically increased, such a practice would not result in higher efficiency of meat production or a reduction in livestock.

In summary, the optimal scaffold and biomaterial conditions to grow edible pieces of fat through tissue engineering will be a combination of chemical, biochemical and physical factors. The goals are in part different from fat tissue engineering in, for instance, reconstructive surgery and many variables have not been optimized yet.

SPECIFICS OF FOOD TISSUE ENGINEERING

The two major advantages of tissue engineering of food are that the eventual product can be made in large series, and also that it requires no functional integration. Instead, food tissue engineering faces at least three new challenges.

The first is the opposite of small-scale individualized production of medical tissues. To generate sufficient tissue volume to feed large populations, the scale of cell culture and tissue culture and/or conditioning will be several orders of magnitude higher than needed for medical application. The focus of tissue engineering for food will therefore shift from individual construct production to mass production. This shift has major implications for bioreactor design, biomaterial selection and production, culture medium optimization, optimization of tissue conditioning and quality control of for instance the genetic stability of the cells.

Second, food production by tissue engineering can only be a viable alternative to conventional livestock meat production if the bioconversion of vegetable proteins to edible animal proteins is more efficient than in the common domestic animals such as cows and pigs.

The third challenge is that tissue-engineered food needs to be very similar if not exactly the same as the conventionally produced food it intends to replace. Meat for example, has been replaced with very limited success by products made of vegetable proteins. The typical texture, color and taste of meat are apparently still very difficult to mimic through current innovations in food technology. In some cases, the science of these characteristics is not far enough advanced to design rational strategies for synthesis. For instance, the chemistry of the taste of meat is very complex and incompletely understood and therefore mainly relies on subjective analysis by taste panels [54].

Scale

The volume of global meat production is 293 million tons/year [55]. Given that each gram of muscle tissue contains approximately 5×10 [6] cells, this amounts to 1.5×10 [21] cells/year, provided that all muscle progenitor cells differentiate into mature skeletal muscle cells and get incorporated into skeletal muscle. This number may be an order of magnitude off, due to inaccuracies with respect to muscle type, fat content etc., but it provides an estimate of the rough scale at which cell production needs to be industrialized.

Currently, large bioreactors have a capacity of up to 25,000 liters or more, with a maximum cell load of 7×10 [6] cells/mL; i.e., 35×10 [9] cells/bioreactor [56,57], provided that the cells are cultured in suspension. Mesenchymal cells such as satellite cells need to adhere to surfaces to

sustain proliferation and survival. Several microcarriers have been designed to grow large numbers of adherent cells in large volume bioreactors [58]. This would require a stage in the process where cells are again detached from the carriers, which could be as simple as just changing temperature [59]. The limits on bioreactor size and number of cells per mL further depend on a number of factors such as oxygen transfer, nutrient delivery, and washout of waste. These factors are all related to unequal mixing of the fluid. Stirring or otherwise agitating the cell mixture might solve most of the problems, but there is a limit to the agitation that mammalian cells can handle in the absence of a firm cell wall that withstands high shear stresses [60].

As a result, the cells may suffer from insufficient and inhomogeneous transfer of oxygen and nutrients [60]. Inadequate mixing of bulk fluids also becomes more difficult as the volume of the bioreactors increases. Simulations in smaller tanks show that gradients of pH and nutrients reduce cell growth and maturation [61]. Another important factor in scaling-up cell culture in large bioreactors is adequate removal of CO_2. Carbon dioxide is typically removed from the medium through a combination of agitation and sparging: controlled air bubble inlet to retrieve CO_2 from liquid to the gas phase. Accumulation of CO_2 presents an important limit to mammalian cell culture due to the relatively low agitation and air sparging rates that are utilized [62]. The optimal dissolved carbon dioxide (dCO_2) level at which cells thrive varies between cell types, but relatively high dCO_2 levels universally inhibit cell growth and protein production [63,64].

Even when the technical limitations of large-scale cell culture are overcome, the sheer amount of cells needed to produce sufficient meat to feed the world population in 2050, would still require a mind-boggling amount of bioreactor space. Assuming that each bioreactor has a four week turnover of its cell content and would therefore have 13 operation cycles per year, one would still need 600 million bioreactors of 25,000 L, roughly one for every 10 humans. This already staggering figure does not even take into account that a seed train is needed to get sufficient cells for the initial start of a large volume bioreactor culture [57]. In addition, for skeletal muscle production to produce protein rich and firm muscle tissue, the proliferation phase should be followed by differentiation and conditioning of the muscle progenitor cells, which also requires bioreactor space.

For this volume of bioreactor space one needs equivalent volumes of culture medium. The production and storage of these amounts of medium will be a logistic challenge unless powder formulations are being developed that can be easily reconstituted within the same production line as the cell culture. In making powder formulations of medium, the addition sequence and the milling equipment seem to be important parameters [57].

Directly related with the scale of cell culture is the quality control of the progenitor cells. Cells may undergo differentiation towards undesirable phenotypes, they may be epigenetically modified or they can accumulate karyotypic abnormalities over time. For safety and efficacy reasons these undesirable outcomes should be detected and controlled [65,66]. Current technologies such as polymer chain reaction (PCR) and fluorescent *in situ* hybridization (FISH) are not designed for large sample sizes or for in-line monitoring of quality. Several other techniques based on surrogate physical parameters such as electric conductivity have been developed that are capable of in-line monitoring of the cell culture process, which will hopefully be sufficiently robust to guarantee quality of the cell culture [67].

From these considerations it may be clear that scaling-up mammalian cell culture to the level that is needed for safe and high quality production of one of our basic foods is a non-trivial enterprise and requires substantial innovation through chemical and mechanical engineering in close collaboration with cell biologists.

Efficiency

Although cell culture of mammalian cells has been evolving over the last five decades, relatively little attention has been paid to optimization of the culture process in terms of efficiency.

In such an optimization strategy, hundreds of variables can be – and have to be – controlled to make the process reliable and efficient. These variables include all individual components of medium and serum, but also physical culture conditions. The vast number of variables that likely interact and therefore need to be approached in their contexts creates challenges as well as opportunities. The level of each variable (e.g., feed component, biochemical and biophysical culture conditions), and the possible interactions with other variables need to be established. Current culture protocols have largely developed through trial and error, leading to a gradual optimization, whereas it clearly requires a more systematic approach. For bacteria and simple eukaryotic organisms such as yeast a systems biology approach is starting to be developed [68–70]. Either a biological systems strategy should be developed for more complex mammalian cells as well or a large-scale, high-throughput analysis should be set up to optimize culture media. This is true for the synthetic part of the culture medium as well as the serum part; together, a formidable task. Eventually, culture media should be completely synthetic and devoid of serum products. A limited number of such products have been developed for medical purposes and it is to be expected that more of these will become available [71,72]. In our hands, serum-based media are still superior to synthetic ones (unpublished data).

Opportunities to increase the efficiency of skeletal muscle cell culture are also numerous. In the production phase, recycling mechanisms and combining culture with nutrient supplying systems through for instance photosynthesis would create substantial benefit and value [8]. Given the scale of cell culture, these recycling mechanisms need to be an integral part of the production chain.

Taste, texture, juiciness

A large number of small peptides and fat dissolved aromatic substances have been described that contribute to the taste of meat [54,73–76]. However, the relative importance of each component is unknown. The reaction between certain sugars or glycosylated peptides and fatty acids probably interact especially during heating of the tissue to create the specific taste of meat in the so-called Maillard reaction [77,78]. Taste is a subjective sensation and blinded panels in fact still primarily judge the taste of meat. To add to the complexity, in addition to the chemistry of the meat, the cultural background of the panelists appears to weigh in their evaluation of meat products [54]. It has become clear that the taste of meat can be affected by feed and not so much by the strain of cattle [75], suggesting that the feed conditions of the cultured skeletal muscle is important for taste development. Even postmortem conditions determine the taste of meat, as a result of oxidation of proteins, sugars and fatty acids during controlled decay of the muscle [74]. Thus, in the tissue engineering of meat, taste is an extremely important feature to be investigated and taken into account. On the other hand, culturing of meat while controlling various conditions very precisely will greatly contribute to meat science in general and in particular to the effectors of taste.

The texture of meat is mainly determined by the presence of intramuscular connective tissue and its perimysial distribution [79] and the amount and distribution of fat [80]. Fat is also the main determinant of juiciness, although the percentage of fat in various meats shows modest variability between 0.5% to 8.0% with a 3% average [81]. As intramuscular connective tissue and content can be affected by feed, these characteristics can likely also be optimized in cell culture and should be primary targets for producing high quality meat.

It is not obvious that tissue-engineering food is a cheaper proposition than other alternatives such as vegetable protein meat replacers. Therefore, the outcome should be indistinguishable from livestock grown meat in terms of taste, color, texture, and juiciness. The quality should also be constant and preferable more predictable than for the natural product.

ENHANCED MEAT

Tissue engineering of meat enables the creation of novel products. All vertebrate animals have satellite cells in their muscles and currently there is reason to believe that skeletal muscle can be tissue engineered from these species. We have found that very small adjustments in protocols were needed to transfer satellite cells from mice, rats, pigs or cows into mature skeletal muscle. Novel meats could be made from hitherto unused species or from combination of cells sources. It is however more important to design and produce cultured meat that is healthier than the original product.

One particularly interesting example is increasing the content of conjugated linoleic acid (CLA; octadiendecadienoic acid 18:2). CLA is naturally present in meat, and the main source of our dietary CLA is beef fat and bovine milk [82]. CLA is formed in the stomach by bacteria that conjugate linoleic acid which is subsequently taken up by the fat cells. This mechanism can be used to load tissue-engineered fat with CLA to increase it to levels that are associated with anti-carcinogenic, anti-diabetic, and anti-atherogenic effects, as well as a strengthening the immune system, bone metabolism, and improving body composition [82].

OTHER FOODS

Although the tissue engineering of meat is probably the first and best example of food production through this technology, there are other foods that could be tissue engineered. Currently, the need to create an efficient alternative to agricultural food production precludes tissue engineering of crops and of meat from animals that have a high bioconversion rate, such as fish. However, if some fish species are threatened with extinction, tissue engineering of fish meat might also be considered. In fact, the first showcase of tissue-engineered food constituted some goldfish meat to be used by astronauts on their space missions [83].

Milk production by tissue-engineered mammary glands might also be feasible in the future. If cows are no longer needed in large numbers for meat production, an alternative method to produce milk should also be found. A recent study showed that bovine mammary gland stem cells could be isolated with techniques described earlier for their human counterparts. The bovine stem cells recapitulated the organization of bovine mammary tissue, and they produced milk. The investigators conclude that there is a potential for novel engineering and transplant strategies and a variety of commercial applications, including the production of modified milk components for human consumption [84].

Lastly, organ meats such as stomach, liver, kidney, or sweet breads might be future target foods to be tissue engineered.

CONSUMER ACCEPTANCE

Tissue engineering for medical purposes usually provides treatment options in situations where very few alternatives are present. For food tissue engineering the situation is completely different. In fact, novel tissue-engineered foods are competing with highly valued products that have been around for centuries. It is to be expected that tissue-engineered meat will generate a wide societal interest and a diversity of responses.

It has been proposed by various parties that research into tissue-engineered meat represents one of the more promising and morally responsible efforts to overcome the problems of global meat production [85,86].

Positive responses often stem from considerations of animal welfare, since this technology promises to enable meat consumption that reduces harm to animals. Many people, including many meat eaters, dislike the idea of animal suffering and dying; the prospect of meat with fewer animal victims therefore inspires great moral hope [87,88]. That the production of

tissue-engineered meat may also substantially reduce burdens on land and water use, in comparison with conventional meat production, is another source of hope.

More reluctant responses are also voiced, for example in the form of an immediate adverse opinion, often indicated as 'yuck'. A pilot exploration with the help of brief interviews [89] found that this initial response was connected with two associations: the thought that such meat is increasingly muddled with the idea of genetically modified (GM) food [87,89]. Both associations are informative of the cultural context in which the meaning of tissue-engineered food is taking shape and in which moral judgment and emotion influence each other in complicated patterns of mutual causality [90].

'Muddling with meat' refers to the growing moral ambivalences that surround meat. Latent feelings of uneasiness are inherently connected with meat [90], but they have been enhanced in recent decades by perceptions of how industrial farming deals with animals and their diseases [91,92]. Though the number of vegetarians has not grown spectacularly, many meat eaters are ambivalent about the way animals, as well as meat from them, are being manipulated [93]. The idea of tissue-engineered meat generates thoughts of hot dogs [89].

Associations with GM food also should be understood in a cultural and historical context. Negative consumer responses to GM food have mainly been studied in terms of risk perception, but it is increasingly clear that risk is only part of the story. For example, in one study the great majority of people who rejected GM food were quite willing to taste an apple that they were told to be genetically modified [94]. Consumer distrust is not necessarily directed at the product; it can also be aimed at the producers, and in this respect it has not been helpful that the benefits of GM food for consumers have never been made very clear [89,95].

Initial associations and responses can be fleeting; in the case of tissue-engineered meat they often give way to wider considerations almost within the same breath, for example when people start to reflect on the possible benefits for animals and realize that these benefits come with benefits for consumers, too, in the form of moral relief. Yet, reluctance also exists on second and third levels of consideration. In particular, a widespread ideal among reflective consumers is that food should be as natural as possible. From this perspective, tissue-engineered meat represents a technological approach that may lead to further estrangement from nature [86,96]. Yet it can also be argued that tissue-engineered meat promises to improve our relations with nature, through reduction of intensive farming and of agricultural land and water use. The future development of this theme is hard to predict.

A tasty product is a basic requirement for societal acceptance, and it is probably also vital that information will be clear and transparent. Beyond that, societal framing and perception depends on many uncertain factors. But if the problems of conventional meat continue to increase and if tasty tissue-engineered meat and other tissue-engineered foods lead to an improvement of our relations with animals and with nature, this new meat may well end up as a highly valued as well as routine part of our food system.

INTRODUCTION

Current meat production systems are a major source of pollution and a significant consumer of fossil fuels, land and water resources. Nutrition related diseases, food borne illnesses, resource use and pollution, and use of farm animals are some of the serious consequences associated with them. Globally, 30% of the land surface is used for livestock production, with 33% of arable land being used for growing livestock feed crops and 26% being used for grazing [1]. The livestock sector contributes 18% to anthropogenic greenhouse gas emissions, and 37% of the anthropogenic methane emissions to the atmosphere worldwide [1]. This 18% contribution of livestock sector in the current greenhouse gas (GHG) emissions, as measured in carbon dioxide equivalent, is higher than the share of GHG emissions from transportation [2]. They produce 37% of methane, which has more than 20 times the global warming potential of carbon dioxide, and they emit 65% of nitrous oxide, another powerful GHG, most of which comes from manure [2]. Livestock also contributes 68% to total ammonia emissions [2]. The animals themselves are mostly responsible for the emission of greenhouse gases [3] and the demand for meat is expected to grow worldwide as global meat production is anticipated to increase to 465 million tonnes by the year 2050, accompanied by a rise in annual greenhouse gas emissions to 19.7 gigatonnes of carbon dioxide, carbon equivalent [1]. Meat production is also responsible for emissions of nitrogen and phosphorus, pesticide contamination of water, heavy metal contamination of soil, and acid rain from ammonia emissions [4]. The water use for livestock and accompanying feed crop production has a dramatic effect on the environment, such as a decrease in the fresh water supply, erosion and subsequent habitat and biodiversity loss [5,6]. The irrigation of feed crops for cattle alone accounts for nearly 8 percent of global human water use [2].

Until 2020, meat demand is expected to increase greatly in developing countries and slightly in developed countries [7,8]. To meet these increased meat demands of modern society, animals are intensively kept and production is optimized; disregarding the well-being of the

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00079-3

animals. Much of the growing demand for animal products worldwide is being met by concentrated animal feeding operations, or factory farms [2,9]. Factory farms account for 67% of poultry meat production, 50% of egg production, and 42% of pork production [10]. Globally some 56 billion animals are raised and slaughtered for food each year [11]. Because of the large number of animals being used, an efficient and cheap production system is required. Herding of animals in confined spaces in unfavorable conditions is practiced. Many of the world's 17 billion hens and meat chickens each live in an area that is less than the size of a sheet of paper [12]. Cattle in feedlots often stand knee-high in manure and arrive at slaughterhouses covered in feces [13]. The adaptability of the animals is not high enough to cope with these unnatural conditions, and high stress levels are observed, resulting in disease, abnormal behavior and death [14]. Furthermore, such operations are increasingly located in or near cities in the developing world, making urban areas the center of industrial meat production in some countries. This extraordinary proximate concentration of people and livestock poses probably one of the most serious environmental and public health challenges for the coming decades [15]. The world organization for animal health (OIE) estimates that no less than 60% of human pathogens and 75% of recently emergent diseases are zoonotic [2]. Another problem is that of animal disease epidemics, and a more serious threat is posed by chicken flu, as this can lead to possible new influenza epidemics or even pandemics, which could kill millions of people [16]. Food borne illnesses have become increasingly problematic, with a six-fold increase in gastroenteritis and food poisoning in industrialized countries in the last 20 years [17]. The most common causes of food borne diseases in EU, USA and Canada are contaminated meats and animal products [18–21]. Nutritionally related diseases, such as cardiovascular disease and diabetes, which are associated with the overconsumption of animal fats are now responsible for a third of global mortality [22]. In addition, there is the problem of antibiotics being used as growth promoters for animals kept in intensive farming. This use probably contributes to the emergence of multi-drug-resistant strains of pathogenic bacteria [23]. In the United States, livestock now consume 70% of all antimicrobial drugs [24].

Moreover, livestock competes with humans for crops and grains as they detract more from food supply than they provide. Livestock consumes 77 million tones of protein contained in foodstuffs that could potentially be used for human nutrition, whereas only 58 million tones of protein are contained in foodstuffs that livestock produce and in terms of energy the relative loss is much higher [2]. Thus it is clear that besides the use of farm animals and non-sustainable meat supply, current meat production methods have many health, environmental and other problems associated with them, like high risk of infectious animal diseases, nutrition related diseases, resource use and environmental pollution, decrease in the fresh water supply, erosion, and subsequent habitat and biodiversity loss [5,6]. Continuation of meat production without change will lead to further environmental degradation and destruction of habitats. However, solutions are within reach, many of which originate from the scientific sector. However, although these will not be immediate but will need investment in the form of time and money, and possibly changes in consumer's habits. Scientific innovations can and should come from all sectors involved and an important contribution can be made via the generation of meat alternatives using improvements of already existing concepts and products. An example of such a concept is biofabrication; i.e., production of complex living and non-living biological products. A new approach to produce meat which thereby reduces these risks is probably feasible with existing tissue-engineering techniques and has been proposed as a humane, safe and environmentally beneficial alternative to slaughtered animal flesh. The industrial potential of biofabrication technology is far beyond the traditional medically oriented tissue engineering and organ printing and, in the long term, biofabrication could contribute to the development of novel biotechnologies that can dramatically transform traditional animal-based agriculture by inventing 'animal-free' food, leather, and fur products. The techniques required to produce 'animal-free' *in vitro* meat are not beyond imagination and the basic methodology involves culturing muscle tissue in a liquid medium on a large scale but

the production of highly structured, unprocessed meat faces considerably greater technical challenges and a great deal of research is still needed to establish a sustainable *in vitro* meat culturing system on an industrial scale. In the long term, tissue-engineered meat is the inescapable future of humanity. However, in the short term the extremely high prohibitive cost of the biofabrication of tissue-engineered meat is the main potential obstacle, although large-scale production and market penetration are usually associated with a dramatic price reduction. This chapter discusses the requirements needed for increasing the feasibility of *in vitro* meat production, which include finding an appropriate stem cell source, their growth in a three-dimensional environment inside a bioreactor, providing essential cues for proliferation and differentiation and evolving new processing technologies.

NEED FOR AND ADVANTAGES OF *IN VITRO* CULTURED MEAT

1) With the advent of functional and enriched foods, consumers are more willing to try products that have been altered to have particular nutritional characteristics [25,26]. There are many possibilities through which the designer meat can be produced *in vitro*. The flavor and fatty acid composition of the cultured meat can be influenced by manipulating the composition of the culture medium. Health aspects of the meat can be enhanced by adding factors like certain types of vitamins to the culture medium which might have an advantageous effect on the health [27]. Moreover, co-culturing with other cell types might further enhance the meat quality. The ratio of saturated to poly-unsaturated fatty acids could be better controlled and the fat content can also be controlled by supplementation of fats after production.
2) The chances of meat contamination would be lower in an *in vitro* meat production system due to strict quality control rules, such as Good Manufacturing Practice, that are impossible to introduce in modern animal farms, slaughterhouses, or meat packing plants and thus the incidence of food borne diseases could be significantly reduced. In addition, the risks of exposure to pesticides, arsenic, dioxins, and hormones associated with conventional meat could be significantly reduced.
3) In theory, cells from captive rare or endangered animals (or even cells from samples of extinct animals) could be used to produce exotic meats in cultures as the global trade of meats from rare and endangered animals has reduced wild populations of many species in many countries.
4) The *in vitro* meat production system will significantly reduce the animal use as theoretically a single farm animal may be used to produce the world's meat supply.
5) As only muscle tissues will be developed in an *in vitro* meat production system and no other biological structures like bones, respiratory system, digestive system, skin, and the nervous system will be involved, it will reduce the amount of nutrients and energy needed for growth and maintenance of muscle tissue.
6) It takes several weeks instead of months (for chickens) or years (for pigs and cows) before the meat can be harvested in the current meat production systems. *In vitro* systems will need a significantly shorter time to grow the meat than does traditional meat production. This means that the time that tissue has to be maintained will be much smaller and thus, the amount of feed and labor required per kg of *in vitro* cultured meat will be much lower.
7) The nutritional costs for *in vitro* cultured meat will be significantly lower than for traditionally cultured meat, as bioreactors for *in vitro* meat production do not need extra space and can be stacked up in a fabric hall. The financial advantages are yet unclear and it might very well be that the decrease in costs of resources, labor and land is compensated by the extra costs of a stricter hygiene regime, stricter control, computer management, etc.
8) There are many situations in which it is costly to supply people with food, and in which it is more economical to produce food *in situ*. These include scientific stations in Polar

Regions, troop encampments in isolated theaters of war and bunkers designed for long-term survival of personnel following a nuclear or biological attack. Thus long-term space missions such as a settlement on the moon or a flight to Mars will likely involve some food production *in situ* within a settlement or spacecraft to reduce liftoff weight and its associated costs.

9) The need for other protein sources demands production of cultured meat. Cultured meat may be the preferred alternative because it is, unlike the other products, animal-derived and with respect to composition most like meat.
10) A definite market is available for meat substitutes. Examples are legume-based and mycoprotein-based meat substitutes.
11) A small market comprising vegetarians who do not eat meat for ethical reasons is also available.
12) Demand for meat is increasing with the growing population, and it will not be possible to produce all the meat required in an environmental and animal friendly way. Thus there is a rather conventional meat market for *in vitro* meat.
13) Being comparatively safer than conventional meat and due to the non-sustainability of traditional meat production, there is a huge market for cultured meat.
14) One of the most important reasons to produce *in vitro* meat would be consumer demand. More and more people are interested in cultured meat and it can be a very successful product.
15) Other factors like potential impact on reducing cardiovascular diseases and greenhouse gas emissions, liberation of land for nature (including wild animals), prevention of animal suffering and prevention of food scarcity that can be expected with an increasing world population will push the production of *in vitro* meat in future.

Therefore, cultured meat has the potential to greatly reduce animal suffering and make eating animals unnecessary even while satisfying all the nutritional and hedonic requirements of meat eaters [28]. Cultured meat is potentially a much more reliable alternative. In comparison with animals, a product from a bioreactor could be attractive as it does not come with all the vicissitudes of animals. Furthermore, cultured meat is not bound to soil or place, which opens up possibilities for new places of production and for alternative land use. However, from a perspective of social acceptance, the technological character of cultured meat can have a negative value, and associations with Frankenstein, cloning, transgenesis and unknown risks are close at hand.

IN VITRO MEAT

The idea of cultured meat for human consumption is not new but was predicted some time ago by Winston Churchill in the 1920s. In his essay 'Fifty Years Hence', later published in 'Thoughts and adventures' in 1932, he declared that:

> 'Fifty years hence we shall escape the absurdity of growing a whole chicken in order to eat the breast or wing by growing these parts separately under a suitable medium.'

In 1912, Alexis Carrel managed to keep a piece of chick heart muscle alive and beating in a Petri dish. This experiment demonstrated that it was possible to keep muscle tissue alive outside the body, provided that it was nourished with suitable nutrients. It was much later, in the early 1950s, when Willem van Eelen of The Netherlands independently had the idea of using tissue culture for the generation of meat products. Since at that time the concept of stem cells and the *in vitro* culture of cells still had to emerge, it took until 1999 before van Eelen's theoretical idea was patented. Some efforts have already been put into culturing artificial meat. SymbioticA harvested muscle biopsies from frogs and kept the tissues alive and growing in culture dishes [29]. In 2002, a study involving the use of muscle tissue from the common goldfish (*Carassius auratus*) cultured in Petri dishes was published in which the possibilities of culturing animal

muscle protein for long-term space flights or habituation of space stations were explored. In this study, muscle tissue cultured with crude cell extracts showed a limited increase in cell mass and the cultured muscle explants so obtained were washed, dipped in olive oil with spices, covered in breadcrumbs and fried. A test-panel judged the processed explants and agreed that the product was acceptable as food [30]. Thus some efforts have already been put into culturing artificial meat but obviously, small biopsies will not be practical for large-scale meat production. Therefore, it is proposed to use tissue engineering to produce *in vitro* cultured meat. With the help of tissue engineering it is attempted to mimic neo-organogenesis *ex vivo* for the treatment of various diseases and surgical reconstruction. This is a powerful technique which is mainly being designated for regenerative medicine in a wide variety of tissues and organs [31,32]. In particular, tissue engineering of skeletal muscle has many applications, ranging from *in vitro* model systems for drug-screening [33], pressure sores [34] and physiology to *in vivo* transplantation to treat muscular dystrophy and muscular defects [35]. Obviously, tissue engineering could also be employed for the *in vitro* production of skeletal muscle tissue from farm animals for consumption purposes [36].

Considering the benefits of an *in vitro* meat production system, it is not surprising that a number of parties have proposed and patented the methodology for actualizing this idea [27,36,37]. As of yet none of these processes, though detailed, have been tested, this chapter introduces the techniques so far proposed. This is partly because livestock animal cell lines have not been well-established *in vitro* [38] and also because growing muscle cells *ex vivo* on a large scale is certainly a vast and unexplored undertaking. The technical demands of large-scale production are unseen in the world of medical research, where most efforts in growing tissue *ex vivo* have been directed. The nutritional composition of *ex vivo* engineered muscle tissue has not yet been paid much attention. As a result, establishment of an *in vitro* meat production system is faced with many unique challenges so far unexplored in the field of tissue engineering.

The only aim in developing an *in vitro* meat production system is the proliferation of animal muscle tissue. Meat is already cultured on small scales using a variety of basic procedures, including techniques that use scaffolds and those that rely on self-organization [36]. There are different design approaches for an *in vitro* meat production system, all of which are designed to overcome the diffusion barrier, ranging from those currently in use to the more speculative possibilities.

Scaffolding techniques

In scaffold-based techniques, embryonic myoblasts or adult skeletal muscle satellite cells are proliferated, attached to a scaffold or carrier such as a collagen meshwork or micro-carrier beads, and then perfused with a culture medium in a stationary or rotating bioreactor. By introducing a variety of environmental cues, these cells fuse into myotubes, which can then differentiate into myofibers [39]. The resulting myofibers may then be harvested, cooked, and consumed as meat (Figs. 79.1, 79.2).

Currently there are two detailed proposals based on emerging field of tissue engineering [40,41] for using cell culture for producing *in vitro* meat. Both these proposals are similar in nature and neither of the two has been tested. One of the two proposals to create an *in vitro* meat production system has been written by Vladimir Mironov for the NASA [42], while the other has been written by Willem van Eelen, who also holds a worldwide patent for this system [27]. However, Catts and Zurr [29] appear to have been the first to have actually produced meat by this method. Both of these systems work by growing myoblasts in suspension in a culture medium. The Mironov proposal uses a bioreactor in which cells are grown together with collagen spheres to provide a substrate onto which the myoblasts can attach and differentiate, whereas van Eelen's proposal uses a collagen meshwork and the culture medium is refreshed from time to time or percolated through the meshwork. Once differentiated into myofibers, the mixture of collagen and muscle cells can be harvested and used as meat. Other forms of

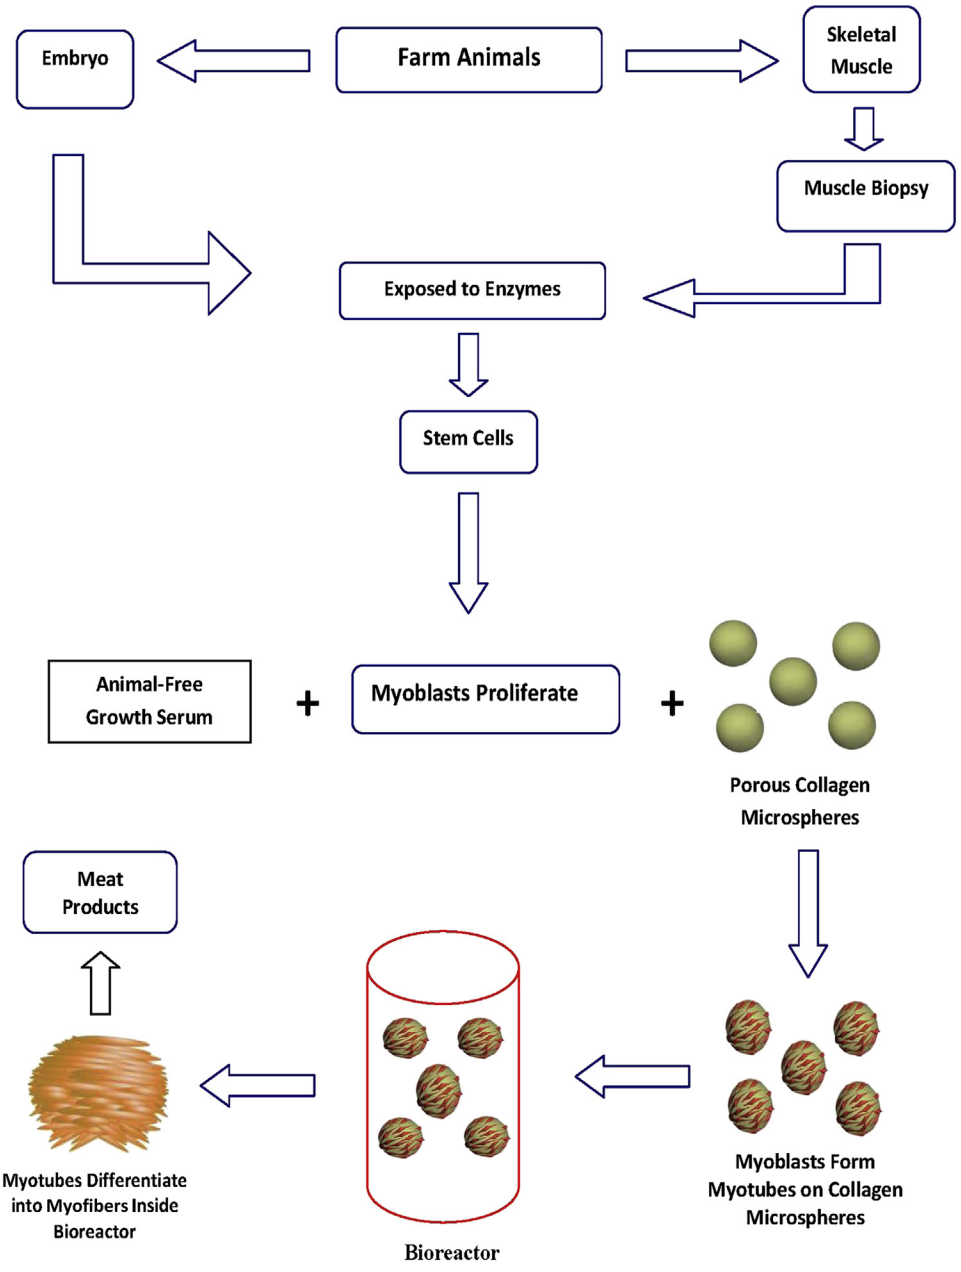

FIGURE 79.1
Scaffold-based cultured meat.

scaffolding could also be used, for example, growing muscle tissue on large sheets of edible or easily separable material. The muscle tissue could be processed after being rolled up to suitable thicknesses [36]. While these kinds of techniques work for producing ground processed (boneless) meats with soft consistency, they do not lend themselves to highly structured meats like steaks. However, cells can also be grown in substrates that allow for the development of 'self-organizing constructs' that produce more rigid structures.

Self-organizing tissue culture

To produce highly structured meats, one would need a more ambitious approach, creating structured muscle tissue as self-organizing constructs [43] or proliferating existing muscle tissue *in vitro*, like Benjaminson et al. who cultured Gold fish (*Carassius auratus*) muscle explants [30]. They took slices of goldfish tissue, minced and centrifuged them to form pellets, placed them in Petri dishes in a nutrient medium and grew them for seven days. The explanted

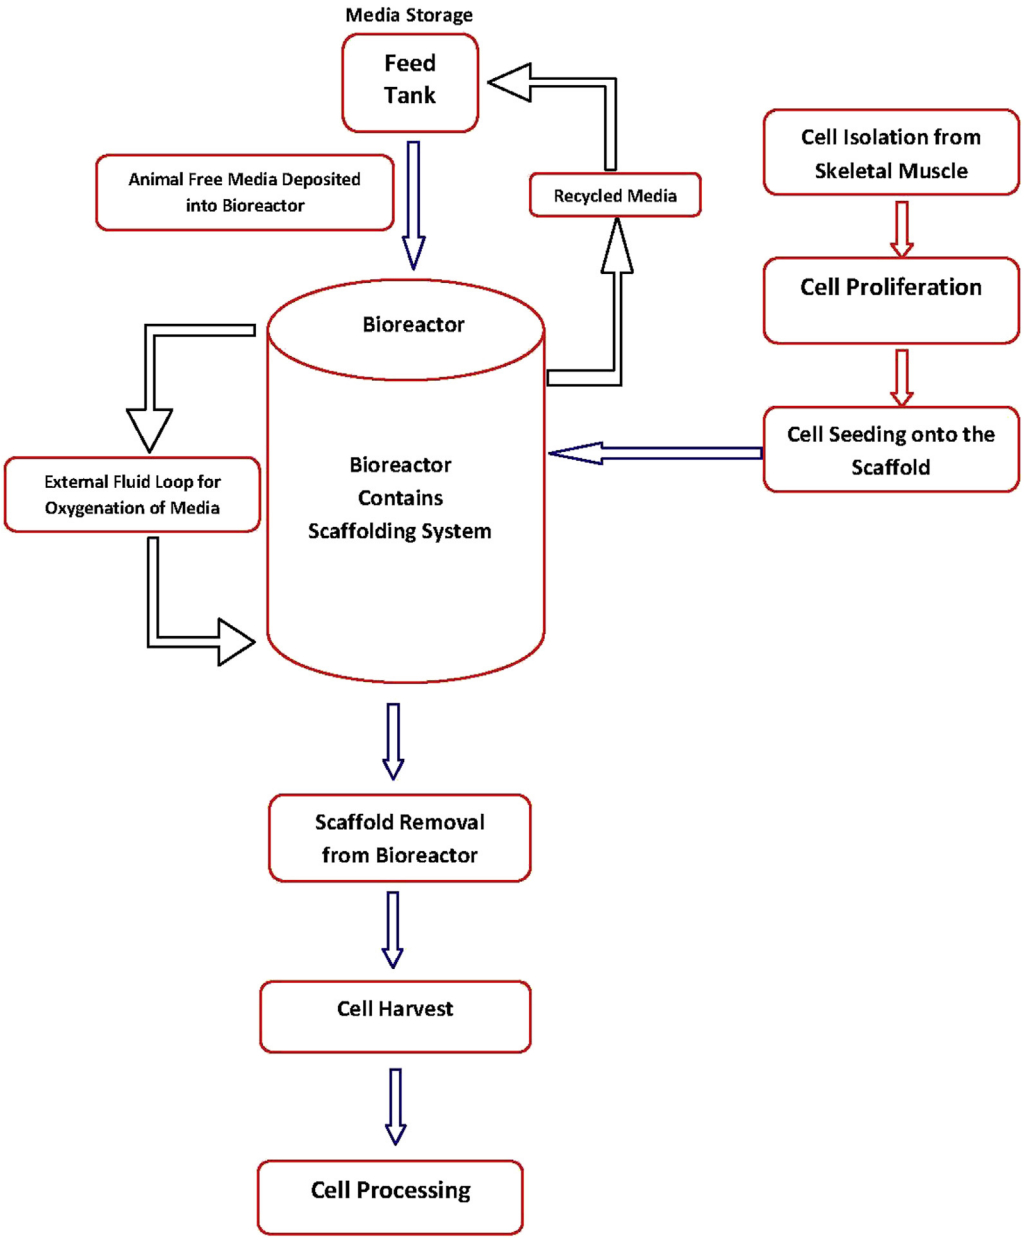

FIGURE 79.2
Possible *in vitro* meat production system.

tissue grew nearly 14% when using fetal bovine serum as the nutrient medium and over 13% when using Maitake mushroom extract. When the explants were placed in a culture containing dissociated *Carassius* skeletal muscle cells, the explant surface area grew by a surprising 79% in a week's time. After a week, the explants and their newly grown tissue, which looked like fresh fish filets, were cooked (marinated in olive oil and garlic and deep-fried) and presented to a panel for observation. The panel reported that the fish looked and smelled good enough to eat [30,44–46]. In another experiment, Benjaminson kept chicken muscles alive in a Petri dish for at most two months before it became necrosed [42].

Tissue culture techniques have the advantages that explants contain all the tissues which make up meat in the right proportions and closely mimics *in vivo* situation. However, lack of blood circulation in these explants makes substantial growth impossible, as cells become necrotic

if separated for long periods by more than 0.5 mm from a nutrient supply [43]. According to Vladimir Mironov, entirely artificial muscle can be created with tissue-engineering techniques by a branching network of edible porous polymer through which nutrients are perfused and myoblasts and other cell types can attach [42]. Such a design using the artificial capillaries for the purpose of tissue engineering has been proposed [41]. Small muscle-like organs have been demonstrated to grow from co-cultures of myoblasts and fibroblasts. These organs, termed myooids, are able to contract both spontaneously and by electrical stimulation, albeit with only a fraction of the force observed in control muscles probably because of lack of innervation [43,47,48]. The diameter of myooids is limited at most to 1 mm [48] due to the lack of perfusion; which is probably the biggest problem to overcome in designing an *in vitro* meat production system. Like the myooids, it is possible to co-culture the myoblasts with other cell types to create a more realistic muscle structure which can be organized in much the same way as real muscles [43,47,48].

Organ printing

The various problems associated with the current tissue-engineering techniques are that they cannot provide consistency, vascularization, fat marbling or other elements of workable and suitably-tasting meat that are not simply versions of ground soft meat. A potential solution to such problems comes from research on producing organs for transplantation procedures known as organ printing. Organ printing uses the principles of ordinary printing technology — the technology used by inkjet printers to produce documents. Researchers use solutions containing single cells or balls of cells and spray these cell mixtures onto gels that act as printing paper. The 'paper' can actually be removed through a simple heating technique or could potentially be automatically degradable. What happens is essentially that live cells are sprayed in layers to create any shape or structure desired. After spraying these three-dimensional structures, the cells fuse into larger structures, such as rings and tubes or sheets. As a result, researchers argue that the feasibility of producing entire organs through printing has been proved. The organs would have not only the basic cellular structure of the organ but would also include appropriate vascularization providing a blood supply to the entire product. For applications focused on producing meat, fat marbling could be added as well, providing taste and structure. Essentially, sheets and tubes of appropriate cellular components could create any sort of organ or tissue for transplantation or for consumption [28,49,50].

Biophotonics

Biophotonics is a new field that relies on the effects of lasers to move particles of matter into certain organizational structures, such as three-dimensional chessboard, or hexagonal arrays. In general, biophotonics refers to the process of using light to bind together particles of matter and the mechanisms of this field are still poorly understood. A surprising property of interacting light, this phenomenon produces so called 'optical matter' in which the crystalline form of materials (such as polystyrene beads) can be held together by nets of infrared light that will fall apart when the light is removed. This is a phenomenon a step-up from 'optical tweezers' that have been used for years to rotate or otherwise move tiny particles in laboratories. This has a binding effect among a group of particles that can lead them not only to be moved one by one to specific locations but that can coax them to form structures. Although primarily sparking interest in medical technologies, such as separating cells, or delivering medicine or other microencapsulized substances to individual cells, there is an intriguing possibility that such a technology could be used for the production of tissues, including meat [28]. Arrays of red blood cells and hamster ovaries have already been created using this technology [51]. Given the success of creating two-dimensional arrays, there is the possibility of producing tissue formations that use only light to hold the cells together, thus eliminating the need for scaffoldings [28].

Nanotechnology

The ability of optical tweezers to rotate or move tiny particles has intrigued nanotechnologists, who have inventive plans for what to do with the molecular scale-sized robots they would like to create (but so far, having few tools with which to make them). Nanotechnology (the production and alteration of materials at the level of the atom and molecule) holds out enormous possibilities and the holy grail of nanotechnology is some version of an 'assembler', a robot the size of a molecule that would allow moving matter at the atomic and molecular level. The obvious power of such a technology — given that everything is made of the same basic atoms but simply arranged in different ways — is that we would be able to construct virtually any substance we wanted from scratch by putting together exactly the molecules we wanted. Interestingly, one of the first examples given of the speculative technology of nanotechnology was that of synthesized meat. Thus technologies ranging from the actual to the speculative promise a variety of ways to create real meat without killing animals. Though still commercially infeasible at the moment or in some cases technologically infeasible for several years to come, the point here is not to be distracted by the fact that we cannot yet make use of these technologies but rather to decide whether we should support the development of these technologies [28].

CHALLENGES IN THE COMMERCIAL PRODUCTION OF *IN VITRO* MEAT

There are two different ideas regarding the concept of the cultured meat. Because people like meat and cultured meat is explicitly introduced as an alternative to the problems of normal meat, it should be as meat-like as possible in order to be a real alternative for 'traditional' meat from animals. It is therefore important that an alternative should have a similar taste and nutritional value. On the other hand, a new product needs a profile of its own; otherwise it will not be able to compete. From this perspective it is not essential for the product to resemble and should in fact be clearly distinctive from traditional meat.

Cultured meat technology is still in its infancy and the most important challenge is sufficient knowledge of the biology of the stem cell and its differentiation into muscle cells. Tissue engineering on a very large scale is the second requirement, along with the maintenance of constant conditions around all individual cells in a large-scale reactor with sophisticated instrumentation for measuring and controlling conditions. The need for cell growth and differentiation and subsequent release from support without damage upon harvesting is the third requirement, along with the need for on-site cleaning and sterilization systems in the large-scale reactors. Studies are required to determine the consumer preferences and marketing strategies. When meat from animals is available, why would a consumer prefer cultured meat and if it is all about sustainability or animal welfare issues, then eating more plant proteins and less animal protein is a good alternative. The following challenges have to be met before cultured meat can be produced on a commercial scale.

Generation of suitable stem cell lines from farm animal species

In vitro meat can be produced by culturing the cells from farm animal species in large quantities starting from a relatively small number. Culturing embryonic stem cells would be ideal for this purpose since these cells have an almost infinite self-renewal capacity and theoretically it is being said that one such cell line would be sufficient to literally feed the world. In theory, after the embryonic stem cell line is established, its unlimited regenerative potential eliminates the need to harvest more cells from embryos however; the slow accumulation of genetic mutations over time may determine a maximum proliferation period for a useful long-term ES culture [52]. While embryonic stem cells are an attractive option for their unlimited proliferative capacity, these cells must be specifically stimulated to differentiate into myoblasts and may inaccurately recapitulate myogenesis [31]. Although embryonic stem cells have been cultured for many generations but so far it has not been possible to culture cell lines with unlimited self-renewal

potential from pre-implantation embryos of farm animal species. Until now, true embryonic stem cell lines have only been generated from mouse, rhesus monkey, human and rat embryos [38] but the social resistance to cultured meat obtained from mouse, rat or rhesus monkey will be considerable and will not result in a marketable product. The culture conditions required to keep mouse and human embryonic cells undifferentiated are different from the conditions that will be required for embryonic cells of farm animal species and fundamental research on the early development of embryos of these species can provide clues.

Different efforts invested into establishing ungulate stem cell lines over the past two decades have been generally unsuccessful with difficulties arising in the recognition, isolation and differentiation of these cells [53]. According to Bach et al. myosatellite cells are the preferred source of primary myoblasts although, they have the disadvantage of being a rare muscle tissue cell type with limited regenerative potential because they recapitulate myogenesis more closely than immortal myogenic cell lines [31]. Myosatellite cells isolated from different animal species have different benefits and limitations as a cell source and that isolated from different muscles have different capabilities to proliferate, differentiate, or be regulated by growth modifiers [54]. Myosatellite cells have been isolated and characterized from the skeletal muscle tissue of cattle [55], chicken [56], fish [57], lambs [58], pigs [59], and turkeys [60]. Porcine muscle progenitor cells have the potential for multilineage differentiation into adipogenic, osteogenic and chondrogenic lineages, which may play a role in the development of co-cultures [59]. Advanced technology in tissue engineering and cell biology offer some alternate cell options having practical applications and multilineage potential allowing for co-culture development with suitability for large-scale operations.

Alternatively, we can use adult stem cells from farm animal species and myosatellite cells are one example of an adult stem cell type with multilineage potential [61]. Adult stem cells have been isolated from several different adult tissues [62] but their *in vitro* proliferation capacity is not unlimited and can proliferate *in vitro* for several months at most. These cells also have the capacity to differentiate into skeletal muscle cells, although not very efficiently but for now, these are the most promising cell type for use in the production of cultured meat. A rare population of multipotent cells found in adipose tissue known as adipose tissue-derived adult stem cells (ADSCs) is another relevant cell type for *in vitro* meat production [63] which can be obtained from subcutaneous fat and subsequently transdifferentiated to myogenic, osteogenic, chondrogenic or adipogenic cell lineages [64]. However, adult stem cells are prone to malignant transformation in long-term culture [65] that is the greatest matter of debate. It has been observed that ADSCs immortalize at high frequency and undergo spontaneous transformation in long-term (4–5 months) culturing [66], while evidence of adult stem cells remaining untransformed have also been reported [67]. To minimize the risk of spontaneous transformation, re-harvesting of adult stem cells may be necessary in an *in vitro* meat production system and as such obtaining ADSCs from subcutaneous fat is far less invasive than collection of myosatellite cells from muscle tissue.

