A large body of literature exists describing the diagnosis and management of structural CHD in the fetus and newborn. There is a paucity of information, however, regarding the diagnosis and management of fetal and newborn cardiomyopathy. When presented with a newborn with signs of CHF, structural heart disease should be ruled out. In the absence of structural problems, the diagnosis of cardiomyopathy should be considered. The causes of neonatal cardiomyopathy include prenatal infections (cytomegalovirus, human immunodeficiency virus, parvovirus), familial or genetic causes, maternal autoimmune disease with anti-Ro or anti-La antibodies, prenatal drug exposure, arrhythmia-induced cardiomyopathy, and twin–twin transfusion syndrome. Postnatal evaluation should include a search for the cause.

Initial management is similar to that used for other types of heart disease. Initial stabilization may require mechanical ventilation, the use of inotropes, afterload reduction, and diuresis. Long-term treatment is dependent somewhat on the cause of the cardiomyopathy, as some forms may be reversible. Cardiac transplantation should be considered if cardiac function is poor, or improvement is not noted.

Acknowledgments

Special thanks to Benjamin E. Reinking and Thomas Scholz for their original contributions to this chapter.

Long-Term Neurologic Outcomes in Children With Congenital Heart Disease

SHABNAM PEYVANDI AND PATRICK MCQUILLEN

KEY POINTS

- Congenital heart disease (CHD) is a common birth defect with continually improving survival of neonates with complex lesions requiring heart surgery.
- Neurodevelopmental (ND) abnormalities are common in school-age children and adolescents after neonatal heart surgery.
- Magnetic resonance imaging (MRI) studies have demonstrated evidence of brain injury and delayed brain development, even before having a corrective operation, in patients with hypoplastic left heart syndrome and transposition of the great arteries.
- Fetal MRI studies suggest this delayed development begins in the third trimester.
- Aberrant fetal physiology resulting in decreased oxygen and substrate supply to the brain may contribute to these imaging and ND abnormalities in addition to other perioperative risk factors.
- Children with complex CHD have a prevalence of pervasive but subtle cognitive problems termed *the neurodevelopmental signature of complex congenital heart disease*.

Severe congenital heart disease (CHD) requiring a corrective operation occurs in 6 to 8 per 1000 live births, with up to half of the cases requiring an operation in the neonatal period to survive.[1] With improved surgical techniques, mortality for CHD has steadily declined.[2] In fact, the number of adults living with CHD has surpassed the number of children with CHD in the United States.[3]

Given the changing epidemiology of CHD, considerable effort has been devoted to evaluating both neurodevelopmental (ND) outcomes and quality of life for patients with CHD. Evidence suggests that although children with CHD may no longer have overt signs of neurologic dysfunction, they may exhibit deficits in multiple domains, including visual-spatial skills, memory, executive function, speech and language, and gross and fine motor function.[4–6] Long-term follow-up data suggest that these deficits continue into adolescence and young adulthood with potentially significant impacts on societal contribution.[7–9]

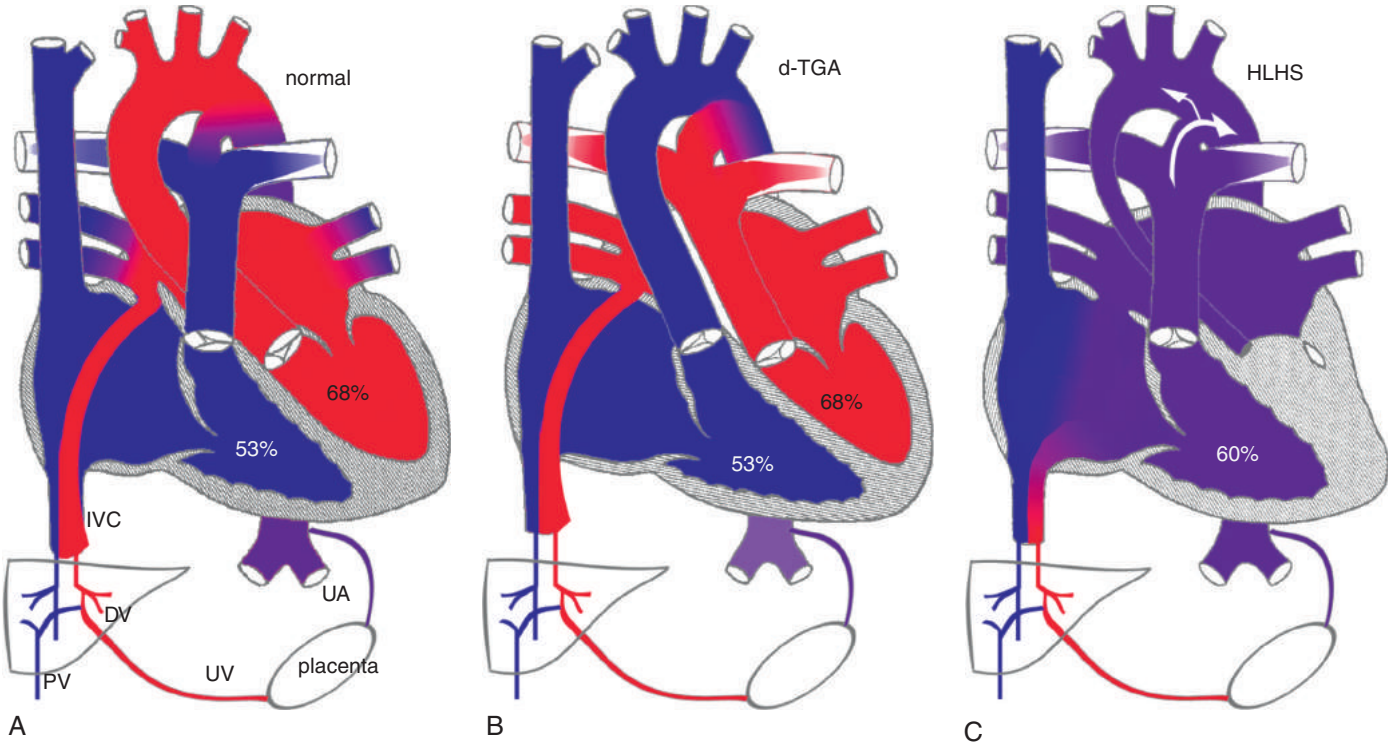
A natural assumption has been that these adverse outcomes were directly related to a brain injury sustained during neonatal cardiac surgical interventions. However, in the recent era it has become apparent that patient-specific risk factors play essential roles in determining the ultimate ND outcome and, furthermore, that the interplay between the brain and the circulation is complex, occurring at many levels throughout fetal and postnatal development. This chapter will review mechanisms influencing neurologic outcomes in CHD, including (1) the physiologic effects of congenital heart lesions on brain blood flow, (2) brain development in the context of CHD, (3) the timing, appearance, and mechanism of acquired brain injuries, and (4) current knowledge on ND outcomes in critical CHD in the short and long term.

Structural and Developmental Abnormalities of the Brain in Congenital Heart Disease

Human cardiac development is largely complete by gestational week 7.[10] In contrast, brain development extends over a much longer time period, with morphologic events (cell proliferation, migration, axon pathfinding, and target selection) occurring predominantly in the first two trimesters, followed by a prolonged period of refinement of circuits that begins in the third trimester and extends into infancy. This stage of brain development includes dramatic growth, myelination, and increasing neuronal electrical activity and depends upon receiving an adequate supply of nutrients and oxygen. Consequently, blood flow to the developing brain increases and is estimated to be a quarter of the combined ventricular output in the third trimester, demonstrating the unique heart–brain interplay critical for normal brain development.[11]

Fetal Circulation in Congenital Heart Disease: Effects on Cerebral Blood Flow

Fetal circulation is unique in many respects that can impact cerebral blood flow and development. In the normal fetus, cerebral blood flow is supplied by highly oxygenated blood from the ductus venosus preferentially streaming across the foramen ovale to the left atrium and ventricle (Fig. 51.1). In contrast, in fetuses with transposition of the great arteries (TGA), the aorta and pulmonary artery are transposed. Thus the higher oxygenated blood reaches the pulmonary vasculature as opposed to the cerebral vasculature. Similarly, in hypoplastic left heart syndrome (HLHS), inadequate left heart structures lead to a reversal of blood flow in the foramen ovale with the mixing of oxygenated and deoxygenated blood in the right ventricle and, in cases of aortic atresia, retrograde flow in the ascending aorta. The effects of these abnormal flow patterns on brain development are uncertain but may involve different mechanisms; despite that both decrease the oxygen



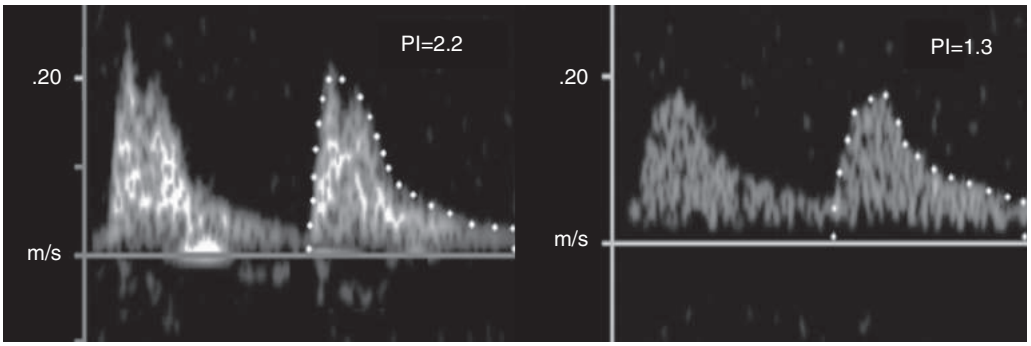
• **Fig. 51.1** Normal and Altered Fetal Circulation. (A) Normal fetal blood flow. (B) d-transposition of the great arteries (d-TGA). (C) Hypoplastic left heart syndrome (HLHS) with aortic atresia. Deoxygenated blood (*blue–purple*) flows to the placenta through the umbilical artery. Blood with higher oxygen content *(red)* returns through the umbilical vein and ductus venosus to the inferior vena cava (IVC). The higher saturated blood from the IVC is preferentially directed toward the foramen ovale into the left ventricle, ascending aorta, and head and neck vessels in the normal fetus. Desaturated blood also returns to the right side of the heart and is directed to the descending aorta through the ductus arteriosus. In the fetus with d-TGA, the aorta arises from the right ventricle such that the brain receives less oxygenated blood, while the higher saturated blood is directed to the descending aorta through the ductus arteriosus. In HLHS, reduced or absent left-ventricular ejection results in elevated left-atrial pressure, limiting or reversing flow at the foramen ovale and resulting in complete mixing of desaturated and well-saturated blood in the right atrium and ventricle. Blood flow to the head and neck may occur in a retrograde fashion from the ductus arteriosus across the aortic isthmus. *d-TGA*, d-transposition of the great arteries; *DV*, ductus venosus; *HLHS*, hypoplastic left heart syndrome; *IVC*, inferior vena cava; *PV*, portal vein; *UA*, umbilical artery; *UV*, umbilical vein. (From McQuillen PS, Goff DA, Licht DJ. Effects of congenital heart disease on brain development. Prog Pediatr Cardiol. 2010;29(2):79–85.)

content of the blood delivered to the brain. Other mechanisms may be involved, such as inadequate substrate delivery (glucose) because of decreased perfusion pressure and flow to the brain.[12] In the d-transposition of the great arteries (dextroposition [d]-TGA), the pulsatility and perfusion pressure of the cerebral circulation are normal. However, in HLHS, the hypoplastic isthmus and aortic arch may function as resistors, potentially decreasing the pulsatility and perfusion pressure to the cerebral circulation. In contrast, in d-TGA, decreased pulsatility and perfusion to the brain can result from preferential blood flow to the pulmonary vasculature because of a lower pulmonary vascular resistance than usual.

Cerebral Doppler ultrasound can assess fetal cerebral vascular resistance in the middle cerebral artery (MCA) and provide insight into fetal cerebral blood flow patterns. By calculating the MCA pulsatility index (PI, a measure of vascular resistance in the circulatory bed downstream from the point of Doppler sampling), studies have identified a pattern of "brain-sparing" in fetuses with intrauterine growth restriction and placental insufficiency as a consequence of autoregulation of fetal cerebral blood flow.[13,14] In normal pregnancies, the cerebral/umbilical PI ratio is more than 1.0, whereas, in many growth-restricted fetuses, the ratio is less than 1.0 and predicts adverse perinatal and neurologic outcomes.[15,16] This autoregulatory mechanism is thus paradoxically a harbinger of poor outcomes in the setting of fetal growth restriction.

There have been several studies examining in utero blood flow patterns in human fetuses with CHD. These have demonstrated lower MCA PI in fetuses who have lesions with the most intracardiac mixing, such as HLHS (Fig. 51.2). In fact, fetuses with HLHS have been shown to have the lowest cerebral/umbilical PI ratio among different types of CHD.[17,18] This is likely secondary to the lower oxygen content of blood delivered to the brain and abnormalities in cerebral perfusion with a hypoplastic aortic isthmus.

Cerebral blood flow characteristics have been shown to predict ND outcomes in fetuses with CHD. In a retrospective multicenter study of infants with HLHS, a lower MCA PI in utero predicted a better ND outcome at 14 months of age as assessed by the Bayley Scales of Infant Development (BSID) II.[19] These findings suggest that the autoregulatory response of cerebral vasodilation in the setting of HLHS may be sufficient and adaptive to



• **Fig. 51.2** Middle cerebral artery Doppler patterns in a normal fetus and a fetus with hypoplastic left heart syndrome (HLHS). The pulsatility index (peak systolic velocity–end diastolic velocity/mean velocity) in the HLHS fetus is lower *(right panel)*, suggesting decreased impedance in the cerebral vasculature. *PI*, Pulsatility index.

a state of chronic hypoxemia, which is in contrast to what is seen in the context of fetal growth restriction. Further large prospective studies are needed to understand the predictive utility of cerebral blood flow patterns in fetuses with CHD.

Preoperative Evidence of Delayed Brain Development by Magnetic Resonance Imaging

Structural brain malformation in neonates with CHD has been identified, even in the absence of a defined genetic syndrome. Autopsy studies have revealed multiple congenital brain anomalies in neonates with HLHS, including microcephaly, abnormal cortical mantle formation, and overt central nervous system malformations such as agenesis of the corpus callosum or holoprosencephaly.[20,21]

In addition to structural abnormalities, there is magnetic resonance imaging (MRI) evidence that brain development is delayed in CHD prior to corrective surgery. Quantitative MRI techniques such as diffusion tensor imaging (DTI) measure the direction and magnitude of water movement and thus microstructural brain development.[22] During normal brain development, the magnitude of water diffusion motion decreases (apparent diffusion coefficient [ADC]), and regional directionality increases in white matter (fractional anisotropy [FA]). Similarly, metabolic brain development can be measured with magnetic resonance spectroscopy (MRS) by measuring major metabolic compounds such as *N*-acetylaspartate (NAA), choline (Cho), creatine (Cr), and lactate. Using these techniques, researchers have discovered that newborns with CHD (d-TGA and single ventricle lesions) have findings suggesting an immature brain with abnormal DTI (4% higher ADC and 12% lower FA) and MRS (10% lower NAA/Cho ratio). Comparing these findings with those obtained in premature newborns without CHD, full-term newborns with CHD appear approximately 1 month delayed.[23] These observations have been replicated in studies assessing brain development by semiquantitative morphologic scoring, specifically the brain total maturation score (TMS). The TMS was found to be significantly lower in full-term newborns with d-TGA and HLHS compared with a normal cohort of newborns.[24] Finally, morphometry studies have demonstrated lower total and regional brain volumes in newborns with CHD compared with controls.[25] These findings help explain the abnormal somatic growth seen in the newborn with CHD. Specifically, those with d-TGA and HLHS have smaller head circumferences that are out of proportion to their weight.[26,27] These brain MRI findings in the neonate with CHD, seen before any corrective operations are performed, have led to the theory that abnormal brain development and susceptibility to acquired injury begin in utero.

Fetal Brain Magnetic Resonance Imaging Identifies Developmental Abnormalities in Congenital Heart Disease

Technical advances in fetal MRI have made it an important tool in the clinical evaluation of fetuses with suspected cerebral abnormalities. A study comparing brain volumes and MRS between normal fetuses and fetuses with CHD between 25 and 37 weeks' gestation showed definitive evidence for delayed fetal brain development.[28] During the third trimester, a progressive impairment of brain volumes was observed, particularly in those fetuses with left-sided obstruction. Additionally, larger delays in the expected increase in NAA/Cho ratio and greater impairment of growth in brain volume were noted in fetuses with aortic atresia, who have no antegrade blood flow in the aortic arch. These observations support the concept that brain development is altered during fetal life because of impaired fetal cerebral blood flow, oxygen, and substrate delivery and that compensatory mechanisms (i.e., brain-sparing effect) may not be adequate.

Recently, novel fetal cardiac MRI techniques have been utilized to understand the heart–brain interplay in CHD. These techniques enable measurements of flow and oxygen saturation in fetal blood vessels. By combining fetal brain MRI and cardiovascular magnetic resonance, researchers found a correlation between fetal cerebral oxygen consumption and brain size (estimated brain weight) among 30 fetuses with CHD in late gestation.[29] There was a direct correlation between estimated brain weight and cerebral oxygen consumption. In addition, there was a modest association between cerebral oxygen delivery and brain size. Other novels and efficient imaging techniques have been developed to understand cerebrovascular physiology while accommodating significant motion artifacts from fetal movement and maternal breathing. These studies revealed that fetuses with both left sided obstructive lesions and d-TGA have lower fetal cerebral oxygenation compared to controls.[30] The predictive value of these findings for postnatal outcomes such as brain injury and ND outcomes remains unknown. Further exploration to potentially identify targets and methods of intervention to modify ND outcome in CHD is warranted.

Trajectory of Brain Development in Congenital Heart Disease

Although much of the literature has been focused on the identification of abnormal brain development in the fetus and newborn with CHD, studies on older patients have emerged suggesting that these delays continue into adolescent years. In a study of single ventricle patients who had undergone a Fontan operation, the frequency of any structural abnormality on MRI was 11 times higher than in a normative cohort.[31] Similarly, in a brain MRI study of adolescents with d-TGA, FA was significantly reduced in several regions of the white matter compared with a normative cohort.[32] Many have postulated that the trajectory of brain development over time may be dependent on the specific cardiac lesion and whether the surgical management is corrective (i.e., d-TGA) or largely palliative (i.e., HLHS). In particular, patients with aortic atresia have been found to have the least robust microstructural brain development.[33] In a direct comparison of HLHS to d-TGA, neonates with d-TGA had a faster rate of global and regional brain growth in the perioperative time period.[34] Another study demonstrated, at 2.5 years of age, more cortical atrophy and lower brain volumes in those with HLHS compared with those with d-TGA, suggesting a lesion-specific influence on the long-term trajectory of brain development.[35]

Acquired Brain Injury With Congenital Heart Disease: Characteristics and Risk Factors

Neonates with CHD are also at risk for newly acquired brain injury. Delayed brain development itself may be a risk factor for new brain injury, particularly preoperative injury.

Focal brain injury in the term newborn can be clearly and reliably detected with conventional MRI and with greater resolution than with either ultrasound or computed tomography. The most common brain injuries observed in newborns with CHD are focal white matter injury (WMI) and small focal strokes (less than one-third to two-thirds of the arterial distribution; Fig. 51.3). These injuries are largely clinically silent and can be overlooked with routine clinical screening cranial ultrasounds.

WMI has specific imaging characteristics defined by punctate periventricular lesions seen as hyperintensity on T1-weighted MRI. Identification of this pattern of injury was unexpected because it was thought to be restricted to premature newborns with brain injury (periventricular leukomalacia). Risk factors for brain injury are summarized below and in Table 51.1. Direct comparison of focal WMI in premature newborns and term CHD newborns confirms similarities in the imaging appearance and magnitude of injury in the two groups, but topological distribution differed with more involvement of central regions in premature newborns.[36] Importantly, longitudinal studies have revealed that WMI on the moderate to severe end of the spectrum is associated with worse neurodevelopmental outcomes in late infancy and early childhood.[37,38] Thus, although these forms of early brain injury are "clinically silent," they appear to be clinically relevant.

Risk Factors for Preoperative Brain Injury

Several large prospective studies have been performed using preoperative and postoperative brain MRI to determine the frequency of acquired brain injury and associated risk factors in newborns with CHD (Table 51.2). Preoperative brain injury in the form of WMI or stroke is present in 28% to 39% of these newborns (see Table 51.2).[39–42,48] This was a surprising finding, given the focus on operative factors causing ND abnormalities in these patients. Risk factors for preoperative brain injury include hypoxemia and time to surgery,[43] preoperative base deficit, preoperative cardiac arrest, and the need for balloon atrial septostomy.[49] Other patient-specific risk factors identified include male sex and the presence of aortic atresia (lack of antegrade flow in the aorta) in those with HLHS.[46]

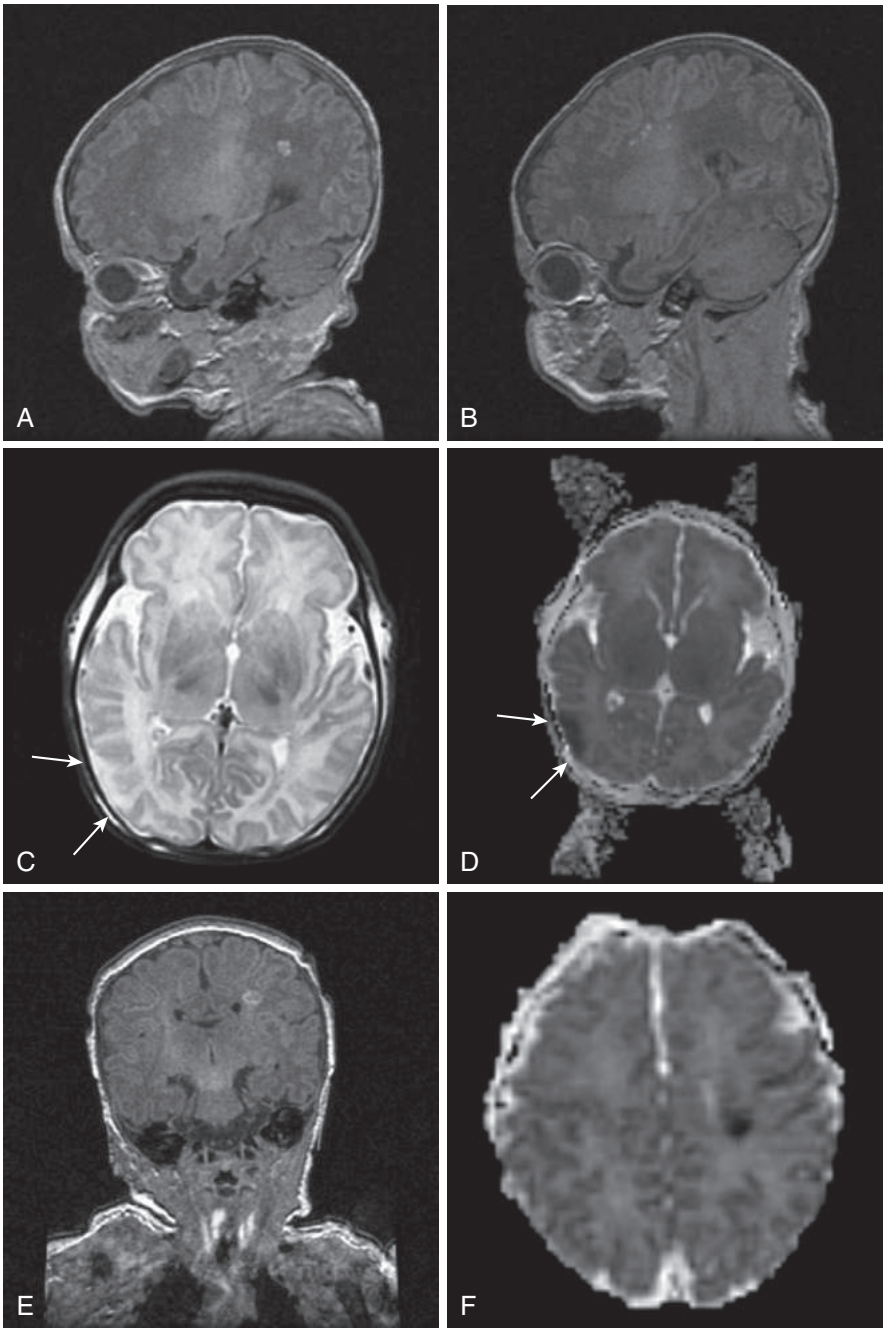
Risk Factors for Intraoperative Brain Injury

Proposed risk factors for intraoperative brain injury relate predominantly to the methods of cardiopulmonary bypass and/or hypothermic total circulatory arrest. The Boston Circulatory Arrest Trial compared two methods of vital organ support in infants undergoing open heart surgery to repair d-TGA with an arterial switch operation.[50] This operation is "corrective" since normal cardiovascular physiology is reestablished with low mortality and excellent long-term cardiac functional outcomes. Although deep hypothermic circulatory arrest, which provides the surgeon with an empty and relaxed heart, clearly allowed intricate surgeries to be performed, there was concern at the time regarding late adverse neurologic outcomes, and the "safe" duration of circulatory arrest was unknown. An alternative method (low-flow bypass) was felt to maintain some amount of brain oxygen delivery while still allowing the surgeon a relatively bloodless field. This landmark study enrolled 171 infants in a single-center, randomized clinical trial comparing deep hypothermic total circulatory arrest with low-flow cardiopulmonary bypass. All early outcome variables pointed to a benefit from low-flow bypass compared with circulatory arrest. Specifically, the circulatory arrest group had more frequent postoperative seizures, higher serum levels of brain-specific enzymes (creatine kinase), worse 1-year motor outcome (BSID—Psychomotor Development Index [PDI]), and abnormalities on a neurologic exam.

In contrast, no differences were found in cognitive development (BSID—Mental Development Index [MDI]) or MRI at 1 year of age. Importantly, these differences between the groups disappeared when the patients were assessed at older ages, but both groups remained below population norms for performance on standardized tests (detailed later in this chapter).[51] Other studies have identified circulatory arrest as a risk factor for new postoperative WMI identified on MRI.[52]

Additional variables examined included hypothermic blood pH management (alpha stat versus pH-stat), hemodilution/hematocrit (25% vs. 35%), and maintenance of regional cerebral perfusion during aortic arch reconstruction.[53,54] Very few of these studies have identified definitively improved neurologic outcomes. Patients who underwent regional cerebral perfusion tended to have worse outcomes, and this technique was associated with new postoperative injury on brain MRI.

These results suggest that although risks remain during the intraoperative period, a major burden of risk for acquired injury occurs outside of the operative period. However, the possibility that unidentified intraoperative risk factors contribute to brain injury cannot be excluded. Analysis of combined cohorts of subjects requiring neonatal cardiac surgery over a 13-year period did not identify substantial improvement in early ND outcomes despite improvements in survival.[55]



• **Fig. 51.3** Magnetic Resonance Imaging Patterns of Brain Injury in Congenital Heart Disease. (A, B) Moderate white matter injury (WMI) in a newborn with hypoplastic left heart syndrome (HLHS) is seen on sagittal T1 images in the postoperative scan. WMIs appear as small focal areas of T1 hyperintensity (brightness). (C, D) Term newborn with HLHS imaged postoperatively at day 17 of life, after a modified Norwood procedure. A small middle cerebral artery distribution infarct is seen as cortical T2 hyperintensity (*arrows* in C) and corresponding reduced diffusion (*arrows* in D) in the right parietal–occipital lobe. (E, F) Term newborn with transposition of the great arteries imaged preoperatively after a balloon atrial septostomy. A single focus of T1 hyperintensity is seen in the periatrial white matter on the coronal sequence (E). This same focus has reduced water diffusivity on the average diffusivity map (F, dark spot). This spot is larger than the typical solitary white matter lesion and may represent a small embolic stroke.

Risk Factors for Postoperative Brain Injury

Risk factors for postoperative brain injury include hypotension and hypoxemia related to low cardiac output syndrome, defined as a combination of clinical signs (tachycardia, oliguria, cold extremities, or cardiac arrest) and a greater than 30% difference in arterial–mixed venous oxygen saturation or lactic acidosis. Multiple studies have identified hypotension as a risk factor for new postoperative WMI, including low systolic blood pressure on admission, low mean blood pressure during postoperative day 1, and low diastolic blood pressure during postoperative days 1 to 2.[42,56]

TABLE 51.1 Risk Factors for Brain Injury

Preoperative	Intraoperative	Postoperative
Low arterial hemoglobin saturation	Prolonged total circulatory arrest (>40 min)	Low blood pressure
Length of time to surgery	Decreased cerebral oxygen saturation (NIRS)	Low arterial PaO_2
Catheter-based procedure (e.g., balloon atrial septostomy)	Cardiopulmonary bypass strategy (regional cerebral perfusion)	Prolonged cerebral regional oxygen saturation (NIRS <45% for >3 h)
Preoperative base deficit	Air or particulate emboli	Morphologically immature brain (total maturation score)
Preoperative cardiac arrest	Inflammation	Single ventricle physiology
Morphologically immature brain (total maturation score)		
Male sex		
Aortic atresia		

NIRS, Near-infrared spectroscopy; *PaO_2*, partial pressure of oxygen.

TABLE 51.2 Magnetic Resonance Imaging Evidence of Preoperative Brain Injury in Newborns With Congenital Heart Disease

Study	Sample	CHD	Findings	Risk Factors
Mahle et al. 2002[39]	CHD = 24	Mixed	PVL = 16% Infarct = 8% Elevated brain lactate = 53%	N/A
Miller et al. 2004[40]	CHD = 10 Control = 5	TGA	Brain injury (stroke) = 40% Elevated brain lactate = 2.7 × higher than controls	N/A
Licht et al. 2004[41]	CHD = 25	Mixed	PVL = 28%	• Decreased cerebral blood flow • Hypercarbia
McQuillen et al. 2007[42]	CHD = 62	Mixed	WMI = 18% Stroke = 21% IVH = 8%	• Low Apgar score at 5 min • BAS
Petit et al. 2009[43]	CHD = 26	TGA	PVL = 38%	• Lower preoperative oxygen saturation • Longer time to surgery
Andropoulos et al. 2010[44]	CHD = 68	Mixed	WMI = 16% Infarct = 18%	• Low total maturation score (brain immaturity)
Glass et al. 2011[45]	CHD = 127	Mixed	WMI = 24%	• Bloodstream infection in TGA subjects
Goff et al. 2013[46]	CHD = 57	HLHS	PVL = 19%	• Male sex • Aortic atresia • Low total maturation score (brain immaturity)
Peyvandi et al. 2016[47]	CHD = 153	Mixed	WMI = 24% Stroke = 20% Hypoxic–ischemic = 1%	• Postnatal diagnosis of CHD

BAS, Balloon atrial septostomy; *CHD*, congenital heart disease; *HLHS*, hypoplastic left side heart syndrome; *IVH*, intraventricular hemorrhage; *N/A*, not applicable; *PVL*, periventricular leukomalacia; *TGA*, transposition of the great arteries; *WMI*, white matter injury.

Studies utilizing cerebral near-infrared spectroscopy have also suggested that low regional cerebral oxygen saturation (<45%) for more than 3 hours was a risk factor for new ischemic injury.[57] In general, patients with single ventricle lesions carry a higher risk of postoperative brain injury, which correlates with higher postoperative hemodynamic instability, morbidity, and mortality.

Brain Immaturity as a Risk Factor for Brain Injury

The relationship between brain immaturity and brain injury has been explored in the literature although with variable results. Qualitative MRI (TMS) techniques have suggested an association between brain immaturity and the risk of preoperative and

postoperative brain injury.[44] However, quantitative MRI techniques (DTI and MRS) have demonstrated an association between brain immaturity and the risk of preoperative brain injury but not postoperative brain injury.[58] Both studies suggest that brain immaturity may be a risk factor for brain injury, with slightly different results. These differences likely relate to the method of measuring brain development. MRS and DTI exhibit changes with brain development and can be influenced by acquired brain injury based on severity, timing, and mechanism. Although overt brain injury has not been identified in the fetal period, indolent brain injury may be present influencing developmental changes and further injury in the preoperative and postoperative period.

Neurodevelopmental Outcomes

There is an increasing body of literature reporting short-term and long-term ND outcomes in patients with various types of CHD. Despite heterogeneity among these reports because of various methodologies for age at follow-up, assessment tools used, and type of cardiac lesion, these outcome data have provided us with useful knowledge on ND outcomes and provide the foundation for understanding imaging and clinical data in the fetal and neonatal period. Longitudinal studies are needed to assess the typical trajectory of brain growth and pattern of injury as these children grow older.

Immediate Neurologic Outcomes After Surgical Repair

Although the prevalence of overt neurologic dysfunction postoperatively has declined, a small percentage of infants continue to exhibit neurologic abnormalities, including clinical seizures, hypotonia, and asymmetry of tone. Combining several reports, the prevalence of postoperative subclinical seizures appears to be 4% to 11% and has been detected by continuous electroencephalogram monitoring in up to 20% of patients in the immediate postoperative period.[50,59–63] In a more recent study, a large percentage of young infants had evidence of ND abnormalities before surgery, suggesting that fetal and neonatal factors play a significant role in brain injury and development.[64] In addition, there is a higher prevalence of feeding abnormalities (swallow or suck dysfunction) in neonates undergoing cardiac surgery, which may be an early indicator of abnormal neurodevelopment later in life.[65]

Short-Term and Long-Term Neurologic Outcomes After Surgical Repair

Although there have been several reports of ND outcomes in a mixture of CHD types, it is important to recognize that outcomes can vary significantly by the cardiac lesion. Outcome studies have been carried out in two specific high-risk patient populations: those with d-TGA and those with defects requiring single ventricle palliation (i.e., HLHS).

In patients with d-TGA after an arterial switch operation, the Boston Circulatory Arrest Trial (described previously) has demonstrated that intelligence quotient (IQ) scores, although below the national average, fall within the normal range at 8 and 16 years of age.[8,9] However, d-TGA patients at 16 years of age continue to exhibit deficits in academic achievement, memory, executive function, visual-spatial skills, attention, and social cognition. A high percentage of children were judged to have behavioral problems by parents and teachers; 37% required remedial education services, and 10% had repeated a grade. Interestingly, in a multivariable regression model, socioeconomic status was a strong predictor of ND outcome in these patients at 16 years of age. These studies demonstrate that early ND testing may underestimate the ultimate burden of functional impairment in subjects with subtle but diffuse brain injuries.

Patients with single ventricle lesions, particularly HLHS, are at the highest risk of ND abnormalities based on the underlying physiology, hemodynamics, and complexity of surgical repair. These children must undergo a series of palliative surgical procedures, typically culminating in a Fontan operation. Various studies have demonstrated that children with HLHS tend to have lower IQs (typically below the general population mean) and problems with visual–motor skills, expressive language, attention, and externalizing behavior. In the largest series reported to date, children with HLHS at 12 months of age had a median MDI of 90 (range 50 to 129) and a lower PDI of 73 (range 50 to 117).[4] Risk factors for poor outcomes were mainly patient-specific and included genetic syndromes, earlier gestational age at delivery, and perioperative instability. Other studies have assessed the impact of growth and feeding issues on ND outcomes. Infants requiring device-assisted feeding and with lower weight, length, and head circumference at 3 months of age were at increased risk for ND delay at 6 and 12 months of age.[65] Long-term studies have identified persistent ND abnormalities in adolescents with Fontan physiology, including lower IQ and abnormal neuropsychological testing compared with a normative population.[31]

Genetic Susceptibility to Neurodevelopmental Abnormalities

An important point to consider is the impact of genetic comorbidities on ND outcomes in the context of CHD. Approximately one-third of children with CHD have an underlying genetic disorder such as aneuploidy or deletion syndromes (i.e., 22q11.2 deletion syndrome). Studies have shown greater impairments in cognition, IQ, motor skills, hearing, and visual skills in those children compared with children with CHD who do not have genetic comorbidity.[66,67] Several studies have been performed in children with CHD who also have 22q11.2 deletion syndrome. This microdeletion encompasses three megabases of DNA, representing 30 to 40 genes, and the syndrome is highly heterogenous with a variable phenotype. These patients have also been noted to have psychiatric disorders such as anxiety, attention deficit hyperactivity disorder, and psychosis. Interestingly, the presence of CHD does not change the prevalence of these psychiatric abnormalities.[68]

Studies have also identified patient-specific genetic risk factors that can modify ND outcomes. This has been described for apolipoprotein E (APOE) alleles in which the ApoE ε4 allele is associated with adverse outcomes in many adult conditions (e.g., Alzheimer's disease, traumatic brain injury, stroke, and subarachnoid hemorrhage). This has been explored in infants with CHD, and the ApoE ε2 allele is associated with worse outcomes.[69] Finally, in a large study of children with various forms of CHD, exome sequencing of trio samples (including the mother and father) revealed a higher burden of de novo deleterious mutations in genes with high heart and high brain expression, particularly in those that endorsed any degree of developmental impairment.[70]

Overall, more than 30% of newborns with CHD have a genetic anomaly. Ten percent of newborns have de novo single nucleotide variants (SNV) causing CHD, and this fraction increases to more than 20% in the setting of neurodevelopmental disability. Interestingly, SNVs most commonly occur in genes involving primary cilia or chromatin-modifying pathways.[71] Thus, it is likely that multiple genes and environmental factors influence ND outcomes in these patients.

Neurodevelopmental Signature of Congenital Heart Disease

Although children with complex CHD have intelligence testing results in the range of the normal population, there is a prevalence of pervasive but subtle cognitive problems that some have termed *a neurodevelopmental signature of complex congenital heart disease*. These children show behavioral and attention problems that are often not detected on standardized testing but result in poor school performance. Among a large cohort of children who were followed prospectively after undergoing cardiac surgery as infants, abnormalities on a neurologic exam at school entry were present in 28%, although less than 5% were severe. Most of the abnormalities involved fine motor coordination and tone. Cognitive difficulty and behavioral problems were identified in 30%. Certainly, survivors of CHD exhibit a "developmental profile" that changes in each stage of life and affects the quality of life and the ability to perform everyday tasks.[64] It is important to note that the American Heart Association released a statement paper recommending serial ND assessments for at-risk children with CHD.[67] This includes neonates requiring open heart surgery (before 30 days of life) and other cyanotic heart lesions such as tetralogy of Fallot that may not require a neonatal operation. In addition, serial evaluation is recommended whenever CHD is seen in combination with prematurity (<37 weeks gestation), developmental delay recognized in infancy, suspected genetic anomaly, history of extracorporeal life support, heart transplantation, the need for cardiopulmonary resuscitation, prolonged perioperative hospitalization, perioperative seizures, and abnormal neuroimaging findings.

Other populations with an increased risk of neurologic abnormalities include the rising number of premature infants with CHD. Rates of CHD are higher in premature newborns, and mortality and morbidity of CHD increase with decreasing gestational age at birth.[72,73] Both prematurity and CHD are independent risk factors for neurodevelopmental abnormalities; thus, as surgical techniques evolve and allow for intervention on premature and smaller neonates, attention must be paid to neurologic outcomes, including rates of brain injury and neurodevelopmental outcomes, to identify optimal management strategies for this unique group of patients.

Conclusion

Advances in prenatal diagnosis and care and cardiovascular surgical techniques have contributed to the overall increased survival of neonates born with CHD. Given this improvement in survival, greater emphasis is now being directed toward improving ND outcomes. More specifically, understanding the predictive value of imaging studies both in the fetus and neonate provides an opportunity for potential intervention trials to improve outcomes among this patient population. In addition, as the prenatal detection of CHD increases, informing families about potential noncardiac adverse outcomes is critical to ensure recognition and timely intervention for ND abnormalities.

52 Central Nervous System Development

BOBBI FLEISS, HELEN STOLP, VALERIE MEZGER, AND PIERRE GRESSENS

KEY POINTS

- The brain of the preterm and term newborn infant is actively developing, with several key steps occurring during the third trimester, such as the end of neuronal migration, programmed cell death, the generation of axons and dendrites, and the first wave of synaptogenesis.
- These processes are controlled by genetic programs but are also very sensitive to environmental factors.
- Epigenetic mechanisms appear to play a central role in these processes, with long-term and potentially trans-generational consequences.

Brain development results from the accomplishment of successive genetic programs during the different ontogenic stages. It starts with the individualization of the neural plate at the beginning of the third week post-conception and is mostly complete by adolescence. However, some neuronal production persists lifelong. This late neurogenesis has been well described at the level of the olfactory bulbs and the dentate gyrus of the hippocampus, but its importance to the associative neocortex remains to be shown.

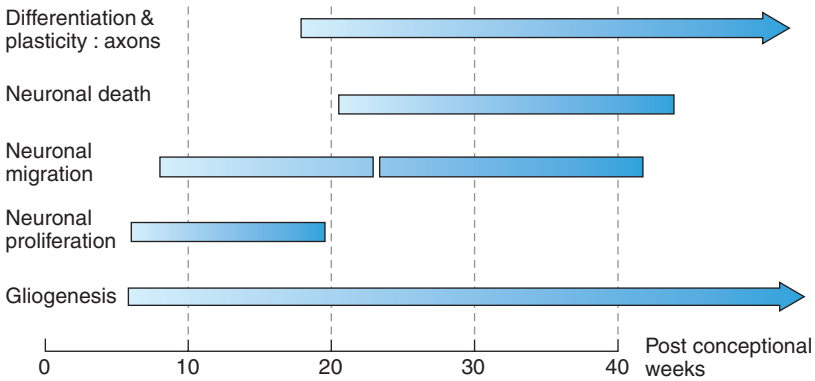
The principal stages of brain development can be summarized as follows: induction of the neuroectoderm, formation of the neural tube followed by the telencephalon, neurogenesis (production of neuronal progenitors and then of mature neurons), neuronal migration, programmed neuronal death, generation of neurites (axons and dendrites), elimination of superfluous neurites, synaptogenesis, elimination and selective stabilization of synapses, angiogenesis, gliogenesis (production of astrocytes and oligodendrocytes), and myelination (Fig. 52.1). These different stages of the development and maturation of the brain are controlled by intrinsic factors (determined genetically) and modulated by extrinsic environmental factors. This modulation by environmental factors could bring epigenetic mechanisms into play. The perturbation of the unfolding of any of these different stages of brain development leads to a deficit in brain growth and/or brain malformations. The functional consequences to the child depend on the developmental stage in question. This raises the notion of "critical periods," which we will touch on throughout this chapter; a critical period is a maturational stage in the lifespan of an organism during which the nervous system is especially sensitive to certain environmental stimuli.

Neuronal Production and Migration

The expansion of the cortex occurs through two processes that take place in parallel: a lateral expansion process that allows the surface of the cortex to grow, and a radial expansion process that leads to an increase in its thickness. The total number of neurons in a mature human brain is estimated at between 3 and 100 billion. The cortex is initially generated from a radially oriented monolayer of proliferative neuroepithelial cells lining the walls of the lateral ventricles—the ventricular zone (VZ). Around the seventh gestational week in humans a second proliferative zone, the inner subventricular zone (SVZ), appears, derived from precursors in the VZ.[1] The cells of the inner SVZ do not adopt a radial conformation. More recently, a third proliferative zone has been identified in the developing neocortex: the outer SVZ, which appears in humans around gestational week 11. In humans, this outer SVZ displays prolonged proliferation. This difference in the behavior of neuronal precursors has been hypothesized to explain the impressive evolutionary expansion and folding observed in the surface of the neocortex.

These proliferative zones, situated on the dorsal side of the lateral ventricles, give rise to the excitatory (glutamatergic) neurons of the different cortical layers (the cortex in mammals consists of six layers), as well as potentially (as this is still controversial and seems to be species/cell subtype-dependent) a portion of inhibitory neurons (GABAergic interneurons). The other inhibitory neurons derive from another proliferative structure located on the lateral wall of the lateral ventricles, the ganglionic eminence (which is also the source of thalamic neurons) and one located in the preoptic area. Migrating neurons can adopt a radial trajectory by migrating in contact with specialized glial cells, the radial glia, which serve to guide them.[2,3]

After exiting the mitotic cycle, neurons migrate from the proliferative zones toward the future cortex.[1,4–8] The first wave of migratory neurons forms the primitive cortical plate or preplate (Fig. 52.2). The second wave of migratory neurons then splits this primitive plate into two, around gestational week 7, giving rise to a three-layered structure: layer I, which contains the Cajal-Retzius neurons, is located just below the meninges, layer VI, which contains neurons that have already completed their migration, and finally the subplate—a transient structure located below the future neocortex. Consecutive waves of migratory neurons subsequently cross the subplate and the cortical layers already in place, but stop



• **Fig. 52.1** The major ontogenic events taking place in the human neocortex.

Arrows and green circles indicate migrating neurons.

below layer I, thus successively forming layers V, VI, III, and II along what is known as an "inside-out" gradient.[9] Until recently, it was thought that the migration of neurons to the neocortex was complete by around gestational week 24.[10] However, recent studies suggest that GABAergic interneurons continue to be added to the neocortex practically until term.[11] In animal models of encephalopathy of prematurity and in human post mortem tissues of preterm neonates, a rarefaction of some subclasses of cortical interneurons has been demonstrated.[12–14]

Several molecules involved in controlling neuronal migration and their navigation to the appropriate destinations have been identified. These molecules can be schematically divided into four categories.[15,16]

1. Cytoskeletal molecules, which play an important role in the initiation and progression of neuronal movement (extension of the apical process and nucleokinesis). Molecules controlling initiation include Filamin-A (an actin-binding protein that is implicated in periventricular nodular heterotopias) and Arfgef2 (a molecule that plays a role in vesicular trafficking and is involved in periventricular nodular heterotopias associated with microcephaly). Among the molecules controlling progression are Doublecortin (a microtubule-associated protein—MAP—implicated in double cortex syndrome), Lis1 (a MAP implicated in type 1 lissencephaly and Miller Dieker syndrome) and Alpha-1 Tubulin (involved in the formation of tubulin heterodimers).
2. Signaling molecules that play a role in lamination, such as Reelin (a glycoprotein implicated in a human disorder combining lissencephaly with cerebellar hypoplasia).
3. Molecules modulating glycosylation that provide a stop signal to migrating neurons, such as POMPT1 (protein *O*-mannosyltransferase, associated with Walker-Warburg syndrome), POMGnT1 (protein *O*-mannose beta-1,2-N-acetylglucosaminyltransferase, implicated in muscle-eye-brain disease), and Fukutin (a glycosyltransferase implicated in Fukuyama congenital muscular dystrophy). These three human disorders display type 2 lissencephaly.
4. In addition to these three principal groups of molecules, neuronal migration can be modulated by other factors such as certain neurotransmitters (glutamate and GABA), molecules derived from peroxisomal metabolism, and certain environmental factors (inflammation, ethanol, and cocaine).

Programmed Neuronal Death

Depending on the brain region under consideration, 15% to 50% of the neurons initially produced die through a physiological process termed programmed cell death or apoptosis. Approximately 70% of the neurons that disappear seem to die between gestational weeks 28 and 41 in humans.[17]

Programmed cell death is a complex mechanism governed by a balance between cell death- and survival-inducing signals, genetic programs involved in cell death or survival, effectors of cell death, and inhibitors of these effectors.[18] Cells that have initiated programmed cell death eventually go onto to be phagocytosed by neighboring glial cells (microglia) without inducing inflammatory phenomena or scar formation. This process is facilitated by changes in the composition of the apoptotic cell membrane ("eat me signals") which are sensed by the microglia which occurs very early in the apoptotic process. Within the cell death process, the activation of caspases (proteolytic enzymes) in the form of a cascade is a key stage that culminates in DNA fragmentation and the death of the neuron. In addition, it is reported that direct interaction between healthy neurons and microglia can initiate cell death programs or even engulfment of the live cell, which is then "digested" by the microglia in a process called phagoptosis.[19]

Electrical activity appears to be a critical factor for neuronal survival. During the peak period of brain growth in rodents, the administration of substances that block electrical activity induces a serious aggravation of developmental neuronal death in various brain regions. These substances include NMDA receptor inhibitors (MK-801 or ketamine), GABA-A receptor agonists such as antiepileptics (phenytoin, phenobarbital, diazepam, clonazepam, vigabatrin, and valproic acid), and anesthetics (a combination of midazolam, nitric oxide, and isoflurane).[20]

Organization of the Central Nervous System

Subplate Neurons

Subplate neurons constitute a transient structure during brain development.[21] They are generated around gestational week 7, and the subplate itself appears around gestational week 10. This structure, located under the neocortical plate, reaches its maximum thickness between gestational weeks 22 and 36.

Subplate neurons express various neurotransmitters, neuropeptides, and growth factors. They receive synapses and form connections with cortical and subcortical structures. These neurons play an important role during brain development: (1) they produce axons that project to the internal capsule, which act as guides for neurons from layers V and VI; (2) between gestational weeks 25 and 32, they produce axons for the corpus callosum; and (3) they constitute a "waiting zone" for thalamocortical axons (with which they establish transient? synapses) before the latter invade the neocortical plate to reach layer IV. This waiting area is necessary for the adequate targeting of thalamocortical afferents.

Subplate neurons may be destroyed in preterm newborns presenting with lesions of the periventricular white matter,[22] findings which have been confirmed in animal models of periventricular white matter injury.[23,24] This damage to the subplate could participate in the thalamocortical connection anomalies demonstrated by MRI in preterm infants,[25] as well as in the associated cognitive and/or motor disorders.

Axonal and Dendritic Growth

The final morphology of the mature neuron and the formation of connections between neurons depend on complex cellular dendrite-axon interactions.[26,27] Maturing neurons develop axons and dendrites that extend as a result reorganization of the cytoskeleton, based on intrinsic and extrinsic cues. Many of the extrinsic cues include secreted chemoattractant or chemorepulsive factors, and adhesion molecules on target neurons that facilitate synapses formation. The interaction between these different ligands and their receptors leads to modifications in calcium levels at the growth cone/dendritic tip, which play a key role in motility and orientation. This ontogenic stage occurs largely, but not exclusively, during the second half of pregnancy, and extends into the postnatal period.

The formation of corticospinal projections occurs at early stages from the subplate, and then from neurons that populate the deep cortical layers (V and VI). Corticothalamic projections also appear, from both the subplate and the deep cortical layers. Corticocortical projections appear later.

A number of transcription factors (e.g., Ctip2, Satb2, Fezf2) regulate the commissural, corticothalamic, and corticospinal projections of the cortex.

Dendritic arborization progresses at slightly different rates for each neuronal subtype, though the stereotypical early branch formation is generally established in the third trimester. Even though genetic programs control the molecular mechanisms of axonal and dendritic growth and determine the initial pattern of these connections, experience and the environment then sculpt this global pattern to generate the final set of connections (through brain plasticity).

The processes underlying cortical expansion are still not fully understood,[28,29] but recent advances have strengthened a link to differences in neurite density in addition to neuronal production.[30]

Synaptogenesis

In the occipital neocortex of the monkey, five successive waves of synaptogenesis have been described.[31] Based on data obtained from the human occipital cortex,[32] the following chronology has been proposed for the human cortex: (1) a first phase starting at gestational week 6 to 8 and limited to the deep layers, such as the subplate; (2) a second phase starting at gestational week 12 to 17, with relatively few synapses produced in the cortex; (3) a third phase starting at around the middle of pregnancy and finishing at around the eighth month after birth (this phase is characterized by a rate of production of new synapses estimated at around 40,000 per second in the monkey); (4) a fourth phase that extends up to puberty and is also characterized by a high rate of synapse formation; and (5) a last phase that extends up to adulthood but is somewhat masked by the significant loss of synapses with age. Experimentally, the two first phases are not influenced by the deprivation of sensory stimuli. The third phase is partly dependent on sensory input whereas the fourth phase is strongly controlled by sensory stimuli and experience.