Matsumoto et al. reported that mature adipocytes can be dedifferentiated *in vitro* into a multipotent preadipocyte cell line known as dedifferentiated fat (DFAT) cells, reversion of a terminally differentiated cell into a multipotent cell type [68]. These DFAT cells are capable of being transdifferentiated into skeletal myocytes [69] and appear to be an attractive alternative to the use of stem cells. This process known as 'ceiling culture method' certainly seems achievable on an industrial scale, but [70] has put forth the argument that many of the claims of transdifferentiation, dedifferentiation and multipotency of once terminally differentiated cells may be due to abnormal processes resulting in cellular look-alikes.

Safe media for culturing of stem cells

In vitro meat would need an affordable medium system to enjoy its potential advantages over conventional meat production and that medium must contain the necessary nutritional

components available in free form to myoblasts and accompanying cells. Myoblast culturing usually takes place in animal sera, a costly media that does not lend itself well to consumer acceptance or large-scale use. Animal sera are from adult, newborn or fetal sources, with fetal bovine serum being the standard supplement for cell culture media [71]. Because of its *in vivo* source, it can have a large number of constituents in highly variable composition and potentially introduce pathogenic agents [72]. The harvest of fetal bovine serum also raises ethical concern and for the generation of an animal-free protein product, the addition of fetal calf serum to the cells would not be an option and it is therefore essential to develop a serum-free culture medium. Commercially available serum replacements and serum-free culture media offer some more realistic options for culturing mammalian cells *in vitro*. Serum-free media reduce operating costs and process variability while lessening the potential source of infectious agents [73]. Improvements in the composition of commercially available cell culture media have enhanced our ability to successfully culture many types of animal cells and serum-free media have been developed to support *in vitro* myosatellite cell cultures from the turkey [74], sheep [75] and pig [76]. Variations among different serum-free media outline the fact that satellite cells from different species have different requirements and respond differentially to certain additives [77]. Ultroser G is an example of a commercially available serum substitute containing growth factors, binding proteins, adhesin factors, vitamins, hormones, mineral trace elements and has been designed specially to replace fetal bovine serum for growth of anchorage-dependent cells *in vitro* [30,78]. succeeded in using a serum-free medium made from Maitake mushroom extract that achieved higher rates of growth than fetal bovine serum and recently it has been shown that lipids such as sphingosine-1-phosphate can replace serum in supporting the growth and differentiation of embryonic tissue explants. In most cases, serum-free media are supplemented with purified proteins of animal origin [79].

Indeed such media have already been generated and are available from various companies for biomedical purposes; however, their price is incompatible with the generation of an affordable edible product. Therefore, a cell culture medium has to be developed that does not contain products of animal origin and enables culturing of cells at an affordable price.

Safe differentiation media for producing muscle cells

For stem cell culturing, it is important that these cells remain undifferentiated and maintain their capacity to proliferate and for the production of cultured meat a specific and efficient differentiation process initiated with specific growth factors is needed. An appropriate array of growth factors is required to growing muscle cells in culture in addition to proper nutrition and these growth factors are synthesized and released by muscle cells themselves and, in tissues, are also provided by other cell types locally (paracrine effects) and non-locally (endocrine effects). The myosatellite cells of different species respond differentially to the same regulatory factors [54], and as such extrinsic regulatory factors must be specific to the chosen cell type and species. Furthermore, formulation may be required to change over the course of the culturing process from proliferation period to the differentiation and maturation period, requiring different set of factors. A multitude of regulatory factors have been identified as being capable of inducing myosatellite cell proliferation [80], and the regulation of meat animal-derived myosatellite cells by hormones, polypeptide growth factors and extracellular matrix proteins has also been investigated [76,77]. Purified growth factors or hormones may be supplemented into the media from an external source such as transgenic bacterial, plant or animal species which produce recombinant proteins [81]. Alternatively, a sort of synthetic paracrine signaling system can be arranged so that co-cultured cell types can secrete growth factors which can promote cell growth and proliferation in neighboring cells. Appropriate co-culture systems like hepatocytes may be developed to provide growth factors necessary for cultured muscle production that provide insulin-like growth factors which stimulate myoblast proliferation and differentiation [82] as well as myosatellite cell proliferation in several meat animal species *in vitro* [77]. Typically, investigators initiate differentiation and fusion of

myoblasts by lowering the levels of mitogenic growth factors and the proliferating cells then commence synthesis of insulin-like growth factor-II, which leads to differentiation and formation of multinucleated myotubes [83] and stimulate myocyte maturation [84]. So the successful system must be capable of changing the growth factor composition of the media. Currently the most efficient method to let (mouse) stem cells differentiate into skeletal muscle cells is to culture them in a medium that contains 2% horse serum instead of 10 or 20% fetal calf serum. However, for the generation of cultured meat, it is essential that the cells are cultured and differentiated without animal products, so a chemically defined culture medium has to be developed that enables the differentiation of stem cells to skeletal muscle cells.

Tissue engineering of muscle fibers

The possibility to form a three-dimensional structure of cells is restricted in the absence of blood flow that provides oxygen and nutrients to the cells and removes metabolic end products. Because of the limitations in nutrient diffusion, the *in vitro* culturing of cells is limited to only a few layers of cells. A solution to this problem may be provided by culture of cells on edible or biodegradable synthetic or biological scaffolds which would provide shape and structure to the engineered tissue. Another solution would be the processing of these thin layers of cells into a meat based product. Alternatively, deformable micro-carrier beads of edible (non-animal) material may be developed that enable production of secondary myotubes in suspension which may be used as an animal protein ingredient in a wide variety of products. Alternatively, products of animal origin with a meat-like appearance and texture can be made by addition of fibroblasts (for firmness) and fat cells (for taste) to the myotubes.

Scaffolds

As myoblasts are anchorage-dependent cells, a substratum or scaffold must be provided for proliferation and differentiation to occur [85]. Scaffolding mechanisms differ in shape, composition and characteristics to optimize muscle cell and tissue morphology. An ideal scaffold must have a large surface area for growth and attachment, be flexible enough to allow for contraction as myoblasts are capable of spontaneous contraction, maximize medium diffusion and be easily dissociated from the meat culture. A best scaffold is one that mimics the *in vivo* situation as myotubes differentiate optimally on scaffold with a tissue-like stiffness [86] and its by-products must be edible and natural and may be derived from non-animal sources, though inedible scaffold materials cannot be disregarded. New biomaterials may be developed that offer additional characteristics, such as fulfilling the requirement of contraction for proliferation and differentiation [87]. Thus challenge is to develop a scaffold that can mechanically stretch attached cells to stimulate differentiation and a flexible substratum to prevent detachment of developing myotubes that will normally undergo spontaneous contraction.

Edelman et al. proposed porous beads made of edible collagen as a substrate [36] while as Van Eelen et al. proposed a collagen meshwork described as a 'collagen sponge' of bovine origin [27]. The tribeculate structure of the sponge allows for increased surface area and diffusion, but may impede harvesting of the tissue culture. Other possible scaffold forms include large elastic sheets or an array of long, thin filaments. Cytodex-3 micro-carrier beads have been used as scaffolds in rotary bioreactors but these beads have no stretching potential. One elegant approach to mechanically stretch myoblasts would be to use edible, stimuli-sensitive porous microspheres made from cellulose, alginate, chitosan, or collagen [36] that undergo, at minimum, a 10 percent change in surface area following small changes in temperature or pH. Once myoblasts attach to the spheres, they could be stretched periodically provided such variation in the pH or temperature would not negatively affect cell proliferation, adhesion, and growth. Jun et al. have found that growing myoblasts on electrically conductive fibers induces their differentiation, forming more myotubes of greater length without the addition of electrical stimulation [88] but use of such inedible scaffolding systems necessitates simple and non-destructive techniques for removal of the culture from the scaffold.

Furthermore, there are greater technical challenges in developing a scaffold for large and highly structured meats due to the absence of vascular system. There is a need to build a branching network from an edible, elastic, and porous material, through which nutrients can be perfused and myoblasts and other cell types can then attach to this network. [36] acknowledge that a cast of an existing vascularization network, such as that in native muscle tissue, can be used to create a collagen network mimicking native vessel architecture. Taking this a step further Borenstein et al., has proposed an approach to create such a network by creating a cast onto which a collagen solution or a biocompatible polymer is spread and after solidification seeding the network with endothelial cells [89]. Following dissolution of the polymer mold, successful proliferation could theoretically leave behind a network of endothelial tissue, a branched network of micro-channels, which can be stacked onto each other to form a three-dimensional network onto which one could grow myocytes.
A synthetic vascular system would then require a circulation pumping system and a soluble oxygen carrier in the medium to be fully functional. But at this moment creation of these artificial vascular networks does not translate well into mass production due to the microfabrication processes required. Alternatively Benjaminson et al., proposed an attempt to create a highly structured meat without a scaffold by solving the vascularization problem through controlled angiogenesis of explants [30].

Another important factor is the texture and microstructure of scaffolds as texturized surfaces can attend to specific requirements of muscle cells, one of which is myofiber alignment. This myofiber organization is an important determinant for the functional characteristics of muscle and the textural characteristics of meat. Lam et al. cultured myoblasts on a substrate with a wavy micropatterned surface to mimic native muscle architecture and found that the wave pattern aligned differentiated muscle cells while promoting myoblast fusion to produce aligned myotubes [90]. While using scaffold-based techniques for meat culturing, micro-patterned surfaces could allow muscle tissue to assume a two-dimensional structure more similar to that of meat of native origin. Riboldi et al. utilized electrospinning, a process that uses electrical charge to extract very fine fibers from liquids, by using electrospun microfibrous meshwork membranes as a scaffold for skeletal myocytes [91]. These membranes offer high surface area to volume ratio in addition to some elastic properties. Electrospinning creates very smooth fibers, which may not translate well into a good adhesive surface and coating electrospun polymer fibers with extracellular matrix proteins, such as collagen or fibronectin, promotes attachment by ligand-receptor-binding interactions [91]. Electrospinning shows promise for scaffold formation because the process is simple, controllable, reproducible and capable of producing polymers with special properties by co-spinning [91].

Production of meat by the scaffold-based techniques also faces a technical challenge of removal of the scaffolding system. Confluent cultured cell sheets are conventionally removed enzymatically or mechanically, but these two methods damage the cells and the extracellular matrix they may be producing [92]. However, thermoresponsive coatings which change from hydrophobic to hydrophilic at lowered temperatures can release cultured cells and extracellular matrix as an intact sheet upon cooling [93]. This method known as 'thermal liftoff,' results in undamaged sheets that maintain the ability to adhere if transferred onto another substrate [93] and opens the possibility of stacking sheets to create a three-dimensional product. Lam et al. have presented a method for detaching culture as a confluent sheet from a non-adhesive micropatterned surface using the biodegradation of selective attachment protein laminin [94]. However, culturing on a scaffold may not result in a two-dimensional confluent 'sheet' of culture. The contractile forces exerted after scaffold removal by the cytoskeleton of the myocyte are no longer balanced by adhesion to a surface that causes the cell lawn to contract and aggregate, forming a detached multicellular spheroid [93]. To remove the culture as a sheet, a hydrophilic membrane or gel placed on the apical surface of the culture before detachment can provide physical support and use of a fibrin hydrogel is ideal for skeletal muscle tissue because cells can migrate, proliferate and produce their own

extracellular matrix within it while degrading excess fibrin [94]. These two-dimensional sheets could be stacked to create a three-dimensional product as suggested by Van Eelen et al. [27].

Industrial bioreactors

Production of *in vitro* meat for processed meat-based products will require large-scale culturing in large bioreactors as stem cells and skeletal muscle cells require a solid surface for culturing and a large surface area is needed for the generation of sufficient number of muscle cells. Cultured meat production is likely to require the development of new bioreactors that maintain low shear and uniform perfusion at large volumes. The bioreactor designing is intended to promote the growth of tissue cultures which accurately resemble native tissue architecture and provides an environment which allows for increased culture volumes. A laminar flow of the medium is created in rotating vessel bioreactors by rotating the cylindrical wall at a speed that balances centrifugal force, drag force and gravitational force, leaving the three-dimensional culture submerged in the medium in a perpetual free fall state [95]. This improves diffusion with high mass transfer rates at minimal levels of shear stress, producing three-dimensional tissues with structures very similar to those *in vivo* [96]. Direct perfusion bioreactors appear more appropriate for scaffold-based myocyte cultivation allowing flow of medium through a porous scaffold with gas exchange taking place in an external fluid loop [97]. Besides offering high mass transfer they also offer significant shear stress, so determining an appropriate flow rate is essential [96]. Direct perfusion bioreactors are also used for high-density, uniform myocyte cell seeding [98]. Another method of increasing medium perfusion is by vascularizing the tissue being grown. Levenberg et al. had induced endothelial vessel networks in skeletal muscle tissue constructs by using a co-culture of myoblasts, embryonic fibroblasts and endothelial cells co-seeded onto a highly porous biodegradable scaffold [99]. Research size rotating bioreactors have been scaled-up to three liters and, theoretically, scale-up to industrial sizes should not affect the physics of the system.

Adequate perfusion of the cultured tissue is required to produce large culture quantities and it is necessary to have adequate oxygen perfusion during cell seeding and cultivation on the scaffold as cell viability and density positively correlate with the oxygen gradient in statically grown tissue cultures [98]. Adequate oxygen perfusion is mediated by bioreactors which increase mass transport between culture medium and cells and by the use of oxygen carriers to mimic hemoglobin provided oxygen supply to maintain high oxygen concentrations in solution, similar to that of blood. Oxygen carriers are either modified versions of hemoglobin or artificially produced perfluorochemicals (PFCs) that are chemically inert [100]. Many chemically modified hemoglobins have been developed but their bovine or human source makes them an unfit candidate and alternatively, human hemoglobin has been produced by genetically modified plants [101] and microorganisms [102].

Fields

Proliferation and differentiation of myoblasts have been found to be affected by the mechanical, electromagnetic, gravitational, and fluid flow fields [39,87]. Repetitive stretch and relaxation equal to 10% of length, six times per hour increase differentiation into myotubes [103]. Myoblasts seeded with magnetic microparticles induced differentiation by placing them in a magnetic field without adding special growth factors or any conditioned medium [104]. Electrical stimulation also contributes to differentiation, as well as sarcomere formation within established myotubes [39].

Atrophy and exercise

One of the potential problems associated with cultured meat is that of atrophy or muscle wasting due to a reduction of cell size [105] caused by lack of use, denervation, or one of a variety of diseases [106,107]. Regular contraction is a necessity for skeletal muscle and

promotes differentiation and healthy myofiber morphology while preventing atrophy. Muscle *in vivo* is innervated, allowing for regular, controlled contraction whereas *in vitro* system would necessarily culture denervated muscle tissue, so contraction must be stimulated by alternate means. It might be possible that mechanical or electrical stimulation can promote growth and structure of the cultured meat as newly formed myotubes in culture start to contract spontaneously [108] or as a matter of fact, myooids also contract spontaneously at approximately 1 Hz. once formed [43]. So exercise by electrical stimulation might be a viable solution to overcome atrophy in an *in vitro* meat production system. Cha et al. have found that administration of cyclic mechanical strain to a highly porous scaffold sheet promotes differentiation and alignment of smooth muscle cells [109]. Edelman et al. and Van Eelen et al. proposed mechanical stretching of scaffolds and expandable scaffold beads to fulfill the requirement of providing contraction [27, 36]. De Deyne noted that external mechanical contraction is less effective than electrical stimulation in promoting muscle development [87]. Electrical stimulation, feasible on a large scale, induces contraction internally as opposed to passively and aids in differentiation and sarcomere formation. Even growth on electrically conductive fibers without application of electrical stimulation sufficed in reaping the benefits of induced contraction [88].

Neuronal activity can be mimicked by applying appropriate electrical stimuli *in vitro* cultures [110] and has proven to be pivotal in the development of mature muscle fibers [111]. It has been shown that induction of contractile activity promoted the differentiation of myotubes in culture by myosin heavy chain expression of different isoforms and sarcomere development [112,113]. Electrical stimulation can provide a non-invasive and accurate tool to assess the functionality of engineered muscle constructs [114]. Functional muscle constructs will exert a force due to active contractions of the muscle cells by generating a homogeneous electrical field inside the bioreactor but so far, these forces generated by engineered muscle constructs only reach 2−8% of those generated by skeletal muscles of adult rodents [47]. Thus, functional properties of tissue-engineered muscle constructs are still unsatisfactory at this moment.

Mechanotransduction is the process through which cells react to mechanical stimuli and is a complex mechanism [115,116] that is another important biophysical stimulus in myogenesis [117]. It is mainly by means of the family of integrin receptors that cells attach to the insoluble meshwork of extracellular matrix proteins [118] transmitting the applied force to the cytoskeleton. The resulting series of events shows parallels to growth factor receptor signaling pathways, which ultimately lead to changes in cell behavior, such as proliferation and differentiation [115]. Muscle growth and maturation is affected by different mechanical stimulation regimes and the application of static mechanical stretch to myoblasts *in vitro* results in a facilitated alignment and fusion of myotubes, and also results in hypertrophy of the myotubes [117]. Furthermore, cyclic strain activates quiescent satellite cells [119] and increases proliferation of myoblasts [120]. Thus all these results indicate that mechanical stimulation protocols affect both proliferation and differentiation of muscle cells and different parameters that presumably influence the outcome of the given stimulus are percentage of applied stretch, frequency of the stimulus and timing in the differentiation process.

Senescence

In vitro meat production system based on satellite cells still imposes a challenge of senescence that can be tackled either by starting fresh cell culture whenever needed or by immortalizing cell culture or by using embryonic stem cell cultures. Fresh satellite cells can be extracted without harming the animal donors [27] from time to time to start new cell cultures, although animal slaughter is a more common practice [54]. A second approach involves modification of the cells in culture so that senescence can be overcome by involving the ectopic expression of the gene for the telomerase enzyme [121]. An additional expression of an oncogene may be required to overcome senescence [122–125], but this method falls within the domain of genetic modification, which might severely hinder consumer acceptance. A third approach

involves embryonic stem cells which are pluripotent and apparently have an unlimited capability for division [126] and thus, embryonic stem cell culture derived from a single donor can be theoretically propagated unlimited but embryonic stem cells have to differentiate to muscle cells before they can be used.

Food processing technology

New food processing technologies need to be developed to make *in vitro* meat based products attractive and that will depend on the starting material whether suspensions of small myotubes, myofibers on scaffolds or microspheres, etc., are utilized. The first *in vitro* meat based product may be developed using small pieces of cultured muscle fiber as raw material.

Risks of contamination

Cultured meat will be safer and more sustainable than conventional meat but production may be less safe because of risks of contamination. Cultured meat may have a completely different risk profile to conventional meat, and much attention will have to be paid to the safety of added substrates and other compounds of the culture medium. So, there are fewer risks with respect to microbial contamination but more risk of contamination of substrates.

Future efforts in culturing meat will have to address the limitations of current techniques through advances that make cultured cells, scaffolds, culture media, and growth factors edible and affordable.

CONCLUSION

Continuing the production of meat by current methods is going to further aggravate the problems and *in vitro* meat production system seems to be an appealing alternative and is becoming increasingly justifiable in light of the sizable negative effects of current meat production systems. *In vitro* meat production is a sustainable, humane and safer system that offers a number of benefits including animal welfare, process monitoring, environmental considerations, efficiency of food production in terms of feedstock, decrease in intense land usage and greenhouse gas emissions. Furthermore, the composition, flavor and functional role of cultured meat could be better controlled. Thus *in vitro* meat holds great promises as an alternative to traditionally produced meat provided consumer resistance can be overcome. However, *in vitro* meat production on an industrial scale is feasible only when a relatively cost-effective process creating a product qualitatively competitive with existing meat products is established and provided with governmental subsidization like that provided to other agribusinesses.

CHAPTER 80

Current State of Clinical Application

Shaun M. Kunisaki[1], **Dario O. Fauza**[2]

INTRODUCTION

The overall impact of tissue engineering in biomedical science has been fairly diverse in nature. Directly and indirectly, it has enhanced our understanding of the structure-function relationships within normal and pathological tissues and of multi-dimensional physiologic processes. It has also broadened the possibilities for testing pharmacological therapies [1]. Still, the ultimate benchmark for the success of tissue engineering, as a multidisciplinary field, remains its ability to generate new and more effective therapies for patients afflicted with severe tissue loss and/or organ failure [2]. Based on this measure, only a handful of tissue-engineered products have reached the bedside. By and large, thus far these clinically tried tissue-engineering therapies have demonstrated mostly adequate safety, with only modest, if any, therapeutic benefits in small, defined patient populations, or even simply through anecdotal data [3]. Therefore, it is safe to say that tissue engineering has yet to fulfill its promise for the vast majority of patients in need [4].

As discussed in previous chapters, tissue-engineering technologies fall into a variety of ever expanding strategies, including (but not limited to): simple delivery of isolated cells (cell transfers); tissue-inducing substances and/or devices; extracorporeal and/or encapsulation techniques (closed systems); and transplantation of cells within matrices (open systems). This chapter outlines some of the present challenges in the clinical development of the field, while offering a concise, general outlook on the current state of clinical application of so-called open systems tissue engineering. More detailed reviews of the clinical experience involving the many other tissue-engineering approaches are discussed elsewhere in this book.

CURRENT CHALLENGES

Practical considerations

Timing is an inherent limitation of many tissue-engineering applications, not the least open systems. Although autologous approaches obviate the risk of immunologic rejection, they typically involve weeks, if not months, of processing in order to culture a sufficient number of cells for a given composite construct. Yet time is often an unaffordable luxury for many

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00080-X

patients, particularly those with life-threatening conditions and/or for whom limited treatment alternatives currently exist.

Another practical barrier has been the relatively high cost of these technologies. Because elaborate and expensive infrastructures are often necessary for the development and manufacture of engineered tissues, products designed to address relatively rare disease processes are often difficult to remain sustainable in the long term. Indeed, many firms with considerable interest in tissue engineering and regenerative medicine therapies have exited the market despite early studies suggesting efficacy. Production within Good Manufacturing Practice (GMP) facilities are a prerequisite for Food and Drug Administration (FDA) approval of cell-based therapies, which, in turn, cannot be pursued without a critical mass of highly trained personnel [5–7]. Furthermore, certain tissues require preconditioning in complex bioreactors, which may not be readily amendable to scaled-up manufacturing and shipping [1]. All of these issues translate into a chronic difficulty in establishing multicentric clinical trials, which are in turn essential for the widespread application of new therapeutic strategies.

Regulatory matters

Despite the common goal of introducing safe tissue engineered products within the clinical arena, most have perceived the regulatory constraints imposed on the field to constitute a significant barrier towards clinical translation [8]. In the United States for example, the FDA has a long history of being notoriously slow at initiating and conducting product approval processes in tissue engineering. This problem has been attributed, at least in part, to the lack of clear regulatory frameworks and occasionally to uncertainties regarding whether tissue engineered products should be classified as mechanical implants, biological materials, or both. Furthermore, unlike many other biotechnology developments, cell-based tissue engineering technologies are rather unique in that they need to be thoroughly tested for infectious pathogens, tumorigenic potential, and immune reactions (the latter even in autologous applications, stemming from cell processing and/or scaffold composition). Engineered tissues also need to be rigorously studied in animals prior to clinical application. Depending on the particular product, such testing may require costly large animal models as a means to provide final proof of principle and safety to the FDA prior to implantation in humans [9].

For many companies devoted exclusively to tissue-engineering technologies, such regulatory burdens and delays, combined with strict reimbursement policies and intermittently poor business models, have often conspired to a commercially untenable enterprise. A few American biotechnology companies have been able to seek different tactics by accumulating clinical data overseas at lower costs, given that many other countries tend to have far less stringent regulatory procedures with regard to the marketing and clinical application of novel medical products than those enforced in the United States. Recently, this has been evidenced by several US regenerative medicine firms initiating their pilot tissue-engineering clinical trials in countries such as Mexico, Argentina, Korea, and Poland [10,11].

Scientific limitations

The rapidly changing technologies within the broad, multidisciplinary field of tissue engineering have sometimes made clinical evaluations fairly difficult. For example, the ideal cell type or even cell source for many clinical applications remain undetermined. In many cases, while differentiated autologous cells would be ideal, their use simply may not be a viable option in humans, either because of current isolation and expansion limitations (e.g., hepatocytes, neurons, cardiomyocytes, pancreatic islet cells) or because they tend to dedifferentiate over time (e.g., chondrocytes). Each cell type has its own unique advantages and disadvantages, which are discussed in depth in other chapters. Human embryonic stem (hES) cells and induced pluripotent stem cells (iPS) are relatively new and potent alternative sources for tissue

engineering, but also carry potential tumorigenic behavior, peculiar immunologic limitations, or have remained hampered by social and ethical constraints, particularly in the case of hES cells. Even autologous cells in culture may not be completely free of pathogens, since the culture media often requires xenogeneic growth factors, such as fetal bovine serum, for optimal growth, or because certain cells can only propagate consistently on murine feeder layers. At this time, infectious risks cannot be completely eliminated with these xenogeneic techniques.

Another scientific limitation is the lack of an optimal biomaterial for many clinical tissue-engineering applications. Many of the currently available synthetic scaffolds are still metabolized by the body leaving a significant foreign-body reaction behind. These conditions can lead to a reduction in the diffusion of nutrients and waste products, fibrosis, and other complications. Additionally, the cytotoxic effects of macrophage-generated nitric oxide can reach and destroy the transplanted cells. Thus, it is not surprising that most of the scaffolds that have been implanted in humans to date are derived from natural scores (e.g., bone, dermis, interstinal submucosa). Unfortunately, at the same time, natural scaffolds have been associated with unfavorable mechanical properties (e.g., rapid or inconsistent degradation, low or erratic tensile strength). Further, some chemicals used in the decellularization process are known to negatively affect the properties of the scaffold.

For these reasons, there remains a continued interest in the development of novel biocompatible synthetic biomaterials amongst materials scientists and others. For example, electrospinning is a somewhat novel, alternative approach for creating scaffolds that can be made with finely tuned biomechanical specifications. The advantages of this technique include the ability to make scaffolds with high porosity as well as high surface area to volume ratio, while mimicking the dimensions and structure of native collagen and elastin fibrils. Finally, scaffolds impregnated with growth factors or specific peptide sequences may also allow for better control of the surrounding microenvironment. Indeed, these newer synthetic materials, discussed in depth in other chapters, will be instrumental in helping to broaden the types of engineered tissues that can be rendered viable for human use.

Vascularization hurdles

Typically, any tissue greater than 1 cm in thickness cannot rely solely on vascular ingrowth from the host's vascular bed in order to remain viable *in vivo*. It is therefore not surprising that most successful clinical applications involving tissue engineering have dealt with the implantation of either surface lining (e.g., skin); simple, hollow organs (e.g., bladder); or relatively small, vessel-like conduits (e.g., blood vessels, trachea). A major challenge in the clinical implementation of more sizable and complex engineered structures and organs such as liver, heart, kidney, and lungs continues to revolve around how to best optimize the blood supply to the graft after implantation. One interesting, already preclinical approach to address this problem has been to create a preformed microcirculation within the engineered scaffold itself [12]. This strategy has been employed by Vacanti and his colleagues using microelectromechanical systems (MEMS) technology in a large animal model [13]. Preliminary work has enabled this group to develop a robust computational model of the vascular circulation, which includes the fractal nature of network topology, the rheology of blood flow through this computational system, and the mass transfer of oxygen and nutrients across the vascular bed. Vascular channels can be etched onto silicon wafers, which can then be transferred to biodegradable polymer systems. Multiple monolayers of this architecture can then be stacked to form three-dimensional structures. Another described approach to organ revascularization has involved seeding of the vasculature of a decellularized organ with endothelial cells in a bioreactor prior to anastomosis of the engineered graft, albeit so far only in rodent models [14]. Conceivably, some of these approaches might possibly become instrumental in facilitating the formation of other complex accessory networks (e.g., neural, lymphatic, biliary) between the host and engineered tissue itself. Two other approaches to enhance construct

vascularization, namely gene therapy and scaffold-based encapsulation of angiogenic growth factors (e.g., vascular endothelial growth factor), have also been pursued in preclinical models [15].

CLINICAL APPLICATIONS

As with many other novel medical technologies, translation of tissue-engineering applications from the bench to the bedside has not been easy, and many hurdles still need to be surmounted. Over the last decade, we have seen a number of tissue-engineered products that have either been abandoned following Phase I/II clinical trials, or have failed in Phase III clinical testing [16]. Nevertheless, there remains a slow but steady introduction of tissue-engineering products into the clinical arena. Below is a small yet illustrative sampling of some of the clinical experiences with open systems tissue engineering within the past decade. It is by no means purported to be a comprehensive, all-encompassing list.

Cardiovascular repair

Congenital heart disease is the leading cause of neonatal death due to congenital anomalies. In particular, single ventricle anomalies are especially threatening, often requiring several life-saving operations within the first few months of life in order to prevent irreversible congestive heart failure. A commonly performed procedure in these patients involves separation of the pulmonary circulation from the systemic circulation by creating a cardiac total cavopulmonary connection with a biocompatible synthetic conduit (e.g., Dacron, du Pont de Nemours, Wilmington, DE; or Gore-Tex, W.L. Gore & Associates, Newark, DE). Unfortunately, these synthetic conduits are prone to thromboembolic complications, are susceptible to infection, and do not grow with the patient through childhood. As a result, some of these patients are forced to undergo risky re-operations to revise the conduit. These procedures are associated with significantly higher rates of mortality and morbidity.

A tissue-engineered blood vessel conduit composed of autologous cells seeded on a biodegradable scaffold would be a significant advance towards avoiding the many disadvantages associated with synthetic conduits. In both large animal models (lambs) and humans, investigators have shown that tissue-engineered blood vessels can be made using a tubular scaffold composed of polyglycolic acid woven with either ε-caprolactone or L-lactide [17]. These scaffolds are seeded with autologous bone marrow mononuclear cells for two hours prior to implantation (Fig. 80.1). In 2001, Shin'oka and colleagues in Japan described their initial case report — a 4-year-old girl who developed total occlusion of her right pulmonary artery after a pulmonary artery angioplasty and a Fontan procedure, and subsequently underwent reconstruction with an autologous vessel graft engineered from cells obtained from a peripheral vein [18]. The construct remained patent for more than seven months after implantation. Between 2001 and 2004, a total of 25 children with congenital heart disease with a mean age of 5.5 years at the time of implantation were followed for over nine years postoperatively with tissue-engineered grafts as described above, with encouraging results [19].

This early experience supported the overall feasibility and safety of tissue-engineering technologies within pediatric cardiac surgery but also highlighted the problem of graft stenosis secondary to neotissue formation in approximately 15 to 20% of patients (Fig. 80.2) [20]. Fortunately, this complication has not been associated with any known clinical sequelae and has generally been amendable to percutaneous angioplasty. After further, more extensive studies in animal models by Shin'oka and Breuer, the first US patients were finally approved to receive tissue engineered vascular implants by the FDA in 2012. Whether the next generation of tissue-engineered blood vessel conduits for pediatric cardiac repair will be associated with lower long-term morbidity remains to be determined [21].

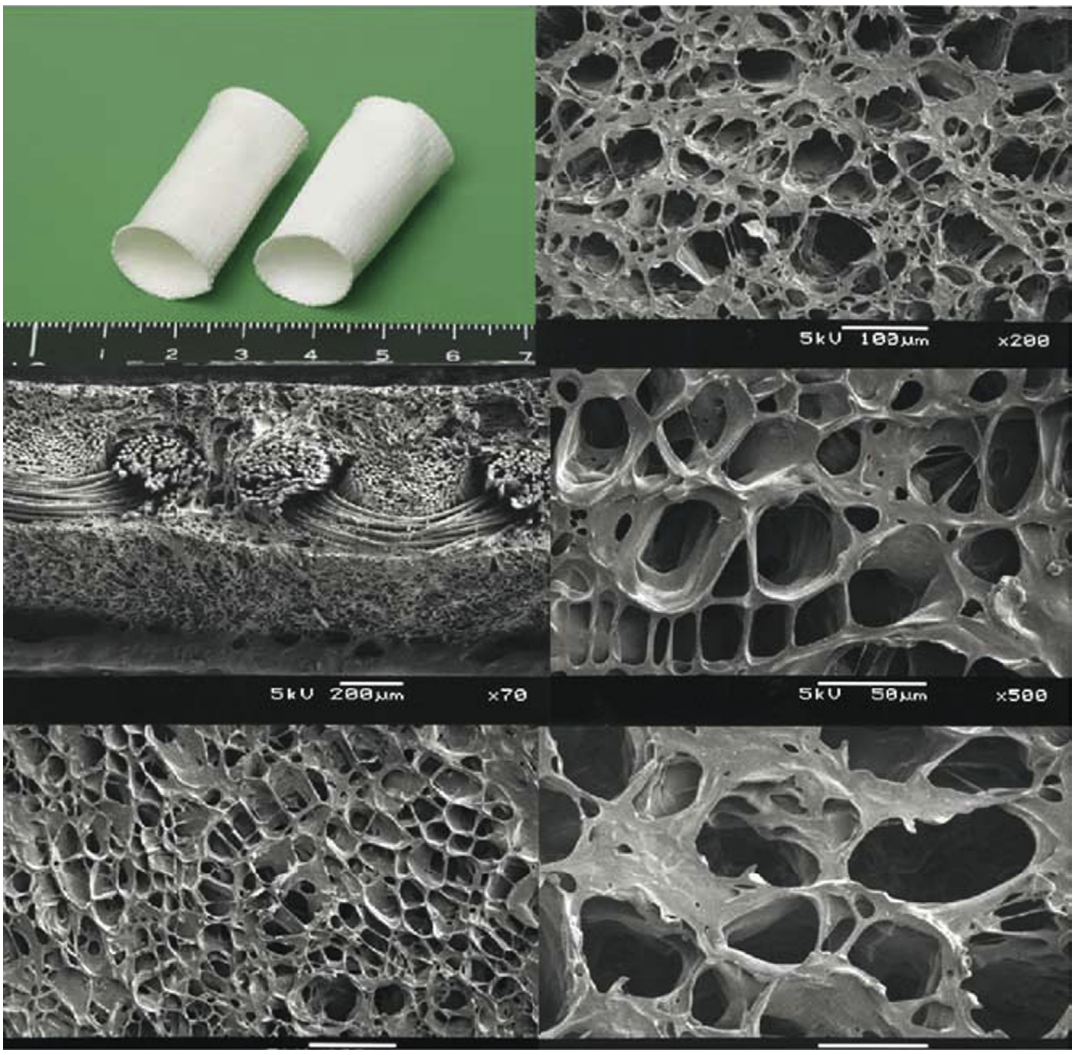

FIGURE 80.1

Macroscopic and scanning electromicroscopic appearance of biodegradable scaffolds used for cardiovascular tissue engineered conduits. The scaffolds are based on a copolymer of lactide acid and polycaprolactone. *(From Shin'oka et al. (2005).)*

Recently, clinical reports from Germany have demonstrated some success with tissue-engineered heart values when implanted into the lower pressure, right ventricular outflow tract. The rationale for tissue engineering of heart valves is similar to that for pediatric cardiovascular conduits – to provide an implant that has long-term durability and growth potential while avoiding thromboembolic complications. In a study of two pediatric patients, a tissue-engineered pulmonary valve was created following decellularization of a human donor valve with trypsin/EDTA with subsequent seeding using autologous endothelial progenitor cells isolated from peripheral blood [22]. The construct had been preconditioned for up to 21 days in a bioreactor prior to implantation. After a mean follow-up of 3.5 years, the tissue-engineered valves functioned well and seemed to have increased in dimensions over time based on echocardiography, in parallel with the overall somatic growth of the child. In a separate study of 11 patients, autologous endothelial progenitor cells were isolated from forearm vein and were used to seed valve allografts with good long-term results at 10 years follow-up [23]. Since most conventional unseeded allografts tend to fail between 15 and 20 years after implantation, longer follow-up will be required to ultimately define the utility of tissue-engineered heart valves in cardiac surgery.

(b) Three-dimensional computed tomography angiogram of an engineered graft one year after implantation. Red arrows indicate location of the implant. *(From Duncan and Breuer (2011).)*

VASCULAR REPLACEMENT

Tissue-engineered small-diameter conduits capable of withstanding arterial blood pressures are of great interest to vascular surgery, largely because of the epidemic of atherosclerotic peripheral vascular disease in the United States and other developed countries [24]. Unfortunately, the use of such conduits has yet to achieve widespread success in humans thus far. This has been due to a variety of factors, including the relatively easy availability of autologous grafts, usually taken from the saphenous vein or radial artery. As a result, the need for an alternative vascular conduit capable of long-term function has not been as compelling for most vascular surgical applications. Nevertheless, certain patients may be ideal candidates for a tissue-engineering approach, either because of the lack of adequate donor tissue, or because of a prior history of graft thrombosis. In a recently completed adult trial, vascular conduits were investigated as arteriovenous shunts for dialysis in patients with end-stage renal disease (Cytograft Tissue Engineering, Novato, CA) [11]. In that study, autologous fibroblasts and endothelial cells were isolated from skin and superficial vein biopsies, respectively. Fibroblast sheets were then wrapped around stainless steel mandrels (4–8 mm diameter) and matured for 10 weeks in culture. The endothelial cells were then seeded into the lumen prior to implantation. Despite early success following implantation in a high-risk population, graft patency of these tissue-engineered vessels at three months was only 60%, implying that immunogenicity and thrombogenicity have not been completely eliminated with the use of autologous endothelial cells. Another caveat of this approach has been the extended production time required to fabricate these grafts (over seven months).

Airway reconstruction

Despite the relative rarity of surgical diseases involving airways, tissue-engineered airway conduits have been of considerable interest for the treatment of fetal, neonatal, and adult tracheal and other airway anomalies for well over a decade [25–29]. Currently, tracheal reconstruction, except for primary resection, often leads to suboptimal functional results

and is associated with substantial morbidity and mortality. Although the trachea appears to resemble a simple hollow conduit at first glance, its structure and biomechanical characteristics are actually fairly complex and demanding. The ideal tissue-engineered substitute needs to have a unique combination of properties, including being airtight, non-immunogenic, non-collapsible, well-vascularized, well-epithelialized, and conducive to sustained chondrogenesis [30].

Based on previous work done primarily in large animal models, the early clinical experience with tissue-engineered tracheas has been arguably promising. To date, a number of patients, mostly in Europe have undergone tracheobronchial replacement with a cellularized tissue-engineered construct without the need for immunosuppression, with interesting results [28]. Both decellularized airway and synthetic scaffolds have been used, typically seeded with autologous bronchial epithelial cells and bone marrow-derived mesenchymal stem cells and/or differentiated chondrocytes.

Like many of the vascular conduits implanted into humans, a limitation of the current approach in tracheal engineering has been the extended length of time required to fabricate these constructs. To address this problem, more recent techniques have attempted to streamline this process by using nano-composite polymer and growth factor-induced endogenous stem cell mobilization to enhance engraftment and remodeling *in vivo* [31]. However, regardless of the approach, long-term follow-up, a better understanding of how the airway changes and remodels over time *in vivo*, along with comparisons in controlled Phase III trials will be essential before more widespread application of this technology can be justified.

Urinary tract repair

Traditionally, complex urologic reconstruction of the bladder, ureter, and urethra has relied on the use of heterotopic autologous grafts such as stomach, intestine, or colon. None of these structures constitute ideal urologic replacements as they lack urothelium and are associated with significant morbidity, including urolithiasis, metabolic disturbances, and malignant degeneration. As a result, investigators have long been evaluating tissue-engineering approaches for urologic reconstruction, leading up to some clinical experience.

The early clinical applications of tissue engineering in urology focused on bladder augmentation (cystoplasty). This procedure is commonly indicated for high-pressure, low compliant bladders secondary to spina bifida, spinal cord injury, or urge incontinence. Although anti-cholinergic medication and intermittent bladder catheterization can be effective, surgical reconstruction with intestine remains the current standard in severe cases. To date, tissue engineered bladders, referred to as Neo-Bladder Augment™ (Tengion, East Norriton, PA), have been implanted into several myelomeningocele (MMC) children with end-stage bladder disease, albeit only in a Phase I trial. In a report by Atala and colleagues, patients underwent a bladder biopsy ($1-2$ cm^2) through a small suprapubic incision; the muscle and urothelial layers were separated and expanded *ex vivo* in the laboratory [10]. After approximately two months, scaffolds composed of bladder submucosa with or without polyglycolic acid were seeded with both cell types and sutured to the dome of the bladder three to four days later. Post-operatively, bladder capacity seemed increased based on urodynamic studies at a mean follow-up of 46 months. Despite these early feasibility results, Tengion abandoned plans for Phase II trials and further work in 2011 based on a variety of factors, including limited to no clinical efficacy and the occurrence of serious adverse events. The trial was also hampered by the lack of a control group (i.e., standard enterocystoplasty), as well as the absence of data on innervation, in part because of the underlying voiding dysfunction within the MMC population.

In contrast to bladder augmentation, one area of urologic tissue engineering that has received considerable attention in recent years is urinary diversion for bladder cancer [32]. Bladder cancer is one of the most common cancers worldwide with over 20,000 urinary diversions

performed in the United States and Europe annually. The current standard for urinary diversion uses a piece of intestine to transport urine through a hole in the abdominal wall into a standard ostomy bag. As of early 2012, Phase I clinical trials at five US medical centers were ongoing for Tengion's tissue-engineered urinary conduit (Neo-Urinary Conduit™) in patients requiring urinary diversion following cystectomy for bladder cancer. Instead of using a segment of ileum, Neo-Urinary Conduit™ carries urine from the ureters to the skin surface using a polylacetate glycolate scaffold seeded with autologous smooth muscle cells isolated from autologous abdominal fat.

Similar techniques have been used to implant other tissue-engineered urological structures in humans, including tubularized conduits for posterior injuries of the membranous urethra secondary to trauma. In a Mexican study involving five boys, polyglycolic acid-based cellularized constructs were used to repair 5 cm long urethral injuries [33]. Further controlled analyses are needed to determine the role of precise tissue-engineered urethras as an alternative to buccal mucosa or skin in patients requiring urethroplasty. As it is the case in virtually all other reports involving clinical application of engineered grafts to date, the clinical experience with tissue engineering in urology lacks trials with suitable controls, and none of the products are approved by the FDA as of this writing.

CONCLUSIONS

Based on the classic open systems tissue-engineering paradigm of cells seeded onto biodegradable scaffolds, clinical application of engineered blood vessels, airways, heart valves, urinary tract, and other tissues is no longer considered fiction. A graduated approach, based on extensive background work by multiple disciplines testing these products in both small and large animal models, has enabled this technology to reach the bedside for selected patients with difficult problems requiring surgical reconstruction. However, much like the early clinical experience with human organ transplantation, the enthusiasm and excitement over the clinical possibilities uncovered by tissue engineering should be tempered until significant advancements, both in the laboratory and at the bedside, demonstrate better results in carefully controlled studies well beyond short descriptive case series or mere anecdotal data. The transition of many of the current approaches to tissue engineering towards sizable clinical scale remains to be seen, as the notion that off-the-shelf, fully cellularized 'products' can replace faulty tissues on a routine basis is still, for the most part, a dream. Perhaps this should not come as a surprise as this is still a relatively immature field.

Although the state-of-art in experimental tissue engineering continues to change rapidly, significant refinements in laboratory protocols and techniques are needed if further progress in the clinical arena is to be achieved. Persisting challenges including enhancements in scaffold materials and design, along with headway in xeno-free cell expansion, among other technical advances, will be essential to allow for optimal phenotypic control of the final tissue-engineered product. Furthermore, defining the ideal target population that can readily and safely benefit from tissue-engineering strategies in significant numbers remains challenging, to some extent due to the progress constantly taking place in other approaches to surgical reconstruction. Nevertheless, it is reasonable to hope that continued efforts in this vibrant, ever expanding multidisciplinary endeavor should contribute to broaden its impact, so as to eventually reach a large number of patients in need of tissue repair and/or replacement.

CHAPTER 81

Tissue-Engineered Skin Products

Jonathan Mansbridge
Histogen Inc., San Diego, California

INTRODUCTION

Skin tissue engineering was perceived as the simplest tissue-engineering application and was the earliest to be explored. The culture of fibroblasts, derived from skin biopsies, was established early. The cells were comparatively easy to grow and were used to develop many of the early systems of tissue culture. The culture of keratinocytes was achieved by Rheinwald and Green in the late 1970s [1], and using a different system, by Karasek [2]. Skin biology was second only to immunology in the application of the techniques of molecular and cell biology to medical problems, which has led to great advances in the understanding of the physiology of skin. Examples of methods that have been applied include the use of classical techniques of molecular and cell biology and transgenic animals.

The skin acts as a barrier between internal structures and the external environment. In the 1980s it was realized that the skin, in addition to acting as a barrier, also has significant interaction with both the innate and the adaptive immune systems [3,4]. It is thus much more than a passive barrier and actively recruits defensive mechanisms to protect against infection, colonization by microorganisms and other external noxious entities.

With its long history of development, tissue-engineered skin substitutes have achieved market exposure and have some of the most extensive experience with the application of such products in a therapeutic setting. From its inception in 1979 [5], engineered skin was seen as potentially a clinical product and trials started in the 1980s. Preclinical testing was inaugurated, and demonstrated that fibroblasts were apparently not rejected and persisted for a considerable period in experimental animals [6–8]. This led to human clinical trials in the late 1980s and early 1990s. Tissue-engineered skin products first gained regulatory approval and appeared on the market in 1997. The first was TransCyte (Advanced Tissue Sciences, which was a non-viable burn product produced by tissue-engineering techniques). It was followed by Apligraf (Organogenesis) in 1998, the first tissue-engineered, viable, organotypic product, Dermagraft in 2000 and Orcell in 2001. At the same time, many applications of such products for *in vitro* testing applications and models of skin physiology were developed.

Much of the discussion in this article is based on experience with Dermagraft and TransCyte. Both products have a similar basis in growth of fibroblasts on three-dimensional scaffolds. The systems, however, differ substantially in detail.

Dermagraft is grown on 2 inch × 3 inch sheets of a knitted polylactide/glycolide scaffold under static conditions in a bag bioreactor. Following seeding, the cultures are refed with medium every few days until harvest after about two weeks. Initially, the fibroblasts proliferate rapidly,

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00081-1

much as in monolayer, but as they become confluent, at about 8–10 days, they lay down increasing amounts of extracellular matrix. At harvest, medium is replaced with cryoprotectant, the bioreactor is welded closed without exposure of the product to the environment, boxed and frozen under controlled conditions. Dermagraft is stored below −65°C for up to six months. During the first month, sterility and analytical testing is performed and the paperwork completed to allow release of the product by the Quality Assurance Department. On thawing, which is performed by the end user, the cells of Dermagraft show 50–80% viability.

TransCyte was grown using a similar process on two 5 inch by 7 inch sheets of a knitted nylon (non-degradable) scaffold with a silastic backing in a continuous flow, hard bioreactor. This system has advantages in the ease of taking medium samples and in slightly superior cell growth but it adds considerably to the complexity of the system. At harvest, the cultures were rinsed, the bioreactors sealed from the system by welding, packaged and frozen without any care taken to maintain viability.

The three-dimensional structures formed by the cells under these conditions consist of cells embedded in extracellular matrix that they, themselves, have secreted. It comprises a complex series of molecules. The process of secretion may be thought of as formation of a foreign body capsule *in vitro*.

TYPES OF THERAPEUTIC TISSUE-ENGINEERED SKIN PRODUCTS

The development of tissue-engineered skin has taken two fundamentally different approaches using alternative methods for the three-dimensional culture of fibroblasts and a third which has intermediate characteristics. One is the use of fibroblasts suspended in collagen gel, in which the gel acted as a substrate for the growth of keratinocytes and forms a structure that has some resemblance to human skin. The second involves culture on a three-dimensional non-biologically derived, polymeric scaffold. Fibroblasts are responsive to signals from their environment and respond in quite different ways to the two types of culture. In a third system, fibroblasts are grown on a collagen sponge in serum-containing medium. Since collagen adsorbs fibronectin and vitronectin, this system initially shows cell adhesion to both collagen, fibronectin and vitronectin and the cultures show intermediate properties.

In collagen gel suspension, fibroblasts are surrounded by collagen, and respond through $\alpha_1\beta_1$ and $\alpha_2\beta_1$ integrins which are collagen receptors, by becoming quiescent and non-proliferative [9]. Characteristically, the collagen gel is contracted by the fibroblasts to less than 10% of its original volume in about 20 hrs, through the $\alpha_1\beta_1$ integrin. At the same time, many genes, notably those for collagen type I and proliferation, are repressed [10] and the cells show mechanosensitivity [11]. The collagen repression is mediated through the $\alpha_1\beta_1$ integrin [9]. If the gels are mechanically stressed, usually by preventing contraction with a ring, many genes, including collagen type I and proliferation related genes are somewhat induced relative to contracting gel fibroblasts, although not to the level of monolayer fibroblasts [11]. The cells also show a substantial upregulation of genes associated with inflammation such as the genes for IL-1, IL-6 and cyclooxygenase [12].

When grown on scaffolds, fibroblasts proliferate rapidly and then deposit large amounts of extracellular matrix. Initially, the conditions on the scaffold are not dissimilar from monolayer culture. The scaffold adsorbs proteins from the serum, which is a component of the medium still used for fibroblast culture. The proteins include fibronectin and vitronectin as in monolayer culture [13]. However, as the cells reach higher densities and the fibroblasts cease to proliferate, they proceed to lay down extracellular matrix at rates approaching their own weight per day. The matrix is loose connective tissue, much like the provisional matrix of granulation tissue. The cells are clearly very active and induce several genes, among the most notable of which are neutrophil chemoattractant chemokines, CXCL1, CXCL5, CXCL6 and CXCL8. They also induce the expression of IL-6 and IL-11. The conclusion from these

observations is that the fibroblasts act to recruit neutrophil granulocyte components of the innate immune system, which is important in responding to the most likely type of environmental insult to which the dermis is liable, physical injury followed by bacterial colonization.

COMPONENTS OF TISSUE-ENGINEERED SKIN GRAFTS AS RELATED TO FUNCTION

Scaffold

Several types of scaffold have been employed for tissue-engineered skin implants. They include collagen gels, knitted polylactate/glycolate fabrics (PLGA) and collagen sponges. As discussed above, the scaffold has profound effects on gene expression and the function of the fibroblasts.

The Dermagraft and TransCyte processes used scaffolds obtained as finished commercial products from other companies, which already had regulatory approval. While this simplified the development of the products, it ultimately proved an expensive decision. A solution to this is to obtain a second source of raw material that is not a finished product and establish its equivalence.

A further point here is that, while the use of already approved products as scaffolds may be an easy initial path, the available materials may not be ideal for the particular application envisaged. There remains a need to expand the range of scaffolds available for commercial tissue engineering. An example is enzymatically, rather than spontaneously, degrading scaffolds.

An interesting direction is the development of scaffolds incorporating a vascular capability. Revascularization of skin substitutes is a limitation in their application and the ability to be perfused by the host circulatory system would be a major advance. Scaffold with this type of capability may be made by decellularizing a perfused tissue and then using the extracellular matrix structure [14].

Keratinocytes

Keratinocytes generate the impervious surface of the skin (the stratum corneum) and also have been thought of as having a major role in defense against microbial colonization as activators of immune responses. As a consequence, keratinocytes have been included either alone or in combination with other components in many skin implants [15]. Their role in forming a physical barrier is important, but they also have the ability to produce antimicrobial peptides, such as β-defensin, psoriasin and cathelicidin [16,17] and a wide variety of cytokines capable of activating immune responses [18,19]. The epidermis contains antigen presenting cells that are capable of activating T-lymphocytes under suitable conditions to both cell mediated and humoral adaptive responses. This is largely a function of Langerhans cells, but it is possible that the keratinocytes also take part under special conditions. It has been argued that the application of a bag containing keratinocytes to a wound, that would be permeable to proteins, but not to cells, may be beneficial without incorporation of the cells into the patient (United States Patent 5972332).

It is notable that the keratinocytes show a higher expression of the fibroblast stimulating platelet-derived growth factor PDGF A chain gene than do fibroblasts. This may constitute part of the secretion of reciprocal paracrine growth factors by the epidermis and the dermis [20]. Such a pathway has been described by Fusenig, involving IL-1α secretion by keratinocytes, which stimulates secretion of FGF-7 (keratinocyte growth factor 1) and granulocyte-macrophage stimulating factor (GMCSF) that promote keratinocyte proliferation [21]. Such interactions may well be of importance during wound repair when proliferation of both types of cells is important [22].

In practice, allogeneic keratinocytes in skin implants appear to remain for some weeks and then disappear. This has been attributed to immunological rejection, but this is not clear

as keratinocytes, cultured to the numbers required for a skin implant, consist almost entirely of transiently amplifying cells that follow a differentiation pathway that leads to a modified form of apoptosis. They may, thus, be expected to be lost from the implant without the intervention of the immune system.

An approach that has been explored for increasing the coverage and survival of grafted epidermis is to mix allogeneic with autologous keratinocytes. This permits a comparatively small number of autologous keratinocytes, without extensive expansion, to cover a large area [23]. The allogeneic cells provide initial coverage, while the autologous population, which retains stem-like cells, provides the persistence. Most of the allogeneic cells are eventually lost, but the epidermis remains.

An alternative application of keratinocytes to wounds by spraying has been explored. The cells survive the experience and the technique provides a very simple and convenient way of applying them [24]. It is possible to envisage a system spraying largely allogeneic keratinocytes together with a fresh autologous keratinocyte suspension isolated intraoperatively from skin or scalp [25].

Fibroblasts

Fibroblasts are the major producers of extracellular matrix, discussed below. They are not antigen presenting cells and have been regarded as not having a major role in interactions with the immune system. However, their ability to secrete neutrophil attractant chemokines, CXCL-1, CXCL-4, CXCL-5 and CXCL-8, and the cytokines IL-6 and IL-11, discussed below, suggests that they may have a more important role in activating innate immune responses.

Fibroblasts do not appear to produce significant quantities of defensins, cathelicidin or other antimicrobial peptides. Their major antimicrobial activity appears to be through recruiting neutrophils.

Extracellular matrix

Fibroblasts express a large array of extracellular matrix genes. Proteins giving the 30 highest signals on Illumina expression arrays are listed in Table 81.1. Expressed genes represent collagens, types 1, 3, 5, 6, proteoglycans (decorin, lumican), thrombospondins, fibulins, fibronectin, tenascin C, metalloprotease inhibitors, lysyl oxidase, tissue factor inhibitor and Secreted protein, acidic, cysteine-rich (SPARC). It also includes matrix-bound growth factors, such as FGF-2 and TGF-β. The matrix includes multiple kinds of integrin ligand, including those for integrins $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_3\beta_1$, $\alpha_4\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_1$, $\alpha_v\beta_1$, $\alpha_7\beta_1$, $\alpha_6\beta_4$ and proteins that are known to modify adhesion. It provides complex stimulation that, since it is secreted by fibroblasts, is presumably appropriate for cell migration. In systems where fibroblasts are cast in collagen gels, the initial signal is through the $\alpha_1\beta_1$ and $\alpha_2\beta_1$ integrin and that remains the dominant stimulus until the cells elaborate other signaling molecules.

Subcutaneous fat

Subcutaneous fat has received little attention thus far in the engineering of skin. However, it has been shown to undergo major structural changes during the hair cycle in the mouse and is a highly vascular organ. Fat-derived stem cells have been used successfully in the production of skin substitutes and may provide advantages over fibroblasts [26].

Components of the immune system

Inclusion of Langerhans cells has been accomplished in test systems but has not been applied to therapeutic products.

TABLE 81.1 Extracellular matrix proteins secreted by fibroblasts in three-dimensional culture, as a percentage of the protein giving the highest signal on an illumina expression array (SPARC)

Extracellular matrix protein	Signal as percent of SPARC
Collagen, type I, alpha 1	18.83%
Collagen, type I, alpha 2	36.51%
Collagen, type III, alpha 1	30.96%
Collagen, type IV, alpha 1	4.67%
Collagen, type V, alpha 1	12.54%
Collagen, type V, alpha 2	11.85%
Collagen, type VI, alpha 1	17.60%
Collagen, type VI, alpha 2	5.66%
Collagen, type VI, alpha 3	16.85%
Collagen, type VIII, alpha 1	6.61%
Collagen, type XVI, alpha 1	6.20%
Decorin	15.13%
Biglycan	5.92%
Lumican	42.19%
Secreted protein, acidic, cysteine-rich (SPARC, osteonectin)	100.00%
Testican	7.49%
Spondin 2	7.83%
Fibrillin 1	10.24%
Elastin microfibril interfacer 1	5.72%
Microfibrillar-associated protein 2	0.29%
Microfibrillar-associated protein 4	8.34%
Fibulin 1	0.27%
Fibulin 2	7.77%
Fibulin 2	7.77%
EGF-containing fibulin-like extracellular matrix protein 2	6.86%
Fibronectin 1	0.39%
Tenascin C (hexabrachion)	10.98%
Thrombospondin 1	30.53%
Thrombospondin 2	8.50%
Tissue factor pathway inhibitor 2	21.16%
Laminin, gamma 1	12.91%

Melanocytes

Other cells of the epidermis have been incorporated into test systems and have also been considered for transplant into epidermal tissue-engineered therapeutic products. An example is the inclusion of melanocytes as a treatment for vitiligo, which is a clinical problem in countries such as India. Systems including melanocytes have been used extensively in test systems for ultraviolet radiation (UV) protective preparations.

Adnexal structures

The self assembly of hair follicles and their use as a therapeutic product is discussed later in this chapter. Inclusion of sweat glands has been explored, but they have not yet been included in tissue-engineered constructs. The early fear that patients treated with keratinocyte allografts might have problems with temperature control has not eventuated.

COMMERCIAL PRODUCTION OF TISSUE-ENGINEERED SKIN PRODUCTS

Commercial production of tissue-engineered skin products takes place in a precisely controlled and highly regulated environment, which imposes many constraints if the process

is to be successful. These will be discussed under a series of headings, dealing with physical constraints, such as bioreactor design, growth system design, cell sources and with broader considerations of the nature of preclinical and clinical assessment, government regulation, reimbursement and the market place. It is central to a commercial enterprise that it ultimately make a profit if it is to be successful. Since tissue engineering is inherently an expensive undertaking, minimizing costs at all stages is essential.

Regulation

Regulation of tissue-engineered products by the FDA or other regulatory authorities is still developing. Since commercial products have only been available for less than 20 years and since they are very different from other medical products, establishing a regulatory pathway has been complex. Tissue-engineered skin substitutes do not fit readily into any of the standard FDA categories; drugs Center for Drug Evaluation and Research (CDER), biologics Center for Biologics Evaluation and Research (CBER) or devices Center for Devices and Radiological Health (CDRH). Classification is important as requirements, criteria and guidelines differ substantially between the centers. Skin implants were originally considered as dermal or skin replacements and classified as devices. As it became evident that growth factor activity played a part in their mode of action, considerations appropriate to biologics played an increasing role. There is now within FDA an Office of Combination Products responsible for assembling reviewers from different FDA centers to form a team to review such products. While tissue-engineered skin substitutes generally have more biochemical activity than would be expected of a pure device, they do not fit easily as a biologic. For instance, the concept of 'dose' is not straightforward. If a component of the activity of these materials is through secretion of growth factors, growth factor production would seem to be a reasonable release criterion. However, unlike a purified growth factor preparation, these products are living, and the secretion of growth factors may vary depending on conditions. The cells adjust their cytokine output to the environment in the wound bed. It may be possible to devise conditions under which secretion of a growth factor (for instance, vascular endothelial growth factor (VEGF)) is maximal (with optimal platelet-derived growth factor (PDGF) stimulation) and determine output under those conditions. To avoid such problems, a 'dose' of Dermagraft has been defined as a piece.

Also, at this stage, the composition of tissue-engineered skin can only be determined to a limited extent. Usually, it is desirable that a biologic contains well-defined constituents, including an active ingredient at a known dose and excipients. Thus far, studied components of skin implants have included those that are known and, to some degree understood, from other work. There is no comprehensive identification of constituents, and several that appear on expression arrays, such as lumican and collagen type 6, which are prominent, have received inadequate attention.

However, despite these difficulties, the FDA is placing increasing emphasis on the biological aspects of skin substitutes and overseeing them as biologics and as drugs.

Product development

Development of a commercial product should start with a Product Concept from which a Design Requirements document is developed. As an example, Table 81.2 shows the product concepts for Dermagraft and TransCyte. The product is then developed to meet the design requirements by a series of hierarchical, more and more detailed design processes that ultimately comprise the Design Master File. The requirements can be divided into groups: in each case, the first statement is concerned with the therapeutic purpose of the product, the next three describe intrinsic characteristics of the product and the last three are concerned with

TABLE 81.2 Design concepts for dermagraft and TransCyte

Dermagraft	TransCyte
Dermal replacement, later as a cytokine factory	Transitional covering for third degree burns to replace cadaveric skin
Allogeneic	Allogeneic
Viable product	Non-viable

Long shelf life (~6 months)	Long shelf life
Suitable size	Suitable size (from Biobrane size)
User friendly presentation – modified bag	User friendly presentation – clamshell bioreactor

practical issues of importance to the final user. All these factors need to be considered from the earliest stages of development.

Overall concept

The initial application for Dermagraft was a dermal replacement for burn patients. Initial clinical application indicated that it provided little benefit and was slightly deleterious. As trials for chronic wound applications progressed, and it became evident that it was efficacious, the concept of Dermagraft as a cytokine source replaced the notion of a dermal replacement.

TransCyte, a replacement for cadaveric skin for covering third degree burns after debridement, was seen as a means to overcome problems with rejection and potentially with disease transmission.

Allogeneic cell source

The second item in both product concepts was that the products would be allogeneic. The decision whether a product will be allogeneic or autologous is fundamental to the entire development process. While not impossible, the development of a commercially successful (profitable), autologous, tissue-engineered product is very difficult. It requires separate, independent, tissue culture suites (hood, incubator, centrifuge, microscope and air conditioning), which will be occupied by a product for a single individual for the entire period of culture. It is a service industry, with complex logistics and high cost. As an alternative, it would be possible, in principle, to construct an automatic machine that would accept a patient's tissue and produce the tissue-engineered construct in the hospital with minimal intervention. The one advantage to an autologous process from a commercial point of view is the comparatively low requirement for safety testing and the lack of immunological rejection by the patient.

Allogeneic tissue engineering has advantages in using only one tissue culture facility per product type, allowing economies of scale and straightforward logistics. The major disadvantages are the very large amount of safety testing required for the master cell banks and the potential for immunological rejection. The first of these disadvantages is ameliorated by the infrequency of making master cell banks. In the case of Dermagraft and TransCyte, one master cell was used for more than 20 years, so the investment could be amortized over a long period. Required testing is determined by regulatory authorities and may be increased from time to time as new risks become known. It includes testing of the donor and, in the case of fibroblasts, the donor's mother for major human pathogens (Human Immunodeficiency Virus (HIV), hepatitis, cytomegalovirus (CMV), etc.). The cells isolated from the donor are tested for the major human pathogens, xenogeneic pathogens (which might be introduced from the reagents used in tissue culture), karyotype, identity (isoenzyme, variable number of tandem repeats (VNTR), single nucleotide polymorphisms (SNP), etc.), tumorigenicity, latent viruses,

etc. This is tested both on the initial Master Cell Bank and again on cells reisolated from final product (the End-of-Production Cell Bank).

Viability of product and no sterile fill

The viability of the product depends on its intended function and differs for Dermagraft and TransCyte. As discussed below, to package sterile material is a matter of some difficulty and it was decided, in this case, to avoid the issue. The bioreactor in which the tissue was grown was designed to form part of the final packaging.

Shelf life

Extended stasis preservation is important for commercial products including tissue-engineered products. It allows time for quality control testing, for off-the-shelf availability, and for distribution. In addition, the Dermagraft and TransCyte processes take 12 weeks from thawing a vial from the Manufacturer's Working Cell Bank (MWCB), cell expansion, three-dimensional growth and Quality Control (QC) testing. The difficulty of predicting the market so far ahead so as to minimize waste is greatly aided by extended shelf life. This was achieved through cryopreservation at −70°C. Other systems for long-term stabilization of tissue-engineered constructs have been explored with varying degrees of success, including trehalose, DMSO and 3-O-methyl glucose [27–29].

Size, user convenience

The remaining items in the product concept are related to convenience of use by the physician applying the product. This is an important item for a commercial product and needs much work in focus groups and thought. Thawing the product is already a major issue, requiring time and, in the case of TransCyte, careful estimation of the amount required to avoid wasting expensive material or having to wait for a piece to be thawed. The Dermagraft bioreactor was designed so that it would open easily and the tissue would be positioned (through the use of a Z-weld that attached opposite sides of the scaffold to opposite walls of the bioreactor) so as to be easily rinsed prior to use. The bioreactor is translucent to aid in marking out the piece to be cut out for implantation.

THE MANUFACTURE OF DERMAGRAFT AND TRANSCYTE

Overall schemata for the manufacture of Dermagraft and TransCyte are illustrated in Fig. 81.1. As can be seen, as much of the two processes as possible are identical. This economizes resources and reduces cost. In this case, the Master Cell Bank (MCB), MWCB, the cell expansion process and much of the release testing, are all in common. In addition, the clean room facility, all its ancillary equipment and monitoring are the same.

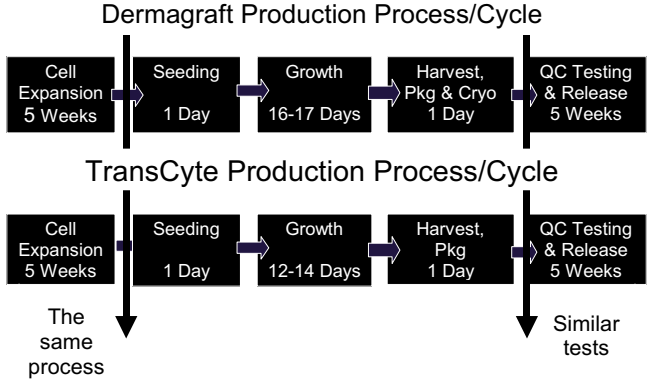

FIGURE 81.1
Overall comparison of the Dermagraft and TransCyte processes.

Cells

Several times per week, fibroblasts used in manufacture are recovered from liquid nitrogen storage (the MWCB) and expanded in roller bottles from fifth to eighth passage. This is a conventional procedure, but may not be ideal. Fibroblasts for Apligraf are expanded on beads in a mixed bioreactor. It has become evident that the proliferation of fibroblasts is improved at low oxygen (2–6%) [30] and, at this oxygen concentration, the development of a senescent phenotype may be reduced [31–33]. A tank bioreactor lends itself to active control of parameters such as oxygen tension and pH and is worth exploring before a system gets fixed by regulation. The cells should ideally be grown just to the beginning of stationary phase. Further incubation seems to be slightly deleterious.

Expansion of fibroblasts for Dermagraft and TransCyte manufacture was performed in roller bottles. These are well established for production of large numbers of cells under ambient conditions. Various other systems have been devised that may provide superior performance and greater control of the conditions of growth [34,35].

Medium

The Dermagraft and TransCyte systems are grown in Dulbecco's-modified Eagle medium, supplemented with 10% calf serum, non-essential amino acids and glutamine. All tissue culture beyond initial cell isolation from the foreskin is free of antimicrobial agents. Antimicrobial agents might hide otherwise significant contamination, which might only become evident in therapeutic application.

With the increased concern with the transmission of prion diseases, there has been great interest in developing serum-free systems. While serum-free media are available for keratinocytes, it has been found difficult to achieve such systems for fibroblasts. Serum-free fibroblasts media are commercially available, but while these have been successful in the research laboratory, transferring them to scaled-up systems and manufacturing has proved elusive. The major issue is that the cells do not grow to the extent required apparently because, early on, they acquire a senescent phenotype. It was early established that serial subculture of fibroblasts leads to senescence after about 60–80 population doublings. While this can be attained in serum-containing medium, experience with serum-free media have indicated a lifespan of about nine doublings. Since Dermagraft is made at about the 28th generation, which is about 10 doublings from the MWCB, 19 from the MCB, and implanted fibroblasts should not be too close to senescence, serum-free media do not provide sufficient proliferation potential.

The alternative solution to serum-free medium is to take extreme caution in the source and treatment of serum. By regulation, all materials used in manufacture must be traceable to their sources, but in addition, bovine serum is obtained only from countries that are free from bovine spongiform encephalopathy (BSE), which include Australia and New Zealand, from closed herds with a known pedigree history that includes no animals from outside the country. Serum is also irradiated sufficiently to eliminate possible viral contamination.

Bioreactor design

Many of the considerations of bioreactor design involve questions of mass transport, conditions under which cells are able to grow and so forth, much as in non-commercial tissue-engineering systems. A second series of considerations deals with the large-scale production process. These include ease of scale-up, ease of handling, minimal footprint and maximal automation. In addition, the use of the product by a community not experienced with products of this type is also important. This leads to features to make the product easy for the end user to work with and apply.

The bioreactor used for the growth of Dermagraft consists of a bag with eight cavities welded into it, each of which contains a sheet of the scaffold. Such bags are attached in groups of 12 to

manifolds, with a solid support, for cell, medium or cryopreservative addition, to form a system. Several systems may be connected and all fed at the same time to form a lot, which is the unit of manufacture. The bag reactors, systems and even lots may be assembled under clean, but not necessarily sterile conditions and sterilized by 25–43 Grays gamma radiation prior to seeding. From this point, the process only requires nine sterile connections, and is substantially automatic.

The TransCyte bioreactor systems are similarly assembled under clean conditions, complete with all associated tubing, and attached in groups of 12 to a manifold to form a system. This entire assembly is then sterilized by gamma radiation as described above. Several systems can then be connected to form a lot. In this case, the inlets to each bioreactor are individually passed through a peristaltic pump to provide even flow. (Attempts to use constrictions to control flow were found to be inferior.) Again, as with the Dermagraft system, once set up and seeded, the TransCyte system is substantially automatic.

Automation in tissue-engineering systems is an important feature. Apart from reducing labor costs, automation greatly reduces the number of errors that have to be investigated, requiring time, effort and cost. While operator errors are generally less serious than machine failures, they are much more numerous and still require individual investigation. Backup systems can be installed to minimize the impact of machine failure.

THE DERMAGRAFT AND TRANSCYTE PRODUCTION PROCESSES

The production of Dermagraft and TransCyte started with the cryopreserved Master Cell Bank that was stored at passage three in liquid nitrogen. About four times per year, cells were taken from this bank and expanded in roller bottles to fifth passage when they were stored again as the MWCB. This was tested to ensure identity to the Master Cell Bank. Several times per week, cells were taken from the MWCB and expanded to eighth passage in roller bottles when they were seeded to the three-dimensional bioreactors. This process is conventional, large-scale tissue culture. It uses batch feeding and exposes the cells frequently to atmospheric oxygen. As discussed elsewhere in this article, fibroblasts grow better and senesce less rapidly in a lower oxygen environment.

On seeding, the bioreactors were manipulated to ensure even distribution of the cells. In the case of Dermagraft, the bioreactors were rolled; in the case of TransCyte, each side was seeded successively under static conditions. The medium was replaced one day after seeding and then the cells fed every 2–4 days until harvest.

The time of harvest was determined from the glucose metabolism of the cultures. In the case of TransCyte, glucose consumption and lactate production were determined daily and interpreted as notional ATP turnover, assuming a P:O ratio for mitochondrial oxidative phosphorylation of 3. The resulting values were correlated with the performance of the system relative to release specifications and appropriate target values selected. In the case of Dermagraft, there was a concern that lactate release from the degradation of the scaffold might interfere with the ATP turnover estimation, so the time of harvest was determined on cumulative glucose utilization alone.

At harvest of Dermagraft, medium was replaced by cryopreservative solution that consisted of 10% dimethylsulphoxide in phosphate buffered saline, supplemented with calf serum and the individual pieces of Dermagraft sealed, removed from the surrounding bag, packaged, cooled slowly at a rate that fell within design parameters and frozen. It was then stored in a freezer set to −75°C. The time between cryopreservative addition was at least 4 hr and was validated to a 12 hr delay. This time interval did not appear to affect the viability of the cells and it was conjectured that it allowed induction and synthesis of stress proteins in response to the high osmotic pressure.

Release specifications

The release specifications include sterility, for bacterial, fungi, mycoplasma, and endotoxins as well as for analytical criteria that ensure consistency of the product. Dermagraft uses four analytical release criteria, (3-(4,5-Dimethylthiazol-2-yl)-2-5-diphenyltetrazolium Bromide) (MTT) reductase activity before freezing (in-process MTT) and after thawing, collagen content by Direct Red binding [36] and DNA content. MTT reductase was used to determine the metabolic activity of the product, collagen as a surrogate for the amount of extracellular matrix and DNA content was used to establish adequate cellular content. MTT reduction was an assay that was established early in the development of Dermagraft. Since then, several other substrates measuring essentially the same activity have been developed, several of which are less toxic to the cells than MTT and can be used repeatedly. It would be wise in the development of a new product to examine these early and select a method carefully. MTT reductase is frequently viewed as measuring mitochondrial activity. However, 70% of the activity is extramitochondrial [37] and it is better regarded as a general measure of cellular activity. The MTT reductase assay was originally developed to evaluate toxicity or cell proliferation, where values obtained after treatment were compared with control values. In determining the metabolic activity of tissue-engineered products, this is not possible and a great deal of fruitless effort has been expended in trying to obtain a standard for the MTT assay. MTT determination before and after cryopreservation might be interpreted in the same manner as in toxicity assays. However, changes occur in the viability and metabolic activity of cells for up to three days after cryopreservation, due to necrosis, apoptosis and repair, so the MTT values are better regarded as independent absolute determinations rather than relative values.

In the case of TransCyte the microbiological criteria and the collagen and DNA determinations are similar to those for Dermagraft. However, as the cells are non-viable in the final TransCyte product, there is no MTT determination. Determination of MTT reductase prior to final freezing (in-process MTT) was replaced by release specifications applied to ATP consumption as described above.

Definition of specifications was initially within three standard deviations of the process performance. This was refined by clinical experience. In the case of MTT, it was evident during the clinical trial that the specifications needed to be refined, requiring a mid-trial correction and ultimately an additional clinical trial.

Distribution and cryopreservation

The use of −70°C cryostorage for Dermagraft was a compromise between an ideal solution and practicality and turned out to have several benefits. If the goal was 100% cell viability and indefinite shelf life, the ideal solution is likely to have been storage at liquid nitrogen temperatures, probably using a vitrification procedure in which high concentrations of cryoprotectant and very rapid cooling is used to achieve the formation of a glass with minimal ice crystallization. While the technical difficulties of achieving sufficiently rapid cooling of a therapeutically useful structure and problems with the brittleness of plastics at low temperatures can probably be overcome, the method would still entail transport at liquid nitrogen temperatures and safety issues. Cryopreservation at dry ice temperatures provided adequate shelf life and allowed shipping in a container capable of maintaining −65°C for 4 days. This allowed distribution throughout the world and would generally permit 2−3 days leeway for patient and physician scheduling at the site of use. If a center had a −70°C freezer, storage at this temperature would allow much longer shelf life at the treatment site.

In addition to logistical advantages, the induction of stress proteins by the cryopreservation procedure [38], combined with the suboptimal viability recovery meant that necrotic cell debris, including heat shock proteins, were released from lysed cells. Such proteins activate

macrophages through CD91 and toll-like receptors [39]. While such necrotic products are likely not to be scarce in a chronic wound, this property may have contributed to the efficacy of Dermagraft.

While discussing cryopreservation, an important point that has received little attention is the thawing process. In the case of Apligraf, the thawing process involved solutions that had to be replaced, requiring a procedure of several hours, which was performed at the company. This provided shelf life, but not off-the-shelf convenience, and required additional resources from the company. Therefore, the procedure was not continued. In the case of Dermagraft, thawing is performed in the physician's office, out of the control of the company.

During the controlled freezing process, after the majority of the osmotic water removal has occurred, the cell contents reach a eutectic and freeze. While most of the intracellular material forms a glassy state, small ice nuclei may be formed. The slow growth of these nuclei during −70°C storage is probably what limits shelf life. During thawing, conditions arise that allow the growth of ice crystals, the nuclei enlarge and, if they become big enough, will kill the cells. It is important to take the cells through this stage as rapidly as possible to minimize ice crystal growth. So rapid thawing, straight from the −70°C storage is critical. The procedure that was adopted involved a thawing tub with a thermometer, which could be filled with warm water from the tap, or a water bath at 37°C. A few seconds unprotected in ambient air was sufficient to reduce viability drastically.

Problems with commercial culture for tissue engineering

In large-scale tissue culture, procedures are followed that differ from those found in a research laboratory. As a result, problems have arisen from time to time that have no counterpart in culture on a smaller scale. Frequently, it is difficult to establish the cause unequivocally because of the scale and cost of the experiments that would be required. When such a problem occurs, it is usual to assemble all those with potentially valuable ideas, analyze the incident with respect to changes in procedure (new batches of medium or other raw materials, newly implemented changes, etc.) and prioritize possible solutions. Usually the most likely and cheapest suggestions are explored first. These tend to be implemented more or less at the same time and immediately. This means that, when the problem ceases, as it usually does, it is very difficult to determine which suggestion solved it. At best, the solution relies on a plausible rationale.

Examples of the causes of such occurrences include light damage to medium and deterioration of cell banks. It has been known for many years that medium is light sensitive and will degrade if left exposed to daylight or fluorescent light. However, such an event is never seen in the research laboratory, as medium is normally stored in a refrigerator in the dark. In commercial operation, it is sometimes necessary to make up medium a few weeks in advance and store it in a cold room. If the lights in the cold room are fluorescent and are left on, deterioration of medium will be observed. Indeed, the Dermagraft plant was illuminated with yellow light to avoid such problems.

In a research laboratory, cell stocks frozen in liquid nitrogen are manipulated rarely, a few times per year. In commercial scale tissue engineering, vials from the MWCB are required several times per week. While one or two vials are identified and removed, the remainder of the cell bank stock taken out of cryostorage is warming up. We noticed that, after some years of this, the fibroblasts could be shown to demonstrate a decreased lifespan. This was attributed to ice recrystallization during periodic warming to perhaps −120°C to −90°C during recovery of other vials. It is, thus, necessary to store the MCB independently of the MWCB and to devise a method of recovering selected vials with minimal disturbance to other vials.

CLINICAL TRIALS

The design and implementation of clinical trials is specialized and beyond the scope of this discussion. The process requires a great deal of time and expense. In the case of the CDRH division of the Food and Drug Administration (FDA), the initial trial is a pilot or feasibility trail, equivalent to a Phase I trial in the CBER or CDER. This consists of a small number of patients (6–20) per treatment regime, and is primarily concerned with safety. Any information obtained on efficacy in a trail of this magnitude is unlikely to be statistically significant but may provide useful information on the size and variability of the therapeutic effect that is valuable in design of the subsequent, pivotal trial.

The pivotal trials (equivalent to Phase II trials in biologics and devices) involve much larger numbers of patients (50–500 in the case of devices) which is determined by a sample size calculation, based on the results from the pilot trial, to give about 80% probability of a significant result ($p < 0.05$) if one exists.

Trials with chronic wounds take about two years or more to complete. The design phase, deciding on protocols, obtaining institutional approval for multiple centers and preliminaries to the recruitment of patients is likely to take at least six months. The actual trial involves screening many more patients than will actually take part in the trial, as many fail to conform to exclusion criteria, which reduce irrelevant and interfering factors, established in the design phase. With a trial involving a 12 week follow-up period, most should be completed within 18 months to two years. There is then a period of six months while the data are checked, discrepancies resolved and the results of the trial evaluated. This period could be shortened substantially by logging the patient outcomes to an internet site and checking them on line as they are generated.

The design of the clinical trial should be conducted in close consultation with the relevant regulatory authorities. It is critically important that all aspects should be thoroughly discussed and agreed beforehand. In the case of Dermagraft, failure to follow advice from the FDA precisely led to considerable delay and additional expense.

Considerations in the selection of clinical trials include the size and value of the potential market, the expected efficacy of the product and the difficulty of completing the trials. Five major areas of chronic wounds include venous stasis ulcers, diabetic foot ulcers, arterial ulcers, pressure (decubitus) ulcers and all other chronic wounds. Of these, venous stasis ulcers represent the largest market. Diabetic ulcers are a valuable market, as, while smaller in number, the consequence of failure to heal such an ulcer is limb amputation, an expensive and seriously debilitating procedure. It is very difficult to perform a trial on decubitus ulcers, as the patients are frequently elderly, very infirm and may need approval from a guardian. Such trials are very arduous, may be difficult to complete and are best undertaken by a specialized group with well-developed access to such patients. In no cases does the treatment of chronic wounds with skin implants address the underlying cause of the ulcer, which lies in venous insufficiency, metabolic abnormalities, reduced arterial supply or repeated ischemia. This is particularly evident in ulcers caused by arterial insufficiency. While the angiogenic activity implant may be capable of improving vascularity in the region of the wound, little may be gained if blood supply to the limb is inadequate.

The pivotal clinical trial for Dermagraft for diabetic ulcers was initiated in 1994. Dermagraft gave a statistically significant increase in healing of 19.1% that was similar to results obtained in similar trials with other products. These data were used in combination with mechanism of action and clinical instruction to support the clinical use of Dermagraft commercially. Since then, it has grown to a several $100M/year business.

The indications for which the product may be marketed (its labeling) are strictly limited by the clinical trials and new trials are required to extend them. However, in certain categories,

there may be insufficient patients to support both a clinical trial and a commercial market. Examples are monogenetic congenital diseases, where, although the conditions may be very distressing, the entire population may number in the hundreds or a few thousand. An example in the chronic wound field is epidermolysis bullosa (EB). For such diseases, the FDA has a category, Humanitarian Device Exemption (HDE), which allows much reduced clinical testing. It does, however, require Institutional Review Board (IRB) approval from each institution where it will be used. In the case of dermal implants, such a route has been used for Apligraf and Orcell for all genetic forms of EB, and for Dermagraft for the dystrophic forms of EB. The category, 'all other chronic wounds' includes many miscellaneous conditions, such as pyoderma gangrenosum, necrobiosis lipoidica diabeticorum, for which there is too small a patient population to perform a trial, but would be expected to benefit from treatment with Dermagraft or TransCyte. The HDE pathway may not be appropriate or available. However, since the FDA does not regulate the practice of medicine, some approach to these patients may be obtained through off-label use, although this cannot be formally promoted by the manufacturer.

IMMUNOLOGICAL PROPERTIES OF TISSUE-ENGINEERED SKIN

Immunological rejection of tissue-engineered products is, at the time of writing, a controversial question. As was clearly established by Medawar in the 1940s, allogeneic transplants of whole live organs invariably cause immunological reactions that lead to rejection [40]. However, experience with some cultured cells and tissue-engineered constructs indicates that, in some cases, no clinically significant rejection occurs. At this point, some hundreds of thousands of patients have been implanted with Dermagraft, in many cases several times to the same patient, without a single example of immunological rejection and experience with Apligraf has been similar. The fibroblasts from Dermagraft have been found to persist in the wound site for six months and survival for about a month been obtained with Apligraf [41].

There are two major pathways of transplant rejection, direct and indirect. The direct pathway involves recognition of donor histocompatability antigens (HLA) by the host immune system leading to acute rejection over about two weeks. This involves both HLA, of which Class II molecules, such as HLA-DR, are the most important and also co-stimulatory molecules on the transplant, CD40 and the CD80 group. These molecules are not normally expressed by fibroblasts. However, in monolayer tissue culture, the presence of γ-interferon, which may be present in chronic wounds, will cause induction of HLA-DR, CD-40 and genes involved with the physiological function of Class II HLA (antigen presentation). In three-dimensional culture, many of the cells show a selective response to γ-interferon, that does excludes induction of these molecules [42]. The indirect pathway of rejection involves display of transplant antigenic peptides by host antigen presenting cells (macrophages, tissue dendritic cells and endothelial cells). This gives rise to chronic rejection which may cause destruction of the transplant over many months. While it cannot be excluded that this may occur, Dermagraft fibroblasts have been detected at 6 months from the time of implantation and no clinical evidence for chronic rejection has been observed.

Acute rejection is primarily an attack on the endothelial cells of the vascular system, which are antigen presenting cells and do express the component of the antigen presentation system (HLA Class II, CD40, CD80). It is possible that the lack of rejection of tissue-engineered skin products is related to the absence of such cells. Indeed, adding antigen presenting cells (in this case, B lymphocytes) to a tissue-engineered construct has restored susceptibility to immunological rejection [43].

COMMERCIAL SUCCESS

There are many contributors to the commercial success of a product. They include a satisfactory clinical trial, a good rationale for the performance of the product, convenience

in use, a reasonable price, adequate reimbursement from third party payers, sensitivity to complaints, efficient distribution. Some of these require long-term effort and must be initiated early in the development process.

New products frequently find themselves selling into a conservative and skeptical market that arises from the hype that is involved in developing and funding the product. The first requirement in overcoming this view is a satisfactory clinical trial. This process is determined by regulatory bodies. The major criteria for the American authorities (FDA) are safety and efficacy. Unless the product is safe and efficacy is extraordinary, clinical results need to be backed up by a mechanism of action that, while it may not be fully established, must provide a logical reason for using the product. In the case of Dermagraft, this has led to a great deal of fundamental wound healing research.

Equally important is the convenience of use, cost and process for reimbursement of the physician applying it. Convenience of use and cost are functions of bioreactor and process design, and company structure and are discussed elsewhere. Third party reimbursement and health economics are major and specialized subjects that are outside the scope of this article. However, a major component of establishing satisfactory reimbursement in the United States involves the Center for Medicare and Medicaid Services (CMS). Government authorities with similar responsibilities are involved in other countries. Their criteria, in contrast to the FDA, are reasonableness and effectiveness/cost ratio. Both the FDA-type and CMS-type criteria have to be met for a product to be successful.

An activity that would prove very valuable in establishing the performance of a product is a system for tracking the clinical performance subsequent to regulatory approval to market the product. While complaints and adverse events are carefully tracked and reported, performance has not been. It may, however, become a regulatory requirement to confirm safety, efficacy and cost effectiveness with a larger patient population than possible in a clinical trial. It is also valuable to the manufacturer because, while anecdotes of positive clinical experience may be heartening, they do not provide objective quantitative data. This was not performed in the cases of Dermagraft or TransCyte, making it difficult to assess the actual performance of the product in clinical use.

Mechanism of action

Understanding the mechanism of action of a product required some understanding of the underlying pathology of the disease the product is intended to treat. Wound healing, and particularly the etiology and maintenance of chronic wounds was poorly understood during the development of Dermagraft and TransCyte. Many phenomena have been observed, particularly in chronic wounds. The problem is sorting out how they relate to one another, which are etiological, and which are symptomatic; the difference between cause and response. The problem was less acute in the case of TransCyte as the product was only designed as a temporary covering for third degree burns.

Changes from normal skin observed in chronic wounds include lack of keratinocyte migration, capillary cuffing, protease activity , abnormalities in macrophage activation, diminished vascular supply and senescence in fibroblasts [44]. In developing a rationale for the action of Dermagraft, the first aspects considered were vascular supply and keratinocyte migration. Much study was undertaken on the angiogenic activities of Dermagraft and it was shown that the tissue produced VEGF and hepatocyte growth factor. It was also shown to be angiogenic in the chick chorioallantoic membrane assay and to increase blood supply to diabetic ulcers in patients *in vivo* using laser-Doppler techniques. Thus, a case could be made that one mode of action was through its angiogenic effect.

The high protease activity of chronic wounds was combined with the lack of keratinocyte migration to hypothesize that the extracellular matrix in a chronic wound was degraded to the extent that the migration substrate was lacking. Indeed it was demonstrated that fibronectin

was degraded by neutrophil elastase [45]. This led to work on the properties of Dermagraft and TransCyte as substrates for keratinocyte migration.

During comprehensive surveys of genes induced by three-dimensional culture, it was found that the most highly upregulated gene was IL-8. Other ELR CXC chemokines were also highly induced. This led to studies of the secretion of these proteins and to changes in their production that might relate to the etiology of chronic wounds and the possible role of Dermagraft. It was found that Dermagraft secretes IL-8, sometimes in large quantities. The secretion is extremely variable. Monolayer fibroblasts also secrete CXCL-1, CXCL-5 and CXCL-6 (gro-α, ENA-78 and GCP-2 respectively) that are all chemoattractive for neutrophils and activate them to a bactericidal phenotype. At the same time, it was observed that bacterial products (lipopolysaccharide) inhibit keratinocyte migration. This led to the hypothesis that a major function of fibroblasts in a wound context is the recruitment of neutrophil leukocytes to destroy colonizing bacteria and that failure of this system in chronic wounds results in the establishment of bacterial contamination that leads to failure of re-epithelialization. It is known that fibroblasts in chronic wounds display a senescence-like phenotype [46] that grows slowly and is unresponsive to growth factors. The condition is probably related to stress-induced premature senescence caused by ischemia reperfusion injury, metabolic abnormality, extravasated red cells and the inflammatory conditions of the chronic wound. It has been found that the production of CXCL-1, CXCL-5, CXCL-6 and CXCL-8 decline in senescent fibroblasts. Thus, in chronic wounds, a decline in the ability of the fibroblasts to recruit and activate neutrophils allows wound colonization by bacteria and failure of keratinocyte migration to close the wound. Chronic wounds seem to involve an arrest of normal healing at about the stage of neutrophil immigration. On this hypothesis, a major role of Dermagraft is to provide non-senescent fibroblasts that are able to respond to the presence of bacteria with appropriate secretion of neutrophil chemoattractant chemokines.

In the case of TransCyte, the formation of a foreign body capsule-like material *in vitro* leads to lack of ingrowth of the scaffold into the wound through a host foreign body reaction, and, thus, comparative ease of removal. The ability of TransCyte to reduce the pain of second degree burns is common to many occlusive dressings.

A remarkable feature of dermal implants is that they do not appear to have led to an increase in infection. Indeed the general experience has been a slight reduction in infections. Preparations with keratinocytes included secretion of antimicrobial peptides, but this is not known to be the case for fibroblasts. The most likely explanation is a combination of fibroblasts secretion of neutrophil chemoattractant CXC chemokines and the provision of an extracellular matrix substrate for leukocyte migration.

FUTURE DEVELOPMENTS

The major direction of development in skin products is towards simpler, possibly non-viable systems. Inclusion of live cells in a product entails many issues such as the use of allogeneic cells, cryopreservation, distribution, inconvenience to the customer (for instance, the thawing procedure) and many manufacturing problems. Hence, studies were initiated to explore the possibility that a possibly less effective but substantially less expensive product could be developed. This is a direction that has also been explored by other companies in the field.

It is a general principle that value is likely to be obtained by exploiting a technology base as far as possible. A major product of fibroblasts is collagen, in this case human. As a non-viable product, human collagen was extracted from the extracellular matrix laid down by fibroblasts and used, by injection, for the treatment of wrinkles.

An alternative to cryopreservation that has been explored is the possibility of storage by desiccation. Many natural systems, such as plant seeds, tardigrades, *Artemia*, yeast have developed the

ability to survive desiccation and, in that state may be able to survive extreme conditions of temperature, vacuum, radiation and time [47]. Many factors appear to be involved in this ability [48], but one that has attracted attention is trehalose, which is a disaccharide (1,1,α,α diglucose) that is produced in large quantities by many desiccation-resistant organisms. It was found that TransCyte could be dried at room temperature in the presence of trehalose, irradiated to 25–40 Grays to provide terminal sterilization and would recover its structure and wound adhesion on rehydration. Similar results could be obtained by careful lyophilization. While some success has been obtained in the retention of viability of human cells in the desiccated state, it is not yet possible to obtain the shelf life (at least one month and preferably at least six months) required for a tissue-engineering application. It is also questionable whether the radiation treatment possible with a non-viable product would be appropriate with living cells, and an aseptic drying and packaging system would have to be devised.

Thus far, the therapeutic applications of skin tissue engineering have encompassed acute and chronic wounds and comprise dermal components alone or dermal components with epidermal structures. In the future, it is likely that adnexal structures will be added. Remarkable success in this direction has been achieved with hair follicles [49], where it has been found that hair follicle-inducing cells can be cultured so that they retain their properties and, mixed with hair follicle-derived keratinocytes, will, on injection form a hair. This has also been achieved with human cells. The remarkable feature of this system is that the entire organ, hair follicle, sebaceous gland and erector pili muscle is formed. This constitutes one of the few examples of true organogenesis observed using adult cells.

CONCLUSION

Experience with the commercial production of tissue-engineered skin has developed many principles that are important beyond the simple development of a tissue-engineered product. Most of these are based on well-known concepts used in other manufacturing processes, as applied to tissue engineering. They include:

1) Optimized cryostorage of Master Cell Banks with minimal access
2) Intermediate storage of expanded cell banks (MWCB)
3) Use of allogeneic cells
4) Bioreactors that permit scale-up, minimize footprint
5) Minimal aseptic connections
6) Maximal automation, to minimize errors
7) Avoidance of aseptic fill, so that the bioreactor forms part of the final package
8) Bioreactor designed for end user convenience
9) Cryostorage

While it may not be possible to incorporate all of these principles, as many as possible should be used. The major problem with tissue-engineered products in the market place is cost and all these principles are directed towards reducing cost. Some, such as the use of allogeneic cells, may be difficult to implement. While experience with fibroblasts indicates that immunological rejection is not a major issue, this is not known for other cells. The possible use of allogeneic cells should, however, be checked, preferably in animals other than mice, because the advantages for a commercial product are great. Optimal cryostorage is a compromise between ideal tissue survival and other factors, such as ease of distribution.