The concept of synaptic stabilization (by the elimination of non-stabilized synapses) was first proposed by Changeux and Edelman.[33] During brain development, there is a systematic overproduction of labile synapses in successive phases that lead to redundant connections in a fairly random manner. This stage is mainly controlled by genetic factors. Each wave of overproduction is followed by a period of stabilization of synapses that are

of functional value and the elimination of redundant or useless ones by glial cells. This period of stabilization and elimination is strongly influenced by environmental stimuli and experience. In this model, the moderate increase in the number of genes involved in synaptogenesis during the course of evolution has resulted in a richer substrate upon which the environment and experience act to generate a more complex network.

Glial Proliferation, Differentiation, and Myelination

Astrocytes

Neocortical astrocytes are of two origins.[34] At the end of neuronal migration, radial glial cells (which are both neural stem cells and play a role in guiding migrating neurons) are transformed into astrocytes, which then reside in the deep cortical layers and the white matter. In contrast, the astrocytes of the superficial cortical layers are primarily derived from glial precursors that multiply in the SVZ and then migrate into the cortex.

In the human neocortex, astrocytic proliferation begins around gestational week 24, with a peak around gestational week 26 to 28. The exact date at which the production of astrocytes ends is not known, but it could be supposed that the major part of astrocytic production is over by the end of a normal pregnancy. This peak in the production of astrocytes around gestational weeks 26 to 28 could be of particular importance for preterm newborns. Indeed, astrocytes play several important roles, including in axonal guidance, the stimulation of neuronal growth, synapse formation, the transfer of metabolites between blood vessels and neurons, the establishment of the pattern of certain brain structures, the production of extracellular matrix components, the production of trophic factors, neuronal survival, myelination, and maintenance of the blood-brain barrier. For example, experimentally blocking astrocyte production temporarily in the neocortex of rodents induces an increase in programmed cell death in neurons and long-term changes in neocortical synaptic equipment.[35] In addition, recent studies show that astrocytes can acquire different phenotypes which depend upon the physiological or pathological conditions they are exposed to.[36] These different phenotypes can have beneficial or toxic effects on neighboring cells.

Oligodendrocytes and Myelination

Oligodendrocytes can be divided into four types depending on their degree of maturation[37]:

1. Oligodendrocyte precursors that arise from the SVZ are bipolar and mitotically active; their differentiation into preoligodendrocytes occurs during their migration into the future/putative white matter.
2. Preoligodendrocytes that are multipolar cells that retain their proliferative capacity. This second cell type is predominant in the periventricular white matter during the second half of pregnancy.
3. Immature oligodendrocytes that are multipolar cells that appear during the third trimester and wrap axons in preparation for their myelination.
4. The last stage is their differentiation into myelinating and extremely multipolar mature oligodendrocytes.

The oligodendrocyte precursors and preoligodendrocytes, the predominant varieties in the brain of preterm newborns, are extremely vulnerable to injury caused by inflammatory mediators including oxidative stress, the excitotoxic cascade, and hypoxic-ischemic insults.[38] This death of preoligodendrocytes has been implicated in cystic periventricular leukomalacia. This type of severe lesion has progressively decreased in incidence and has been replaced by more diffuse lesions.[39] In this diffuse white matter lesion in preterm infants, the primary phenomenon is a blockade of oligodendrocyte maturation,[12,40,41] in which the hypoxia inducible factor (HIF)[42] and the Wnt[43] pathways play a role.

Myelination occurs during a prolonged period, persisting into childhood. The chronology and the degree of myelination vary according to the brain structure studied. There is no detectable myelination in the prosencephalon before the seventh month of pregnancy. Myelination in the telencephalon is most intense during the third trimester and postnatally and is mostly complete by the age of 2 to 3 years. The olfactory and auditory pathways and the sensorimotor cortex are the first to be myelinated, while projection and association pathways (in particular the prefrontal cortex) are the last.[44]

It is also worth noting that preoligodendrocytes are currently indistinguishable from another glial population—the polydendrocytes, or NG2 glia. Polydendrocytes give rise to oligodendrocytes, but these proliferative, lineage plastic, motile cells also play independent roles in reposes to injury and form unidirectional synapses with neurons.[45,46] However, very little is known about the function of these cells due to the current lack of specific tools with which to study them, an issue that should be a research priority for understanding brain development and health.

Microglia

Microglia constitute 5% to 15% of the total number of brain cells. Microglia are derived from a pool of embryonic myeloid precursors that arise from the yolk sac and infiltrate the developing brain, distinct from tissue resident macrophage.[47] They have distinct maturational stages, are self-renewing, and can live for up to 4 years in the human brain.[48] During the first trimester of pregnancy in humans, microglia have an amoeboid morphology that evolves progressively toward an intermediate and then a mature phenotype with a small cell body and long processes. Around mid-pregnancy, microglial populations are principally detected in white matter fascicles such as the internal and external capsules, the corpus callosum, and axonal fascicle crossings.[49] Experimental data support the hypothesis that these microglia play an important role in the origin of injury to these developing white matter tracts in preterm infants.[12,50,51]

Microglia play a suite of key roles in brain development,[52] including regulating synaptic and neurite pruning and thus connectivity, regulating programmed cell death including the formation of cortical layers, and the initiation of oligodendrocyte maturation impacting myelin production. Like astrocytes, microglia can acquire various phenotypes in response to injury or insult. Depending on brain regions and pathological conditions the microglia can be directly deleterious or can attempt to repair the brain. These diverse roles for microglia mean that during brain development they can directly injure the brain via their inflammatory responses, and by not being capable of participating in brain building due to "distraction" by inflammatory activation. This is particularly relevant for preterm born infants, as the systemic

inflammation commonly seen in these premature babies spreads to the brain and leads to the immune activation of microglia. This "double jeopardy" for the developing brain is an important contributor to the subsequent onset of cognitive and behavioral deficits seen in many formerly very premature babies.[53,54]

The Environment and Epigenetics

The different stages of brain development are finely controlled by diverse genetic programs. Nevertheless, experience, the environment, or stimulation can modulate, adapt, or refine the initial pattern to allow the brain to adjust to its environment. These adaptive processes are the expression of the great plasticity of the developing brain and allow the acquisition of new skills throughout childhood and adolescence. This is true even regarding developmental stages that were initially thought to be almost completely controlled by genetic programming, such as the proliferation of neuronal precursors. Experimental studies have shown that a maternal factor (vasoactive intestinal peptide or VIP) can change the proliferative capacity of these precursors by up to 20%.[55] However, the environment can also have deleterious effects on brain maturation. Preterm newborns are exposed to numerous stimuli that exist only sparingly or not at all with a fetus of the same age, such as excessive or repeated sensory stimulation, painful stimuli, stress, several neuroactive drugs, as well as the withdrawal of maternal and placental factors. Any environmental factor or drug that affects the brain is capable of altering a few or several stages of brain development.

The major mechanisms by which these environmental factors (positive or deleterious) act on brain maturation depend on the epigenetic events that control the organization and compaction of the genome, and thus the expression of genes. Chromosomes in eukaryotes result from a complex between DNA and a protein sheath called "chromatin," whose basic unit is the nucleosome, around which the DNA is wrapped. Each nucleosome is composed of an octamer of histones (H2A, H2B, H3, and H4). The compaction of DNA—and thus the accessibility of genetic information to the transcriptional machinery—is regulated on the one hand by covalent modifications of the DNA (including DNA methylation), and on the other by post-translational modifications that decorate the N-terminal regions (tails) of histones (acetylation, phosphorylation, and methylation). The combination of these two types of events governs the opening or closing of chromatin, and the transcription or repression of the gene in question.

The methylation of DNA at CpG islands located in transcriptional regulatory regions of genes represses their transcription by blocking the binding of transcription factors to the DNA.[56] DNA methyltransferases (DNMTs) catalyze the methylation of DNA by using S-adenosyl-methionine (SAM) as a methyl group donor. In addition, the information deposited by the methylation of the DNA is "read" and "translated" by proteins that recognize methylated DNA: the methyl-CpG-binding proteins (MBPs). These MBPs recruit histone-deacetylases, HDACs (and thus constitute the link between DNA methylation and the post translational modifications of histones), as well as other chromatin remodelers, and contribute to the establishment of transcriptionally inactive chromatin. The crucial role of histone acetylation in brain development is illustrated, for example, by the role of the histone-acetyl-transferase CBP, whose mutation in the heterozygous state is characteristic of Rubinstein-Taybi syndrome in humans, and leads to anomalies of cortical gyration, a reduction of white matter, and regional hypoplasia in association with intellectual disability.[57]

The level of DNA methylation is much higher in the brain than in other tissues and is essential for brain development in mouse models.[56] DNA methylation especially affects neuronal differentiation and survival and the neurogenesis/gliogenesis "switch." In humans, several syndromes with intellectual disability have a developmental origin linked to the DNA methylation pathway. This is the case with Rett syndrome, which is associated with mutations of the MBP MeCP2, and ICF syndrome (combined immunodeficiency, instability of the pericentromeric heterochromatin, and facial dysmorphia), caused by mutations in Dnmt3b.[57,58] The recent discovery that DNA methylation occurs in a non-CPG context, mostly in brain neurons after birth, has greatly modified our understanding of the role of this epigenetic mark in pathophysiological brain development, in particular for RETT syndrome.[59] There are numerous imprinted genes (i.e., those expressed uniquely from the paternal or maternal allele), which are affected by epigenetic regulation, expressed in the brain. The deregulation of their expression is often associated with intellectual disability. This is the case, for example, with the neurodevelopmental syndromes, Prader-Willi and Angelman syndromes.[60] Interestingly, fetal stress modifies the pattern of DNA methylation of key genes involved in neurodevelopment and the integrity of the adult brain (such as BDNF, Reelin, or GAD67).[57,61] Thus, women suffering from depression or anxiety-related disorders during the third trimester of pregnancy give birth to newborns in whom the promoter region of the glucocorticoid receptor gene is hypermethylated. Additionally, neuronal plasticity as well as learning and memory rely on the establishment of epigenetic events, and neuronal activity modifies patterns of DNA methylation.[62]

In summary, one could speak of "neuro-epigenetics" and all that this entails in terms of future therapeutic possibilities, since an in-depth knowledge of epigenetic events and their reversibility opens the door to the search for compounds that could remodel the epigenome of the brain and reprogram neural cells. In this context, diets poor in methionine (the precursor of SAM) and treatment with HDAC inhibitors (such as valproic acid) have been widely prescribed for psychiatric disorders such as schizophrenia or bipolar disorder.[57]

Congenital Malformations of the Central Nervous System

BENJAMIN DEAN AND DAN DOHERTY

KEY POINTS

- Brain malformations are a significant source of morbidity and death in neonates.
- Advances in imaging and genetics now allow more specific diagnoses.
- Early and specific diagnosis allows more precise prognostication, including improved monitoring for complications and treatment decisions.
- Early diagnosis and management of patients with brain malformations require multidisciplinary team management.

Prosencephalic Cleavage and Related Events

Normal Prosencephalic Development

The prosencephalon refers to the future forebrain, which includes the telencephalon and the diencephalon; these structures give rise to the cerebral hemispheres, thalamus, and hypothalamus. The prosencephalon develops after the closure of the anterior neuropore, through processes that induce the bifurcation of the rostral extent of the fluid-filled neural tube (Fig. 53.1) to form the right and left forebrain structures.[1] During the fifth and sixth weeks of development, the structure of the forebrain is defined by cleavage along three major planes. As the anterior neuropore is closing, the first major event is the formation of the optic vesicles and nasal placodes, separated along the *horizontal* plane. When the embryo has reached a length of about 5 mm, both anterior and posterior neuropores have closed, isolating the developing ventricular system from the amniotic fluid. The retinal and lens placodes also develop at this time. In the hindbrain, the cerebellum begins to form, along with somatic and visceral efferent nuclei, the common afferent tract, and the ganglia for most of the cranial nerves. At about day 32 of gestation, when the embryo is 5 to 7 mm long, the forebrain divides in the *sagittal* plane to give rise to the paired structures. Specific areas, including the hypothalamic, amygdala, hippocampal, and olfactory regions, are identifiable at this time. The third major event in forebrain development occurs shortly thereafter when the forebrain divides in the *coronal* plane. This event separates the telencephalon from the diencephalon, defining the epithalamus, subthalamus, and hypothalamus. During the remainder of the second and third months of gestation, multiple midline structures form, including the corpus callosum, anterior and hippocampal commissures, optic nerves, optic chiasm, and hypothalamus.

Disorders of Structures Derived From the Prosencephalon

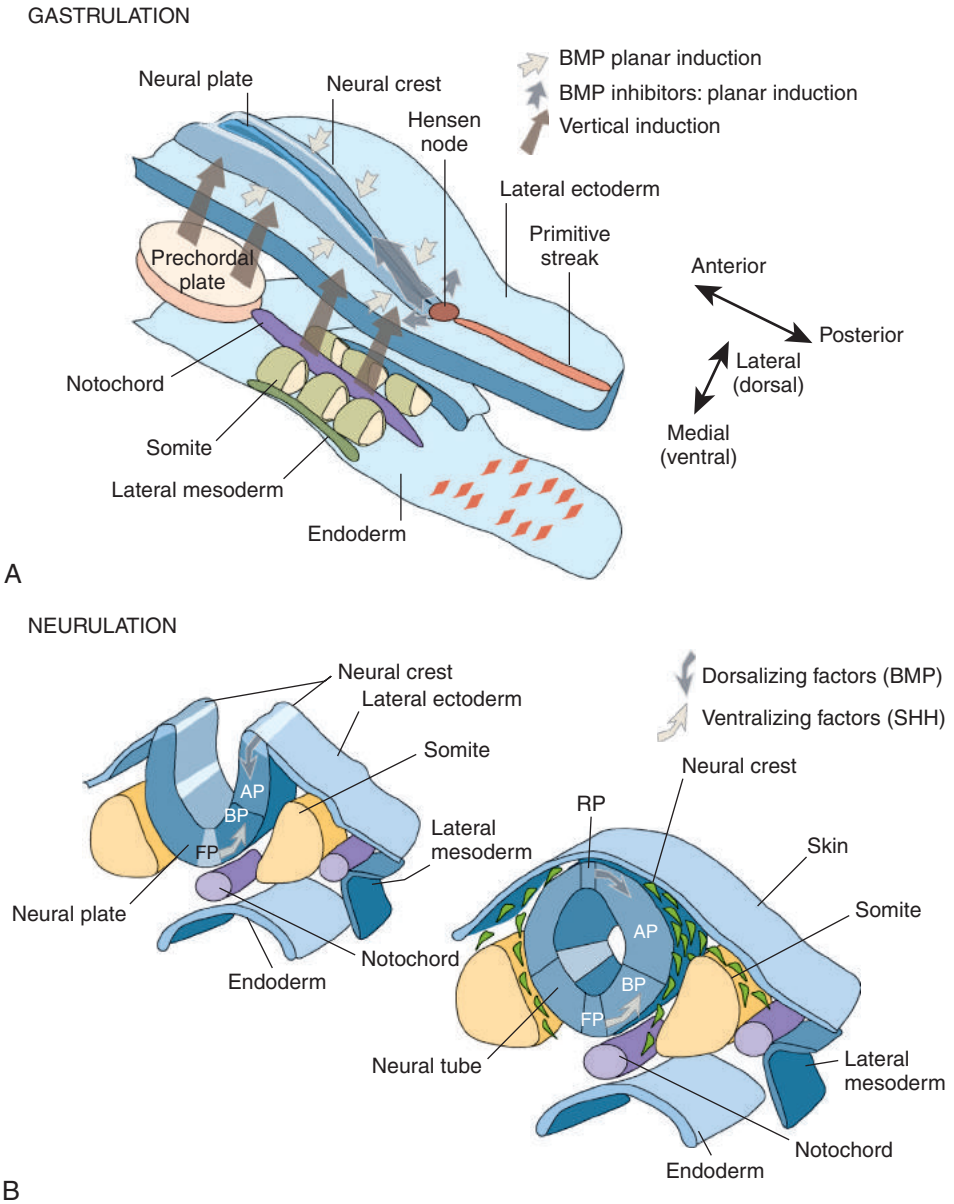
Disorders of development of the prosencephalon include the severe malformations: atelencephaly, aprosencephaly, and holoprosencephaly (HPE). Milder defects include agenesis of the corpus callosum (ACC), septo-optic dysplasia (SOD), and isolated absent cavum septi pellucidi (CSP).

Aprosencephaly and Atelencephaly

Aprosencephaly and atelencephaly are two rare and very severe cerebral malformations. In aprosencephaly, neither telencephalic nor diencephalic structures develop. In atelencephaly, there remains a rudimentary prosencephalon. Craniofacial abnormalities associated with this condition are secondary to deformation brought on by the absence of the telencephalon, rather than true malformation.[2] These disorders may result from possible autosomal recessive inheritance versus an abnormality of chromosome 13.[3] Aprosencephaly/atelencephaly has also been reported in a family with pathogenic variants in the *SIX3* gene, which has also been associated with HPE.[4] Typically, these are diagnosed prenatally by ultrasound and fetal magnetic resonance imaging (MRI).[5] Although considered "lethal" malformations, it is important for the neonatologist to be prepared for infants with severe malformations to live longer than expected and even go home from the hospital.

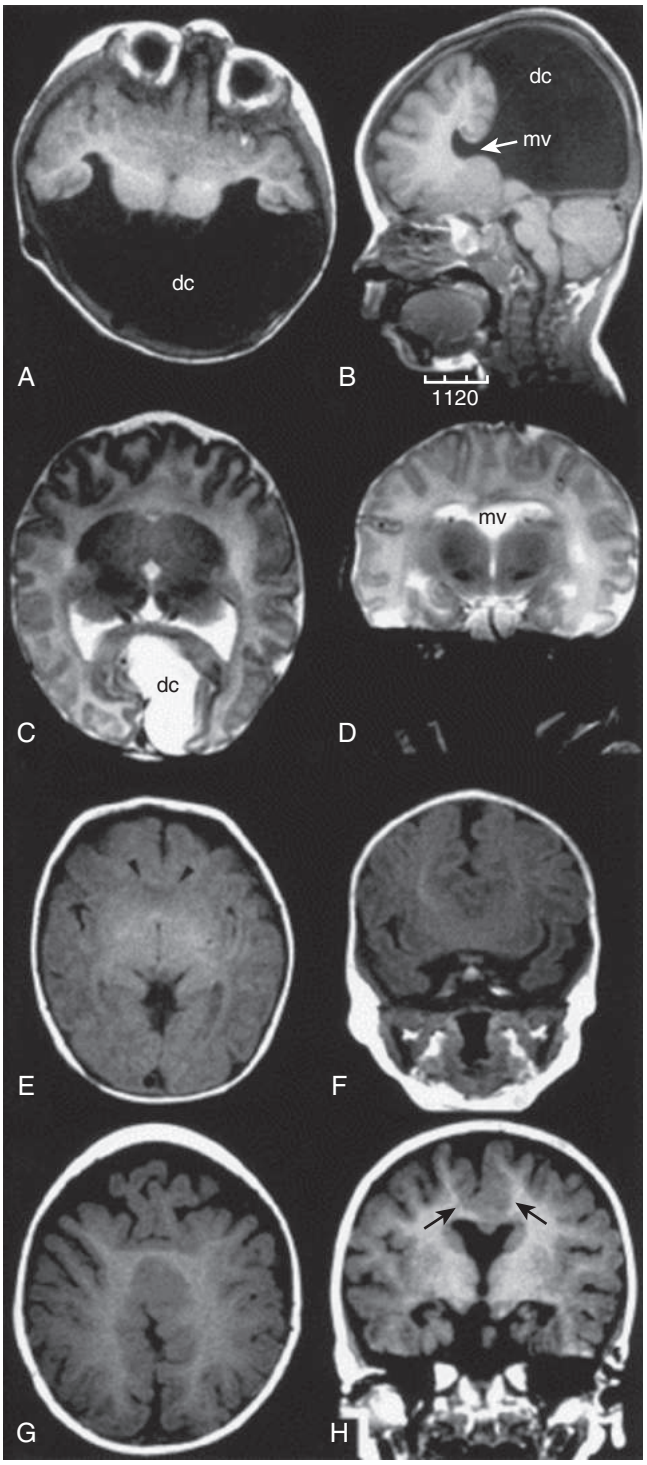
Holoprosencephaly

HPE represents a spectrum of defects in forebrain development and is the most common brain malformation,[6,7] although most affected fetuses are miscarried early in gestation. HPE represents a variable degree of incomplete separation of the prosencephalon along one or more of its three major planes during the third and fourth weeks of gestation (discussed earlier). The DeMyer classification scheme groups the degree of separation as "alobar," "semilobar," and "lobar" as well as a milder middle interhemispheric



• **Fig. 53.1** Formation of the Neural Tube. (A) During gastrulation, at the neural plate stage, dorsoventral polarity and early anteroposterior regionalization are defined by a process of vertical induction by fibroblast growth factor 8 and other factors *(long gray arrows)* derived from mesendoderm (notochord and prechordal plate). Planar induction occurs via bone morphogenetic proteins *(BMPs)* and BMP inhibitors that are derived from lateral ectoderm *(short light gray arrows)* and the Hensen node (*short dark gray arrows*) respectively. (B) The process of neurulation proceeds with the approximation of the neural folds toward the dorsal midline. Before the closure of the neural tube, neural crest cells delaminate and migrate from the neural folds. Dorsalizing factors (BMPs; *dark gray arrow*) derived from the dorsal midline roof plate *(RP)* and ventralizing factors (sonic hedgehog [SHH]; *light gray arrow*) from the floor plate *(FP)* establish dorsal-ventral gradients of these key signaling molecules that induce the formation of the alar plate *(AP)* and the basal plate *(BP)* from the lateral wall of the neural tube. (Adapted from Vieira C, Pombero A, García-Lopez R, et al. Molecular mechanisms controlling brain development: an overview of neuroepithelial secondary organizers. Int J Dev Biol. 2010;54:7–20; Courtesy Dr. Salvador Martinez, Institute of Neuroscience, Universidad Miguel Hernandez, San Juan de Alicante, Spain.)

variant subtype, also referred to as *syntelencephaly*[8]; however, HPE can be difficult to classify in a given patient. In alobar HPE (Fig. 53.2), a single anterior ventricle is contained within a holosphere with complete lack of separation of the prosencephalon. Alobar defects may be classified by fetal imaging findings. Depending on the severity of the defect, other midline structures such as olfactory bulbs/tracts, the corpus callosum, the anterior commissure, and the optic nerves may be affected. In addition, midline deep structures such as the basal ganglia, hypothalamus, and thalamic structures are fused, and vascular malformations may also be present.[9] The milder semilobar and lobar forms have distinct hemispheres and the presence of at least a portion of



• **Fig. 53.2** The Spectrum of Holoprosencephaly as Demonstrated by Magnetic Resonance Imaging. (A, B) Magnetic resonance imaging *(MRI)* of the brain in a patient with alobar holoprosencephaly. The T1-weighted axial image (A) reveals a lack of separation of the two hemispheres and deep gray nuclei. A large dorsal cyst *(dc)* is observed posteriorly. The T1-weighted sagittal image (B) reveals a midline monoventricle *(mv)* that communicates posteriorly with the dorsal cyst *(dc)*. (C, D) MRI of a patient with semilobar holoprosencephaly. The T2-weighted axial image (C) indicates separation of the hemispheres posteriorly but not anteriorly. Anterior horns of the lateral ventricles are absent, whereas the posterior horns are well formed and separated. Note the formation of a posterior dorsal cyst (dc). There is also an incomplete separation of the basal ganglia. The T2-weighted coronal image (D) reveals a lack of interhemispheric fissure and a monoventricle *(mv)*. (E, F) MRI of the brain in a patient with lobar holoprosencephaly. The T1-weighted axial image (E) reveals that the two hemispheres are fairly well separated as manifested by the presence of an interhemispheric fissure both anteriorly and posteriorly. Note that the frontal horns of the lateral ventricles are only rudimentary *(black arrowheads)*. The T1-weighted coronal image (F) documents incomplete separation of the inferior frontal lobes near the midline. (G, H) MRI of the brain in a patient with the middle interhemispheric variant of holoprosencephaly. The T1-weighted axial (G) and coronal (H) images demonstrate the continuity of gray matter in the posterior frontal lobes across the midline *(black arrows)*. (From Hahn JS, Plawner LL. Evaluation and management of children with holoprosencephaly. *Pediatr Neurol*. 2004;31:79–88.)

the corpus callosum. In "semilobar" HPE, the frontal lobes are more than 50% fused, and the thalami and hypothalamus may also be fused. "Lobar" HPE is associated with the fissure along almost the entire midline, separation, or near separation, of the thalami and absence of the CSP. A middle hemispheric variant has been described in which the posterior, frontal, and parietal lobes fail to separate, with an absence of the body of the corpus callosum.[10,11] Typically, patients with the middle interhemispheric variant are not identified in the neonatal period unless the variant was diagnosed prenatally. Finally, a septo-preoptic type has been suggested, where the nonseparation is restricted to the septal and preoptic areas.[12]

Diagnosis

With the advent of prenatal ultrasonography, patients with HPE are usually identified before birth. Alobar HPE may be identified as early as 10 weeks' gestation and can be reliably identified by 14 weeks. False-positive findings by ultrasonography are common,[13] so fetal MRI can be very useful for clarifying the diagnosis and severity of the malformation, particularly if pregnancy

termination is being considered. Subtle findings such as the absence of CSP may suggest the milder forms of HPE, although absent CSP can be isolated or associated with ACC.[9] Given the high rate of chromosome abnormalities seen in HPE (25% to 50%), amniocentesis for chromosome array and possibly DNA sequencing is indicated.[12,14]

Clinical Features

Up to 80% of children with HPE have a craniofacial anomaly.[12] The findings may range from cyclopia (a single central eye) with a nose-like structure (proboscis) above the eye, to cebocephaly (a flattened single nostril situated centrally between the eyes), to median cleft lip. Mild cases may have a single central incisor or hypotelorism. The concept of "the face predicts the brain," refers to the fact that more severe facial malformations are often associated with more severe brain malformations; for example, patients with alobar HPE can have normal facies, while those with lobar or semilobar HPE can have severe facial malformations.[8,15,16]

Newborns with HPE present with low tone and microcephaly. However, the microcephaly may be obscured by a co-occurring hydrocephalus due to the blockage of cerebrospinal fluid (CSF) flow through the fused thalami[17]; these cases are often associated with a large dorsal cyst.[18] Ventriculoperitoneal shunts can relieve symptoms of increased intracranial pressure.[19] Over time, patients may develop spasticity and dystonia. Oromotor dysfunction is frequent, and many children with HPE require tube feedings.

As with other midline brain defects, endocrinologic abnormalities are very common. Diabetes insipidus occurs in up to 70% of patients, with hypothyroidism, hypoadrenocorticism, and growth hormone deficiency being less common.[20] These endocrine abnormalities can develop over time, requiring periodic monitoring. Hypothalamic dysfunction may also cause irregularities of sleep, temperature regulation, appetite, and thirst.

Approximately 40% of children with HPE have epilepsy, but one-third of these will have intractable epilepsy.[16,19] Seizures may also be provoked by endocrinologic abnormalities such as hypernatremia or hypoglycemia. Given the range of possible medical issues, a multidisciplinary approach to the care of these children is necessary, including continued surveillance for future complications such as hydrocephalus, seizures, and pituitary insufficiency.

Prognosis is related to the severity of the defect, the involvement of other organ systems, and the genetic cause.[9] Fetal or neonatal death is typical for most individuals with chromosome abnormalities.[21] In contrast, more than 50% of cytogenetically normal patients with all types of HPE are alive at 12 months.[7,22] Survival into late adolescence and adulthood has been reported.[16,19]

Epidemiology and Etiology

The live birth prevalence of HPE is 1 in 10,000 to 1 in 20,000.[21,23–25] The prevalence is higher in miscarried embryos and fetuses, representing as many as 1 per 250 pregnancies.[26]

The cause of HPE is multifactorial, with both genetic and environmental factors appearing to contribute to the variable spectrum of presentations.[27,28] Up to 45% of HPE is caused by chromosomal abnormalities detectable by standard karyotyping.[9] The most common chromosome abnormalities are trisomies 13 and 18.[29] Chromosome microarrays can identify smaller copy number variants in 10% to 20% of individuals with HPE with normal karyotypes.[30] Pathogenic variants in at least 14 genes have been associated with HPE, accounting for up to 25% of syndromic forms (e.g., Smith–Lemli–Opitz, Meckel, Rubenstein–Taybi, Kallman, and Pallister–Hall syndromes).[28] Six genes have been well established to cause nonsyndromic HPE: *SHH, ZIC2, SIX3, TGIF, GLI2*, and *PTCH1*. *SHH* accounts for up to 40% of familial cases of HPE.[26,31]

Genotype-Phenotype Variability

HPE is characterized by extreme intrafamilial variability. The same loss-of-function pathogenic variant can be found in asymptomatic or mildly affected family members as in family members who are severely affected. Incomplete penetrance can result in "microforms," including hypotelorism, midface hypoplasia, or a single central incisor.[32] One explanation for these observations comes from studies suggesting that the mode of inheritance for HPE may be multigenic,[33] though examples of digenic, "double hit," cases are quite rare.[34] This suggests a certain complexity to genetic modifiers of known pathogenic variants. Furthermore, the severity of expression of the HPE phenotype throughout a given family may be influenced by the additive contributions from multiple genetic factors as well as environmental or teratogenic effects.

Still, some genotype-phenotype correlations have emerged. Patients with *ZIC2* pathogenic variants can have a characteristic facial appearance (bitemporal narrowing, upslanting palpebral fissures, large ears, and a short nose with anteverted nares). *ZIC2* pathogenic variants also appear to be the most common de novo pathogenic variant and have a high penetrance.[35]

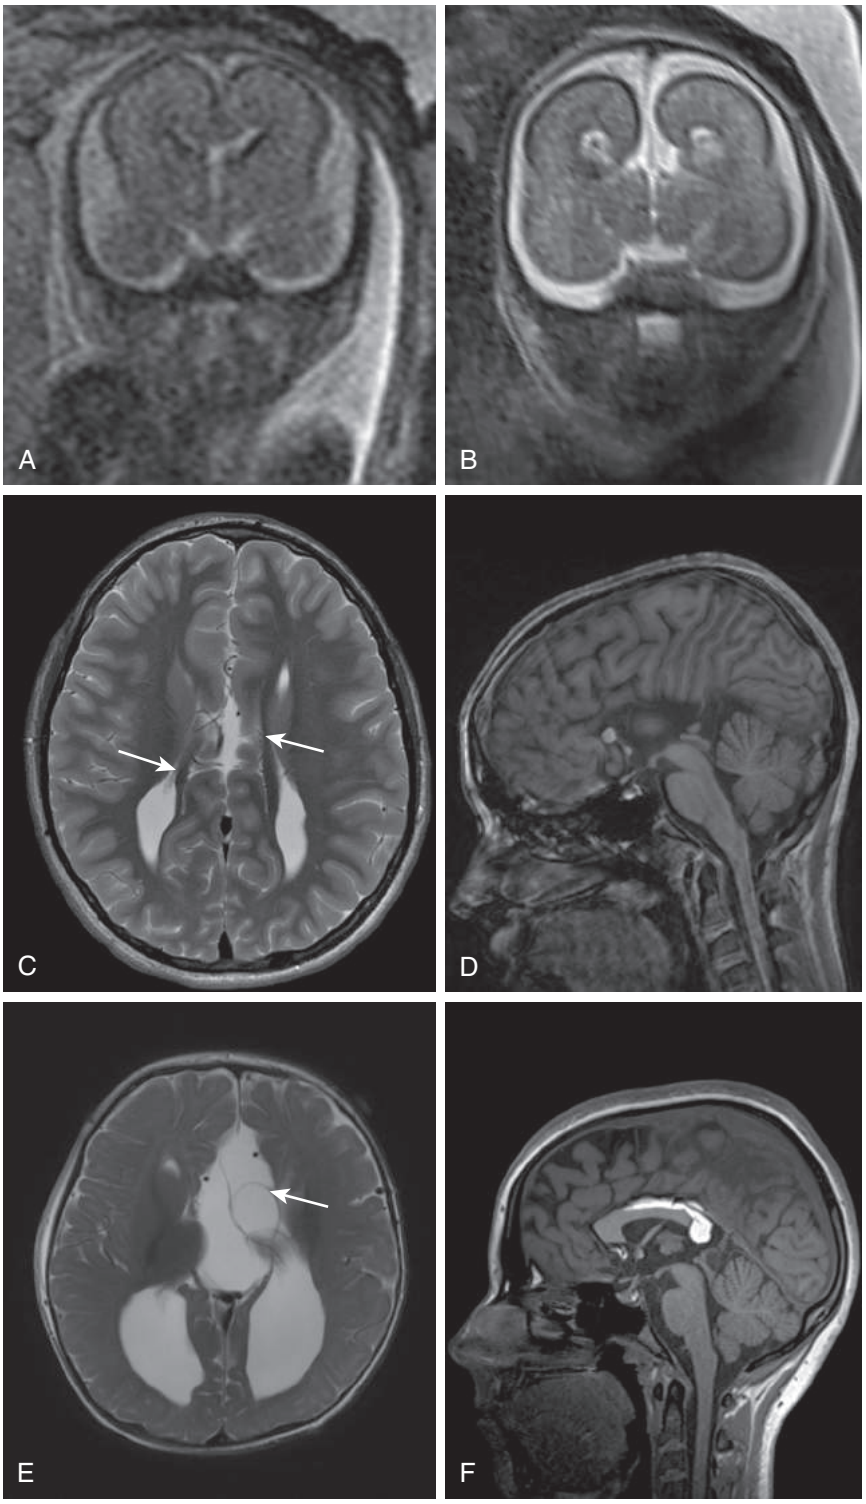
Environmental Factors

Environmental factors (e.g., ethanol, vitamin A toxicity) can produce cyclopia during the early phase of gastrulation. Maternal diabetes mellitus increases the risk of HPE to approximately 1% to 2% of all pregnancies. Cholesterol-lowering agents have been associated with HPE,[36] presumably because of their effects on *SHH* signaling. Smith–Lemli–Opitz syndrome is caused by a defect in the terminal step of cholesterol biosynthesis, and HPE manifests itself in approximately 5% of affected individuals. Additionally, ingested plant alkaloids have caused epidemics of cyclopia in sheep by processes that inhibit cholesterol biosynthesis. Other environmental associations (cytomegalovirus [CMV] infection, medications, assisted reproductive technologies) have been suggested by case reports or animal studies.[32]

Agenesis of the Corpus Callosum

The corpus callosum consists of approximately 190 million axons and is formed by a complex, multistep process that involves midline patterning, cellular proliferation, migration, and axonal growth.[37] Initial formation of the corpus callosum proceeds over 11 weeks or so and is mediated by multiple gene networks.[38] Development continues through adolescence as these connections are refined.[39] Genetic as well as environmental factors affect callosal formation.

ACC results in abnormal gyration of the medial portion of each hemisphere, eversion of the cingulate gyri, and sulcation perpendicular to the long axis of the hemisphere.[40] The external angles of the lateral ventricle are oriented parallel and upward, and the fornices are widely separated. If present, a useful distinguishing feature is Probst bundles (Fig. 53.3), which are fiber bundles



• **Fig. 53.3** Findings Associated With Agenesis of the Corpus Callosum as Demonstrated by Magnetic Resonance Imaging. (A) Coronal fetal magnetic resonance imaging *(MRI)* demonstrating the presence of the corpus callosum. Note that the medial cortex curls toward the midline. (B) Coronal fetal MRI demonstrating agenesis of the corpus callosum *(ACC)*. Note that the medial cortex curls away from the midline. (C) Postnatal axial T2-weighted image of ACC demonstrating colpocephaly and classic Probst bundles *(arrows)*. (D) T1-weighted sagittal section demonstrating near complete ACC (rostrum remains). (E) Postnatal axial T2-weighted image demonstrating a multiloculated cystic structure *(arrow)* that can be seen with ACC. (F) T1-weighted sagittal image demonstrating a lipoma *(bright white area)* that can be seen with ACC.

that run parallel to the ventricle in an anterior-to-posterior direction. ACC can be partial, more often involving loss of posterior segments.[41,42]

ACC often occurs in association with other structural abnormalities. These may be minor, such as cysts or lipomas (see Fig. 53.3), or more severe, such as heterotopia, polymicrogyria (PMG), microcephaly, abnormal sulcation, commissural and white matter abnormalities, and malformations of the posterior fossa.[38,43]

Epidemiology and Etiology

The prevalence of ACC ranges from 0.5 in 10,000 in the general population to 600 in 10,000 in children with neurodevelopmental disabilities.[39] ACC can also be associated with prenatal infections, vascular accidents, and teratogen effects.[39] Infection results in a thinner corpus callosum with a typical rostral-to-caudal extent and is a rare cause of isolated ACC. Ethanol exposure has the strongest association with ACC, which was reported in 7% of children with fetal alcohol syndrome in one series.[44]

ACC is a feature of hundreds of different disorders, and all modes of inheritance have been observed. Glass et al. (2008) found that callosal anomalies were associated with a chromosomal abnormality 17% of the time, commonly aneuploidy (chromosomes 13, 18, and 21).[45] ACC may be associated with either inherited or de novo copy number variants, some overlapping with those found in patients with autism.[46] ACC is also a primary feature of several important disorders, such as Mowat–Wilson, Aicardi, acrocallosal syndromes, *L1CAM*-related spastic paraplegia, and X-linked lissencephaly with ACC and ambiguous genitalia. Given the number of genetic syndromes associated with ACC, some authors have suggested a subdivision of groups based on the associated conditions (craniofacial, metabolic, ocular, ciliopathies), which aids in the diagnostic evaluation of these patients.[39]

Prenatally, fetal MRI at 20 to 22 weeks' gestation maximizes the identification of additional cerebral findings when pregnancy decision-making is still an option. Earlier MRI scans yield more false-negative results and miss structural changes. Additional diagnostic options include genetic (chromosomal microarray, cell-free fetal DNA) and infectious (serologic tests, polymerase chain reaction testing on amniotic fluid) disease testing. Given the challenges with accurate prenatal diagnosis, newborns should be evaluated by brain MRI shortly after birth and by subspecialty consultations (neurology, ophthalmology, genetics, developmental pediatrics, audiology). Laboratory testing (chromosome microarray, DNA sequencing, metabolic testing) should be considered, depending on the examination and MRI findings. Surveillance for neurodevelopmental issues, visual impairment, and pituitary insufficiency is recommended.[39]

Prognosis

The outcomes of ACC are variable. A systematic literature review revealed that up to 75% of patients with MRI-confirmed isolated ACC were developing typically at early school age, while 11% had severe disability.[47] Associated microcephaly, epilepsy, cerebral palsy, and cerebral dysgenesis are correlated with a higher risk of the abnormal neurodevelopmental outcome. Neuropsychological studies have shown specific impairment in abstract reasoning, problem-solving, and category fluency.[48,49] Difficulty with higher-level language such as comprehension of syntax and linguistic pragmatics is also evident.[50] These findings underscore the need for continued evaluation for learning and language difficulties in these patients.

Septo-Optic Dysplasia

Classic SOD is the triad of the absence of the septum pellucidum, optic nerve hypoplasia, and pituitary dysfunction. The diagnosis of SOD is made when two or more features of the triad are present[51]; 30% of patients have all three features.[52] SOD is a clinically and etiologically diverse group of disorders and overlaps with isolated optic nerve hypoplasia.[53] This diversity makes it difficult to provide counseling about prognosis and associated medical issues.

Diagnosis and Prognosis

Prenatally, SOD may be suspected in fetuses with absent CSP or ACC, although most fetuses with isolated absent CSP do not have SOD, posing a challenge for counseling. Postnatally, SOD may be suspected in a patient with growth failure, visual abnormalities, or genital abnormalities secondary to pituitary dysfunction. Early diagnosis is important to reduce the risk of adrenal crisis and hypoglycemia and requires brain MRI, ophthalmologic evaluation, and laboratory testing for pituitary insufficiency.

Children with SOD may be blind or have a visual impairment, presenting with roving gaze, nystagmus, or strabismus. Neurodevelopmental prognosis is controversial and may be correlated with the presence of other brain abnormalities. In early studies, cerebral palsy was found in 57% of children with SOD, intellectual disability was found in 71%, epilepsy was found in 37%, and behavioral problems were found in 20%.[54,55] A later neurodevelopmental study of seven children with unilateral or bilateral optic nerve hypoplasia with the absence of CSP found normal cognitive development, intact neurologic status, normal language development, and age-appropriate behavior in six of the seven children.[56] Conversely, a descriptive series of three children with SOD plus cortical dysplasia showed that all three had abnormal development and neurologic examination findings.[57] Specialists in development, neurology, endocrinology, and ophthalmology should follow these children. Hypopituitarism is seen in up to 80% of patients, with growth hormone deficiency being the most common. Lifelong monitoring is needed as pituitary insufficiency can become clinically apparent over time.[51]

Epidemiology and Etiology

The prevalence of SOD is 1 in 10,000 births, with increased risk in younger mothers.[58] Pathogenic variants in several genes are associated with SOD (e.g., *HESX1, SOX2, SOX1, OTX2*)[51,59]; however, a genetic origin is not identified in most patients, suggesting environmental or complex genetic causes. The disease is sporadic in most patients, and SOD can exhibit dominant and recessive modes of inheritance. Some instances of SOD have been associated with prenatal drug and alcohol exposure or a vascular pathogenesis[60–62]; however, causation remains unproven. The recurrence risk is less than 1% in the absence of consanguinity.

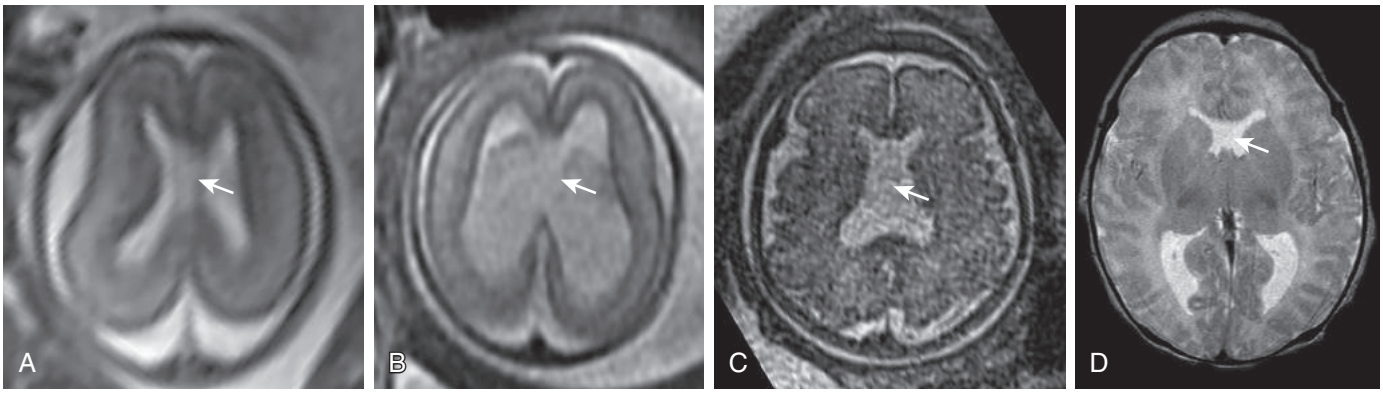
Absent Cavum Septi Pellucidi

The presence of the CSP is a normal finding on ultrasonography and MRI of fetuses and premature infants. This normal finding represents a fluid-filled space between the lamellae of the septi pellucidi, which typically fuse as the fetal brain matures. The absence of the CSP in fetuses and premature infants may be associated with neuroanatomic anomalies.[63] It may be an isolated finding (Fig. 53.4), but MRI is recommended for further evaluation.[64] In addition, a larger than expected CSP width should prompt a detailed ultrasound evaluation as this anomaly can be seen in fetuses with aneuploidy.[65]

Cortical Defects in Size and Organization

Defects in proliferation and neuronal survival include microcephaly and macrocephaly as well as cortical dysplasia. Migration defects result in disruption of the layered cortical structure, which can be seen grossly (as with lissencephaly) or microscopically (focal dysplasia). We will also discuss cortical defects such as heterotopia, PMG, cobblestone cortex, schizencephaly, and other destructive lesions. We will not discuss disorders of neuronal crest migration (e.g., neuroblastoma, Hirschsprung disease).

Projection neurons originate from neural progenitor cells that reside in the periventricular zone and subventricular zones. These progenitors undergo symmetric and asymmetric cell divisions to generate more progenitors as well as post-mitotic neurons, which



• **Fig. 53.4** Fetal and Postnatal Magnetic Resonance Imaging With Absent Cavum Septi Pellucidi. (A) Fetal magnetic resonance imaging (MRI) demonstrating expected cavum septi pellucidi (CSP) at 21 weeks' gestation *(arrow)*. (B–D) MRI demonstrating absent CSP *(arrow)* at 20 weeks' gestation (B), 34 weeks' gestation (C), and birth (D). The fetus in (B) also has mild ventriculomegaly.

subsequently differentiate into projection neurons.[66] The cerebral cortex develops in an inside-out pattern, with early-born neurons forming the deepest layers and later-born neurons populating the superficial layers. This process occurs during weeks 7 to 11 of gestation. Intrinsic and extrinsic signals direct appropriate arrest of migration, positioning of the final cell layers, and terminal differentiation of projection neurons into a variety of subtypes. Disruption of any of these processes can result in the malformations we discuss.[67] Most interneurons are born in the median ganglionic eminences and migrate long distances to populate the brain, a process termed tangential migration. Non-neuronal cells (astrocytes and oligodendrocytes) arise from the same neural progenitors that generate projection neurons, but form later.[68]

Disorders of cortical development may be genetic or caused by in utero insults (hypoxia, ischemia, metabolic derangements, toxins, and infection). Diagnosis is based on clinical presentation, imaging, pathology, and genetic testing. Malformations can manifest clinically as epilepsy or intellectual disability and may be part of syndromic disorders with other organ involvement. Management includes both medical and surgical interventions for seizure control, therapy support for motor and cognitive disabilities, and appropriate surveillance and involvement of specialists if needed. The framework of cerebral cortex development has been used to classify cortical malformations and is being updated on the basis of expanding genetic knowledge.[69]

Cortical Defects in Proliferation and Neuronal Survival

Microcephaly

Disorders caused by abnormal proliferation include microcephaly (small brain) and megalencephaly (large brain). Microcephaly is defined as an occipitofrontal circumference greater than two standard deviations (SDs) below the mean and can be either primary (evident at birth) or secondary (normal to small occipitofrontal circumference at birth with progression to greater than two SDs below the mean after birth). The causes for either can be genetic or acquired. Microcephaly may be associated with other extracranial malformations (syndromic microcephaly) or may be an isolated finding. Von der Hagen et al.[70] described a retrospective cohort of 680 children with microcephaly and found that around 60% had an identifiable etiology.[70] Of these patients, roughly half had genetic causes of various types (aneuploidies, de novo copy number variants, autosomal dominant, autosomal recessive, and X-linked). The remaining cases were secondary to injury around or after birth (which can include birth complications, infection, maternal disease, teratogen exposure, infarction, and craniosynostosis). This leaves 40% of cases without a clear etiology.

Imaging may suggest a normal brain organization, but oligogyria, gray matter disruption, and hypomyelination may be microscopic and not easily identified on imaging. Patients with microcephaly can also have other cortical malformations, suggesting an overlap in mechanisms. It is not surprising that genetic defects that cause primary microcephaly affect cell cycle progression, cell proliferation, mitotic spindle formation, and DNA repair—processes that a crucial to generating the appropriate number of neurons.[71,72] Secondary microcephaly becomes apparent only after birth and is associated with defects in genes regulating protein synthesis and a number of syndromes, including Rett and Angelman.[73] The later onset of this subgroup of microcephaly may afford opportunities for early diagnosis and treatment.

Primary microcephaly can be detected in utero by ultrasonography, and when severe, it is associated with a high risk of abnormal neurodevelopmental outcomes. Additional prenatal evaluation may include fetal MRI, infectious evaluation, and genetic testing. Recently, the Zika virus has been implicated as the causative agent of microcephaly in infants whose mothers were exposed to the virus during pregnancy.[74,75] Diagnosis of secondary microcephaly occurs via routine head measurements after birth, and then further evaluation can include brain imaging (ultrasonography or MRI), infectious disease evaluation, and subspecialty consultation (e.g., neurology, genetics, ophthalmology) as indicated.

Prognosis is related to the severity of microcephaly,[76] as well as the presence of other brain abnormalities, somatic malformations, and genetic diagnosis. Developmental disabilities and imaging abnormalities are seen in approximately 80% of children with severe microcephaly, which is defined as a head circumference greater than three SDs below the mean, while the risk is much lower in children with a head circumference greater than two SDs below the mean. Comorbid conditions include intellectual disability, epilepsy, cerebral palsy, and ophthalmologic disorders.

Macrocephaly and Megalencephaly

Macrocephaly refers to a large head size (greater than two SDs above the mean) that can be due to a variety of causes, such as hydrocephalus, thick skull, or megalencephaly (large brain size). *Megalencephaly* is rare in neonates since it is usually due to increasing brain size over time and is often associated with developmental delay and epilepsy.[77] Increasing head circumference in infancy needs to be followed closely, and imaging should be considered to evaluate the infant for causes of increased intracranial pressure. In the absence of other malformations or neurodevelopmental issues, accelerated head growth with increased extra-axial fluid during the first year or two after birth is generally thought to be benign and may be due to an imbalance in CSF production versus CSF absorption by immature subarachnoid granulations.[78,79]

Macrocephaly can be seen in a diverse group of conditions characterized by a large brain, most commonly manifesting itself as an isolated finding in familial and sporadic cases. At birth, the head circumference is greater than the 90th percentile. Macrocephaly can also be seen in fragile X syndrome and Klinefelter syndrome and in neuroendocrine disorders (Beckwith–Wiedemann syndrome, cerebral gigantism, and achondroplasia).[80,81] The prognosis depends on the cause.

The causes of megalencephaly can be divided into metabolic and anatomic categories. Metabolic causes include organic aciduria (e.g., glutaric aciduria), lysosomal storage diseases, and leukoencephalopathies, while anatomic megalencephaly can be due to pathogenic variants in genes affecting the pathways involved in cell growth such as *PI3K/AKT/mTOR, Ras/MAPK*, and *SHH*.[77] Megalencephaly can present syndromically as in *megalencephaly, polymicrogyria, polydactyly, and hydrocephalus (MPPH) syndrome* and *megalencephaly–capillary malformation (MCAP) syndrome*.[82,83] Pathogenic variants in *AKT3, PIK3R2*, and *PIK3CA* have been identified.[84–86] Interestingly, pathogenic variants in the PI3K/AKT/mTOR pathway seem to drive less extensive overgrowth conditions such as hemimegalencephaly and focal cortical dysplasias.[87] *PIK3CA* is also associated with other overgrowth disorders, including MCAP, congenital lipomatous overgrowth, vascular malformations, epidermal nevi, skeletal/spinal abnormalities (CLOVES) syndrome, and fibroadipose hyperplasia.[88]

Megalencephalic brains are most often dysplastic showing ectopic tissues (periventricular heterotopias), atypical cells on pathology, white matter abnormalities, and altered gyral patterns (often coarse). Clinically, they are associated with intellectual disability and intractable epilepsy, with onset usually in infancy.[67,72] If the dysplastic overgrowth is limited to a single hemisphere (as in hemimegalencephaly), hemispherectomy may be considered as the neonatal period to treat severe epilepsy.[89] Given the growing molecular understanding of brain overgrowth syndromes, novel medical therapies, including mechanistic target of rapamycin (mTOR) inhibitors, offer an alternative to nonsurgical candidates.[90]

Megalencephaly may also be associated with neurocutaneous syndromes such as sebaceous nevus syndrome, hypomelanosis of Ito, facial lipoma, and tuberous sclerosis.[91–95] The prognosis and recurrence risk for macrocephaly and megalencephaly depend on the underlying cause.