INTRODUCTION

Building upon the first clinical implantation of autologous cultured chondrocytes by Peterson and Brittberg just over 25 years ago [1], the field of articular cartilage repair continues to advance. While the repair of damaged articular cartilage remains a long-standing challenge, significant clinical progress has been made since the third edition of this textbook. This progress includes an improved understanding of the spectrum of cartilage injury, comorbid conditions, and the importance of the subchondral plate and joint homeostasis, as well as further long-term experience with first-through third-generation autologous cultured chondrocyte cell-based repair. Awareness has increased for the need to address concomitant pathology such as joint instability and malalignment to optimize treatment success and the importance of rehabilitation for development of high-quality repair tissue.

Progress has also been made in improving the quality of study design and conduct in the cartilage repair field. Additional guidance for the cartilage repair field has become available in recent years. This includes the European Medicines Agency (EMA) reflection paper on *in vitro* cultured chondrocyte containing products for cartilage repair of the knee [2], the Food and Drug Agency (FDA) guidance for industry for products intended to repair or replace knee cartilage [3,4], and the International Cartilage Repair Society (ICRS) guidelines for the design and conduct of clinical studies in knee articular cartilage repair [5]. Notable in these guidances is the emphasis on the need for long-term follow-up, prospective study design with rigorous controls, and clinical outcomes for pain and function as the most important and clinically valid endpoints.

The challenges of articular cartilage repair relate to both the biologic characteristics of the tissue and the epidemiology of cartilage injury. Articular cartilage lacks intrinsic capacity for repair. The clinical strategy for autologous cultured chondrocyte cell therapy derived from the observations that articular cartilage is avascular and has a limited supply of cells adjacent to injuries to mediate a repair process [6]. The articular chondrocytes that maintain normal cartilage homeostasis are embedded in an extracellular matrix that limits a cell's ability to migrate to a zone of injury and carry out tissue repair.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00082-3

Articular cartilage injuries are common, especially in the knee, and are often associated with damage to other joint structures. There is a spectrum of clinical presentations, ranging from some lesions that may be asymptomatic on initial diagnosis, often in the setting of an incidental finding during an arthroscopy initially indicated for another more evident injury, to lesions that may cause disabling symptoms. The public health impact of these latter types of lesions is magnified because they often occur in relatively young adults and may progress to end-stage arthritis. There clearly is a subset of patients with articular cartilage injury that are very disabled. For example, in a study of patients with focal cartilage defects of the knee, the extent of pain and impairment in function experienced was rated worse in comparison with ratings from patients with anterior cruciate ligament (ACL)-deficient knees, and quality of life was rated at the same level to that reported by patients scheduled for knee-replacement surgery [7].

Although the incidence and prevalence of symptomatic full-thickness chondral injuries in the general population have not been established, it is known that cartilage lesions are a common finding at knee arthroscopy. Curl et al. [8] reviewed records from 31,516 knee arthroscopies and reported Outerbridge Grade III cartilage lesions in 41% and Outerbridge Grade IV lesions in 19%. They reported an incidence of 5% Grade IV lesions when considering only lesions on the femoral condyle in patients less than 40 years old. Other authors have reported a similar incidence of full-thickness cartilage lesions in other arthroscopy series [9–11].

Cartilage injury in the knee is often associated with other injuries, especially ACL rupture, meniscus tears, and patella dislocation [12–15]. For example, Maffulli et al. reported that 42% of patients in a series of 378 patients with ACL tears had associated articular cartilage injuries [12]. In a multicenter registry of 1,095 knee cartilage injuries, the etiology of the injury was associated with falls (25.9%), sports (27.4%), activities of daily living (21.2%), and motor vehicle accidents (5.5%), and the etiology could not be identified in 20% of cases (Cartilage Repair Registry Volume 7, 2001). In this same study, the onset of symptoms was noted to be acute in 64.6% of cases and gradual in 35.4% of cases. Another distinct etiology for articular cartilage lesions is osteochondritis dissecans (OCD) [16,17].

Since the mid-1990s, treatment algorithms have evolved that reflect the range of cartilage lesion presentations, the different indications for different treatment modalities, and the outcome data [18–21]. While these algorithms may differ in specific detail, they are directionally similar and base treatment guidelines on such factors as lesion size and location,

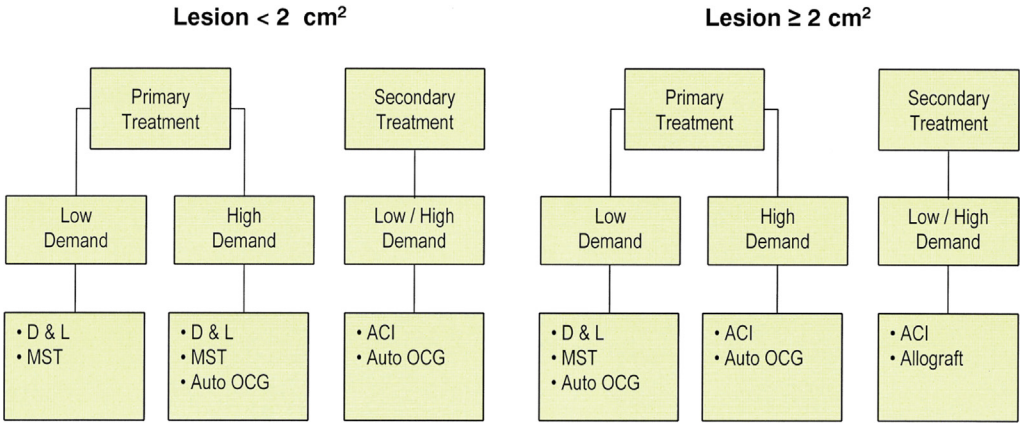

FIGURE 82.1
Illustrative example of current treatment algorithms for repair of symptomatic cartilage lesions. The algorithm gives an overview of treatment options based on lesion size, patient functional demands, and prior surgical history. Given other factors and the complexity of decision making for individual patients, the authors of this algorithm, caution against a mechanistic "menu-driven decision making process." D&L = Debridement & Lavage; MST = Marrow Stimulation Technique; Auto OCG = Autologous osteochondral graft (Cole and Farr 2001).

Choosing the most appropriate and optimal cartilage repair treatment for an individual patient depends upon multiple factors.

prior surgical history, and patient expectations and functional demands. Fig. 82.1 is provided as an illustrative example of one of these treatment algorithms [19]. Clinical decision-making for a given individual patient can be complex, and the multiple factors to evaluate and consider are outlined in Fig. 82.2. In decision-making for treatment of articular cartilage lesions, it is critical to consider the whole joint and the whole patient.

While it is beyond the scope of this chapter to review the outcome literature for all articular cartilage treatment modalities, it is helpful to understand where traditional first-line arthroscopic treatments and the cell-based tissue-engineering experience fit in current treatment algorithms. In general, first-line arthroscopic treatments are used in less severe lesions, and autologous chondrocyte implantation (ACI) is used in more severe lesions and failed first-line treatments (Fig. 82.3). The impetus for developing ACI came from the recognition that while traditional treatments such as debridement and marrow stimulation techniques (Pridie drilling, abrasion arthroplasty, microfracture) may provide some benefit in smaller and/or less symptomatic lesions, they tend to be less effective and less durable in larger and/or more symptomatic lesions due to production of fibrocartilage which has weaker mechanical properties than native cartilage [6,22,23]. A recent, evidence-based, systematic analysis of microfractures showed decreasing knee function and increasing failure rate were associated clinical limitations in the long-term [24].

CLINICAL EXPERIENCE WITH FIRST-GENERATION ACI

Initial experience

Lars Peterson and colleagues, in Gothenburg, Sweden, pioneered the clinical application of autologous cultured chondrocytes to repair symptomatic articular cartilage lesions in the knee

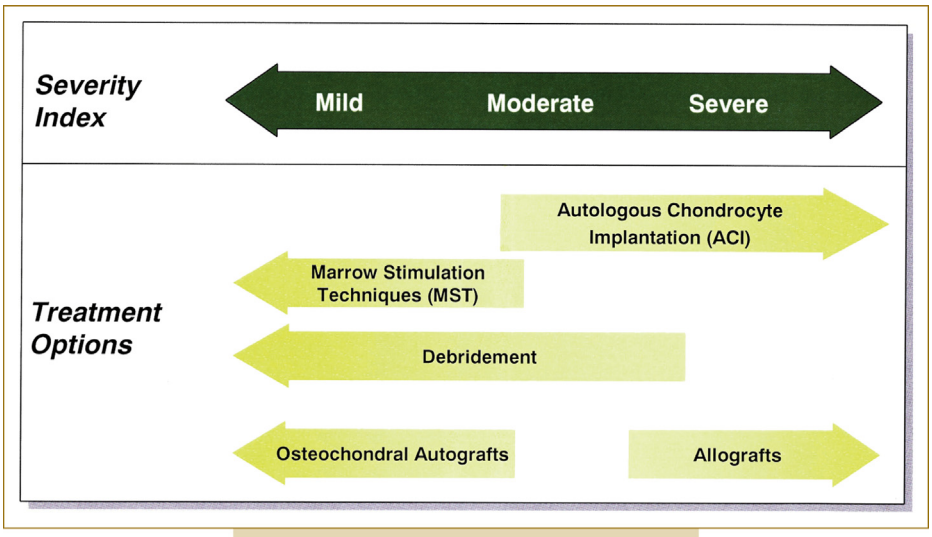

FIGURE 82.3
There is a wide range of clinical presentations of articular cartilage injury in the knee. Treatment options reflect severity based on a combination of patient, lesion, and co-morbity factors. The clinical experience with ACI has been at the more severe end of the spectrum of full thickness articular cartilage injury.

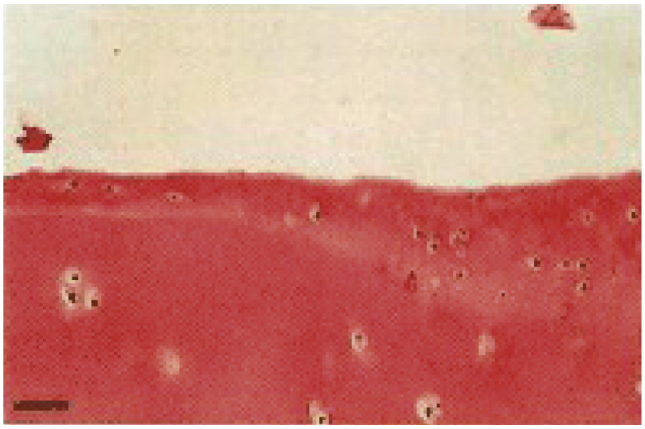

FIGURE 82.4

joint. The initial results in 23 patients with a mean follow-up of 39 months were published in a landmark paper in 1994 [1]. Results were reported for clinical outcome scores, macroscopic appearance during second-look investigational arthroscopies, and histology evaluation of repair tissue biopsies (Fig. 82.4). Clinical results were good to excellent in 14 of 16 lesions (87.5%) on the femoral condyles. Eleven of 15 biopsies (73%) on the femoral condyles had the appearance of hyaline cartilage. Initial results in the sevem patella lesions were less promising. Later experience with patella implants, in which patella alignment was addressed concurrently with cell implantation, yielded better results [25,26].

Cell processing and surgical technique

The basic techniques and promising results reported in this initial study became the basis for a larger long-term experience at Peterson's center as well as the commercialization and multicenter experience with ACI. In 1995, Genzyme Corporation established (and subsequently obtained an FDA license for) a commercial GMP (cGMP) facility in the United States (US) to perform the isolation and expansion of chondrocytes from cartilage biopsies. Also in 1995, a multicenter registry was established to track outcomes of ACI and other cartilage procedures. In 1997, the FDA approved Carticel® (autlogous cultured chondrocytes) as the first cell therapy in orthopedics. More than 20,000 patients have now been treated with Carticel®. Other commercial cell-culturing facilities have been established outside the US.

ACI, the only FDA approved cell-based cartilage repair product, is a two-stage procedure. In the first stage, a 200 to 300 mg specimen of cartilage is harvested arthroscopically from a lesser weight-bearing area of the trochlear ridge or the intercondylar notch. In the US, the procedure is to send this sample to the Genzyme facility (Cambridge, MA), where it is enzymatically digested and the chondrocytes isolated, expanded through primary and secondary culture, and then cryopreserved. Once the facility has been notified of an implantation date by the surgeon and the hospital, the cryopreserved cells are thawed and cultured to expand the cell population *in vitro*. The final product, a suspension of approximately 12 million cells, is shipped for implantation in a second-stage surgery (Fig. 82.5). All implants are tested for appropriate chondrocytic morphology, sterility, endotoxin, and cell viability as part of the release specifications. The extensive process validation and sterility-testing procedures for this unique, patient lot-specific manufacturing process have been described in detail elsewhere [6,27–29].

The cells are implanted via an arthrotomy, in which an autologous periosteal flap is harvested from the proximal tibia or distal femur, and sutured over the defect and the cells are injected into the defect under the patch after testing for a watertight seal. Fibrin glue is used to ensure a watertight seal (Fig. 82.6).

After chondrocyte injection, catheter is removed and the catheter entry site is sealed with additional suture. *Copyright 2006 Genzyme Corporation. All rights reserved.*

Long-term outcomes in the Swedish series

Peterson et al. [25] reported outcomes for 94 patients implanted between 1987 and 1995, with only one patient lost to follow-up. The patients were divided into five treatment groups based on defect classification and concurrent ACL procedures. Baseline characteristics and mean follow-up varied by defect category. In general these patients had large, chronic lesions and multiple prior surgeries. The mean defect size ranged from a 4.2 cm^2 in isolated femoral lesions to 4.7 cm^2 in OCD lesions. Mean follow-up ranged from 2.7 years in the multiple-lesion group to 4.2 years (range: 2 to 9) in the isolated femoral condyle group. Outcome results based on patient assessment varied by defect category, with isolated femoral condyles 92% improved, femoral condyles with ACL reconstruction 75% improved, OCD lesions 89% improved, multiple lesions 67% improved, and patella defects 68% improved.

Subsequent studies have provided evidence on durability of ACI treatment from 2 to 20 years post-treatment [30–32]. Long-term treatment durability from 10 to 20 years post-ACI (mean follow-up of 12.8 years) was assessed in a study of 341 patients who received patient-reported outcome measures by mail [32]. Of the 224 patients who responded (mean defect size of 5.3 cm^2), 74% reported their status as better or the same as previous years and 92% reported being satisfied with the ACI treatment. Improved average assessment scores from preoperative to follow-up timepoints included the Lysholm (from 60.3 to 69.5), the Tegner-Wallgren (from 7.2 to 8.2), and the Brittberg-Peterson (from 59.4 to 40.9). The authors reported that final treatment outcome was not associated with age at time of ACI, lesion size, or history of marrow stimulation treatment or meniscal injury.

Other studies of ACI

Zaslav et al. evaluated ACI treatment outcome in 154 patients who had failed at least one prior non-ACI procedure for the repair of a full-thickness articular cartilage defect of the knee [33]. For the majority of patients, the defect was located on the medial femoral condyle (67%); the mean defect size was 4.6 cm^2. The authors described the patient population as very challenging with a mean pretreatment modified Cincinnati Knee Rating System score of 3.0 for pain and 3.3 for overall knee condition (0 = severe, 10 = normal). At four years post-treatment, 76% of the 126 patients who completed the study had a successful treatment outcome while 24% were considered treatment failures. Subsequent surgical procedures (SSPs) were reported for 49% of patients; need for SSP was not associated with treatment failure. Mean improvements from pretreatment were significant for all outcome measures assessed in the study. The authors concluded that ACI can be expected to provide a durable improvement in pain and function for patients with moderate to large cartilage defects who have failed a prior cartilage repair treatment.

Cole et al. reported on a subset of patients with OCD from the Zaslav et al. study [34]. Of the 40 patients with OCD treated with ACI, 80% completed the 4-year study follow-up and 35% underwent a SSP. From pretreatment to four-year follow-up, significant mean improvements in pain and function were observed in this challenging patient population. For example, the mean modified Cincinnati Knee Rating System score for overall knee condition rose from 3.1 ($\pm$ 1.1) at pretreatment to 6.8 ($\pm$ 2.0) at follow-up. The authors conclude that the patients' clinically relevant and statistically significant improvements have shown ACI to be a viable treatment for OCD. Thirty-five percent of patients experienced an SAE which most commonly involved new areas of cartilage involvement, graft hypertrophy, graft complication, chondromalacia, graft delamination, and arthrofibrosis. Further discussion of safety aspects of ACI treatment is provided below in the section on complications of ACI.

Fu et al. [35] directly compared two Cartilage Registry Repair cohorts at three-year follow-up: a cohort of 58 debridement patients and a cohort of 58 ACI patients. The two cohorts had similar demographics and defect pathologies at baseline. However, more ACI patients failed a previous

debridement or marrow stimulation procedure than the debridement patients. The mean total defect area for the debridement cohort was 4.5 cm^2, and for the ACI cohort it was 5 cm^2.

Fifty-six ACI patients and 42 debridement patients completed follow-up outcome assessments; 81% of the ACI patients and 60% of the debridement patients reported median improvements of 5 and 2 points, respectively, in the overall condition score. ACI patients also reported greater improvements in the median pain and swelling scores than debridement patients. The treatment failure rate was the same for both ACI and debridement patients. Based on the *a priori* definition of treatment failure, there were three (5.2%) failures in the debridement group and four (6.9%) in the ACI group. The authors concluded that:

> 'Although patients treated with debridement for symptomatic, large, focal, chondral defects of the distal femur had some functional improvement at follow-up, ACI patients obtained higher levels of knee function and had greater relief from pain and swelling at 3 years.'

Micheli et al. [17] reported on ACI outcomes in children and adolescents. Thirty-seven registry patients with a mean lesion size of 5.2 cm^2 and a mean age of 16 at implant were in the cohort. Despite the young age of these patients, they were similar to adult ACI cohorts, in that the majority (70%) had undergone at least one prior knee procedure before the index arthroscopy for cartilage specimen harvest. Thirty-two patients completed follow-up assessments at a mean follow-up of 4.3 years. Twenty-eight patients (88%) reported a favorable outcome at a minimum of two-year follow-up. These results are encouraging, however, no cell therapy product for cartilage repair is indicated in the US for use with pediatric patients. The first Advanced Therapy Medicinal Product (ATMP) approved in Europe by the EMA for cartilage repair (ChondroCelect, TiGenixNV), is also indicated for adults only.

Knutsen et al. [36] in Norway conducted a four-center, 80-patient randomized controlled trial comparing ACI to microfracture at a two-year follow-up. Endpoints were clinical outcome scores (Lysholm, VAS pain score, and SF-36) and a histology score. Both groups were improved at two years, with no statistically significant difference between the ACI and microfracture groups in Lysholm, VAS pain score, or SF-36 mental health subscale (results reported in aggregate, not stratified by lesion size). The authors do report a statistically significant difference in the SF-36 physical component score in favor of the microfracture arm; however, the authors also report different SF-36 physical component mean scores at baseline between the arms.

The authors report that microfracture outcomes varied by lesion size with lesions smaller than 4 cm^2 associated with better clinical results. With regard to the histology comparison, the authors conclude:

> 'There was a tendency in our study for the ACI procedure to result in more hyaline repair cartilage than the microfracture procedure, but this was not a significant finding with the numbers available.'

The authors' overall conclusion was that:

> 'because microfracture is a relatively simple 1-stage procedure, it may be more suitable for a primary first-line cartilage repair of a local contained defect. In patients in whom microfracture has failed and in those with bigger, non-contained defects, ACI may be a better option.'

At the five-year follow-up, both treatment groups continued to show significant clinical improvement [37]. There were no significant differences between the ACI and microfracture groups in clinical scores or failure rate at five years post-treatment. The authors report that there was no correlation between histological score and clinical outcome. Further, there was no significant difference in histological score when comparing patients with and without treatment failure. The authors report that none of the patients with treatment failure had the

best histological scores. The authors conclude that in their chronic patient group, both treatments resulted in satisfactory outcome in the majority of patients at five years.

In the United Kingdom, Bentley et al. [38] conducted a single-center, 100-patient randomized controlled trial comparing two ACI arms (ACI with periosteal flap coverage and ACI with type I/III collagen membrane coverage) to mosaicplasty, with a mean follow-up of 1.7 years. Outcome measures included clinical scores, second-look arthroscopy with ICRS scoring, and histology.

The overall results favor ACI over mosaicplasty in all measured parameters, including clinical outcome, histology, and ICRS scores on follow-up arthroscopy. Overall, 88% of the ACI patients vs. 69% of the mosaicplasty patients were graded as 'excellent or good result.'

Study strengths include that it is a prospective, randomized design with follow-up arthroscopy evaluation as well as clinical outcome scores. Mean lesion size was 4.66 cm^2. Mean duration of symptoms was 7.2 years, and all but six patients had undergone previous surgical interventions. Limitations of the study include that while the study showed better scores for ACI vs. mosaicplasty in all parameters, the differences in clinical scores were statistically significant for only one anatomic location, the medial femoral condyle.

The authors conclude:

> 'There is definite evidence, however, that ACI is valuable for selected patients in that it gives healing of hyaline cartilage in chondral and osteochondral defects. It can also dramatically reduce the symptoms of pain and disability. The continued use of mosaicplasty, however, appears to be dubious.'

The results of follow-up of these 100 patients at a minimum of 10 years (94% follow-up rate) continue to show significantly better outcome for patients treated with ACI compared to mosaicplasty [39]. Functional outcome assessed with the modified Cincinnati score was significantly better for the ACI group; no significant difference between the treatment groups was seen for the Stanmore-Bentley score. There was a significant difference in rate of treatment failure favoring ACI treatment (17%) over mosaicplasty (55%). The authors state, 'The timing of more rapid deterioration after two years in the mosaicplasty patients might reflect the known pattern of deterioration of fibrocartilage.'

A Phase 3 pivotal study comparing an ACI treatment (ChondroCelect, TiGenix NV) to microfracture was designed to show superiority of structural outcome and non-inferiority of clinical outcome at one year post-treatment [40]. The study showed that the chondrocyte implantation technique resulted in superior structural repair at the one-year follow-up, with no clinically significant difference observed between the two treatments. At the three-year follow-up, mean clinical improvement from baseline was significantly greater for ACI versus microfracture, while assessment by MRI did not reveal significant differences between treatment groups in structural repair [41]. The authors observed that patients with shorter duration between symptom onset and ACI treatment had significantly better clinical improvement compared to microfracture treatment.

There are several other published studies on ACI from other centers. They are too numerous to review in detail here. In general, the results are similar to the studies just discussed. A few specific additional points are worth noting with regard to special populations or indications treated with ACI and health economics of this technology. Mithofer et al. [42] reported on ACI to treat adolescent athletes. Overall, they report a 96% rate of return to high-impact sports and 60% achieving an athletic level equal to or higher than the preinjury level. Return rate to preinjury sports correlated with shorter preoperative symptom duration and a lower number of prior operations. This suggests that earlier intervention may optimize cell therapy outcomes, an especially important consideration in younger patients.

Minas has reported successful outcomes in young adults with complex joint pathology for which ACI was performed as an alternative to an artificial joint arthroplasty [26,43]. Further, while the vast majority of ACI cases are in the knee, there are reports of successful use in other joints, especially the ankle. While the patient lot-specific manufacture of a live cellular product with stringent quality controls is inherently expensive, favorable health economics were demonstrated in three studies that assessed economic parameters [44–46].

Complications of ACI

Patients who undergo ACI may require SSPs on the treated knee. The majority of these procedures are arthroscopic interventions. Such procedures frequently have no findings causally attributable to ACI. Frequently encountered findings following the original ACI method include graft or periosteal hypertrophy (18%), delamination (5%), and arthrofibrosis (3%) [47]. In a study comparing the original ACI method with collagen-covered autologous chondrocyte implantation (CACI, a second generation treatment method similar to ACI but with the periosteal flap replaced by a collagen membrane), re-operation due to symptomatic graft hypertrophy was reported for approximately 36% of patients treated with the original ACI method and for none of the patients treated with CACI at one year post-treatment [48]. A systematic review aimed at comparing rates of failure, re-operation, and complications between different methods of ACI treatment indicated that although the overall failure rate is low for all methods of ACI, ranging from 1.5 to 7.5%, the original ACI method using a periosteal cover is associated with higher rates of failure, unplanned operation, hypertrophy, and delamination [47].

Multiple prior surgeries and a history of ligament reconstruction or meniscal procedures concomitant with ACI appear to be risk factors for a post-ACI subsequent procedure. The frequency of arthroscopic intervention after ACI is likely due to a combination of factors, including the associated arthrotomy necessary for implantation, complex knee pathology, including comorbid conditions, concurrent procedures and prior surgical history, and a hypertrophy of the graft or periosteal patch in some patients.

Summary of first-generation ACI clinical experience

Multiple factors make direct comparisons or data synthesis of these varied studies challenging. These factors include differences in study design, data collection instruments, length of follow-up, evaluation criteria, treatment failure definitions, and patient populations. However, bearing these factors in mind, these different studies are generally consistent and complementary in supporting the following overall conclusions regarding the efficacy of first-generation ACI:

- ACI has demonstrated successful clinical outcomes in challenging patients where other treatment modalities, such as debridement and microfracture have been less successful.
- ACI has demonstrated successful clinical outcomes in patients who have failed prior to cartilage repair procedures.

While these are important advances, first-generation ACI has limitations. These include the harvest and suturing of a periosteal flap to secure the implanted chondrocytes in the defect. Not only does this prolong the operative time and require a more extensive arthrotomy, some authors have postulated that the periosteal flap may contribute to the formation of hypertrophic tissue, the most common complication of first-generation ACI [38,49]. These limitations have led to efforts to develop improved technology for chondrocyte implantation. Goals include maintaining the benefits of achieving biological cartilage resurfacing and functional repair tissue while improving surgical delivery and reducing complications.

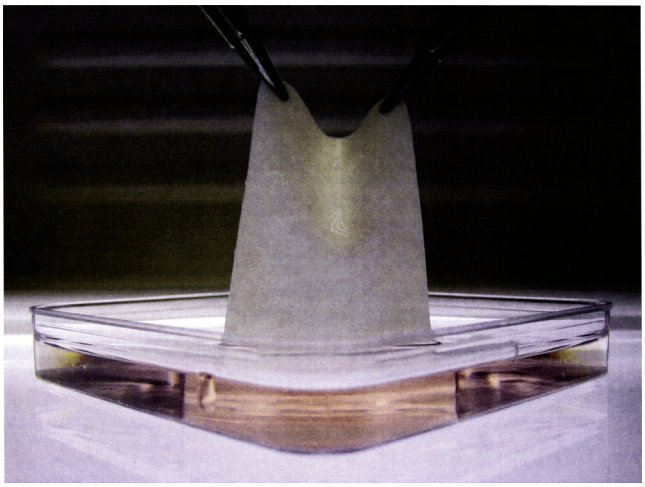

FIGURE 82.7
Third generation autologous cultured chondrocyte graft technology. In Matrix-induced Autologous Chondrocyte Implantation (MACI®), the cultured chondrocytes are seeded on 4×5 cm Type I/III collagen membrane. This eliminates the need for the periosteal patch and extensive suturing use in first generation ACI and facilitates less invasive surgical implantation. *Copyright 2005 Genzyme Corporation. All rights reserved.*

CLINICAL EVOLUTION OF ADVANCED-GENERATION ACI

Significant clinical experience with advanced-generation ACI has been obtained in Europe and Australia. The first clinical step was to replace the autologous periosteal flap with a porcine type I/III collagen patch. This has been termed CACI, or collagen-covered ACI. Early results suggested clinical and histological results similar to periosteum-covered ACI, but with a lower incidence of post-implant hypertrophy [38,48,50].

With CACI, the chondrocytes are still delivered to the defect in a liquid suspension that requires suturing a collagen patch in place with a watertight seal. Development of matrix-induced autologous chondrocyte implantation (MACI®, Genzyme Biosurgery), a third-generation ACI product, began as a further improvement on the CACI technique in markets outside the US (Fig. 82.7) following the acquisition of Verigen Corporation by Genzyme. MACI® optimizes the delivery of cultured chondrocytes by seeding them onto a purified, resorbable, porcine-derived collagen type I/III membrane (ACI-Maix™), thereby removing the need for the harvest, placement, and suture of a periosteal flap to retain the suspension of chondrocytes in the cartilage defect (as required for ACI). At implant, the MACI® cell-seeded membrane is trimmed to the size and shape of the cartilage defect, implanted cell-side down into the defect, and secured in place using fibrin sealant. Controlled seeding of the cultured cells directly on the type I/III collagen membrane eliminates the need for extensive suturing of a periosteal or collagen patch and facilitates a simpler, more rapid, and less morbid operation to implant the autologous cultured chondrocytes. With another membrane-assisted product, Hyalograft C® (Anika Therapeutics), a patient's chondrocytes are seeded on a hyaluronic acid scaffold. Hyalograft C® is positioned in the defect using a delivery device where it is fixed to the subchondral bone without the use of fibrin glue or sutures [51]. The membrane-assisted product CaReS® (Arthrokinetics) uses a type I collagen gel, into which a patient's chondrocytes are mixed. The product is cut to slightly larger than the cartilage defect and positioned into the defect using fibrin glue [52].

CLINICAL EXPERIENCE WITH THIRD-GENERATION ACI

Several different types of membrane and construct are used in third-generation ACI products and marketed outside the US. With MACI® the cultured, characterized chondrocytes are seeded on a 14.5 cm^2 porcine type I/III collagen membrane. In Hyalograft C®, chondrocytes are seeded on a 2×2 cm Hyaff 11 membrane, an esterified derivative of hyaluronan [51]. Other biomaterial approaches to delivering chondrocytes for cartilage repair are being pursued by several entities, but have limited clinical experience to date. Although products such as MACI®, Hyalograft C®, and CaReS® are currently marketed in Europe, the transitional phase of the

ATMP Regulation will expire on 30 December 2012. Both MACI® and Hyalograft C® have pending applications with the EMA for Marketing Authorization as ATMP [53].

A recently reported study compared Hyalograft C® delivered by arthroscopy (n = 22) with an earlier developmental form of MACI that used a Chondro-Gide membrane delivered by arthrotomy (n = 39) in patients over 40 years of age [51]. At one year post-treatment, a significant ($p = 0.049$) improvement on one measure of clinical outcome suggested a faster improvement for those treated with arthroscopic Hyalograft C®. At 2 and 5 years post-treatment, both groups improved clinically and no significant difference in outcome was seen. There was no significant difference between groups in treatment failure and no severe product-related Adverse Events (AEs) occurred during the study or follow-up period. The authors concluded that:

> 'a clinical improvement was found in patients more than 40 years old, … with good results lasting at the medium-term follow-up. However, the results were inferior with respect to those previously found for younger populations, and the failure rate at medium-term was also higher.'

The first comparison of CaReS® (n = 10) versus microfracture (n = 10) treatment for patello-femoral cartilage defects was recently reported [52]. At three years post-treatment, clinical improvement from baseline was statistically significantly better for those treated with CaReS®, however, clinical outcome at three years post-treatment was not significantly different between the treatment groups. The authors reported that the comparable results for CaReS® with microfracture call for a larger prospective randomized study comparing the two treatments.

Of the third-generation ACI products, MACI® has the largest accumulated clinical experience, including a just completed Good Clinical Practise (GCP), randomized, comparative Phase III pivotal clinical trial. More than 8,000 patients have been implanted with MACI® to date. A number of studies reporting on the efficacy and safety of MACI® with follow-up to two and five years post-treatment have been completed.

In a study by Ebert et al, 41 patients treated with MACI® were followed for five years post-treatment [54]. The treated lesions had a mean surface of 3.0 cm^2 (range: 1 to 9). Of the 41 patients, 85% had undergone one or more previous surgical procedures due to knee pain and/or other symptoms. The results reported are for the 35 patients with complete five-year follow-up data. The mean Knee Injury and Osteoarthritis Outcome Score (KOOS) score for each of the five subscales improved significantly over the five years following treatment. Most improvement in knee pain, symptoms, and activities of daily living took place in the first year following surgery; most improvement in knee-related quality of life and sport and recreational activities took place in the first two years. Improvement was maintained through five years post-treatment. Significant improvement over time was also observed for the SF-36, 6 minute walk test, and knee extension range-of-motion. The authors report that MACI® treatment results in functional tissue infill to 24 months and improved clinical outcome that were maintained to five years following MACI® treatment.

In a recent publication, results of five year follow-up of 21 patients treated with MACI® were reported [55]. For each of the five KOOS subscales, significant improvement was observed ($p < 0.05$), and maintained up to five years post-treatment in 90.5% of the patients. Significant improvement up to five years post-treatment was also reported for other patient-reported outcome measures including the International Knee Documentation Committee (IKDC) and the modified Cincinnati. Positive evidence of structural repair was demonstrated by MRI at five years post-treatment. The MRI composite score significantly improved up to five years post-treatment ($p < 0.001$); complete defect fill (83%) and graft integration (82%) were reported for the majority of patients. The authors conclude:

> 'The MACI® procedure was shown to be a safe and effective treatment for symptomatic, traumatic chondral knee defects in this study.'

A large GCP, randomized, comparative, multicenter study has recently been completed in Europe comparing patients treated with MACI® vs. microfracture (SUMMIT study, Genzyme Biosurgery; ClinTrials.gov Identifier: NCT00719576). It is expected that the results will be published in 2013. The study design closely follows the guidelines for the study of cartilage repair currently available from the EMA, the FDA, and the ICRS, including clinical outcome of pain and function as the co-primary efficacy endpoint. Outcome up to two years post-treatment has been assessed and five-year follow-up is ongoing.

The clinical development of third-generation products has built on the earlier ACI experience by addressing some of the limitations of the original ACI and continuing to advance the field of cellularly-based therapies for cartilage repair. These products were designed to remove the need for the harvest, placement, and suture of a periosteal flap and thereby provide implantation of autologous chondrocytes for cartilage repair with less invasive techniques. In general, studies of third-generation ACI have shown significant improvement in pain and function, structural evidence of repair tissue maintained in the longer-term, and few adverse safety findings. The next steps for clinical development may include arthroscopic application and expansion of treatment to joints other than the knee.

CONCLUSIONS

Further progress in treating articular cartilage lesions is likely to come from a number of approaches, including continued improvement of autologous cultured chondrocyte implantation. Given the range of clinical presentations outlined in the chapter introduction, it is unlikely that a single technology will be applicable to the entire spectrum of articular cartilage pathology. More likely is an array of diagnostic and therapeutic tools to enable orthopedic surgeons to effectively treat each stage of cartilage injury and comorbid injury. There is a continuum from early chondral injury, identified when it may still be relatively asymptomatic, to symptomatic focal cartilage injury, to end-stage arthritis. At the early end of this continuum is a need to better identify and mitigate the risk of progression of disease.

Third-generation ACI focuses on improved delivery of autologous cultured chondrocytes for treatment of symptomatic cartilage lesions. This is well along in clinical development. Additional work is needed to assess the applicability of cell therapy approaches to arthritis and to joints other than the knee. This is likely to focus on indications where traditional arthroplasty has the most limitations (e.g., younger, athletic patients, need for revision, and bone stock loss).

The clinical applications of cell therapy tissue engineering to date have focused on autologous cultured chondrocytes. As discussed elsewhere in this book, there is extensive research on a wide range of other cell sources, such as adipose cells, embryonic stem cells, mesenchymal and induced pluripotent stem cells, and allogeneic chondrocytes. These have the potential to expand the clinical applications to other cell types. Cell optimization and modification strategies using gene therapy or growth factors to mediate cartilage repair with different cell types are also under investigation and have the potential to broaden the scope of cell therapy clinical applications.

Developing and producing surgical implants with live cells poses scientific, logistical, commercial, and clinical challenges that are very different from the challenges with the development and production of more traditional orthopedic implants. To the extent that future cell therapy applications in cartilage repair require *in vitro* cell processing on a manufacturing scale, the experience with Carticel®, MACI®, Hyalograft C®, and CaReS® demonstrate the feasibility of manufacturing a high-quality cell product for surgical implantation. The clinical success with first-through third-generation ACI in patient populations with very symptomatic and challenging cartilage lesions has laid the foundation for further progress in cell-based orthopedic tissue engineering in general and cartilage repair in particular.

INTRODUCTION

Unlike softer skeletal tissues, bone has inherent regenerative capabilities that enable self-repair of fractures and limited tissue loss. However, when the bone loss due to trauma or tumor removal is too extensive, bone defects do not completely heal and require surgical intervention. In orthopedics, the clinical management of a critical diaphyseal defect (a large discontinuity in bone that cannot spontaneously regenerate) continues to be a major challenge. The two available treatment options are limb salvage or amputation, and both have high rates of self-reported disability [1,2]. These clinical scenarios can be complicated further by infections and/or non-union fibrosis. Moreover, these problems and the high morbidity and associated costs of care are not limited to the civilian population, but represent a major concern in the ever-increasing non-lethal combat casualties [3]. The treatment of diaphyseal bone defects has advanced over the years from amputation to reconstruction with bone grafts (vascularized, cancellous, autologous, allograft) to distraction osteogenesis with Ilizarov devices to the emergent translational possibilities of tissue engineering and regenerative medicine [4].

Similarly, oral cancer is a major reason for mandibulectomy and maxillectomy, and major neurosurgical procedures typically involve craniotomy. *In vivo* bone formation is a major challenge in various craniofacial reconstructions and dental procedures that involve jawbone [5,6]. Currently, major mandibular defects can be repaired with an autologous vascularized bone from a variety of donor sites including fibula, scapula, iliac crest, or rib. A major disadvantage of this technique is that harvesting these grafts always creates a skeletal defect at

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00083-5

the donor site, and induces significant secondary morbidity. Other therapeutic options including allografts, xenogenic tissue grafts, synthetic materials, or prosthesis unfortunately do not yield consistent and efficient regenerative repair and are fraught with complications [7]. Significant progress in tissue engineering could yield more favorable outcomes than current clinical approaches used to repair craniofacial defects.

CELLS, SCAFFOLDS, AND BIOFACTORS: FROM *FUNCTIONAL* TO *TRANSLATIONAL* TISSUE ENGINEERING

Regenerative medicine approaches based on engineering cells and biomaterial scaffolds into 'spare-part' tissues promise to shape the future of reconstructive surgery and organ transplantation. To date, use of growing *functional* engineered tissues *in vitro* for subsequent implantation into tissue defects *in vivo* remains experimental, despite some early clinical successes [8]. In this approach, combinations of cells and bioactive molecules are seeded onto three-dimensional biomaterial scaffolds [9–14]

Cells can be retrieved from a variety of sources, including embryonic stem cells, postnatal and adult stem/progenitor cells, or the most recently discovered induced pluripotent stem cells (iPS). The common approach in engineered tissue regeneration has been to isolate cells from tissue biopsies or aspirates, manipulate them and reintroduce them into the host [12]. For bone regeneration, multiple cell sources have been investigated, including fresh bone marrow aspirates [7]; purified, culture-expanded bone marrow mesenchymal stem/progenitor cells [15], osteoblasts and cells that have been modified genetically to express osteogenic factors such as rhBMP [16], umbilical cord blood cells [17], adipose derived stem/progenitor cells [18], or embryonic stem cells [19]. Perceived advantages and disadvantages of these cell sources in bone tissue engineering have recently been reviewed [6].

One of the pivotal challenges of cell transplantation is the cost and complexity associated with the development of experimental strategies into regulatory approved products. Intra-operative cell processing, while immune from regulatory approval, can only serve as a *point-of-care* service for one patient at a time. Once the cells are manipulated off site, regulatory approval is automatically required. Cell transplantation has encountered a number of barriers towards clinical translation, including potential immune rejection for non-autologous cells, pathogen transmission, potential tumorigenesis, costs associated with packaging, storage and shipping, shelf life and reluctance of physicians and insurance in clinical adoption [6]. Cell survival in the host is also an unsettled issue, regardless of the cell source, and there is debate on whether the transplanted cells are regenerative *per se* or simply act as a pleiotropic source of factors and signals, especially in their ability to regulate inflammation [19a]. These barriers will continue to be challenges for the implementation of engineered bone as a clinical treatment in foreseeable future. An alternative paradigm is to activate endogenous stem cells to participate in bone regeneration. A case in point is periosteal progenitors cells, which are activated by injury and play an indispensible role in fracture repair [20,21]. Whether simple mobilization and homing of endogenous stem cells to the defect site will suffice for regeneration and have advantages over exogenous cell transplantation remains to be proven.

The assembly of the cells into the required three-dimensional (3D) form of the bone defect requires a scaffolding biomaterial that delivers and retains the cells, and potentially stimulates and guides their induction of tissue regeneration. The minimum requirements of biomaterial scaffolds in addition to sustenance of *Form* (3D shape and size) include *Fixation* (securing the attachment to the host bone and minimization micro-motion), *Function* (establishment of temporary or permanent mechanical load bearing), and *Formation* (provision of appropriate porosity for mass transport, revascularization, osteoinduction and osteoconduction) [22]. Additional biocompatibility characteristics must also be met in biomaterial scaffolds including

the lack of immunogenicity and toxicity. Furthermore, scaffolds can be enhanced by surface functionalizing to elicit affinity to cell binding and interactive modulation of the cells' response, and can be designed for localized, controlled delivery of various bioactive molecules.

Scaffolds can derive from native tissues and biological polymers and/or synthetic polymers, and can be fabricated using a variety of conventional techniques (reviewed in [23]). Among these techniques, solid freeform fabrication (SFF) offers distinct advantages in enabling exquisite control of the scaffold form and internal architecture based on medical image-guided 3D modeling of the bone defect [24]. Recently, 3D-bioprinting has been enabled by the commercial availability of low temperature, high resolution, multi-injector 3D printing systems, which were originally developed for rapid prototyping applications. This technology has been successfully adapted for bone tissue engineering with biocompatible and osteoinductive calcium phosphate powder and biocompatible binder system for CT-guided 3D printing of patient-specific scaffolds [25]. The multi-injector capabilities of a *colored* 3D printer potentially allow the embedding of combinations of biofactors and molecules within the scaffold with spatial control, which can be attractive in scenarios that might require spatiotemporal control over release kinetics. However, a recent review of scaffolds for bone tissue engineering has painted a bleak picture for translational progress of the field [22], which remains riddled with technical challenges of designing, manufacturing, and functionalizing scaffolds, regulatory approval barriers, business challenges related to meeting identifying niche markets and generating large initial investments necessary to sustain the business through the long-drawn-out regulatory process, and intellectual property (IP) lifecycle issues that must protect the product long enough beyond the regulatory process to recoup the investment and make these products commercially viable.

Delivery of biofactors and molecules can alter cell signaling in the defect milieu and has been shown to influence the outcome of regeneration. A popular paradigm in tissue engineering suggests that reactivating developmental factors and signaling might be necessary for true regeneration of the lost adult tissue [26]. However, it is unclear whether the complex developmental signaling gradients and cascades need to or can be replicated faithfully in postnatal tissue repair. Regardless, our understanding of the developmental biology of the musculoskeletal system, and more specifically endochondral and intramembranous bone formation in the embryo provides us with a plethora of information about factors, which when applied individually can enhance bone regeneration. This latter, simpler approach is preferable for therapeutic translation.

A case in point has been the discovery of bone morphogenetic proteins (BMP), which were discovered by Marshall Urist and touted for their osteoinductive properties [27–29]. Basic science studies using transgenic mice in which individual BMPs have been selectively knocked out from the limb skeleton have identified BMP-2 as a critical factor in the innate regenerative capacity of bone [30]. The combination of recombinant human BMP-2 on an absorbable collagen sponge (ACS) carrier has been one of the most studied systems in preclinical and clinical investigations, and represents one of the most significant therapeutic orthopedic discoveries [31]. With supporting level 1 clinical trial data, rhBMP-2/ACS (INFUSE® Bone Graft) is commercially available, at the time of this writing, for three Food and Drug Administration (FDA)-approved clinical indications including spinal fusion, open tibial fractures with an intermedullary (IM) nail fixation, oral and maxillofacial augmentation (sinus augmentations, and alveolar ridge augmentations for defects associated with extraction sockets) [31]. However, the efficacy of INFUSE Bone Grafts requires supraphysiological concentrations of BMP-2, and numerous adverse events have been filed at the FDA and reported in the literature in approved indications and off-label uses [32,33]. Therefore, the identification of effective doses of BMP-2 (and perhaps other osteogenic and vasculogenic factors) for the regeneration of critical bone defects, preferably with tolerable and subclinical side effects, remains a common challenge for tissue regeneration community.

An exciting prospect has been the discovery of the therapeutic value of systemic hormones such as parathyroid hormone (PTH) in fracture repair [34–37] and tissue engineering of critical diaphyseal defects in preclinical models [38–40]. This systemic delivery approach might overcome the challenges associated with local delivery, but remains to be clinically validated.

To sum, each of the individual components of the conventional tissue-engineering triad (cells, scaffolds, and biofactors) brings unique sets of challenges. Optimization of these *composite* constructs into *functional* tissue substitutes, is typically performed empirically in the laboratory *ex vivo* using cell and tissue culture models and *in vivo* using preclinical animal models. However, this approach has faced difficult barriers to translation from the bench to the bedside. A three-component medical product would have at least 3^{n_i} possible combinations of independent variables (where n_i is the number of possible variables associated with the i^{th} component of the three-component product), which makes the feasibility of testing the experimental matrix in a comprehensive investigation impossible. This has limited advances in the field to only incremental discoveries, despite exciting developments and breakthrough technologies that have been reported in small animal and preclinical models. The regulatory requirements of the multicomponent bone regeneration products have hindered and continue to slow down clinical translation. Nevertheless, innovative '*point-of-care*' regenerative approaches guided by the tissue engineering paradigm have been reported in the clinical literature with remarkable early successes.

CLINICAL SUCCESSES AND OPPORTUNITIES IN REGENERATIVE REPAIR OF DIAPHYSEAL DEFECTS

Segmental diaphyseal defects are common in long bone in scenarios involving tumor resection, trauma, and debridement following infections or atrophic non-unions. Previously, substantial bone defects have required amputation. In the 1960s an innovative technique for *in vivo* bone regeneration was developed in Russia by G.A. Ilizarov [41,42,62]. In the late 1980's this technique, referred to as distraction osteogenesis was extended into Western Europe and the United States. Distraction osteogenesis is a process in which a bone is gradually separated at an osteotomy site. The bone on either end of the osteotomy is stabilized with an external fixation device (Fig. 83.1a). The regeneration of bone involves three stages [43].

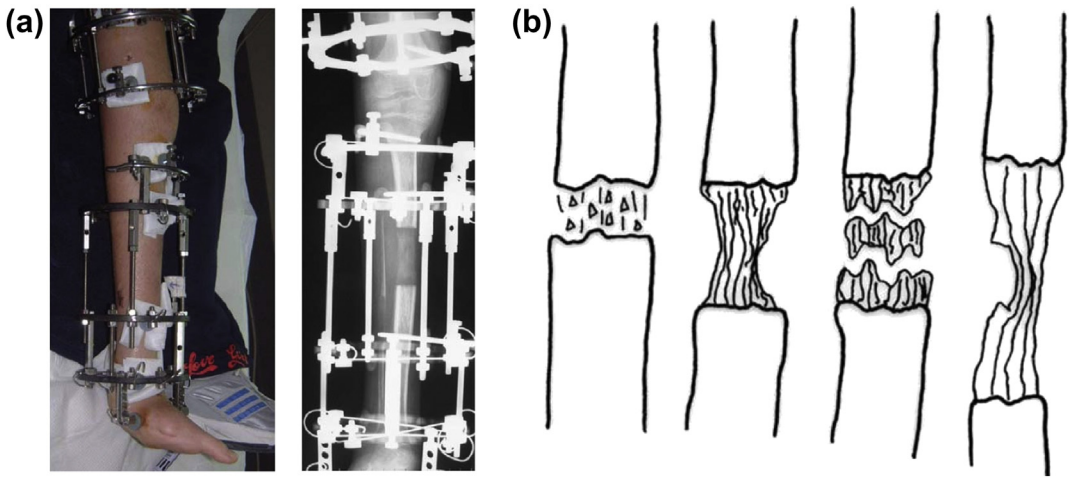

FIGURE 83.1

Bone regeneration using distraction osteogenesis. (a) Typical distraction osteogenesis hardware (frame and rings) is shown. (b) Distraction osteogenesis proceeds in stages, the first of which is the '*latency*' stage during which the injury and repair process initiates and fracture callus forms, followed by the '*distraction*' stage in which the bone is gradually distracted through the osteotomy site at a rate of approximately 1 mm per day resulting in a fibrous interzone composed of mesenchymal progenitors. The interzone eventually re-vascularizes, and the cells differentiate and form regenerate bone through intramembranous and endochondral ossification. Finally, in the '*consolidation*' stage, the immature bone that formed in the defect is remodeled into lamellar bone. *(Reproduced with permission from Catagni et al., 2011.)*

The initial stage is termed latency and consists of a 5–10 day period of during which the injury and repair process initiates and fracture callus forms. During the second, or distraction phase, the bone is gradually distracted through the osteotomy site at a rate of approximately 1 mm per day. Separation of the bone results in a repetitive tensile force in the distraction gap between the bone segments. In the center of the distraction a fibrous interzone composed of mesenchymal progenitors forms, while at each of the osteotomy surfaces bone the tissue is re-vascularized, and the cells differentiate and form regenerate bone through intramembranous and endochondral ossification. The final phase of the process is termed 'consolidation' in which the immature bone that formed in the defect is remodeled into lamellar bone (Fig. 83.1b).

Distraction osteogenesis has been used successfully to reconstruct limb defects resulting from tumor, trauma, infection, and developmental diseases [44–46]. The approach is also frequently used for the treatment of craniofacial defects [47]. The process of bone formation in distraction osteogenesis is dependent upon the mechanical stimulation of the healing bone callus that is generated by the tensile forces resulting from the daily separation of the bone fragments [43,48]. The tensile force results in the release of cytokines and growth factors that stimulate the proliferation and differentiation of mesenchymal stem cell progenitors and lead to angiogenesis and re-vascularization of the tissue. Growth factors associated with distraction osteogenesis include BMPs, VEGF, FGF, and Wnt signaling factors [49–51]. Thus distraction osteogenesis includes the various features associated the successful engineering of regenerate bone: stabilization of the skeleton, mechanical stimulation, recruitment and stimulation of stem cell populations, angiogenesis, and bone incorporation and remodeling.

Despite these advantages, distraction osteogenesis is not an ideal approach to regenerate bone. While effective, distraction osteogenesis has a high complication rate. The stabilization of the bone with an external frame connected to pins or wires inserted into the bone are associated with pin tract infections in nearly all cases. Bone lengthening is also associated with a risk of joint contractures or stiffness, nerve palsy, and limb deformity [52]. Moreover, the entire process, and particularly the consolidation phase, requires an extensive period of time. In patients with war-related bone loss, fixation was maintained at approximately 1.5 months per centimeter of bone regeneration [44].

One area of need for bone tissue regeneration involves device-associated infections. These are typically treated with a two-stage reconstruction approach. This approach involves complete removal of the hardware and tissue debridement, and later reconstruction after eradication of the infection with antibiotics [53,54]. The use of poly(methyl methacrylate) or PMMA cement spacers impregnated with antibiotic agents in two-stage reconstruction has been common practice in Europe and has experienced widespread clinical use in US hospitals over the past few years [55,56]. These temporary spacers, which are typically installed after tissue debridement, are intended to provide sustained local elution of effective tissue concentrations of antibiotics to treat the infection while maintaining limb length, preserving tissue stock, minimizing soft tissue fibrosis and contraction, and in the case of articulating spacers, maintaining joint mobility until the lost tissue is reconstructed [57].

An innovative regenerative approach to treat this complicated scenario follows the two-stage guidelines of the Masquelet technique [58], which described the *in situ* formation of a periosteum-like pseudosynovial membrane around temporary antibiotic-eluting bone cement implants, which if preserved can provide nutrition and vascularization during the regenerative phase of the reconstruction. Fig. 83.2a shows an X-ray of a classic fractured tibia with atrophic non-union and clinical evidence of osteomyelitis [4]. Stage 1 treatment of this case involved thorough debridement of the infected, necrotic bone and the placement of vancomycin-eluting polymethylmethacrylate cement beads in the resulting defect alongside the intramedullary nail (Fig. 83.2b). This resulted in eradication of the infection and the

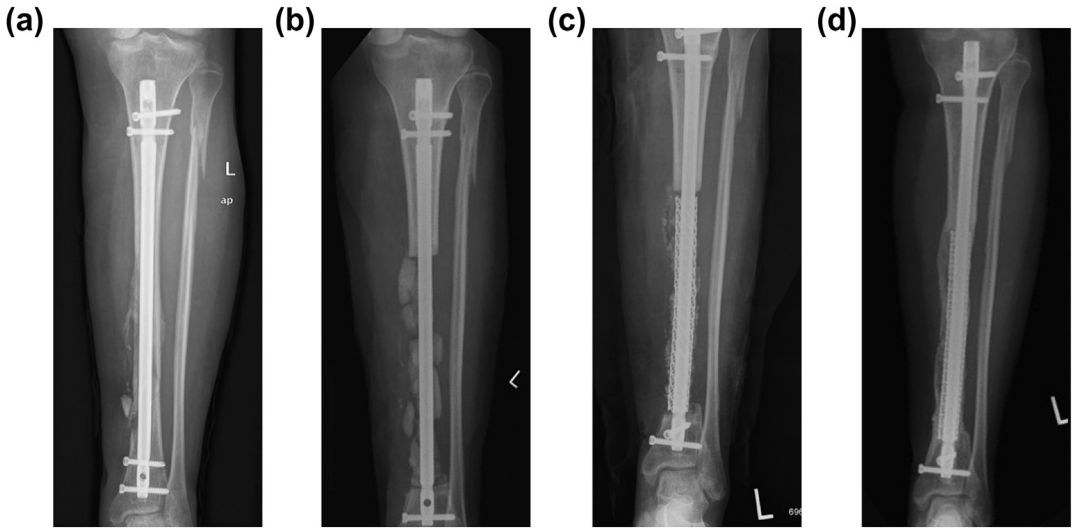

FIGURE 83.2

Tissue engineered reconstruction of a Methicillin-resistant Staphylococcus aureus (MRSA) infected tibial non-union. (a) Radiograph of the MRSA infected tibia five months after fracture, with no clinical evidence of healing. (b) Radiograph of the infected tibia after the 1st stage of the Masquelet technique, which involves resection of 17 cm of necrotic bone and insertion of vancomycin-eluting cement. (c) Radiograph following the second stage of the Masquelet technique, which involves exchanging the IM nail, with spinal cage support for INFUSE® Bone Graft and autologous cancellous bone reamings. (d) Radiograph of the tibia 1 year following the two-stage Masquelet reconstruction, showing bone regeneration in the massive tibial defect. *(Reproduced with permission from O'Malley and Kates, 2012.)*

endogenous formation of a pseudosynovial membrane over almost one year. The second stage then involved removal of antibiotic-eluting cement beads with careful preservation of the nutritive, induced biologic membrane, and subsequent installation of two titanium 15 mm diameter spinal cages to provide structural scaffolding for osteoinductive rhBMP-2 (INFUSE® Bone Graft) that was placed 'off-label' in the defect (Fig. 83.2c). To introduce BMP-2 responsive cells, autogenous cancellous bone and bone marrow were mixed with β-tricalcium sulfate granules (chronOS Bone Void Filler) and used to augment the defect, and the biological membrane was closed around the implanted biologics, morselized cells and tissue, and metallic scaffold. Four months following reconstruction, there was radiological evidence of new bone formation, and one year later there was resumption of independent ambulation with evidence of radiological and clinical healing [4] (Fig. 83.2d).

A similar approach to treat defects created by tumor resection exploits the endogenous osteoinductive properties of the periosteum and the osteoprogenitors it harbors. The concept is to circumferentially elevate a periosteal membrane off of healthy diaphyseal bone adjacent to the bone defect, and to then osteotomize the healthy bone (sans the periosteum) and transfer it to the defect out of the periosteal membrane. The retained periosteum with its soft tissue attachment maintains vascularity and osteogenesis can be augmented with cancellous bone grafts [59] (Fig. 83.3a). The feasibility of this approach was demonstrated in an osteosarcoma case by the reconstruction of an iatrogenically created defect in the fibula following lifting and *in situ* retention of its periosteal membrane (Fig. 83.3b). The fibula graft was transferred to augment regeneration of a surface defect in the tibia that resulted from resection of a low-grade surface osteosarcoma. The periosteum membrane that was left behind was activated *in situ* to serve as an osteoinductive and osteoconductive sleeve, and led to complete regeneration of the fibula defect within just six months (Fig. 83.3c).

The two approaches described above utilize the principles of tissue stabilization, recruitment/delivery of stem cells, bone tissue differentiation, angiogenesis and remodeling. The approaches also represent a presonalized *point-of-care* method of tissue engineering of critical

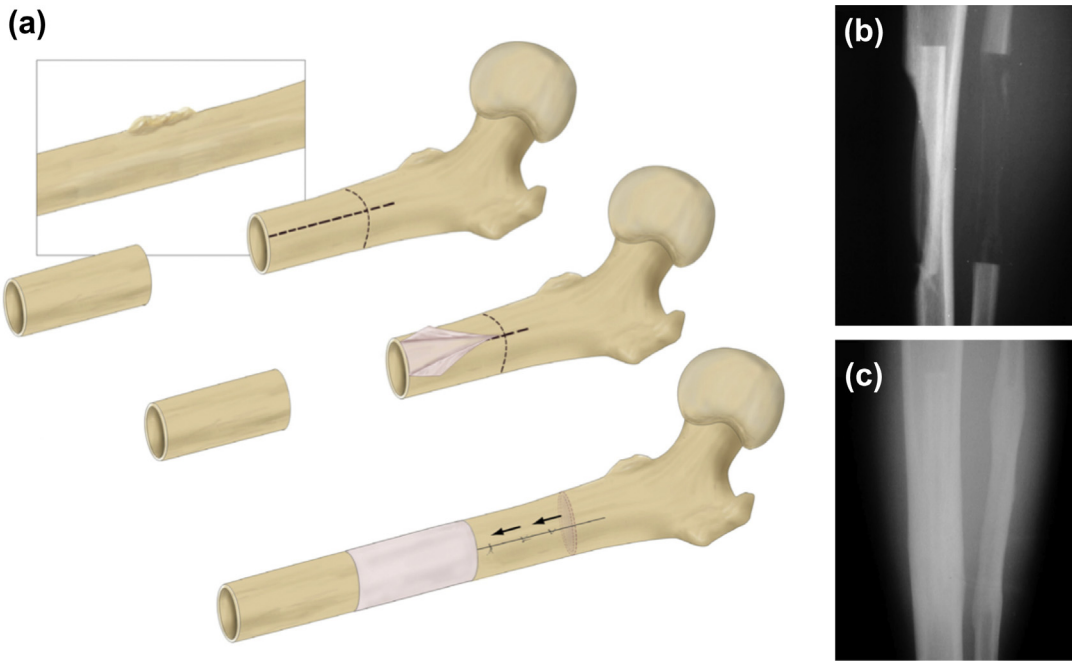

FIGURE 83.3

Exploiting the inherent regenerative capabilities of the periosteum to reconstruct the massive diaphyseal defects. (a) Schematic representation of the concept, which involves circumferential elevation a periosteal membrane off of healthy diaphyseal bone adjacent to the bone defect, and to then osteotomize the healthy bone (sans the periosteum) and transfer it to the defect out of the periosteal membrane. In theory, the retained periosteum with its soft tissue attachment maintains vascularity and osteogenic progenitors. (b) Radiograph showing the reconstruction of a tibia with malignant cortical tumor with an autologous, pedicled fibula transfer, following elevation and *in situ* retention of the fibular periosteum. (c) Complete periosteum-enabled regeneration of the fibula is achieved by 3 months post reconstruction. *(Reproduced from Knothe and Springfield, 2005, under the terms of the Creative Commons Attribution License (http://creativecommons.org/licenses/by/2.0).)*

diaphyseal defects. They clearly borrow from the first principles of conventional tissue engineering, but circumvent the regulatory process via '*off-label*' use of several approved products (e.g., INFUSE, chronOS, bone marrow, etc). These cases represent individual success stories and demonstrate the safety and efficacy of biologics, scaffolds, and cells without *in vitro* manipulation; an alternative paradigm in tissue engineering that has been recognized for some time but one that has received less attention in the basic science literature. Advances in image-guided fabrication of biocompatible, osteoinductive scaffolds such as 3D bioprinting, which in theory enables simultaneous printing of biofactors and antibiotics within the patient-specific scaffold for sustained release can potentially lead to single stage reconstruction procedures, accelerated recovery time, and improved the clinical outcome.

CLINICAL SUCCESSES AND OPPORTUNITIES IN REGENERATIVE REPAIR OF CRANIOFACIAL DEFECTS

The face distinguishes one human being from another. When the face is disfigured because of trauma, tumor removal, congenital anomalies, or chronic diseases, there is a critical need for functional and esthetic reconstruction [6]. These scenarios lend themselves to image-guided scaffold fabrication to restore the original shape of the face or jawbone. Success in this approach was first demonstrated by a report in the Lancet [7]. In this case, the patient, who lost a significant part of their mandible due to cancer, underwent 3D computed tomography (CT) of the head and computer-aided design (CAD) to generate an idealized virtual replacement of the missing parts of the mandible (Fig. 83.4a,b). A titanium mesh scaffold was then

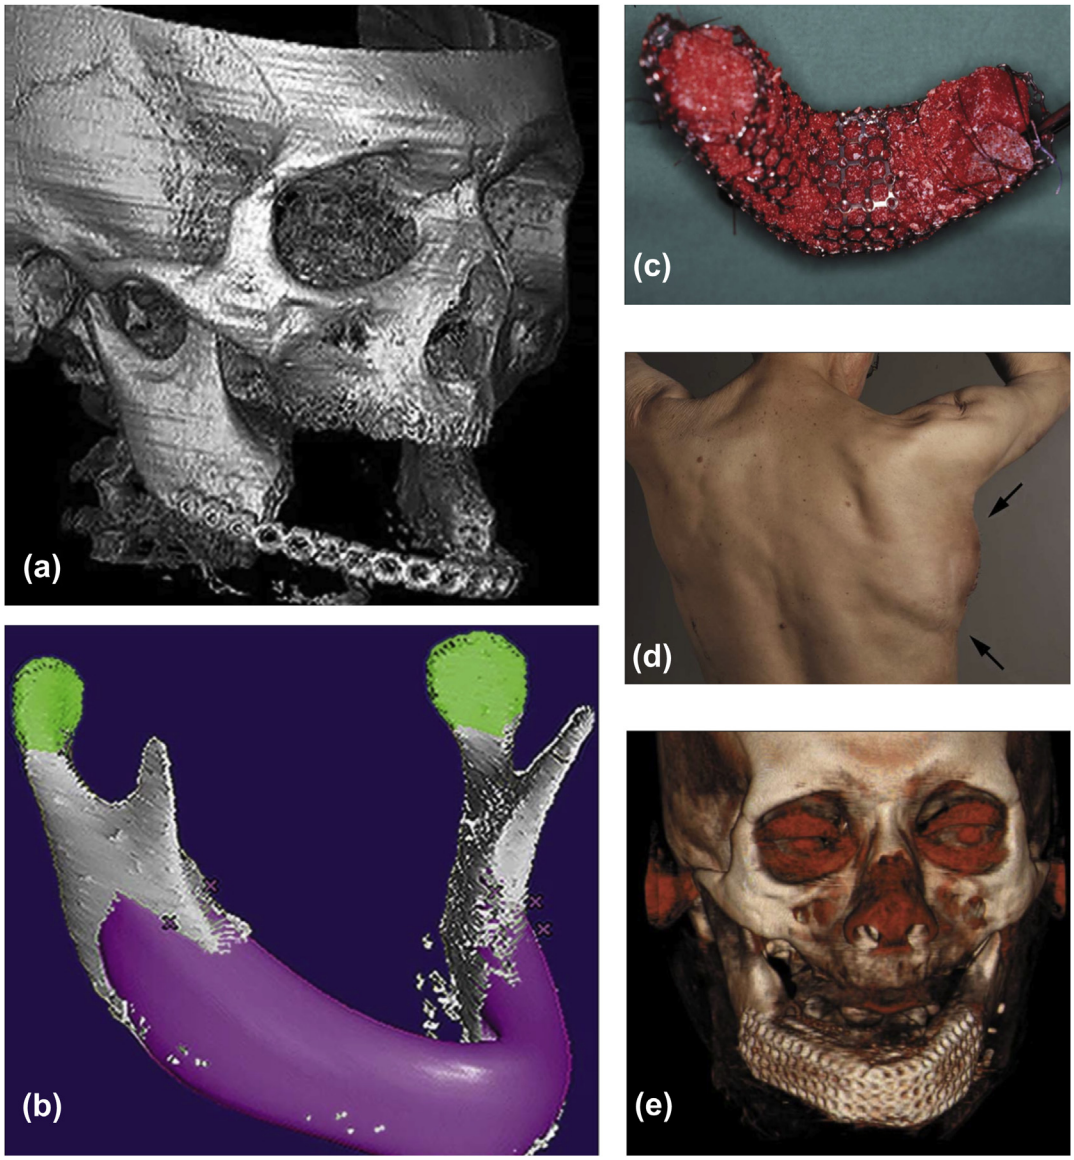

FIGURE 83.4
Image-guided tissue-engineered reconstruction of a massive mandibular defect. (a) The region of interest (jaw) is imaged using 3D computed tomography (CT). (b) The CT data is then fed to computer-aided design (CAD) software to generate an idealized virtual replacement of the missing parts of the mandible. (c) A titanium mesh is then formed in the shape of the missing bone model and augmented with BioOss hydroxyapatite blocks, OP-1 collagen implant, rhBMP-7, and autologous bone marrow aspirate. (d) The engineered mandibular graft is implanted in a heterotopic muscular pouch in the patient to establish vascularization and initial osteogenesis. (e) The graft was finally implanted orthotopically to reconstruct the mandibular defect. The patient had functional mastication and satisfactory aesthetic outcome. *(Reproduced with permission from Warnke et al., 2004.)*

formed in the shape of the model, and was filled with bone mineral blocks (BioOss-Blocks) and augmented with bovine collagen type 1 (OP-1 implant) soaked with recombinant human BMP-7, and an autologous bone marrow aspirate to provide BMP-responsive osteo-regenerative cells (Fig. 83.4c). The titanium mesh cage was then implanted heterotopically into a pouch of the patient's right latissimus dorsi muscle (Fig. 83.4d) to establish vascularization and initial osteogenesis prior to orthotopic implantation to reconstruct the mandible (Fig. 83.4e). Skeletal scintigraphy bone scans showed evidence of uptake indicative of viable bone metabolism within the engineered mandible at both the heterotopic and orthotopic implantation sites, and post-operative CT imaging demonstrated radiographic evidence of healing and incorporation, with patient reported functional improvements in

chewing and a satisfactory aesthetic outcome [7]. Other reports have since followed suit and demonstrated similar patient-specific, *point-of-care* reconstruction of the mandible with successful functional and aesthetic outcomes [60,61].

CONCLUSIONS

Despite regulatory bottlenecks, surgeons and scientists will likely, and should, continue to push the frontiers of what is surgically possible, armed with innovations in cell-free tissue engineering products, their skill and ingenuity, and most importantly their professional ethics and the vow they live by to do no harm. Cell-free refers to the recruitment of endogenous cells, including stem/progenitor cells, towards bone regeneration. Cell-free approaches arguably do not represent orthodox or conventional medical or tissue-engineering products from a regulatory or business standpoints, and the debates might not be settled by these n = 1 clinical reports, a far cry from randomized clinical trials required for level 1 data of safety and efficacy for regulatory approval. Nevertheless, these cases and similar ones not described herein successfully restored form, function, and quality of life to the afflicted patients. These *point-of-care* innovations might just be the bridge to wide clinical translatability and adoption of bone tissue-engineering approaches and products.

INTRODUCTION

Cardiovascular disease is by far the most common reason for morbidity and mortality in the Western world. It comprises malfunction of heart valves, blood vessels, and myocardium, all of which are subject to tissue-engineering programs. The development of tissue-engineered heart valves is fueled by the idea to create a 'growing valve' for children with congenital cardiac malformations and a 'totally autologous biological valve' for adults with acquired valve defects. Here the tissue-engineered product has to compare favorably to the existing spectrum of quite sophisticated and long-term approved biological and mechanical prostheses. Recent clinical trials with decellularized homografts, i.e., variations of standard procedures rather than truly tissue-engineered products, gave promising results [1–2]. Blood vessel engineering predominantly aims at generating small-diameter vessels (<6 mm; e.g., coronary arteries). Driving forces in the field are the low long-term patency rates of classical saphenous vein grafts and the paucity of suitable arterial vessels in coronary bypass surgery. The first fully engineered medium diameter blood vessels have been successfully applied in 10 patients with end-stage renal disease as arterio-venous fistulas for chronic hemodialysis, representing exciting progress in the field [3]. Myocardial tissue engineering aims at creating force-developing cardiac tissue patches to correct cardiac congenital malformations in children ('the growing patch') and replacing or supporting heart muscle function after myocardial infarction or in patients with cardiomyopathies. The total bioartificial heart remains a distant goal, despite some encouraging successes. Engineered human heart tissues are on the cusp of entering preclinical drug development [4] and the first patient with heart failure has been treated with a stacked cell sheet construct, not with cardiac but skeletal muscle cells [5]. The relatively slow progress of cardiovascular tissue engineering compared to e.g., skin engineering has two major causes. On the one hand, the risk is higher than in other fields. Failure of a heart valve, a coronary artery conduit, or a load-carrying heart muscle patch would have disastrous consequences. On the other hand, cardiovascular cells (myocytes in particular) cannot or not easily be

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00084-7

propagated and therefore require the use of pluripotent stem cells with their inherent limitations.

This chapter gives an overview of current development of the three major tissue-engineered cardiovascular products (valves, vessels, and myocardium), but focuses on myocardial tissue patch engineering, being the field the authors are actively involved in. For more thorough reviews on valves and vessels see [6–9].

CLINICAL NEED FOR TISSUE-ENGINEERED CARDIOVASCULAR PRODUCTS

Cardiovascular medicine has been among the most successful medical fields since the mid-1980s. Its contribution to the increase in life expectancy in the United States is impressive (3.9 out of a total of 6 years) and outnumbers that of all other fields [10]. Yet mortality and morbidity from cardiovascular causes remain high, and it is unquestionable that new therapeutic paradigms must be introduced.

Heart valves

Malfunctioning heart valves are generally replaced surgically by either mechanical or biological prostheses, a procedure performed in more than 100,000 patients per year in the United States and 280,000 worldwide [11]. While valve replacement is often life-saving and has a tremendous impact on quality of life, drawbacks do exist. Mechanical prostheses require lifelong anticoagulation, with its potential hazards, and are still associated with a markedly increased rate of thromboembolism (4% per year [12]). Biological prostheses do not share these problems, but they have a limited half-life. None of the existing models grow, with the consequence that children with congenital valvular malformation have to be re-operated on several times during childhood and adolescence. The ideal tissue-engineered living valves would overcome all of these problems. Yet the strength of these arguments has to be critically weighed. In particular, the best biological prostheses, such as the aortic homografts and the Edwards pericardial valve, have a durability close to 20 years [13]. In fact, this will often be 'lifelong', given that the majority of patients undergoing valve replacement are over 50 years old. Moreover, surgical techniques have improved, and the high mortality rate associated with repeated valve replacements (formerly approximately 20%) has gone down considerably to approximately 4% [6], allowing the option of repeated use of bioprosthetic valves rather than implanting a mechanical valve. Thus, progress through tissue engineering appears most likely to be relevant in children with congenital malformations, where the availability of growing valves would constitute a major advancement. Most effort is directed towards this aim.

Blood vessels

Considering that the market for heart valves is large, the need for blood vessels is even larger. Every year, 500,000 procedures are being performed that involve small-caliber blood vessels just in the United States [7]. For many years, poly(ethylene terephthalate) (PET; Dacron) or poly(tetrafluorethylene) (PTFE; Teflon) grafts have been in clinical use for the replacement or repair of large-diameter blood vessels, such as the aorta and the carotid arteries, with good results [14,15]. In contrast, replacement of small-diameter vessels, such as coronary arteries, still requires venous or arterial autografts. The standard saphenous vein graft as used in coronary artery bypass grafting (CABG) has a high risk of acute or chronic vessel occlusion and requires a second surgical procedure. This does not apply to arterial autografts, such as the internal mammery artery, but this graft is often not available in sufficient number (e.g., for a three-vessel disease) or quality. Another important clinical application is arterio-venous (AV) fistulas needed for patients undergoing chronic hemodialysis, currently the most common vascular surgery in the US. Thus, there is a clear need for tissue-engineered small arteries.

Myocardial patches

Compared to current treatment options (drugs, devices, transplantation, prostheses, cell therapy), cardiac repair with tissue-engineered myocardial patches appears ambitious. Yet there are at least two areas where tissue engineering could prove to be valuable. The first, and maybe the most obvious, is reconstructing malformed hearts in children [16]. The other, quantitatively more important, is repairing infarcted or failing hearts in adults [17]. Heart malformations that might benefit from restoration using biological, autologous muscle patches include several forms of ventricular dysplasia, such as the hypoplastic left heart syndrome or tricuspid atresia with right ventricular dysplasia. Right now most of these infants undergo palliative surgery (a univentricular correction) ('Fontan-surgery'). Biologic active muscle patches might allow biventricular correction and true ventricular restoration. In addition, indications for a right ventricular outflow tract patch plasty are quite frequent in patients with pulmonary atresia or 'Fallot'-type malformations, which might also benefit from a biological solution. In contrast to cardiac malformations, myocardial infarction and its consequences belong to the most common diseases with huge socioeconomic impact. Present cell-based clinical studies employed bone marrow-derived cells and heart-derived progenitors in patients with relatively well-preserved left ventricular (LV) function after acute myocardial infarction and yielded mixed results [18]. The patient population included in these trials is large and easy to study, but not best-suited for tissue-engineering strategies, because it is 'not sick enough' and existing therapies are effective. Implantation of tissue patches could be rather considered in patients with chronic heart failure resulting from large myocardial infarctions. These patients might in fact benefit from a combination of tissue-engineered patch grafting, ventricular restoration surgery ('Dor-plasty'), surgical revascularization, and valve repair, although the data of the recently published 'Stitch'-trial are somewhat controversial with respect to the benefit of ventricular restoration [19]. A combination of the Dor-plasty and subsequent implantation of a contractile patch seems especially promising and would ideally enable functional regeneration of the ventricle [20]. Whereas it is hardly disputable that numerous patients would profit from a direct support of contractile function, the question is whether tissue-engineered patches could play a significant role in this scenario when compared to current alternatives.

1) Mechanical left ventricular-assist devices (LVADs) acutely support the pumping activity of the left ventricle and unload the heart, a process leading to 'reverse remodeling' and improved microvascularization [21], rarely even to recovery [22]. The established place of LVADs has been bridging to transplantation. Since the new third generation LVADs are much smaller in size, easier to implant and show less device-related complications, they are increasingly used as long-term, so-called 'destination-therapy'
2) Implantable defibrillators/cardioverters protect against lethal arrhythmias and thereby prolong survival [23], but in themselves have no effect on contractile function and heart failure symptoms. In contrast, the negative impact on patient's well-being is increasingly recognized [24].
3) Cardiac resynchronization therapy by means of biventricular pacing, in contrast, leads to improved heart function and has a documented effect on survival [25]. Yet only a limited number of patients (those with conduction abnormalities) profit from this new therapy.
4) The ACORN CorCap device, a bag-like polymer-mesh that prevents the heart from further dilatation [26] may be valuable in a limited subset of patients with large ventricles, but it is also hampered by severe complications, e.g., constrictive cardiomyopathy–like symptoms.

Thus, heart transplantation remains the only curative therapy for terminal heart failure. However, the number of candidates largely exceeds the number of suitable donor organs, and this ratio has not improved over the years [27].

When considering a tissue-engineering strategy for patients with terminal heart failure, three scenarios can be envisioned. The simpler one is to add patches of tissue-engineered heart

muscle on the diseased heart. A more elaborated and invasive one is to excise non-functioning myocardium and replace it with an engineered heart muscle patch. Obviously, the latter approach requires high mechanical stability of the patch to withstand systolic pressure, and this may be quite difficult to achieve. Finally, replacement of the entire heart by a fully engineered new heart is a thinkable, as yet unrealistic option. At this point, the addition of tissue-engineered patches to the heart seems to be the most realistic perspective.

CONCEPTS AND ACHIEVEMENTS IN ENGINEERING CARDIOVASCULAR PRODUCTS

The principal strategies in tissue engineering of valves, vessels, and myocardium are quite similar and have been developed in parallel, partly independently of each other (Table 84.1). They can be broadly categorized into five approaches:

1) Decellularization of native tissues (valves, vessels),
2) Re-cellularization of decellularized native tissues,
3) Cell seeding onto biodegradable polymer scaffolds,
4) Cell entrapment in naturally occurring biogels such as collagen I, Matrigel, and fibrin, and
5) The cell sheet technique.

Consistently, tissue formation can be significantly improved by mechanical loading and electrical stimulation.

Decellularized tissue

Decellularization of native tissues is a simple technique and, in fact, does not require any specific tissue engineering or cell biology procedure. Driven by companies such as CryoLife, decellularized valves and vessels entered the clinics decades ago. Conceptionally, the natural tissue provides the ideal 3D form, and decellularization is expected to reduce immune reactions directed against the cellular component of the valve. Indeed, immune responses have been detected in patients receiving cryopreserved allografts [28] and may limit the long-term function of the graft. This problem seems particularly relevant in children with their high immunological competence [29]. On the other hand, the process of decellularization, usually performed with hyper- or hypotonic solutions, mild detergents such as Triton X-100, sodium dodecylsulfate (SDS) or sodiumdesoxycholate, and proteolytic enzymes, exerts detrimental effects on the matrix that can give rise to thromboembolic complications and mechanical instability of the graft. Moreover, porcine extracellular matrix itself also seems to be immunogenic [30]. This may be one reason of the catastrophic failure of the first series of implantations of decellularized porcine valves in children in Vienna, Austria, in which at least three children died [31]. The exact number of patients that received these grafts has never been reported. Despite these disastrous results, a series of 50 patients in Berlin received such a graft during a Ross operation (replacement of the defective aortic valve by the endogenous pulmonary artery valve and implantation of the porcine valve in the pulmonary, low pressure position), with apparently good results [32]. However, there is evidence that a number of patients have indeed died from valve-related complications [6], casting serious doubts on the xenogenic approach. In contrast, decellularized, cryopreserved valved allografts (Synergraft, CryoLife) are a variant of the current gold standard of cryopreserved homografts and have been clinically evaluated in larger series of patients. As expected, these grafts did not induce immune responses [33] and compared favorably with standard cryopreserved allografts [1,34,35]. Lower peak transvalve gradients suggest better preservation and long-term outcomes, but the rates of insufficiency were similar [1]. More data are needed to draw definite conclusions. Another variation is freshly decellularized (unpreserved) pulmonary valves. In a recent report, they compared favorably with conventional cryopreserved homografts and valves made from glutaraldehyde-fixed bovine jugular vein [2]. Evidence was provided that the fresh

AVF = AV fistula, CABG = coronary artery bypass graft, CM = cadiac myocytes, EC = endothelial cells, FB = fibroblasts, hESC = human embryonic stem cells, hips= human induced pluripotent stem cells, hTERT = human telomerase reverse transcriptase subunit, MNC = mononuclear cells, myoFB = myofibroblast, PA = pulmonary artery, PG = polyglactin, PGA = polyglycolic acid, PV = pulmonary vein, Ross proc. = replacement of defective aortic valve by endogenous PV and insertion of new PV, RVOT = right ventricular outflow tract, SMC = smooth muscle cells.

decellularized grafts exhibited improved freedom from explantation and low peak gradients, but again, in the absence of prospective randomization it is difficult to make definite conclusions.

Decellularized blood vessels are being used for decades already, mainly as AV fistulas for hemodialysis patients [36]. The decellularized bovine carotid artery was introduced in 1966, the glutaraldehyde-fixed, non-decellularized bovine mesenteric artery in 2003 (ProCol Vascular Bioprosthesis). It has been tested in several smaller and one multicenter trial in 183 hemodialysis patients with encouraging results [37]. The primary and secondary patency rates were higher than in patients receiving a prosthetic graft (36% vs. 28% and 60% vs. 43%). This compares favorably with cryopreserved saphenous or femoral vein grafts, marketed by Cryo-Life since the early 1990s, that exhibited inferior patency rates than prosthetic grafts when used as infrainguinal bypass material [38]. The decellularized bovine ureter (Synergraft SG100) has been successfully applied as an alternative to PTFE grafts as AV fistula [39]. However, recent papers reported high failure rates [40] and a case of massive aneurysm formation in two weeks [41], both possibly related to residual bovine cell material in the graft. These data recall the catastrophic failure of decellularized porcine valves [31] and the Federal Drug Administration (FDA) ordering Cryolife to recall distributed human tissue in 2002.

Recellularization of decellularized tissues

A more elaborated approach is to repopulate the decellularized valve with autologous, patient-derived cells *in vitro*. This procedure may restore the biology of the graft, reduce thromboembolic complications, immune responses, and mechanical deterioration over time, and ultimately allow the graft to grow with the recipient. Positive results have been reported from heart valve experiments in sheep [42] as well as from two children who received reseeded decellularized allografts in the pulmonary position [43]. However, evidence exists that normal allografts show similar age-related enlargement in the pulmonary artery position [44]. Moreover, the logistical challenges related to cell seeding and mechanic conditioning of the valves in bioreactors are considerable, potentially explaining why no further reports with this technique were published.

An ultimate form of tissue engineering would be to decellularize whole hearts and repopulate the matrix with heart cells. Indeed, such experiments have been successfully performed with rat and porcine hearts [45]. Simple Langendorff-perfusion (through the canulated aorta and the coronary arteries) of whole hearts with SDS and Triton X-100 resulted in structurally preserved hearts devoid of cellular DNA. One conceptional problem was that the beneficial integrity of the extracellular matrix of the coronary vasculature also prevented egress of cells from the vascular lumen into the empty matrix of the ventricular walls. Therefore, reseeding had to be done by injecting (neonatal rat) heart cells at multiple sites into the matrix. This resulted in measurable contractions and pressure development ($\sim$2–5 mmHg), but the tissue quality was limited. Despite the apparent appeal of the idea, such a totally bioartificial heart appears a rather unlikely option for therapy, because it would have to be implanted as a substitute for the diseased heart. This means that it would have to work perfectly at the time of implantation on the scale of a human heart. A simpler alternative would be to devise a repopulated heart muscle patch derived from decellularized heart pieces, potentially with a perfusing vessel. Such experiments are ongoing in different laboratories but have not been published.

Biodegradable polymer scaffolds

The second principal tissue-engineering approach is to seed cardiovascular cells onto porous, biodegradable polymer scaffolds. Conceptionally the polymer serves as a three-dimensional template for the desired organ, and the cells are expected to degrade the polymer and produce their own extracellular matrix. This 'conventional' tissue-engineering approach has the

advantage that the scaffold can theoretically be manufactured at any desired size, form, or microstructure and with various chemical and biological properties. A principal problem is the difficulty to find the right balance between premature polymer degradation, with the risk of rupture (of a blood vessel or valve), and too little degradation, preventing tissue formation. Two variations of this technique in the blood vessel field have recently made important progress towards clinical application (Table 84.1). A Japanese group have reported a series of implantations of tissue-engineered vascular grafts in the pulmonary artery position in children, performed since 2001 [46]. They used tubular scaffolds made from a porous polycaprolactone-polylactic (PLA] acid co-polymer reinforced by a woven polyglycolic acid (PGA) sheet and seeded it with endothelial cells from a peripheral vein or, more recently, directly at the time of surgery with bone marrow cells. After a mean observation time of 17 months grafts were all patent and showed evidence for limited growth. Parallel experiments in mice suggested that the bone marrow cells were very quickly replaced by macrophages and then by ingrowing endothelial and smooth muscle cells from the adjacent ends of the blood vessel [47]. The second approach is more elaborated in that tubular PGA scaffolds are seeded with allogenic (cadaveric) smooth muscle cells *in vitro* and cultured for extended periods [48]. During this phase, the smooth muscle cells degrade the PGA scaffold and replace it by their own extracellular matrix. After chemical decellularization, an extracellular matrix tube remains and can be stored until time of implantation ('off-the-shelf'). Alternatively, the tubes can be reseeded with autologous endothelial cells before implantation, a procedure likely more effective in small-diameter vessel replacement. The method was successfully tested in a baboon model for AV fistulas for hemodialysis, and also in dogs as coronary artery bypass [48].

A similar hybrid approach using polymer scaffolds and decellularization has recently been developed for heart valves [49]. The rationale for this approach is twofold. On the one hand, heart valves generated by cell seeding of polymer scaffolds show retraction of the leaflets over time, leading to valvular insufficiency [50,51]. This response is thought to be cell-mediated. On the other hand, generation and implantation of cell-seeded polymer valves require complicated logistics, not well compatible with clinical requirements. Decellularized cell-seeded valves, based on a quickly biodegradable PGA scaffold, can be stored long-term, appear to retain their mechanical properties and showed better functional properties when tested *in vitro* [49]. Testing in an animal model has not yet been performed.

Prefabricated, biodegradable polymer scaffolds have also been used for myocardial tissue engineering. Cardiac myocytes have been seeded on scaffold blocks made from porous collagen [52], alginate [53], PGA [54], PGA/PLGA-collagen co-polymers [55] or silk fibroin [56]. A common observation is that cells preferentially populate the surface of the matrix. Moreover, cells remain randomly oriented if they lack mechanical guidance as is the case in solid scaffolds. Both factors limit cardiac tissue formation and maturation. Much effort is directed toward newer matrix materials that may overcome the current limitations. Material sciences and nanotechnology are progressing rapidly, and it may be that in a collaboration between engineers, physicists, biotechnologists, biologists, and morphologists the ideal scaffold material for creating truly 'artificial' heart tissues will be designed.

Biopolymers

The third approach is based on the entrapment of the desired cardiovascular cell type in biopolymers such as collagen I, matrigel or fibrin and the provision of a suitable casting mold. These natural polymers form a gel in which the cells are trapped in a given 3D form. The main advantage of this approach is that collagen I and fibrin are approved materials in clinical use and clearly promote tissue formation. Weinberg and Bell generated blood vessels using this technique more than 30 years ago [57], and in the meantime many groups have adopted a similar approach using fibroblasts or smooth muscle cells to create blood vessels [58–60] or heart valves [6] and cardiac myocytes for myocardial patches [61–65]. A disadvantage of the

biopolymer approach is that the tensile strength of the resulting tissues is normally low. This can be advantageous in the case of cardiac patches which should not increase passive stiffness of the heart and thereby impede diastolic relaxation. But it is a clear shortcoming in case of heart valves and blood vessels. By culturing dermal fibroblasts in tubular fibrin gels for extended periods (7–9 weeks in a bioreactor), their burst strength could be increased to 1400–1600 mmHg, and suture retention rates were sufficient to successfully implant the grafts into rats or sheep [66]. Others have used this approach to generate low pressure constructs for the replacement of venous vessels [67]. No clinical application has been reported.

Cell sheets

The fourth tissue-engineering strategy differs from all others in that it goes without any scaffold material. In this approach, first described by Auger's group [68] vascular smooth muscle cells were grown on plastic culture dishes as normal monolayers until confluency, were then removed from the culture dish as a cellular sheet and wrapped around a porous mandrel to form the media, nourished from the inside through the mandrel. In the same manner, a second layer of fibroblast sheets was wrapped around the media to form the adventitia. Finally, the mandrel was removed and the tube populated with endothelial cells by installation and rotating overnight. These sheet-based blood vessels exhibited, for the first time, a very good burst pressure, much better than what had been reported from the cell-seeded fibrin or PGA grafts. Moreover, the engineered vessels showed vasoactive responses to several known receptor ligands [69]. Sheet-based blood vessels made exclusively from human fibroblasts and human endothelial cells have been tested successfully in non-human primates [58] and as AV fistulas in 10 patients with end-stage renal disease receiving hemodialysis [3]. A 75% patency rate in this high-risk population can be considered a very good value and represents one of the first successful applications of basic tissue-engineering principles in the cardiovascular field [70]. Recent efforts are being directed to simplifying the method, making it faster, cheaper and readily available to improve clinical applicability (for review see [8], Fig. 84.1). Proposed steps are to omit the endothelium (e.g., in AV fistula with high flow rates), to air-dry the grafts (thereby get rid of living cells), store them at −80°C, rehydrate before implantation and reseed with autologous endothelial cells [71] and finally to use allogenic instead of autologous fibroblasts, considering that many patients already received allogenic tissue-engineered skin (Appligraf® or Dermagraft®) without apparent immune responses. The most recent twist of the technique is to produce threads from fibroblast-made sheets and use textile technologies to assemble threads into three-dimensional structures [8]. Apparently, this technique allows the production of vascular grafts in relatively short periods with burst pressures and suture retention rates exceeding those of the original technique.

Cardiac myocyte sheets can also be stacked to form contracting three-dimensional myocardial tissues [72], but here the absolute need for living, force-generating myocytes that are metabolically very active impose other problems than in the vascular field. Details will be discussed below.

STATE OF MYOCARDIAL TISSUE ENGINEERING

Heart-like tissue structure

Early experiments with biodegradable polymer scaffolds such as polyglycolic acid, alginate, and preformed collagen sponges showed that cardiac cells survive on these preformed 3D structures, but do not form synchronously beating, force-developing heart-like structures [52–54], likely because the scaffolds prevented the intense cell-to-cell contacts necessary for tissue formation. In contrast, tissue-engineering approaches based on biopolymers such as liquid collagen [61], collagen/Matrigel [73] or fibrin/Matrigel [74] hydrogels or prefabricated collagen sponges + Matrigel [75] as well as the cell sheet technique [72] yielded spontaneously contracting myocardial tissues that exhibit a characteristic cardiac muscle-like structure,

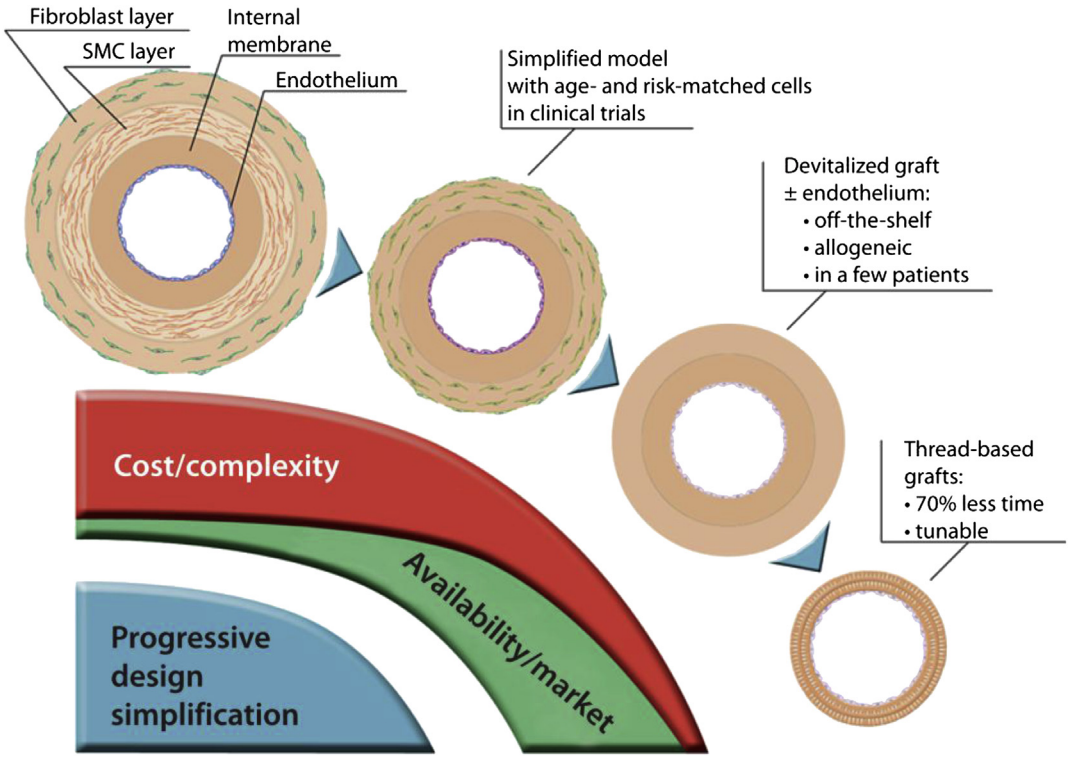

FIGURE 84.1
Evolution of a vascular tissue-engineering strategy (*tissue engineering by self-assembly;* TESA) [68] that led to the first application of a fully tissue engineered biological product in the cardiovascular field. The development went through a first phase in which a positive clinical outcome with a complex product was the major goal. Second and third phases are directed to make the process simpler, faster and cheaper. *(Adapted from [8].)*

both on the cellular and sub-cellular levels (Fig. 84.2). All of these approaches make use of the intrinsic capacity of immature cardiac cells to assemble into heart-like muscle structures spontaneously [76]. This process can be enhanced not only in a 3D growth environment, but also by mechanical loading [61,65,73,77], electrical stimulation [75], oxygenation and perfusion [65,78], growth factors [62], and non-myocytes [79] Other concepts for generating heart muscle *in vitro* are based on the formation of self-assembling cardiomyocyte aggregates/microtissues [80–82], cell seeding on foils [83] or fusion of small encapsulated tissue modules [84]. Applications of these alternative technologies are envisaged in basic cardiovascular science and drug screening rather than heart muscle repair *in vivo*.