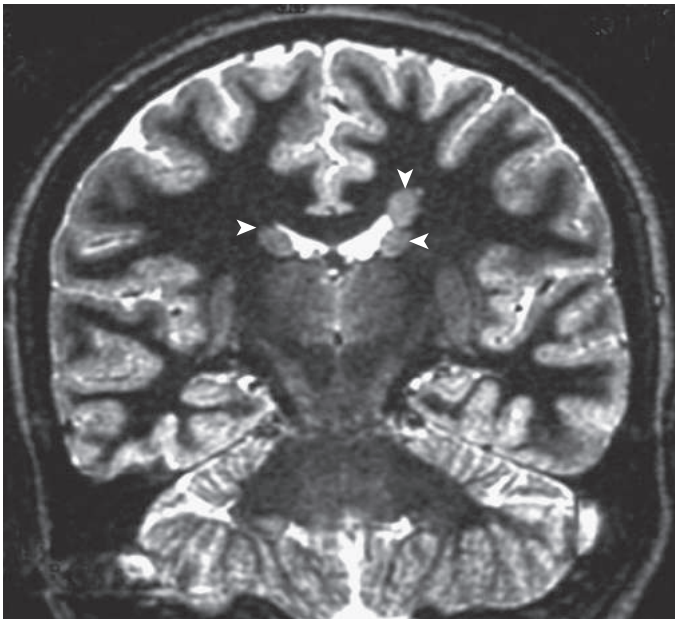
Cortical Defects in Migration

In addition to appropriate proliferation, cortical development requires appropriate neuronal migration. Disruption in the initiation, continuation, or arrest of neuronal migration results in several organizational abnormalities, including heterotopia, lissencephaly, and cobblestone cortex. These abnormalities are often accompanied by other malformations, such as hypoplasia or ACC, pointing to a complex interplay between the mechanisms that determine neuronal migration and axon path finding. Structural imaging has identified many defects in radial migration of projection neurons, while defects in tangential migration of interneurons are not typically identified.

Heterotopia

Heterotopia can be periventricular (suggesting disruption of initiation of migration), subcortical (as in subcortical band heterotopia), or transmantle (as seen with injury). Periventricular heterotopia (PVH) is characterized by masses of gray matter adjacent to the walls of the lateral ventricles (Fig. 53.5). Patients with PVH often present with focal seizures. Bilateral PVH may be associated with other malformations such as hypoplasia of the corpus callosum. *FLNA* pathogenic variants cause bilateral contiguous PVH. There is a clinical predominance of cases in females as hemizygous FLNA mutations are usually lethal in males. *FLNA* is a key component of the cytoskeleton, a cellular structure needed for motility, offering a mechanistic explanation for this malformation.[94] Among cases of familial PVH, 80% have *FLNA* pathogenic variants. Twenty percent of sporadic cases have *FLNA* pathogenic variants, indicating the importance of environmental influences, or unidentified genetic causes.[96] Given associated cardiac problems with *FLNA*-related PVH, echocardiogram and cardiac surveillance are recommended. Neurodevelopmental outcomes are varied and may be associated with learning disabilities.[97] Pathogenic variants in *ARFGEF2* have also been identified in patients with PVH.[98]

Subcortical band heterotopia is characterized by a band of heterotopic gray matter within the white matter (Fig. 53.6). Somatic pathogenic variants in *DCX* and *LIS1* have been



• **Fig. 53.5** Magnetic Resonance Image Scan Demonstrating Periventricular Nodular Heterotopia. Periventricular nodular masses *(arrowheads)* are visualized adjacent to the lateral ventricles in this T2-weighted coronal image. (Courtesy Dr. Martin Salinsky, Department of Neurology, Oregon Health and Science University, Portland, OR.)

associated with subcortical band heterotopia.[73] Patients typically present with developmental delay, intellectual disability, and/or epilepsy but have less severe disability than those with lissencephaly, and 25% have normal or near normal intelligence. Neurologic deficits roughly correlate with the thickness and extent of the subcortical band.[99]

Lissencephaly

The lissencephalies are characterized by reduced or absent gyri, giving the cortical surface a smooth or nearly smooth appearance.[100] Patients with lissencephaly have intellectual disability, hypotonia, epilepsy, and feeding difficulties.[94] The classification

Gleeson, Department of Neurology, School of Medicine, University of California, San Diego, CA; M. Elizabeth Ross, Department of Neurology, University of Minnesota, Minneapolis, MN; Christopher A. Walsh, Department of Neurology, University of Minnesota; and Christopher A. Walsh, Department of Neurology, Harvard Medical School, Boston, MA.)

of the lissencephalies reflects the rapidly evolving molecular basis of these disorders (see Fig. 53.6).[101,102] Most patients are included in the classic lissencephaly/subcortical band heterotopia spectrum (previously type 1), which is associated with deletions or missense pathogenic variants in *LIS1*.[103] Other associated genes include *DCX*, *YWHAE*, and several tubulin genes.[104] These gene products have roles in neurogenesis, cell motility, and microtubule polymerization.[105,106]

Lissencephaly is not only seen in isolation. Pathogenic variants in the *ARX* gene, which encodes a transcription factor, result in X-linked lissencephaly with abnormal genitalia and, in the CNS, abnormal basal ganglia, immature white matter, and ACC.[107] Lissencephaly can also be seen with cerebellar hypoplasia.[96,100–102,108] The most common causes of this phenotype are dominant pathogenic variants in tubulin genes, which can often be distinguished by characteristic basal ganglia, brainstem, and cerebellar dysplasia.[109] Less frequently, lissencephaly with a moderately thick cortex, severe global cerebellar hypoplasia, and a malformed hippocampus is caused by recessive pathogenic variants in the *RELN* gene, which encodes a large extracellular matrix protein involved in signaling via the apolipoprotein E and very low-density lipoprotein receptors.[108,110] Pathogenic variants in very low density lipoprotein receptor (VLDLR) cause a less severe phenotype with mildly thickened and simplified cortical gyri and cerebellar hypoplasia.[111]

Clinical Features

Lissencephaly may be diagnosed in utero or present as hypotonia, developmental delay, or seizures during infancy. Spasticity may develop later in the first year. Isolated lissencephaly carries a poor long-term prognosis dominated by cognitive disability, spastic quadriparesis, and epilepsy. Craniofacial anomalies can be subtle in patients with *LIS1* pathogenic variants or more pronounced as in Miller–Dieker syndrome caused by deletion of *LIS1* and *YWHAE*.[112] Miller–Dieker syndrome is characterized by severe lissencephaly, a high forehead with bitemporal hallowing, short nose, upturned nares, downturned vermillion border, and small jaw.[113] Head circumference is typically normal at birth, but progressive microcephaly occurs during the first year. Neonatal seizures may occur, and severe myoclonic epilepsy typically develops in the latter half of the first year (e.g., infantile spasms or Lennox–Gastaut syndrome).[114]

Cobblestone Malformation Syndromes

Cobblestone cortex (previously known as *lissencephaly type II*) is characterized by a nodular appearance of the cortex, which is due to disruption of the normal arrest of cells at the pial surface.[67] On MRI, T2/fluid-attenuated inversion recovery signal is often markedly increased in cortical white matter. Cobblestone cortex is seen in the congenital muscular dystrophies: Walker–Warburg syndrome, muscle–eye–brain disease, and Fukuyama congenital muscular dystrophy.[115] These autosomal recessive disorders belong to a class of glycosylation-deficient muscular dystrophies,[116] the dystroglycanopathies, that are related to pathogenic variants in enzymes that catalyze the posttranslational O-glycosylation of a small number of mammalian glycoproteins.[117,118]

Walker–Warburg syndrome is the most severe congenital muscular dystrophy associated with cobblestone cortex.[119] Macrocephaly is present at birth or develops in the first year and is due to hydrocephalus. Kinked brainstem, cerebellar hypoplasia, and elevated creatine kinase level are strongly suggestive of the diagnosis. Ocular anomalies include retinal detachment, optic nerve hypoplasia, microphthalmia, and coloboma; muscular weakness is typically severe.[120] Survival beyond the first year is uncommon. The brain malformations and neurodevelopmental outcomes in patients with muscle–eye–brain disease are less severe, but patients still have substantial disability and most experience seizures. Individuals with Fukuyama congenital muscular dystrophy can have variable cortical and eye findings. Hypoplasia and cysts can be seen in the cerebellum while the cortex can show PMG. Moderate cognitive disability can be seen, and some patients may walk independently.[115]

Pathogenic variants in the laminin subunit β_1 (encoded by *LAMB1*), which localizes to the pial basement membrane, also result in cobblestone cortex and other brain conditions, but these malformations do not exhibit the ocular or muscular abnormalities seen in the syndromes mentioned above.[121] Similarly, G protein-coupled receptor 56 (*GPR56*) pathogenic variants can cause a recessive syndrome with cobblestone-like cortex, abnormal white matter signal, and cerebellar cysts as well as bilateral frontoparietal PMG.[122,123] Neuroimaging shows bilateral white matter changes, small brainstem, and small dysmorphic cerebellum, which is unique for the PMG syndromes.[124,125]

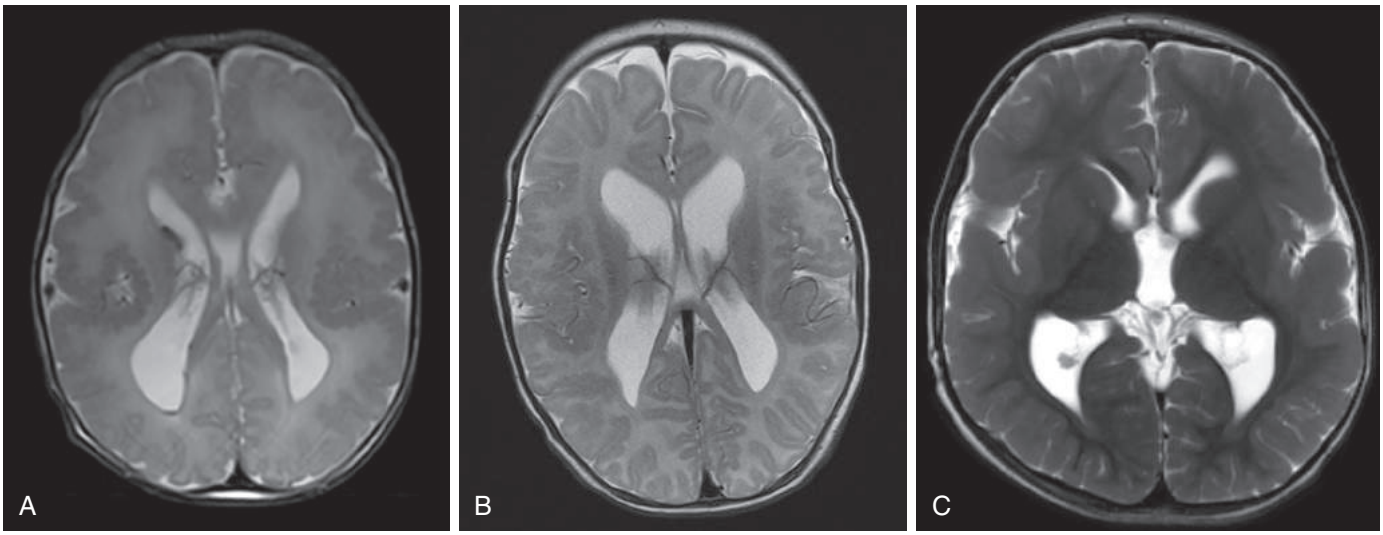
Polymicrogyria

PMG was originally defined by histopathologic findings. With the advent of brain MRI, the term is now commonly used to refer to a variety of appearances with an irregular gray–white border and many very small gyri or a thickened cortical ribbon (Fig. 53.7). PMG or PMG-like appearances can be caused by pathogenic variants in a variety of genes, as well as by infection (CMV, toxoplasmosis), ischemic/vascular anomalies, and metabolic disorders. A variety of other malformations, such as schizencephaly, can be seen in association with PMG. Recently, some ischemic etiologies have been found to be genetic in origin (*OCLN* or *COL4A1* pathogenic variants, 22q11 deletions, and Sturge–Weber syndrome).[126]

Historically, two major types of PMG have been proposed: layered and unlayered. *Layered PMG* has four rather than six distinct cortical layers. This "classic" form is localized adjacent to regions of encephalomalacia and is thought to be frequently caused by injury. *Unlayered PMG* is cortex that lacks distinct cortical layers and is associated with other migrational disturbances, such as subcortical nodular heterotopia, lissencephaly, and schizencephaly. At times, multiple types of PMG may be present in the same patient,[127] and the term has been used to refer to a variety of appearances on structural MRI without correlation to pathologic findings (see Fig. 53.7). PMG is usually sporadic, but it can be seen in association with several syndromes, especially if it is bilateral, and has been seen in multiple modes of inheritance in rare familial cases.[108,128]

Clinical Features

The clinical presentation of PMG relates to the extent of cortical dysplasia and the underlying cause and is difficult to predict on the basis of imaging findings alone. Bilateral PMG or involvement of more than half of a single hemisphere carries a high risk of moderate-to-severe developmental disability and significant motor dysfunction.[129] Hemiparesis or quadriparesis is often seen. Refractory epilepsy with complex focal seizures or multiple generalized seizure types may be delayed in onset beyond the neonatal period.



• **Fig. 53.7** Spectrum of Findings With Polymicrogyria. T2-weighted axial images (A–C) showing the varied magnetic resonance findings with polymicrogyria: (A) frontal and perisylvian polymicrogyria; (B) predominantly perisylvian; (C) globally thickened cortex.

Bilateral perisylvian PMG is the most commonly observed pattern. Patients with bilateral perisylvian PMG are likely to have epilepsy and intellectual disability.[130–132] In bilateral frontoparietal PMG, patients have global developmental delay, dysconjugate gaze/esotropia, and bilateral pyramidal and cerebellar motor signs.[124]

Tubulinopathy-Related Dysgyria

Pathogenic variants in α- and β-tubulin genes have been implicated in a range of cortical malformations.[133] So-called 'tubulinopathies' are usually due to de novo dominant pathogenic variants, with rare examples caused by germline mosaicism.[109] A more subtle malformation, called *tubulinopathy-related dysgyria*, shows a subtle irregular cortical gyral pattern with basal ganglia and brainstem dysplasia, associated with *TUBA1A, TUBB2B*, and *TUBB3* pathogenic variants that occur de novo or are inherited from a mosaic parent.[134] Patients can present with motor, cognitive, and language delays that can be mild, abnormal eye movements, behavioral issues, and seizures.

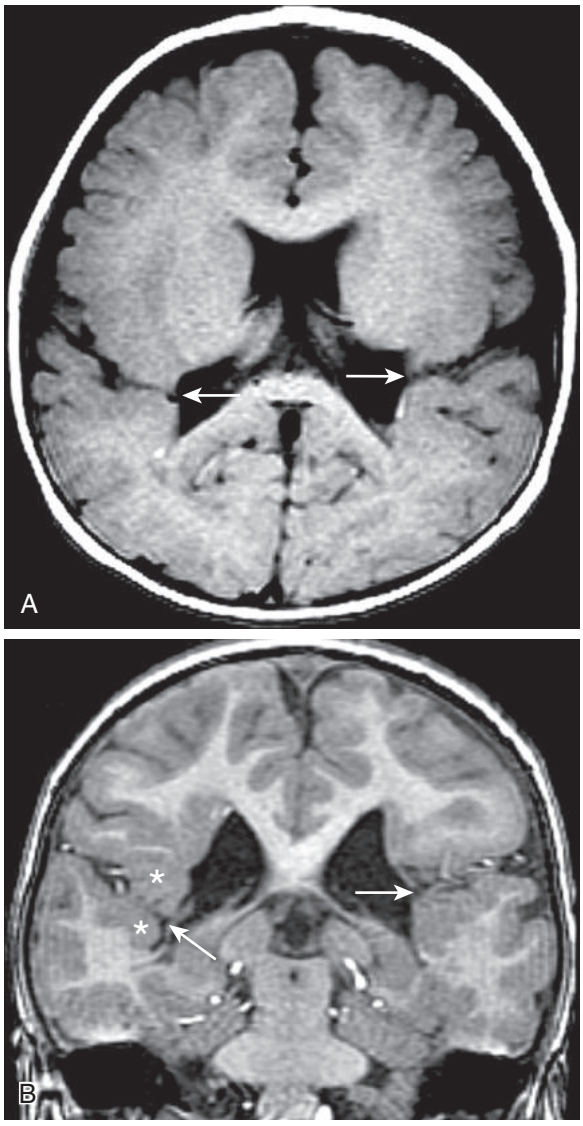
Destructive Lesions

Schizencephaly, porencephaly, and hydranencephaly are descriptive terms for malformations that result from destructive lesions during development. Schizencephaly may be unilateral or bilateral and "open-lipped" or "closed-lipped" (Fig. 53.8). When it is severe, both lateral ventricles communicate widely with the extra-axial space (bilateral open-lipped). Unsurprisingly, patients with schizencephaly have significant cognitive, motor, and communication difficulties, and epilepsy is common.[135] The severity of the epilepsy is not correlated with the severity of the brain malformation, and two studies found that patients with unilateral schizencephaly had an earlier age of seizure onset and more refractory epilepsy than those with bilateral schizencephaly.[136,137] Diagnosis is by MRI, and findings may include other brain malformations, such as cortical dysplasia, corpus callosum dysgenesis, and absent septum pellucidum. Presumed causes of schizencephaly include destructive events such as ischemia and infection, however, familial cases are known.[94] Schizencephaly may also result from an extreme failure of neurons to migrate. This is supported by histology showing that the schizencephalic cleft has features of a migrational disturbance, such as large neuronal heterotopia bordered by adjacent PMG.[138] Pituitary insufficiency is seen in a substantial subset of patients with schizencephaly, particularly if optic nerve hypoplasia is also present.

Porencephaly is a fluid-filled cavity within the cerebral hemispheres, caused by loss of tissue secondary to trauma, infection, or hemorrhage. Porencephaly can develop prenatally and postnatally. Pathogenic variants in *COL4A1* are associated with an autosomal dominant form of hereditary porencephaly. Pathogenic variants in *COL4A1* can also cause lesions of the kidneys, eyes, cardiac muscle, or skeletal muscle.[139] *COL4A2* has been associated with familial and sporadic porencephaly. These two genes encode collagen subunits that help form the basement membrane. Most hypothesize that collagen-related porencephaly is secondary to vascular events. *COL4A1* and *COL4A2* pathogenic variants can be associated with stroke and other highly variable manifestations in family members with the same pathogenic variant, so the affected infant and at-risk family members should undergo neurologic, ophthalmologic, renal, and cardiac screening.

Hydranencephaly is due to the replacement of the hemispheres with a fluid-filled sac and may be considered an extreme form of porencephaly. This rare condition has several proposed mechanisms, including infarction, leukomalacia, necrosis, infection, and thromboplastic material from a cotwin. In addition to the etiologies previously mentioned, there may be an association of destructive lesions, such as porencephaly, hydranencephaly, and schizencephaly, with in utero exposure to vasoactive drugs such as cocaine, heroin, and methamphetamine.[140]

A rare genetic disorder called *Fowler syndrome*, caused by pathogenic variants in *FLVCR2* causes severe hydrocephaly and also hypokinesia, CNS vasculopathy, and arthrogryposis. This disorder is also called *proliferative vasculopathy and hydranencephaly–hydrocephaly (PVHH) syndrome*. Although case reports have described two siblings that survived beyond infancy, most infants do not live beyond the first year.[141,142] Hydrocephalus and feeding difficulties are frequent complications, and decisions about



• **Fig. 53.8** Magnetic Resonance Image Scan Demonstrating Bilateral Open-Lip Schizencephaly. (A) Axial T1-weighted image. Note that the bilateral clefts *(arrows)* extend to the lateral ventricles. James Barkovich, Department of Radiology, School of Medicine, University of California, San Francisco.)

whether to treat the infant with CSF diversion or tube feeding can be difficult given the limited developmental potential and life span.

Malformations of Structures in the Posterior Fossa

Normal Midbrain and Hindbrain Development

The brainstem comprises the midbrain, pons, and medulla, while the cerebellum is composed of a vermis and hemispheres. The development of these structures occurs after the closure of the neural tube and coincides with prosencephalic development.[143] The development of the cerebellum, like that of the cortex, is influenced by both intrinsic (genetic) and extrinsic (inductive/environmental) factors.[144] The midbrain structures derive from the mesencephalon and myelencephalon, and the hindbrain derives from the rhombencephalon by gestational week 4. The cerebellar vermis derives from both the caudal third of the mesencephalon and the hindbrain.[145] Cerebellar development continues into the second postnatal year, making the cerebellum particularly vulnerable to injury in premature infants.[146] The posterior fossa is evaluated by ultrasonography or MRI during the second and third trimesters of pregnancy, but MRI is the modality of choice if abnormalities are suspected.[147]

For this section, we will characterize posterior fossa malformations on the basis of imaging findings.[148] Embryonic and genetic classifications have also been used.[149,150] Alternatively, posterior fossa malformations can be classified on the basis of inherited (metabolic, structural, neurodegenerative, or the spinocerebellar ataxias) versus acquired causes (vascular, hypoxic-ischemic encephalopathy infection, disrupted development, toxic, neoplastic, or teratogenic).[151] Clinical features of posterior fossa abnormalities are nonspecific but include hypotonia, developmental delay, nystagmus, and decreased visual attention. Depending on the malformation, seizures and apnea may also be present, as may cranial nerve dysfunction. The combination of clinical, imaging, and genetic testing information is required for accurate diagnosis.

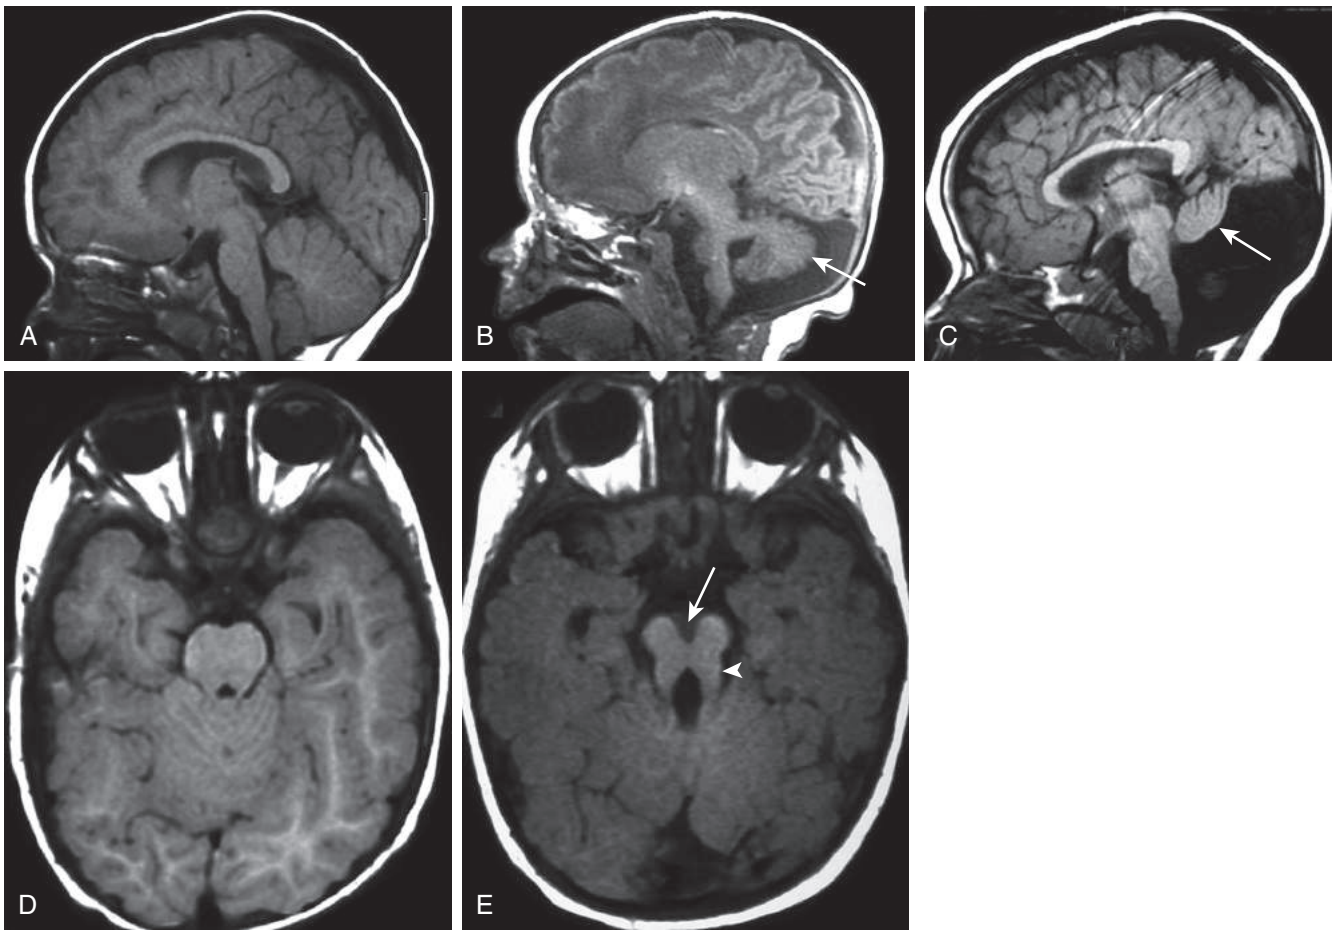
Malformations With Major Cerebellar Involvement

Dandy–Walker Malformation

Dandy-Walker malformation (DWM) is typified by aplasia or hypoplasia of the vermis of the cerebellum, cystic dilation of the fourth ventricle, and enlargement of the posterior fossa with an upward displacement of the lateral sinuses, tentorium, and torcula (Fig. 53.9).[152–155] The pons may also appear hypoplastic given the interconnectedness of these structures.[145] Diagnosis may be made in utero by ultrasonography and fetal MRI. Prenatal ultrasonography and MRI are increasingly used, but both continue to be limited in the precise anatomic definition of these malformations.[156] The enlargement of the posterior fossa and displacement of its contents may be related to communication of the fourth ventricle with a retrocerebellar cyst, often of considerable size. Hydrocephalus is also a common feature that may present in the neonatal period with macrocephaly.[154,157]

Epidemiology and Etiology

Estimates of the prevalence of DWM are affected by the lack of agreement regarding the definition. While some estimates are as high as 1 in 5000 liveborn infants,[158] the prevalence is likely substantially lower. DWM may be isolated or associated with a number of syndromes (e.g., Walker–Warburg syndrome, Meckel syndrome) as well as trisomies 9, 13, and 18. Given the low recurrence risk of 1% to 3%, DWM is likely due to de novo pathogenic variants, environmental insults, and vascular and multifactorial causes. Using exome sequencing, pathogenic variants in seven different genes were identified in 16% of DWM patients without a known diagnosis, highlighting the etiologic heterogeneity of DWM.[159]



• **Fig. 53.9** Posterior Fossa Abnormalities. Sagittal images of a normal brain (A), the brain of a child with Joubert syndrome (B), and the brain of a child with Dandy-Walker malformation *(DWM)* (C) illustrate the features of these hindbrain malformations. Note the presence of cerebellar vermis hypoplasia *(arrow)* in both (B) and (C). By contrast, the patient with Joubert syndrome (B) has only a slightly enlarged fourth ventricle, whereas in the DWM (C) the fourth ventricle is massively dilated. (D, E) Molar tooth sign. Comparison of axial images from a normal brain (D) with that of a child with Joubert syndrome (E). Note two key features of the molar tooth sign: a deepened interpeduncular fossa *(arrow)* and the elongated superior cerebellar peduncles *(arrowhead)*. (A–C, Courtesy Dr. Joseph G. Gleeson, Department of Neurology, School of Medicine, University of California, San Diego; and Dr. William B. Dobyns, University of Chicago School of Medicine, Chicago; D, E, Courtesy Dr. Joseph G. Gleeson, Department of Neurology, School of Medicine, University of California, San Diego.)

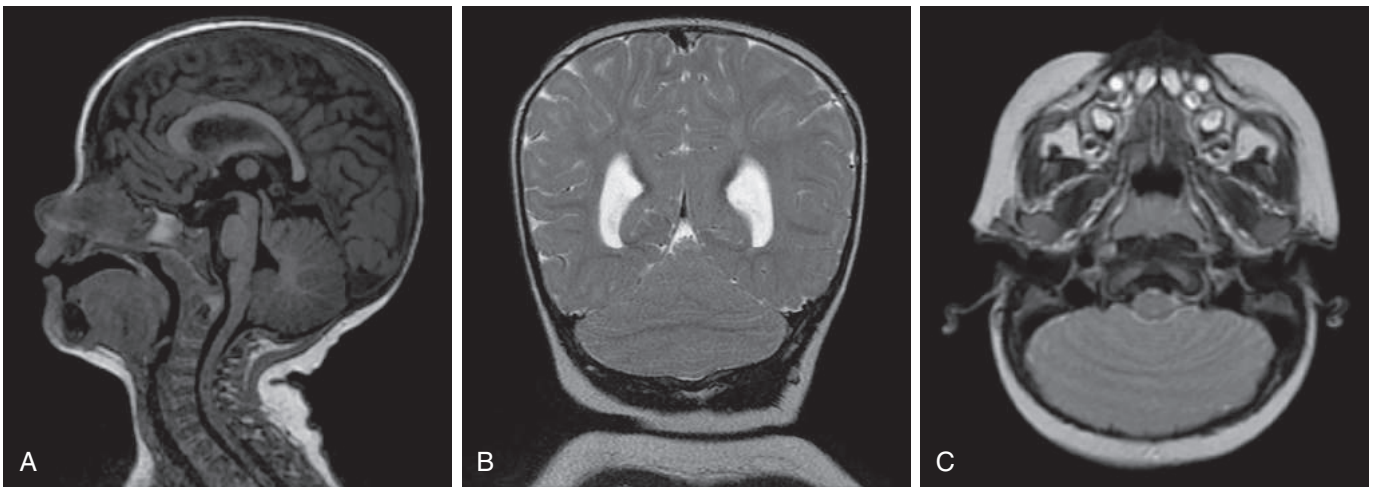
Clinical Features and Management

DWM can be associated with other brain imaging abnormalities, particularly ACC and hydrocephalus. In addition, cardiac and other organ malformations can be present. Management is similar to that for other neurodevelopmental conditions and can include surgical correction of hydrocephalus with shunt placement within the lateral ventricles and/or posterior fossa. The outcome is broad: patients with isolated DWM often have mild developmental issues, while those with additional malformations and specific genetic conditions are at much higher risk.[160]

Rhombencephalosynapsis

Rhombencephalosynapsis (RES) is unique among the cerebellar vermis hypoplasias. Instead of the cerebellar hemispheres being widely separated, the hemispheres, white matter, and deep cerebellar nuclei are variably fused (Fig. 53.10).[161] Clinically, patients with RES may present with ataxia, muscle hypotonia, abnormal eye movements, dysarthria, head shaking, and developmental delay with variable severity. RES may be isolated or seen in combination with other syndromes such as vertebral, anal, cardiac, tracheoesophageal, renal, and limb anomalies (VACTERL) and may be associated with other CNS abnormalities, such as hydrocephalus.[162–165] Additional proposed causes include other genetic defects (particularly postzygotic-mosaic variants) and environmental factors (such as maternal diabetes and other exposures).[163]

RES can be diagnosed prenatally by fetal MRI and should be suspected in fetuses with ventriculomegaly and cerebellar hypoplasia identified by ultrasonography. In the absence of ventriculomegaly or other imaging abnormalities, RES is rarely diagnosed prenatally. In addition, when aqueductal stenosis is suspected prenatally or postnatally, the cerebellum should be closely scrutinized for RES.[162]



• **Fig. 53.10** Rhomboencephalosynapsis as Demonstrated by Magnetic Resonance Imaging. (A) T1-weighted sagittal image showing excessive white matter centrally in the cerebellum and absent primary and horizontal fissures. The T2-weighted coronal (B) and axial (C) show continuous folia across the midline and the smooth dorsal cerebellar surface caused by vermian agenesis and hemisphere fusion.

Malformations With Both Cerebellar and Brainstem Involvement

Joubert Syndrome and Related Disorders

Joubert syndrome (JS) is a recessive disorder usually presenting with hypotonia, abnormal eye movements, and developmental delays. The prevalence has been estimated to be 1 in 100,000. Apnea and tachypnea may be notable in infancy and early presentation may include head titubation, which is a subtle nodding of the head seen in JS and other posterior fossa malformations.[166–168] JS is defined by the "molar tooth sign" on imaging (see Fig. 53.9): cerebellar vermis hypoplasia/aplasia, deep interpeduncular fossa, and thick, elongated superior cerebellar peduncles. Historically, several other names have been used to refer to JS, including cerebellar ocular renal syndrome, cerebellar hypoplasia/aplasia, oligophrenia, cerebellar vermis hypoplasia/aplasia, oligophrenia, congenital ataxia, ocular coloboma, and hepatic fibrosis (COACH) syndrome, and Varadi–Papp syndrome.[169] Pathogenic variants in more than 35 genes have been identified in more than 70% of patients with JS, most commonly in five genes *AHI1, CC2D2A, CEP290, TMEM67*, and *CPLANE1*.[170,171] Distinguishing JS from other hindbrain malformations is essential, since the recurrence risk can be as high as 25%, and substantial subsets of patients with JS develop progressive retinal dystrophy, fibrocystic kidney disease, and liver fibrosis, requiring lifelong monitoring and treatment.[172] Some genetic causes are associated with a higher risk of complications (e.g., loss of *CEP290* is associated with retinal dystrophy). Therefore, genetic testing can be used to inform family planning to guide the monitoring of affected patients.[171]

Pontocerebellar Hypoplasias

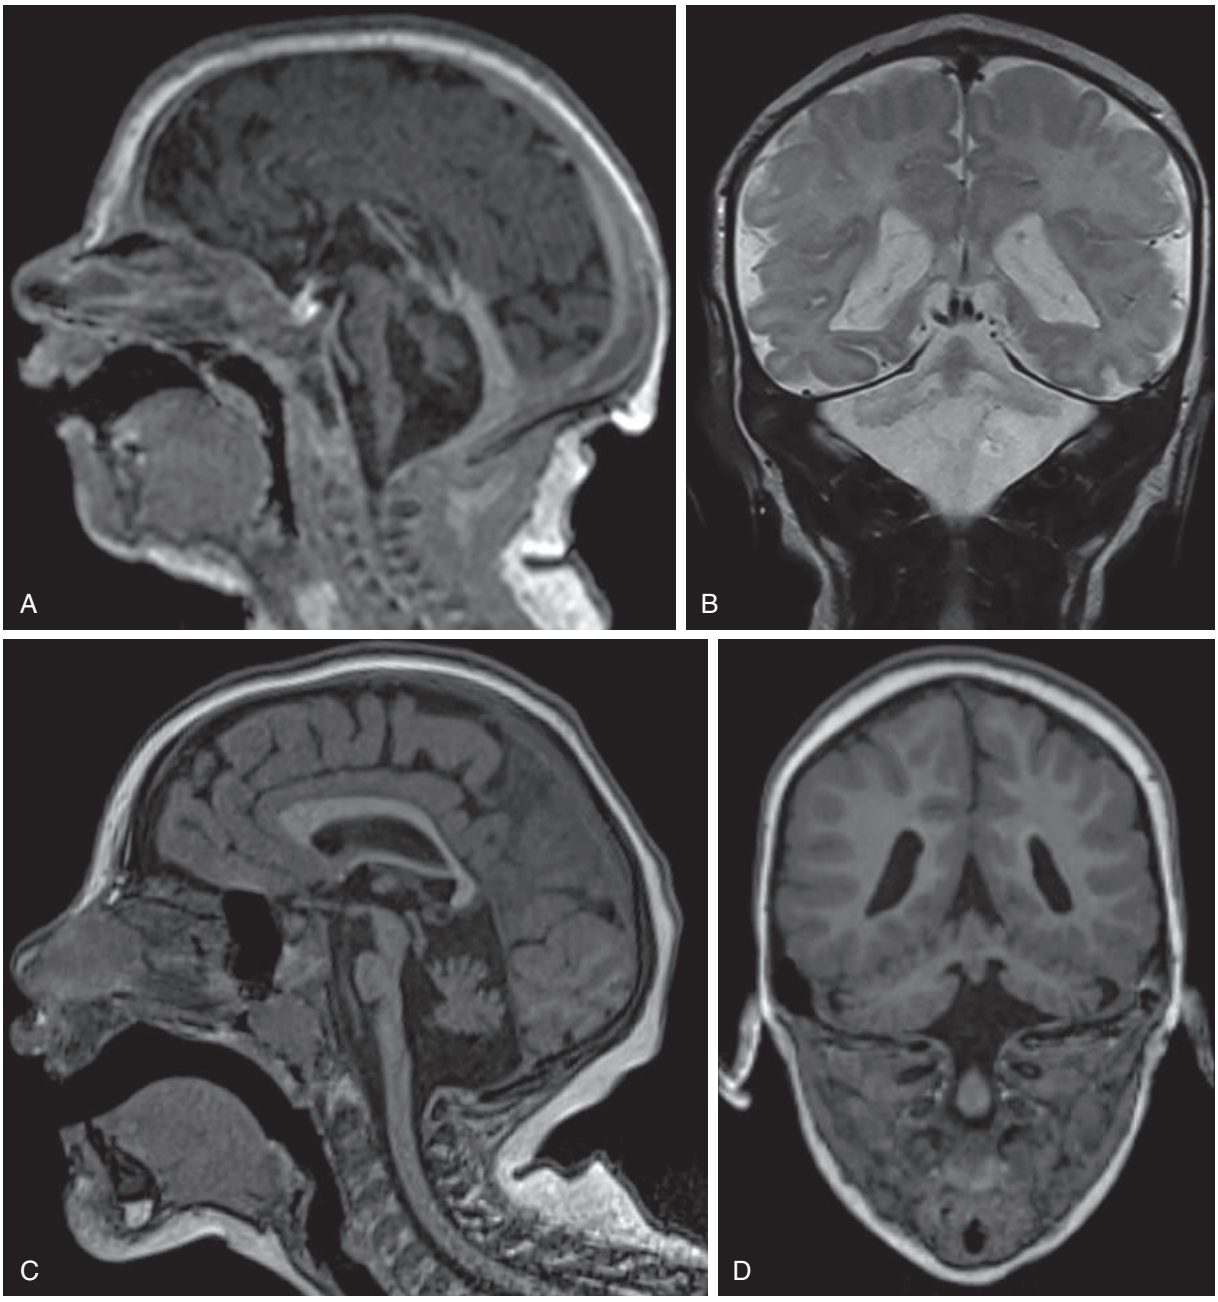
Pontocerebellar hypoplasia (PCH) is a diverse group of largely autosomal recessive disorders characterized by a variable degree of pontine and cerebellar hypoplasia (Fig. 53.11). PCH can occur in association with congenital disorders of glycosylation, mitochondrial diseases, and congenital muscular dystrophies. At least 13 overlapping subtypes of PCH have been proposed, many presenting in the neonatal period.[150] Multiple genetic causes of PCH have been identified, most commonly pathogenic variants in *TSEN54*, but up to 40% of patients do not have an identified cause.[173,174] Given the phenotypic and genetic overlap in these subtypes, the use of a combination of genetic, clinical, and imaging findings is more specific in describing these disorders (Table 53.1).[175] In patients with *TSEN*-related PCH, the vermis is often relatively preserved compared with the hemispheres, in contrast to most other PCH disorders. Outcome data are sparse and depend on the type of PCH, but typically patients have severe developmental delays, tone abnormalities, feeding issues, and respiratory compromise.[175] A number of PCHs have distinctive imaging features that point to specific diagnoses and should be sought through careful review of clinical and radiologic features. For instance, the combination of PCH, asymmetric brainstem, bulbous asymmetric basal ganglia, and cerebellar dysplasia, with or without lissencephaly, in the absence of other malformations, is strongly suggestive of tubulinopathy conditions caused by dysfunction of one of the nervous system specific tubulin genes.[176] *MACF1*-related conditions combine PCH and some degree of lissencephaly without brainstem asymmetry or other malformations.[177] Pontine tegmental cap dysplasia is diagnosed by a characteristic "cap" on the dorsal surface of the pons, with absent inferior cerebellar peduncles, hypoplastic middle cerebellar peduncles, and prominent cranial nerve deficits including sensorineural hearing loss, trigeminal anesthesia, facial palsy, and swallow dysfunction.[178] Improvements in MRI and genetic testing will continue the remarkable progress in our understanding of human hindbrain malformations.

Malformations With Brainstem Involvement

Chiari Malformations

Historically, three numbered types of Chiari malformations have been defined, but they are not etiologically related.

Chiari type I malformation is characterized by inferior ectopia of the cerebellar tonsils into the spinal canal, often with compression of the tonsils and restricted CSF flow. It is uncommonly



• **Fig. 53.11** Pontocerebellar Hypoplasia. (A) T1-weighted sagittal and (B) T2-weighted coronal images of a patient with *TSEN45*-related pontocerebellar hypoplasia *(PCH)*. *TSEN54* pathogenic variants have been identified in PCH types 1, 2, 4, and 5 and can be associated with additional malformations, including atrophic cortex and cerebellar hemisphere hypoplasia more than vermin hypoplasia, cerebellar hemisphere more than vermian hypoplasia. (C) T1-weighted sagittal and (D) T1-weighted coronal images of a patient with *CASK*-related PCH. *CASK*-related PCH may be associated with mild small pons and cerebellum, with proportionate hypoplasia of the cerebellar vermis and hemispheres.

diagnosed in neonates. Diagnosis is based on clinical and imaging findings; patients may have headache and lower cranial nerve, cerebellar, and brainstem dysfunction. Herniation of the tonsils greater than 5 to 10 mm in the presence of symptoms is diagnostic, but similar herniation can be seen in the absence of symptoms. Other findings include syringomyelia and scoliosis.[179] Mild inferior tonsillar ectopia without compression of the tonsils or restricted CSF flow is common and is not usually associated with symptoms. Chiari type I malformation may be either congenital or acquired. In acquired Chiari malformations the posterior fossa size is normal.

Chiari type II malformation is seen almost exclusively in association with open neural tube defects (NTDs) and is defined by displacement of the cerebellar vermis, medulla, and the fourth ventricle into the spinal canal and is associated with a small posterior fossa, "beaked" tectum, and frequently, hydrocephalus. MRI

TABLE 53.1 Pontocerebellar Hypoplasia*

Pontocerebellar Hypoplasia	Clinical Findings	Radiologic Findings	Associated Genes (Major Listed First)
Type I	Spinal muscular atrophy	Mild hypoplastic pons, with proportional hypoplasia of the vermis and hemispheres	*EXOSC3, RARS2, TSEN54, VRK1*
Type 2	Neonatal encephalopathy, progressive microcephaly, increased tone, dyskinesia, seizures, cortical visual impairment	Postmigrational microcephaly, small pons and cerebellum, atrophic cortex with thin corpus callosum, vermis less affected than hemispheres	*TSEN54, TSEN2, TSEN34*
Type 3	Hypotonia, hyperreflexia, infantile seizures, developmental delay	Small pons and cerebellum, reduced amount of cerebral white matter	*PCLO*
Types 4 and 5	Severe type 2	As type 2	*TSEN54, TSEN2, TSEN34*
Type 6	Elevated CSF lactate level	Small pons and cerebellum, vermis affected more severely than hemispheres	*RARS2*
Type 8	Acquired microcephaly, increased tone and contractures, moderate to severe developmental delay	Small pons and cerebellum with proportionate hypoplasia of the vermis and hemispheres	*CHMP1A*
Type 9	Progressive microcephaly, seizure onset in infancy, hypertonia, and visual impairment. Severe developmental delay	Small cerebellum with atrophy, pons with ventral flattening, mega cisterna magna and brainstem with a figure-of-eight appearance, atrophy of cerebral cortex, and corpus callosum hypoplasia	*AMPD2*
Type 10	Progressive microcephaly and neurodegeneration by 6 months, absent or delayed speech, progressive spasticity, spontaneous seizures, severe developmental impairment	Small cerebellum, pons, and corpus callosum with atrophy	*CLP1*

CSF, Cerebrospinal fluid.
*All with autosomal recessive inheritance.

can be used to confirm these findings and often demonstrates cerebellar hypoplasia and ACC, although these features have not been associated with a higher risk of neurodevelopmental issues. Rarely, migration defects, HPE, and interhemispheric cysts can also be seen.[179]

The term *Chiari type III malformation* has been used to refer to a variety of hindbrain malformations that include occipital or high cervical encephalocele, often in combination with kinked brainstem or cervical spinal cord. A review of 57 patients noted encephalocele in about half; symptom severity was largely in proportion to the type and amount of material in the encephalocele.[180] The medical literature on outcomes is extremely limited, but several reported patients have had limited life spans and substantial disabilities.

Neural Tube Defects and Spinal Cord Dysraphisms

Open NTDs result from a failure of primary neural tube closure during the fourth week of gestation.[42] Anencephaly results from failure of anterior neuropore closure, while myeloschisis and myelomeningocele (MMC) result from failure of posterior neuropore closure. Craniorachischisis totalis occurs with the complete failure of neural tube closure and typically results in pregnancy loss during embryogenesis or early fetal development. The remainder of the NTDs discussed here result in malformations of the CNS and the overlying axial skeleton, meninges, and skin that are associated with various degrees of viability in the newborn period.

Epidemiology and Etiology

NTDs are one of the most common congenital malformations encountered in newborns, with 0.5 to 2 in 1000 pregnancies affected worldwide.[181,182] The prevalence differs widely and is particularly influenced by ethnicity, geographic area, and socioeconomic status.[183] In the United States, for example, the risk of NTDs is higher in people of Hispanic descent but lower in people of African American descent. After the first affected pregnancy, the risk of recurrence increases with each subsequent affected pregnancy.[184]

A marked decline in the prevalence of both anencephaly and spina bifida has occurred in recent decades. In 1960 the prevalence for England and Wales was about 6 in 1000 births; in 1990 this rate dropped to about 1 in 1000. The lower rates reflect two major interventions: in utero diagnosis with the termination of affected pregnancies and maternal periconceptional folate therapy. Maternal folate therapy is estimated to prevent approximately 60% to 70% of NTDs, so a combination of interventions may

be required to optimally prevent NTDs, and other factors need to be considered.[183,185–192] Most countries now recommend a healthy diet and folate supplementation before conception through the 12th week of pregnancy, with additional supplementation based on risk.[193,194]

Gene–Environment Association of Neural Tube Defects

The etiology of NTDs is complex and multifactorial, and both genetic and environmental factors interact to determine risk; however, most defects occur sporadically.[182,195] Environmental risk factors linked to NTDs include maternal hyperthermia, hyperglycemia, lower socioeconomic status, dietary factors, and prenatal exposure to a number of drugs, including antiepileptic medications such as valproate and carbamazepine.[182,183,195–198] In addition, the fungal toxin fumonisin has been associated with NTDs. A fourfold to fivefold higher prevalence of NTDs occurs in a Mexican-American population because of fumonisins in corn flour used to make tortillas.[198,199] NTDs have been associated with genes implicated in diabetes mellitus, obesity, and glucose and oxidative stress. The genetics influences on NTDs are also complex, encompassing chromosomal abnormalities (e.g., trisomies 13 and 18), single gene disorders (e.g., Waardenburg syndrome), and risk alleles (*MTHFR* and *VANGL1* variants).[200] Approximately 200 genes are known to be required for neurulation, many of which are involved in folic acid metabolism or transport.[201] Epigenetic mechanisms (such as histone modification, methylation, and nucleosome remodeling) may also play a role in neurulation.[198]

Fetal Diagnosis of Neural Tube Defects

Diagnosis of open NTDs may be suspected in the case of maternal serum elevation of alpha-fetoprotein (AFP) level and can be confirmed by fetal ultrasonography or MRI (Fig. 53.12).[202] AFP screening is designed to detect open NTDs and Down syndrome.[203] The optimal time for determination in maternal serum is 16 to 18 weeks' gestation and in amniotic fluid is 14 to 16 weeks' gestation. In open NTDs (anencephaly, open spina bifida, and open encephalocele), fetal AFP leaks directly into the amniotic fluid, indirectly increasing maternal serum protein levels. By contrast, skin-covered NTDs are not associated with elevated maternal serum AFP levels.[204] A false-positive AFP result can occur with misdating of the fetus (if older than predicted) and a multiple-gestation pregnancy.[205] Other causes of a high maternal serum AFP level include contamination of the amniotic fluid by fetal blood (which may occur in cases of esophageal and duodenal atresia), omphalocele, gastroschisis, congenital nephrosis, polycystic kidneys, renal agenesis, annular pancreas, or fetal demise.

Ultrasonography can be used as early as the end of the first trimester for evaluation of the radiographic signs of NTDs, but more typically the diagnosis is made during the second trimester. Abnormal head and cerebellar shape (the "lemon" and "banana" signs) are more sensitive ultrasound indicators for NTD diagnosis than spinal imaging findings. Historically, fetal MRI has not been superior to ultrasonography for identifying the spinal cord defect; however, for those patients electing to have in utero surgery, MRI is used for surgical planning.

Open Neural Tube Defects

Typically, NTDs are characterized as either open lesions (craniorachischisis, anencephaly, MMC, or myeloschisis) or closed lesions (encephalocele, meningocele, and occult spinal dysraphism).