Contractile function

Tissue-engineered heart muscle must have the capacity to contract and develop force. Reported values for muscle diameter-corrected force of contraction in tissue-engineered myocardium range between 0.08 and 66 mN/mm [17,24]. Native myocardium and single cardiomyocytes have been reported to develop up to 89 mN/mm^2 [85]. The variability and overall lower contractile force in tissue-engineered myocardium is mainly due to tissue heterogeneity, i.e., highly variable cross-sectional content of muscle and extracellular matrix. In engineered heart tissues (EHTs) developing ~5 mN/mm^2, ~10–30% of the cross-sectional area is composed of cardiomyocytes. Thus, specific muscle cross-sectional force would be 17–50 mN/mm^2. The notion that cardiomyocytes in EHTs develop similar absolute force as native cardiomyocytes is further substantiated by the observation of clearly anisotropic cardiomyocyte morphology with 'normal' sarcomere anatomy and shortening [86]. Two options exist to 'enhance' muscle cross-sectional area in engineered myocardium: 1) decrease its size at the expense of extracellular matrix components and 2) increase the amount of myocytes or myocyte volume per

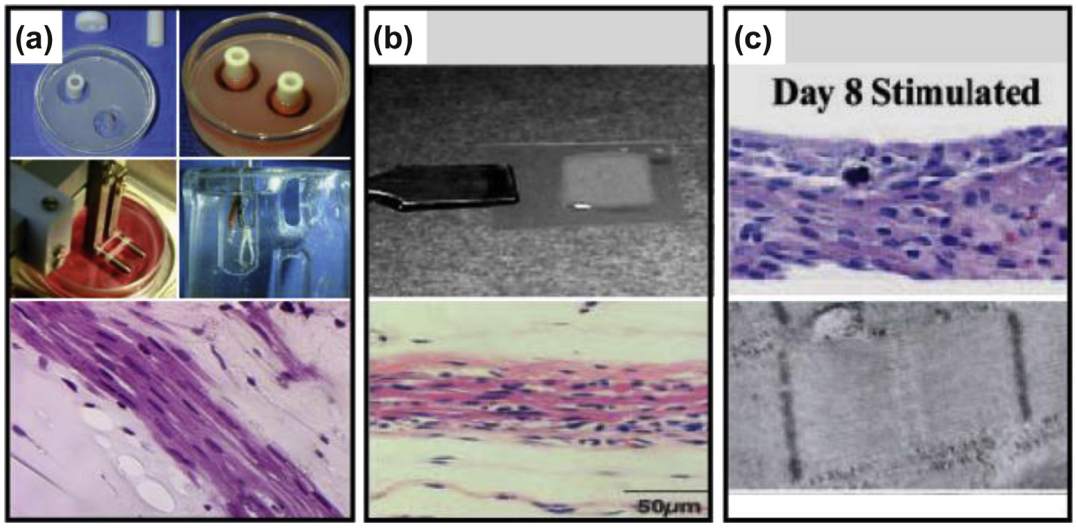

FIGURE 84.2

Current approaches to myocardial tissue engineering. (a) Macroscopic view of the setup to cast, culture, phasically stretch, and measure the contractile force of engineered heart tissue (EHT) based on collagen I/Matrigel hydrogels [62]. (b) Macroscopic (top) and microscopic view (H&E stain bottom) of stacked monolayers forming a beating three-dimensional tissue [72]. (c) Tissue formation (H&E stain, top) and sarcomere structure (bottom) in electrically stimulated collagen I + Matrigel-based constructs (Ultrafoam sponges) seeded with neonatal rat heart cells [75].

cross-sectional area. The first can be achieved easily by miniaturizing tissue constructs; an example is the cell sheet technology with close to 100% muscle cross-sectional area at a width of 45 μm [72]. Conversely, increasing cardiomyocyte number is complicated by limited oxygen and nutrient mass transport in tissues exceeding 100 μm. An alternative approach is to generate grafts with small and thin myocytes which undergo hypertrophy if exposed to a growth supporting environment. The capacity for hypertrophic growth is clearly present in EHT *in vitro* [86] and *in vivo* [65,87]. Cardiomyocyte proliferation in tissue-engineered myocardium appears to be just as limited as it is in postnatal hearts [86].

Critical size and vascularization

The width and length of tissue-engineered constructs can be easily expanded by adapting the dimensions of the scaffold material, casting device, or growth substrate, respectively. On the contrary, thickness of avascular myocardium is limited to 50–100 μm by physical constraints (nutrient and oxygen mass transport). This may be partly overcome by tissue perfusion and environmental oxygen enrichment [78]. However, the most straight forward approach to address this natural barrier is to perfuse tissue constructs *in vitro* [88]. Another approach is to adapt the tissue design to accommodate for the limits of nutrient and oxygen mass transport. This may be achieved by designing single tissue units at dimensions that are not oxygen deprived [86], followed by their fusion into larger tissues under the condition that mass transport remains sufficient to maintain proper tissue oxygenation (Fig. 84.3). A first step in this direction was introduced with the multiloop EHT model [65,79]. Here, complex beating tissue could be assembled and employed to re-build compact new layers of myocardium *in vivo*, reaching a thickness of 0.5–1 mm when implanted onto infarcted rat hearts. Alternatively, thin cell sheets have been repeatedly implanted on top of each other, generating similarly sized myocardium [89] (Fig. 84.4). In both cases, intense *in vivo* vascularization was observed. This process may have been facilitated by the presence of capillary-like structures in EHT *in vitro* [65,90]. However, rebuilding human heart sized muscle replacements (LV wall thickness mean: 9 mm) will likely require addition measures, such as for example attaching large caliber in and outflow vessels [91]. An elegant method of '*in situ* tissue engineering' cultured Matrigel-embedded cardiac myocytes in a silicone chamber that had been implanted

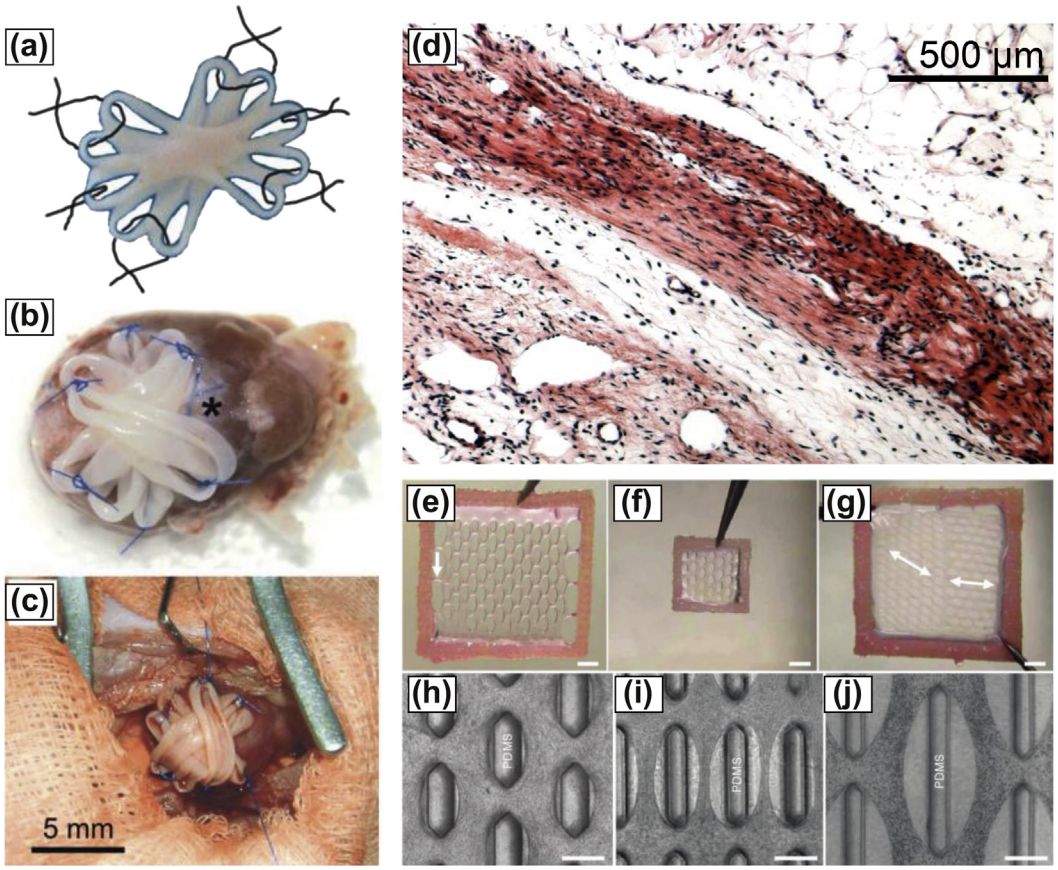

FIGURE 84.3

Strategies for cardiac repair using hydrogel-based tissue grafts of principally unlimited size. (a—d) Engineered heart tissue (EHT) approach. Several EHTs are fused *in vitro* to form multiloop EHT. Shown is one multiloop EHT with sutures before implantation. (b) Rat heart with multiloop EHTs sutured onto an infarcted rat heart *ex vivo*. (c) Rat heart situs showing a heart with a multiloop EHT fixed with six single-knot sutures placed in healthy myocardium just adjacent to the infarct scar through a left lateral thoracotomy. onto an isolated A/V loop of the epigastric blood vessels in rats [92] (Fig. 84.4). This approach generates a pulsatile cardiac tissue with perfusing artery and vein that can be surgically connected to carotid blood vessels and transplanted onto the heart [93]. Though not directly transferrable to humans, this study may point towards the right direction.

Electrical integration and improvement of function after implantation

Available data suggest that engineered sandwich constructs [94] and EHTs [65] find electrical contact with the host myocardium after implantation. This is in accordance with careful studies of isolated cardiac myocytes injected directly into the myocardium [95]. Studying electrical integration in engineered myocardium is particularly difficult in epicardial grafts. Here, motion artifacts and false positive signals from underlying native myocardium have to be controlled for. New developments in genetically encoded sensors, such as the calcium sensor GCaMP3, appear particularly useful in studies of cell integration [96]. Histological demonstration of gap junction formation is certainly not enough to unambiguously demonstrate graft-host coupling, also because cardiomyocyte integration may be via electrotonic contact or even via fibroblasts [97]. Electrical integration of tissue-engineered grafts into host myocardium appears essential, but, if incomplete, carries the risk of re-entry circuit formation. Hence, it was surprising to observe no evidence for enhanced arrhythmia in rats with EHT [65] or cell

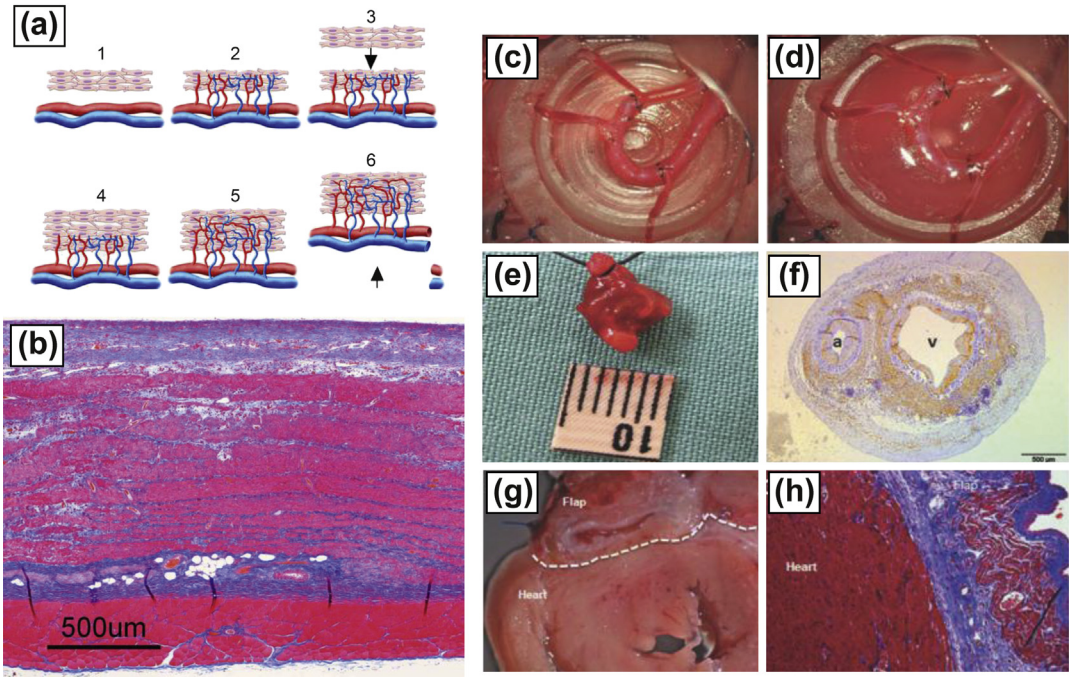

FIGURE 84.4

Strategies to generate vascularized cardiac tissue grafts. (a, b) Cell sheet polysurgery. Three cell sheets are layered on top of each other *in vitro* and implanted into a host animal over a surgically accessible artery and vein (1). This leads to vessel ingrowth (2) and allows implantation of a second multilayered graft (3), which is then also vascularized (4, 5). Finally, the vascularized construct (of principally unlimited thickness) is fully perfused by host vessels and can be surgically resected (6) and transplanted onto the heart. Adapted from 89. (c—h) *In vivo* bioreactor technique. An arterio-venous (A/V) loop is isolated from the femoral blood vessels of adult rats and surgically fixed in a polycarbonate chamber (c). A cardiac cell-matrigel mix is poured into the chamber (d). During a period of weeks a cardiac tissue flap develops that is perfused (e) and shows desmin-positive cardiac muscle tissue (f). Cardiac flaps with a long vessel pedicle are sutured to the carotid artery and vein and fixed on the heart of a second rat (g). Histology shows the formation of compact cardiac muscle tissue four weeks after implantation (h). *(Adapted from [93].)*

sheet grafts [94]. This may be explained by the comparably low spontaneous beating frequency of rat EHT grafts (2 Hz) compared to the high endogenous heart rate in rat (~5 Hz) and the mismatch in current load between graft and recipient heart muscle. Interestingly, a recent study studying the effect of isolated human ESC-derived cardiomyocyte injected in infarcted guinea-pig hearts suggested anti-arrhythmic rather than pro-arrhythmic effects [96].

Electrical coupling is clearly a prerequisite for functional myocardial support by tissue-engineered heart patches. In a large-scale study in rats in which multiloop EHTs were implanted above the infarct scar 14 days after ligation of the left anterior descending (LAD) coronary artery (Fig. 84.2) we could provide proof-of-concept for tissue-engineered heart repair by electrically integrated patches. Enhanced myocardial performance was observed especially in animals with a very poor LV function prior to implantation (fractional area shortening <30%; [65]). Despite these encouraging results, it should be noted that even the implantation of a relatively large (surface approximately 1 cm^2) and thick (Ø 1—4 mm) patch with nominally 12 million heart cells for a 1 g rat heart did not restore normal function, emphasizing the need for further improvement.

Considerations for clinical applications

True force-generating EHT grafts have not entered the clinic, mainly because an autologous and safe approach to generate heart muscle *in vitro* is not at hand yet. A case report on the implantation of autologous myoblast sheets in a patient with end-stage dilated cardiomyopathy observed contractile recovery associated with the procedure [5]. However, the negative

outcome of a clinical trial on myoblast injections [98] and the solid evidence that skeletal myoblasts do not acquire a cardiac myocyte phenotype make it unlikely that the reported benefit in this case was related to the generation of new contractile mass. An important step towards clinical application has recently been reported from a study in rhesus monkeys [99]. Allogeneic (rhesus) embryonic stem cell-derived cardiac progenitor cells were cultured on autologous adipocyte cell sheets and implanted onto experimentally infarcted rhesus monkey hearts under immunosuppression. Implanted cells formed cardiac myocytes, and no teratomas were observed in the five animals studied.

Clinical application of tissue-engineered myocardial patches requires a means to scale-up the procedure under the strict regulations of good manufacturing (GMP). This is primarily a biotechnological hurdle. In essence all cellular and extracellular components of EHTs are available at GMP-grade. Translation of the presently available technologies would also be facilitated by automation of the production process. The cell sheet stacking technology has already been automated and attempts to combine this with means to vascularize the cell sheet stacks are underway in the Okano/Shimizu group. Another important issue to consider is transplant immunology. Autologous approaches would clearly be preferred, but their realization appears unrealistic, mainly because personalized tissue-engineered products in heart repair would require generation and quality control of individual cardiogenic cell lines and heart muscle products. Induced pluripotent stem cells could in principle be used as autologous cell source, but its development under GMP-practice (integration free, [epi-]genetic stability ensured, quality controlled directed differentiation, quality controlled engineered heart muscle) in a timely manner appears unrealistic. Thus, the challenge will be to develop procedures to allocate off-the-shelf allogeneic products by making use of stem cell banking and tissue-engineering process optimization.

BOTTLENECKS

The critical bottlenecks in tissue engineering of heart valves, vessels, and myocardial patches differ. It appears that the main hurdle for tissue-engineered heart valves is the relatively good performance of conventional prostheses and the disastrous consequences of any failure. Decellularized allograft valves may have advantages over standard homografts, but more data are needed. The main challenge in vascular tissue engineering is the generation of small to medium size vessels with sufficient burst strength and long-term stability. Very encouraging progress has been made with tissue-engineered blood vessels, both with the sheet-based technique and smooth muscle cell-populated scaffolds that are decellularized before implantation. The former have already been tested successfully in patients [3,71], the latter in non-human primates and dogs [48]. Recent efforts successfully simplified the procedures and made them available 'off-the-shelf' [16,104]. This is the first time that true tissue-engineered cardiovascular products (in a stricter sense than decellularized valves) entered the clinic. Myocardial tissue patches are still far from this stage. On the one hand, they require less mechanical strength than vessels and valves, because they will likely be, with the exception of congenital malformations, applied as an add-on to an infarcted or failing heart. On the other hand, engineered myocardium, in contrast to valves and blood vessels, definitely requires functioning cells. The fact that cardiac myocytes do not (sufficiently) proliferate, impeded the progress in this field for long. However, much has changed today. The following issues require particular attention in heart muscle engineering.

Cell source

Having been a major hurdle for clinical realization of myocardial tissue-engineering concepts until recently, the exciting progress in stem cell technologies clearly changed the picture today. Human cardiomyocytes are available from embryonic and induced pluripotent stem cells at reliable quantity and quality [100]. Direct programming of fibroblasts may be

an alternative strategy to generate myocytes [101] but the low efficiency of this procedure currently precludes its application in myocardial tissue engineering. Whether adult stem cells can ever be stimulated to provide the necessary amount of therapeutic cardiomyocytes for *in vitro* tissue engineering appears questionable. It is very likely that human embryonic stem cell-derived cardiomyocytes will reach clinical application in cardiac tissue engineering first, similar to other pluripotent stem cell-based approaches [102,103]. In fact, GMP-compliant ESC-derived cardiomyocytes have already been generated by Geron. Given the clear unmet need for better heart failure therapeutics it is palpable that this biotechnological know-how will be exploited for clinical testing in the near future.

Size/vascularization

Engineered myocardium will have to be adjusted in size to reach optimal therapeutic results. During a normal myocardial infarction roughly 1 billion myocytes are lost. To have a meaningful therapeutic impact, it seems that grafts capable of replacing at least 20% of a given defect need to be engineered at a centimeter scale thickness. Whether this will require pre-vascularization of grafts or be sufficiently supported by *in vivo* vascularization to support hypertrophic growth of an engineered implant remains to be investigated.

Unwanted side effects

Demonstrating safety of tissue-engineered heart repair will be a key challenge of preclinical testing. The risk of tumor formation (especially if pluripotent stem cells will be applied) and induction of arrhythmias will have to be addressed in appropriate large animals such as the pig or non-human primate for a meaningful duration (6–12 months). Whether these studies need to be powered for established clinical endpoints such as mortality appears questionable. More likely, meaningful surrogate parameters with predictive value will have to be defined prior to first clinical studies. Here it becomes a matter of using the right model that ideally simulates human physiology and responsiveness to the respective intervention. This problem has been especially evident in large animal valve trials. Sheep tend to develop massive fibrosis, which can be misleading in two respects – overestimation of the risk of valve degeneration, but also underestimation of mechanical instability because the fibrosis has in fact stabilizing effects on the valve. Pigs show a high level of calcification. Eventually, non-human primates seem to be an ideal test bed. Raising the necessary resources for these large animal trials via traditional academic funding schemes is a challenge, but efforts are undertaken worldwide.

CHAPTER 85

Tissue-Engineered Organs

Steve J. Hodges and Anthony Atala
Wake Forest University School of Medicine, Department of Urology and Institute for Regenerative Medicine, Winston Salem, North Carolina

INTRODUCTION

Human organs are exposed to a variety of possible injuries from the time the fetus develops. Individuals may suffer from congenital disorders, cancer, trauma, infection, inflammation, iatrogenic injuries, or other conditions that may lead to organ damage or loss and necessitate eventual reconstruction or replacement. Whenever there is deficient organ function, replacement may be achieved with artificial organs or organ transplantation. These are flawed therapies, however, as artificial organs are not able to replace all physiologic functions and cannot fully integrate functionally into body systems, while organ transplantation is marred by donor shortages and immunologic rejection, and requires chronic and morbid medical therapy. In most cases, the replacement of lost or deficient tissues with functionally equivalent autologous tissues would improve the outcome for patients immensely. Tissue-engineering therapies have been developed in order to achieve this goal.

The development of functional organ systems from the building blocks of cells, scaffolding, and growth factors is a Herculean task, however, as evidenced by the few successful tissue-engineering technologies currently in clinical use. There have been successes, however, as evidenced by functioning autologous bioengineered tissues that have been implanted in humans — including trachea, blood vessels, pulmonary valves, endothelialized vascular stents, and urinary bladder [1]. An examination of the building blocks of tissue-engineering strategies, as well as the successful applications of these techniques in human clinical applications, provides an insight into the difficulties facing scientists as they seek to develop more complex bioengineered organs.

TISSUE ENGINEERING: STRATEGIES FOR TISSUE RECONSTITUTION

The field of regenerative medicine encompasses various areas of technology, such as tissue engineering, stem cells, and cloning. One of the major components of regenerative medicine, tissue engineering, follows the principles of cell transplantation, materials science and engineering towards the development of biological substitutes that can restore and maintain normal function. Tissue-engineering strategies generally fall into three categories: the use of acellular matrices (where matrices are used alone and which depend on the body's natural ability to regenerate for proper orientation and direction of new tissue growth), the use of simple cells, and the use of matrices combined with cells. The main obstacles that must be overcome for the clinical application of these strategies are: localizing reliable, immunocompatible cell sources; developing biocompatible and functional scaffolding; and providing growth factors and vascularization for bioengineered organs.

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00085-9

Acellular tissue matrices are usually prepared by manufacturing artificial scaffolds, or by removing cellular components from tissues via mechanical and chemical manipulation to produce collagen-rich matrices [2–5]. These matrices tend to slowly degrade on implantation and are generally replaced by the extracellular matrix (ECM) proteins that are secreted by the ingrowing cells. Cells can be used in combination with scaffolds or injected as simple cell therapy, either with carriers (such as hydrogels), or alone [90].

CELL SOURCES

When cells are used for tissue engineering, a small piece of donor tissue must be harvested and dissociated into individual cells. These cells are either implanted directly into the host, or are expanded in culture, attached to a support matrix, and then reimplanted into the host after expansion. The source of donor tissue can be heterologous (such as bovine), allogeneic (same species, different individual), or autologous. Ideally, both structural and functional tissue replacement will occur with minimal complications. The most preferred cells to use are autologous cells, where a biopsy of tissue is obtained from the host, the cells are dissociated and expanded in culture, and the expanded cells are implanted into the same host [5–17]. The use of autologous cells, although it may cause an inflammatory response, avoids rejection, and thus the deleterious side effects of immunosuppressive medications can be avoided.

One of the limitations of applying cell-based regenerative medicine techniques towards organ replacement has been the inherent difficulty of growing specific cell types in large quantities. Even when some organs, such as the liver, have a high regenerative capacity *in vivo*, cell growth and expansion *in vitro* may be difficult. By studying the privileged sites for committed precursor cells in specific organs, as well as exploring the conditions that promote differentiation, one may be able to overcome the obstacles that could lead to cell expansion *in vitro.* For example, urothelial cells could be grown in the laboratory setting in the past, but only with limited expansion. Several protocols were developed over the last two decades which identified the undifferentiated cells, and kept them undifferentiated during their growth phase [8,18–20]. Using these methods of cell culture, it is now possible to expand a urothelial strain from a single specimen which initially covers a surface area of 1 cm^2 to one covering a surface area of 4202 m^2 (the equivalent area of one football field) within eight weeks [8]). These studies indicated that it should be possible to collect autologous bladder cells from human patients, expand them in culture, and return them to the human donor in sufficient quantities for reconstructive purposes [8,18,21–25]. Major advances have been achieved within the last decade on the possible expansion of a variety of primary human cells, with specific techniques that make the use of autologous cells possible for clinical application.

A recent discovery may well influence cell sourcing for regenerative medicine strategies. A new type of interstitial cell, termed telocytes, has been isolated, and these cells have been found to be crucial to the process of evolution of progenitor cells toward mature development. Their architecture (tracks for migrations) and paracrine secretions (including microRNA) provide the environment for progenitor cells maturation. These cells have been found in many organs including myocardium, and have been demonstrated to be crucial to neo-angiogenesis following myocardialischemia. These cells and their signals may hold clues to creating more appropriate milieus for precursor cell development and angiogenesis [26].

An area of concern in the field of tissue engineering in the past was the source of cells for regeneration. The concept of creating engineered constructs involves initially obtaining cells for expansion from the diseased organ. One study recently showed that cultured neuropathic bladder smooth muscle cells possess and maintain different characteristics than normal smooth muscle cells *in vitro*, as demonstrated by growth assays, contractility and adherence tests *in vitro* [27]. However, when neuropathic smooth muscle cells were cultured *in vitro*, and seeded onto matrices and implanted *in vivo*, the tissue-engineered constructs showed the same

properties as the tissues engineered with normal cells [28]. It is known that genetically normal progenitor cells, which are the reservoirs for new cell formation, are programmed to give rise to normal tissue, regardless of whether the niche resides in either normal or diseased tissues. The stem cell niche and its role in normal tissue regeneration remains a fertile area of ongoing investigation.

In circumstances where source cell gene expression may be pathologically altered as demonstrated by Hodges et al. [28a], gene modifying techniques have been aggressively explored — including epigenetic therapies, and gene transfer techniques (using viral vectors or polymer-based gene delivery). Although the precise control of new gene expression remains complex, the use of gene delivery in combination with varying cell populations may expand the cell sources available for regeneration [26].

ALTERNATE CELL SOURCES

Stem cells

Most current strategies for tissue engineering depend upon a sample of autologous cells from the diseased organ of the host. However, for many patients with extensive end-stage organ failure, a tissue biopsy may not yield enough normal cells for expansion and transplantation. In other instances, primary autologous human cells cannot be expanded from a particular organ, such as the pancreas. In these situations, pluripotent human embryonic stem cells are envisioned as a viable source of cells, as they can serve as an alternative source of cells from which the desired tissue can be derived [29].

Human embryonic stem cells exhibit two remarkable properties: the ability to proliferate in an undifferentiated, but pluripotent state (self-renew), and the ability to differentiate into many specialized cell types [30]. They can be isolated by immunosurgery from the inner cell mass of the embryo during the blastocyst stage (five days post-fertilization), and are usually grown on feeder layers consisting of mouse embryonic fibroblasts or human feeder cells [31]. More recent reports have shown that these cells can be grown without the use of a feeder layer [32], and thus avoid the exposure of these human cells to mouse viruses and proteins. These cells have demonstrated longevity in culture by maintaining their undifferentiated state for at least 80 passages when grown using current published protocols [33,34].

Human embryonic stem cells have been shown to differentiate into cells from all three embryonic germ layers *in vitro*. Skin and neurons have been formed, indicating ectodermal differentiation [35—37]. Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation [38—40]. And pancreatic cells have been formed, indicating endodermal differentiation [41]. In addition, as further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers, while in culture, and can form teratomas *in vivo* [42].

Adult stem cells have the advantage of avoiding the ethical issues associated with embryonic cells, and also they do not transdifferentiate spontaneously to a malignant phenotype. The use of adult stem cells is limited for clinical therapy due to the difficulties encountered with cell expansion into large quantities.

Fetal stem cells derived from amniotic fluid and placentas have been recently described and represent a novel source of stem cells. The cells express markers consistent with human embryonic stem cells, such as OCT4 and SSEA-4, but do not form teratomas, and do not spontaneously transdifferentiate to a malignant phenotype. The cells are multipotent and are able to differentiate into all three germ layers. In addition, the cells have a high replicative potential and could be stored for future self-use, without the risks of rejection, and without ethical concerns [43].

THERAPEUTIC CLONING

While there has been tremendous interest in the field of nuclear cloning since the birth of Dolly the sheep in 1997, the first successful nuclear transfer was reported over 50 years ago by Briggs and King. Cloned frogs [44], which were the first vertebrates derived from nuclear transfer, were subsequently reported by Gurdon in 1962 [45], but the nuclei were derived from non-adult sources. In the past several years, tremendous advances in nuclear cloning technology have been reported, indicating the relative immaturity of the field. Dolly was not the first cloned mammal to be produced from adult cells; in fact, live lambs were produced in 1996 using nuclear transfer and differentiated epithelial cells derived from embryonic disks [46]. The significance of Dolly was that she was the first mammal to be derived from an adult somatic cell using nuclear transfer [47]. Since then, animals from several species have been grown using nuclear transfer technology, including cattle [48], goats [49,50], mice [51], and pigs [52].

Two types of nuclear cloning, reproductive cloning and therapeutic cloning, have been described, and a better understanding of the differences between the two types may help to alleviate some of the controversy that surrounds these technologies. Banned in most countries for human applications, reproductive cloning is used to generate an embryo that has identical genetic material to its cell source. This embryo can then be implanted into the uterus of a female to give rise to an infant that is a clone of the donor. On the other hand, therapeutic cloning is used to generate early stage embryos that are explanted in culture to produce embryonic stem cell lines whose genetic material is identical to that of its source. These autologous stem cells have the potential to become almost any type of cell in the adult body, and thus would be useful in tissue and organ replacement applications [53]. Therefore, therapeutic cloning, which has also been called somatic cell nuclear transfer, may provide an alternative source of transplantable cells. According to data from the Centers for Disease Control, it has been estimated that approximately 3,000 Americans die every day of diseases that could have been treated with stem cell-derived tissues [33]. With current allogeneic tissue transplantation protocols, rejection is a frequent complication because of immunologic incompatibility, and immunosuppressive drugs are usually administered to treat and hopefully prevent host-versus-graft disease [54]. The use of transplantable tissue and organs derived from therapeutic cloning may potentially lead to the avoidance of immune responses that typically are associated with transplantation of non-autologous tissues [43].

While promising, somatic cell nuclear transfer technology has certain limitations that require further improvements before therapeutic cloning can be applied widely in replacement therapy. Currently, the efficiency of the overall cloning process is low. The majority of embryos derived from animal cloning do not survive after implantation [53,55,56]. In practical terms, multiple nuclear transfers must be performed in order to produce one live offspring for animal cloning applications. The potential for cloned embryos to grow into live offspring is between 0.5 to 18% for sheep, bovine, pigs, and mice [57]. However, greater success (80%) has been reported in cattle [58], which may be in part due to the availability of advanced bovine supporting technologies, such as *in vitro* embryo production and embryo transfer, which have been developed for this species for agricultural purposes. To improve cloning efficiencies, further improvements are required in the multiple complex steps of nuclear transfer, such as enucleation and reconstruction, activation of oocytes, and cell cycle synchronization between donor cells and recipient oocytes, that will more readily produce viable sources of cells.

Furthermore, common abnormalities have been found in newborn clones if they survive to birth, including enlarged size with an enlarged placenta ('large-offspring syndrome') [59], respiratory distress and defects of the kidney, liver, heart, and brain [60], obesity [61], and premature death [62]. These may be related to the epigenetics of the cloned cells, which involve the reversible modifications of the DNA or chromatin, while the original DNA (genetic) sequences remain intact. Faulty epigenetic reprogramming in clones, where the DNA

methylation patterns, histone modifications, and the overall chromatin structure of the somatic nuclei are not being reprogrammed to an embryonic pattern of expression, may explain the above abnormalities [63]. Reactivation of key embryonic genes at the blastocyst stage is usually not present in embryos cloned from somatic cells, while embryos cloned from embryos consistently express early embryonic genes [64,65]. Proper epigenetic reprogramming to an embryonic state may help to improve the cloning efficiency and reduce the incidence of abnormal cloned cells.

BIOMATERIALS

For cell-based tissue engineering, once cells have been cultured and expanded, they are seeded onto a scaffold synthesized using the appropriate biomaterial. In tissue engineering, biomaterials replicate the biologic and mechanical function of the native ECM found in tissues in the body by serving as an artificial ECM. As a result, biomaterials provide a three-dimensional space for the cells to form into new tissues with appropriate structure and function, and also can allow for the delivery of cells and appropriate bioactive factors (e.g., cell-adhesion peptides, growth factors), to desired sites in the body [66]. As the majority of mammalian cell types are anchorage-dependent and will die if no cell-adhesion substrate is available, biomaterials provide a cell-adhesion substrate that can deliver cells to specific sites in the body with high loading efficiency. Biomaterials can also provide mechanical support against *in vivo* forces such that the predefined three-dimensional structure is maintained during tissue development. Furthermore, bioactive signals, such as cell-adhesion peptides and growth factors, can be loaded along with cells to help regulate cellular function.

The ideal biomaterial should be biocompatible in that it is biodegradable and bioresorbable to support the replacement of normal tissue without inflammation. Incompatible materials are destined for an inflammatory or foreign-body response that eventually leads to rejection and/or necrosis. In addition, the degradation products, if produced, should be removed from the body via metabolic pathways at an adequate rate that keeps the concentration of these degradation products in the tissues at a tolerable level [67]. Furthermore, the biomaterial should provide an environment in which appropriate regulation of cell behavior (e.g., adhesion, proliferation, migration, and differentiation) can occur such that functional tissue can form. Cell behavior in the newly formed tissue has been shown to be regulated by multiple interactions of the cells with their microenvironment, including interactions with cell-adhesion ligands [68] and with soluble growth factors. In addition, biomaterials provide temporary mechanical support that allows the tissue to grow in three dimensions while the cells undergo spatial tissue reorganization. The properly chosen biomaterial should allow the engineered tissue to maintain sufficient mechanical integrity to support itself in early development, while in late development, the properly chosen biomaterial should have begun degradation such that it does not hinder further tissue growth [66].

Generally, three classes of biomaterials have been utilized for engineering tissues: naturally-derived materials (e.g., collagen and alginate), acellular tissue matrices (e.g., bladder submucosa and small intestinal submucosa), and synthetic polymers [e.g., polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA)]. These classes of biomaterials have been tested in respect to their biocompatibility [69,70]. Naturally-derived materials and acellular tissue matrices have the potential advantage of biological recognition. However, synthetic polymers can be produced reproducibly on a large scale with controlled properties of their strength, degradation rate, and microstructure.

Collagen is the most abundant and ubiquitous structural protein in the body and may be readily purified from both animal and human tissues with an enzyme treatment and salt/acid extraction. Collagen implants degrade through a sequential attack by lysosomal enzymes. Controlling the density of the implant and the extent of intermolecular crosslinking can

regulate the *in vivo* resorption rate. The lower the density, the greater the interstitial space and generally the larger the pores for cell infiltration, leading to a higher rate of implant degradation. Collagen contains cell-adhesion domain sequences (e.g., RGD) that exhibit specific cellular interactions. This may assist to retain the phenotype and activity of many types of cells, including fibroblasts [71] and chondrocytes [72].

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell delivery vehicle [73] and a cell immobilization matrix [74] owing to its gentle gelling properties in the presence of divalent ions such as calcium. Alginate is relatively biocompatible and approved by the food and drug administration (FDA) for human use as wound dressing material. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of poly-guluronate block in the alginate chains [73].

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues [2,4,5,74]. The matrices are often prepared by mechanical and chemical manipulation of a segment of tissue. The matrices slowly degrade upon implantation and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrown cells.

Polyesters of naturally occurring α-hydroxy acids, including PGA, PLA, and PLGA, are widely used in tissue engineering. These polymers have gained FDA approval for human use in a variety of applications, including sutures. The ester bonds in these polymers are hydrolytically labile, and these polymers degrade by non-enzymatic hydrolysis. The degradation products of PGA, PLA, and PLGA are non-toxic, natural metabolites and are eventually eliminated from the body in the form of carbon dioxide and water. The degradation rate of these polymers can be tailored from several weeks to several years by altering crystallinity, initial molecular weight, and the copolymer ratio of lactic to glycolic acid. Since these polymers are thermoplastics, they can be easily formed into a three-dimensional scaffold with a desired microstructure, gross shape and dimension by various techniques, including molding, extrusion [75], solvent casting, phase separation techniques, and gas foaming techniques [76]. Many applications in tissue engineering often require a scaffold with high porosity and ratio of surface area to volume. Other biodegradable synthetic polymers, including poly(anhydrides) and poly(ortho-esters), can also be used to fabricate scaffolds for tissue engineering with controlled properties [77].

A recently developed polymer, Polyhedraloligomeric silsesquioxane/poly(carbonateurea) urethane (POSS-PCU) is a highly biocompatible nanocomposite which has demonstrated many of the ideal characteristics for tissue engineering numerous implants [1].

Other advances in biomaterial engineering include the development of conducting polymers which may find roles in neural tissue engineering, and ionic polymer metal composites that can induce movement with appropriate stimulation and therefore may serve roles in the development of artificial muscles or dynamic sensors [1].

GROWTH FACTORS

A key component to scaffold function is the presence of the appropriate growth factors for cell growth and maturation. Growth factors may be produced by cells themselves (autocrine), or the surrounding environment (paracrine). Scientists have employed various strategies to enhance desirable growth factor production, in order to promote the cell growth and maturation needed for particular organ systems. Some investigators have attempted to influence cell growth factor production with gene therapy, by incorporating genes for growth factor transcription in the transplanted cells. Others have sought to simply inject the growth factors into the cells milieu, but this method often results in rapid dissipation of the agents due to diffusion [78].

A novel method of growth factor use in tissue engineering involves the incorporation of growth factors into carriers or cell scaffolds. The goals of these techniques are to provide localized and controlled release of growth factors necessary for cell development. Extensive research is underway to define the exact combination of growth factors needed for specific organ growth and maturation, with an emphasis on the use of these factors to induce more rapid cell development and differentiation, appropriate cell function and orientation, and ECM development and vascularization [79].

In addition to the influence of growth factors, the simple topography of a scaffold has been demonstrated to greatly affect cell growth. For example, the shape of grooves in scaffolds can influence cell proliferation, cell alignment, and assist in cell differentiation [1].

VASCULARIZATION

One of the restrictions of the engineering of tissues is that cells cannot be implanted in volumes exceeding 3 mm^3 because of the limitations of nutrition and gas exchange [80]. To achieve the goals of engineering large complex tissues, and possibly internal organs, vascularization of the regenerating cells is essential.

Three approaches have been used for the vascularization of bioengineered tissue:

1) Incorporation of angiogenic factors in the bioengineered tissue;
2) Seeding EC with other cell types in the bioengineered tissue;
3) Prevascularization of the matrix prior to cell seeding.

Angiogenic growth factors may be incorporated into the bioengineered tissue prior to implantation, in order to attract host capillaries and to enhance neovascularization of the implanted tissue. There are many obstacles to overcome before large entire tissue-engineered solid organs are produced. Recent developments in angiogenesis research may provide important knowledge and essential materials to accomplish this goal.

The modern strategies of neo-organ vascularization have investigated the aforementioned use of growth factors and cytokines such as vascular endothelial growth factor (VEGF), the use of progenitor cells, or biomaterials, or fabricated vessel conduits, or combinations of those techniques. Because tissue engineering is often required in the setting of severe tissue damage (such as following radiation for tumor therapy) and immediate oxygenation of a large construct may be needed (where neoangiogenesis may not be possible or rapid enough) the *in vivo* creation of arteriovenous loops have been favored, and the most efficacious vascularization of solid organs has been found to be accomplished with the anastamosis of prevascularized constructs in combination with the local and controlled release of angiogenic growth factors [21].

CLINICAL APPLICATIONS

The assimilation of all these complex technologies into functional bioengineered organs is a complex task. By examining the early attempts at the application of tissue engineering for clinical use, the difficulties and challenges facing scientists in the future become more clearly delineated. The application of bioengineered organs for human use has been addressed in a logical fashion, beginning with the most simple organs system (e.g., skin) and extending to hollow organs (e.g., bladder) and finally complex solid organs (e.g., kidneys).

Skin

The concept of the clinical application of skin tissue engineering had its origins in Massachusetts around 1980, when Yannas and Bell developed the technologies necessary for the growth of skin-like structures from single cells. Bell was able to create dermal skin tissue by culturing human neonatal foreskin fibroblasts in collagen gels [81]. Yannas and associates expanded this

approach, and were able to engineer skin by applying the modern principles of biomaterial scaffolding and molecular cues to influence the growth of skin cells [82,83]. These efforts resulted in several commercially available bioengineered skin replacement therapies. Yannas and co-workers developed 'Integra', a collagen template for dermal regeneration. This was followed shortly by Bell's development of a full-thickness skin substitute with keratinized epidermis and dermis, Apligraft. The most recent development in the skin substitute market is Dermagraft, or a composite of dermal fibroblasts and collagen developed by culturing neonatal foreskin fibroblasts on PLGA scaffolds [84].

Although all these products function well, their clinical use has not been widespread. The failure of any of these excellent technologies to dominate the skin replacement market emphasizes the somewhat ignored factors of tissue engineering. Mainly, for a technology to be widely accepted as an organ replacement technology, it must function better than all available options, be easy to use, and not be cost prohibitive. Indeed, a bioengineered organ that functions better than available therapies, may never be accepted into widespread clinical use if it is difficult to use, or far too expensive.

Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair [85,86]. Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative reconstructive procedures for bladder replacement or repair such as the use of tissue expansion, seromuscular grafts, matrices for tissue regeneration, and tissue engineering with cell transplantation [85].

Cell-seeded allogeneic acellular bladder matrices are one of the few strategies of bioengineered bladder replacement with human clinical applications. The early work with this technology was performed in dogs, where a group of experimental canines underwent a trigone-sparing cystectomy with closure of the trigone without a reconstructive procedure, or reconstruction with a non-seeded bladder-shaped biodegradable scaffold, or reconstruction using a bladder-shaped biodegradable scaffold that delivered seeded autologous urothelial cells and smooth muscle cells [15].

The results were promising, with the cystectomy only and non-seeded controls demonstrating decreased capacities and compliance as compared to preoperative values, while the cell-seeded tissue-engineered bladders showed increased capacity and compliance, with histology depicting normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle [15].

Preliminary clinical trials for the application of this technology have been performed and have produced promising results. Recently published data demonstrated that engineered autologous bladder tissue may be used to safely augment the bladder in children with end-stage bladder disease secondary to myelomeningocele [87]. In this study, seven patients aged 4–19, with high pressure or poorly compliant bladders were selected as candidates for autologous augmentation cystoplasty. Bladder biopsies were obtained from each patient and smooth muscle and urothelial cells were cultured, expanded, and seeded on a composite scaffolds. Approximately seven weeks after the biopsy, the autologously generated neobladders were used for bladder reconstruction with or without omental wrapping. At a mean follow-up of 46 months, the increase in bladder volume and compliance was greatest in the engineered bladders coated in the omental wrap. Bowel function returned promptly after surgery, there were no metabolic complications, stone formation or mucous production, and renal function was preserved. In addition, engineered bladder biopsies demonstrated normal structural architecture and phenotype. Thus, this study provided good evidence in support of the use of engineered bladder tissue (created with autologous cells seeded on a composite scaffold, and wrapped in omentum following implantation), for patients in need of cystoplasty.

Kidney

Solid organs are the most challenging to reconstruct by tissue-engineering techniques because of their complex structure and function. Due to these complexities, some scientists approach the replacement of solid organ function, such as liver or kidney, with bioartificial approaches, combining the function of the organs predominate cells, with an artificial structure and organization.

An example of this strategy is extracorporeal renal replacement. Although dialysis is currently the most prevalent form of renal replacement therapy, the relatively high morbidity and mortality have spurred investigators to seek alternative solutions involving *ex vivo* systems. In an attempt to assess the viability and physiologic functionality of a cell-seeded device to replace the filtration, transport, metabolic, and endocrinologic functions of the kidney in acutely uremic dogs, a combination of a synthetic hemofiltration device and a renal tubular cell therapy device containing porcine renal tubules in an extracorporeal perfusion circuit was introduced. It was shown that levels of potassium and blood urea nitrogen (BUN) were controlled during treatment with the device. The fractional reabsorption of sodium and water was possible. Active transport of potassium, bicarbonate, and glucose and a gradual ability to excrete ammonia was observed. These results showed the technologic feasibility of an extracorporeal assist device that is reinforced by the use of proximal tubular cells [88].

Using similar techniques, the development of a tissue-engineered bioartificial kidney consisting of a conventional hemofiltration cartridge in series with a renal tubule assist device containing human renal proximal tubule cells provides was used in patients with acute renal failure (ARF) in the intensive care unit. The initial clinical experience with the bioartificial kidney and the renal tubule assist device suggests that renal tubule cell therapy may provide a dynamic and individualized treatment program as assessed by acute physiologic and biochemical indices [89].

The ultimate goal of tissue engineering, however, is the growth of fully functional and fully integrated replacement organs. Thus, another approach towards the achievement of improved renal function involves the augmentation renal tissue with kidney cell expansion *in vitro* and subsequent autologous transplantation. The feasibility of achieving renal cell growth, expansion, and *in vivo* reconstitution with the use of tissue-engineering techniques has been explored.

Most recently, an attempt was made to harness the reconstitution of renal epithelial cells for the generation of functional nephron units. Renal cells were harvested and expanded in culture. The cells were seeded onto a tubular device constructed from a polycarbonate membrane, connected at one end with a Silastic catheter that terminated into a reservoir. The device was implanted in athymic mice. Histologic examination of the implanted devices over time revealed extensive vascularization with formation of glomeruli and highly organized tubule-like structures. Immunocytochemical staining confirmed the renal phenotype. Yellow fluid was collected from inside the implant, and the fluid retrieved was consistent with the makeup of dilute urine in its creatinine and uric acid concentrations [90]. Further studies have been performed showing the formation of renal structures in cows using nuclear transfer techniques [91]. Challenges await this technology, including the expansion of this system to larger, three-dimensional structures.

CONCLUSION

Tissue-engineering efforts are currently being undertaken for almost every major type of tissue and organ within the body. Most of the effort expended to engineer these organs has occurred within the last decade. Tissue-engineering techniques require a cell culture facility designed for human application. Personnel who have mastered the techniques of cell harvest, culture,

and expansion as well as polymer design are essential for the successful application of this technology. Before these engineering techniques can be applied to humans, however, further studies need to be performed in many tissues.

In addition to the challenges mentioned above, there are numerous other hurdles that face the tissue engineers of tomorrow. For example, physiologically accurate bioreactors must be developed and refined if complex organs are to be grown and functionalized prior to implantation in humans. Also, a refinement in the approaches to tissue engineering must be achieved, as scientists explore whether pre-engineered, functional bioengineered replacement organs must be produced to repair tissue function, or whether the goal of tissue engineering should be to use simple biomaterials, cells, or growth factors to induce the repair or regrowth of these damaged organs.

INTRODUCTION

The US Food and Drug Administration (FDA) is responsible for regulatory oversight for a wide range of products, including food, medical products, products for veterinary use, and most recently, tobacco products. The FDA is comprised of seven centers, three of which, the Center for Drug Evaluation and Research (CDER), the Center for Devices and Radiological Health (CDRH), and the Center for Biologics Evaluation and Research (CBER), are charged with oversight of medical products. The Office of Cellular, Tissue, and Gene Therapies (OCTGT) in CBER, regulates a wide range of products, including: gene therapies, cell-based products, tumor vaccines, human tissues for transplantation, xenotransplantation products, certain combination products, and certain medical devices. This chapter discusses issues relevant to the development of products regulated by OCTGT, specifically, cell-based products or therapies.

Most of the products under OCTGT purview are regulated as biologics, which primarily include cellular and gene therapy products. Therefore, this chapter mainly discusses the Investigational New Drug/Biologics Licensing Application (IND/BLA) pathway. However, since biologics can be combined with or delivered by medical devices, some device-related issues will also be covered within these specific contexts.

REGULATORY BACKGROUND

In order to understand the regulatory process, it is helpful to have some background knowledge of the relationship between laws, regulations, and guidances. Laws, which are enacted by Congress and signed by the President, provide the legal mandate for FDA's

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00086-0

regulatory oversight. In many cases FDA publishes regulations ('rules') to implement a law's legislative mandates.[a] Rules can be modified by FDA over time to allow for changes in science or technology as long as the revised rule remains responsive to the legislative mandates. As an example, FDA recently published a revised rule regarding sterility testing for biological products [6]. This new rule provides manufacturers of biological products with greater flexibility and encourages use of the most appropriate and state of the art test methods.

Unlike laws and regulations, which are both legally enforceable by FDA, guidance documents represent the Agency's current thinking on specific topics and are not legally enforceable. Guidance documents are intended to provide general advice to interested stakeholders and product developers (sponsors) on how to comply with certain laws and regulations. FDA issues guidances that provide advice on topics ranging from overarching regulatory process to the Agency's scientific expectations for meeting requirements for specific product classes. For example, if FDA recognizes a need for developers of a specific product type, or for a specific clinical need, FDA may provide guidances that explain its thinking on the applications of the regulations to those specific areas.

Over the last decade FDA has published numerous guidance documents that are relevant to the development of cellular and cell-based products. These include guidance on cell manufacturing characterization for cell therapy products [1], and on potency [5], as well as guidance documents that address Agency cross-cutting issues, such as evidence of effectiveness [8]. Investigators may also wish to refer to other resources, such as OCTGT Learn, a web-based educational series that provides outreach to OCTGT stakeholders on a broad range of topics [29], or the CDRH Device Advice [32] webpage, which provides links to extensive regulatory information including CDRH Learn. References to these and other resources, including guidance documents and draft guidance documents,[b] can be found at the end of this chapter.

EARLY-STAGE DEVELOPMENT

In order to successfully develop a cell-based therapy for marketing approval, the development program must address certain key issues: a consistent, controlled manufacturing process incorporating characterization of the product's core attributes; preclinical testing incorporating proof-of-concept (POC) and toxicology studies that provide scientific rationale and support the proposed use of the product; clinical evidence of effectiveness; and clinical evidence of an acceptable safety profile weighed against the benefit of the therapy. Forward-looking consideration to each of these key areas at an early stage may improve the overall efficiency of product development.

Chemistry, manufacturing, and controls (CMC)

There are a number of key CMC issues to consider early in the development of a cell-based product. For example, if the cells to be delivered were not derived from the recipient (e.g., cells collected from an allogeneic donor), donor screening and testing will be necessary (21 CFR Part 1271) [17,18]. It is important to give early consideration to this issue, since incomplete or insufficient information often necessitates additional product safety testing.

[a] The Government Printing Office annually publishes all current regulations (rules) in the Code of Federal Regulations (CFR) (in print and electronically). The CFR is divided into 50 titles or subject areas, and Title 21 pertains to food and drugs. Specific parts of CFR are referred to throughout this chapter and the Appendix to this chapter provides a summary of the parts of the Title 21 that are most closely related to material in this chapter.
[b] Draft guidances are published for comment and are not for implementation until finalized. Stakeholders should contact the relevant product office or division for the most up-to-date Agency perspective on an issue discussed in draft guidance.

The strategy for manufacture of a cellular product from a characterized source of cells can, in some cases, mean establishment of a two-tiered cell bank, the Master Cell Bank (MCB), and the Working Cell Bank (WCB), which is derived from the MCB [4]. Early consideration of a cell banking program capable of supporting aspects of both preclinical and clinical development is important. In the event it is necessary to establish new cell banks during product development, plans should be in place to demonstrate their comparability to the previous cell banks used for product manufacture.

Comprehensive cell characterization is a cornerstone in the development of cell-based products. A multi-parametric analytical testing approach designed to assess distinguishing attributes of a cell-based product will help meet regulatory expectations for demonstration of product identity, purity, and potency. Characterization of the cellular product serves to inform development of an overall testing strategy and establishment of appropriate acceptance criteria to ensure product quality. Careful efforts devoted to characterization during the initial stages of premarket development may aid in detection of sub-populations of cells in the final product that could present safety concerns.

Early attention to details associated with the design of a robust manufacturing process is recommended. Consideration should be given to the feasibility of reproducibly generating cells with the desired attributes in sufficient numbers to support overall product development. This includes assessing the quality and accessibility of reagents critical to execution of the manufacturing process. It should be noted that unanticipated changes in critical reagents are likely to have an impact on product quality.

In certain instances, a cell-based product will be regulated as a combination product, as a cellular component is physically or chemically combined with a drug and/or device (21 CFR Part 3), often as a 'cell-scaffold' product. For such cases, sponsors need to design a testing strategy that adequately tests the final product and the individual components [14].

Pharmacology/Toxicology

Prior to initiation of a clinical trial, a sponsor will need to provide adequate data generated from pharmacological and toxicological studies to establish that it is reasonably safe to conduct the proposed clinical investigation. The results of these studies provide data critical to:

1) Establishing the scientific rationale and biological plausibility of the proposed approach (i.e., demonstration of POC);
2) Identifying and characterizing potential local and systemic toxicities, including the time frame for onset (i.e., acute vs. long-term), incidence, severity, and duration;
3) Determining a possible dose-response relationship for guiding dosing for the planned clinical trial;
4) Supporting subject eligibility criteria; and
5) Identifying physiologic parameters to help guide appropriate clinical monitoring.

Multiple *in vitro* and *in vivo* studies, spanning several iterative prototypes of the product and delivery device, may be necessary to translate a cell-based product from the bench to the initial clinical trial. During this process, the incorporation of forward-looking features into the design of early discovery phase animal studies may maximize the relevance and interpretability of collected data and facilitate translation to the clinic. For example, if safety endpoints are incorporated into discovery phase studies, it may be possible to identify potential safety concerns early in product development, which can then be managed (such as through changes to product design or manufacturing) and investigated further in future preclinical studies. Similarly, archiving relevant biospecimens during preclinical development allows for the opportunity for subsequent analysis if unanticipated adverse events arise in later studies,

which may help identify the cause of an observed toxicity. In turn, this may inform the design of appropriate follow-on investigations.

For cell-based products, early investigations in discovery phase studies into cellular distribution and the rate of resorption/degradation of the construct will be beneficial. As the product degrades or the injured tissue undergoes remodeling, structural properties, donor and host cell activity (such as migratory activity, proliferation, phenotype), and the rate of tissue in-growth will likely change. An understanding of these *in vivo* parameters and their impact early in product development will help identify appropriate endpoints, outcomes measurements, and study durations for later-stage definitive preclinical studies. For example, if the product is designed to provide mechanical support or structure, an assessment of biomechanical properties and function at multiple time points during degradation or remodeling may be particularly important. In some instances it may not be possible to conduct complete functionality testing of a product prior to implantation, as it may undergo remodeling *in vivo* with accompanying changes in biomechanical performance. This product characteristic would then be an important consideration when designing the POC and safety studies.

Some additional early considerations for preclinical development may include choosing a biologically-relevant animal model, random assignment of animals to groups, the use of appropriate control groups (such as implantation of the scaffold alone), assessment of effects of any changes to product manufacturing on *in vivo* activity, and characterization of both the final product and the individual components.

Clinical

Development of novel cell-based therapies is an iterative process. Therefore, even well-considered investigational plans are likely to need revision as additional data are acquired. However, early thought to the tentative design of the clinical studies can provide a framework for the overall development program, including preclinical studies. Preclinical studies usually mimic the clinical situation as closely as possible; therefore, integrating the preclinical and clinical programs may help improve efficiency. For example, if a preclinical animal study uses a specific delivery procedure, and then it is decided that the Phase 1 trial will use a different delivery procedure, additional preclinical studies may be necessary to support the safety of the new clinical procedure.

Phase 1 trials generally have a primary objective of assessing safety. However, co-primary or secondary objectives usually include bioactivity assessments. Such preliminary activity data can help guide the subsequent development program.

When selecting the study population for a Phase 1 trial, sponsors should consider the target indication, interpretability issues, and the risk of the study procedure. A product which can potentially cause long-term adverse effects is usually felt to have an unacceptable risk when administered to normal healthy volunteers. Therefore, Phase 1 biologics trials usually enroll a study population of subjects who have a specific disorder.

In the absence of preliminary evidence of safety for a single dose and data regarding the time course for bioactivity of the biologic, repeat dosing may represent an unreasonable risk. Therefore, a single dose regimen is appropriate for most first-in-man trials. Additionally, prior to the collection of preliminary safety data for the product, a first-in-man study should avoid concurrent administration of the product to multiple subjects. Staggered administration to sequential subjects provides an inter-subject interval to monitor for acute and sub-acute adverse events (AEs). This approach may prevent multiple subjects from experiencing an AE related to the product.

The safety monitoring plan should include assessments that can capture early, intermediate, and delayed AEs that may be expected, based on pre-clinical and clinical data, as well as on theoretical concerns.

Stopping rules are criteria, usually based on a number or frequency of specific AEs, that if triggered would temporarily halt the study, pending a safety review. Stopping rules should be considered for all studies, and may be required for higher risk studies.

Selection of the number of subjects that will be enrolled into a Phase 1 trial should consider the power of the sample size to rule out AEs that occur at a clinically meaningful rate. In general, the number of subjects in Phase 1 trials reviewed by OCTGT is less than twenty. Enrolling a relatively small number of subjects avoids exposing a large number of subjects to risk, while allowing for collection of preliminary evidence of safety.

FDA/SPONSOR MEETINGS

OCTGT holds informal and formal meetings with sponsors prior to and during product development. Informal meetings generally occur via phone, while formal meetings are conducted via phone or face-to-face. There are several different types of formal meetings that can occur between OCTGT and sponsors. These meetings often represent critical points in the regulatory process, and each is subject to different procedures.

Pre-submission meetings provide sponsors the opportunity to obtain non-binding feedback from FDA on specific questions prior to submission of an investigational (IND) or marketing (BLA) application. Such meetings may help sponsors to avoid missteps or delays that may be costly in terms of time and financial resources.

A meeting package that includes targeted, thoughtful, and clearly articulated questions, as well as a detailed summary of information, facilitates a productive meeting. Information about what should be included in meeting packages, meeting timelines, and meeting procedures can be found in FDA guidances [16,20,22], the OCTGT Learn webinar series, or by contacting the Branch Chief or Team Lead of the Regulatory Management Staff in OCTGT.

SUBMITTING AN IND

An IND is required (21 CFR 312) prior to clinical testing of a cell-based product that has not been approved by the FDA. A complete IND package consists of all required forms and sections, as specified in 21 CFR 312.23(a) and itemized in the checklist on page 2 of Form FDA 1571. A more detailed description of the key information that should be submitted with the original IND application is provided below.

Required FDA forms

Forms 1571, 1572, and 3674 should be included in an IND submission. These forms can be found on the FDA website, along with more detailed instructions for completing the forms [25,27].

Form 1571 is a formal contract indicating that a sponsor will adhere to the principles of informed consent, obtain Institutional review boards (IRB) review of the IND, and comply with the IND regulations. Form 1571 also contains basic administrative information regarding the sponsor, investigational drug and proposed clinical trial (e.g., indications(s), phase of investigation, data monitoring), and includes a checklist of submission components. A signed Form 1571 is required for all original IND submissions.

Form 1572, the Statement of Investigator, is an agreement that an investigator will provide certain information to the sponsor and will comply with FDA regulations. This form serves the dual purpose of enabling the sponsor to establish and document the qualification of the investigator and clinical site, and informing the investigator of his/her obligations. Although it is the IND sponsor's responsibility to obtain a signed Form 1572 from each investigator (21CFR 312.53(c)), the FDA does not require that Form 1572 be submitted to the Agency.

However, since Form 1572 collects all the information that must be submitted to the FDA as per 312.23(a)(6)(iii)(b) [31], many sponsors choose to submit Form 1572 along with the curriculum vitae (CV) of the investigator(s) [26].

Form 3674, 'Certification of Compliance with Requirements of ClinicalTrials.gov Data Bank', ensures compliance with the requirement for registering and reporting results from clinical trials of human drugs (including biological products) and devices to the clinical trials data-bank [21].

IND contents

In addition to the forms described above, all IND submissions must include a table of contents, an introductory statement, and a general investigational plan. An Investigator's Brochure (IB) is required unless the IND is submitted by a sponsor-investigator (21 CFR 312.23). A well-organized IND includes distinct, stand-alone sections for the clinical protocol, product/CMC information, preclinical pharmacology/toxicology information, and other sections described below.

CLINICAL PROTOCOL

An IND submission should contain a clinical protocol for each planned study. The complexity of the protocols will vary with the phase and size of the planned clinical investigation, however, some key elements include: the study objectives, selection of the study population, dosing, safety monitoring plan, and sample size.

CMC SECTION

The CMC portion of the IND contains information about manufacturing, including details about the starting material and reagents used in the manufacturing process [1,2]. For processes that use materials and reagents of human or animal origin, it is important to provide documentation of compliance with 9 CFR 113.53. The CMC section should describe the safety and quality testing that will be performed on the final product prior to release for administration to subjects. If the manufacturing process is complex and involves multiple steps executed over an extended period of time (e.g., days to weeks), the CMC section should include details of the in-processing testing performed at key stages of the manufacturing process. This section should also include data regarding product stability and shelf-life and other controls, such as information regarding the containers, labels and tracking information.

For cellular-device combination products, where the device components may be scaffolds/matrices or delivery devices, the IND should contain detailed source, manufacturing, and testing information for those components. This information should include device composition, physicochemical/mechanical testing, and specifications. Information regarding sterilization and stability/shelf-life are also important. If degradable biomaterials are used as scaffolds or for encapsulation, detailed information regarding the profile/kinetics (e.g., molecular weight, diffusion/mechanical properties, degradation by-products) should be provided. In general, the type of information that should be provided in the IND for the device component is generally similar to what should be provided in an Investigational Device Exemption (IDE) application (21 CFR Part 812). Therefore, relevant CDRH guidances may provide helpful information about what to include in an IND for a combination product [33].

PHARMACOLOGY AND TOXICOLOGY DATA

The FDA determines whether the pharmacology/toxicology data submitted with the IND provide sufficient evidence that the investigational product is reasonably safe for initial testing

in humans (21 CFR 312.23 (a)(8)). For each preclinical study intended to support the safety and rationale of a proposed clinical trial, a complete study report should be provided which includes:

1) a prospectively designed protocol,
2) A detailed description of the study performed (i.e., description of animal model, control and test articles used, dose levels, detailed procedures for test article administration and collection of all study parameters),
3) Results for all parameters evaluated (i.e., individual animal data as well as summarized and tabulated results),
4) An analysis and interpretation of the resulting data, and
5) A statement of compliance with Good Laboratory Practice (GLP) regulations (21 CFR Part 58).

PREVIOUS HUMAN EXPERIENCE

The IND should include detailed summaries of any available safety and efficacy data from previous clinical experience with the study agent or related products. The FDA will consider this safety and efficacy data, along with the comparability of the study products, the study populations, and the delivery procedures, when reviewing the IND.

ADDITIONAL INFORMATION

All other pertinent information can be submitted in this section. This could include copies of relevant publications, plans for assessing safety and effectiveness in a pediatric population, certificates of analysis obtained from manufacturers/suppliers of non-clinical grade reagents, and copies of meeting minutes from pre-IND interactions. Also in cases in which information for the product has been wholly or partially submitted to the FDA in previous pre-market submission(s) and/or master file(s), cross-reference authorization may be provided in this section of the IND. A letter of cross-reference grants FDA permission to review specific information contained in these files to support other premarket or marketing applications. The letter of cross-reference authorization is provided by the sponsor/holder of the referenced IND(s) and/or master file(s).

FDA review of an original IND application

When a sponsor submits an original IND, the FDA reviews the submission within the next 30 calendar days. Unless the FDA imposes a clinical hold, the clinical studies described in the original IND submission may be initiated at the conclusion of the 30 day review period. A clinical hold is an order by the FDA to delay a proposed clinical investigation or to suspend an ongoing study. When FDA review of an IND results in a clinical hold, within 30 days of being notified that the IND is on hold, the sponsor receives a clinical hold letter. The clinical hold letter summarizes the deficiencies that caused the clinical hold.

The IND regulations outline the general reasons for which an IND can be placed on clinical hold (21 CFR 312.42). A retrospective analysis performed by FDA staff evaluated clinical hold letters issued over a three year period. This analysis identified some common reasons for clinical hold of INDs regulated by OCTGT including CMC deficiencies (donor screening and testing, MCB qualification), insufficient information to assess the risks to the subjects, and issues with the proposed study population or procedures (e.g., an unacceptable risk of performing the investigational procedures in the proposed study population) [38].

LATER-PHASE DEVELOPMENT TOPICS

Compliance with current good manufacturing practice

Similar to other aspects of product development, the Current Good Manufacturing Practice (CGMP) requirements become more tightly controlled over the course of the product lifecycle. For Phase 1 studies, investigational cell-based products are excluded from complying with CGMP regulations (21 CFR Parts 210 and 211). However, the statutory GMP requirement in the Federal Food, Drug and Cosmetic Act (section 501(a)(2)(B)) is applicable for manufacture of clinical product during all phases of clinical study, including Phase 1, to ensure consistent product performance. In addition, CGMPs appropriate for Phase 1 investigational products should be in place for production of clinical lots to ensure product safety. These include sterility assurance, quality oversight, and facilities control. Adequate documentation and records management should also be in place for all phases of clinical study. FDA has issued a guidance document regarding CGMP requirements for Phase 1 studies [3]. Complete CGMP regulations should be followed for Phase 2 and 3 clinical studies of cell-based products.

Because CGMP applies to both the manufacturing process and the facilities, it is important to note that many elements of product manufacturing and characterization and CGMP compliance cannot be separated and should develop concurrently. Examples of CGMP activities that may develop over time as clinical development progresses include process improvements and process validation, as well as analytical methods development and validation. Process controls and acceptance criteria should be further refined prior to Phase 3 based on knowledge of the manufacturing process and critical product attributes related to safety and efficacy. Sponsors can request a meeting with CBER's Office of Compliance and Biologics Quality (OCBQ), specifically with the Division of Manufacturing and Product Quality (DMPQ), to obtain specific advice on facility design, manufacturing controls, and process validation.

Product readiness for Phase 3

To initiate Phase 3 clinical studies that are intended to demonstrate clinical efficacy, it is necessary to have in place a consistent, reproducible, and adequately controlled manufacturing process. Standard operating procedures that direct each stage of manufacturing should be finalized prior to Phase 3. Critical analytical assays for process intermediate and final product evaluation should have already been identified, developed and implemented. Acceptance criteria for these assays should be identified and appropriately narrowed to reflect the range of test result values accumulated through previous manufacturing experience. Any manufacturing changes introduced at this point in product development will usually be conservative in their character. One such example would be modification of procedures to boost production capacity or a change in suppliers of a key reagent. Final formulation, storage, handling and shipping conditions should also be established prior to Phase 3.

Potency assay

By Phase 3, an assay or compilation of assays developed to measure product potency should be identified and incorporated into the panel of product tests (21 CFR 600.3(s)). The potency assay provides information on the consistency of the manufacturing process, attests to the comparability of products manufactured from different starting materials, is useful in assessing the impact of changes made to the manufacturing process on final product attributes, and provides evidence of product stability under storage and shipping conditions.

The appropriate assessment of potency for each product will be determined based on attributes specific to the product. These include molecular, biochemical, immunologic, phenotypic, physical and biological properties. Accordingly, the FDA assesses the adequacy of a specific potency assay on a case-by-case basis.

Cell-based products are characterized by dynamic biological properties that present significant challenges to the development of a reliable, quantitative potency assay. As such, development of a potency test for these products is frequently done in a step-wise, incremental approach that allows for its modification as new information about the product characteristics, including mechanism of action, are discovered during the process of clinical development. However, even though establishing a potency assay may not be a reason for clinical hold prior to Phase 3 clinical testing, it is important to emphasize the role of the potency assay. In conjunction with other lot release tests, the potency assay is intended to demonstrate that only those manufactured product lots which meet pre-defined specifications or acceptance criteria are administered throughout the entire lifecycle of product development [5].

In many cases, a single biological or analytical assay may not provide an adequate measure of potency and it may be more appropriate to use a panel of complementary assays (i.e., potency assay matrix) that assess different product attributes associated with quality, consistency and stability to demonstrate product potency. The potency assay matrix could include testing for relevant non-biological attributes such as mechanical properties that are important for product function.

Pharmacology and toxicology

Preclinical studies supportive of the initial safety of a proposed clinical program will have been completed prior to initiation of a Phase 3 trial. However, additional animal studies may be necessary in certain circumstances. For example, depending on the product type, target population, and any concerns that arose during earlier phases of testing, reproductive/developmental toxicity studies may be needed to support licensure. These studies can usually be conducted concurrently with Phase 3 trials [7]. In other instances, additional preclinical studies may be necessary prior to initiation of later-phase trials, such as following any significant changes to the dose level(s), dosing regimen, or target population. Similarly, if there is a modification to the manufacturing of the product, the comparability of the later-phase product to the product evaluated in earlier-phase clinical trials may be unclear. In this case, bridging preclinical studies may be necessary to establish comparability.

After clinical development has begun, additional preclinical studies are sometimes warranted to provide insight into the *in vivo* pharmacology and mechanism of action of the product. For example, preclinical data may aid in the identification of an appropriate potency assay for Phase 3.

Phase 3 clinical development

By the time the Phase 3 clinical studies are planned, it is important for sponsors to understand some of the key issues that inform the design of Phase 3 trials. Early-phase trials offer an opportunity to optimize study procedures in terms of product delivery, dosing, and concomitant treatments. Early-phase clinical trials can also provide an understanding of the appropriate study population, the treatment effect size for the Phase 3 primary endpoint, the time frame for product bioactivity, and the durability of response.

When submitting a Phase 3 protocol, the FDA recommends that sponsors consider submitting a request for a Special Protocol Assessment (SPA) [9]. Concurrence on a protocol under the SPA program is an agreement between the FDA and a sponsor on the design and size of a Phase 3 trial that is intended to provide evidence of effectiveness.

MEDICAL DEVICES

An IDE application is required for a clinical investigation of an investigational product that meets the legal definition of a medical device, or of a combination device which has a primary mode of action that is consistent with that of a medical device, (i.e., the structure or function of man is affected, but not through a chemical action or metabolism within or on the body) [30]. Information about the required contents of an IDE can be found in 21 CFR 812.20. CDRH is one of the three FDA Centers that regulate medical products for human use. Specifically, CDRH determines the appropriateness of initiating commercial distribution of many diagnostic and therapeutic medical devices as well as combination products.

A risk-based approach determines the level of information for premarket review of medical devices. A Premarket Notification (510(k)) application seeks to demonstrate that a Class II medical device is substantially equivalent to another device already being marketed within the US by presenting data on device design, preclinical testing and possibly clinical studies (21 CFR Part 807) [35]. When insufficient experience exists to predict the clinical performance of a specific product based on comparisons with similar devices, sponsors submit a Premarket Approval (PMA) application that describes device composition and manufacture as well as the results of preclinical and clinical studies (21 CFR Part 814) [34]. Many of the cellular and cell-based products reviewed by CDRH are combination products regulated as Class III devices under the Medical Device Authorities. A limited number of these products have also entered commercial distribution after approval of Humanitarian Device Exemption (HDE) applications, because these Class III medical devices were designed to treat limited patient populations (i.e., less than 4,000 cases per year) (21 CFR Part 814 Subpart H).

CBER and CDRH often collaborate in the premarket review of combination products that contain both device and biological components. Regarding the device component (e.g., a scaffold), insight into issues of product manufacture, biocompatibility, physicochemical and mechanical testing may be obtained by review of FDA guidance documents and the published summaries of 510(k) and PMA applications. CDRH has published guidance documents that address such issues as approaches for evaluating the biological responses to biomaterials [13] and material sourcing issues, physiochemical analyses and preclinical tests that may be appropriate for scaffolding materials [15]. Although the latter document focuses on a particular type of product, both are informative as to the types of issues that may need to be addressed. Review of relevant CDRH-recognized standards may also be helpful [36]. A common misconception when developing tissue-engineering products is the importance of using 'FDA approved biomaterials'. This misunderstanding may arise, because CDRH uses both sponsor-derived test data and published scientific literature, (when sufficient physicochemical data exist to demonstrate the similarity of previous and proposed biomaterials), to determine the safety of a product. Thus, one should understand that FDA does not 'approve biomaterials', because the clinical behavior of a product can be profoundly affected by other components in the final product. When weighing the value of previously published data (and/or the need for additional studies), one should consider the intended use, route of administration, and composition of the previous product.

OTHER REGULATORY TOPICS

Clinical research involving children

FDA regulations in 21 CFR Part 50 Subpart D outline special protections for children, which are in addition to the safeguards for all clinical trial subjects that are contained in 21 CFR 312. In general, initial studies of cell-based products should be conducted in an adult population prior to investigations in a pediatric population. However, in some situations, first-in-human studies may be ethical in a pediatric population.

The regulations require IRBs to review clinical investigations involving children and to make an independent determination regarding the degree of risk to the subject. For pediatric studies that involve more than minimal risk, which is most likely to be the case for first-in-man pediatric trials of cell-based products, the considerations for IRB approval are outlined in 21 CFR 50.52 [10].

Expanded access to investigational drugs for treatment use

FDA's expanded access regulations (21 CFR 312 Subpart I) allow access to investigational drugs for the primary purpose of diagnosing, monitoring, or treating a patient's disease or condition, rather than for generating scientific data intended to characterize the drug [24]. The intent of these regulations is to facilitate availability of these products to patients with serious diseases or conditions when no comparable or satisfactory alternative therapy exists. The regulations describe the criteria that must be met to authorize expanded access.

Charging for investigational drugs under an IND

The IND regulations allow sponsors to charge for the administration of investigational products in clinical trials, and to charge for investigational products made available under FDA's expanded access regulations (21 CFR 312.8) [24]. These regulations specify general criteria for authorizing charging, specific criteria for charging for an investigational drug in a clinical trial, and specific criteria for charging under the expanded access provisions, and clarify what costs can be recovered.

Responsibilities of sponsors and investigators

Sponsors and investigators are responsible for specific activities to ensure that the rights, safety, and welfare of subjects are protected, to ensure the quality of the clinical trial, and to meet regulatory requirements (21 CFR 312 Subpart D). The FDA regulations (21 CFR 312.3) divide clinical trial responsibilities among these two parties: sponsors are responsible for communicating with FDA through the IND and managing the clinical trials; clinical investigators conduct the studies and administer the investigational product to subjects.

SPONSOR RESPONSIBILITIES

Sponsors have several responsibilities for managing the clinical trials under an IND. Sponsors must select investigators who are qualified by training and experience to administer the investigational product to study subjects and conduct safety and efficacy monitoring. Each study site should have an investigator who signs Form FDA 1572, listing the name, address, and the locations where the study will be conducted, all sub-investigators, and the IRB responsible for review of the study (21 CFR Part 56). The investigator is not required to be a physician, but it is reasonable to assume that a physician will be part of the study team. The FDA expects that the sponsor will evaluate potential clinical sites to determine that the facilities and resources are adequate to conduct the study [23].

Sponsors must provide investigators with the protocol, the IB, and any other instructions necessary to conduct the study. As the study progresses, the sponsor must communicate any protocol revisions and new information about the safety of the investigational product to the investigators. Sponsors must also monitor the progress of all investigations conducted under the IND to ensure they are conducted in accordance with the general investigational plan and protocol [11]. If an investigator is not complying with the protocol, the sponsor must either obtain an assurance of compliance from the investigator or discontinue shipments of the product to the investigator.

IND safety reporting is another sponsor responsibility (21 CFR Part 312.32). Sponsors must promptly ($\leq$15 calendar days) notify FDA and all investigators receiving investigational product in an IND safety report of potential serious risks. Sponsors must also promptly

(≤7 calendar days) notify FDA of any unexpected fatal or life-threatening suspected adverse reaction. The investigator shall also notify the IRB (21 CFR 312.66) of all unanticipated problems involving risk to human subjects or others.

Sponsors must maintain adequate records of financial interest and records of the receipt, shipment, use, or other disposition of investigational product. All records related to the IND must be retained for two years after a marketing application is approved, or for two years after shipment and delivery of the investigational product was discontinued and FDA was notified. Sponsors must permit access for FDA to inspect the study records. A sponsor may transfer any or all of the sponsor's IND obligations to contractors, who then assume the obligations of the sponsor for the designated activities.

CLINICAL INVESTIGATOR RESPONSIBILITIES

Clinical investigators are responsible for protecting the rights, safety, and welfare of the subjects under the investigator's care. Investigators are required to conduct the study in accordance with the protocol, for example ensuring that subjects meet the eligibility criteria and that all follow-up assessments are performed as scheduled. They must personally supervise the administration of the investigational product and the conduct of the study. The investigator may delegate certain duties to the sub-investigators that are under his/her supervision, but he/she cannot transfer his/her regulatory obligations to others. Investigators must obtain a review of the study by the IRB that oversees their clinical site and must obtain the informed consent of study subjects prior to enrolling them into a study.

Investigators must limit the use of the investigational product to only the subjects enrolled in the study, and must maintain records of the storage and use of the product. Investigators must report AEs and progress reports to the IRB and to the sponsor so both are aware of new information about the safety of the investigational product. Investigators must also submit financial disclosure forms to the sponsor and update them when required. Investigators must prepare and maintain adequate and accurate case histories for each subject, and must retain all study records for two years after a marketing application is approved, or for two years after the investigation is discontinued and FDA is notified. Investigators should plan for how they will maintain these records for several years, especially if they are participating in early-phase studies. When the study at a clinical site has been completed, the investigator must submit a final report to the sponsor and must allow access for FDA to inspect the study records.

SPONSOR-INVESTIGATOR RESPONSIBILITIES

A sponsor-investigator is an individual who is the IND sponsor and is the only clinical investigator for a clinical study of the product he/she is developing. Sponsor-investigators are required to fulfill all of the responsibilities of sponsors and all the responsibilities of investigators, with the exception of the requirement for an IB. Sponsor-investigators must consider how to monitor the clinical trial he/she is personally conducting. Some options include review of the study by someone unaffiliated with the research, such as a colleague in another department, from an institution's research office, or by a contract research organization.

Clinical research conducted outside of the United States

A sponsor who is conducting a foreign clinical study may choose, but is not required, to conduct the foreign clinical study under an IND. When a foreign clinical study is conducted under an IND, all FDA IND requirements must be met unless a waiver is obtained. FDA may accept a well-designed, well-conducted, non-IND foreign study as support for an IND or application for marketing approval if the study was conducted in accordance with good clinical practice (GCP) and if FDA is able to validate the data from the study through an onsite inspection, if necessary (21 CFR 312.120). Regarding the ability of data from a non-IND

foreign study to support a marketing application, one consideration is the applicability of the data to the US population [12].

Use of standards

For FDA, standards describe how manufacturers might meet regulatory requirements defined in FDA regulations. Standards used for regulatory purposes may be 'physical standards' or 'reference materials' that are highly characterized reagents distributed nationally and internationally to assure consistent quality and safety of a product. Standards may also be in the form of documents that describe standard nomenclature, test methods, recommended practices and guides, specifications, and performance standards. For tissue-engineered medical products (TEMPs), the use of standards may help to facilitate product design and testing and lead to improved time to market. Standards Development Organizations (SDOs) that are actively engaged in developing standards for TEMPs products are ASTM International (formerly known as American Society for Testing and Materials) and International Organization for Standardization (ISO). FDA staff actively engages in standards development activities with SDOs by participating in workshops and meetings, and by commenting on standards documents [19,28].

FDA international regulatory activities

FDA has a history of productive working relationships with international regulatory authorities around the globe. Such interactions help facilitate FDA's goals to safeguard global public health and facilitate the availability of safe and effective products. FDA's global efforts for products regulated by OCTGT have focused on activities that foster the independent development of national guidelines and regulations that reflect a shared regulatory perspective internationally. International activities for regenerative medicine and cell-based products range from formal arrangements with international regulatory authorities, such as the Advanced Therapy Medicinal Product Cluster and Parallel Scientific Advice with the European Medicines Agency, to ad hoc product-specific discussion with international regulatory partners. FDA also participates in regulatory convergence activities with international groups such as the Regulators Forum Cell Therapy Convergence Group (of the International Conference on Harmonization) and the Asia-Pacific Economic Cooperation (APEC) Life Sciences Innovation Forum [37].

The role of cell-based products in medical product testing

A major priority of the FDA's strategic plan for advancing regulatory science includes efforts to modernize toxicology to enhance product safety. This emphasis recognizes the need to improve the predictive value of preclinical studies for all medical products, and the potential role for cell and tissue-based assays (a subset of bioengineered tissue products) in achieving this goal [31]. Implicit in this goal is the need to improve manufacturing processes, to increase the understanding of the biology, and clinical applicability of cell and tissue-based assays. These knowledge gaps are similar to those that exist for bioengineered tissue products that are being developed for therapeutic indications. Although the markets and regulatory considerations for *in vitro* assays to be used in development of traditional pharmaceutical products, and investigational bioengineered tissue products are distinct in many ways, the scientific challenges facing the widespread development of both are similar, and therefore the potential is that both may benefit from increased cross-talk between these specialized areas.

CONCLUSION

Federal regulations address many aspects of drug development, including CMC, preclinical development, and clinical trials. Efficient drug development depends on an understanding of these regulations and the regulatory process. OCTGT collaborates with sponsors to address the challenges that arise during the development of cellular and cell-based products.

CHAPTER 87

Business Issues

Matthew Vincent
Advanced Cell Technology, Inc., Marlborough, Massachusetts

INTRODUCTION

Imagine a world of medicine where replacement or repair of body parts could be accomplished using tissues grown in a laboratory. Or better yet, the body could be induced to repair and regenerate itself — to harness the body's natural healing processes, and activate these processes when and where they are critically needed. A recent headline announced that 'The First Person to Live to 150 has Already Been Born'; a headline which could all too easily be dismissed as being overly boastful. The question to ask ourselves, however, is should we be so quick to write off such a possibility? Whether or not the first sesquicentenarian is already among us aside, the progress in preclinical and clinical regenerative medicine programs, particularly stem cells, has picked up considerable pace and is being continually primed by a growing pipeline of promising research and therapeutic programs aimed at repair and regeneration. In the last 120 years, as a consequence of lifestyle and non-regenerative advances in medicine, we have seen an increase in average life expectancy from 43 years to 85 years. As we achieve the ability to extend or replace tissues and organs — to begin to realize the aspirational goals of tissue engineering, and regenerative medicine in general — would doubling life expectancy over the next 150 year period in fact be a possibility? And if so, what are the societal and commercial implications?

The past thirty or so years have seen the emergence of an area of medicine called tissue engineering and regenerative medicine. This discipline is a truly multidisciplinary field, involving scientists, engineers, and physicians working to construct biological substitutes which can replace (or help regenerate) diseased and injured tissues. It promises to revolutionize the ways we approach health and quality of life for tens of millions of people worldwide. The field has already produced notable examples of actual therapies, including skin replacement and cartilage repair. The pump is primed, but companies, payers and policy makers will need to assess long-range cost benefit trade-offs for engineered tissues and cell therapies when compared to traditional therapies. Understanding the interplay giving rise to opposing pressures — one from an expanding elderly population to improve health in old age, and the other a growing concern for containing healthcare costs — will be critical to tissue and cell therapy companies as they plan for and address concerns about how to patients can afford innovation in this important area of treatment.

THE AGING POPULATION

To consider the implications that further enhancing longevity through tissue engineering may have on society and medicine, one needs to start by understanding current trends and projected impacts. The age structure of the overall population is projected to change greatly

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00087-2

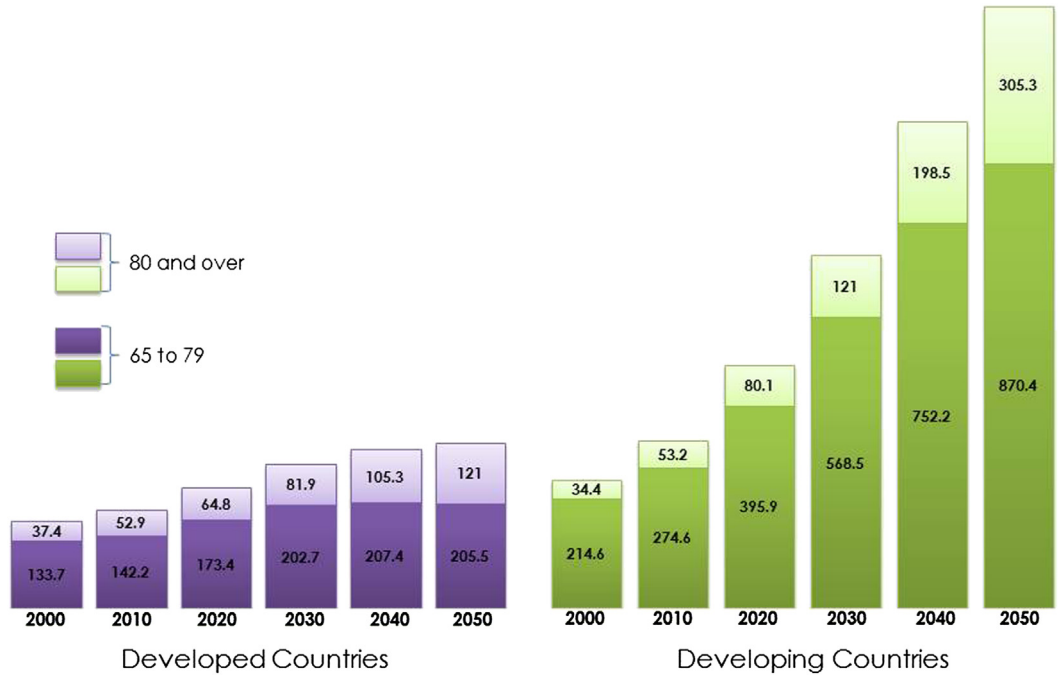

FIGURE 87.1

over the next forty years. The world's population is aging, primarily as a function of declining fertility coupled with increasing life expectancy. Aging is occurring not only in high-income countries, but also in middle- and low-income countries. In fact, between now and 2050 the world is projected to experience rapid growth in its older population. Fig. 87.1 shows the projected growth of two groups of older people — those aged 65—79 and those 80 years and older. The rapid growth of the over-80 group is related to increases in life expectancy related to improving medical care and nutrition which have occurred during the century.

People live longer now than at any time in the past; with advances in medicine promising to extend life expectancy even further. US life expectancy at birth rose from 47.3 years in 1900 to 76.9 years in 2000. Greater longevity, combined with relatively low fertility rates, has rapidly increased the proportion of the oldest old among the total older population. In 1900, only 4.0 percent of all older people were aged 85 and older; by 2000, that proportion had grown to 12.1 percent [1].

In 2050, the number of people over the age of 65 living in (now) developed countries is projected to exceed 325 million, with more than 1.5 billion persons in this over-65 category when including the developing countries in the equation — a nearly tripling of the number of over-65 people living in all these countries today. In the United States, as an example, the number of Americans aged 65 and older is projected to be 88.5 million, more than double the population of 40.2 million in 2010. The baby boomers are largely responsible for this increase in the older population, as they recently began crossing into this category in 2011. By 2050, the US population is projected to grow by 439 million, an increase of 42 percent relative to the 2010 census numbers of 310 million. The nation will also become more racially and ethnically diverse. The population is also expected to become much older, increasing from 15 percent today to nearly 20 percent of the US population being aged 65 and older by 2030, and continuing to increase to about 22 percent by 2050. Those over the age of 85 accounted for 5.8 million Americans in the 2010 census, and are expected to reach 8.7 million by 2030 and then 19 million by 2050. In terms of overall population, this 'oldest' old population will

increase to 4.3 percent of the population by 2050 — representing only 1.8 percent of the population in the 2010 census.

Much of the advances in longevity early in the 20th century arose from improvements in socioeconomic and living conditions and a decrease in infectious disease deaths. Gains during the latter part of that century came from periodic breakthroughs in public health and biomedical research that have led to new treatments for, and a later onset of, chronic diseases [2]. If improvements in treating and even preventing onset of chronic diseases can be sustained and further enhanced, then the age structure of the older population will be even more positively affected than the above projections suggest. This aging of the population will have wide-ranging implications. The projected growth of an older population will present challenges to policy makers and programs, such as Social Security and Medicare in the United States. The health status of the aging population is essential not only to those who comprise this age group, but also to the broader population because of the impacts on social and economic systems. As the older population grows not only in size, but more importantly in their proportion of the total population, the potential implications for families, businesses and healthcare providers will become increasingly significant.

Chronic diseases and impairments, which are among the leading causes of disability in older people, can negatively impact quality of life, lead to a decline in independent living, and impose an economic burden. About 80 percent of seniors have at least one chronic health condition and 50 percent have at least two [3]. Indeed, of the roughly 150,000 people who die each day, about two thirds die of age-related causes. In industrialized nations, the proportion is much higher, reaching 90% [4].

Concern is growing that medical advances leading to longevity will in turn lead to an older population who have a higher incidence of functional and cognitive impairment. With increases in life expectancy and a simultaneous rise in the number of people with chronic diseases and disability, researchers are focusing on facilitating both longer life and disability-free healthy life. Focusing on the quality as well as length of life, the World Health Organization (WHO) has introduced estimates of 'healthy life expectancy' (HALE), which is defined as the average number of years of life free from disability, physical performance limitations or impairments, other disabilities, or social handicaps [5]. Using various measurements and methods of analysis, including HALE, recent studies conclude that in addition to living longer, the current generation of older people is healthier and less disabled than the preceding ones [6–8]. But as Fig. 87.2 illustrates, as life expectancy increases so does the incidence rate of chronic and degenerative health conditions, threatening to create a wider gap between HALE and total life expectancy.

Currently, the vast majority of treatments for chronic and/or life-threatening diseases are palliative. Others delay disease progression and the onset of complications associated with the underlying illness. Only a very limited number of therapies available today are capable of curing or significantly changing the course of disease. The result is a healthcare system burdened by costly treatments for an aging, increasingly ailing population, with few solutions for containing rising costs. Fig. 87.3 demonstrates the predicted impact that our aging population is expected to have on the cost of healthcare in less than twenty years time. The demographics shift in aged populations towards older adults in the United States alone will likely add more than one trillion dollars to the direct cost of healthcare, and multiples of that amount for the indirect costs associated with accommodating the needs of older Americans. According to a June 2009 report from the Council of Economic Advisers (CEA) to the White House, healthcare expenditures in the United States are currently about 18 percent of GDP, and this share is projected to rise sharply. If healthcare costs continue to grow at historical rates, the share of GDP devoted to healthcare in the United States is projected to reach 34 percent by 2040. Viewing the distribution of the cost across all working Americans, Fig. 87.4 shows the potential impact on total compensation when the projected rising cost of healthcare is factored into predicted salaries.

RISE OF REGENERATIVE MEDICINE

The best way to address the escalating economics of healthcare includes developing more effective treatments, and even cures, for the most burdensome diseases – diabetes, neurodegenerative disorders, stroke, macular degeneration and cardiovascular disease, for

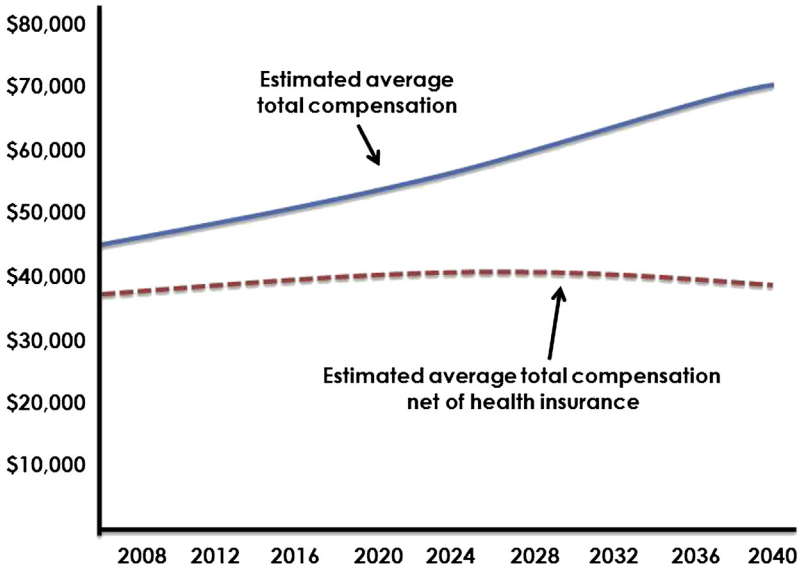

FIGURE 87.4
Projected annual compensation and compensation less health insurance premiums. *(Source: Office of the President, Council of Economic Advisors "The Economic Case for Healthcare Reform" June 2009).*

example — to facilitate longer, healthier, and more productive lives. Regenerative technologies, such as cell and tissue-based therapies, have the power to be a critical component in reducing the otherwise predicted increase in healthcare costs resulting from aging. A more effective, sustainable healthcare system is a potential as a consequence of the innovations occurring in regenerative medicine. However, it will require the concerted efforts of patients, government and private insurance companies, doctors, life science companies, private investors, and governments. Regenerative medicine promises to completely change the way we think about disease, aging, and even the practice of medicine itself — and, as the promise goes, to help bend down the ascending curve of projected healthcare costs.