Anencephaly

Anencephaly results after failed anterior closure where exencephaly converts to anencephaly by degradation of the neural tissue.[206] This is the most severe disorder of anterior neural tube closure. Anencephaly accounts for roughly half of all open NTDs.[182] As an early neurulation defect, it occurs no later than 24 days' gestation. Anencephaly can be diagnosed by fetal ultrasound examination (Fig. 53.13) during the first or second trimester[207,208]; it is frequently associated with polyhydramnios.[209]

Anencephaly most commonly involves the forebrain and upper brainstem. It is characterized by absence of the calvaria, and the intracranial contents are replaced by vascularized, disorganized glial tissue (area cerebrovasculosa).[42,210] The hypothalamus and cerebellum are usually malformed, the anterior lobe of the pituitary is present, and the internal carotid arteries are hypoplastic, which may be secondary to reduced brain parenchyma. Because the anencephalic infant has a period of exencephaly, where brain tissue extrudes through the unformed calvaria and is degraded by exposure to the amniotic fluid, some investigators have hypothesized that the primary defect is abnormal skull formation. There are some cases in which remnants of calvarial bones are present, with brain tissue under the protective bones.[42]

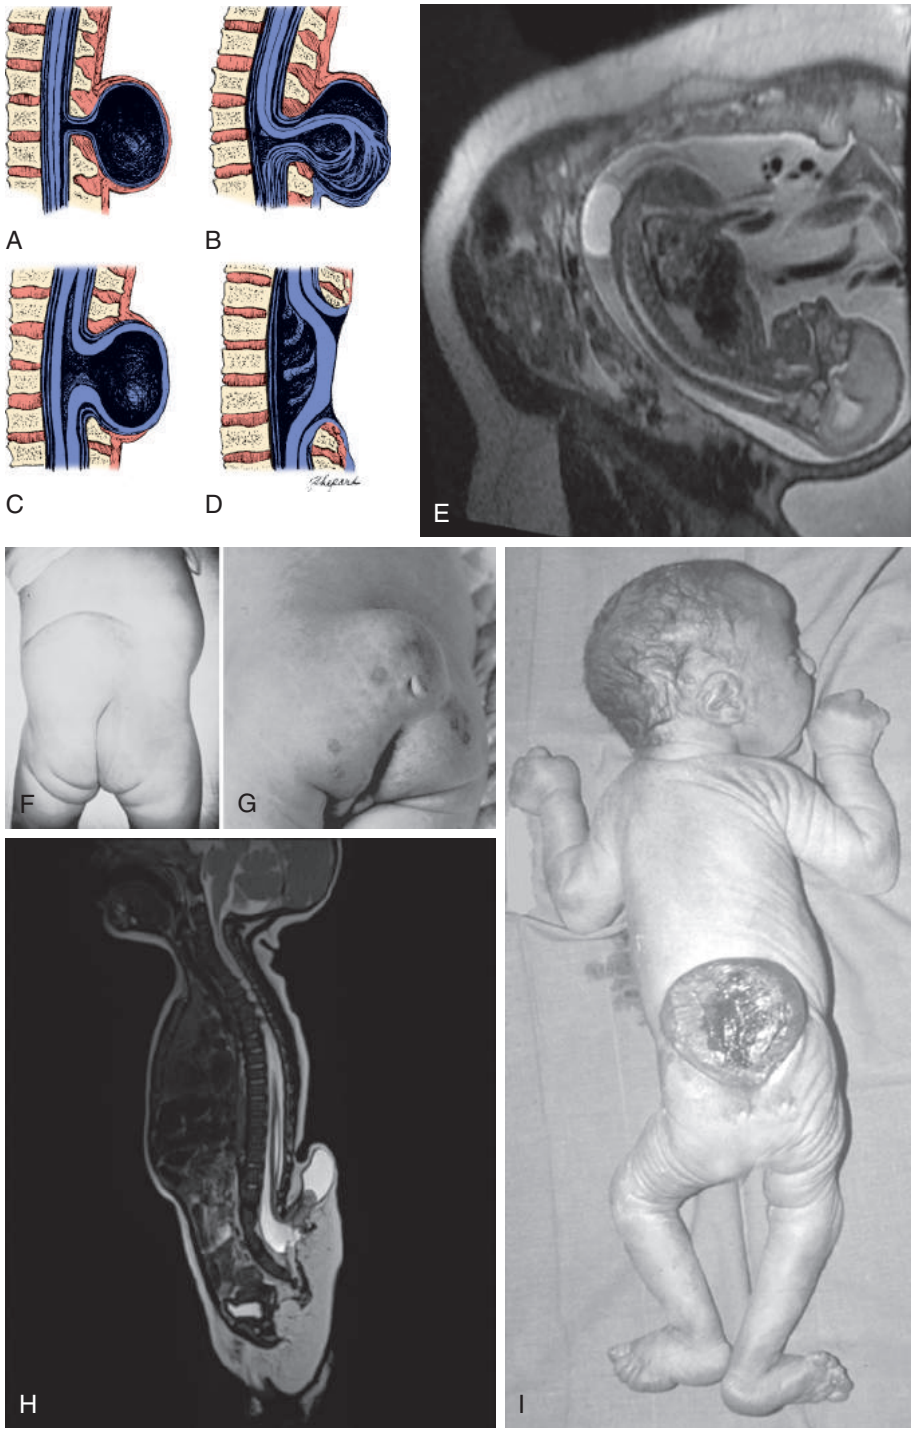
Most neonates are stillborn, and the physical examination is notable for a lack of the brain and cranial vault.[192] Liveborn neonates live less than 1 or 2 months at the most.[211,212] Without intensive care, survival has not been reported beyond the neonatal period. In a series of 211 women who reported choosing to deliver fetuses with an in-utero diagnosis of anencephaly, 72% were liveborn, approximately 67% of the liveborn infants died within 24 hours, and six infants lived for 6 days or more (maximum of 28 days). This study suggested that continuation of pregnancy is a preferred option for some women after they have been counseled about the expected outcomes.[213]

Myelomeningocele

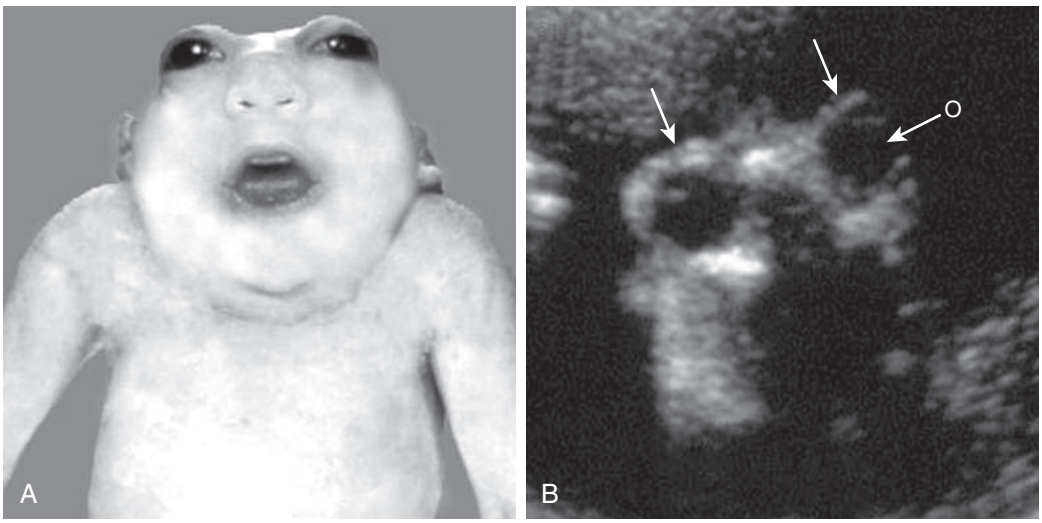
MMC and similar malformations of the spinal cord arise from the failure of posterior neuropore closure, probably no later than day 26 of gestation. Open spinal NTDs are exposed lesions on the back without vertebral or dermal covering (see Fig. 53.12).[210] MMC is characterized by herniation of the meninges and spinal cord at the site of the defect, and most often occur in the lumbar or lumbosacral regions.[155,210]

The diagnosis of MMC is usually made prenatally by ultrasonography and/or increased AFP level.[206] MMC is usually accompanied by other clinically significant CNS abnormalities, including Chiari II malformation and obstructive hydrocephalus.[214] Based on historical data, 60% of patients with occipital, cervical, thoracic, or sacral lesions develop hydrocephalus, in contrast to 90% of those with thoracolumbar, lumbar, or lumbosacral lesions.[215] Because of decompression caused by leakage of CSF from the MMC at birth, hydrocephalus and increased pressure may become evident only after surgical closure of the back.[216]

Clinical management of the newborn with an NTD must be individualized. At present, surgical closure is advocated for



• **Fig. 53.12** Neural Tube Defects. (A) Meningocele. Through the bony defect (spina bifida), the meninges herniate and form a cystic sac filled with spinal fluid. The spinal cord does not participate in the herniation and may or may not be abnormal. (B) Myelomeningocele. Spina bifida with myelomeningocele; the spinal cord is herniated into the sac and ends there or may continue abnormally further downward. (C) Myelocystocele or syringomyelocele. The spinal cord shows hydromyelia; the posterior wall of the spinal cord is attached to the ectoderm and undifferentiated. (D) Myelocele. The spinal cord is araphic; a cystic cavity is in front of the anterior wall of the spinal cord. (E) Fetal magnetic resonance image of lumbosacral dysraphism. Note the ventriculomegaly and crowded posterior fossa. (F–H) Three examples of skin-covered neural tube defects. (F, G) Lesion presented in the left buttock as a firm, well-circumscribed, lobulated tumor that became tense when the infant cried. (G) Macular erosions and a congenital skin tag and dimple over the surface. This last feature may be a pilonidal dimple displaced by the tumor. (H) T2-weighted image of a lipomyelomeningocele. (I) Newborn with a large thoracolumbar myelomeningocele. The distal musculature in the lower extremities was weak. (A–D, From Benda CE. Developmental Disorders of Mentation and Cerebral Palsies. New York, NY: Grune and Stratton; 1952; F–H, Courtesy Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University, Portland, OR.)



• **Fig. 53.13** Anencephaly. (A) Infant with anencephaly. (B) Ultrasonogram of a fetus with anencephaly. Note the absence of the normal cranial structures *(arrows)* superior to the orbits *(O)*. (Courtesy Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University, Portland, OR.)

most infants, resulting in decreased infection, improved cognitive abilities, ambulation, a lower prevalence of incontinence, and lower mortality.[217-219] To prevent infection, surgical closure of the spinal defect should occur within 48 hours after birth. The involvement of a plastic surgeon should be considered, particularly with wide or complex lesions. CSF diversion may be needed concurrently or after the back has healed. Additional surgical procedures may be required for shunt malfunction or infection, sequelae of Chiari II malformation (apnea, stridor, dysphagia), tethered cord, or syringohydromyelia. Initial evaluation of all neonates with a suspected NTD should include assessment of lower extremity sensory and motor function. Attention should be paid to spontaneous movements, response to touch and pain, and voiding and stooling pattern (particularly urinary retention and dribbling). Babies should be closely evaluated for other malformations, including congenital heart disease unless these have been excluded by prenatal ultrasonography. Monitoring neonates for Chiari symptoms (apnea, stridor, poor feeding) and signs of increased intracranial pressure is also required. The overall approach should be multidisciplinary, with the involvement of the neurosurgery, urology, and physical therapy departments at a minimum. Long-term care of the child with MMC also requires symptom management for neurogenic bladder and bowel, as well as endocrine, orthopedic, rehabilitative, and neuropsychiatric care.[220] Developmental pediatric, neurologic, or rehabilitation medicine specialists are often the primary point of contact for long-term management, depending on the resources available.

Fetal surgery has become an option for MMC repair before birth. A randomized trial demonstrated that fetal surgery was associated with a lower rate of shunt placement, possibly better motor function, and slightly higher quality of life scores through school age but was also associated with premature delivery and maternal complications.[221–224] In addition, mothers can require prolonged bedrest during the pregnancy and cannot deliver subsequent children vaginally. No improvements in neurogenic bowel/bladder have been observed as compared with those with standard postnatal care.[225] Fetoscopic back closure holds promise for benefiting the fetus while minimizing risks associated with hysterotomy.[226] In light of these positive results under ideal research conditions, some centers promote fetal surgery as the standard of care; however, the American College of Obstetrics and Gynecology recommends an approach that balances the risks and benefits to both the fetus and the mother.[227]

Myeloschisis

Myeloschisis defects also lack overlying vertebrae and skin but differ from MMC lesions in that there is no overlying CSF-filled sac. This results in a continuous CSF leak. Similar to MMC, myeloschisis is associated with neurogenic bladder and bowel, and their mobility depends on the anatomic level of the defect. Closure may be more difficult than with MMC, and, as with MMC, postclosure hydrocephalus may result.[228] Prenatal diagnosis is by elevated AFP level and/or prenatal ultrasonography.

Skin-Covered Neural Tube Defects

Encephalocele

Encephalocele is considered a postneurulation disorder and likely occurs by mechanisms distinct from those for open NTDs.[192] Encephaloceles typically present as cranial skull defects through which brain tissue protrudes. Less severe defects include cranium bifidum, where there is a failure of midline fusion of the skull, and cranial meningoceles that contain meningeal but not neural tissue. In up to 80% of patients, encephaloceles are occipital (Fig. 53.14), with the remainder in the parietal, frontonasal, intranasal, or nasopharyngeal regions. Geographic or ethnic–genetic factors influence the location of the lesion. Frontal encephaloceles are more prevalent in Southeast Asia, while occipital lesions are more common in Western populations.[229] A role for genetic factors is supported by increased risk in patients with chromosomal disorders and a number of recessive syndromes (e.g., Meckel and Joubert syndromes; see earlier).[230] Overall, about half of infants with encephaloceles have other major congenital anomalies, including microcephaly, arrhinencephaly, anophthalmia, cleft lip or palate, craniosynostosis, complex congenital heart disease, and other malformations.[230]

(C) Postnatal T2-weighted axial magnetic resonance image of a patient with an occipital encephalocele. (D) Postnatal T1-weighted sagittal magnetic resonance image of a patient with an occipital encephalocele. (A, B, Courtesy Dr. Marjorie Grafe, Department of Pathology, Oregon Health and Science University, Portland, OR.)

Encephaloceles are also associated with various other CNS defects that influence surgical management and the severity of the outcome. In a series of 129 patients with anterior encephaloceles (including frontoethmoidal, orbital, transethmoidal, transsellar, and interfrontal), 22 had associated hydrocephalus, and ACC was seen in 16.[231] In addition to hydrocephalus, other anomalies include anomalous draining veins and nodular heterotopia.[210,232] The occurrence of lower occipital lobe encephalocele with skull base defects and malformations of the cerebellum and lower brainstem characterizes Chiari type III malformations.

Evaluation of the infant with an encephalocele can be aided by transillumination, skull radiographs, cranial ultrasonography, computed tomography scan, and MRI. Typically, MRI with magnetic resonance angiography and magnetic resonance venography is the study of choice, particularly for surgical planning. Frontonasal encephaloceles pulse or bulge with brief bilateral jugular vein compression, indicating communication with the subarachnoid space. Nasal gliomas, dermoids, and teratomas can all occur in the same region. Intranasal encephalocele should be suspected when an intranasal mass is found in a child with a broad nasal bridge and widely spaced eyes. Some of these children may also present with recurrent meningitis.[210] Basal encephaloceles are not usually diagnosed in infants and can be located in the nasopharynx, sphenoid sinus, or posterior orbit.

In most patients with encephalocele, neurosurgical management is indicated during infancy; however, large lesions or other severe CNS anomalies may preclude intervention, since typically, brain tissue exterior to the skull cannot be salvaged. Early treatment is imperative for those infants at high risk of meningitis caused by lesions that externally communicate and leak CSF. Surgical repair goals include dural closure and improving cosmesis. Complications can include postoperative CSF leakage or pseudomeningocele formation.[233] For patients who are not surgical candidates, a palliative course should be pursued, although it can be quite challenging to decide which interventions are appropriate for a given patient. Ongoing discussions involving the family, subspecialists, and, ideally, dedicated palliative care providers are essential for good care of these patients.

Encephaloceles can be associated with medically intractable seizures, which may be responsive to surgical resection.[234] Survival

and outcome remain difficult to predict because of the variability of presentation and surgical selection bias. One study of a series of children with encephaloceles reported overall mortality of 29% (45% in infants with posterior defects; 0% in infants with anterior defects).[230] Neurologic deficits were severe in 33% of survivors. Mild neurologic deficits were found in 17% of survivors with anterior defects and in 50% of survivors with posterior defects. Developmental prognosis depends on the amount of neural tissue within the defect,[233] and the outcome can be quite favorable in patients with normal brain anatomy.

Meningocele

Meningoceles are skin-covered lesions containing meningeal tissue that typically herniate through the posterior skull or vertebral column.[192] This occurs more commonly in the lumbosacral spine than in the cervical spine, and while the spinal cord does not extend into the defect, it may still be tethered and eventually cause symptoms. Postnatally, meningoceles may be evaluated by spinal ultrasonography or MRI to evaluate the spine for tethering, syringohydromyelia, and diastematomyelia.[235] At centers without extensive ultrasound expertise, MRI is the study of choice, and computed tomography is used mainly to delineate bony landmarks. Chiari II malformation is not typically seen with posterior meningocele.[236]

Occult Spinal Dysraphisms

Occult spinal dysraphisms are closed defects of the distal part of the spinal cord with an intact dermal covering and are a result of defects of caudal neural tube formation (secondary neurulation). In some instances, these defects are truly occult without any overlying abnormalities of the skin and may go undetected until they become symptomatic. Prenatally, they may be detected by fetal imaging as a mass.[237] In most newborns, an occult spinal dysraphism is accompanied by cutaneous stigmata. Such stigmata include abnormal hair tufts, hemangiomas, pigmented spots, skin tags, aplasia cutis congenita, cutaneous dimples or tracts (particularly with CSF leak), or a subcutaneous mass, often apparent because of an asymmetric gluteal cleft.[237–239] Sacral dimples or deep gluteal clefts between the buttocks without other features are rarely associated with spinal dysraphism, while dimples clearly above the gluteal cleft are associated with a higher risk of spinal dysraphism.

Spinal dysraphisms are classified by a clinical, imaging, and developmental approach.[240–242] MRI is indicated for evaluation and diagnosis, when available. For closed dysraphisms, the initial distinction is based on the presence of a subcutaneous mass.[243] Skin-covered lesions without a subcutaneous mass should be examined clinically for skin tags, evidence of spinal cord dysfunction, and anorectal malformations. Defects with subcutaneous masses are classified by the tissue types involved: lipomyelocele (fat and meninges), lipo-MMC (fat, nerve, and meninges), meningocele (meninges only), and terminal myelocystocele, a complex lesion with persistence of the terminal syringohydromyelic cavity.[237]

Other spinal cord lesions associated with occult dysraphism include diastematomyelia–diplomyelia, lipoma, teratoma, and other tumors, dermal sinus with or without dermoid or epidermoid cyst formation, and tethered cord.[203,210] More severe lesions include neurenteric cysts, anterior meningocele, and caudal regression syndrome (dysraphia of sacrum and coccyx, atrophy of muscles and bones of the legs, fusion of spinal nerves and sensory ganglia, or agenesis of the distal part of the spinal cord).[244] As with other NTDs, infants of diabetic mothers are at increased risk of these lesions.[245] Abnormal conus and a thickened filum are usually present, and a symptomatic tethered cord is a common presentation after surgical repair of both skin-covered lesions and MMC.[246] Thickened filum with or without a small amount of fat can be seen frequently on spinal MRI and is usually not significant in the absence of a low-lying conus and neurologic symptoms. Hydrocephalus is rare in patients with occult spinal dysraphisms.

Clinical Features and Diagnosis

Progressive functional impairment can occur as the cord is stretched against the fixed filum,[247] but neurologic impairment rarely presents in the neonatal period.[248] Atypical voiding and stooling (particularly continuous dribbling) should prompt bladder volume measurement and urologic and neurosurgical referral. Delay in walking, disturbed sphincter control, contractures of the feet or legs, and pain in the back or legs may present in infancy or childhood, while gait and sphincter abnormalities, foot deformities, and scoliosis are more common in older patients. Rarely, recurrent meningitis and acute loss of function are seen.

Because prophylactic surgical intervention may prevent deterioration, early diagnosis is a necessity.[242,248,249] In neonates this evaluation may be facilitated by spinal ultrasonography, which permits a dynamic evaluation of lower spinal cord mobility, and MRI to define structural anomalies of the cord. Evaluation should occur as soon as a closed spinal dysraphism is suspected. The timing of surgical management depends on the presence or progression of neurologic symptoms and signs. The care of these children requires a multidisciplinary approach for the management of neurosurgical issues and comorbidities.[250]

Brain Injury in the Preterm Infant

ART RIDDLE, STEVEN P. MILLER, AND STEPHEN A. BACK

KEY POINTS

- Intraventricular hemorrhage (IVH) remains a common cause of chronic neurologic morbidity. Despite a gradual decline in the incidence of most grades of IVH, the increased survival of very low birth weight infants has resulted in an increase in the absolute number of infants with IVH.
- Preterm infants are currently at much lower risk of severe white matter injury (WMI), which typically results in focal cystic necrosis and secondary gray matter degeneration. Cystic WMI is commonly associated with cerebral palsy, cortical visual impairment, and a spectrum of cognitive and learning disabilities.
- Preterm infants commonly display less severe diffuse WMI that results primarily in myelination disturbances related to the death of oligodendrocyte progenitors (preOLs). As applied clinically, both diagnostic cranial ultrasonography and magnetic resonance imaging (MRI) appear to underdiagnose the full extent of diffuse WMI.
- Chronic diffuse WMI is accompanied by reduced cerebral white matter growth related to a series of dysmaturation events that result in the regeneration of preOLs that fail to differentiate into myelinating oligodendrocytes. Chronic diffuse WMI is also accompanied by reduced cerebral gray matter growth that appears to be related to widespread disturbances in neuronal maturation rather than loss of developing neurons. These changes are evident in experimental models and in preterm neonates studied with quantitative MRI.
- Diffuse WMI, often reflected in punctate WMI on diagnostic MRI, is linked to a broad spectrum of persistent neurobehavioral disabilities that include impairments in motor and cognitive skills. Punctate WMI is most readily diagnosed on early-preterm MRI scans, becoming harder to detect at term-equivalent age. The burden of punctate WMI, referring to lesion volume *and* location, predicts motor and cognitive dysfunction. The spectrum of neurodevelopmental impairments that follow WMI in the preterm neonate are consistent with the dysmaturation in white matter and cerebral gray matter.
- These recently recognized forms of cerebral gray and white matter dysmaturation present new challenges for diagnosis and suggest new therapeutic strategies to promote the reversal of the processes that cause dysmaturation of neurons and preOLs.

General Principles of Preterm Brain Injury

The preterm brain is susceptible to a broad spectrum of injury that ranges from diffuse nonnecrotic lesions to hemorrhage to severe necrotic tissue destruction. Brain injury is initiated by two major *upstream mechanisms—hypoxia* and *ischemia*—with the potential for infection/inflammation to interact with these triggers and potentiate each other. Because the developing brain is rapidly evolving, the susceptibility to injury is critically related to the timing and severity of the insult. As brain development progresses, distinct populations of cells are selectively more vulnerable to injury, whereas others display greater resistance. Moreover, a wide variety of additional factors may sensitize the brain's susceptibility to injury. The preterm brain may be exposed to a variety of subclinical factors that in isolation may not be injurious but in combination may synergize to potentiate injury. Such factors include nutritional status, systemic illnesses, exposure to glucocorticoids, analgesics, and sedatives, the burden of painful procedures, and other sources of neonatal stress. Equally important to consider is the concept of tolerance in which an antecedent subinjurious insult may reduce the severity of a subsequent one. For example, a low-grade fetal infection or chronic hypoxia in a child with congenital heart disease may be protective against a subsequent more severe hypoxic-ischemic insult.

This chapter addresses three common and frequently overlapping forms of preterm cerebral injury: intraventricular hemorrhage (IVH), white matter injury (WMI), and gray matter injury. The impact of preterm cerebral injury is considerable. Among children born very preterm, even with modern neonatal intensive care, 5% to 10% have major motor deficits, including cerebral palsy related to significant WMI, and more than half have significant cognitive, behavioral, or sensory deficits.[1] These cognitive and neurobehavioral deficits are increasingly observed in the absence of significant motor impairments or cerebral palsy,[2] which has also suggested *primary* involvement of multiple gray matter structures. Gray matter injury was previously attributed to cystic necrotic WMI that led to *secondary* cortical and subcortical gray matter degeneration. Although contemporary cohorts of preterm survivors commonly display less severe injury, these milder forms of injury are associated with both reduced cerebral gray matter growth and reduced cerebral white matter growth.

WMI is tightly linked with brain dysmaturation. The primary mechanism of myelination failure in preterm neonates is dysmaturation, a disrupted cellular response whereby pre-oligodendrocytes fail to differentiate, that is, maturation arrest.[3] This is often accompanied by *neuronal* dysmaturation, a process that may also be initiated by hypoxia alone.[4–9] There is emerging evidence that neonatal brain dysmaturation is the most important predictor of neurodevelopmental impairments in preterm neonates in the first years of life.[10,11] Dysmaturation leads to impairment in cerebral growth that arises from complex and disparate responses of neurons and glia that fail to fully mature during a critical window in the development of neural circuitry.[8] Thus, preterm children are at increased risk for a broad range of cognitive impairments,

including reduced IQ, processing deficits in attention and executive functions (e.g., processing speed, working memory), and challenges with information processing and language that impact educational performance and behavior[12,13] and persist through childhood.[14] Adult survivors of prematurity have increased rates of cognitive, behavioral, and psychological problems that correlate with altered markers of brain development on MRI.[15–18] Hence, these highly prevalent neurocognitive impairments that span early development to adulthood support widely distributed disturbances in brain growth and connectivity that involve both gray matter and white matter.[19]

Intraventricular and Periventricular Hemorrhage

Pathogenesis

IVH is a common injury in the preterm brain, originating in the subependymal germinal matrix, a highly vascularized region with highly active angiogenesis during this period in development.[20] Cortical neuronal and glial progenitors develop from the germinal matrix and adjacent ventricular germinal zone during the late second and early third trimesters. The consequences of IVH are thus potentially several fold. IVH triggers degeneration of progenitor populations that are actively establishing cerebral connectivity.[21] Hemorrhage disrupts the blood-brain barrier exposing the preterm brain to toxic and pro-inflammatory substances, which may potentiate the risk for further hemorrhage by disrupting pathways that stabilize the vasculature.[22,23] Moreover, disruption of the germinal matrix disrupts neonatal neurogenesis, with a particular impact on later maturing populations of neurons including interneurons, which are key to the regulation of synaptic activity.[24,25] Severe IVH with parenchymal white matter extension additionally targets vulnerable glial progenitors leading to disturbances in myelination.

Involution of the germinal matrix occurs with advancing gestation. The subependymal germinal matrix derives its arterial supply from the anterior and middle cerebral arteries as well as the anterior choroidal artery. These arteries feed an elaborate capillary network of thin-walled vessels that is continuous with a deep venous system that terminates in the vein of Galen. The terminal, choroidal, and thalamostriate veins course anteriorly to form the internal cerebral vein, which courses posteriorly to join the vein of Galen. Several of these veins make a pronounced U-shaped turn as they join with the internal cerebral vein. This turn may influence venous drainage and pressure in the germinal matrix. Visualization of subependymal venous anatomy using susceptibility-weighted venography recently identified five anatomical variants that differ from the classical anatomical pattern and were associated with increased risk for IVH.[26]

The predisposition of the preterm infant to IVH is due to several hemodynamic factors.[27] A pressure-passive state exists because of the lack of autoregulation of blood flow in the cerebral arterioles of the preterm brain. In the presence of a highly vascularized subependymal germinal matrix, the risk of IVH is enhanced by the lack of a supporting basement membrane for the germinal matrix blood vessels, an increased amount of fibrinolytic activity, and a decrease in extravascular tissue pressure in the first few days of extrauterine life. Thus, IVH may occur in the setting of elevated venous pressure or an increase in fluctuations in cerebral blood flow (CBF) velocity triggered by factors that include respiratory distress, pneumothorax, asphyxia, myocardial failure, patent ductus arteriosus, arterial hypotension, hypothermia, and hyperosmolarity.[28] Fluctuating pressure passivity is common in preterm infants and may be associated with and precede IVH.[29–31]

• BOX 54.1 Pathogenic Factors Leading to Intraventricular Hemorrhage

Increase in cerebral blood flow
Fluctuation in cerebral blood flow
Increase in cerebral venous pressure
Endothelial injury
Vulnerable germinal matrix capillaries
Coagulation disturbances
Increased fibrinolysis

IVH has been produced experimentally when hypotension is followed by reperfusion.[32,33] These studies support the finding that IVH is more likely when an early period of prolonged hypotension is followed by an increase in blood pressure.[34,35] Isolated hypertension associated with seizures, intubation, and suctioning also predisposes the brain to IVH.[36,37] Even gavage feeding and surfactant administration can lead to changes in cerebral hemodynamics, as measured by near-infrared spectroscopy, that lead to IVH.[38–40] Box 54.1 lists key factors that may interact to produce IVH.

Cellular injury in infants with grade III or grade IV (periventricular hemorrhagic infarction [PVHI]) IVH may occur from antecedent ischemic injury, a decrease in cerebral blood flow, increased intracranial pressure, or vasospasm. More severe IVH is associated with cerebral WMI, cerebellar injury, and less frequently, pontine neuronal necrosis.[41] In this setting, venous infarction leads to neuronal as well as glial death. In a contemporary multi-center cohort, grade II-III intraventricular hemorrhage was associated with a higher risk of punctate WMI, suggesting links to the less severe spectrum of brain injury.[42]

The contribution of coagulation disorders and genetic factors to the pathogenesis of fetal or neonatal IVH remains unresolved. Fetal IVH occurs infrequently and in association with a wide variety of conditions, which include fetal bleeding disorders, anticoagulation, and conditions associated with thrombocytopenia including alloimmunization and hypoxemia.[43] Fetal IVH is also associated with apparent remote perinatal strokes in term newborns who present with hemiparesis related to periventricular venous infarction.[44] Mechanisms for coagulopathies in neonatal IVH may include thrombocytopenia related to platelet consumption or destruction in the setting of sepsis or pro-inflammatory states.[45] Roles for factor V Leiden or prothrombin variants in IVH also are of unclear significance.[46] Currently under study are many potential IVH risk genes including those involved in collagen-mediated vascular stabilization (e.g., COL4A1), nitric oxide-mediated vasomotor function (e.g., NOS3, encoding endothelial nitric oxide synthase), and vasoconstriction-mediated cerebral autoregulation (e.g., END1, encoding endothelin 1).[47]

Site, Incidence, and Timing of Hemorrhage

In preterm infants, germinal matrix hemorrhage is most commonly seen at the junction of the terminal, choroidal, and thalamostriate veins in the germinal matrix overlying the body of the

caudate nucleus at the level of the foramen of Monro. Parenchymal hemorrhage occurs most commonly in the frontoparietal regions, where it appears not to be an extension of IVH but rather a separate process—a hemorrhagic infarction. The hemorrhage is more often unilateral or, in less than a third of cases, asymmetrically bilateral.

The incidence and severity of IVH increase with decreasing gestation and peak at the limit of viability.[48,49] IVH occurs infrequently in term newborns, but often in association with birth-related complications.[50] The overall incidence of grade III IVH and PVHI in VLBW infants varies among centers and generally ranges from 10% to 20% for the majority of population-based studies worldwide.[48,49,51] Recent data from over 50,000 VLBW infants found an overall incidence of IVH of 24.6% and 8.1% for grade III IVH and PVHI.[52] Importantly, in very preterm neonates, even low-grade IVH is associated with an increased risk of WMI.[42] Although there has been a decline in the incidence of most grades of IVH, the increased survival of VLBW infants has resulted in an increase in the absolute number of infants with IVH who are at risk for adverse neurodevelopmental outcomes,[53,54] which include cerebral palsy, developmental delay, hydrocephalus, and epilepsy.

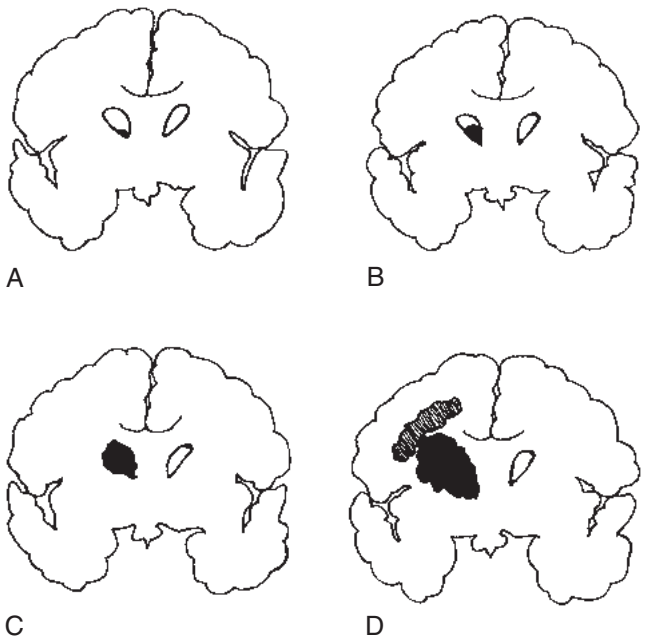
The high-risk period for IVH is the first 3 or 4 days of life. Hemorrhage is rarely seen at birth, although it has been reported as early as the first hour of life.[55] Around half of neonatal hemorrhages occur by the sixth hour of life, and only about a third occur after the first 24 hours of life.[56] Less than 5% of newborns develop IVH after the fourth or fifth day of life with a small percentage occurring by 7 to 10 days of life.[28] Both early and later onset of hemorrhage may occur because of systemic hypoperfusion that results in disturbances in cerebral blood flow.[57]

Clinical Presentation

The clinical presentation of IVH in the newborn depends on the extent of the hemorrhage.[58] It may range from *asymptomatic* to a sudden and catastrophic deterioration that manifests itself with neurologic signs such as stupor or coma, seizures, decerebrate posturing, or apnea. A tense fontanel together with a sudden drop in hematocrit, hyperglycemia, hyperkalemia, hypotension, or bradycardia may herald an IVH. Inappropriate secretion of antidiuretic hormone may occur. The more common presentation, however, is that of a gradual clinical deterioration with an altered level of consciousness, hypotonia, abnormal extremity, or eye movements. In 25% to 50% of cases, clinical signs are lacking and IVH is identified on routine cranial ultrasound screening.[59]

Grading of Intraventricular Hemorrhage

Ultrasound examination is a reliable and sensitive bedside technique for the evaluation of IVH. Papile et al.[60] adapted the standard grading system originally applied to computed tomographic images of IVH to ultrasound images. They classified IVH into four grades of severity related to the location and extent of the hemorrhage (Fig. 54.1, Table 54.1). This classification system was previously used widely for outcome studies. Currently, the more widely used grading system is that proposed by Volpe et al.,[41] which relies on the cranial ultrasound examination to define the extent of ventricular hemorrhage. Because parenchymal involvement is a distinct process, it is not included in the continuous grading of IVH severity (Table 54.1). PVHI appears to arise from venous infarction of the periventricular white matter rather than from a direct extension of the IVH



• **Fig. 54.1** The Progressive Grades of Intraventricular Hemorrhage from Mildest to Most Severe. (A) Grade I hemorrhage involves less than 10% of the ventricular volume of the lateral ventricles. (B) Grade II involves 10% to 50% of the ventricular volume. (C) Grade III involves more than 50% of the ventricular volume and is frequently associated with ventricular dilatation. (D) Hemorrhage is associated with parenchymal infarction.

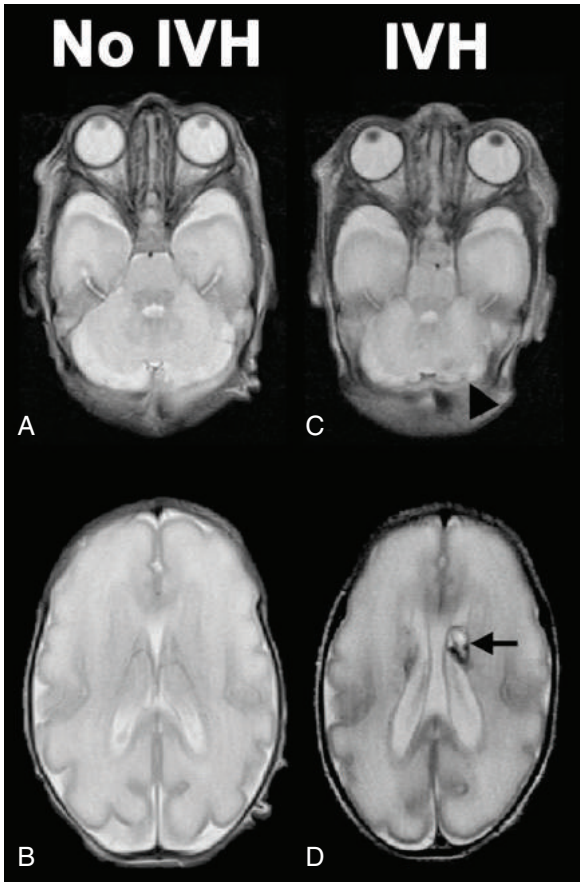
TABLE 54.1 Grading of Intraventricular Hemorrhage by Cranial Ultrasound

PAPILE GRADING SYSTEM[60]		VOLPE GRADING SYSTEM[41]	
Grade	**Findings**	**Grade**	**Findings**
I	Subependymal hemorrhage with minimal or no IVH	I	Germinal matrix hemorrhage IVH <10% of the ventricular volume
II	Definite IVH without distention of the ventricles	II	IVH 10%–50% of the ventricular volume
III	Enlargement of the ventricles secondary to distention with blood	III	IVH >50% of the ventricular volume, usually with distention of lateral ventricle
IV	Extension of the hemorrhage into the parenchyma along with IVH and enlargement	Periventricular hemorrhagic infarction (PVHI)	Periventricular echodensity signifying parenchymal lesion

IVH, Intraventricular hemorrhage.

into the parenchyma.[41] Hence the presence of intracerebral hemorrhage or parenchymal lesions is described separately and is not designated as grade IV. Intraparenchymal hemorrhage is followed in 1 to 8 weeks by tissue destruction and the formation of a porencephalic cyst. Serial ultrasound examinations are especially important in linking the severity of IVH with neurodevelopmental outcomes.[61–63]

In addition to various forms of cerebral WMI, IVH may cause graded injury to the cerebellum (Fig. 54.2) that manifests as magnetic resonance imaging (MRI) defined changes in microstructure[64] and reductions in cerebellar growth.[65] This reduced growth appears to be related to a large population of proliferative external granule cells that are the progenitors that generate the internal granule cell layer, and which account for most of the cells in the human cerebellum. These cerebellar progenitors may be particularly vulnerable to the toxicity of IVH-derived blood products, which are detected by MRI as hemosiderin deposition on the surface of the brainstem and cerebellum.[66,67] The heightened vulnerability of cerebellar progenitors is consistent with serial neuroimaging studies of human preterm survivors that demonstrated disrupted cerebellar growth in response to postnatal glucocorticoid exposure.[68] Furthermore, with the increasing use of MRI with "blood-sensitive" sequences such as susceptibility weighted images, primary hemorrhage in the cerebellar germinal matrix is increasingly recognized. Neurodevelopmental assessments at 4.5 years show that the size and location of cerebellar hemorrhages are associated with dose-dependent disturbances in motor and visuomotor function and increased externalizing behaviors.[69] Given this, the volumetric quantification and localization of a cerebellar hemorrhage, even when small, may allow for targeted rehabilitation interventions.



• **Fig. 54.2** Intraventricular Hemorrhage is Associated with Impaired Growth of the Cerebellum. (A, B) The normal appearance of the brain and cerebellum in a preterm neonate born at 28 weeks' gestational age who was imaged by magnetic resonance imaging (MRI) at 30.3 weeks. (C, D) Smaller cerebellum *(arrowhead)* associated with intraventricular hemorrhage (IVH) *(arrow)* in a preterm neonate born at 28 weeks' gestational age who was imaged by MRI at 30.1 weeks.

Outcome and Prognosis

Isolated grade I and II hemorrhages generally resolve without evolution. Grade III hemorrhages evolve over a period of 1 to 3 weeks and may produce a fibrotic reaction that obliterates the subarachnoid space with subsequent ventricular dilatation and hydrocephalus. Clinical symptoms of progressive hydrocephalus, such as rapid head growth, a full anterior fontanel, or separation of cranial sutures, often appear days or weeks after the onset of ventricular dilatation. The delayed onset of clinical symptoms is related to the presence of a large subarachnoid space as well as the paucity of myelin in preterm infants.

Outcomes differ between studies, but in general, mortality rates are not significantly increased in infants with a grade I or grade II hemorrhage. Grade III hemorrhages and PVHI are associated with increased mortality. In 15% of cases of IVH, areas of PVHI occur that are associated with mortality rates that approach 50% greater than those in infants without IVH.[54,70,71]

Several studies have focused on the relationship between IVH and subsequent neurodevelopmental outcomes. In extremely low birth weight (ELBW, <1000 g) survivors, even grade I and grade II IVH have been associated with a modest increase in morbidity relative to those infants without IVH in some,[72–74] but not all studies.[75,76] However, given the considerable morbidity associated with extreme prematurity, it can be challenging to independently assess the increased risk of neurologic complications associated with lower grades of IVH. One study of nearly 1500 ELBW survivors found that grade I and grade II IVH were associated with a 7% greater rate of poor neurodevelopmental outcomes after the exclusion of other cranial ultrasound abnormalities such as WMI or porencephaly.[54] Long-term outcome studies at 8 years of age found that even low-grade IVH was associated with higher rates of CP compared to infants without IVH.[77] The prognosis for infants with grade I and grade II IVH thus may not be benign if there is a comorbid brain injury. This increased risk of abnormal outcome may be related to underrecognized WMI or gray matter injury.[42,78,79] Follow-up studies have shown that the degree of IVH at birth and the presence of ventriculomegaly are predictors of neurologic status at a corrected age of 24 months. Neurologic sequelae occur in up to 35% of infants with grade III IVH and 55% with grade IV IVH.[70] The persistence of ventriculomegaly in grade III or grade IV IVH is associated with a greater risk of more severe neurologic sequelae that include seizures, cerebral palsy, and severe impairment of vision or hearing.[80] Posthemorrhagic ventricular dilatation (PHVD) is a common sequela of severe IVH and of PVHI and may precede posthemorrhagic hydrocephalus (PHH). Variation in management in PHVD likely contributes to the wide variance in outcome following PHVD. The management of PHVD and its relationship with the outcome is addressed later in this chapter.

Prevention

Prevention of preterm birth is the most effective method of reducing the incidence of IVH. In the event of preterm labor, it is advisable that the neonate be born at a center specializing in high-risk deliveries. The risk of IVH is higher in neonates who are outborn and transported after birth.[81,82] Prenatal administration of steroids is associated with a decreased risk of mortality, IVH, and cerebral palsy.[49,83–85] Dexamethasone and betamethasone appear to be equally effective to reduce mortality, neurodevelopmental disabilities, and IVH.[86,87] Prenatal administration of magnesium sulfate reduces the combined risk of fetal/infant death and CP.[88,89] However, there is no clear benefit of magnesium sulfate to reduce the risk for IVH.[90,91]

Neonatal delivery room or resuscitation practices may be associated with increased IVH risk. At some gestational ages, VLBW infants were at risk for worse outcomes including higher rates of IVH after cardiopulmonary resuscitation.[49,92,93] Delivery of high tidal volumes during positive pressure ventilation carries an increased risk for severe IVH.[94] Umbilical cord milking was also associated with a higher rate of severe grades of IVH when compared with delayed umbilical cord clamping.[95] A relatively small trial found reduced rates of IVH with delayed cord clamping, potentially mediated by improved cerebral autoregulation.[96]

Optimization of neonatal nursing care to avoid abrupt fluctuations in systemic pressure also appear to decrease the risk of IVH.[97,98] Optimal neurologic intensive care of the preterm infant includes reduced exposure to hyperventilation, hypocarbia, or hypoxemia, as well as maintenance of adequate mean arterial pressure (MAP).[99–101] Abrupt elevations in CBF may be precipitated by excessive handling or tracheal suctioning. Other risks for IVH include pneumothorax, acidosis, rapid infusions of sodium bicarbonate, and volume expanders.

Because of the increased risk of adverse neurodevelopmental sequelae in infants with IVH, several clinical trials have been performed to evaluate the role of prolonged neuromuscular paralysis in preterm infants. A meta-analysis of five trials concluded that although neuromuscular paralysis with pancuronium may decrease the risk of IVH and pneumothorax in asynchronously breathing infants, its routine use was not recommended because of concerns about safety and long-term pulmonary and neurologic effects.[102]

A low MAP or increased fluctuations of blood pressure have been associated with an increased risk of IVH.[103] Although close monitoring of the MAP is recommended, there is no evidence that pharmacologic manipulation of systemic blood pressure (e.g., with pressors, steroids, or volume expanders) to achieve a set goal (e.g., MAP >30 mmHg) alters the incidence of IVH or improves neonatal outcome. In early studies, phenobarbital administration appeared to be beneficial by preventing fluctuations in blood pressure.[104,105] However, a subsequent multicenter trial of prenatal administration of phenobarbital (10 mg/kg) to 110 women provided no reduction in the postnatal frequency of IVH in preterm infants between 24 and 33 weeks' gestational age.[106] A larger trial confirmed these findings, and long-term follow-up at 18 to 22 months found no difference in neurodevelopmental outcomes.[107,108] A meta-analysis of 10 trials of postnatal administration of phenobarbital showed no difference in the rates of severe IVH or ventriculomegaly.[109] Therefore, postnatal administration of phenobarbital does not appear to be beneficial for the prevention of IVH.

Pharmacologic doses of vitamin E, an antioxidant, were associated with a reduction in the incidence of IVH in low birth weight infants when given intramuscularly.[110] However, after reports of the association of such large doses of vitamin E with sepsis and necrotizing enterocolitis, its use for prevention of IVH was curtailed.[111,112]

Indomethacin, a prostaglandin synthase inhibitor, was originally found to decrease the incidence of IVH in infants weighing less than 1250 g.[113] However, later studies on the long-term effects of indomethacin prophylaxis in ELBW infants showed no increase in the rate of survival without neurosensory impairment, despite a reduction in the rate of severe IVH.[114–116] A meta-analysis of 19 trials involving 2872 infants found an increased risk of oliguria, which was not associated with major renal impairment. There was no difference in the incidence of necrotizing enterocolitis, a modest reduction in the number of infants with severe IVH, and no difference in long-term neurosensory impairments.[117] Prenatal administration of indomethacin, as a tocolytic to arrest preterm labor, is associated with increased risks of severe IVH and WMI.[118] However, recent evidence suggests the decreased risk of WMI with prolonged postnatal indomethacin exposure in the preterm neonate.[119,120]

Prenatal administration of steroids[121–126] and surfactant replacement therapy[127,128] decrease the incidence of IVH as well as neonatal mortality in low-birth-weight infants. However, an increase in the incidence of IVH may occur with surfactant administration as a result of the mode of instillation[129–131] and a drop in $Paco_2$ with improved ventilation. Since a significant drop in MAP and CBF volume can occur during surfactant administration, attention should be paid to the speed and volume of instillation.

Mechanical ventilation may be associated with an increased risk of IVH.[132] Several studies evaluated the early use of high-frequency ventilation versus conventional ventilation for infants with respiratory distress syndrome. These studies found either an increased risk of IVH with high-frequency oscillatory ventilation[133–135] or no increase in IVH risk.[136,137] The results of a recent meta-analysis of 19 studies and 4096 infants found no increased risk of severe IVH or WMI in preterm infants treated with high-frequency versus conventional ventilation.[132]

It is important to avoid both hypocarbia (PCO_2 <30 mmHg) and hypercarbia (PCO_2 >55 mmHg) because of their significant effects on CBF.[138–143] Avoiding low PCO_2 has been shown to be neuroprotective in animal studies.[144,145] Hypocarbia is associated with hypotension and an increased risk of IVH and WMI.[146,147] Hypercarbia promotes increased cerebral blood flow, which in the presence of other therapies aimed at increasing blood pressure increases the risk of IVH.[147–149]

Free radicals and iron have been shown to be damaging to oligodendrocyte progenitors (preOLs) in both cell culture and animal studies,[150,151] and iron-chelating agents have been shown to be neuroprotective in animal models of IVH.[152,153] However, clinical studies are lacking to evaluate the benefit of antioxidants such as iron chelators in the setting of IVH. As 80% of iron transfer occurs in the third trimester, it is also important to emphasize that iron sufficiency is required for normal brain development, and so withholding or chelating iron may be detrimental.

Management

Because of the high risk of IVH and ischemic WMI in the early perinatal period, short-term management should be focused on the elimination of factors shown to promote excessive fluctuations

in CBF[103] and the prevention of nosocomial infections.[154,155] Clinical practices to limit fluctuations in CBF include delayed cord clamping, maintenance of blood gases and metabolic status within a normal range, avoidance of excessive suctioning and handling, and detection and treatment of seizures. Systemic blood pressure should be maintained with particular attention to the rate of administration of fluids.

Infants with birth weights of less than 1500 g or a gestational age of less than 32 weeks should undergo a screening ultrasound examination to detect IVH in the perinatal period when the risk of IVH is the highest.[156] An initial routine cranial ultrasound scan is optimally done within 4 to 7 days of age, as an ultrasound scan on the fourth postnatal day detects 90% of lesions.[157] If normal, a repeat scan at 4 to 6 weeks of age improves detection of WMI and at term-equivalent age may inform risk for neurodevelopmental disabilities.[158,159] If IVH is detected, a repeat ultrasound examination after 5 to 7 days may be necessary to establish the IVH grade because the hemorrhage may extend during the next several days. Serial imaging is often necessary because about half of infants with ventricular enlargement from IVH develop rapidly progressive ventricular dilatation during the next 4 to 8 weeks. In the setting of severe IVH, regular screening ultrasound examinations every 1 to 2 weeks to reevaluate the neonate for progressive ventricular dilation and WMI should complement measurement of head circumference, examination of the fontanel, and assessment of clinical status until 36 weeks of life.[160] Clinical recommendations for the surveillance and management of PHVD have recently been revised.[161] The decision to continue intensive care support is partly informed by the severity of the IVH and associated brain injury as assessed by a combination of cranial ultrasound and MRI examinations. MRI is the optimal imaging modality to detect smaller cerebellar hemorrhages and potentially more subtle forms of noncystic WMI.[160]

There is a lack of broad consensus for evidence-based guidelines on the optimal clinical management of PHVD,[162] though more recent evidence favors earlier intervention. Serial lumbar punctures or ventricular taps were previously used in the nonsurgical management of PHVD to temporarily prevent the progression of hydrocephalus and potentially reduce the need for shunt placement. A systematic review of four controlled trials found that the early removal of debris from liquefied blood clots did not reduce mortality, developmental disabilities, or the risk of permanent shunt dependence, and was associated with an increased risk of central nervous system (CNS) infection.[163,164] However, other studies suggest that increasing ventricular size predicts more adverse neurodevelopmental outcomes and that earlier intervention with lumbar punctures and/or reservoirs may reduce the eventual need for ventriculoperitoneal (VP) shunts.[165,166] In preterm infants with PHVD, those with early intervention, had outcomes indistinguishable from those without intervention, even when eventually requiring a shunt. Remarkably, outcomes in this group were all within the normal range.[167] In infants managed with a late approach to intervention, the need for intervention predicted worse outcomes.[167] In a post hoc analysis of a randomized control trial examining the treatment threshold for lumbar puncture to manage PHVD, earlier intervention was associated with lower odds of death or severe neurodevelopmental disability in preterm infants with progressive PHVD.[168] The accumulating evidence suggests that earlier intervention approaches for PHVD support better neurodevelopmental outcomes and outweigh potential risks.[161]

A randomized controlled trial of the combined use of furosemide and acetazolamide in 177 infants with PHVD was ineffective in reducing VP shunt placement and was associated with an increased risk of adverse neurologic outcomes.[169] Several studies also found no benefit of early intraventricular delivery of a fibrinolytic agent (tissue plasminogen activator, urokinase, or streptokinase) to reduce complications associated with PHH.[163,170] A multicenter randomized clinical trial of 77 patients compared drainage, irrigation, and fibrinolytic therapy (DRIFT) with the removal of excess cerebrospinal fluid (CSF) via a reservoir. DRIFT reduced severe cognitive disability in survivors at 2-year follow-up as well as overall death or severe disability, but was associated with a much greater increase in secondary intraventricular bleeding.[171] At 10-year follow-up, the benefit of DRIFT to improve cognition persisted, supporting the need for a larger more balanced trial.[172]

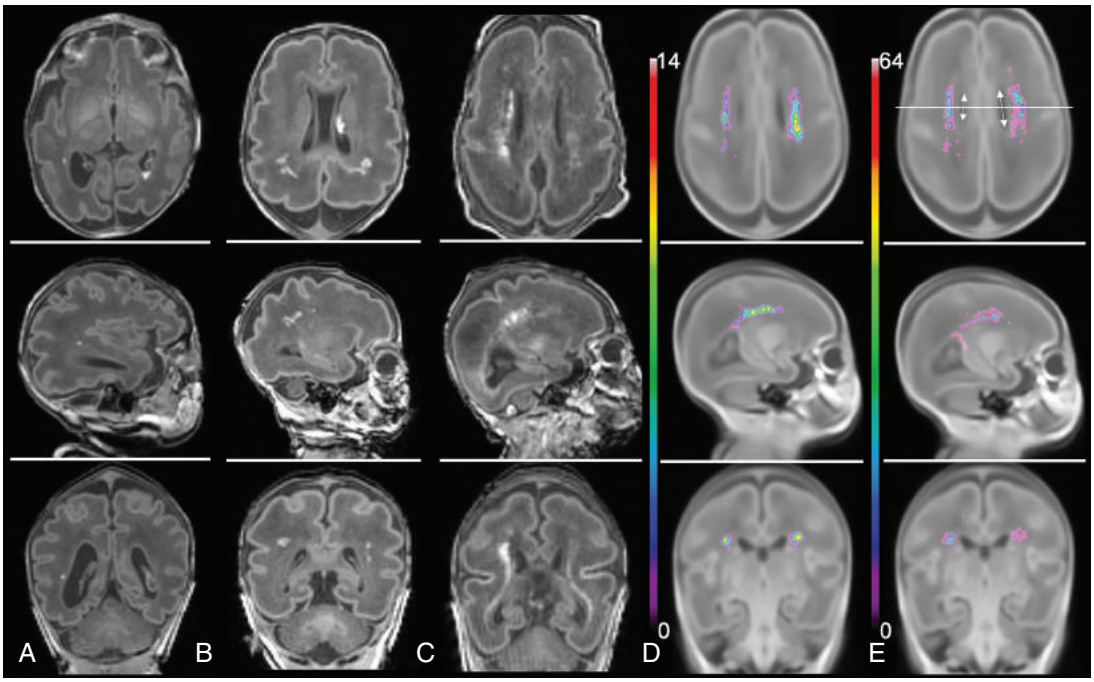
Definitive management by the early placement of a VP shunt that diverts cerebrospinal fluid from the lateral ventricles to the peritoneal cavity in a preterm infant weighing less than 2.5 kg is problematic because of the risk of skin breakdown, shunt obstruction, and infection. Placement of a ventricular access device (e.g., Ommaya/Rickham reservoir), an external ventricular drain, or a ventriculosubgaleal shunt is a temporary measure for the early management of PHVD. A small retrospective historical cohort study found that ventriculosubgaleal shunts compared with ventricular access devices may reduce the need for daily CSF aspiration.[173] However, both approaches had similar complication rates, and similar numbers of infants ultimately required VP shunt placement.[174] Either placement of VP shunts or endoscopic third ventriculostomy are long-term treatment options for PHVD or PHH, and both have similar clinical outcomes.[175]

White Matter Injury

Spectrum of White Matter Injury

The spectrum of WMI includes three major identifiable forms of disease: focal cystic necrosis, punctate WMI with focal microscopic necrosis, and diffuse nonnecrotic lesions. Focal cystic necrosis or cystic-PVL is characterized by necrotic lesions greater than 1 mm in diameter with the corresponding loss of all critical tissue elements, including glia, axons, vasculature, and neural progenitors.[176] Both ultrasound and MRI imaging modalities can adequately detect focal cystic necrosis, which characteristically occurs within the deep periventricular white matter.[41,177] Cysts form in the WM two to six weeks after injury or birth and can resolve after several additional weeks.[159] These cysts can be late in onset and may be missed if imaging is performed only in the first weeks of life or soon after an injurious episode.[157,178] Large cystic necrotic lesions greater than about 1 mm in diameter are the most severe, but their incidence has decreased markedly in recent years (Fig. 54.3C). In several series, focal cystic lesions were detected by MRI in less than 5% of cases.[179–185] In fact, the incidence of all forms of necrotic WMI were found to have decreased by approximately 10-fold in contemporary cohorts of autopsy cases relative to retrospective cases from earlier decades.[186]

Although the incidence of large necrotic lesions has decreased markedly, discrete small foci of microscopic necrosis (microcysts) less than 1 mm in diameter appear to be much more common.[187] Similar to focal cystic necrosis, microcysts are destructive lesions



• **Fig. 54.3** Spectrum of White Matter Injury (WMI) and Relationship with Neurodevelopmental Outcome. Axial *(top)*, sagittal *(middle)*, and coronal *(bottom)* early-life T1-weighted MRI images from three very preterm neonates demonstrating a range of WMI. (Column A) *Minimal WMI* reflected in a punctate focus of T1-hyperintensity in the right occipital lobe. Note is made of left sided grade 2 IVH with T1 hyperintensity in the occipital horn of the lateral ventricle. (Column B) *Moderate WMI* reflected in multiple confluent areas of T1-hyperintensity bilaterally, involving the parieto-occipital lobes predominantly. On the axial image, note is made of prior Grade 2 IVH with T1 hyperintensity in the body of the left lateral ventricle. (Column C) *Severe WMI* reflected by confluent areas of T1 hyperintensity bilaterally, involving all lobes, including areas of T1 hypointensity reflecting cystic lesions. (Column D) *Cumulative WMI* map: Probabilistic WMI map of 58 very preterm neonates overlaid on a T1-weighted early preterm brain template. Punctate WMI that occurred at a homologous region in two or more very preterm neonates is displayed. The color bar on the left indicates the color coding of the WMI summation. The maximum value on the map is 14 on the brain template. (Column E) *Odds ratio (OR) map of WMI for adverse motor outcome* at 18 months on the brain template. OR maps of punctate WMI for motor outcomes overlaid on the T1-weighted neonatal brain template. The maximum OR value on the motor OR maps is 64. Note that lesion location is an important predictor of motor outcome. The mid-ventricle line from the simple imaging prediction rule based on these maps is also shown here, with lesions anterior to this line being predictive of adverse motor outcomes. enriched in cellular debris, degenerating axons, and phagocytic macrophages (Fig. 54.4A–C). Because of their small size, these areas evolve into focal collections of astrocytes and macrophages but may not form persistent fluid-filled cysts.[186,188] Microcysts are typically not detected on clinical MRI scans at field strengths of 3 Tesla (T) but can be detected experimentally at higher magnetic field strengths of 12T (Fig. 54.4D).[188] In a study of human archival and contemporary autopsy cases, microcysts were observed in at least 30% of cases, but they constituted approximately 1% to 5% of the total burden of WMI.[186] Hence, although microscopic necrosis occurs with high incidence, the burden is typically low. It should nevertheless be emphasized that the clinical significance of these small necrotic lesions remains an important but clinically inaccessible question since microcysts are not readily detected by clinical MRI. It is thus possible that microcysts may be clinically silent or a significant contributor to motor or cognitive disabilities, depending on the extent to which they localize to functionally important regions of white matter.

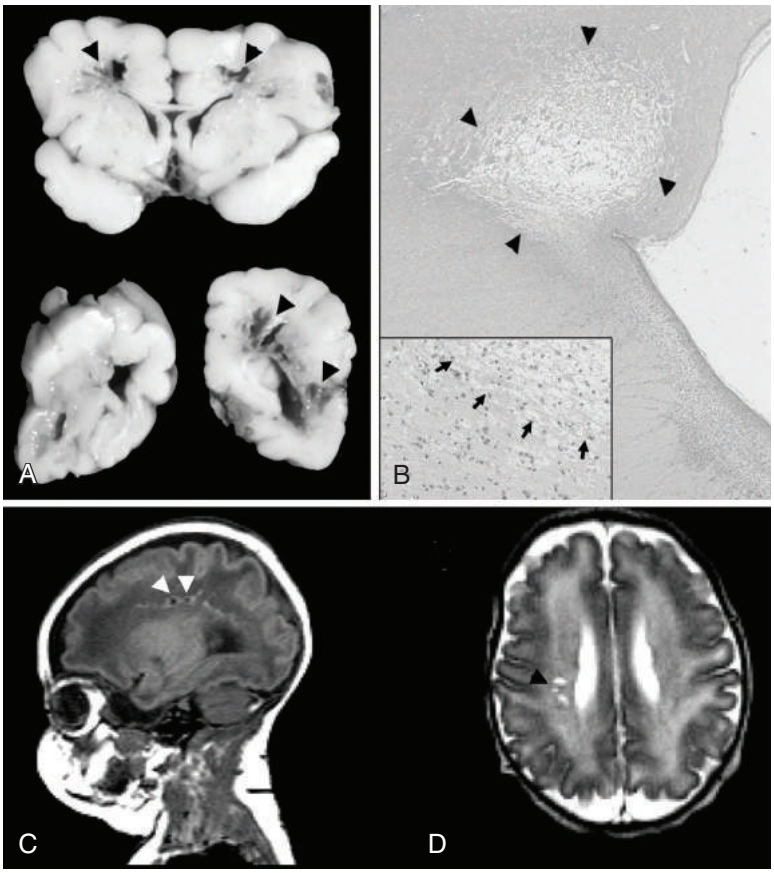
Punctate WMI is an increasingly recognized pattern of injury in preterm survivors. The pathological correlate of punctate WMI is not clearly defined and may include a pathological spectrum between focal cystic and microscopic necrosis.[41] Lesions characterized by small (1 to a few mm) discrete necrotic foci that do not evolve into true cysts, but rather result in focal gliotic changes have been described in an experimental model of moderate preterm brain injury.[188] In contrast to microscopic necrosis, these lesions are detectable at clinical MRI field strength as punctate areas of hyperintensity on T1-weighted MRI images (Fig. 54.3A and B).[189,190] Ultrasound, however, is not of adequate sensitivity to detect these lesions. Early-life MRI is the preferred method and timing to detect the maximal extent of this WMI pattern.[11,191] The distribution of punctate lesions on MRI varies



• **Fig. 54.4** Severe White Matter Injury Results in Focal or Diffuse Tissue Destruction (Periventricular Leukomalacia). (A) This autopsy brain, from an infant who died of complications of prematurity, shows large foci of severe cystic necrosis *(arrowheads)* in frontal *(upper specimen)* and parietal *(lower specimens)* periventricular white matter. (B) Histologic analysis of the frontal lesion (stained with hematoxylin and eosin) shows a large focus of necrosis *(arrowheads)* adjacent to the lateral ventricle. The *inset* shows a high-power detail of the edge of the lesion *(arrows)*, where marked rarefaction of the tissue can be appreciated adjacent to a region of gliosis at the *lower left*. (C) Appearance of cystic necrotic white matter injury on magnetic resonance imaging. Images from a preterm infant born at 33 weeks' gestational age and scanned at 5 weeks of age (38 weeks' adjusted gestational age). (D) Small areas of cavitation *(arrowhead)* are appreciated as hypointensity on the sagittal T_1-weighted image and as hyperintensity on the axial T_2-weighted image. along a characteristic topology.[11] Lesions clustering within WM areas are suspicious for an ischemic parenchymal injury, while those with a linear pattern are more likely to have associated susceptibility changes, and reflect microhemorrhage or venous congestion that may not have a parenchymal injury component.[192] There is, however, unexplained variability in the nature of lesions detected at different centers, which may reflect differences in management, clinical acuity, or modes of detection. In a single center, the incidence of punctate WMI appears to be decreasing over time; in this cohort prolonged exposure to indomethacin predicted reduced WMI.[120]

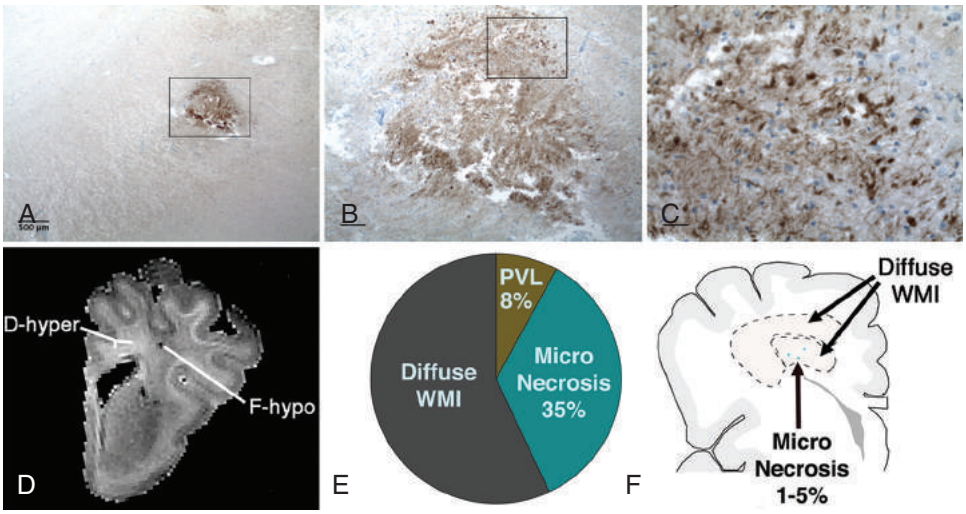
Diffuse WMI is the most frequently observed form of injury in contemporary cohorts of preterm newborns.[186] Diffuse WMI is much more widely distributed than previously appreciated and comprises activated astrocytes and microglia that can occur independently from or extend widely beyond foci of necrosis (Fig. 54.4E and F). In contrast to necrotic injury, diffuse WMI is defined by selective degeneration of preOLs, whereas axons are mostly spared except in necrotic foci.[193,194] Human preOLs are a population of late oligodendrocyte progenitors, which are the precursors of all the myelinating cells of the CNS. They are particularly susceptible to significant oxidative damage of a magnitude seen with hypoxia-ischemia (HI) in the clinical context.[195] The susceptibility to preterm WMI peaks at approximately 23 to 32 weeks' postconceptional age and coincides with a developmental window when preOLs predominate in human cerebral white matter. Paradoxically, it was shown experimentally that ischemia is necessary but not sufficient to cause WMI. Even under conditions of moderately severe ischemia, some regions of white matter may be relatively spared. The regions of particular vulnerability to WMI are defined by both the timing of the appearance and the distribution of susceptible preOLs.[196] Although cranial ultrasound examination is the preferred bedside imaging technique for diagnosing necrotic WMI, it has limited sensitivity for diagnosing diffuse WMI.[160] MRI is the preferred method to visualize diffuse WMI (Fig. 54.5A–C),[197] but much of the widespread WM abnormalities within injured WM are not detected by conventional MRI techniques.[41] Experimental studies (Fig. 54.5D–F) demonstrated that early WMI is particularly well visualized at high magnetic field strength (11.7T),[188]



• **Fig. 54.5** Microscopic Necrosis Occurs Commonly but Constitutes a Small Fraction of the Total Burden of Preterm Cerebral White Matter Injury. (A) Typical sparse distribution of microcysts visualized with a marker of degenerating axons in a human autopsy brain at 32 weeks' postconceptional age. (B, C) Higher-power detail of the degenerating axons in the microcyst seen in the *box* in (A). (D) A microcyst visualized by high-field (12T) ex vivo magnetic resonance imaging as a focal hypointense lesion *(F-hypo)* on T2. This lesion was detected 2 weeks after global cerebral ischemia in a fetal sheep model of preterm white matter injury (WMI) (Riddle et al., 2011). Note the surrounding diffuse WMI, which is seen as a diffuse hyperintense signal *(D-hyper)*. (E) Pie chart showing the relative percentages of human diffuse WMI, cystic periventricular leukomalacia (PVL), and microscopic necrosis. Note that microcysts often overlap in distribution with regions of diffuse WMI. (F) The relative burden of human microcysts *(blue dots)* compared to diffuse WMI *(tan shading)*, which typically constitutes more than 80% of the total burden of WMI. Scale bars: (A) 500 μm; (B) 100 μm; (C) 25 μm. (From Back SA, Miller SP. Brain injury in premature neonates: a primary cerebral dysmaturation disorder? *Ann Neurol*. 2014;75:469–486.)

which suggests that currently used clinical MRI field strengths of 1.5 to 3T may be a limiting factor to detect both diffuse and microscopic WMI. However, diffuse WMI may be detected with advanced MRI techniques, even at current clinical field strengths. In particular, diffusion tensor imaging (DTI) and magnetic resonance spectroscopic imaging (MRSI) can be used to detect disturbances in WM maturation.[198,199] DTI measures the three-dimensional spatial distribution of water movement along axons in the white matter. Fractional anisotropy is a DTI parameter that describes the directional preference of water diffusion and varies between 0, equal diffusion of water in all directions (isotropic, e.g., CSF), and 1, all diffusion is along a single vector (anisotropic, e.g., mature axons). FA values increase with WM maturation as immature oligodendrocytes progress toward early myelination during the preterm period.[200,201] DTI measurements, such as FA, can be used to assess microstructural changes in brain development that occur with the delay or failure of myelination within regions of diffuse WMI.[202] Similarly, MRSI, which measures the concentration of brain metabolites, has a typical pattern of development in the WM and disturbances in WM development may be detected as reduction in the expected increase in N-acetylaspartate (NAA)/choline ratio, for example.[154,203]

It should also be emphasized that preterm survivors frequently display diffuse abnormalities in gray and white matter maturation by virtue of the clinical morbidities associated with preterm birth that may be more common than focal or diffuse WMI.[197,204] These diffuse abnormalities are apparent on MRI as enlarged subarachnoid spaces, a reduction in the amount of white matter, ventriculomegaly, and impaired gyral development that persists to adulthood.[205,206] However, many preterm newborns do not have these dramatic abnormalities, and up to 20% with adverse outcomes do not have significant qualitative abnormalities on MRI, which highlights the need for quantitative MRI metrics of brain maturation.[191,207] Importantly, the regional differences in brain maturation in adults born preterm that predict cognition differ from those that predict mental health.[17]

Physiologic Factors Related to the Pathogenesis of White Matter Injury

Role of Hypoxia-Ischemia

HI contributes to the pathogenesis of preterm cerebral injury via several maturation-dependent mechanisms. Since direct measurements of CBF in WM are technically challenging in human preterm neonates, experimental studies have often been used to define the role of CBF disturbances in the generation of cerebral WMI. The developmental epoch when CBF disturbances occur is a critical factor that influences susceptibility to hypoxia-ischemia. For example, acute injury to the cerebral cortex is relatively low compared with that to the white matter in the preterm fetal sheep, even with prolonged ischemia, whereas severe panlaminar cortical necrosis occurs in term animals.[208,209] After global cerebral hypoperfusion, midgestation sheep displayed a predilection to periventricular and subcortical WMI, whereas near-term animals displayed predominantly parasagittal cortical neuronal injury.[208–210] Cerebral ischemia in conjunction with hypoxia appears to be a critical factor to generate significant preterm WMI. WMI was infrequently observed when a restriction in uteroplacental blood flow resulted in decreased oxygen delivery to and mild acidemia in the fetus without systemic hypotension or cerebral hypoperfusion.[211–213] Similarly, in models

of maternal-fetal infection, preterm ovine WMI was observed only when repeated systemic fetal endotoxin exposure resulted in both transient hypoxemia and hypotension.[214,215]

Pressure-Passive Circulation

Disturbances in cerebral autoregulation appear to be a key factor that predisposes preterm neonates to cerebral WMI from hypoxia-ischemia. *Cerebral autoregulation* refers to the maintenance of constant CBF over a range of changes in systemic arterial blood pressure or cerebral perfusion pressure.[216–218] Cerebral autoregulation appears to involve an intrinsic property of arterial smooth muscle cells that respond to changes in transmural pressure to modify muscle tone. Autoregulation may be mediated in part by a balance between endothelial cell-derived constricting and relaxing factors.[219] This autoregulatory range has both upper and lower limits. When blood pressure changes above or below these limits, CBF fails to remain constant and increases or decreases passively, along with changes in arterial blood pressure. Preterm infants are particularly prone to display a "pressure-passive" circulation, especially in the setting of critical illness and the presence of impaired autoregulation is associated with greater mortality and increased radiographically defined cerebral injury.[29,220–223] Cerebral autoregulation disturbances in preterm infants were initially studied by means of xenon clearance and Doppler and more recently by near-infrared spectroscopy and spatially resolved spectroscopy.[218,224] Severe perinatal asphyxia, hypoxia, growth restriction, congenital heart disease, head trauma, and hypercapnic acidosis, even when relatively mild, attenuate or even abolish autoregulation.[225–229] Delayed cord clamping has been associated with improved cerebral autoregulation, which may mediate some of its effect on IVH.[96] Fundamental questions regarding cerebral autoregulation remain unanswered, including the optimal clinical practices for blood pressure regulation.[218,230] Novel ultrafast Doppler technology may offer new insights into cerebral hemodynamics in the preterm neonate.[231,232]

Factors That Influence the Distribution of White Matter Injury

Multiple factors that influence cerebral blood flow (CBF) or white matter metabolism determine the severity of WMI. It was originally proposed that the topography of more severe WMI was determined by the distribution of arterial end and border zones within the white matter. This attractive hypothesis provided an explanation for the propensity of more cystic necrotic lesions to localize to the deeper periventricular white matter. It was proposed that when periventricular white matter flow falls below a critical threshold, periventricular white matter would sustain greater WMI relative to a putatively better-perfused cerebral cortex. It has been feasible to test this hypothesis experimentally, but not in humans. Quantitative measurements of fetal CBF were done in utero in histopathologically defined regions of the cerebral cortex and white matter in preterm fetal sheep.[233] In the setting of moderately severe ischemia, no pathologically significant gradients of fetal blood flow were detected between the cerebral cortex and periventricular white matter during either ischemia or reperfusion. Moreover, although WMI preferentially localized to deeper white matter regions, they were not susceptible to greater ischemia (Figs. 54.6 and 54.7). Neither were less vulnerable superficial regions of white matter characterized by greater blood flow during ischemia. As discussed earlier, the distribution of WMI was explained by the relatively higher density of preOLs in susceptible regions of white matter.

It is currently unclear if recurrent HI predisposes to more severe WMI. In preterm-equivalent neonatal rats, a pronounced increase in cell death was observed in chronic WMI after recurrent HI.[234] However, in preterm fetal sheep, whose lesions more closely resemble those of humans, recurrent HI did not trigger enhanced WMI, which suggested that recurrent HI may confer protection against more severe WMI through an ischemic tolerance-like mechanism.[235]

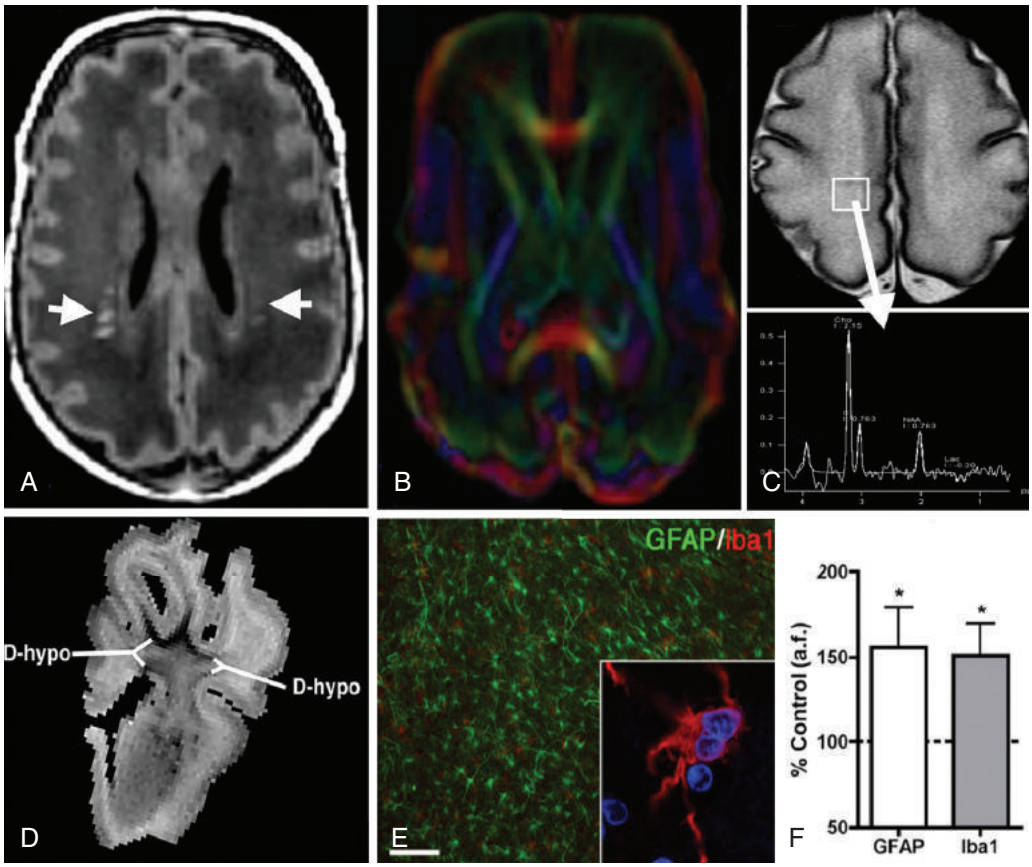
Clinical Factors Related to the Severity of White Matter Injury

Several common clinical conditions have been associated with an increased risk of more severe WMI (Box 54.2). Among these is neonatal sepsis, which occurs in up to 25% of preterm newborns who weigh less than 1500 g at birth[236–238] and is associated with a significantly increased risk of WMI.[239] Postnatal infections have been linked to altered development of white matter pathways[240,241] and widespread impairments in brain development,[154] especially when multiple.[155] Both culture-proven and culture-negative suspected infections have been associated with increased rates of cerebral palsy and other neurodevelopmental disabilities that are consistent with neonatal brain imaging findings.[154,191,242,243] Recurrent (≥3) postnatal infection, but not infection type or specific pathogen is associated with progressive WMI and adverse neurodevelopmental outcomes.[155,244,245] This suggests that exposure to infection may sensitize the preterm brain to subsequent episodes of infection, ischemia, or other insult.[246]

Necrotizing enterocolitis (NEC) has also been associated with an increased risk for adverse cognitive and motor outcomes.[247–250] In addition, in a large preterm cohort, infants with both NEC and sepsis were found to have the greatest risk for adverse neurodevelopmental outcomes.[242] This association yields further support for a two-hit hypothesis of brain injury.[251]

In contrast to postnatal infections, chorioamnionitis is not strongly associated with WMI in modern cohorts. Although studies as recently as 2000 found an association between cystic PVL and histological or clinical chorioamnionitis,[252] multiple subsequent studies using MRI-defined WMI have failed to show that histological chorioamnionitis is associated with WMI or adverse childhood outcomes.[202,239,253,254] This evolution is likely reflective of the shift in the spectrum of WMI from classic PVL to punctate and diffuse forms of WMI. Despite the lack of strong associations between prenatal chorioamnionitis and adverse neurodevelopmental outcomes, chorioamnionitis may indirectly increase the risk of postnatal infections and hypotension as independent risk factors for cerebral ischemia and WMI. Placental insufficiency has been associated with WMI in animal models of preterm brain injury.[212] Ongoing research continues to evaluate the role of the placenta in perinatal brain injury as new MRI technology yields novel insights into human fetal hemodynamics and brain development.[255,256]

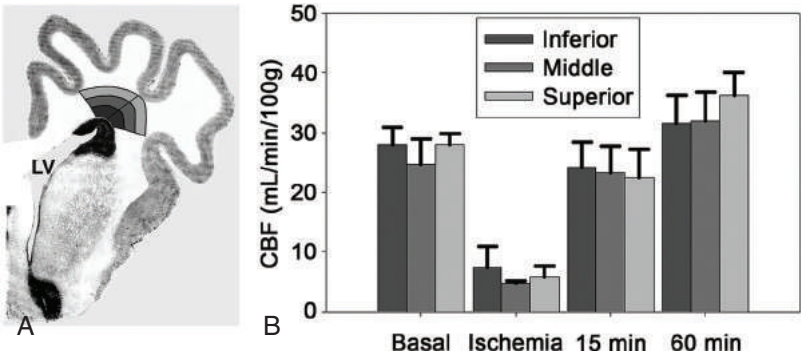
Bronchopulmonary dysplasia (BPD) and the duration of mechanical ventilation exposure have been associated with adverse white matter, cortical, and brainstem development.[257–260] Although a history of BPD is a strong predictor of cognitive outcome, even after birth weight and neurologic morbidity have been controlled for,[261] a causative role for isolated hypoxemia in WMI remains unclear from clinical or experimental studies[262] and multiple other factors related to the development of BPD may contribute to observed association with adverse neurodevelopmental outcomes.[116] Postnatal exposure to corticosteroids for



• **Fig. 54.6** Diagnostic and Experimental Magnetic Resonance Imaging Approaches to Define Dysmaturation Processes Related to Diffuse White Matter Injury. (A) Diffuse human white matter injury (WMI) on diagnostic magnetic resonance imaging (MRI) (1.5 T; T1) has the appearance of bilateral multifocal signal hyperintensities (*arrows*). (B) Diffusion tensor imaging defines the microstructure of white matter tracts and can be used to follow the long-term progression of diffuse WMI. (C) Magnetic resonance spectroscopic imaging can be applied to define biochemical and metabolic abnormalities associated with diffuse WMI. Both diffusion tensor imaging and magnetic resonance spectroscopic imaging detect abnormalities beyond the areas of signal abnormality on T1-weighted images. (D) Diffuse WMI defined by high-field ex vivo MRI at 12 T in a preterm fetal sheep model of global cerebral ischemia. Diffuse WMI was visualized as extensive hypointense regions *(D-hypo)* on a T2-weighted image at 1 week after ischemia. (E) The typical histopathologic features of diffuse WMI seen on MRI. Note the pronounced staining of reactive astrocytes *(green)* and microglia/macrophages (*red* and *inset*) indicative of a diffuse inflammatory response quantified in (F); the *asterisks* indicate $P < .05$. *Scale bar* in (E) 100 μm. *GFAP*, Glial fibrillary acidic protein.

the prevention and treatment of chronic lung disease is linked to impaired brain growth and adverse neurodevelopment, and this effect may be more pronounced with dexamethasone treatment.[68,263–265] Ongoing research continues to evaluate the dose and timing of corticosteroid therapy for BPD in order to optimize neurologic and pulmonary outcomes.[266]

Hypoxemia, as an independent risk factor for WMI, was proposed on the basis of a suspected association between cystic WMI and BPD.[267] However, a direct association between hypoxemia from chronic lung disease and severe WMI is difficult to establish, because cystic WMI is also commonly associated with IVH and PVHI. The response of the fetus to acute hypoxemia without ischemia has been extensively studied in preterm fetal sheep. Transient hypoxemia was found to cause variable degrees of combined WMI and gray matter injury in the midgestation or near-term sheep.[211,268] However, WMI was notably more severe when significant hypotension was observed, which resulted in *both* cerebral hypoxia and ischemia.[269] Midgestation chronic hypoxemia, generated by chronic placental insufficiency, caused disturbances in hippocampal, cerebellar, and white matter development.[213,268] Exposure of neonatal rodents to chronic hypoxia results in a spectrum of somatic and cerebral growth retardation that is accompanied by disturbances in white matter development that include ventriculomegaly, reduction in white and gray matter volumes, and disrupted myelination.[267,270–272] Interestingly, acute moderate hypoxia with or without ischemia has been recently shown to cause disruptions in the maturation of fetal subplate within the developing WM.[273] This transient population of neurons is important for the normal development of thalamocortical circuits and disruption may underlie indirect cerebral maturational changes. Several studies of moderate to severe intermittent hypoxia in neonatal rodents, which model apnea of prematurity, have shown disturbances in myelination that correlate with hypoxia severity but the relative contribution of ischemia secondary to bradycardia remains



• **Fig. 54.7** Periventricular White Matter Injury Is Not Explained by Gradients of Reduced Cerebral Blood Flow in Cerebral White Matter. (A) Analysis of fetal sheep cerebral blood flow (CBF) in preterm cerebral white matter during hypoxia-ischemia and reperfusion. CBF measurements were made in inferior, middle, and superior regions of the white matter, as illustrated (*gray gradient*). Typically, white matter injury localized to the inferior region of the white matter. (B) There were no differences between baseline CBF values and those obtained during ischemia or reperfusion at 15 or 60 minutes after ischemia in inferior, middle, and superior regions of the white matter. Hence white matter injury was not preferentially associated with regions that sustained the most severe ischemia. *LV*, Left ventricle. (From McClure M, Riddle A, Manese M, et al. Cerebral blood flow heterogeneity in preterm sheep: lack of physiological support for vascular boundary zones in fetal cerebral white matter. *J Cereb Blood Flow Metab*. 2008;28:995–1008.)

• BOX 54.2 Pathogenic Factors Contributing to More Severe White Matter Injury

Postnatal sepsis may promote postnatal cerebral hypotension or modify the response to hypoxia-ischemia.
More severe hypoxemia coupled with hypotension may increase the magnitude of energy failure mediated by hypoxia-ischemia.
Hypocarbia may exacerbate hypoxia-ischemia by promoting more severe hypoperfusion.
Hypoglycemia may exacerbate energy failure associated with hypoxia-ischemia.
Steroid exposure (e.g., dexamethasone) may increase the risk of white matter injury.
Exposure to multiple painful or stressful procedures may increase the risk of white matter injury.
Bronchopulmonary dysplasia is associated with multiple cerebral risk factors including hypoxemia, hypocarbia, mechanical ventilation, and steroid exposure.
Necrotizing enterocolitis may potentiate the interaction of inflammation and ischemia leading to increased white matter injury.
Nutrition deficiencies in calories, lipids, or parenteral administration may predispose infants to impaired cerebral repair and growth.

unclear.[274,275] However, central features of human preterm WMI, such as preOL degeneration and reactive gliosis, are not observed in rodents. In addition, in children with cyanotic heart disease, WMI may occur due to antenatal factors[155,276] independently of the perioperative risk associated with surgical correction of cyanotic congenital heart disease.[277,278] It thus appears that hypoxemia is related to disturbances in white matter maturation that are distinct from the injury generated by acute hypoxia-ischemia.

Hyperoxia is also a potential complication of neonatal resuscitation and ventilation of the preterm infant during intensive care, but a direct association with human preterm WMI has not been demonstrated. A rabbit model of neonatal resuscitation found no increase in IVH or cerebral injury in response to hyperoxia.[279] Tissue culture models of hyperoxia have demonstrated the enhanced vulnerability of preOLs to cell death from oxidative stress, and transient disturbances in myelination in neonatal rodents were observed.[262]

WMI is a prominent and common feature of symptomatic hypoglycemia in term infants that has a predilection for the posterior limb of the internal capsule and posterior cerebral regions. WMI often occurs in association with cortical or subcortical gray matter abnormalities seen on MRI.[280] Experimental studies support the observation that even mild hypoglycemia exacerbates cerebral injury from HI.[281,282] Studies in preterm fetal sheep found that hypoglycemia was the most significant factor associated with more severe WMI generated by global cerebral HI.[283]

Preterm infants are often routinely exposed to multiple painful and stressful procedures that have been linked to altered brain maturation that involves white and gray matter structures, as well as impaired brain function.[284] A higher number of painful procedures in the NICU is associated with delayed white matter maturation and adverse cognitive outcomes into early childhood.[285–287] Procedural pain has also been linked with impaired postnatal growth,[288] a predictor of poor cortical development,[289] and interacts to predict cognitive outcomes at school age.[290] Further studies have provided support for the association between procedural pain and anomalous gray matter development in multiple regions including the thalamus,[5,7] subcortical gray matter,[286] and cerebral cortex.[291]

Importantly, analgesic and sedative medication exposure in the preterm neonate have also been linked to regional dysmaturation that is specific to the exposure: increasing midazolam exposure predicts slower growth of the hippocampus,[6] whereas increasing morphine exposure predicts slower growth of the cerebellum.[4] Exposure to painful procedures is also associated with more adverse neurodevelopment, which may be modulated by more optimal parent-child interactions,[292,293] as well as parental stress and anxiety.[294–296] Importantly, experimental models and human studies support the potential of parent-infant interactions to compensate for compromised early brain maturation

and adversity.[293,294,297–300] In addition to these medical factors, social factors such as socioeconomic status are recognized as robust predictors of brain maturation and outcomes, and most recently as a modifier of cognitive outcomes in response to early-life WMI.[301–303]

There is increasing attention to the role of biological sex in pathways related to brain injury and neurodevelopmental outcome in children born preterm.[304] Meta-analyses reveal a consistent female advantage in cognitive and motor development in children born preterm.[305,306] Male preterm neonates are at higher risk of developing IVH than females.[307–310] However, in contrast with other clinical risk factors, female preterm neonates demonstrate a stronger association of pain with abnormal brain development and slower basal ganglia growth with exposure to glucose for analgesia.[5] Sex is also recognized as a predictor of brain volumes and microstructural development at term equivalent age[311,312] and in adolescence in preterm children.[313,314] Yet, volumetric difference between preterm and term-born female children narrows by age 8 to 12 years, whereas that in males persists.[315,316] Additional studies are needed to more definitively delineate how biological sex modifies longer-term responses to preterm birth and brain injury.

Pathogenesis of Chronic White Matter Injury

Emerging Roles for Myelin in Brain Development, Learning, and Memory

Myelination disturbances are one of the central features of chronic WMI. Myelination begins in the preterm brain and normally progresses in well-defined sequences that continue for years postnatally. The central role of myelin is to wrap axons to ensure optimal nerve conduction throughout the CNS. However, emerging studies are challenging the long-held belief that myelin is a stable structure that simply provides static insulation to nerve fibers. Recent studies report that myelin sheaths are dynamic structures that contribute importantly to learning and memory by remodeling the thickness of myelin sheaths so as to enhance or diminish the relative strength of nerve conduction.[317,318] Hence adaptive myelin plasticity appears to provide a mechanism whereby the nervous system can strengthen or weaken the flow of information along competing pathways so as to optimize new learning.[319] Whereas synaptic plasticity operates on millisecond dynamic timescales to fine-tune learning and memory, myelin plasticity occurs on longer timescales to enable the nervous system to solidify the acquisition of new skills. For example, in adult animals, the generation of new oligodendrocytes and myelin is required for the learning and acquisition of new motor skills.[320–322] Several studies in humans have shown a microstructural change in WM tracts after exercise and skill training,[323,324] including in children,[325,326] and provide indirect evidence of myelin plasticity in humans.

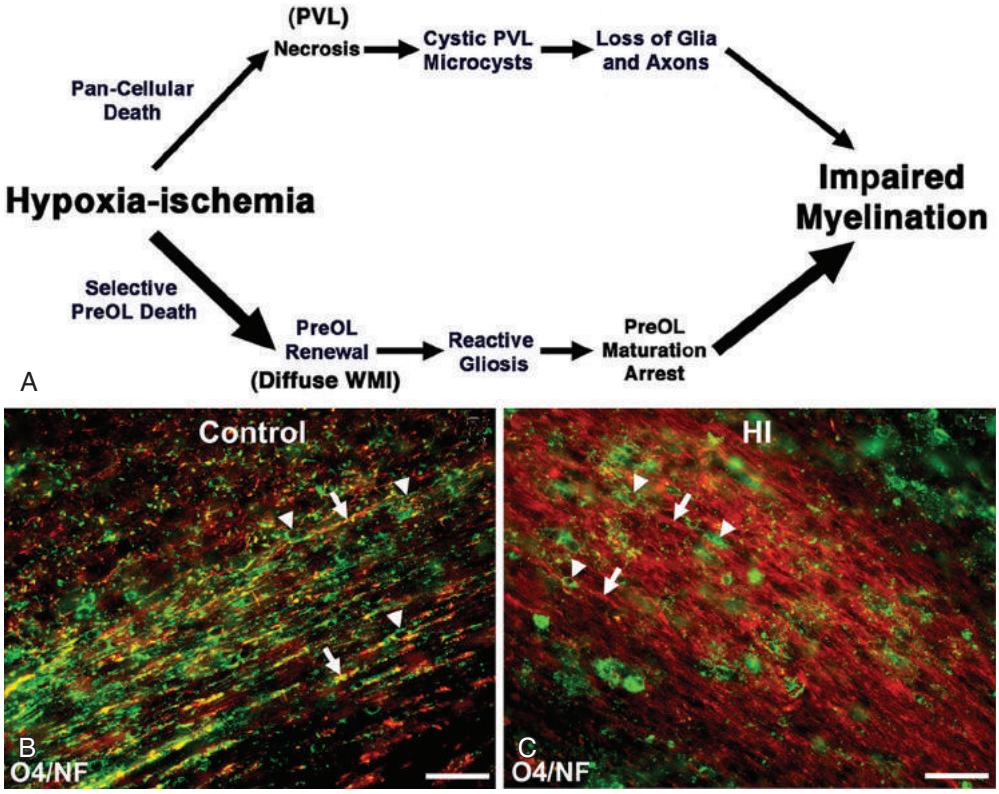
Hence the definition of these new roles for myelin underscores the potential impact that WMI may have on the disruption of the timing and sequences of myelination during a critical period in preterm brain development. Preterm brain development involves multiple cell maturational and activity-dependent events that coincide with sequential waves of late neurogenesis, gliogenesis, glial and neuronal maturation, synaptogenesis, and myelination. Aberrant myelination is likely to disrupt both gray matter and white matter development by causing enduring disturbances in the ultimate establishment of neural networks and connectivity that are integral to normal brain function.

Pathogenesis of Chronic Myelination Failure and Potential Therapeutic Strategies

Myelination disturbances are related to aberrant regeneration and repair responses to acute death of preOLs. The preterm developing brain contains a population of early oligodendrocyte progenitors that serve as an apparent reservoir of cells that can mount repair responses after WMI. In response to injury, early progenitors rapidly proliferate and partially differentiate to regenerate preOLs that are lost in early WMI.[3,234] Thus, the preterm human white matter is capable of mounting a robust repair response to injury. Despite this inherent plasticity, the injured white matter displays robust astrogliosis, which diffusely extends beyond the core of injury as a functional "glial scar" that blocks the normal maturation of preOLs to myelinating cells.[3,327] Hence the pathogenesis of chronic diffuse WMI leads to a disruption of the normal progression of myelination through a series of dysmaturation events that result in regeneration of preOLs that accumulate in chronic lesions but fail to differentiate into myelinating oligodendrocytes (Fig. 54.8). By contrast, focal necrotic WMI results in a loss of both glia and axons that causes an irreversible block on myelination (Fig. 54.8).

The mechanism by which this glial scar contributes to myelination failure is an active area of investigation. It appears likely that pronounced disturbances in the composition of the extracellular matrix result in the generation of inhibitory molecules that block preOL maturation. One widely studied molecule is hyaluronic acid, which is generated by reactive astrocytes within the glial scar and is digested by hyaluronidases that are upregulated in response to WMI.[235,328,329] These hyaluronidases generate bioactive fragments of hyaluronic acid that block preOL maturation.[330] Preclinical studies demonstrated that functional remyelination was promoted by a broad-spectrum hyaluronidase inhibitor.[328] The downstream signaling involved in chronic WMI appears to include Wnt pathway members as well as epidermal growth factor receptor and toll-like receptor-mediated pathways.[272,331,332] It is currently unknown whether this chronic injury environment will have a negative influence on stem cell-based therapies to promote myelination.[333–335]

Since multiple signaling pathways appear to be involved in the pathogenesis of chronic WMI and myelination failure, one potential therapeutic strategy is to target multiple signaling pathways via the pleiotropic growth factor erythropoietin (Epo), which is widely used to stimulate neonatal erythropoiesis. Epo is currently under evaluation as a protective agent for WMI, because of its demonstrated actions to promote angiogenesis, neurogenesis, and gliogenesis during normal brain maturation.[336] A randomized controlled trial of repeated intravenous administration of recombinant high-dose Epo to preterm neonates in the first 2 days of life was found to be safe and was associated with enhanced white matter maturation as defined by diffusion tensor imaging,[337,338] but 2-year neurodevelopmental outcomes were not improved.[339] Building on these overall positive but small studies, the Preterm Erythropoietin Neuroprotection (PENUT) trial, which randomized 741 neonates born between 24 and 27 6/7 weeks gestation to high-dose Epo therapy for 2 weeks followed by maintenance Epo therapy until 32 completed weeks, was undertaken and showed no reduction in severe neurodevelopmental disability or death.[340] Despite the failure to prevent neurodevelopmental disability in this well-designed study, outstanding questions remain about the potential of Epo to enhance preOL maturation in diffuse WMI if administered for longer durations.[341,342] Potential benefit for



• **Fig. 54.8** Pathogenesis of Myelination Failure in Chronic Diffuse White Matter Injury. (A) Distinctly different pathogenetic mechanisms mediate abnormal myelination in focal necrotic lesions (periventricular leukomalacia [PVL]; *upper pathway*) versus lesions with diffuse white matter injury (WMI; *lower pathway*). When it is most severe, hypoxia-ischemia (HI) triggers white matter necrosis (*upper pathway*) with pancellular degeneration that depletes the white matter of glia and axons. Severe necrosis results in cystic PVL, whereas milder necrosis results in microcysts. Milder HI (*lower pathway*) selectively triggers early oligodendrocyte progenitor (preOL) death, but preOLs are rapidly regenerated in chronic lesions enriched in reactive astrocytes that contribute to a block in preOL differentiation to myelinating oligodendrocytes. Myelination failure in diffuse WMI thus results from preOL arrest rather than axonal degeneration, as occurs with white matter necrosis. Note that the lower pathway is the dominant one for many contemporary preterm survivors, whereas the minor upper pathway reflects the declining burden of white matter necrosis. (B) Typical appearance of normal early myelination in neonatal rodents. Axons are visualized in *red* and early myelination of axons is in *green*. (C) Arrested maturation of preOLs in a chronic white matter lesion where numerous preOLs (*green*) are seen, but the axons (*red*) are diffusely unmyelinated. Scale bars 100 μm. *HI*, Hypoxia-ischemia; *PreOL*, oligodendrocyte progenitor; *PVL*, periventricular leukomalacia; *WMI*, white matter injury. (B, C adapted from Segovia KN, McClure MM, Moravec M, et al. Arrested oligodendrocyte lineage maturation in chronic perinatal white matter injury. *Ann Neurol* 2008;63:517–526.)

neonatal encephalopathy in term infants was demonstrated in a recent double-blinded, placebo-controlled trial of Epo administered with therapeutic hypothermia. A significant reduction in MRI-defined brain injury was observed in the perinatal period as was improved motor function at 1 year of age in 50 infants with hypoxic-ischemic encephalopathy (HIE).[343] Several phase III trials to test the efficacy of Epo as a neurotherapeutic for HIE in combination with hypothermia are ongoing or planned. The effectiveness of therapeutic hypothermia in infants ≥36 weeks' gestational age with HIE and in preterm animal models[344] has prompted investigation of potential benefits in preterm infants. Results in smaller trials have been mixed,[345,346] and a randomized controlled trial of 168 infants 33 to 36 weeks' gestational age has finished recruiting, but results will not be available until neurodevelopmental follow-up is completed.

Preterm Cerebral Gray Matter Injury

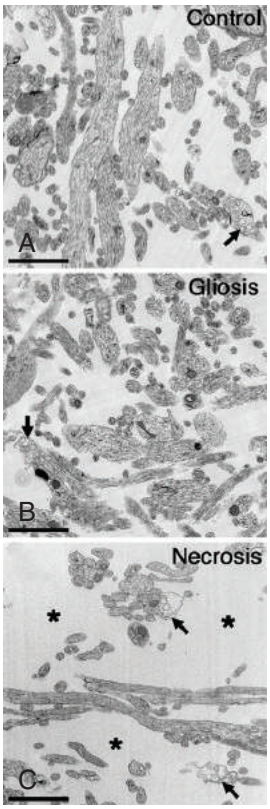
During the last trimester, the cerebral gray matter structures undergo dramatic growth and maturation. Several neuroimaging studies have identified significant reductions in the growth of human cortical and subcortical gray matter structures, including the basal ganglia, thalamus, hippocampus, and cerebellum.[64,198,204,289,347,348] Consistent with the findings of these structural studies, preterm newborns also exhibit reduced functional connectivity between the cortex and thalamus on functional connectivity MRI.[349–351] Children and adults born preterm with normal neurocognitive function nevertheless express altered cortical activation and functional connectivity during language and visual processing.[19,352–354] Thalamocortical connections are also disrupted in preterm newborns with WMI, resulting

in visual dysfunction.[355] Regionally specific altered functional connectivity in children and adolescents born preterm is thus a significant risk factor for multiple adverse neurocognitive outcomes.[352,356–359] Importantly, functional connectivity is dependent on both the relevant gray matter structures and their white matter connections.

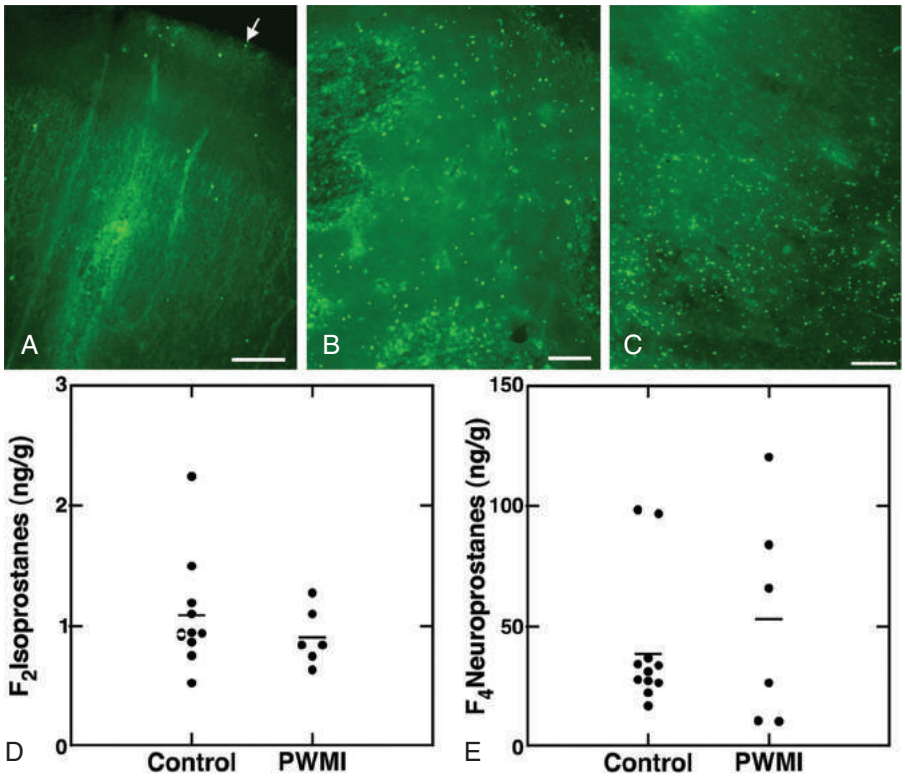
The relative contributions of destructive versus dysmaturational processes to these common structural, functional, and neurobehavioral abnormalities are under active investigation. These two complementary potential mechanisms may explain impaired cerebral growth in preterm survivors. The first may involve primary degeneration of neurons in multiple cortical and subcortical gray matter structures or secondary neuronal degeneration related to axonal injury in foci of white matter necrosis. Subplate neurons, for example, were proposed to be particularly vulnerable to HI in neonatal rodents. Subplate neurons are a transient population required to establish cortical circuitry through guidance cues for thalamocortical connections. They were reduced in a number of human autopsy cases with diagnosed necrotic WMI.[360] These findings are consistent with the link between impaired thalamocortical connectivity and cognitive delays in preterm children.[361] Similarly, in rodents, significant subplate neuron loss appears to occur only in association with more severe cortical neuronal degeneration[362,363] and was not observed in preterm fetal sheep, where neither severe gray nor white matter injury was sustained.[273] Human autopsy studies also found neuronal loss in the cortex, basal ganglia, thalamus, and cerebellum in association with necrotic WMI and axonal degeneration.[187,360,364,365] The apparent mechanism relates to retrograde degeneration of neurons in response to axonal injury in the white matter. As discussed earlier (Fig. 54.4A–C), axonal injury is a prominent feature of WMI where necrosis is present.[193,366] Significant axonal degeneration has not been observed in diffuse nonnecrotic WMI (Fig. 54.9) in either human or experimental models.[3,194] Hence primary or secondary neuronal degeneration appears to occur in the setting of more severe cerebral injury, where cystic necrotic WMI would also be common.