Regenerative medicine, and particularly cell and tissue therapies, has already had some clinical impact. Hundreds of thousands of patients have already had bone marrow or hematopoietic stem cell transplants, with more than 50,000 new transplants being carried out each year [9]. A more recent category of approved products include tissue-engineered skin, with more than 250,000 patients having now received artificial skin grafts [10]. While the number of patients treated with cell therapies is still low by the standards of conventional drug- or biologics-based treatments, there is a robust pipeline of new therapies in clinical or preclinical testing.

However, the realization of the power of cell therapies, and with it the emergence of this growing area of medicine, is not only dependent on resolving the science but also on a number of business factors unique to cells as therapeutic agents. Regulatory oversight, clinical end-points, drug labeling, pricing and reimbursement, manufacturing, cold chain, and essential infrastructure are some of the many components from the business perspective which typically have unique and far reaching consequences in the path from the laboratory bench to patient treatment. Laminated onto these business issues can be layers of political, legal and ethical sensitivities which need to be considered. Regenerative medicine is uniquely capable of altering the fundamental mechanisms of disease; however, to realize its potential we must think differently about therapeutic development and commit to investing in these trans-formative technologies. A more effective, sustainable healthcare system is possible through regenerative medicine, but it will require the combined efforts of patients, payers, healthcare providers, biotech and pharmaceutical companies, private investors and governments working together.

The reality is that not every new company or technology in this space can or will succeed. Not every new invention relating to regenerative medicine is necessarily commercially tractable. The technology may be too complex or high touch to be used in an FDA-regulated commercial setting, or too costly, particularly where reimbursement by insurance entities or the government needs to be considered. Unfortunately, great science does not always translate into great business. The history of the life science industry is littered with many examples of brilliant research and breakthroughs unable to be translated into a viable commercial product. Understanding what are often the gating issues, and how to manage through those issues, including recognizing the 'go/no go' decision points, can greatly increase the likelihood of success. Realizing the promise of regenerative medicine from the perspective of the life science company will require understanding the regulatory policies in the major markets, appreciating the impact of final manufacturing, final formulation and the cold chain of the distribution, as well as developing strategic business and reimbursement plans. Added to this equation for success is the inevitable complexity of intellectual property issues.

PRODUCT DEVELOPMENT

Tissue engineering encompasses an array of technologies in biology, chemistry and physics into materials, devices, systems, and a variety of therapeutic approaches — including cell-based therapies — to augment, repair, replace or regenerate organs and tissues (see Fig. 87.5), with the end goal often being curative by targeting the root cause of disease. This rapidly evolving, interdisciplinary field in healthcare is transforming the practice of medicine, medical innovation and the production of medical devices and therapies.

Living cells are incorporated into regenerative medicines to achieve a variety of positive effects, such as: replacing damaged or diseased cells and/or tissue; stimulating healing and regeneration in diseased tissue; and delivering small molecule therapies to targeted areas. However, by their very nature, cell and tissue therapies face fundamentally different development and regulatory pathways to market when compared to traditional small molecule-based drugs or protein therapeutics. Alongside the complexity of the agent being administered to patients come added layers of safety and efficacy concerns. Cell therapies face the challenge of manufacturing a living product alongside associated difficulties in their storage and delivery. Depending on the solutions, companies may need to decide whether to focus on manufacturing a product or becoming a service-based entity, each of which requires a fundamentally different business strategy. As of 2012, the regenerative medicine industry to include more than 700 companies ranging from divisions of global pharmaceutical companies

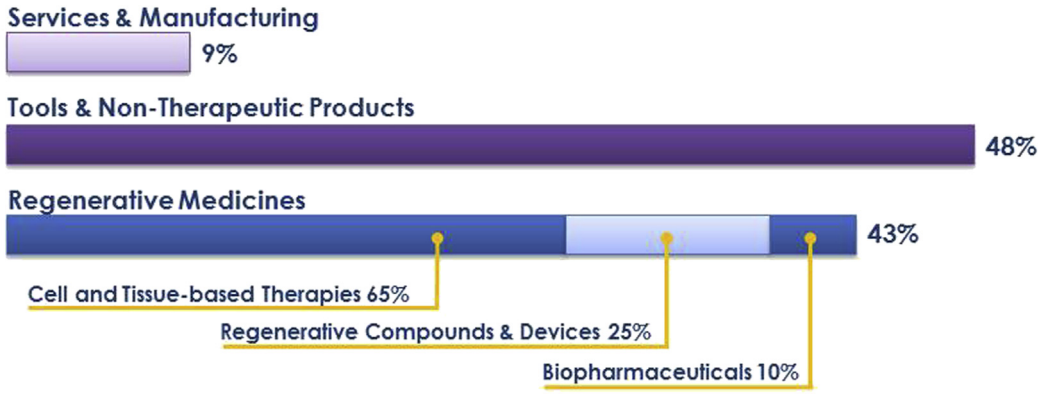

FIGURE 87.5
Regenerative medicine industry sectors. *(Source: Alliance for Regenerative Medicine 2012 Annual Industry Report).*

to smaller life science companies focused solely on regenerative medicine technologies [11]. The product pipeline of these groups includes hundreds of cell-based therapies, small molecules, biologics, tissue-engineered cells and materials and implantable devices. Other companies work toward providing research tools such as equipment, consumables, software, cells as drug discovery or toxicity testing tools as well as clinical tools, bioprocessing tools and platforms that include equipment, consumables, reagents and storage systems. The field also incorporates a variety of service companies specializing in clinical trial management, manufacturing, engineering and financing among others.

An important concern for emerging life science in the regenerative medicine field relates to developing a compelling business model. It is important to understand the consequences arising from, for example, the choice of technology by a company with how it relates to the practical realities of commercialization, particularly manufacturing, distribution and adoption by healthcare providers, not to mention coding and reimbursement. There are fundamental differences in the business models arising from the choice between an allogeneic cell or tissue product (a source which can be scaled-up and universally applied to patients), versus providing autologous cells or tissues requiring the manipulation of a patient's own tissues. The choice between the allogeneic and autologous therapy routes is proving to be a fundamental one for early adopting companies with significantly different production, infrastructure, logistics, skills, and storage requirements for each approach. Autologous cell therapies already represent a significant industry, though principally as a service-based model rather than something more akin to a pharmaceutical or biologics business model. One advantage of autologous transplants is that the body recognizes the cells as self and therefore does not reject the transplanted materials. For example, bone marrow transplants have been successfully used for many years to restore immune function after chemotherapy, and therapeutic trials using patients' own stem cells to restore other tissues are already underway. The allogeneic cell transplants have greater potential for scale-up and widespread distribution, thus potentially benefiting from greater economies of scale. This model is closer to the traditional pharmaceutical model, and shares many similarities to biomanufacturing processes that pharma have already invested in heavily over the last decade. However, allogeneic therapies face a greater risk of immunological rejection as the cells are typically not HLA matched to the intended recipient patient. For these reasons, the allogeneic business model is anticipated to develop more slowly, beginning first with cells and tissues that are transplanted in immune privileged sites in the body such as the CNS or sub-retinal space, or for which the cell is itself immune privileged, as is the case with mesenchymal stem cells.

In many respects, regenerative medicine companies are no harder to start up than other life science companies. Yet establishing a successful cell therapy company poses some unique challenges, in part because the field is only recently emerging and the regulatory oversight and reimbursement for patient therapy is still undefined in many ways. In the end, cell and tissue therapies are likely to be more expensive to develop than small molecule or protein therapeutics largely because the safety and proof-of-concept in relevant animals, if available at all, that the regulatory agencies want as part of the preclinical package. Yet those risks can be dwarfed by the concern that potential therapies will get entangled in regulatory red tape before they can even work their way through clinical trials.

Embryonic stem cells

One of the fundamental issues arising from the use of adult-sourced human stem cells for allogeneic therapies or *ex vivo* engineered tissues derives from the limited replicative capacity that adult stem cells have in culture. Very often, the adult cells will undergo only a handful of cell doublings before large percentages of the cells in culture senesce or differentiate into unwanted cell types. In contrast, a human embryonic stem cell (hESC) line represents a nearly inexhaustible supply of pluripotent cells. Derived from a single clonal embryonic stem cell, the

replicative capacity of an hESC line is enormous. However, for a long time there was a concern in the industry around whether or not the regulatory agencies would permit a differentiated cell made from an hESC line to even be tested in patients. The concern, at least as it manifests itself in the industry and among potential investors, arose from the ability of embryonic stem cells to form any tissue in the body – including tumors. The fundamental question was under what circumstances would the FDA or EMA (for instance) permit a differentiated cell product to be tested in human patients? How would they control for the risk that a cell therapy product might be contaminated with an undifferentiated cell, particularly an embryonic stem cell?

That question was finally answered in 2010 when two companies, Advanced Cell Technology and Geron each obtained FDA to conduct Phase I/II studies in human patients using cells derived from hESC lines. While Geron ultimately abandoned its cell therapy programs to focus on oncology product lines, Advanced Cell Technology moved forward in clinical trials both in the Unites States and the United Kingdom for treating various forms of macular degeneration using retinal pigment epithelial (RPE) cells derived from an hESC line. In the company's IND and IMPD filings with the US and U.K. regulatory agencies respectively, Advanced Cell Technology described a carefully controlled cell culture process which, when shifted from proliferation to differentiation was incapable of supporting growth of undifferentiated embryonic stem cells. Moreover, the company had developed a release assay for the final RPE cellular product that was several orders of magnitude more sensitive than PCR for detecting contamination with undifferentiated cells. Putting these two manufacturing steps together, along safety data from hundreds of animals injected with the human RPE cells, the company was able to establish an acceptable reduced risk profile to be permitted to test the RPE cells in human patients.

In July 2011, Advanced Cell Technology treated its first two patients with hESC-derived RPE cells. One patient suffered from Stargardt's disease, a juvenile onset form of macular degeneration, and the other patient suffered from dry Age-Related Macular Degeneration (dry AMD), the most prevalent form of AMD and the leading cause of blindness in people over the age of 65. In 2012, the company published its preliminary findings on these first two patients, reporting that there were no adverse events associated with the RPE cells, and demonstrating both anatomical and functional evidence that the injected cells engrafted, persisted and were apparently recapitulating the function of the missing native RPE cells [12].

Induced pluripotent stem cells

As described in greater detail in earlier chapters, terminally differentiated somatic cells can be reprogrammed to generate induced pluripotent stem (iPS) cells by the enforced expression of a few embryonic transcription factors. The resulting iPS cells are morphologically and phenotypically similar to embryonic stem (ES) cells and thus offer exciting possibilities in stem cell research and regenerative medicine. The first iPS cells were produced in 2006 from mouse cells and subsequently in 2007 from human cells [13,14]. The most widely used set of reprogramming factors, Oct4, Sox2, Klf4 and c-Myc, was identified initially by screening 24 pre-selected factors in mouse embryonic fibroblasts (MEFs) by Takahashi and Yamanaka. Forced expression of these factors initiates phenotypic and molecular changes in the targeted somatic cell, eventually leading to the reactivation of endogenous pluripotency genes and acquisition of pluripotency [15]. The ability to restore pluripotency to adult cells through the induction of a small number of reprogramming factors promises to create powerful new opportunities for modeling human diseases, and perhaps more excitingly, offers hope for patient-specific cell therapies.

However, the challenge now is to better define differences in the epigenetics and gene expression of the resulting cells and subsequently improve the reprogramming methods in order to make human iPS cells a truly tractable alternative to human ES cells. While at first

approximation ES cells and iPS cells appeared equivalent and suggested interchangeability, recent studies indicate that significant variations can exist that markedly affect the epigenetic and functional properties of the iPS cells. Through different mechanisms and kinetics, these two reprogramming methods reset genomic methylation, an epigenetic modification of DNA that influences gene expression, leading various groups to hypothesize that the resulting pluripotent stem cells might have different properties. Indeed, a number of reports have indicated that iPS cells often have some DNA methylation patterns which are characteristic of the somatic cell origin prior to induction of pluripotency. This 'epigenetic memory' can favor differentiation of the resulting iPS cell back along lineages related to the original parent cell, and often also results in restriction of alternative cell fates. Indeed, techniques such as high-resolution methylation analyses demonstrated that differences in methylation patterns could consistently distinguish between iPS and ES cells [16] and produced variety in the level of expression of gene programs. Even subtle changes in expressions levels for just a handful of genes have given rise to rejection of iPS cells in mouse transplantation models, indicating that some iPS cells are immunogenic and raising concerns about their therapeutic use [17].

In the coming years, the efficiency of generating iPS cells and the understanding of the mechanisms of cell programming and reprogramming is likely to improve. However, there are ongoing concerns over safety presenting a significant hurdle before we will see significant progress towards therapies. At this point, considering just the regulatory issues alone, the differences between iPS and ES cells becomes the emphasis in calculating the remaining steps necessary to sufficiently characterize the properties and differentiation capabilities of iPS cells as sources of potential commercial therapeutic products. Such studies will be crucial for determining the suitable iPS cell types for future stem cell-based therapies for human degenerative diseases.

Direct reprogramming of differentiated cells

In the last few years a number of studies have shown that a direct route can be taken to convert one differentiated cell to another, without going through an embryonic-like undifferentiated state. Direct reprogramming of differentiated cells has already been demonstrated, as explained earlier and the ability of certain genetic factors to dominantly specify cell fate has been known for some years. However, based on recent advances, this technology is likely to progress significantly over the next five years. Direct reprogramming has a number of major advantages including the potential to produce therapies based on small molecules and/or biologics for *in vivo* reprogramming. This method would also produce cell therapies without the need to use a pluripotent cell stage, thus greatly reducing the risk of rogue cells leading to uncontrolled cell growth or inappropriate differentiation into an unwanted cell type.

Small molecule-induced differentiation

Small molecules can also induce differentiation and have advantages in terms of the ability of the clinician to control dosage. For example small molecules have been used to generate iPS cells by acting as substitutes for genetic reprogramming factors. Such approaches offer the longer-term potential to activate dormant stem cells in the adult body, and proof-of-concept for this has been most recently demonstrated through the use of a small naturally occurring molecule, thymosin-β4, to stimulate cell mediated repair of a damaged mouse heart [18]. Other small groups also are making inroads with chemically induced pluripotency, for instance, showing that specific DNA-binding hairpin pyrrole-imidazole polyamides (PIPs) could be conjugated with chromatin modifying histone deacetylase inhibitors like SAHA to epigenetically activate certain pluripotent genes in mouse fibroblasts [19].

REIMBURSEMENT

At the end of the day, life science companies developing new drugs and treatments, including those in the regenerative medicine space, must justify their existence to the shareholders who invested and therefore funded the translation of a therapy from animal models to an authorized therapeutic product. That justification is largely based on the ability of the developing company to sell the product into the market place. Accordingly, before deciding to invest in developing a new regenerative medicine product, especially a cellular or tissue product, the company needs to carefully consider the sunk cost to get to an approved product and the resulting cost-of-goods once approved and weigh that against the likelihood of private insurance companies (private payers) and governmental payers (such as Medicare) being willing to reimburse the company for treatment of patients with the approved product, and if so, at what amount. Reimbursement is a multipronged process that requires evaluation of several components: coding, coverage and payment.

It is the responsibility of companies to demonstrate clinical and economic value for new regenerative medicine therapies. The field of establishing cost-benefit trade-offs associated with new treatments is known as pharmacoeconomics. A pharmacoeconomic study evaluates the cost (expressed in monetary terms) and effects (expressed in terms of monetary value, efficacy or enhanced quality of life) of a pharmaceutical product. There are several types of pharmacoeconomic evaluation: cost-minimization analysis, cost-benefit analysis, cost-effectiveness analysis and cost-utility analysis. Pharmacoeconomic studies serve to guide optimal healthcare resource allocation, in a standardized and scientifically grounded manner. In this regard, pharmacoeconomic analysis will determine whether regenerative medicine approaches are clinically and economically effective, capturing such factors as the downstream costs associated with managing disease, assessing direct, and in some cases indirect, costs associated morbidity and mortality in the patient population. This analysis includes assessing the downstream impact of a new treatment on patient quality of life and comparing it with the incremental cost of treatment over time. For example, living with reduced vision due to ischemic retinopathy, or an amputated limb due to a diabetic ulcer would each significantly reduce the quality of life value for a diabetic patient. When appropriate data is available, it is possible to develop a reliable set of outcomes and economic scenarios, consider trade-offs and make better decisions regarding the value of a novel therapy.

Emphasis on economic justification for patient care is evident across all aspects of healthcare, from reimbursement decisions by government and private insurance entities, to payers demanding data that support treatment pathways, to large payer systems that collect and analyze their own data. Companies are incorporating pharmacoeconomic assessment tools and decision analysis processes earlier in product development. More frequently pivotal clinical studies are designed to capture cost data as well as clinical outcomes. Every advanced cellular therapy developed today will undergo some level of pharmacoeconomic analysis.

Obtaining a medical procedure code is important for reimbursement purposes, and this process begins prior to FDA approval. The Healthcare Common Procedure Coding System (HCPCS), developed and maintained by the Centers for Medicare & Medicaid Services (CMS), is the major medical procedure code system used for billing in the United States. Medicare is the largest single payer of healthcare services in the United States, with almost 50 million beneficiaries and a budget in excess of $425 billion in FY2012. While Congress has the authority to change Medicare benefit categories, CMS makes the decision whether to approve new treatments and these decisions also influence private health plans' coverage decisions, because of Medicare's size. CMS decisions are based on the statutory requirement to cover treatments that are 'reasonable and necessary' from a clinical perspective; neither comparative effectiveness nor cost effectiveness is currently an explicit criterion.

Medical providers submit claims to public and private insurance payers to receive payment for their services. This information is conveyed to payers through codes — numeric and

alphanumeric characters which represent a specific service, procedure or product provided to a patient. Two code sets are used. Current Procedural Terminology (CPT) codes are maintained by the American Medical Association (AMA) and are used to report office visits, surgeries and other services reported by physicians. Changes to CPT codes (additions, revisions or deletions) are made annually by the AMA. HCPCS Level II codes are alphanumeric codes maintained by CMS. These codes are typically used to identify supplies, products and services not included in CPT, such as drugs and durable medical equipment. Changes to HCPCS codes are made quarterly by CMS.

To assess a new technology's clinical effectiveness and safety, CMS and private payers undertake technology assessments. For example, the assessment may determine if a technology achieves particular goals, which may include:

1) The technology must have received final approval from the appropriate governmental regulatory bodies, such as FDA;
2) The scientific evidence must allow conclusions to be drawn concerning the technology's effect on health outcomes;
3) The technology's beneficial effects must outweigh any harmful effects;
4) The technology must be as beneficial as any established alternatives; and
5) The health improvement must be attainable outside investigational settings.

That being said, even if a product has a code, it is not always reimbursed. Some insurance payers, including Medicare, have separate coverage determinations that indicate when a service is or is not covered. Coverage determinations describe whether specific services, treatment procedures, and technologies can be reimbursed and under what conditions. Most frequently, Medicare coverage determinations are made by local insurance contractors through local coverage determinations (LCD) and address coverage, coding, and billing guidance. Medicare also issues National Coverage Determinations (NCD) for an item or service to be applied on a national basis.

For Medicare, services and products are reimbursed through payment systems determined by the site-of-service. The following payment systems are relevant to regenerative medicine: outpatient prospective payment system (OPPS) for outpatient hospital, ambulatory surgery center services; physician fee schedule (PFS) for physician office services; and the inpatient payment prospective system (IPPS) for hospital inpatient services. Each payment system is unique and reimbursement strategies will need to be developed with site-of-service in mind.

Often insurers will require companies to demonstrate the cost effectiveness of their products, especially relative to the costs of existing treatments for the underlying condition. In addition, payers are becoming more interested in the comparative clinical effectiveness of new products versus existing treatments. The burden is on the companies bringing forward new and innovative products to demonstrate why insurers should be paying for them. Accordingly, early in their clinical programs companies should begin to plan their reimbursement strategy by conducting an initial reimbursement analysis of their product. The following questions will help companies determine where they should focus their efforts.

- *Where will the product be administered?* The reimbursement strategy will vary based on the site-of-service. If the product is performed in different settings (physician's office, hospital outpatient, etc), it may require several different strategies based on the location where the service is performed.
- *Who is the customer?* Strategies will be different for physicians, hospitals or specialty pharmacies as each one is reimbursed through different payment systems.
- *What patient population will receive the product?* For example, if the product is intended primarily for an over age 65 population, the payers of concern might be private commercial insurance, but more likely would be Medicare and Medicaid.

- *Is the product unique or are other similar products on the market?* If similar products are on the market, it is possible that payment and codes already exist for the product.
- *Does a code exist that accurately reflects the product?* If no code exists, begin the process to secure a new code assignment. If it does exist, is the payment level appropriate for the product?
- *What clinical evidence exists?* Medicare and private payers examine clinical evidence when determining coverage. Companies should begin early with compiling clinical evidence as this will be needed for coverage and coding requests. In addition, the company should compile economic data related to the use of its product.

Emphasis on economic justification for patient care is evident across all aspects of healthcare, from reimbursement decisions by CMS, to payers demanding data that support treatment pathways, to large payer systems that collect and analyze their own data. Companies are incorporating pharmacoeconomic assessment tools and decision analysis processes earlier in product development. More frequently, pivotal clinical studies are designed to capture cost data as well as clinical outcomes. Every advanced cellular therapy developed today will undergo some level of pharmacoeconomic analysis. The following is a checklist for companies, along with timeframes, to help guide executives through the reimbursement process.

- *Conduct a reimbursement analysis and formulate a strategy.* The analysis ideally should be prepared as the company prepares for Phase II clinical trials, but if not, it should be done prior to commencing Phase III trials. The analysis should include an assessment of where and how the product will be administered, how the product will be coded, and how similar/comparative products and existing treatments are reimbursed. Based on this assessment, the company should begin formulating a reimbursement strategy.
- *Gather health economics and comparative clinical effectiveness data.* During Phase II and Phase III trials, the company should collect pharmacoeconomic data to demonstrate the cost effectiveness and clinical effectiveness of the product relative to existing treatments. More and more frequently, payers are expecting companies to demonstrate the 'value' of their product prior to reimbursing it.
- *Secure a meeting with CMS (Medicare), private insurers, or both.* This will accomplish two goals. First, it will educate payers about the technology and its clinical and economic value. This is especially important for new technologies such as in regenerative medicine. Second, it will give the company an opportunity to ask questions and get a better understanding of the data needs that payers have when making coverage and payment decisions. This information can be used when designing your Phase II and III trials.

CONCLUSION

Regenerative medicine is not just a future hope, it is a reality today. Cell-based therapies and products are on the market now and many more are in advanced stages of being tested in patients. These products provide insight into what the future holds in terms of patient health and economic impact. Regenerative medicine is a multidisciplinary field, and to increase the likelihood of success, it is incumbent on those involved to draw on the expertise of a wide range of fields and stakeholders. Collaboration between academia, industry and clinicians is a vital component for the future success of the regenerative medicine field. This rapidly emerging field of medicine, particularly cell-based therapies, has the potential to deliver dramatic clinical benefits and address important unmet medical needs. It is possible to translate clinical improvement into a robust assessment of the economic benefit derived from superior clinical outcomes.

CHAPTER 88

Ethical Issues

Laurie Zoloth
Feinberg School of Medicine and Weinberg College of Arts and Sciences, Northwestern University, Evanston, Illinois

INTRODUCTION

Case study: The small black box holds a perfectly shaped ear. The scientist at the front of the room explains how it was made. A scaffold of nanoparticles supports fibroblast cells that grew over the form, and the ear now looks and feels actual: it can be transplanted to tissue. For burn patients, this represents an enormous chance and change. It is the prototype of a new genre of medicine, one that uses powerful technologies and methods of bioengineering and cellular biology to transform the matter of the world.

The ear in the box is not a freak example of a new technique. It is, in fact, one of a number of new devices that utilize the convergent technologies of several different fields of science and engineering to create tissue that can mimic the structure and function of the natural world. Other examples include the creation of skin grafts, corneas, bone, cartilage, and, in some pilot studies, bladders. Based on the new technologies of genomics, informatics, nanoscale engineering, molecular biology, and stem cell research, tissue engineering can be said to alter the concept of medicine itself. Instead of treating ailing tissues or organs with drugs intended to repair their structure or function, tissue engineering aims at replacing the diseased or injured or aging tissues of the body with new ones entirely, made from component parts of the material of the world, both naturally occurring and synthetic.

Such an advance heralds a remarkable ability to heal, a long-awaited solution to several intractable problems, and a serious alternative to cadaveric or living-donor whole organ transplants, which have long been an ethically challenged sector of medicine [1,2]. Yet such a remarkable construction of the human body asks a great deal of any social world into which it is introduced, for it is the body that is the place of the self, the location of the acts of the sacred, and the sensory arbiter of the real. In fact, tissue engineering queries two of the very aspects of our humanity that we consider distinctive: our integral embodiment and our finitude. If we are indeed a collection of replaceable and adaptable parts, some people reason, what is it that separates us from any other engineered machine? If we can engineer, for example, a synthetic and improved lymphatic system, might we improve our chances to adapt to and overcome infectious disease? What other capacities for healing or alteration of our bodies might be prudent? How do we ensure that such changes are indeed ethical?

It is this query that has greeted the new biotechnologies of the body, one based, this chapter argues, in social reactions largely shaped by culture both ancient and contemporary. We then ask: What are the ethical challenges to the field of tissue engineering? Does tissue engineering raise new ethical issues, or is it a description of one of the modalities enabled by the convergence of other technologies that have been understood to be individually ethically freighted?

Principles of Tissue Engineering. http://dx.doi.org/10.1016/B978-0-12-398358-9.00088-4

In this chapter, I suggest using an established ethical framework that was suggested in 1999 by a committee of the American Association for the Advancement of Science on inheritable genetic germline modification and used far more widely by the field of bioethics to assess new technologies. We then review the responses given to new technologies in the past from a variety of sources in bioethics, philosophy, and theology. Finally, we reflect on how the legal and regulatory structure for tissue engineering impacts on our reflections on ethical norms [3].

Research evaluation (adapted from the AAAS Working Group on Human Inheritable Genetic Modifications 1998–2000 [3])

- Are there reasons, in principle, why performing the basic research should be impermissible?
- What contextual factors should be taken into account, and do any of these prevent the development and use of the technology?
- What purposes, techniques, or applications would be permissible and under what circumstances?
- On what procedures and structures, involving what policies, should decisions on appropriate techniques and uses be based?

ARE THERE REASONS, IN PRINCIPLE, WHY PERFORMING THE BASIC RESEARCH SHOULD BE IMPERMISSIBLE?

Principled reasons for objections to basic research are extremely difficult to conceive in research that is, by its very nature, intended to be translational and clinical. Yet ethical objections to the manipulation, replacement, and engineering of human tissue can be seen as part of a long continuum of dissent about medical technology that began to assume full voice in the 1970s, when successful genetic manipulation of bacterial genomes became possible [4].

All new technology raises new challenges — in particular, technology that refashions the embodied self, becomes a part of the 'self' and the identity of the subject, and seems to raise the deepest anxieties. Even tissue engineering, an emerging field with clear targets, clinical successes, and patient needs, will raise familiar concerns.

First among these is the argument that humans possess an essential nature and live within an essential natural order that cannot be altered without harm. For C. S. Lewis [5], this is expressed as a concern that the very acts of rational science — dissection, analysis, and quantification — are a violation of the sacred integrity that lies behind all of nature:

> Now I take it that when we understand a thing analytically, and then dominate and use it for our own convenience, we reduce it to the level of 'nature', we suspend our judgments of value about it, ignore its final cause (if any), and treat it in terms of quantity. This repression of elements in what would otherwise be our total reaction to it is sometimes very noticeable and even painful: Something has to be overcome before we can cut up a dead man or a live animal in a dissecting room.

For Lewis, the understanding of the body as replaceable is disturbing:

> 'The real objection', he says, 'is that if man chooses to treat himself as raw material, raw material he will be, not raw material to be manipulated by himself as he fondly imagined, but by mere appetite' (p. 274).

(Lewis imagines that new transformative technology will be manipulated by 'controllers' who will eventually transform man into mere matter.)

Callahan [6] echoes Lewis' concern, both in the sense that limits need to be placed on what is decent to do to nature and in the sense that such action is a part of a larger danger — that power

in the hands of medicine to heal is really power in the hands of the elite, or the state, to manipulate and control. He argues:

> The word No perfectly sums up what I mean by a limit — a boundary point beyond which one should not go. . . . There are at least two reasons why a science of technological limits is needed. First, limits need to be set to the boundless hopes and expectations, constantly escalating, which technology has engendered. Advanced technology has promised transcendence of the human condition. That is a false promise, incapable of fulfillment. . . . Second . . . limits (are) necessary in order that the social pathologies resulting from technologies can be controlled. . . . [W]hile it can and does care, save, and free, it can also become the vehicle for the introduction of new repressions in society.

These objections, made over 30 years ago, are still made (despite, one may note with some irony, 30 years of medicine that have indeed seen rapid and successful advances, without their being used by the state for repression and without any fundamental change in the capacities for intellectual and spiritual self-possession). Nevertheless, the powerful arguments of opposition to the manipulation and replacement of tissues and organs continue, with some people worried that perfection itself is sought when healing is the goal. Such critics, many from the disability community, raise principled objections to the use of tissue engineering if the goal is to alter the disability. Activists in the deaf community, for example, defend their disability as a culture and a language exchange, not as a loss of function. Others are concerned that our society's focus on 'fixing things' will allow a devaluation of the persons that currently bear the broken bodies and parts. Adrienne Asche suggests that there is a 'troubling side to every cure, that those of us who are uncured are seen as less valuable, perhaps even expendable'. For Gerald McKenney [7], a community needs to embrace brokenness and to: 'deny that the worth of one's life is determined to how closely one conforms to societal standards of bodily perfection'. McKinney is also concerned that if medicine is successful, it will create a social and economic system that: 'virtually demands that we be independent of the need to care for others'.

Duty and healing: natural makers in a broken world

While the opposition to medical technology has indeed been persistent, it has not been unchallenged. For many, the response lies in the nature of brokenness and the human duty to respond to the need of the suffering other [8,9]. The principle at stake in the assessment of tissue engineering as an ethical act is not how its use might potentially violate an abstract community in the future, but the actual problem of what one must do as a moral being when one's neighbor is in need. In this important sense, the duty to heal cannot be overridden by a 'sense' of discomfort (as Lewis notes in the earlier quote).

It is the nature, goal, and meaning of science to address the human condition in all its yearning and capacity for defeat and failure. In this sense, there is no principle objection to the science of tissue engineering, and in fact there may well be a strong moral imperative to develop the technology.

Joseph Fletcher [10] noted, in speaking of an earlier generation of medical technology and answering the critics of science, wrote:

> 'The belief that God is at work directly or indirectly in all natural phenomena is a form of animism or simple pantheism. If we took it really seriously, all science, including medicine, would die away because we would be afraid to 'dissect God' or tamper with His activity'. 'Every widening and deepening of our knowledge of reality and of our control of its forces are the ingredients of both freedom and responsibility'.

McKinney, Childress, and Lewis use an argument that is rooted in Christian moral theology: that since human persons are fallen creatures in a fallen world, we cannot really be counted on

to know the right and the good. God, who is transcendent, from this fallenness, has set us in this place, not essentially to alter it toward our own transonic, but to find its meaning and purpose. Yet the traditions of other faiths differ. For Jewish and Islamic theorists, the world is morally neutral. Human persons may — and will — fail in their aspirations but can be trusted to have the capacity for moral behavior and moral yearnings. Finding meaning in suffering is not the core task. The task is to alleviate suffering, which is understood as chaotic, meaningless, and agonistic. Hence, many of the core objects in principle are rooted in religious constructions and understandings.

To make is to know: notes on an old problem about knowledge

The classic debates of the 1970s are not the only set of problems engendered in the history of ethical responses to the technological gesture at the heart of tissue engineering. At stake as well is the special kind of knowledge that such making implies. For Aristotle and the Hellenists, useful knowledge, 'practical wisdom', was phronesis. Phronesis implied actually doing an act; making, in order to know. The act of making, not the act of perception or contemplation alone, was how wisdom and, indeed, rationality and power were achieved. Hence, making new tissue is a somewhat different moral gesture than curing the body by altering it with drugs that essentially allow the body to heal itself.

Second, the use of technology within the body of the patient is a different matter than the use of technology essentially to enhance the body of the practitioner. For all earlier technology, the thing that was changed or enhanced was the sense perceptions of the doctor. Stethoscopes and otoscopes allowed the sounds of the body to be more audible. X-rays, CT scans, and MRIs allow the inner vistas of the body to be revealed. EEGs and EKGs allow the electrical currents that animate the central and peripheral nervous systems to be charted in quantifiable units. Microscopes allow invasive bacteria to be seen at the microscopic and, increasingly, molecular levels. These earlier technologies extended the reach of what Bacon increasingly trusted and that the Greeks did not: the perception and observation of the phenomena of the world and the perception of the outcome of its deliberate perturbation.

Bacon's method presupposes a double empirical and rational starting point. True knowledge is acquired if we proceed from lower certainty to higher liberty and from lower liberty to higher certainty. The rule of certainty and liberty in Bacon converges… For Bacon, making knows and knowing is making (cf. Bacon IV [1901], 109—110). Following the maxim 'command nature . . . by obeying her' (Sessions [11]; cf. Gaukroger [12]), the exclusion of superstition, imposture, error, and confusion are obligatory. Bacon introduces variations into 'the maker's knowledge tradition' when the discovery of the forms of a given nature provide him with the task of developing his method for acquiring factual and proven knowledge (Stanford Encyclopedia of Philosophy website, 2003).

Thus, the world is known by understanding the parts of the world and, from that, theorizing (knowing), by induction, to principles or axioms or laws of nature, physics, and chemistry. In contemporary science, knowing is done largely by 'unmaking', by deconstruction of the component parts in ways scientists of Bacon's era were unable to imagine. Many of these 'unmaking' techniques, such as the splicing of alternative DNA and the manipulation of cellular structures, allow a sense of inherent interchangeability, as if the real and the person were merely a set of Lego parts awaiting clever recombination.

What is a thing? The perils of deconstruction

Making actual tissue in mimesis of the real tissue of the actual body extends the Baconian act in radical ways. Here, the experimental perturbation is the unmaking of tissue and the remaking of tissue, only in more controllable form. This cannot help but excite concern about the nearly infinite possibilities for technological shaping of the self. Heidegger asks: 'What is a

thing?' and in so reflecting, understands a thing as an object separate from the self. But what of a made thing, an object that becomes the self?

The technology of the alteration of the patient is distinctive. Devices for altering the functioning of the body that become a part of the body and are actually a tissue of the body are a step beyond the idea of a device held within the body. This is important in any ethical assessment of the technology, because the patient's consent and participation are needed for the final act of the technology to be completed. Such an event only happens in a specific context, for technologies, patients, and practitioners operate in a social, religious, and economic context. Here we turn to the second ethical consideration.

WHAT CONTEXTUAL FACTORS SHOULD BE TAKEN INTO ACCOUNT, AND DO ANY OF THESE PREVENT THE DEVELOPMENT AND USE OF THE TECHNOLOGY?

Tissue engineering is a complex procedure still in experimental stages. Yet to be an ethical technology, it must be directed toward accessibility, just distribution, and efficacy. Hence, the troubling context of widespread healthcare disparity is a problem not only for this advanced technology but for all newly emerging technologies. Emergence into an unjust world asks certain moral questions of new technological advances. First among these is the query about burdensomeness versus benefit in a context in which the vast majority of the world's people suffer from easily treatable infectious diseases such as tuberculosis, malaria, AIDS, and infant diarrhea. How can tissue engineering be justly promoted in the face of other, pressing needs?

This objection can typically be met by noting that it would be deeply inappropriate to withhold medical knowledge until the world is entirely perfected, and that applications not only will be increasingly available to the poor (as in vaccines, once rare) but also that the very process of research has typically uncovered new and useful ways to understand disease.

The goal of tissue engineering is the widespread use of the technique. Unlike solid-organ transplants, which would always require significant resources far outside the capacities of developing-world clinics, tissue replacement, stem cell therapies, and other transportable therapies are designed for widespread use. The possibility to create a method for allografts that uses the patient's own cells and the possibility for allologous cells to provide an 'off-the-shelf' source of tissue may provide the basis for access (but only if research priorities are discussed in advance of design), a process, as we describe later, that will need careful support and monitoring. The question of how to achieve this and how to enable a more just use of each technology has not yet been solved.

A second contextual factor for tissue engineering is that all human tissue is marked by its genomic identity. It is the very nature of cells, what allows them to copy and reproduce, to carry identifying markers linked to some person somewhere. In the past, such use has raised serious objections. Such tissue can be traced and known, which may have implications for the person who is the source of the tissue, raising significant new issues in genetic privacy for the donor.

Further, whose is the tissue that is derived from the cells of a particular body? Who should have the rights to, and a fair share of, the profits derived from its use? In the seminal case in the field, Moore v. the Regents of the University of California [17], the issue of ownership was addressed. In this case, Mr. Moore had his T cell lymphocytes taken from his spleen during the course of treatment for hairy-cell leukemia, cells that proved effective in deriving resistant cell cultures. Patented after manipulation to make a new 'product', the cells were indeed profitable. Mr. Moore's complaint was that he was not informed of, much less a part of, the scientific enterprise and the lucrative payout for his cells. The case was decided in favor of the

research labs. But in the ensuing decades, alert patients with unique cell types or unusual cancers sought for research have been selling their materials as personal possessions to the lab that wishes to procure them. Ownership is limited, however, by the common law of the United States and the European Union which constrains this ability to claim tissue as property. The goals of such restraints were put into place to prohibit the buying and selling of human tissue and organs, for fear, given the desperation of the poor, that selling the bodies of the poor would become permissible and lead to their exploitation. Thus, the entire process that allows for the derivation of tissue sources needs to be noted. The current context for tissue donation is a mixed system. Organs, tissues such as blood, corneas, and marrow are donated or exchanged without compensation. Gametes, however, are another matter entirely. Because the use of human sperm and eggs emerged in the context of fertility treatment and because this treatment was largely conducted in stand-alone, private clinics that functioned without public oversight or regulation, the marketplace standards prevailed. What originally began as a compassionate exchange of gametes between family members when an infertile couple could not conceive quickly changed into a robust marketplace in human gametes. As of this writing, international standards prohibit the use of marketplace incentives for gametes or embryos (International Society for Stem Cell Research, 2006).

A final context for the debate about the ethics of tissue engineering in general is the special case of human stem cells to make tissues. Because some applications of tissue engineering use stem cells as a part of the method of treatment [13], the debate about the ethics of the use of human stem cells is directly adjacent to this technology. For many, the origins of tissue matter a great deal. For some Christians, many Roman Catholics, and some Hindu sects, the destruction of the human embryo, even at the blastocyst stage, is tantamount to killing. For these faith traditions, the derivation of stem cells from embryos is always impermissible. For many other faith traditions, such as Judaism, Islam, Jainism, Buddhism, Confucian philosophy, and Daoism, the use of these cells is permissible within certain constraints, as we will see later. For all faith traditions, however, the manipulation of adult somatic cells in their precursor form is completely sanctioned. Precursor cells are not as flexible as pluripotent cells, and it is that very pluripotency and immortality that are important in tissue engineering. These factors raise concern. Yet the contextual factors alone do not prohibit entirely the use of this technology, for justice in distribution, the possibility of the loss of genetic privacy, and the controversy over stem cell research when pluripotent embryonic cells are used affect many aspects of the new techniques in medicine. Hence, we turn to the third major issue.

WHAT PURPOSES, TECHNIQUES, OR APPLICATIONS WOULD BE PERMISSIBLE AND UNDER WHAT CIRCUMSTANCES?

Many of the salient, justifying arguments for the use of tissue engineering hinge on the telos, or goal, of the treatment: If the goal is to cure or treat human disease, then the benefits will outweigh the burdens of the work — controversy, cost, and difficulty. Clearly, then, tissue engineering ought not to be used in a trivial or wasteful fashion. Human tissue is understood by many as deserving a special sort of 'respect' (Nelson, 2002) [14].

This proviso may not be so simple, for a core problem in genetic engineering has been the use of the technique for 'enhancement' of human characteristics or traits. The initial ethical discussions about therapeutic uses of medicine versus cosmetic ones imagined ethical bright lines that would define the boundary between the use of such technology to restore 'species normal functions' [15] for each tissue and for the person as a whole. Yet medical practice has long gone beyond these lines, using surgery, for example, for cosmetic purposes. Will it be possible to restrict tissue replacement to burn victims, spinal cord injury, and diabetics? How can such a distinction be made?

Some tissue replacement therapies, such as the use of skin grafts for full-face transplant, may also raise questions about the nature of identity. Indeed, the notion of a full-face transplant alerted us to the depth of resistance to identity — altering tissue replacements. (Could persons use any face? What if persons in need of facial transplants wished to change ethnicity? Should faces 'match', and why?) Like many other aspects of this technology, this tension about identity was not new, only heightened. For example, the first years of organ transplant raised the same issues for recipients of hearts, a key aspect of identity in many cultures. If the face is our key determinant of the self in modernity and, even more so, if the brain is such, then how are we to understand the use of tissue engineering to transform identity?

Hence, linked inexorably to this technology are larger considerations of the use of tissue engineering for neuroscience, both for therapy and for enhancement. The applications of tissue transplant in Parkinson's disease are important. Yet will there be concern about this use of the neurons of a stranger in the brain of the self? Of all the possible uses of tissue engineering, the ones that may alter consciousness and memory are the most troubling. (What capacities or memories could neurons store?) Here, the need for restrictions on applications may be the clearest, yet it is not clear who ought to decide and who ought to ensure that the restrictions on unethical applications are maintained. By what criteria will such limits be set?

New research possibilities also offer applications to engineer gametes for use and storage. Engineered follicles may now be saved, frozen, matured, and used in animal models to create the possibility of human fertility after cancer chemotherapy or other environmental risk (Woodruff et al., 2006).

With this, as with all such technology, there will have to be careful attention to how the market may drive technology toward specific research goals rather than others or to whether research goals will be framed only by the values of profit and efficacy and not by ones of more general interest: compassion, healing, and solidarity. The powerful applications and the potential for widespread use itself create the possibility for serious conflicts of interest, for serious market forces may be the core drivers of technology, especially in an aging population with increasing needs for all manner of new tissues and organs. This turns us to the consideration of our final set of issues.

ON WHAT PROCEDURES AND STRUCTURES, INVOLVING WHAT POLICIES, SHOULD DECISIONS ON APPROPRIATE TECHNIQUES AND USES BE BASED?

Much of the first reviews of the ethical issues in tissue engineering have in fact focused on the issues of policy:

Safety, patents, and gating. Products and drugs are typically controlled via four levels of restraints. The first is elaborate premarket gating, first involving animal models and then typically done for pharmaceuticals in a decade-long series of tests, phased to test the drug on an increasing but controllable number of human subjects. Such trials must be gender balanced, and subjects must give full, informed consent and be able to leave the trial at any time (which could be difficult in cases of implanted tissues).

The next gating is the system of intellectual property. Patents and licensing control the use of the products, and even the replication of the experiments. The next gating is that of financial backing. To perform the enormous clinical trials, to do premarket investigation, and, of course, actually to make and sell the product require a production apparatus, which must be assembled and supported. Finally, each drug or device must be approved for use by the insurers. As David Smith (2004) notes, tissue engineering faces a gauntlet

of issues and a 'new order of magnitude in interactions and science patents'. Additionally, notes Smith, the 'things' engineered are hybrids of two jurisdictions, that of drugs and that of devices.

Are genetically engineered insulin cells a drug, like insulin, a device, like a stent, or a biologic? Unlike stents, which are entirely synthetic, tissue engineering uses actual human cells, only manipulated in *de nova* ways.

Standards will need to be set for safety, efficacy, and fair use. Standards for clinical use, standards for clinical trial, and standards for tissue stability and purity will be needed for the research and application to be safe.

Getting informed consent in this case will present significant challenges. Patients in need of organs, for example, are particularly desperate, and their consent may be deeply affected by their utter lack of options. Eight percent of the medical system is already devoted to organ transplantation, and the lack of organs is an overwhelming problem for nearly half of the patients hoping for transplants [16]. Yet the first year of the use of engineered tissue will be experimental and will need to be conducted under the strongest possible set of NIH guidelines. How the first trials of engineered tissue are conducted will set the tone and the future for all subsequent use.

The question of policy and the regulation of policy are manifested in many of the first documents that evaluate the ethical and legal implications of tissue engineering. While, as Smith notes, the United States faces a complex regulatory system, the European Union has regulated such research products as medical products, and these will fall under the regulatory gaze of the European Medical Evaluation Agency (EMEA). In both the United States and the EU, the synthetic nature of tissue engineering, the very *de novo* quality of the work and the uneasy greeting that met genetically modified food has created serious political opposition. Policies need to be crafted with transparency and full public participation, for such research needs not only public funding but public understanding of complex theory and practice of tissue engineering — what promises it can hold and what cautions need to be applied prior to use. Policymakers will need to attend to calls for justice in distribution, as was noted earlier, and will need to set in place structures for regulation.

How can new technologies best be regulated? I contend that a full array of regulatory structures can be employed. First among these are local committees, IRBS, and local review boards. The National Academies have played a large role in policy writing for both recombinant DNA and for stem cell research and, in both instances, called for special, national, ongoing oversight on such research. It would be prudent to reflect on the need for such a process for tissue engineering, for established structures largely address issues involving the use of donated tissue, not engineered tissue. Structures that protect human subjects also need strong enforcement, as noted earlier, both for donors and for recipients of tissues.

But regulation, government oversight, and market forces can only go so far in shaping just research goals and commitments. The goal of ethics is to develop moral agents who are aware of a constancy of duty toward subject and to humanity, who not only follow rules correctly but who, given the chance and grace to work at the frontiers of science, act with courage and decency in their research.

CONCLUSION

Tissue engineering suggests that an old dream — the replacement of human body parts — may be realized. While any sober and reflective scientist understands the long way to success of this idea, the science described in this volume clearly suggests that our society is on the road to the enactment of the possibility.

EPILOGUE

The emergence of the field of Tissue Engineering and Regenerative Medicine tracks with the publication of new editions of this textbook, now in its fourth iteration. Like any active field in science, ongoing evolution in ideas, discovery, and innovation will never allow a final chapter. The 2012 Nobel Prize in Physiology and Medicine was awarded for stem cell work resulting in the induced pluripotential stem cell, a stunning and important achievement not mentioned in the third edition. Likewise, a new scaffolding approach involving decellularization of tissues and organs with preservation of vascular architecture is now being studied world wide but had not been published prior to the last edition. The important lesson is that the field is healthy and active because of the engagement of creative and passionate young investigators who have a desire to make a difference in the lives of the many humans who desperately need our help.