White matter necrotic lesions are a minor component of diffuse WMI in experimental models, and in contemporary cohorts of human WMI cases dysmaturational processes predominate.[3,188] In human autopsy cases, with early diffuse WMI and preOL degeneration, neither the preterm gray matter nor the preterm white matter displayed evidence of significant oxidative stress to degenerating neurons or axons (Fig. 54.10).[195] Significant early neuronal loss was not observed in association with human nonnecrotic diffuse WMI.[187,195] Diffuse WMI thus triggers selective preOL degeneration but appears to spare axons and migrating neurons in the white matter.

These observations support the notion that significant neuronal loss may be uncommon in contemporary cohorts of preterm survivors and that altered gray matter morphology may instead be related to altered development in surviving neurons. While there is a strong relationship between region and extent of WMI and gray matter abnormalities,[350,354] preterm infants can have more extensive gray matter abnormalities than "injuries" identified by MRI signal abnormalities.[6,204,351] The underlying cellular responses that accompany impaired cerebral gray matter development have been studied in a model of global preterm ischemia in preterm fetal sheep. This model closely reproduces the spectrum of WMI and gray matter injury in humans.[367] In fact, diffuse WMI in preterm fetal sheep resulted in reduced growth of the cerebral cortex,[368] caudate nucleus,[369] and hippocampus[370] without loss of neurons. Interestingly, reduced hippocampal growth was also observed in animals treated with hypoxia alone, which did not induce significant WMI. These experimental findings are consistent with observations of microstructural dysmaturation of the cerebral cortex in preterm neonates with restricted postnatal growth,[289] who also show a predilection for WMI.[202,371] Reduced cerebral growth was accompanied by a significant *reduction* in the complexity of the dendritic arbors of the major populations of cortical and caudate projection neurons (Fig. 54.11). Importantly, during normal fetal sheep and human development, significant cerebral cortical growth is accompanied by a pronounced *increase* in the dendritic arbor of projection neurons. These morphologic disturbances in the dendritic maturation of dysmature projection neurons were accompanied by significant reductions in the density of dendritic spines, which are the major sites where synaptic transmission occurs. Regional specificity remains important as hippocampal CA1 neurons show an increase in basal dendrite



• **Fig. 54.9** Axon Degeneration Is Uncommon in Chronic Diffuse White Matter Injury. White matter injury resulted from hypoxia-ischemia in preterm fetal sheep. Injured axons were identified by electron microscopy since optimal markers of axon degeneration have not been developed for light microscopy. (A) Normal preterm white matter contained numerous axons with normal axoplasm and intact microtubules. A swollen degenerating axon (*arrow*) was rarely seen in control white matter. (B) Regions of diffuse white matter injury were very similar to normal controls in the paucity of degenerating axons. (C) By contrast, regions of focal white matter necrosis (i.e., periventricular leukomalacia) contained large areas devoid of axons (*asterisks*) as well as numerous degenerating axons (*arrows*). Scale bars: 2 μm. (From Riddle A, Maire J, Gong X, et al. Differential susceptibility to axonopathy in necrotic and non-necrotic perinatal white matter injury. *Stroke*. 2013;43:178–184.)

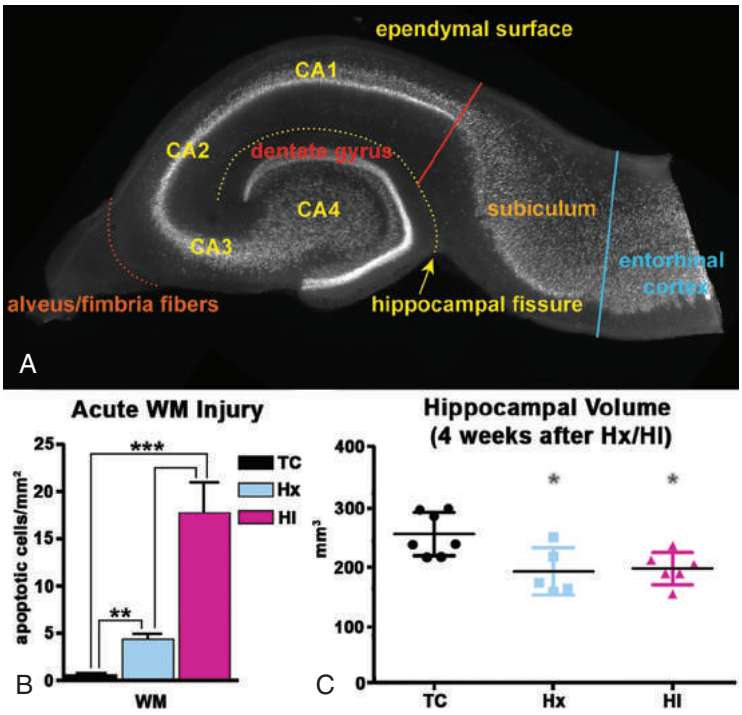


• **Fig. 54.10** Neurons and Axons Are Markedly More Resistant to Oxidative Injury in Gray and White Matter than Oligodendrocyte Progenitors. (A) Typical paucity of cell death in the overlying cerebral cortex from a preterm infant with diffuse white matter injury at autopsy. Cell death is visualized in (A–C) by TUNEL staining, which detects DNA fragmentation of apoptotic and necrotic cells. The *arrow* marks the pial surface. (B, C) The periventricular white matter from the same case showed extensive oligodendrocyte progenitor degeneration. The individual degenerating cells appear as *bright green dots*. (D, E) When compared with controls, no significant oxidative injury to the cerebral cortex was observed in autopsy brains where significant preterm white matter injury was observed. Oxidative injury was measured with two stable markers optimized for preterm human autopsy brains: F_2-isoprostanes are a general marker of oxidative injury to cells and F_4-neuroprostanes specifically detect injury to neurons and axons. Scale bars: (A, C) 200 μm; (B) 100 μm. *PWMI*, Preterm white matter injury. (Adapted from Back SA, Luo NL, Mallinson RA, et al. Selective vulnerability of preterm white matter to oxidative damage defined by F2-isoprostanes. *Ann Neurol*. 2005;58:108–120.)

complexity in response to HI, likely due to homeostatic developmental regulation driven by functional changes within hippocampal circuits.[370]

Electrophysiologic studies found significant abnormalities in excitatory synaptic function at 1 month after preterm HI in multiple brain regions.[369,370] These findings are consistent with the notion that dysmaturation of the dendritic arbor of projection neurons is accompanied by persistent disturbances in neuronal function.[372] Hence these findings support the observation that milder forms of cerebral injury nevertheless result in impaired cerebral growth that involves disturbances in neuronal maturation that affect large distinct populations of neurons in multiple cortical and subcortical gray matter structures.

Since disturbances in the maturation of preterm neurons occur during a critical window in the establishment of human neuronal connections, even transient neuronal dysmaturation may have persistent global effects on the subsequent development of CNS circuitry. Consistent with this notion, recent neuroimaging studies have evaluated whether reduced cerebral growth is accompanied by disturbances in the microstructure of the developing cerebral cortex. During normal development, the cerebral cortex displays a normal progressive loss of cortical fractional anisotropy.[373] This loss of anisotropy is related to the progressive maturation of cortical projection neurons, which are the major population of neurons in the cortex. Immature cortical projection neurons display an "anisotropic morphology" related to their simplified dendritic arbor, which causes asymmetric diffusion of water along their dendrites. As neuronal maturation progresses, the dendritic arbor assumes an "isotropic morphology" in which water diffusion along dendritic processes is similar in all directions. Thus, dysmature cortical projection neurons have a simplified dendritic arbor that results in greater "anisotropic morphology."[368] This reduced dendritic arbor complexity accounted for the greater anisotropy that was observed experimentally in chronic gray matter lesions relative to the reduced anisotropy in normal gray matter (Fig. 54.12). Delayed maturation of regional cortical microstructure in preterm survivors[374] and related macrostructural markers such as cortical surface area and curvature[206,375] correlate with neurodevelopmental outcomes in preterm survivors. In the setting of reduced cortical growth,



• **Fig. 54.11** Hippocampal Growth is Reduced Similarly after Fetal Hypoxia *(Hx)* and Hypoxia–Ischemia *(HI)*. (A) Neuronal staining of a transverse slice through the hippocampal formation reveals the neuronal subfields of the fetal sheep hippocampus and dentate gyrus in the stereotypical "jelly-roll" configuration. Area calculations included the CA1–CA4 subfields and the dentate gyrus of each slice and excluded the subiculum, entorhinal cortex, and alveus. (B) Peak cellular degeneration in the white matter *(WM)* 25 hours after HI analyzed by apoptotic marker caspase-3 reflects the vulnerability of the WM to hypoxic-ischemic injury. Minimal injury was noted after Hx without ischemia. No increase in cellular injury was found in the hippocampus in either condition (data not shown). (C) After 4 weeks, the hippocampal volume of fetuses exposed to Hx or HI was similarly reduced versus controls *(TC)*. $*p < .05$, $**p < .01$, $***p < .001$. (Adapted from McClendon E, Wang K, Degener-O'Brien K, et al. Transient hypoxemia disrupts anatomical and functional maturation of preterm fetal ovine CA1 pyramidal neurons. *J Neurosci*. 2019;39[40]:7853–7871.)

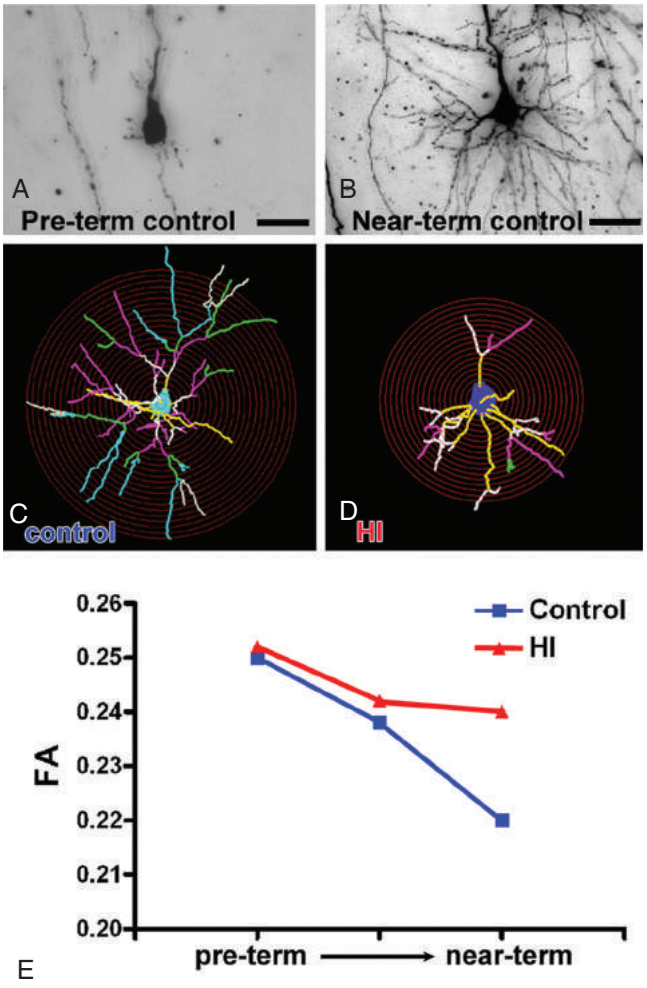
the gray matter of human preterm survivors was found to display increased anisotropy, consistent with greater dysmaturity.[9,289] Disturbances in cortical fractional anisotropy were associated with impaired somatic growth (weight, length, and head circumference), even after coexisting brain injuries on MRI (e.g., WMI) and other aspects of systemic illness (e.g., infection) had been accounted for.[289]

Recent studies in very preterm neonates highlight the critical link between nutrition in the first 2 to 4 weeks of life with subsequent growth of the brain to term-equivalent age and neurodevelopmental outcomes in early childhood.[376,377] While these studies point to the importance of early life energy and lipid intake, even more specific aspects of nutrition are being investigated. Improved microstructural white matter development and less IVH are linked to higher postnatal docosahexaenoic acid levels, suggesting the potential of nutrition strategies to promote optimal brain maturation.[378] Consistent with these observations, higher serum docosahexaenoic acid levels in the first 28 days of life are positively associated with brain volumes at term-equivalent age in extremely preterm neonates.[379] More recent evidence from preterm born children studied at 7 years of age with functional MRI measures of thalamic network connectivity, suggests that optimizing early protein intake may promote long-term brain maturation.[380]

These studies support that dysmaturation of cerebral neurons and circuits are major underlying mechanisms that lead to various neurocognitive impairments seen in survivors of preterm birth and that these dysmaturation events do not require significant cell death or classic neuropathological injury. As in developing WM, multiple factors including nutritional status and exposure to cerebral hypoxia or ischemia, or infection may contribute to the pathogenesis of neuronal dysmaturation in preterm survivors. It is unclear, however, the extent to which dysmaturation occurs secondary to or independent from diffuse WMI, or, perhaps most likely, both. This distinction has important implications for the development of neurotherapeutic approaches. Further studies are needed to define how disturbances in neuronal maturation arise and contribute to the widespread disturbances in cerebral connectivity that appear to underlie the enduring neurocognitive and behavioral deficits observed in preterm survivors.

Summary

Advances in neonatal neurologic intensive care have been accompanied by considerable progress in the reduction in the incidence and overall severity of IVH in preterm neonates. These advances



• **Fig. 54.12** After hypoxic-ischemic white matter injury, the preterm brain is enriched in immature neurons that do not degenerate but are highly susceptible to impaired maturation that manifests itself as a less complex dendritic arbor. (A) A typical pyramidal projection neuron from the preterm cerebral cortex of a control fetal sheep that was visualized with a Golgi silver stain. Note the paucity of processes and the simplified appearance of this typical preterm neuron. (B) Neurons undergo a dramatic increase in complexity of the dendritic arbor in near-term animals. (C, D) Four weeks after preterm ischemia, cortical projection neurons display disrupted maturation. A typical control neuron (C) displays highly arborized dendrites, whereas a brief preterm exposure to hypoxia-ischemia *(HI)* resulted in neurons with a significantly more simplified dendritic arbor (D). The reduced complexity of the dendrites can be appreciated from the overlay of the red concentric Scholl rings, which illustrate that the processes of the dysmature neurons intersect less frequently with the rings. The *yellow, white, pink, green*, and *blue lines* represent first-order, second-order, third-order, fourth-order, and fifth-order branches respectively from the soma. Note the overall reduction in the size and complexity of the branching pattern of the ischemic neurons in (D). (E) Reductions in cortical growth also manifest themselves as disturbances in cortical fractional anisotropy (FA), a magnetic resonance imaging measure of maturation and complexity of the white matter microstructure. Note the normal progressive decline in FA in controls *(blue)* between preterm and near-term cortical development. In response to ischemia, higher cortical anisotropy (more restricted water diffusion) was observed in response to ischemia *(red)* relative to controls *(blue)*, which was related to the reduced complexity of the dendritic arbor of the ischemic neurons, for example, in (D) versus controls, for example, in (C). Scale bars: (A, B) 20 μm. (From Back SA, Miller SP. Brain injury in premature neonates: a primary cerebral dysmaturation disorder? *Ann Neurol*. 2014;75:469–486.)

have contributed to similar reductions in the incidence of more severe cystic necrotic cerebral WMI and gray matter injury. Unexpectedly, despite these pronounced reductions in injury severity, neurodevelopmental morbidity persists at very high rates[381] while the number of preterm births continues to rise.[382] Preterm neonates are surviving with an evolving constellation of motor, cognitive, and behavioral disabilities that appear to be related to a broad spectrum of injury that ranges from relatively uncommon severe forms of injury to more moderate injury that is accompanied by widespread disturbances in cellular maturation. This translates to large numbers of brain cells that fail to fully mature during a critical window in the development of neural circuitry. These recently recognized forms of cerebral gray and white matter dysmaturation raise new diagnostic challenges and support the urgent need for new therapeutic strategies focused on regeneration and repair to reverse the processes that promote dysmaturation.

Neonatal Encephalopathy

ULRIKE MIETZSCH AND SANDRA E. JUUL

KEY POINTS

- Neonatal encephalopathy is a clinical syndrome that can result from a variety of underlying causes.
- Hypoxic-ischemic encephalopathy (HIE) is a major cause of neonatal brain injury and mortality worldwide.
- Magnetic resonance imaging and magnetic resonance spectroscopy are useful imaging tools to identify brain injury and help predict long-term neurodevelopmental outcomes in neonates with HIE.
- Cerebral arterial or venous thrombosis may be the cause of unexplained seizures.
- Infections acquired in utero can present with neonatal encephalopathy.
- Metabolic disorders, genetic conditions, and brain malformations can present as neonatal encephalopathy.

Neonatal Encephalopathy

Neonatal encephalopathy describes a clinical syndrome unique to the term and near-term newborn in the immediate perinatal period.[1] The clinical findings may include seizures and are characterized by an impairment of one or more components of the central nervous system (CNS) including mental status, tone, primitive reflexes, autonomic functions including respiration, as well as abnormal feeding.[2–4] The causes of neonatal encephalopathy are diverse and include infections, stroke, genetic conditions, metabolic disorders, and brain malformations (Table 55.1).[2,3,5] The incidence of neonatal encephalopathy in high-income countries ranges from 2 to 6:1000 term live births with a combined average of 3.9:1000; the exact incidence, however, is difficult to determine due to the heterogeneous nature of the presenting clinical picture and might be much higher than currently described in the literature.[6–10] Factors associated with neonatal encephalopathy are plentiful and can be divided into maternal, utero-placental, and fetal in origin (Table 55.2).

Recent placental pathology studies have given insight into pathophysiologic changes associated with neonatal encephalopathy. Commonly observed findings in placentas from newborns with neonatal encephalopathy can be acute or chronic, and include infection, inflammatory changes, and vasculopathies, particularly those altering fetal vascular perfusion.[11,12] It is understood that findings consistent with fetal vascular malperfusion take at least 48 hours to evolve[13] and therefore can be an indicator of the acuity of neonatal encephalopathy. Changes consistent with global fetal vascular malperfusion, including avascular villi and fetal thrombotic vasculopathy (FTV), occurred in 20–24% of cases diagnosed with neonatal encephalopathy, 3 to 4× higher than in control newborns.[14–16] The severity of clinical encephalopathy can be linked to the severity of fetal vascular placental changes.[17] In some series, thrombosed placental vessels and fetal vascular malperfusion have been demonstrated in up to 50% of cases with perinatal arterial-ischemic stroke.[15] The impact of placental inflammatory changes is less clear. Those affecting the fetal side of the placenta, histologically known as funisitis, are six times higher in neonates with encephalopathy than in healthy term newborns (31.4% vs. 4.4–5.4%); however, alterations affecting the maternal side, also referred to as chorioamnionitis, are only twice as common.[16] Based on these observations, abnormal fetal vascular perfusion and inflammatory changes can be associated with neonatal encephalopathy.[18–20]

TABLE 55.1 Disorders Associated With Neonatal Encephalopathy

1. Hypoxic-Ischemic Encephalopathy
   - Acute perinatal event (sentinel event)
   - Subacute event
2. Vascular/Inflammatory
   - Arterial ischemic stroke
   - Acute hemorrhagic stroke/parenchymal hemorrhage
   - Cerebral venous sinus thrombosis
   - Severe maternal or fetal anemia
3. Metabolic
   - Hyperbilirubinemia
   - Electrolyte disturbances:
     Hypoglycemia
     Hyponatremia
     Hypocalcemia
   - Inborn errors of metabolism with toxic substrate accumulation
   - Inborn errors of metabolism leading to energy deficient state
4. Genetic
   - Malformations
   - Copy number variations
   - Single gene mutations
5. Infectious
   - Meningitis
   - Encephalitis
   - Ventriculitis

TABLE 55.2 Risk Factors Associated With an Increased Risk for Neonatal Encephalopathy and Hypoxic-Ischemic Encephalopathy

Maternal

Advanced maternal age
Pre-eclampsia/eclampsia
Prolonged second stage of labor
Shock
Cardiac arrest

Uteroplacental

Uterine hyperstimulation
Chorioamnionitis
Chronic vasculitis
Funisitis
Placental insufficiency
Placental chronic villitis
Fetal-maternal hemorrhage

Intrapartum Sentinel Event

Placental abruption
Uterine rupture
Prolapsed cord
Tight nuchal cord
Shoulder dystocia

Fetal

Category III fetal heart rate tracing
Congenital heart disease
Inborn errors of metabolism
Perinatal stroke or thrombosis
Hemolytic disease
Infection
Genetic syndromes
Small for gestational age/intrauterine growth restriction
Large for gestational age

Hypoxic-Ischemic Encephalopathy

Epidemiology

Birth asphyxia is one of the leading causes of neonatal mortality worldwide, accounting for an estimated 20–30% of neonatal deaths.[21,22,24] Hypoxic-ischemic encephalopathy (HIE) accounts for an estimated 25–45% of neonatal encephalopathy and is the most common form of acute brain injury in newborns.[25] The incidence of HIE is approximately 1–3:1000 term/near-term live births[26–28] in high-resource countries and as high as 31:1000 live births in low-resource settings.[29]

Motor disabilities and long-term neurodevelopmental impairment (NDI) including cognitive, neuropsychological, epilepsy, educational, and behavioral problems are common in surviving neonates with moderate or severe HIE.[30,31] Despite advances in therapeutic intervention, 31–55% of neonates with moderate or severe HIE still experience significant sequelae and either don't survive the neonatal period (17–38%) or suffer from significant neurodevelopmental impairment (14–35%), including intellectual disabilities, cerebral palsy (13–32%), and seizures.[32–40] Brain injury secondary to hypoxia-ischemia during labor can be seen in up 24% of term-born children with cerebral palsy.[41] The emotional impact and costs associated with medical and rehabilitative care of infants with HIE are substantial.[42] The Centers for Disease Control and Prevention estimated the lifetime costs for all people with cerebral palsy born in 2000 to be US $14.7 billion, which equals approximately US $1.2 million per person with cerebral palsy.[43]

Pathophysiology

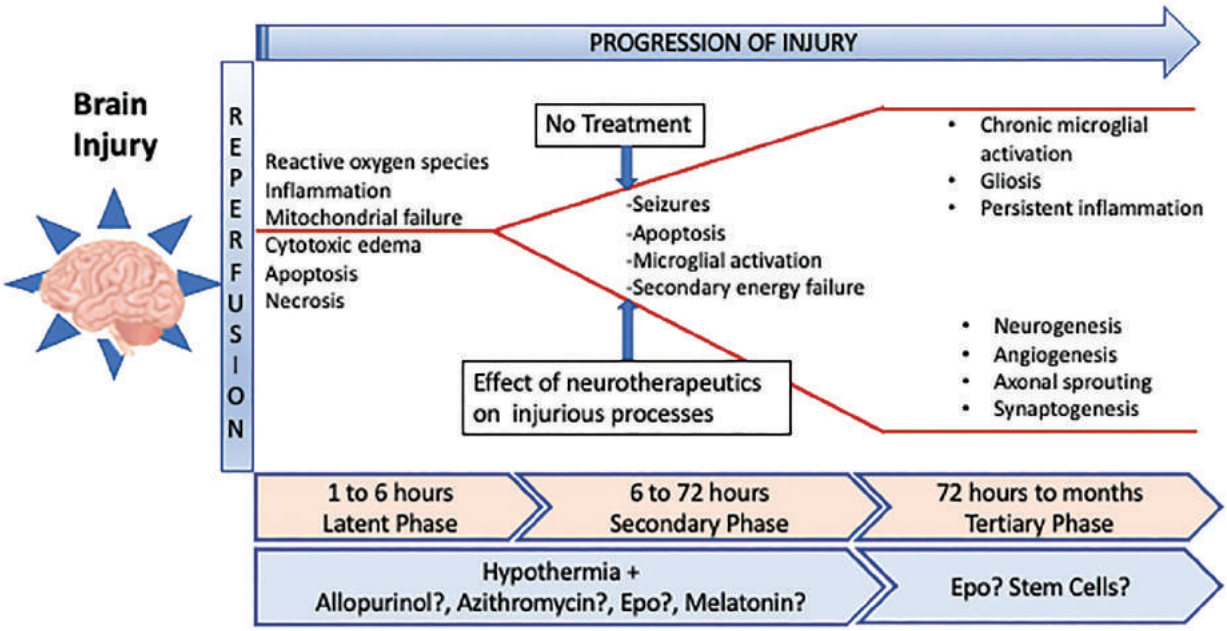
HIE results from a significant intrapartum hypoxic-ischemic sentinel event (acute or prolonged). Factors contributing to such events are plentiful and can be divided into maternal, utero-placental, and fetal in origin (see Table 55.2). Maternal and utero-placental causes are often sudden and severe and are estimated to occur in one-third of HIE cases.[43a]

Factors that increase the risk of a sentinel event include maternal medical conditions associated with impaired placental perfusion such as chronic hypertension, diabetes, autoimmune diseases, preeclampsia, and alterations originating from within the placenta leading to inflammatory changes, such as chorioamnionitis, villitis, vasculitis, and funisitis.[16,44,45] Intrapartum clinical inflammatory factors, such as maternal fever, chorioamnionitis, and prolonged rupture of membranes, may also increase the risk and severity of HIE.[27]

Regardless of the cause, significant hypoxia-ischemia can lead to cardiac and vascular compromise, with subsequent diminished cerebral perfusion and oxidative metabolism, energy failure, cell death, and depending on duration and extent, may result in hypoxic-ischemic brain injury.

The pathophysiologic changes after an acute hypoxic-ischemic event follow characteristic phases defined as primary injury, latent, secondary, and tertiary phases (Fig. 55.1).[46] The primary injury phase is characterized by decreased cerebral oxygen and glucose delivery as the immediate result of compromised cerebral perfusion.[47–49] Glycolysis in an oxygen-poor environment leads to depletion of adenosine triphosphate (ATP), and accumulation of lactic acid. Cellular mechanisms dependent on ATP, such as Na^+/K^+ ATPase pumps, can no longer maintain their functions. This results in depolarization of neuronal cell membranes with a subsequent increase in intracellular sodium and calcium concentration, which generates osmotic and electrochemical gradients across the cell membrane and leads to cytotoxic edema.[48] Induction of destructive enzymes (e.g., phospholipases, proteases, and endonucleases) also occurs. Activated phospholipases (e.g., phospholipase A2) hydrolyze cellular membrane phospholipids and release free fatty acids such as arachidonic acid, which can further increase glutamate release, perpetuate membrane peroxidation, and activate N-methyl-D-aspartate (NMDA) receptors, which results in a further increase in intracellular calcium. Abnormally high intracellular calcium concentrations have toxic effects on intracellular organelles, particularly the mitochondria,[50] and stimulate the activation of nitric oxide synthase resulting in increased production of reactive oxygen species (ROS), including nitric oxide (NO). NO damages the mitochondrial membrane leading to devastating mitochondrial dysfunction.[51] The consequences for cellular health and metabolism are significant and include the induction of necrotic and apoptotic pathways as well as stimulation of the inflammatory cascade.[47,52]

The next phase of injury, referred to as the latent phase, is characterized by reperfusion with active suppression of cerebral



• **Fig. 55.1** Pathophysiologic stages, mechanisms, and opportunities for therapeutic intervention in hypoxic-ischemic encephalopathy in relation to evolution over time.

metabolism. A partial rebound of neuronal oxidative energy metabolism occurs by meeting a decreased demand, leading to improvement of cytotoxic edema, and increased cerebral tissue oxygenation.[53,54] While the neurotoxic cascade is suppressed during this stage, increased perfusion and oxygenation continue to contribute to additional ROS production.[55,56] This phase occurs between 1 and 6 hours after insult and is the optimal window in which to initiate therapeutic hypothermia.[51]

The following, secondary phase, is characterized by secondary energy failure, ongoing inflammation, oxidative injury, and excitotoxicity. This phase may be observed as early as 6 hours after the initial insult and typically lasts for multiple days. While some repletion of energy sources takes place during the latent phase, rapid depletion of these resources occurs again during the secondary phase leading to cytotoxic edema, mitochondrial failure, and accumulation of excitotoxins and cytokines, ultimately resulting in delayed cell death.[57,58] Ongoing injury during secondary energy failure is thought to be directly related to the extent of primary energy failure,[59] partially mediated by neuroglial activation after early neuronal cell death. This leads to the release of proinflammatory cytokines and ROS, which attracts peripheral immune cells that can enter the parenchyma via the disrupted blood-brain barrier and facilitate cell death.[27] The degree of secondary energy failure and degree of cellular energy deficit determines the extent and pathway of neuronal death, for example, necrosis, apoptosis, and autophagy, all of which occur on a continuum.[58,60]

The tertiary phase is characterized by reparative and restorative processes. This phase can last weeks to years. The immune response shifts towards the healing of the neuroinflammatory process, with microglia exerting their phagocytic capabilities alongside penetrating peripheral macrophages. Phagocytosis of dead cells triggers the release of anti inflammatory cytokines and the production of neuronal growth factors, an essential component of the remodeling process that includes neurogenesis, angiogenesis, and axonal sprouting.[27,59]

Clinical Presentation

Newborns who have undergone hypoxic-ischemic compromise often present with encephalopathy, although other organ systems may be affected. Obtaining a careful pregnancy and labor history to identify any acute sentinel events complicating labor and/or delivery such as decreased fetal movement, an abnormal fetal heart rate pattern (bradycardia or category III tracing), or meconium passage prior to delivery may provide important information regarding the timing of the insult.

Following delivery, newborns with HIE commonly present with respiratory failure requiring positive pressure ventilation for a prolonged period of time (≥10 minutes), often needing endotracheal intubation with assisted ventilation. Hypoxia also leads to cardiac and vascular compromise, and newborns with HIE may therefore present with persistent bradycardia or even asystole requiring cardiopulmonary resuscitation including epinephrine administration. The cardio-respiratory compromise is reflected in persistent low Apgar scores (≤5) by 10 minutes of age. Laboratory biomarkers of hypoxia-ischemia include significant fetal acidemia (pH ≤ 7.0 and/or a base deficit of ≥12) and an elevated serum lactate diagnosed from either arterial or venous umbilical cord blood samples, or an arterial or venous sample obtained from the newborn within the first postnatal hour.

At birth, neonates with HIE are commonly depressed and manifest clinical symptoms consistent with neurologic injury. The clinical picture evolves significantly over the first hours after birth. When assessing a depressed neonate for therapeutic intervention, the worst exam between one and six hours of life is the most informative regarding the severity of HIE and eligibility for therapeutic hypothermia. It is, however, important to note that the exam continues to evolve over the first week of life and becomes more predictive for long-term outcomes towards the end of the first week. The Modified Sarnat Exam (Table 55.3A) and the Thompson Encephalopathy Score (Table 55.3B) are the standardized neurologic assessments used to assess the severity of

TABLE 55.3A Modified Sarnat Exam

Category	Normal	Mild	Moderate	Severe
Level of Consciousness	Normal	Hyperalert or irritable	Lethargic or poorly responsive	Minimal or no responsiveness
Spontaneous Activity	Normal	Slightly decreased	Decreased	Absent
Posture	Normal	Mild distal flexion	Distal flexion, complete extension	Decerebrate
Muscle Tone	Normal	Hypertonic	Hypotonic	Flaccid
Primitive Reflexes				
1. Suck reflex	1. Normal	1. N/A	1. Weak or bite	1. Absent
2. Moro reflex	2. Normal	2. Low threshold to elicit	2. Weak or incomplete	2. Absent
Autonomic Reflexes				
1. Pupils	1. Normal	1. N/A	1. Constricted	1. Dilated and either fixed or sluggishly reactive; asymmetric
2. Respirations	2. Normal	2. N/A	2. Periodic breathing	2. Intubated and ventilated

TABLE 55.3B Thompson Encephalopathy Score

Category	Score 0	Score 1	Score 2	Score 3
Muscle tone	Normal	Hypertonicity	Hypotonicity	Flaccid
Level of consciousness	Normal	Hyperalert, stare	Lethargic	Comatose
Seizures	None	Infrequent <3/day	Frequent >2/day	N/A
Posture	Normal	Fisting, cycling	Strong distal flexion	Decerebrate
Moro reflex	Normal	Partial	Absent	N/A
Grasp reflex	Normal	Poor	Absent	N/A
Suck reflex	Normal	Poor	Absent ± bites	N/A
Respirations	Normal	Hyperventilation	Brief apnea	Apnea, ventilated
Fontanel	Normal	Full, not tense	Tense	N/A

HIE and eligibility for therapeutic hypothermia.[61,62] The Modified Sarnat Exam, or alternatively the Thompson Encephalopathy Score, can then be followed sequentially over the first week of life to monitor changes in neurologic status.

Neonates with mild encephalopathy appear hyperalert and irritable with wide-open eyes, often with a "stunned look" or a blank stare, and dilated pupils. An increased muscle tone and a heightened Moro reflex reactive to tactile and sensory stimuli are observed. Neonates with moderate encephalopathy appear lethargic with low tone, a weak suck, constricted pupils, and a decreased Moro reflex. Neonates with severe encephalopathy appear stuporous, flaccid and have decerebrate posture, absent reflexes (suck, gag, and Moro), and poorly reactive pupils. Respiratory disturbances are also common with moderate and severe HIE, with periodic breathing and apnea present in most affected neonates.[63]

HIE is the most common cause of seizures in the neonatal period. Seizures are often subclinical or subtle in presentation, manifesting as apneic events, vital sign instability, or less commonly, with stereotypic movements such as abnormal eye movements (e.g., tonic, horizontal eye deviation with or without jerking, eyelid blinking), oral-buccal-lingual movements (e.g., sucking or lip smacking), or limb movements (e.g., finger flicking, swimming motions or bicycle pedaling). Seizures occur in 56–88% of patients with HIE,[64–69] are subclinical in 43–67%,[70,71] and progress to status epilepticus in 23–67%.[68,70,72,73]

Other organ system involvement is commonly seen in neonates with HIE including cardiac dysfunction, respiratory failure, acute kidney injury, abnormal glucose homeostasis, syndrome of inappropriate antidiuretic hormone secretion (SIADH), liver dysfunction, and disseminated intravascular coagulopathy (DIC).

Evaluation

Laboratory tests and ancillary studies are pertinent in assessing and treating newborns with suspected HIE, particularly since multisystem organ involvement is common. Metabolic derangements such as hypoglycemia, hypocalcemia, hyponatremia, hypomagnesemia, hypoxemia, decreased P_{CO_2} and metabolic acidosis are frequently seen in the first 24 hours after birth. Prompt corrective intervention may avoid further compromise. Serum lactate is often significantly elevated following hypoxia or ischemia, reflecting the anaerobic metabolism of glucose for energy in the setting of decreased tissue oxygenation. A complete blood count may demonstrate leukopenia or leukocytosis, which may suggest

infection, anemia (e.g., in cases of known or suspected abruption), or thrombocytopenia, which may also occur with DIC. Coagulation studies to assess for DIC and to guide clinical management should include prothrombin time (PT), activated partial thromboplastin time (aPTT), international normalized ratio (INR), and fibrinogen level. Liver function may be abnormal and should be assessed by monitoring serum alanine transferase (ALT), aspartate transferase (AST), particularly since many medications given to critically ill newborns are metabolized in the liver. ALT and AST typically don't reach their peak level until 24 to 48 hours after the insult, hence daily monitoring of liver function is crucial for appropriate medication adjustment. Initial newborn creatinine levels may reflect maternal values, but a rising creatinine, especially in the setting of poor urine output, is consistent with acute kidney injury (AKI) and provides pivotal information for managing renally cleared pharmacologic agents in the critically ill newborn. Myocardial perfusion is frequently compromised in neonates with HIE and can lead to decreased ventricular function and reduced cardiac output in as many as 75–100% of patients with HIE,[74,75] Electrocardiogram and cardiac enzymes (serum creatine kinase, creatine kinase-MB isoenzyme, and troponin I) are good markers to assess cardiac dysfunction after perinatal asphyxia, and abnormalities are seen in up to 90% of neonates with HIE; those changes are more significant as the severity of HIE increases.[76,77] However, echocardiography remains the preferred method for assessment of cardiac compromise in this population, allowing for serial examinations and individually targeted treatment.[75] Furthermore, neonates with HIE often have decreased heart rate variability on continuous electrocardiogram, which is associated with the severity of injury and outcome.[78,79]

Neuromonitoring

Electroencephalography

Given the high incidence of seizures and frequent lack of clear clinical expression in this high-risk population, the American Clinical Neurophysiology Society recommends that all neonates with HIE undergoing therapeutic hypothermia are monitored with electroencephalogram (EEG) throughout cooling and rewarming,[80] preferentially as continuous video-EEG (cEEG). Alternatively, in centers where cEEG is unavailable, amplitude-integrated EEG (aEEG) may be used.

Prompt recognition and treatment of HIE-related seizures are indicated, as increased seizure burden is associated with increased brain injury on magnetic resonance imaging (MRI) and worse long-term outcomes independent of the degree of HIE.[81–83] Moreover, acute symptomatic seizures become more difficult to treat the longer they last, which may lead to increased exposure to antiepileptic medications and associated side effects such as respiratory depression and hemodynamic compromise, in addition to worsening brain injury. Seizures in neonates with severe HIE tend to be longer in duration and more frequent, resulting in a higher seizure burden compared to neonates with moderate HIE.[84] Therapeutic hypothermia does not affect the incidence of seizures (54% vs. 60%),[85] but does significantly decrease the seizure burden, particularly in neonates with moderate HIE.[66,68,85,86]

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) allows noninvasive, continuous bedside monitoring of cerebral hemodynamics and oxygenation by measuring the absorption spectra in the near-infrared region of light (700 to 1000 nm) of oxygenated and deoxygenated hemoglobin (Hgb) in the cortical tissue. The calculated percentage ratio of oxygenated Hgb to total Hgb (oxygenated plus deoxygenated Hgb) is commonly referred to as cerebral oxygenation.[87–89] Regional cerebral blood flow measured by MRI showed a strong correlation with mixed venous saturation values measured by NIRS in neonates with HIE undergoing therapeutic hypothermia.[90] Further observations in neonates with HIE showed that cerebral oxygenation decreases in the first 4 to 6 hours of life and then slowly increases within the first 24 hours.[91] The initial decrease is less pronounced in more severely affected newborns, likely due to a lack of metabolic activity within the severely injured brain.[92,93] Correlations with injury on MRI imaging and long-term outcome have shown that neonates who continue to have increased cerebral tissue oxygenation after 24 hours have more significant injury on MRI and less favorable neurodevelopmental outcome at 2 years.[87,94,95]

Neuroimaging

Ultrasound

Cranial ultrasonography (CUS) can be used as a first-line imaging tool in newborns with HIE since it can be performed at the bedside in critically unstable neonates. However, extra-axial structures are poorly visualized, and the sensitivity and specificity of CUS findings in HIE are low and correlate poorly with long-term outcomes.[96] White matter echogenicity detected by early CUS suggests antenatal events rather than acute injury at the time of birth.[97] The accuracy of CUS increases towards the middle and end of the first week of life.[98] Significant cerebral edema may be demonstrated as increased focal or diffuse brain parenchyma echogenicity, slit-like ventricles, and obliteration of the extracerebral cerebrospinal fluid (CSF) spaces and the interhemispheric fissure. Cerebral edema can be seen secondary to HIE, metabolic encephalopathies, seizures, or infections, among other causes. While signs of HIE may be difficult to detect with CUS, this imaging modality may provide preliminary information about brain malformations or other potential causes of neonatal encephalopathy that may clinically resemble HIE.[99] Although CUS is a valuable tool to assess neonates with suspected brain injury, MRI is the study of choice in the diagnostic assessment of neonates with HIE.

Magnetic Resonance Imaging and Magnetic Resonance Spectroscopy

In encephalopathic newborns, MRI done at 4 to 5 days after birth, and following rewarming from therapeutic hypothermia, can be used to assess for injury patterns consistent with HIE and rule out other causes, including neurogenetic, neurovascular, or inflammatory diseases.[100] A combination of conventional imaging sequences (T1- and T2-weighted images), diffusion-weighted imaging (DWI), diffusion tensor imaging, plus magnetic resonance spectroscopy (MRS) can provide information on brain microstructure, connectivity, and metabolism and can assist with determining the timing and severity of brain injury in newborns with HIE.[101,102] MRI performed in the newborn period has a high predictive value for subsequent neurologic impairment at 18 months of age. However, the timing is important, and MRI should ideally be performed on postnatal days 4 to 6. DWI, which measures the random Brownian motion of water molecules within a voxel of tissue, can identify cytotoxic edema and ischemic brain neonatal tissue days before T1 and T2 sequences.[104] Pseudo normalization of the brain MRI occurs after the first week and may underestimate the final extent of basal ganglia and thalamic

lesions.[97,103,105–107] MRS is a tool to assess brain metabolism and is usually focused on a region of interest most commonly the basal ganglia. Elevated lactate peaks on MRS have been associated with poor long-term outcome, while N-acetyl aspartate (NAA), a marker of neuronal viability, is commonly decreased when neuronal loss is observed. The ratio of lactate to NAA can be helpful in estimating the severity of injury and predict long-term outcome.[108]

Characteristic patterns of brain injury seen in HIE give valuable information about onset, extent, and evolution of brain injury, and can be predictive of outcome. The neuropathology and pathogenesis of neonatal brain injury associated with HIE have been thoroughly described by Volpe, who summarizes three major patterns of injury based on historic fetal monkey and human studies.[109–113] The three injury patterns include (1) diffuse, (2) cerebral cortical-deep nuclear, and (3) deep nuclear-brain stem.

A *deep nuclear pattern* of injury is observed in the case of abrupt onset (within 10 to 46 minutes) of complete asphyxia. An example of such a sentinel event is a cord prolapse. The *cerebral cortical-deep nuclear pattern* can be observed after partial and prolonged asphyxia. Sentinel events corresponding to injury in the cerebral cortex and deep gray matter (basal ganglia and thalamus) evolve over longer periods, often hours. If this insult is prolonged and/or profound, additional effect on the brain stem can be observed and this injury pattern is referred to as *deep nuclear-brainstem pattern*.

The parasagittal cerebral injury pattern, also referred to as a *watershed predominant pattern*, is found after subacute partial and prolonged intrapartum hypoxia and involves the parasagittal white matter, in severe cases also the cortical gray matter.

Computed Tomography

Computed tomography (CT) lacks the sensitivity to evaluate the characteristics and extent of brain injury in term encephalopathic infants and is therefore rarely used to assess newborns with HIE.[97,102] An advantage of CT over CUS is that it can detect hemorrhages in areas where CUS is difficult to apply and can visualize the extra-axial regions better. An advantage of CT over MRI used to be the speed at which it can be done. Newer limited-sequence (rapid) MRI protocols are now of similar duration and cost. MRI can detect hemosiderin depositions via susceptibility-weighted images (SWI) and ischemic stroke on DWI more accurately than CT while sparing the developing brain from radiation exposure.[97,114,115]

Management

Neonates with HIE are frequently critically ill and demonstrate signs of multiorgan involvement. For that reason, the initial management steps should focus on promoting adequate oxygenation, ventilation, circulation, and correction of metabolic derangements. Myocardial ischemia can result in a low cardiac output state. Cardiovascular instability and hypotension are commonly observed in affected patients.[49,75] Continuous blood pressure monitoring facilitates prompt recognition of systemic hypotension and timely treatment to avoid additional compromise. Treatment options include inotropic agents as well as support with hydrocortisone. Hydrocortisone may be beneficial given the common compromise of the adrenal glands in HIE patients.

The newborn with HIE oftentimes shows signs of respiratory compromise secondary to the ischemic effects on the lungs, impairment of the central respiratory system, and frequent exposure to meconium-stained amniotic fluid. The resulting clinical symptoms include apnea, periodic breathing, impaired gas exchange, and pulmonary hypertension. Hypoxemia is particularly profound in the initial phase and improves with amelioration of the acidosis. Despite respiratory depression, newborns with HIE are frequently hypocarbic because of respiratory compensation of the metabolic acidosis. This can result in further compromise of the cerebral autoregulation and exacerbation of brain injury. Therefore, tight management of respiratory status and blood chemistry is crucial in this critically ill population.

The fluid and electrolyte status may become imbalanced due to cerebral edema and secondary SIADH. Hypoxic injury to the kidneys can also lead to AKI, which presents with oliguria or anuria, fluid retention, and subsequent electrolyte abnormalities, particularly hyponatremia. When profound, hyponatremia can result in seizures, further exacerbate brain injury, and worsen the cerebral edema. Therefore, fluid and electrolyte management are critical to avoid additional compromise, and significant temporary fluid restriction might be necessary.[49]

Glucose homeostasis is often disrupted in neonates with HIE. Hypoglycemia is an emergency and requires prompt correction as it can exacerbate brain injury and induce seizures.

Seizures can manifest clinically, but more often lack a clinical correlate and can be detected by EEG only. Prompt treatment of the acute symptomatic seizures and correction of electrolyte derangements (hypoglycemia, hyponatremia, and hypocalcemia) is pivotal to avoiding further injury.[116]

Liver injury and DIC are frequently observed in neonates with HIE. DIC warrants monitoring and when associated with bleeding, requires immediate treatment. Liver dysfunction impairs the production of clotting factors and additional vitamin K might be necessary to assist with the production of vitamin K-dependent clotting factors until either the liver injury is recovering or DIC resolves. Abnormal renal and hepatic function have a significant impact on metabolism and clearance of medications commonly used in this critically ill population (e.g., phenobarbital, gentamicin, and furosemide).[117]

Hypothermia Therapy

Hypothermia is currently the only proven neuroprotective therapy for HIE. Hypothermia decreases cellular metabolism by 5–8%/°C,[118,119] attenuates the inflammatory reaction, stabilizes the blood-brain barrier, and reduces glutamate and oxygen free radicals.[48,120] In addition, hypothermia has been shown to have anti-epileptic effects.[121] The beneficial effect of therapeutic hypothermia is most pronounced when applied before the onset of the secondary energy failure, which is approximately within 6 hours of birth, preferably as soon as possible after injury.[122] Applying hypothermia within 6 hours of birth to maintain the core body temperature at 33.5 ± 0.5°C for 72 hours followed by slow rewarming at a rate of 0.5°C/h to normothermia, has been shown in numerous randomized controlled trials to improve outcomes in neonates with moderate to severe HIE.[36,123–125]

Mild cooling has an effect on all organ systems, and physiologic changes are commonly seen after the initiation of therapeutic hypothermia (Table 55.4).[34,36,38–40,123,124,126,127] Alteration in pharmacokinetics, particularly enzyme-dependent metabolism (e.g., cytochrome P450—phenobarbital, fentanyl, midazolam, phenytoin, corticosteroids, and vecuronium) and enzyme facilitated conjugation (e.g., hepatic glucuronidation—morphine), is affected by hypothermia.[126] Therefore, particular attention needs to be given to pharmacotherapy during therapeutic hypothermia.

In animal studies, decreased blood flow to the intestines was described during hypothermia, in human neonates; however,

TABLE 55.4 Effects of Hypothermia

	Effect	Mechanism
Metabolic rate	↓ 5–8% per 1°C below 37.0°C	Decreased—primary energy conserving mechanism
Cerebral blood flow	↓ 5% per 1°C below 37.0°C	Decreased cardiac output and metabolic rate
Heart rate	↓ 10 bpm per 1°C below 37.0°C	Slowing of conduction through the sinoatrial node
Cardiac output	↓ 7% per 1°C below 37.0°C	Decreased metabolic rate
Myocardial contractility	↑	Increased myofibrillar sensitivity to calcium
Peripheral vascular resistance	↑	Peripheral vasoconstriction
Pco_2	↓ 2 mmHg per 1°C below 37.0°C	Increased solubility of gases (Henry's law with Siggaard Andersen correction)
Po_2	↓ 5 mmHg per 1°C below 37.0°C	
pH	↑ 0.015 per 1°C below 37.0°C	
Alteration of platelet function	Mildly thrombophilic	↑ Platelet aggregation
Medication clearance	Delayed clearance at 34°C: • Morphine 25% • Phenytoin 67% • Phenobarbital 99%	Altered CYP450 enzymes and glucuronidation

therapeutic hypothermia has not been associated with an increased risk of necrotizing enterocolitis either with hypothermia alone or in conjunction with initiation of enteral feedings during cooling therapy.[128–130]

Subcutaneous fat necrosis has been described in neonates undergoing therapeutic hypothermia, particularly on the back and shoulders, with an incidence of 2.8% in the Swiss cooling registry.[131] Strict nursing care protocols and awareness can decrease the frequency.[132]

Studies evaluating a different duration (120 hours vs. 72 hours) and depth (32.0°C vs. 33.5°C) of therapeutic hypothermia[133] or later initiation between 6 and 24 hours of life[134] have not shown benefit but did show potential harm.

Since therapeutic hypothermia is most effective when implemented within 6 hours after delivery, timely referral to a center with a therapeutic hypothermia program is crucial. Passive cooling can be done before active cooling with close monitoring of core temperature. However active cooling during transport is preferred as patients reach the target temperature earlier and are less likely to be over or undercooled.[135–137]

Centers offering therapeutic hypothermia should have access to cEEG or aEEG, a trained pediatric neurologist, MRI with neuroradiology interpretation, and access to ancillary services such as physical therapy, speech therapy, and high-risk infant follow-up programs as recommended by the American Academy of Pediatrics[138] and the state of California.[139]

The use of medication to provide sedation and prevent shivering in cooled newborns with HIE is controversial and needs to be studied in more detail. The current use of morphine during therapeutic hypothermia is not evidence-based and may not be ideal due to its side effect profile (e.g., respiratory depression, urinary retention, constipation) and because it does not specifically prevent shivering. Dexmedetomidine and clonidine both α_2-adrenergic receptor agonists, are promising alternative sedatives because they specifically prevent shivering without suppressing respirations. Dexmedetomidine also reduces inflammation,[140,141] without producing abnormal brain histology,[142] and provides neuroprotection in animal models of HIE.[143–145]

Outcomes

Prior to therapeutic hypothermia, mortality for infants with moderate to severe HIE surpassed 60% and the disability rate has been described to be as high as 100% in neonates with severe HIE. With the introduction of therapeutic hypothermia, the death and disability rates have improved significantly. A Cochrane metaanalysis included 1505 term and late preterm infants with moderate to severe HIE from 11 randomized controlled trials and concluded that therapeutic hypothermia results in fewer deaths (25% compared to 34%, risk ratio [RR] of 0.75; 95% CI 0.65–0.88 and better neurodevelopmental outcomes in survivors.[125] For infants with moderate to severe HIE, outcomes at 18 to 24 months (assessed in seven and eight studies in a Cochrane review[125]) and at 6 to 7 years (assessed in two major studies, the NICHD[146] and the TOBY-Xe trial[147]) are summarized in Table 55.5. The number needed to treat (NNT) to prevent death or moderate to severe neurodevelopmental disability in one newborn is 7 (95% CI 5–10). Based on the proven benefits, therapeutic hypothermia is now standard of care for term and near-term newborns with moderate to severe HIE in high-resource environments.

Of course, outcomes vary by severity of presenting HIE. Mild HIE has now been recognized as causing significant brain injury in 18–38% of affected infants on MRI.[148–151] There remains controversy as to whether these infants should be routinely cooled. Common practice trend leans clearly towards cooling,[149] however, the benefit of therapeutic hypothermia for mild HIE remains under investigation.

In general, neonates who have a quick clinical recovery, a normal EEG background pattern, a normal MRI, and a normal neurological examination at 7 to 10 days of age often have a favorable long-term outcome. An early abnormal neurologic examination has limited long-term predictability, in contrast to an abnormal examination noted at the time of discharge which correlates significantly with adverse outcomes.[152] Excellent prediction of outcomes at 18 to 24 months can be made by combining early laboratory data, the need for anticonvulsant and pressor support with MRI evaluation of cortex, basal ganglia/thalami, white matter, and posterior limb of the internal capsule.[153]

Electroencephalogram Findings and Seizures

Seizures are common in neonates with HIE and are independently associated with worse outcomes. Seizures occur more frequently in neonates with severe compared to moderate HIE; the total seizure burden is about 2.5× higher in severe HIE compared to

TABLE 55.5 Outcomes of Neonates With Moderate to Severe Hypoxic-Ischemic Encephalopathy at 18–24 Months and 6–7 Years

	18–24 MONTHS			6–7 YEARS		
Outcome	**Hypothermia**	**Control**	**RR (95% CI)**	**Hypothermia**	**Control**	**RR (95% CI)**
Death overall (moderate and severe HIE)	27%	37%	0.73 (0.61–0.89)	29%	35%	0.81 (0.63–1.04)
Death (moderate HIE only)	14%	23%	0.60 (0.41–0.88)	NA	NA	NA
Death (severe HIE only)	53%	68%	0.77 (0.64–0.93)	NA	NA	NA
Major neurodevelopmental disability overall (moderate and severe HIE)	26%	39%	0.67 (0.67–0.80)	29%	49%	0.60 (0.44–0.81)
Major neurodevelopmental disability (moderate HIE only)	27%	39%	0.67 (0.5–0.90)	NA	NA	NA
Major neurodevelopmental disability (severe HIE only)	37%	51%	0.75 (0.50–1.12)	NA	NA	NA
Cerebral palsy	23%	35%	0.66 (0.54–0.82)	20%	33%	0.59 (0.40–0.87)

HIE, Hypoxic-ischemic encephalopathy; *NA*, not available.

moderate HIE and the duration of individual seizures is longer. The onset of seizures in moderate to severe HIE occurs around 13 hours of life,[64] and in ~10% of patients, seizures are seen for the first time during rewarming.[116] Maximum seizure burden is commonly observed approximately 4 hours after onset of seizures. Kharoshankaya et al. calculated that for every minute of seizures, the odds of an abnormal outcome increased by 2.2%.[64]

In general, the seizures in this population are acute symptomatic and prolonged treatment with antiepileptic medications after seizure resolution is not necessary.[2] However, 4–16% of newborns with HIE and acute symptomatic seizures will go on to develop childhood epilepsy or infantile spasms.[67,154] EEG background activity and the evolution over the first few days of life have been shown to have prognostic value regarding the long-term neurodevelopmental outcome, as it reflects the severity of the injury. The assessment at or after 48 hours of life has been particularly helpful in prognostication.[155] For example, background pattern with persistently low voltage (around or below 5 μV), flat tracing (very low voltage below 5 μV), and burst suppression (discontinuous background pattern with periods of inactivity intermixed with higher amplitude bursts) after 48 hours is highly predictive of an abnormal outcome.[156,157] In contrast, normalization of background pattern, particularly within the first 24 hours is associated with a favorable outcome.[2,157] and return of sleep-wake cycling is seen as a favorable prognostic indicator.[155,156,158] A normal EEG pattern by 6 hours of age that remains normal has a 100% positive predictive value for a normal outcome at 2 years.[159]

Predictive Value of Magnetic Resonance Imaging and Spectroscopy

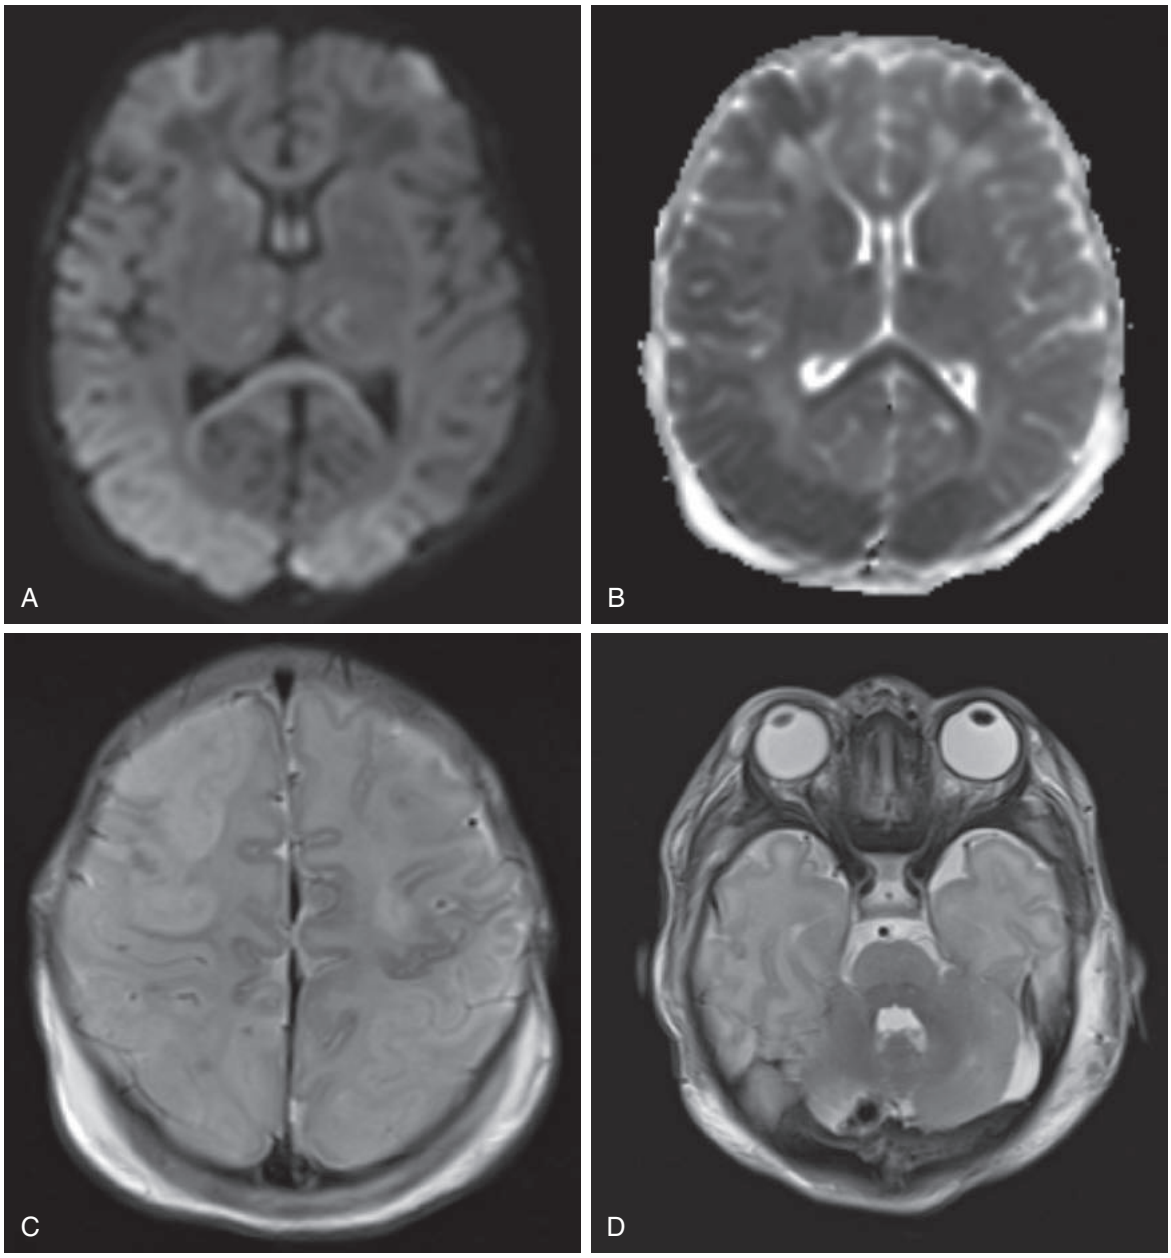
A normal MRI in the first week of life is associated with favorable outcomes, while outcomes with watershed or basal ganglia injury on MRI are more uncertain.[160–162] Watershed patterns are associated with less severe outcomes, whereas deep gray matter involving the thalamus and basal ganglia and abnormalities of the posterior limb of the internal capsule are associated with both motor and neurocognitive impairment at 2 to 3 years of age (Fig. 55.2).[163–167] MRS can also be helpful in prognosticating, as a low NAA peak and high lactate peaks correspond to severe injury and neurodevelopmental outcomes at ≥12 months of age when measured in the basal ganglia.[108,168]

Adjunctive Neuroprotective Treatments Plus Therapeutic Hypothermia

While therapeutic hypothermia has clear and important therapeutic benefits, the risk of poor outcomes from HIE remains significant. Investigators are therefore pursuing adjunctive treatments with the goal of further improving outcomes. In countries where therapeutic hypothermia is available, these therapies are being evaluated to be used in conjunction with hypothermia. In countries where therapeutic hypothermia is not available, these therapies may in some cases be considered as monotherapies (see Fig. 55.1).

Erythropoietin

Erythropoietin (Epo) is a glycoprotein originally identified for its role in erythropoiesis but also has remarkable neuroprotective and reparative effects in the CNS.[169,170] In the setting of hypoxia-ischemia, Epo receptor expression is rapidly upregulated.[171,172] If Epo is available to bind to the upregulated receptor, cell survival is promoted. However, in the absence of Epo, the pathway of programmed cell death predominates.[172,173] Epo has both early and late beneficial effects. Early benefits include anti-apoptotic and anti-inflammatory effects,[174–178] while later effects include increased neurogenesis, plasticity, and tissue remodeling after hypoxia-ischemia.[179–183] This creates an important rationale for exogenous Epo administration.



• **Fig. 55.2** A Term Male Neonate With Severe Hypoxic-Ischemic Encephalopathy. (A) Axial diffusion-weighted image and corresponding (B) apparent diffusion coefficient map shows widespread, patchy cytotoxic edema involving the cerebral cortex, deep nuclei, and corpus callosum. (C) Axial T2-weighted image shows patchy cortical T2-weighted signal abnormality as well. (D) Dark signal in the lower medial right cerebellar hemisphere seen on axial T2-weighted image indicates intraparenchymal cerebellar hemorrhage. (Images courtesy of Drs. Teresa Chapman and Francisco Perez, Seattle Children's Hospital, Seattle, WA.)

Pre-clinical studies of Epo neuroprotection following hypoxic-ischemic brain injury show robust histologic and functional evidence for benefit.[169,170,184–191] In nonhuman primates, Epo reduces the combined outcome of death or cerebral palsy and improves neurologic function in animals undergoing therapeutic hypothermia for HIE.[192] Phase I and II clinical trials have demonstrated safety and feasibility,[193] and suggest that infants with HIE treated with multiple doses of Epo during the first week of life have better neurologic outcomes as measured by early MRI, biomarkers, 6 months, and 12 to 24-month outcomes, even among infants with significant brain injury seen on MRI.[193–196] Phase III trials are now in the final stages of execution internationally, including the Preventing Adverse Outcomes of Neonatal Hypoxic Ischaemic Encephalopathy with Erythropoietin trial (PAEAN trial, Australia—clinicaltrials.gov: NCT03079167) and High-dose Epo for Asphyxia and Encephalopathy (HEAL trial, USA—clinicaltrials.gov: NCT02811263).

Xenon

Xenon, a noble gas that crosses the placenta and the blood-brain barrier, binds to *N*-methyl-D-aspartate glutamate receptors to inhibit function, thus decreasing neuronal apoptosis.[197–199]

Significant benefit from xenon was demonstrated in preclinical studies of HIE.[200] A small multicenter trial adding xenon as an adjunct therapy to therapeutic hypothermia was conducted in the United Kingdom.[201] Although no serious adverse events were recorded, no significant differences in magnetic resonance imaging were detected between groups. Based on the results, 30% xenon for 24 hours begun after 6 hours after birth combined with therapeutic hypothermia is not likely to improve clinical outcomes compared to TH alone for newborns with HIE. The inhibitory effect of xenon on glutamate receptors has anti-epileptic function and has shown to be clinical effective in a small subgroup of five neonates with seizures secondary to moderate to severe HIE in the TOBY-Xe trial.[202] Further studies on animals showed dose-dependent effect of xenon as anti-epileptic therapy after hypoxic injury and thus secondary neuroprotective benefits.[203] Multiple factors such as timing, dose, and duration of treatment may impact inhaled xenon treatment outcomes and need further investigation. Study results of the CoolXenon3 Study (clinicaltrials.gov: NCT02071394) combining TH with 18 hours of 50% xenon inhalation in cooled infants with HIE are pending.

Argon

Argon is a noble gas that has shown promise as an adjunct to hypothermia in preclinical models including in vitro and in vivo models of neonatal encephalopathy.[204,205] Argon is more abundant than xenon, cheaper, and more practical to use clinically as it does not require the complex rebreathing/scavenger setup needed for xenon. As of yet, no clinical trials using argon to treat any neurological injury are reported.

Melatonin

Melatonin exerts its neuroprotective function through anti-apoptotic and anti-oxidative properties.[206] Neuroprotective benefits have been demonstrated in an HIE piglet model, in which intravenous melatonin plus hypothermia significantly improved cerebral energy metabolism based on proton MRS studies, reduced apoptosis in deep brain structures, and decreased microglial activation in the cortex at 48 hours post-injury.[207] In uncooled full-term human newborns with HIE ($n = 10$), oral administration of melatonin (8 doses of 10 mg each separated by 2-hour intervals) started within the first 6 hours after birth reduced serum malondialdehyde, a lipid peroxidation product, and nitrite/nitrate levels at 12 and 24 hours compared to untreated, uncooled controls ($n = 10$), suggesting a role for melatonin in reducing oxidative damage.[208]

In a prospective trial of term newborns with HIE, melatonin (10 mg/kg daily × 5 enteral doses) plus TH ($n = 15$) compared to TH alone ($n = 15$), was associated with decreased seizures on EEG and fewer white matter abnormalities on MRI after 2 weeks of age as well as improved survival without neurological or developmental abnormalities at 6 months of age.[209] In a recent metaanalysis, a trend towards decreased mortality was observed when melatonin was given as an adjunct therapy to therapeutic hypothermia, compared to hypothermia alone.[210] No larger randomized controlled trials have been published yet, but two clinical randomized trials are currently in progress (clinicaltrials.gov: NCT03806816, NCT02621944).

Stem Cells

For several decades stem cells have promised to revolutionize the treatment of diseases from Alzheimer's to cerebral palsy.[211–213] Stem cells have several properties that provide neuroprotection (e.g., anti-apoptotic, anti-inflammatory, paracrine-neurotrophic) and regeneration (e.g., cell differentiation and replacement or regeneration of injured cells).[214] The therapeutic window for stem cell therapy has the potential to be much wider because the beneficial effects target mechanisms that extend well into the secondary and tertiary phases of HIE. Multiple types and sources of human stem cells have been studied in the context of brain injury. The umbilical cord blood contains several stem cell populations: mesenchymal stem cells (see below), endothelial progenitor cells, and umbilical cord blood mononuclear cells.

Neuroprotective mechanisms of mesenchymal stem cells include anti-inflammatory and immunosuppressive properties which mediate anti-apoptotic properties as well as neuro-regenerative functions.[215,216] Preclinical studies have shown promising results toward improved neurologic function.[217] A small clinical trial using autologous umbilical cord blood cells demonstrated feasibility and safety.[218] A phase II study showed that autologous umbilical cord blood-derived stem cells are a safe feasible adjunct therapy to therapeutic hypothermia and trends toward decreased death (11% vs. 24%) and improved neurodevelopmental outcomes (cognitive, language, and motor domain of the Bayley III >85) at 1 year (72% vs. 41%) were observed.[219] A larger phase II clinical trial was planned but stopped early due to poor enrollment. The results showed no difference in mortality between groups (5.9% in the intervention vs. 5.6% in the placebo group), but an improved neurodevelopmental outcome at 22 to 26 months, with 72% of participants having a Bayley III score of greater than 85 in the cognitive, language, and motor domain compared to 40% in the placebo group, was present (clinicaltrials.gov: NCT02612155).

Other stem cell types such as embryonic stem cells, neural stem cells, induced pluripotent stem cells, bone marrow-derived mesenchymal stem cells, and amniotic fluid-derived stem cells all have a potential benefit but ethical problems in obtaining those cells (e.g., embryonic or fetal tissue), time constraints in finding, preparing, and administering matching cells, as well as immunologic concerns as the source is most often not autologous, have made these cell types less feasible for neonates with HIE. However, neural stem cells derived from reprogrammed induced pluripotent stem cells could offer autologous use. The timing of administration of stem cells will need to be studied, as hypothermia may diminish their effect.

Cannabinoids

The activation of the endocannabinoid system decreases glutamate excitotoxicity, attenuates microglia activation, and reduces cell death.[220] Systemic cannabinoid administration in piglets with HIE improved oxygenation and EEG features.[221] At this time, however, no clinical studies in humans are ongoing.

Allopurinol

Allopurinol is a xanthine oxidase inhibitor, which decreases free radical and superoxide formation. Neuroprotective effects of allopurinol have been shown when given shortly after the ischemic insult in an HIE rat model.[222] In small clinical trials, the effect of allopurinol given within 4 hours of birth to neonates with moderate to severe HIE was equivocal, but trends towards improvement, particularly in neonates with moderate HIE, were seen.[223] Allopurinol might be more effective when given prior to reperfusion injury,[224] which is currently being evaluated in a phase III clinical trial (clinicaltrials.gov: NCT03162653).

Azithromycin

Azithromycin has anti-inflammatory neuroprotective effects through its immune-modulatory properties.[225] Pre-clinical trials in a rat model of HIE showed a dose-dependent reduction in brain injury and improvement in sensorimotor function.[226] Clinical trials to study the neuroprotective effects of azithromycin in neonates with moderate to severe HIE alone or in conjunction with therapeutic hypothermia are in the early phases.

Further ongoing research is targeting the inflammatory response, autophagy, and mitochondrial function. Optimal neuroprotection will likely include multiple targeted approaches at different times.

Other Causes of Neonatal Encephalopathy

Neurovascular disorders including perinatal stroke and cerebral sinus thrombosis are discussed in detail elsewhere (see Chapter 56).

Metabolic Causes of Neonatal Encephalopathy

Neonatal Hypoglycemia

Symptomatic hypoglycemia is a well-known cause of neurologic injury, but the exact glucose concentration or duration of hypoglycemia that will result in injury remains unclear. Blood glucose values in the fetus are 70% of maternal levels and rapidly fall in the first hour after birth to as low as 25 mg/dL, with a gradual increase over the next hours and days.[227] Glucose concentration in the brain is approximately 30% of the systemic blood concentration, and this level is tightly controlled via glucose transporter type 1 (GLUT1) since the intact blood-brain barrier prevents the free diffusion of glucose.[228]

Hypoglycemia in the newborn can be transient and physiologic or secondary to an underlying metabolic or endocrine disorder. Risk factors for prolonged and/or symptomatic hypoglycemia include small or large for gestational age, maternal diabetes, perinatal asphyxia, respiratory distress, sepsis, metabolic disorders, and congenital abnormalities, particularly midline defects. Hypoglycemia may be asymptomatic or can manifest as cyanosis, tremors, apnea, seizures, change in consciousness, irritability, high-pitched cry, altered muscle tone, and feeding problems.

The proposed mechanism of hypoglycemia-induced injury is hypoglycemia-induced neuronal depolarization and subsequent increase in presynaptic glutamate, which leads to excessive NMDA receptor activation. This activation induces increased intracellular sodium and calcium concentrations. Increased calcium influx into cells alters mitochondrial function and generates free radicals. ATP production is hampered, which leads to apoptosis and neuronal necrosis.[229] Hypoglycemia may result in brain swelling, necrosis, and white matter demyelination, especially in areas rich with NMDA receptors. On MRI, brain regions affected include the cerebral cortex, dominantly in the parieto-occipital region, corpus callosum, basal ganglia, thalamus, and posterior limb of the internal capsule.[230,231] The degree of injury is likely directly related to the depth and duration of hypoglycemia and the presence of any comorbidities, especially HIE.

Long-term sequelae associated with hypoglycemia include visual impairment, epilepsy, and cognitive deficits. While neurocognitive outcomes at 2 years of age between hypoglycemic and non-hypoglycemic neonates remain similar,[232,233] differences become more apparent during mid-childhood with odds of 3.62 for an abnormal neurodevelopmental outcome in hypoglycemic neonates.[232]

Inborn Errors of Metabolism

Most inborn errors of metabolism that manifest in the immediate neonatal period are accompanied by systemic symptoms including neurologic findings. Encephalopathy is commonly seen in affected infants due to the primary or secondary toxic effects of the involved metabolites (e.g., ammonia) or as a symptom of ongoing energy depletion in organs with high energy demand such as the brain and the heart in the case of mitochondrial disorders, respiratory chain disorders, or pyruvate dehydrogenase deficiency.[234]

Metabolic Encephalopathies due to Toxic Metabolite Accumulation

This extensive category includes a variety of metabolic disorders and can affect an array of metabolic pathways. Fetal development is rarely affected since the placenta clears most of the toxic substrates. Thus, malformations are uncommon, and the pregnancy appears uncomplicated. The newborn often appears well at birth, only to deteriorate over the initial days to weeks. Symptoms can be triggered by catabolic states, initiation of protein intake, or acute illness, depending on the underlying defect. Clinical symptoms are often rapidly progressive in the newborn period and are related to the accumulation of toxic metabolites. While many of the metabolic disorders in this category are now somewhat treatable, massive metabolite accumulation in the presenting stage can impact survival and can impair neurodevelopmental outcomes in survivors. Therefore, rapid removal of the toxic product before it causes permanent damage is crucial. Evaluation of plasma and urine amino acids, urine organic acid profile, and assessment of acylcarnitines can be diagnostic. Some of the more common disorders presenting with neonatal encephalopathy are described below.

Urea Cycle Disorders

Urea cycle disorders (UCDs) are loss of function defects of any of the urea cycle enzymes. The dominant source for ammonia detoxification is via the urea cycle, which converts excess ammonia into excretable urea and produces arginine. Urea cycle disorders are autosomal recessive disorders with the exception of ornithine transcarbamylase (OTC) deficiency, which is X-linked. An estimated 1:35,000 newborns are affected by UCD[235] and 27% become symptomatic in the neonatal period.[236] Neonates with absent urea cycle enzyme activity typically present after the first 24 hours of life with feeding difficulties and progressive lethargy or even coma, which is caused by the rapid accumulation of ammonia and subsequent development of cytotoxic edema and seizure.

Hyperammonemia leads to metabolic acidosis, which initially is often attempted to compensate for by the newborn clinically visible as tachypnea, and on blood gas as hyperventilation. Blood glucose levels are often normal. Diagnosis is made by obtaining plasma amino acids which often show an increase in glutamine and alanine and a decrease in citrulline and arginine. Subsequent targeted genetic testing allows to identify the individual enzyme defect. Outcomes are strongly related to the duration and extent of hyperammonemia. Therefore, the initial treatment has to focus on quickly and effectively decreasing ammonia levels (pharmacological and/or dialysis) and the prevention of further accumulation

(cessation of an exogenous protein supply, and provide a high energy supply to avoid endogenous protein catabolism). Seizures can also be present as ammonia has an epileptogenic effect, and therefore, EEG monitoring is recommended. On MRI, cerebral edema is the most common acute finding but changes in the white matter involving the deep sulci of the insular and peri-rolandic watershed territories can be seen. MR spectroscopy allows direct measurement of metabolites. The mortality of UCD is approximately 24% and neurocognitive morbidities vary among the defects. Global developmental delay and abnormal gross motor function are not uncommon.[236]

Methylmalonic Acidemia

Methylmalonic acidemia (MMA) is a deficiency of the mitochondrial enzyme methyl-malonyl–coenzyme A mutase (MCM), a deficiency of its cofactor adenosyl-cobalamin (*cblA* or *cblB*-MMA), or deficiency of the enzyme methylmalonyl-coenzyme A epimerase. The absence of one of the enzymes results in the accumulation of methylmalonic acid. MMA can present in the newborn who was healthy for the first day to weeks of life, with a presenting history of poor feeding, vomiting, progressive lethargy, and decreased muscle tone. The incidence is about 2:100,000 live births, and approximately 50% of patients become symptomatic in the neonatal period. Typical laboratory findings include significant metabolic acidosis, hyperammonemia, and plasma and urine ketones with or without hypoglycemia. Abnormal acyl-carnitines (C3-carnitine) and unspecific amino acid elevations, most commonly glycine and alanine, can be found in blood specimens. Urine organic acids demonstrate large amounts of methylmalonic acid, 2-methylcitrate, propionic acid, 3-hydroxy propionic acid, and triglycine. Definite diagnosis is made by mutation testing for the five genes associated with MMA: *MMUT (*encodes MCM*)*, *MMAA (*encodes cobalamin A—cblA*)*, *MMAB (*encodes cblB). MRI scans typically demonstrate bilateral involvement of basal ganglia and white matter lesions, with the globus pallidus being selectively affected.[236a] Therapy focuses on the elimination of ammonia, establishing a catabolic state, restricting dietary precursor amino acids, and promoting urinary excretion of MMA by providing adequate hydration. Mortality during early infancy is ~30% and survivors often show neurocognitive disabilities. A liver transplant can significantly reduce episodes of hyperammonemia[237] and thereby improve outcome.

Molybdenum Cofactor Deficiency

Molybdenum cofactor deficiency (MCOD) is a disorder of the sulfur amino acid metabolism that occurs in 0.5 to 1:100,000 live births.[238] There are three types described: MCOD type A results from *molybdenum cofactor synthesis (MOCS) 1* gene mutation, MCOD type B is the result of *MOCS 2* mutations, and type C is associated with *gephyrin (GPHN)* mutations. The absence of molybdenum cofactor results in functional deficiencies of molybdenum cofactor-dependent enzymes (sulfite oxidase, xanthine dehydrogenase, aldehyde oxidase, and mitochondrial amidoxime reducing component) which leads to an accumulation of their metabolites sulfite, taurine, *S*-sulfocysteine, and thiosulfate, which produces the severe neurologic symptoms seen in the affected patient. Newborns become symptomatic soon after birth and present with intractable seizures and an encephalopathic picture often so fast and profound that their clinical appearance is indistinguishable from a newborn with HIE. On MRI, diffusion restriction in the cortex and subcortical necrosis can be seen and in later stages, multicystic white matter lesions and atrophy are seen (Fig. 55.3). Diagnosis is made by targeted genetic testing of the affected genes. Serum uric acid is commonly elevated, and urine studies reveal an elevated uric acid, *S*-sulfocysteine, xanthine, and hypoxanthine. While therapy for MOCD type B and C is supportive and death occurs typically in early infancy,[238] a treatment for MOCD type A has recently become available. Cyclic pyranopterin monophosphate (cPMP), when applied shortly after birth, has shown significant improvement in an otherwise fatal disease.[239]

Nonketotic Hyperglycinemia

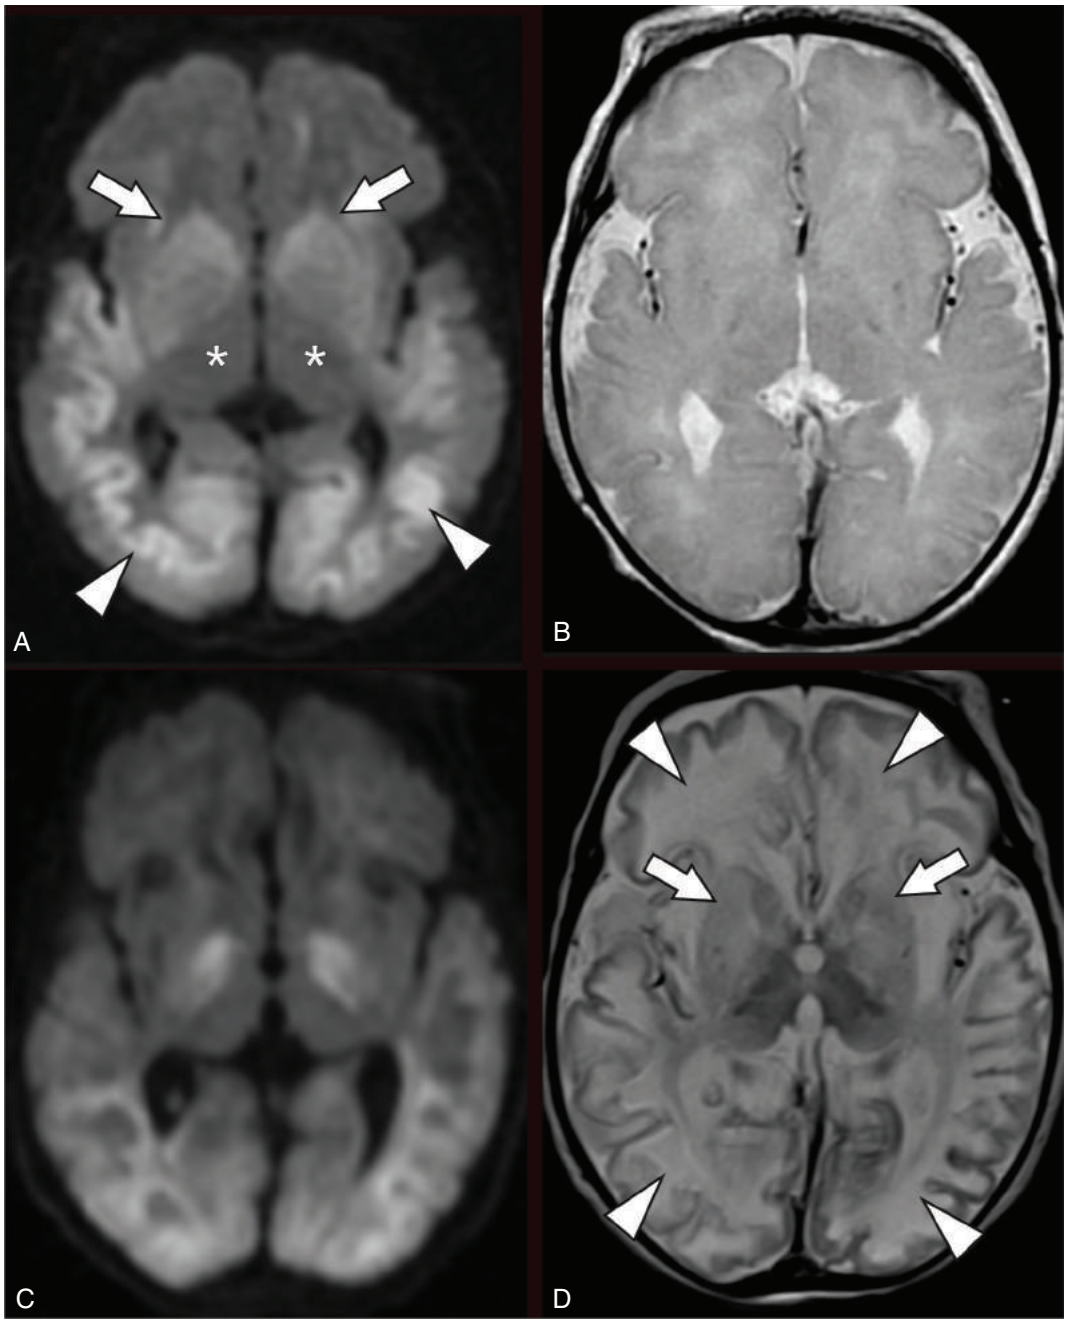
Classic nonketotic hyperglycinemia (NKH) occurs in 1:76,000 live births and is caused by a mutation in the *GLDC* and/or *AMT* gene, which encode protein components of the glycine cleavage enzyme system and results in absent or significantly decreased activity.[240] Glycine accumulates in the body, particularly in the brain and causes overstimulation of the NMDA receptors. Patients usually present in the immediate neonatal period with progressive encephalopathy and intractable seizures. Frequent hiccupping is common and is often present prenatally. Diagnostic testing includes amino acid profiles, which show elevation of glycine in plasma, CSF, and urine samples. CSF glycine is highly suggestive of NKH. Confirmatory testing is done via sequencing of the *GLDC* (affected in 80% of patients) and *AMT* genes. MRS can show high glycine peaks, and on occasion, nonspecific brain anomalies such as abnormal corpus callosum, hydrocephalus, and cerebellar hypoplasia are present. The outcome is universally poor for patients with classic NKH, with up to 30% mortality in the neonatal period and significant developmental delay and intractable seizures in survivors. The treatment is largely symptomatic and supportive and focuses on the elimination of glycine and NMDA-receptor blockage.

Energy Deficiency Disorders

This group of metabolic disorders is characterized by insufficient energy supply, either caused by defects in production or transportation. In contrast to metabolic disorders accumulating toxic metabolites, metabolic disorders affecting the energy metabolism can become symptomatic during fetal development and affected organs are those of high energy demand such as the brain, liver, and heart. Therefore, abnormal development of the brain and cardiovascular system are the most common prenatal findings. Neonates with energy deficiency disorders often do not experience a symptom-free period and can present with encephalopathy at the time of birth. Since the neonatal brain consumes about 30% of the body's energy, it is not surprising that disorders affecting the energy supply frequently present with neurologic symptoms, in particular hypotonia and seizures. Brain imaging can reveal abnormal development of various structures, such as cerebral dysgenesis, thinning of the corpus callosum, and cerebral and/or cerebellar heterotopia.[241] Other common presenting clinical features include cardiomyopathy, liver failure, and adrenal insufficiency.

Mitochondrial Disorders

Mitochondrial disorders are the most severe forms of energy deficiency disorders. This group consists of defects in aerobic glucose oxidation, mitochondrial respiratory chain disorders (including the respiratory chain, mitochondrial energy transporter molecules, or coenzyme Q10 biosynthesis), and fatty oxidation defects.[242] They are caused by mutations in mitochondrial protein-encoding genes, found on either mitochondrial DNA or nuclear DNA, and lead to defects in the mitochondrial electron transport chain and/



• **Fig. 55.3** A Term Female Neonate With Molybdenum Cofactor Deficiency. (A) Axial diffusion-weighted image (DWI) obtained on day of life 2 shows widespread diffusion restriction predominantly in the subcortical white matter *(arrowheads)* and basal ganglia *(arrows)* with relative sparing of the thalami *(asterisks)*. (B) The corresponding axial T2-weighted image shows normal white matter and basal ganglia signal at day of life 2. (C) Axial DWI image obtained on day of life 12 shows persistent and new areas of DWI signal abnormality. (D) The corresponding axial-T2 weighted image at day of life 12 demonstrates evolution of the injury with new abnormal signal hyperintensity in the basal ganglia *(arrows)* and subcortical white matter *(arrowheads)* indicating early cystic changes. (Images courtesy of Dr. Francisco Perez, Seattle Children's Hospital, Seattle, WA.)

or oxidative phosphorylation. The dysfunctional mitochondria are unable to produce and supply enough energy to maintain adequate organ function. Brain, muscle, liver, heart, and adrenal glands are often significantly affected. Therefore, the most common presenting findings are symptoms of encephalopathy, including hypotonia, feeding difficulties, seizures, cardiomyopathy, liver dysfunction, and adrenal insufficiency. Laboratory evaluation commonly reveals lactic acidosis and hypoglycemia, ketones can be normal or elevated, and liver dysfunction and secondary hyperammonemia might be present. Therapy remains symptomatic, and to date only very few defects can be improved with pharmacological intervention. Prognosis is in general poor, and survivors of the neonatal period often experience life-altering disabilities and epilepsy.

Genetic Causes of Neonatal Encephalopathy

Genetic syndromes and disorders often also affect brain development. Genetic epilepsies (covered in Chapter 58) present within the first few days to weeks of life with symptoms resembling neonatal encephalopathy. Brain malformation presenting in the immediate neonatal period is often suspected during pregnancy, but alterations might go unrecognized until the newborn presents with neurologic symptoms after birth.

Holoprosencephaly

Holoprosencephaly is a divergence in brain development that results from an abnormal cleavage of the prosencephalon into the two hemispheres. The incidence is 1:16,000 live births. The three forms of holoprosencephaly are alobar, semilobar, and lobar holoprosencephaly. Alobar holoprosencephaly is the most severe form with a single common central ventricle and complete absence of hemispheric separation. The cortical structure is frequently malformed which results in intractable seizures. Semilobar holoprosencephaly is characterized by partial separation of the frontal and parietal lobes and partial separation of the deep gray matter nuclei. Lobar holoprosencephaly is the least severe form with incomplete separation of the frontal lobe and complete separation of the deep gray matter nuclei.[243]

Chromosomal abnormalities account for up to 50% of cases, and the prevalence is with 70% highest in trisomy 13 but is also relatively common seen in trisomy 18 and triploidy.[243] Copy number variants include multiple described deletion and duplication syndromes often involving genes associated with holoprosencephaly and account for approximately 25% of cases. Mutations in the *SHH* (sonic hedgehog) gene and *ZIC2* (encodes zinc finger protein 2) gene are the most common single-gene mutations described and account for approximately 10% of cases with holoprosencephaly,[244] but multiple other genes have been associated with holoprosencephaly, and with the ability of advances in genetic testing, the list is constantly growing. Neonates with holoprosencephaly commonly present with distinguishing facial features such as cyclopia, single nares, and cleft palate. The severity of facial deformity correlates with the degree of holoprosencephaly.

Heterotopias and abnormal cortical development often cause intractable seizures and other neurologic symptoms such as hypotonia and irritability. Furthermore, the development of the pituitary gland can be absent or incomplete, and structural defects of the thalamus can be seen, both of which may result in significant endocrinopathies, such as panhypopituitarism.[243] The prognosis depends on the severity and form of holoprosencephaly. While newborns with isolated alobar holoprosencephaly often do not survive the first year of life, patients with milder forms can reach early adulthood. In cases of association with cytogenetic abnormalities, as few as 2% survive the first year of life.[245]

Neuronal Proliferation Defects

Cortical dysplasia spectrum, including focal cortical dysplasia and hemimegalencephaly. Patients with significant involvement can present during the neonatal period, most commonly with intractable seizures and feeding difficulties. Since seizures are often refractory to pharmacological treatment, surgical options, including hemispherectomy can be offered.[246]

Neuronal Migration Defects—Lissencephaly

Lissencephaly is the description of a smooth brain appearance on MRI as a result of a simplified gyration pattern (pachygyria). Classic lissencephaly is commonly related to abnormalities in the *LIS1* gene, which affects microtubular functioning and intracellular transport, but a variety of copy number variants and mutations in other genes (*TUBA1A, TUBB2B, ACTB, ACTG1, DCX* among others) have also been associated with classic lissencephaly.[246] Depending on the degree of abnormal structures, patients may present in the neonatal period with seizures, hypotonia, and feeding difficulties.

Postmigrational Development Defects—Polymicrogyria

Polymicrogyria occurs at the end of neuronal migration and during cortical development and results in abnormal cortical folding and cortical disorganization which predisposes affected patients to seizures. The occurrence can be associated with congenital infections (cytomegalovirus), vascular anomalies, genetic syndromes (e.g., Zellweger syndrome, 22q11.2, or 1p36 deletion syndromes), and single-gene mutations.[247] Clinical presentation depends on the extent and location, and affected neonates commonly present with seizures, abnormal tone, and feeding difficulties.

1p36 Deletion Syndrome

This deletion syndrome is one of the most common deletion syndromes and affects 1:5000 newborns.[248] This syndrome is characterized by terminal and interstitial deletions throughout the 30 Mb of DNA constituting the 1p36 region. The phenotype varies widely depending on the size and location of the deletion and involved genes. Multiple of the involved genes have a role in brain development, seizures, and congenital heart defects. Commonly seen clinical features include seizures, fetal akinesia, hypotonia, neurodevelopmental impairment, neuropsychiatric anomalies, brain anomalies (cortical development, hippocampal development, delayed myelination), ventriculomegaly, microcephaly, intellectual disability, developmental delay, vision problems, hearing loss, congenital heart defects, noncompaction cardiomyopathy, orofacial clefting, retrognathia, renal anomalies, and short stature.[248–250] The majority of fetuses affected by this deletion syndrome have signs of perinatal distress, 59% of term-born infants need some form of resuscitation, and 18% present with cardiac arrest.[251] The clinical presentation is consistent with neonatal encephalopathy in many cases and can even mimic HIE.

Hypophosphatasia

Hypophosphatasia is a rare disease of defective mineralization, caused by mutations in the *APLP* gene, which encodes the enzyme tissue-nonspecific alkaline phosphatase (TNSALP). Inheritance, particularly in severe forms, is most commonly autosomal recessive but dominant forms have also been described.[252] Two forms are present in the prenatal or perinatal period: the severe form and the benign form. The severe form is characterized by minimal to no bone mineralization, resulting skeletal deformities, lung hypoplasia, and seizures. The benign form is characterized by poor feeding, hypotonia, irritability, and seizures. Skeletal deformations

are not consistently present in the benign form. The incidence of the severe form is estimated to be 0.2 to 1:100,000 live births and 1 to 5:10,000 live births for milder forms.[252] Affected patients can present in the immediate neonatal period with symptoms of neonatal encephalopathy, resembling HIE.[253]

Seizures in affected patients occur secondary to disruption of pyridoxal-5′-phosphate (PLP) conversion to pyridoxal (PL) by TNSALP in neuronal cells. PL is able to cross the cell membrane and is intracellularly rephosphorylated to PLP, a cofactor in inhibiting excitatory neurotransmitter activity. Therefore, decreased central nervous system (CNS) PLP results in an increase in excitatory neurotransmitter activity and decreased seizure threshold. The seizures are commonly pyridoxine responsive, but the exact mechanism by which pyridoxine mitigates the intracellular PLP deficiency is incompletely understood. Diagnosis can be suspected when plasma PLP levels are elevated, alkaline phosphatase levels are decreased, and hypocalcemia is observed. Definitive diagnosis is made via molecular genetic testing. While the severe form was historically lethal in the neonatal period, enzyme replacement therapy with asfotase alfa is now available which can restore TNSALP levels and improve survival from 42–95% at 1 year and decrease ventilator dependence to 25% among survivors.[254]

Central Nervous System Infections and Neonatal Encephalopathy

Bacterial Meningitis

Bacterial meningitis is a serious infection of the CNS affecting the meninges surrounding the brain and spinal cord. Neonates are at greater risk of meningitis than other age groups because of the inefficiency of the alternative complement pathway, deficient migration and phagocytosis of neutrophils, and decreased T-cell and B-cell activity, leaving them at risk for infections with encapsulated bacteria.[255] *Streptococcus agalactiae*, group B streptococcus (GBS), is responsible for 50% of meningoencephalitis in the term newborn period, followed by *Escherichia coli* (30–40%) and *Listeria monocytogenes* (5–7%).[256]

The incidence of bacterial meningitis is 0.3:1000 live births.[257,258] Neurologic injury can result primarily from the direct insult of the pathogen or its toxin, or secondary to the inflammatory reaction associated with the acute infection, leading to impaired cerebral autoregulation, vasculitis including microthrombi, and oxidative injury. The blood-brain barrier becomes permeable which contributes further to the development of cytotoxic edema and compromise of cerebral perfusion.[258]

Clinical symptoms include temperature instability, apnea or bradycardia, hypotension, feeding difficulty, hepatic dysfunction, irritability alternating with lethargy, and seizures. Any neonate with signs of sepsis or unexplained neurologic symptoms should have a lumbar puncture to examine the CSF. Up to one-third of infants with negative blood cultures have positive CSF cultures, suggesting that cases of meningitis may be missed if lumbar punctures are not performed.[259,260] No single CSF parameter can reliably exclude the presence of meningitis in a neonate.[261] Real-time polymerase chain reaction (RT-PCR) technique allows for increased diagnostic accuracy compared to conventional culture,[262,263] particularly after antibiotic treatment has already been initiated by identifying the DNA of bacterial components.

Seizures occur in up to 40% of newborns with meningitis and therefore, monitoring with EEG is indicated.[256] Cerebral abscesses develop in 13% of neonates with meningitis and should be considered with new seizures, signs of elevated intracranial pressure, or new focal neurologic signs, and brain imaging with contrast is essential for making the definitive diagnosis.[264] Ventriculitis occurs in as many as 20% of neonates with meningitis and results in sequestration of infection to areas that are poorly accessible to systemic antimicrobial drugs.[265] Inflammation of the ependymal lining of ventricles often obstructs CSF flow and can lead to hydrocephalus in up to 24% of infants. Imaging can give information about complications of meningitis. The choice of an antibiotic regimen should be based on the likely pathogen, ability to penetrate the blood-brain barrier, and the local patterns of antimicrobial drug sensitivities. Treatment duration is usually 14 to 21 days but depends on the identified organism and extent of infection (e.g., abscess formation). Most experts suggest a repeat lumbar puncture 2 to 3 days into treatment. Survivors of neonatal meningitis are at significant risk for white matter injury and neurodevelopmental sequelae. The most common sequelae of neonatal meningitis are motor deficits, including cerebral palsy, epilepsy, deafness, and neurodevelopmental impairment. In a prospective sample of more than 1500 neonates surviving to the age of 5 years, 55% had a normal outcome, 29% had mild neurodevelopmental impairment, and 16% had moderate to severe neurodevelopmental impairment. Among survivors of meningitis, motor disabilities (including cerebral palsy) were present in 8.1%, learning disability in 7.5%, epilepsy in 7.3%, speech and language problems in 15.6%, behavioral problems in 11.9%, vision problems in 13.7%, and hearing problems in 25.8%.[266]

Human Parechovirus

In recent decades with the increased diagnostic ability of PCR techniques, human parechovirus (HPeV) meningoencephalitis, particularly type 3, has emerged as a newer virus identified in neonates presenting with seizures, poor feeding, irritability, and sepsis-like symptoms within the first weeks of life. CSF studies often show no to mild pleocytosis. HPeV RNA induces the release of inflammatory substances which compromise preoligodendrocytes and axons.[109] In addition, inflammatory changes particularly in the periventricular white matter are characteristic findings.[267]

On MRI, diffuse abnormalities in the supratentorial white matter tracts with thalamic involvement[268] and later evolution into cystic encephalomalacia have been described.[269] Affected patients are at high-risk for impaired neurodevelopmental outcomes, including cerebral palsy, vision deficits, and developmental delay.[269]

Cytomegalovirus

Cytomegalovirus (CMV) is the most common congenital viral infection, with an incidence of 6 to 7.5:1000 live births in the United States.[270] Primary infection of the mother or reactivation of a latent infection at any gestational age can result in transmission of the virus to the fetus. Congenital infections may result in intrauterine growth restriction, thrombocytopenia, hydrops, jaundice, hepatosplenomegaly, microcephaly, periventricular calcification, seizures, and sensorineural hearing loss. About 40–58% of newborns who are symptomatic at birth go on to develop sequelae, including sensorineural hearing loss, intellectual disability, seizure disorder, cerebral palsy, visual deficits, or developmental delay.[271,272]

The diagnosis of CMV in the neonate can be made by PCR of urine, blood, or saliva.[273] Antibody titers cannot reliably

indicate the diagnosis, as maternal CMV immunoglobulin G crosses the placenta, and neonates mount weak immunoglobulin M responses. Audiologic assessment should be performed on all infants with congenital CMV infection, as sensorineural hearing loss (SNHL) affects greater than 70% of symptomatic newborns; 80% of those show SNHL early on but may be absent at birth and evolve over time.[274] Therefore, frequent assessments throughout childhood are necessary to detect later onset hearing deterioration.[275] SNHL can be ameliorated by early treatment with ganciclovir. One randomized study indicated that 84% of ganciclovir recipients either had improved hearing or maintained normal hearing between baseline and 6 months. In contrast, only 59% of control patients had improved or stable hearing.[276] Results were even more encouraging when the study and control groups were compared for subsequent maintenance of normal hearing, as none of the ganciclovir recipients had a worsening in hearing between baseline and 6-month follow-up, compared with 41% of control patients. Furthermore, neonates treated with ganciclovir show fewer developmental delays at 6 and 12 months compared with untreated infants.[277]

Zika Virus

The World Health Organization declared the rapidly spreading epidemic of Zika virus (ZIKV), an arbovirus (mosquito-borne) member of the Flaviviridae family, a "Public Health Emergency of International Concern" on February 1, 2016, based on emerging evidence that the virus might cause severe fetal brain injury,[278] specifically severe microcephaly much more pronounced than in other congenital viral infections. While many different cell lines can be infected with ZIKV, neural progenitor cells (NPCs) are a direct target of ZIKV.[279] Normal brain development is highly dependent on NPC differentiation, migration, and maturation. ZIKV-infected NPCs had increased cell death, downregulated proliferation, and altered neurosphere production.[279–281] leading to microcephaly and congenital contractures.[282] Children born with congenital Zika syndrome have significant long-term morbidities, including epilepsy in ~50%, hearing loss, blindness, hypotonia, and significant global neurodevelopmental delay.[282]

Toxoplasmosis

The incidence of congenital toxoplasmosis is 0.1 to 1:1000 live births and is caused by *Toxoplasma gondii*.[273] Human infection occurs via ingestion of contaminated meat or soil and can disseminate via the placenta to the fetus. Pregnant women are cautioned to avoid exposure to uncooked meat and cat feces. The immune response resulting from placental and fetal infection as well as direct impact of the parasite causes leptomeningeal and cerebral necrosis, which can lead to dystrophic calcifications in the basal ganglia and periventricular region, white matter lesions, and subsequent development of hydrocephalus.[283] Neonates can present with neurologic symptoms, including microcephaly, seizures, and feeding difficulties, in addition to clinical findings of systemic involvement, such as jaundice, hepatosplenomegaly, chorioretinitis, petechiae or purpura, and intrauterine growth restriction.[284] Congenital toxoplasmosis treatment consists of pyrimethamine, sulfadiazine, and leucovorin for up to 1 year[285] and is most effective in reducing CNS involvement and serious neurologic sequelae when initiated prenatally. Vision impairment due to macular involvement is the most common long-term consequence in addition to cognitive and motor impairment.

Neonatal Neurovascular Disorders

MIHAI PUIA-DUMITRESCU AND SANDRA E. JUUL

KEY POINTS

- Perinatal stroke is a vascular event causing focal interruption of blood supply and can be categorized based on the vascular distribution of stroke (arterial or venous), age at the time of stroke, and age at presentation.
- When a stroke is suspected in a neonate, neuroimaging is required for confirmation of diagnosis, followed by risk factor assessment and creation of a specific treatment plan.
- In infants and neonates, cerebral sinus venous thrombosis usually presents with seizures and/or encephalopathy, and treatment varies from conservative neuromonitoring to anticoagulation.
- Subdural and subarachnoid hemorrhages are both associated with vacuum/forceps-assisted deliveries and coagulopathy. Evaluation includes neuroimaging and monitoring, and outcomes vary based on location and size.
- Vein of Galen malformation is the most common arteriovenous malformation of the newborn, often presenting with cardiac and/or neurologic complications. The clinical picture depends on the age at presentation.

Perinatal Stroke

Epidemiology

Ischemic perinatal strokes (IPS) are focal or multifocal arterial or venous infarctions occurring between 20 weeks' gestation and 28 days' postnatal life and are confirmed by neuroimaging or neuropathologic studies.[1,2] The reported incidence varies between 1 in 1600 and 1 in 5000 live births,[3,4] with likely higher incidence given that most of the studies were retrospective and magnetic resonance imaging (MRI) was not routinely used. The IPS is responsible for one-third of term and late-preterm children affected with hemiplegic cerebral palsy (CP).[5] IPS is slightly more common in males and non-Hispanic black ethnicity when compared to whites and occurs most often in the left middle cerebral artery (MCA) distribution, with the most affected region being the left cerebral hemisphere.

Risk factors for perinatal stroke include maternal primiparity, preeclampsia, prolonged rupture of membranes, chorioamnionitis, and cord anomalies.[6] Presence of more than one of these risk factors can increase the probability of perinatal stroke to 1 in 200.[3] Complicated deliveries involving emergency cesarean section or instrumentation have also been associated with IPS. Table 56.1 includes multiple proposed risk factors for perinatal stroke, mostly from studies presenting associations rather than causation. Most cases lack definitive causes.

Pathophysiology

Ischemic perinatal stroke is pathological or neuroradiological evidence of focal arterial or venous infarction that occurred in the perinatal period. The pathogenesis of IPS is not well understood. Physiologic changes in the mother during pregnancy may cause a hypercoagulable and prothrombotic state. Fetuses are also at increased risk for developing clots as physiologic polycythemia leads to hyperviscosity, and there is a depressing anticoagulant activity present. These factors, coupled with the placenta having areas of reduced blood flow, increase the proclivity for thrombotic generation on the fetal side of the placenta. These thrombi will travel via the umbilical vein and are poised to pass through the patent foramen ovale to enter the systemic and, most importantly, the cerebral arteries. Other fetal conditions leading to increased risk of perinatal stroke include twin pregnancies, twin-to-twin transfusion, arteriovenous malformations, prolonged neck traction, and cardiac defects.[7,8] Perinatal arterial stroke (PAS) lesions are usually singular (70%), involving the anterior circulation (71%), posterior circulation (7%), or both (20%).[9] Strokes are most commonly left-sided (51% of all strokes, 73% of all anterior strokes), with 9% occurring on the right and 20% showing bilateral distribution.[9]

Classification of perinatal strokes can be categorized based on the vascular distribution of stroke (arterial or venous), age at the time of stroke, and age at presentation, with multiple authors using different terms to describe the IPS (Table 56.2).[3,10–17] Because the timing of the vascular event leading to IPS is almost always unknown, it has been suggested that the classification of IPS be based on the gestational or postnatal age at diagnosis.

Clinical Presentation

Diagnosing an infant with perinatal stroke is challenging in the newborn period. Most infants with PAS are asymptomatic at birth, and signs of acute illness are only seen in 25% of cases.[9] Diffuse neurologic signs and symptoms are more common than focal signs, with the abnormal tone, apnea, and depressed level of consciousness more common than hemiparesis, which is usually absent or subtle in the neonate.[18] Nonspecific symptoms include breathing and feeding difficulty. In the week following

TABLE 56.1 Risk Factors for Perinatal Stroke

Maternal/Placental	Fetal/Neonatal
History of infertility	Growth restriction
Primiparity	Multiple gestation
Pre-eclampsia	Twin to twin transfusion syndrome
Maternal diabetes	Trauma to great arteries at birth
Autoimmune disorders (e.g., systemic lupus erythematous)	Intrapartum asphyxia
Maternal prothrombotic disorders	Congenital heart disease
Maternal antiphospholipid antibodies	Vascular anomalies
Coagulation disorders	Col4a1 and 2 mutations
Anticardiolipin antibodies	Infection (e.g., central nervous system, systemic)
Drug use (cocaine, smoking)	Thrombophilia
Maternal infection (chorioamnionitis)	Antiphospholipid antibodies
Maternal fever	Hypoglycemia
Trauma	Extracorporeal membrane oxygenation (ECMO)
Placental abnormalities (e.g., thrombotic vasculopathy, emboli, inflammatory mediators)	Other central catheterization

(From Dr. Catherine Amlie-Lefond and Dr. Nina Natarajan, Seattle Children's Hospital, Seattle.)

birth, most newborns with perinatal arterial ischemic stroke (PAIS) become symptomatic, with the most prevalent symptom being seizures (large range, up to 70% to 90%). Approximately 12% of infants with PAS present with recurrent focal seizures with typical onset at 12 to 48 hours of age.[4,13,19–21] Typical presentation for different forms of perinatal stroke is presented in Table 56.2.

Evaluation

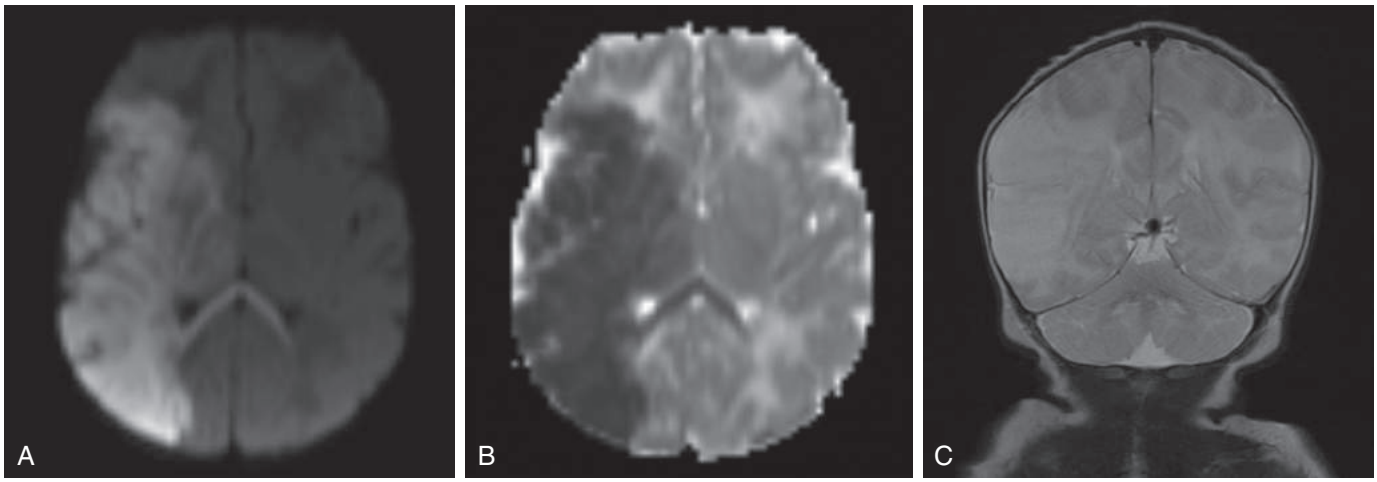
Assessment of the neonate with perinatal stroke includes neuroimaging (cranial ultrasound [CUS], head computed tomography [CT], brain MRI), electroencephalography, and echocardiogram to evaluate for congenital heart disease or intracardiac thrombus. Risk factors include a maternal history of autoimmune disorders, recurrent pregnancy loss, or thrombosis, and placental pathological examination and toxicology screens may also provide helpful information. Given that the most common presenting symptom is seizures, the work-up should begin with ruling out other etiologies of seizure such as hypoglycemia, hypocalcemia, electrolyte disorders, infection, and metabolic syndromes. In nonhemorrhagic stroke, MRI is considerably more sensitive than CUS or CT,

TABLE 56.2 Ischemic Perinatal Stroke Classification

Age at Diagnosis	Terminology	Description	Typical Presentation
ARTERIAL DISTRIBUTION			
Fetal	Fetal Arterial Stroke	Arterial ischemic stroke found on prenatal imaging.	Incidental finding of diffusion restriction on fetal MRI.
Preterm	Perinatal/Neonatal Arterial Ischemic Stroke (P/NAIS)	Arterial ischemic stroke in infants <35 weeks' gestational age.	Incidental finding on cranial ultrasound; less likely to present with seizures.
Term	Perinatal/Neonatal Arterial Ischemic Stroke (P/NAIS) "Early PAS"	Acute symptomatic neonatal arterial ischemic or fresh arterial strokes presenting in the first week of life.	Typically presents with seizures, apnea, or encephalopathy.
Term, 7–28 days	Perinatal/Neonatal Arterial Ischemic Stroke (P/NAIS) "Late PAS"	Acute symptomatic neonatal arterial ischemic or fresh arterial stroke presenting during weeks 2–4 of life.	Typically presents with seizures or encephalopathy.
Infancy and/or later	Presumed Perinatal Ischemic Stroke (PPIS)	Arterial distribution stroke that presumably occurred between 20 weeks' gestation and 28 days of life.	Normal neonatal course; present in infancy with hemiplegia, early handedness, or seizures.
VENOUS DISTRIBUTION			
Fetal	Fetal Venous Stroke	Venous distribution stroke is found in prenatal imaging, typically in the distribution of periventricular hemorrhagic infarction.	Incidental findings on fetal MRI or cranial ultrasound.
Preterm	Periventricular Hemorrhagic Infarction (PVHI)	Ischemic perinatal stroke in preterm infants often involves the periventricular region resulting in presumed venous infarction in infants born before 32 weeks.	Found on routine cranial ultrasound with associated intraventricular hemorrhage. Presentation ranges from subclinical to catastrophic.
Term	Cerebrosinovenous Thrombosis (CSVT)	Venous strokes in the term infant are secondary to partial or complete occlusion of a cranial venous sinus, deep cerebral vein, or smaller cortical veins. These may have a hemorrhagic component. Additionally, medullary vein thrombosis in term neonates may result in a periventricular infarct.	Can present with seizures; any term infant with intraventricular hemorrhage or temporal lobe hemorrhage should be evaluated further for CSVT.

TABLE 56.2 Ischemic Perinatal Stroke Classification—cont'd

ARTERIAL DISTRIBUTION			
Age at Diagnosis	**Terminology**	**Description**	**Typical Presentation**
Infancy and/or later	Presumed Perinatal Ischemic Stroke (PPIS)	"Fetal" stroke not diagnosed prenatally or asymptomatic perinatal stroke. PPIS often involves the periventricular region resulting in presumed venous infarction (PVI) in utero or in infants born prematurely. Criteria suggestive of PVI unilateral injury, focal periventricular encephalomalacia, internal capsule T2 prolongation, relative cortical sparing relative basal ganglia sparing, and remote hemorrhage. Medullary vein thrombosis is an additional venous etiology.	Typically present in infancy with hemiplegia/early handedness or seizures.



• **Fig. 56.1** A 4-Day-Old Term Male Neonate With Right Middle Cerebral Artery Stroke. (A) Axial diffusion-weighted image shows abnormal bright signal throughout the right cerebral hemisphere in the middle cerebral artery territory. The corpus callosum is also involved. (B) Apparent diffusion coefficient map shows a dark signal, confirming this is true cytotoxic edema. (C) Coronal T2-weighted image shows abnormal loss of gray-white matter differentiation, consistent with a subacute time frame (at least 6 hours) for the injury. A head magnetic resonance angiogram showed no definite stenotic lesion (not shown here). (Images courtesy of Dr. Randolph Otto and Dr. Teresa Chapman, Seattle Children's Hospital, Seattle.)

making MRI the preferred imaging modality.[22] MRI is the gold standard test for the detection of PAS.[22] MRI sequences to be used include T1- and T2-weighted images, diffusion-weighted imaging (DWI), and MRI angiography, a technique that is helpful in detecting vascular stenosis, occlusion, or arteriopathy.[23] Fig. 56.1 demonstrates an MRI of a term male with a PAS involving the right MCA. Of these sequences, the most sensitive is DWI performed in the first week of life. The area of infarction appears as a zone of high intensity on DWI and low intensity on the apparent diffusion coefficient (ADC) map. After the first week, the ischemic tissue appears to normalize, even though the area continues to be ischemic, a process known as pseudonormalization. Reduced contrast between cortex and white matter can be seen in the first 48 hours on T2-weighted imaging. Lower signal intensity will be seen on T1-weighted images. As time passes from the injury, cortical highlighting develops.

When a perinatal stroke is associated with a seizure, electroencephalography (EEG) could help localize the origin of the seizures and aid in the management of seizures. EEG is usually abnormal in infants with PAS, and the findings correlate with the location of infarction.[24,25] Cranial US is widely available in most centers that do not have MRI capability. The sensitivity of CUS improves from 68% in the first few days to 87% in the first week.[15] Because strokes may occur in the posterior circulation, posterior fontanelle imaging is necessary. Unlike MRI, CUS is operator dependent, and thus detection rates vary between centers. The use of CT is limited to situations when CUS and MRI are not available. CT is discouraged in neonates because of poor sensitivity and high radiation exposure.

The optimal thrombosis evaluation is currently debated, and laboratory results are usually inconclusive in neonates.[26] Rates of possible thrombophilia as an underlying cause of PAIS vary in

the literature up to as high as 68%. However, the International Pediatric Stroke Study found that only 19% of PAIS infants were diagnosed as having possible increased lipoprotein(a) level, methylene tetrahydrofolate reductase mutations, elevated β_2-glycoprotein level, factor V Leiden, prothrombin gene 20210A, low antithrombin III level, antiphospholipid antibodies, plasminogen activator inhibitor, or low protein S level.[9] Routine thrombophilia testing of the neonate is not indicated without clinical suspicion.

Management

Therapy for PAS is largely supportive and includes neuroprotective measures with avoidance of dehydration, hypoglycemia or hyponatremia, and maintenance of normothermia. Anticonvulsant therapy has the best evidence for use, but most infants will not require long-term therapy, and many experts increasingly suggest early discontinuation.[9] Anticoagulation is currently debated in the literature, and the type of antithrombotic medication used varies from country to country. There is most consensus for the use of anticoagulant therapy in infants with congenital heart disease (CHD) and PAIS, as they are at increased risk of ongoing clot formation.[27] Anticoagulation treatment should be considered in proven cardiac embolism, recurrent AIS, or prothrombotic state.[27–29] Referral to physical, occupational, and speech therapy should be considered, as well as close follow-up after discharge.

Outcomes

In infants with acute PAS, EEG is a useful tool for prognostication. Specifically, abnormal background activity between 2 and 4 days of life can predict abnormal motor outcomes.[30] Abnormal physical exams at discharge and seizures during the neonatal period are also predictive of long-term disability.[31] Neurodevelopmental outcomes depend on the size and location of the stroke. The risk of recurrence and mortality in PAIS is very low.[32,33] PAIS occurring in the MCA distribution may result in a hemiplegia rate of 50%.[10] While most infants will be discharged seizure-free, up to 50% will later develop epilepsy or infantile spasms.[34,35] Occurrence of more than ten neonatal seizures increases the risk of subsequent epilepsy 30-fold.[36,37] Cognitive and language deficits are more common in children with hemiplegia or epilepsy following PAS.[38] Neuromotor impairment and hemiplegia are associated with PAS affecting basal ganglia, thalamus, or posterior limb of the internal capsule.[39,40] In acute settings, motor outcomes may be predicted by the diffusion restriction within the corticospinal tract, while their asymmetry on MRI predicts the development of spastic hemiplegia.[1,41–43] Language is affected, with about half of the cases having delays at 7 years.[44] Visual function may be altered by PAS, and behavioral problems may also be seen.[13]

Sinus Venous Thrombosis

Epidemiology

Cerebral sinus venous thrombosis (CSVT) has a reported incidence of 0.6 to 12 per 100,000 live births.[45–49] The wide range of reported incidence is likely due to variable awareness among clinicians and, therefore, variable use of neuroimaging to detect CSVT. The most commonly affected sinuses in neonates are the superior sagittal and the transverse sinuses. The transverse sinuses are more frequently involved in children older than 2 years of age (60% vs. 39%).[45,50]

Pathophysiology

Impaired venous drainage from CSVT causes increased venous pressure that can result in increased capillary hydrostatic pressure. This elevated pressure leads to vasogenic edema and hemorrhagic infarction in the distribution of the cerebral sinus venous. When venous pressure is higher than arterial pressure, arterial flow decreases, and arterial ischemia and hemorrhagic infarction may occur.[51] Maternal risk factors for CSVT include preeclampsia, chorioamnionitis, and gestational diabetes. Complicated delivery, meconium aspiration, and the need to be intubated have also been associated with CSVT. Similar to PAS, CHD is a major risk factor. Postnatal conditions such as meningitis, sepsis, dehydration, and ECLS are associated with CSVT.

Clinical Presentation

Infants usually present with seizures and/or encephalopathy. Risk factors for sinovenous thrombosis include hypoxic-ischemic encephalopathy, complicated delivery, complicated pregnancy, dehydration, prematurity, congenital heart disease, sepsis, and prothrombotic abnormalities.[52] Presenting signs and symptoms are subtle and nonspecific: seizure is the most common symptom, but respiratory distress, lethargy, apnea, and poor feeding can also be present with CSVT.

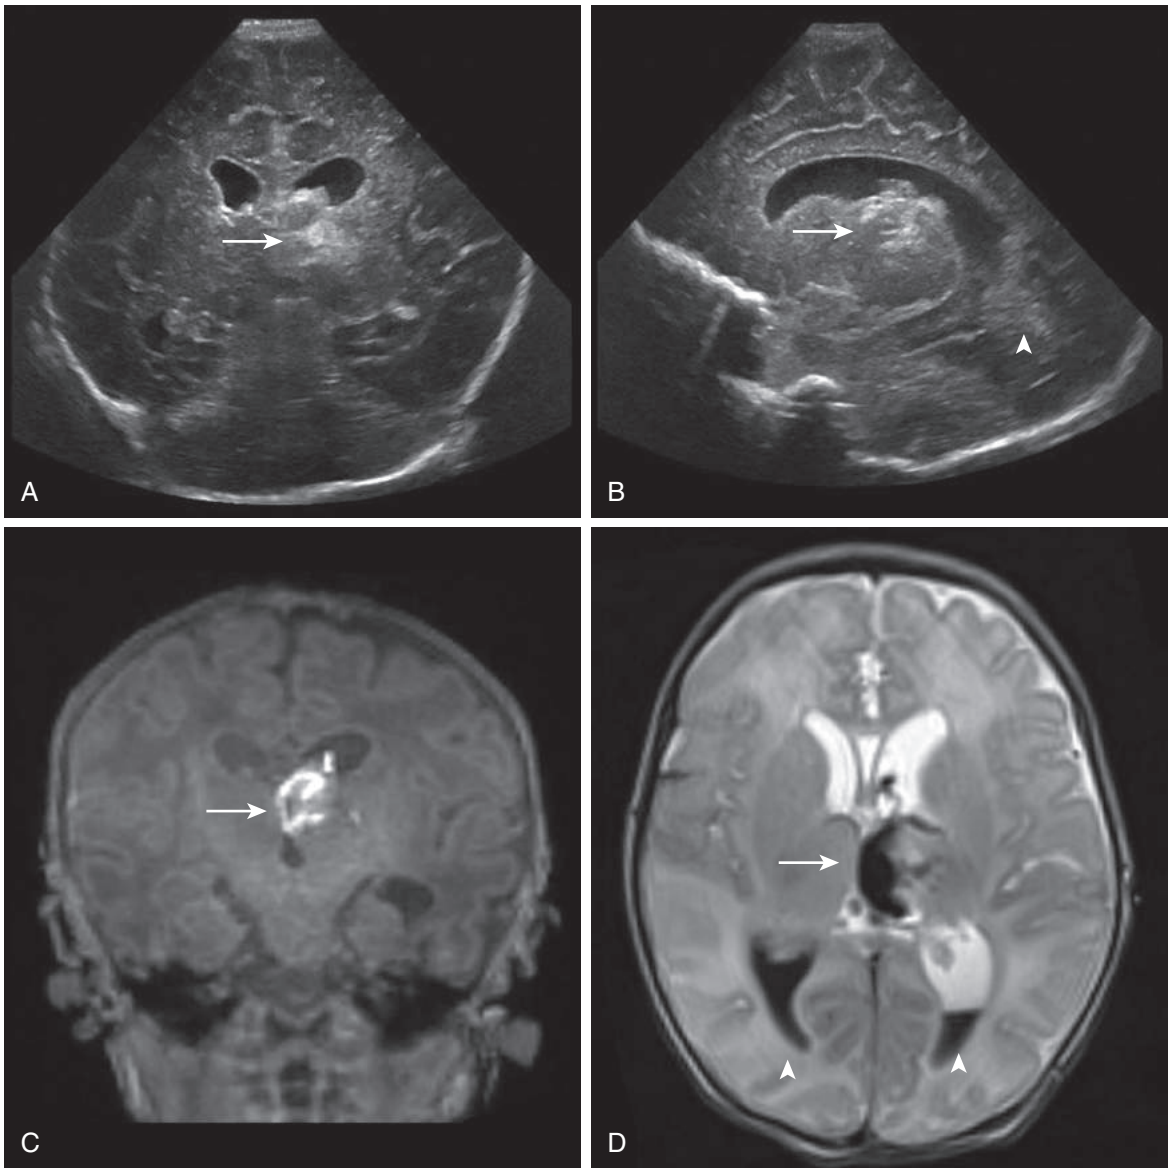
Evaluation

The nonspecific clinical presentation in neonates and children makes the diagnosis of CVST particularly difficult as frequently the symptoms can be attributed to more common diseases such as infections or dehydration. Neuroimaging is necessary for detecting sinovenous thrombosis as well as following patient response to therapy. The superior sagittal sinus has the highest rate of thrombus, followed by straight and transverse sinuses. Most neonates have multiple sinuses involved.

From an imaging standpoint, sinovenous thrombosis is often initially detected by CUS or MRI as IVH with or without associated thalamic hemorrhage (Fig. 56.2).

MRI is the gold standard, especially when the MRI venography (MRV) sequence is performed (Fig. 56.3). MRI serves two purposes: (1) to document the sinus involved and (2) to identify associated lesions. CSVT can sometimes be detected by T1- and T2-weighted images. Restricted diffusion on DWI will be present in areas affected by CSVT. MRV is very helpful for delineating thrombosis, as the involvement of multiple sinuses and veins is relatively common, and this allows the clinician to see the venous system without the use of contrast.

CUS can be used to diagnose CSVT; however, it has a high false-negative rate and requires operator experience in using Doppler to measure venous sinus flow.[53] CUS can detect intraventricular and thalamic hemorrhages with ease, and CSVT should be ruled out in term neonates with unexplained intraventricular hemorrhage.[54] CT has a high false-negative rate and, given the high radiation, is generally not preferred.[55] As with PAS, thrombophilia evaluation should be performed and should include protein-based assays as well as genetic testing. While genetic testing can be done acutely, protein-based studies are most frequently performed at around



• **Fig. 56.2** Images From a Term Newborn With Sinus Thrombosis. (A) A coronal cranial ultrasonography (CUS) image with a bright-appearing thalamic hemorrhage (*arrow*). (B) A parasagittal view of the left lateral ventricle. Note the thalamic hemorrhage (*arrow*) and blood in the occipital horn of the ventricle (*arrowhead*). (C) The coronal T_1-weighted magnetic resonance (MR) image corresponds to the CUS image in A. The thalamic hemorrhage appears bright (*arrow*). (D) An axial T_2-weighted MR image in which hemorrhage appears dark. Note the thalamic hemorrhage (*arrow*) and blood in the lateral ventricles (*arrowheads*).

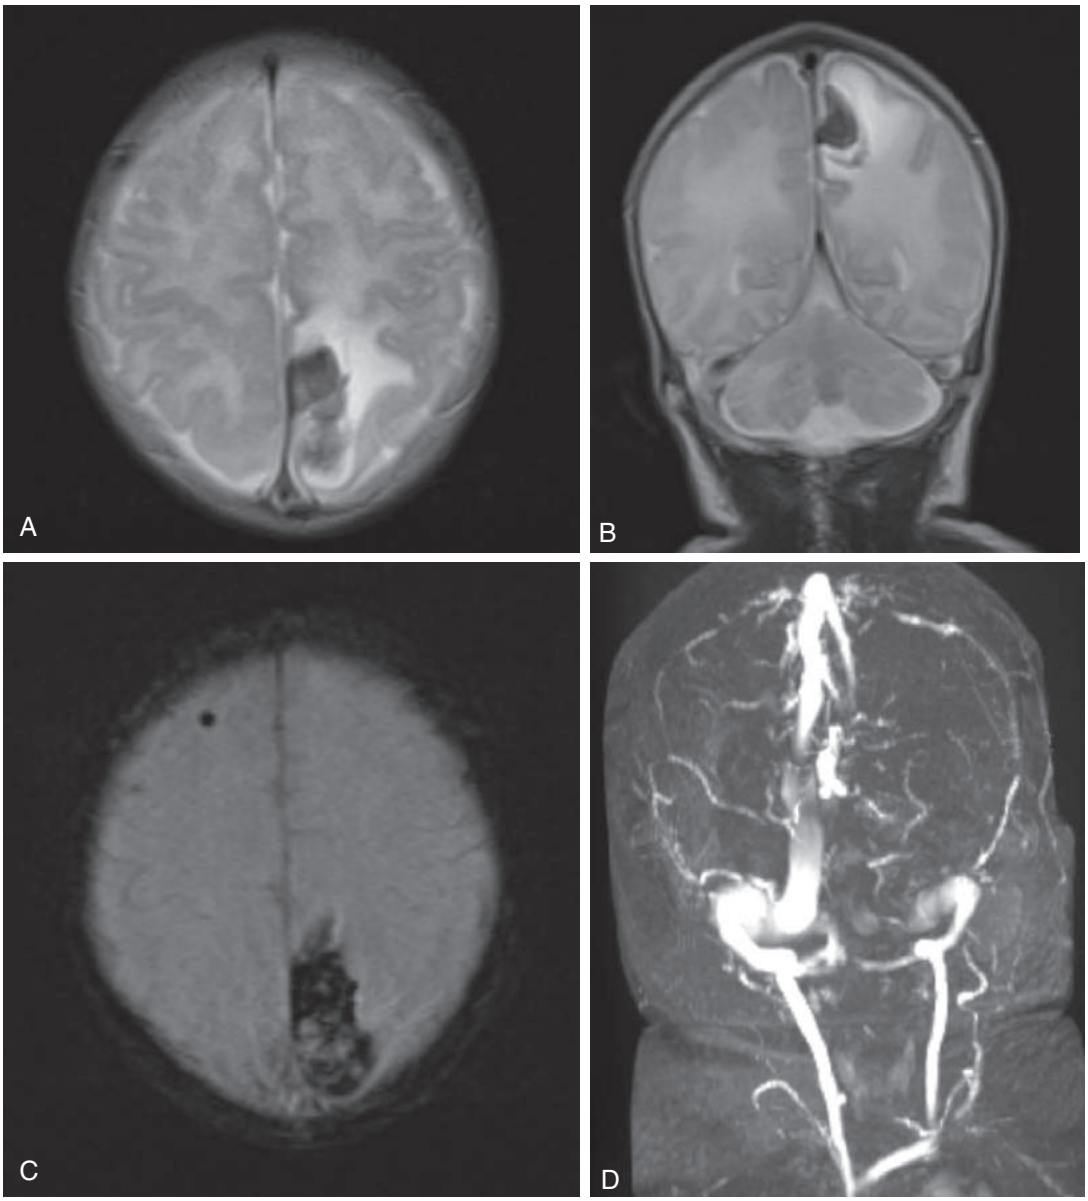
6 months of age because of the large volume of blood required for testing and because consumption of factors during acute thrombosis may lead to inaccurate results.

Management

There is no consensus on the acute phase management of CSVT in neonates, and both anticoagulation and a conservative approach should be considered in treating concomitant illnesses.

Treatment of CSVT should target the inciting factor: for instance, treating dehydration, meningitis, or CHD. Identifying the extent of thrombosis is important because it is a treatable condition, and it is common to use anticoagulant therapy (cautiously, in the presence of significant hemorrhagic injury). MR venography provides a means of evaluating the response to anticoagulant therapy, and follow-up imaging is typically obtained some weeks following the initiation of therapy.

Thrombus progression is seen in 25% of neonates, and no complications have been seen with anticoagulation for infants with associated intracranial hemorrhages.[56] Therefore, most practitioners will treat CVST with unfractionated heparin or low-molecular-weight heparin in neonates without hemorrhage. Those with hemorrhage that show a progression of the CVST at 5 to 7 days should have anticoagulation therapy started. The treatment duration is between 6 and 12 weeks.[57] An emerging treatment using direct oral anticoagulants (factor Xa inhibitors [rivaroxaban, apixaban, edoxaban] and a direct thrombin inhibitor [dabigatran]) represent a fascinating option for the treatment of CVST, taking into consideration their safety profile and the lack of laboratory monitoring required.[58,59]



• **Fig. 56.3** A 15-Day-Old, Former 34 Weeks' Gestation, Preterm Male Neonate With Hypoxic–Ischemic Encephalopathy and Dural Venous Sinus Thrombus. (A) Axial and (B) coronal T2-weighted images show abnormal dark signal in the medial left parietal lobe parenchyma, with surrounding high signal. (C) Axial susceptibility weighted imaging shows a dark signal and blooming artifact consistent with blood products. (D) Coronal maximum intensity projection image from a magnetic resonance venogram shows diminished flow in the lower sagittal sinus and left transverse sinus consistent with thrombus. Findings are consistent with hemorrhaging venous infarct and surrounding vasogenic edema. (Images courtesy of Dr. Jason Wright and Dr. Teresa Chapman, Seattle Children's Hospital, Seattle.)

Outcomes

Few studies of CVST have been performed, and follow-up data are limited. Early mortality figures showed death rates between 2% and 5%; however, more recent studies with improved detection rates of CVST show mortality rates between 19% and 25%.[60] Recanalization rate in neonates and children varies, with a recent study reporting a rate of 85% at 3 months in neonates compared with 56% in children.[56]

Increased recurrence risk (4- to 11-fold) has been associated with the lack of recanalization, the presence of the G20210A prothrombin gene mutation, and in patients not treated with anticoagulant therapy.[61,62] There is very limited follow-up data, including neurodevelopmental outcomes of neonates with CVST. Of the survivors, 60% to 80% develop motor impairment, including CP, cognitive delay, and/or epilepsy.

Subdural and Subarachnoid Hemorrhages

Epidemiology

Aside from the intraventricular hemorrhage seen in preterm infants, which is described in Chapter 54: Brain Injury in the Preterm Infant, the other major, clinically important types of neonatal intracranial hemorrhage (ICH) include: (1) epidural hemorrhage, (2) subdural hemorrhage, including posterior fossa subdural

hemorrhages, (3) primary subarachnoid hemorrhage, and (4) other forms of intraparenchymal hemorrhages (other than cerebellar). Here we will discuss the subdural and subarachnoid bleeds in detail. The approximate incidence, anatomic site of blood, relative frequency in preterm versus term-born neonates, and the usual clinical gravity of these hemorrhages are noted in Table 56.3.

The incidence of ICH has been challenging to define, as most studies have focused on symptomatic newborns, and some hemorrhages are asymptomatic. Hence the incidence of ICH is likely higher than reported.[63] In one small study of symptomatic newborns, the estimated incidence was 4.9 per 10,000 live births.[64] The largest epidemiologic data related to the California Perinatal Database, which includes maternal and neonatal hospital discharge records on 600,000 infants (2500 to 4000 g) born to nulliparous women. In this study, the incidence of symptomatic intracranial hemorrhage associated with spontaneous delivery was 1 per 1900 births, vacuum extraction delivery was 1 per 860 births, and forceps delivery was 1 per 664 births.[65] In contrast, more recent studies utilizing MRI in asymptomatic newborns in the first month of life have revealed a much higher frequency of ICH. A large prospective study found an 8% prevalence of subdural hemorrhage in this population.[66,67]

Table 56.3 provides a summary of the location, incidence, and usual clinical outcomes of the main types of hemorrhage. Table 56.4

TABLE 56.3 Intracranial Hemorrhage

Hemorrhage	Incidence (%)	Site of Blood	Full Term or Preterm	Usual Clinical Outcome
Extradural (Epidural)	Very rare	Between skull and outside of dura	FT > PT	Variable
Subdural	5–25	Between dura and arachnoid	FT > PT	Benign
Subarachnoid	1–2 FT 10 PT	Between arachnoid and pia	PT > FT	Benign
Cerebellar	0.1 FT 0.2 5 PT	Cerebellar hemispheres and/or vermis	PT > FT	Serious
Intraventricular	0.2 FT 15 PT	Within ventricles or including periventricular hemorrhagic infarction	PT > FT	Serious
Parenchymal	0.1 FT 2–4 PT	Cerebral parenchyma	FT > PT	Variable

FT, Full term; *PT*, preterm.

TABLE 56.4 Characteristics of Subdural and Subarachnoid Hemorrhages in Newborns

	Subdural Hemorrhage	Subarachnoid Hemorrhage
Epidemiology	25% (8%–45%) of all intracranial bleeds.[68,69] Rate: between 2.9/10,000 for spontaneous deliveries to 21.3/10,000 when both vacuum and forceps are used in delivery[65]	Rate: 1.3 per 10,000 spontaneous vaginal deliveries, with a higher prevalence in vacuum and/or forceps-assisted deliveries[65]
Location	Below the dura mater and superior to the subarachnoid villi	Below the arachnoid mater, in the subarachnoid space
Pathophysiology	Trauma/tearing of veins and venous sinuses	Trauma to the veins of the subarachnoid villi
Risk factors	Vacuum- or forceps-assisted delivery; coagulopathy	
Clinical presentation	Posterior fossa (infratentorial): severe hemorrhage with acute signs: stupor, lateral eye deviation, unequal pupils, nuchal rigidity, opisthotonos, bradycardia, respiratory compromise, apnea, or death. Insidious onset: may be clinically silent for days, followed by lethargy, full fontanel, irritability, respiratory abnormalities, apnea, bradycardia, and eye deviation. Hemorrhage over convexities: may have minimal or no symptoms; severe hemorrhage with acute signs: seizures, lateral eye deviation, nonreactive dilated pupil on the side of the hematoma, hemiparesis; insidious onset: may be clinically silent for months with initial presentation of increased head circumference (may occur if chronic subdural effusion)	Rarely of clinical significance and often asymptomatic May have early onset refractory seizures (usually on the second postnatal day) due to meningeal and cortical irritation or secondary hydrocephalus[69]
Outcomes	Less severe hemorrhages have variable prognoses: • ~80%–90% will have normal outcomes • ~10%–15% may have serious sequelae, including hydrocephalus requiring shunt placement • ~5% mortality Severe infratentorial hemorrhage has an extremely poor prognosis.	Very good prognosis in general. Frontal lobe or multiple hemorrhages are associated with higher rates of disability.[63]

compares subdural and subarachnoid hemorrhages. Incidence, location, risk factors, presentation, and outcomes are presented side by side. Note that subdural hemorrhage is more frequent, and risk factors for both types are related to delivery mode, instrumentation, and the presence of coagulopathy.

Pathophysiology

Subdural hemorrhages occur when bridging veins that carry blood through the dura mater to the arachnoid mater of the meninges are torn. This bleeding results in blood collecting below the dura and superior to the subarachnoid villi. Subarachnoid hemorrhage occurs when the veins of the subarachnoid villi are torn, resulting in a collection of blood in the subarachnoid space.

Clinical Presentation

Subdural and subarachnoid hemorrhages often occur with no injury to the scalp or head to suggest intracranial injury. Thus, the hemorrhages may go unrecognized. Most neonates with subdural hemorrhage remain asymptomatic, and the lesion resolves without consequence. Clinical signs of subdural hemorrhage arise when there is a large-volume hemorrhage or if bleeding slowly continues over hours or even days, as in cases of bleeding disorders. Symptomatic subdural hemorrhages often present 24 to 48 hours after birth with nonspecific signs, including apnea, respiratory distress, altered neurologic state, or seizures.

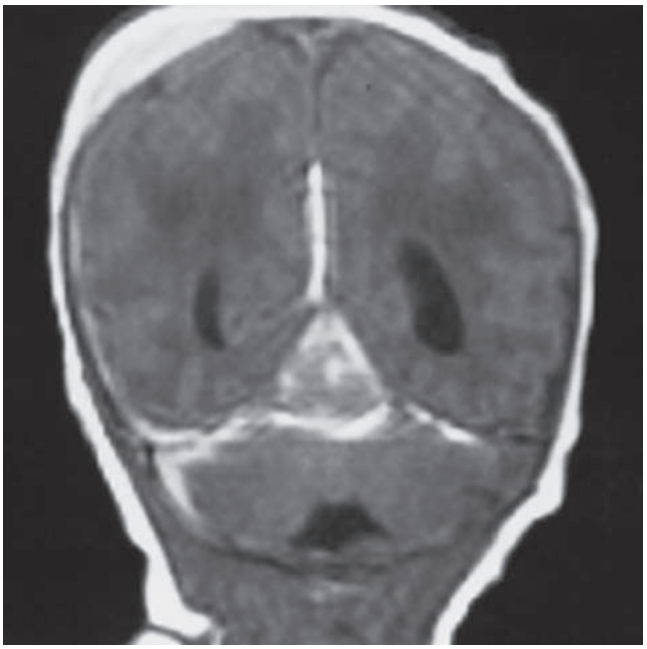
The most common clinical presentation of subarachnoid hemorrhage is seizures, as the blood from the hemorrhage can irritate the meninges and adjacent cortex. In some cases, a large subarachnoid hemorrhage irritates the meninges and causes a secondary impairment of cerebrospinal fluid (CSF) resorption resulting in hydrocephalus.

Evaluation

The three primary brain imaging modalities—CUS, CT, and MRI—have different sensitivities for detecting hemorrhage. CUS is not the modality of choice for all forms of hemorrhage: it lacks the sensitivity of MRI and CT for identifying intracranial injury and hemorrhage (other than intraventricular) and is particularly limited for the detection of extra-axial hemorrhage (subdural, subarachnoid, and extradural).[70,71] CUS also lacks sensitivity in detecting subarachnoid hemorrhage because of the normal increase in echogenicity around the periphery of the brain.[72]

CT was recommended in the 2002 American Academy of Neurology practice parameters for neonates with birth trauma and a low hematocrit or coagulopathy[73] based on data from two small studies reporting on CT diagnoses of ICH leading to interventions.[74,75] However, given the risks of radiation exposure associated with CT imaging, we suggest using MRI, when available, as the preferred method of evaluation. The use of MRI has the added benefit of better sensitivity for detecting parenchymal injury than CT. The development of more rapid MRI sequences to allow for shorter studies to detect cerebral hemorrhage should enhance physician comfort with this as a first-line technique.

MRI is more effective than CT in the delineation of posterior fossa subdural hemorrhage. Detection of subdural hematoma by ultrasound scanning, although reported, generally is difficult and requires imaging through the mastoid fontanelle in addition to the anterior fontanelle. Moreover, even when these hematomas are detected, the extent and distribution of supratentorial lesions are usually demonstrated far better by MRI or CT, and infratentorial lesions are detected better by MRI. In addition, the vast majority of subdural hematomas are infratentorial, where ultrasound has even greater challenges in accurate diagnosis (Fig. 56.4).



• **Fig. 56.4** Tentorial Subdural Hemorrhage With Blood Layering Along Both Leaves of the Tentorium and Posterior Falx. (Adapted from Castillo M, Fordham LA. MR of neurologically symptomatic newborns after vacuum extraction delivery. *AJNR Am J Neuroradiol*. 1995;16:816–818.)

Similarly, the diagnosis of primary subarachnoid hemorrhage is usually made by MRI or CT and, on rare occasions, by ultrasound.[71] On CT, the distinction between the normal, slightly increased attenuation in the regions of the falx and major venous sinuses and the increased attenuation caused by subarachnoid hemorrhage may be difficult. Sometimes, the possibility of primary subarachnoid hemorrhage is raised initially by the findings of an elevated number of red blood cells and an elevated protein content in the CSF, usually obtained for another purpose (e.g., to rule out meningitis). Exclusion of the relatively common (e.g., extension from subdural, cerebellar, or IVH) and uncommon (e.g., tumor, vascular lesions) causes of blood in the subarachnoid space is best done by MRI.

Management

Most neonates with subdural hemorrhage can be managed symptomatically. Serial hematocrits and vital signs should be monitored frequently. In most cases, the blood collection will gradually resorb over weeks to months. In rare cases of large subdural hemorrhage that cause increased intracranial pressure or mass effect, neurosurgical drainage may be required. Seizures are treated with antiseizure medications. Neonates with subarachnoid hemorrhage should receive serial head circumference measurements and serial head ultrasounds to screen for hydrocephalus.

Outcomes

The outcomes of neonates with subdural and subarachnoid hemorrhage are generally good. An estimated 80% of infants with

subdural hemorrhages will have no disability. The location and extent of the subarachnoid hemorrhage can impact outcomes. Hemorrhages in the frontal lobe or in multiple areas of the brain are associated with higher rates of disability.

Vascular Malformations

Arteriovenous malformations (AVM) are fast-flow vascular defects consisting of connections between the arterial and venous vessels through a fistula or a nidus.[76] Intracranial AVM is the most common type of AVM, affecting 1/10,000 people.[77] They represent 27% to 44% of the vascular malformations causing ICH.[78,79] Up to 80% hemorrhagic presentation in children with AVMs has been reported.[80] There is a wide range of vascular malformations; some are only found in children, and the lesion included here for discussion is the vein of Galen malformation.

Vein of Galen Malformation

Epidemiology

The vein of Galen aneurysmal malformation (VGAM) is a rare congenital vascular malformation that constitutes about one-third of the pediatric vascular and about 1% of all pediatric congenital anomalies.[80–83] It is the most common arteriovenous malformation of the newborn, and the majority (approximately 60% of all pediatric cases of VGAM) are identified during the neonatal period.[84] The overall incidence of VGAM is estimated to be 1 in 10,000 to 1 in 25,000 births.[85]

Pathophysiology

The main feature of VGAM is the dilation of the vein of Galen (Fig. 56.5). Vein of Galen malformations arise because of direct arteriovenous communication between the arterial network and the median prosencephalic vein. During neurovascular development in fetal life, between 6 and 10 weeks of gestation, the choroid plexus is responsible for fluid circulation. During this period, the median prosencephalic vein of Markowski develops and is responsible for venous drainage. After the 10th week, the venous drainage from the choroid plexus is the role of the newly developed paired internal cerebral veins. They terminate in the posterior portion of the Markowski vein, which normally disappears by the 11th week, and remnants of it form the vein of Galen.[86–88] The formation of the VGAM is then promoted by the enlargement of the median prosencephalic vein of Markowski, and this is consistent with the variation in drainage through either a normal sinus or a persistent falcine sinus, a normally transient fetal vessel.[89]

The arterial supply to the dilated vein of Galen is the posterior choroidal artery, the anterior cerebral (pericallosal) artery, the middle cerebral artery, the anterior choroidal artery, and the posterior cerebral artery.[84,87,90]

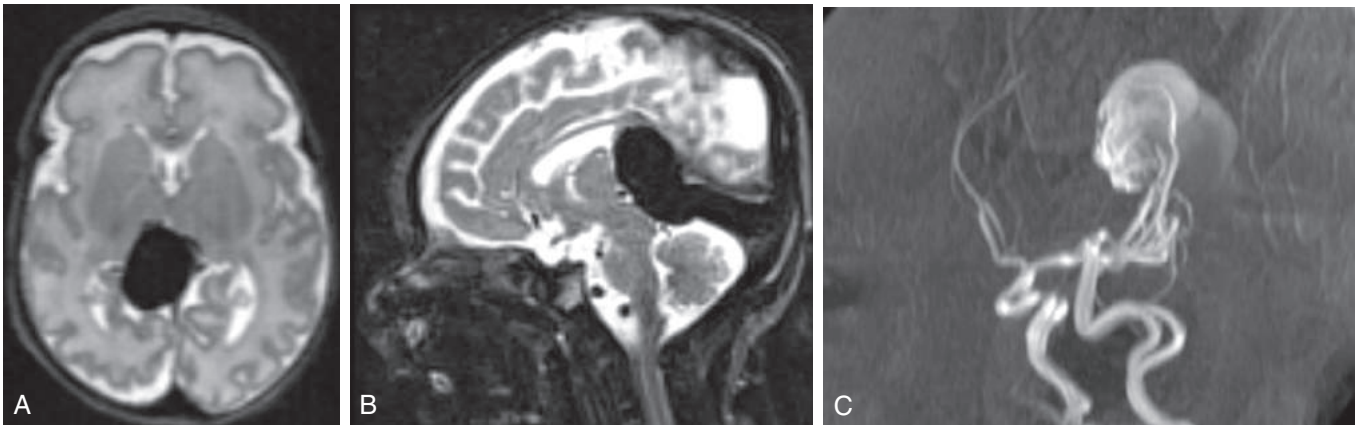
There are two classification systems that are used in clinical practice, proposed by Lasjaunias and Yasargil (Table 56.5). The Lasjaunias system includes two types of aneurysmal malformations: a primary (true) vein of Galen malformation that could be mural or choroidal form, and a secondary type resulting from a deep AVM that drains into the vein of Galen.[91]

A different classification proposed by Yasargil et al. is based on the arterial feeder patterns of drainage into the vein of Galen and is divided into four types.[92] Type I includes direct fistulas between the pericallosal and posterior cerebral arteries and the vein of Galen, type II is made up of numerous fistulas between the thalamoperforators and the vein of Galen, type III consists of multiple fistulous connections from different vessels having characteristics of type I and II malformations, and type IV has adjacent AVMs that drain into the vein of Galen and cause a secondary aneurysmal venous dilatation. Distinguishing between true VGAM (where the vein of Markowski is the pathological vessel) and AVMs that can cause aneurysmal dilatation of the vein of Galen is extremely important in order to describe the features, natural history, and treatment options of VGAMs.[93] Based on the two classifications used in clinical practice, true VGAMs are represented by the primary malformation (Lasjaunias classification) and types I to III malformations (Yasargil classification). In contrast, the secondary vein of Galen malformations (Lasjaunias classification) and type IV malformations (Yasargil classification) are parenchymal AVMs that generate secondary dilatation of the vein of Galen (Table 56.5).

The pathological findings observed with VGAM consist of a variety of ischemic, hemorrhagic, and mass effects of the malformation.[86,87,94,95]

Cardiovascular Findings

The arteriovenous connection present in the VGAM is a high-flow, low resistance system that causes an increase in cardiac output and high-output heart failure. Heart failure is usually present shortly after birth after the loss of the low-resistance



• **Fig. 56.5** Images From a Term Newborn With Vein of Galen Malformation. (A, B) Note large flow void on the T2-weighted images. (C) Corresponding angiogram. (Images courtesy Dr. Bob McKinstry.)

TABLE 56.5 Classification of Vein of Galen Aneurysmal Malformation

Classification	True VGAM	Secondary Aneurysmal Dilation of Vein of Galen Due to Parenchymal Arteriovenous Malformations (AVM)
Lasjaunias[91]	Primary malformation Mural type: • Fistulae in the subarachnoid space in the wall of the median prosencephalic vein • Presents later (infant) with hydrocephalus Choroidal type: • Multiple feeders, including: thalamoperforating, choroidal and pericallosal arteries are located in the subarachnoid space in the choroidal fissure • Presents earlier (neonate) with more severe shunts	Secondary malformation: deep AVM that drains into the vein of Galen
Yasargil[92]	Type I: fistulas between the anterior and posterior pericallosal and posterior cerebral arteries and the vein of Galen Type II: multiple fistulas between the thalamoperforator network that lies between the arterial feeders and the vein of Galen Type III: high-flow type I or II malformations with multiple fistulous connections from different vessels	Type IV: adjacent AVMs of the mesencephalon that drain into the vein of Galen and cause a secondary aneurysmal venous dilatation

VGAM, Vein of Galen aneurysmal malformation

placental circulation. After birth, blood flow increases significantly through the VGAM.[96] As much as 80% of the left ventricular output may be supplied to the brain in severe cases.[97] The high cardiac output, low diastolic pressure, increased intraventricular pressure, and impaired coronary blood flow contribute to myocardial ischemia, making the cardiac failure multifactorial and challenging to manage. The intracranial "steal" caused by the absent or reversed diastolic cerebral blood flow and congestive heart failure result in cerebral ischemia.[97–99] The increased venous return and left to right shunts through the patent foramen ovale and the patent ductus arteriosus can lead to and worsen pulmonary hypertension.[100,101]

Neurologic Findings

The neuropathological findings in the VGAM include impaired cortical development, cerebral atrophy, hemorrhagic lesions (thrombosis of the dilated vein of Galen with hemorrhagic infarction and or intracerebral hemorrhage, vascular rupture, and massive hemorrhage), or hydrocephalus (from compression and obstruction of the cerebral aqueduct or from the high venous pressure in the medullary veins that prevents reabsorption of cerebrospinal fluid due to venous hypertension).[90,95,99,101–105]

Clinical Presentation

The clinical picture of patients with VGAM depends on the age at presentation and is commonly characterized by cardiac and neurologic complications. About 44% of the cases are detected in the neonatal period, and the presentation varies with the size of the malformation. The vast majority of the neonates with VGAM present with high-output cardiac failure, pulmonary hypertension, and, in more severe cases, multiorgan system failure.[82,84,88,100,106–110] The timing of presentation and symptoms are dependent on the size of the aneurysm (the greater the size, the larger the degree of shunting through the lesion, and the earlier the presentation). Neonates tend to present clinical signs and symptoms in the first few hours of age that may worsen over the first 3 days of life. Some of the features present with the VGAM are the bounding carotid pulses with or without prominent peripheral pulses and the continuous cranial bruit over the posterior fontanelle and cranium. Cyanosis may be a presenting sign seen in these patients, and a diagnosis of congenital cyanotic heart disease is often in the differential. Due to congestive heart failure and diastolic flow reversal in the descending aorta, some infants may present with hepatic or renal insufficiency and prerenal azotemia.[96,99]

The clinical presentation differs in infants and older children. Infants present most commonly with hydrocephalus (about 15% of the overall presentation for VGAM), and children present most commonly with neurologic signs and symptoms like headaches, focal neurologic deficits, and syncope.

Evaluation

The antepartum diagnosis for VGAM can be made during the routine prenatal screening ultrasound or with the fetal MRI, which is increasingly used for more detailed characterization prenatally. When a dilated structure is visualized posterior to the third ventricle, pulsatile flow within it helps differentiate VGAMs from other midline cystic lesions.[111–114] However, based on prenatal imaging, the clinical course in neonates with VGAM has been difficult to predict. Every neonate with prenatally suspected or diagnosed VGAM should be admitted to the neonatal intensive care unit for complete evaluation and management, including weight and head circumference. Cardiac evaluation, including echocardiography, renal and liver function tests, and head imaging, should be part of the initial evaluation. When there is no prenatal data or suspicion, the diagnosis of VGAM should be considered in any neonates with high-output congestive heart failure, unexplained intracranial hemorrhage, or hydrocephalus. In this scenario, the initial evaluation is performed using cranial ultrasonography with a Doppler.[115,116] The use of ultrasound adds important value to the follow-up of patients after treatment to assess the status of the shunt and the presence of thrombosis.

Another useful imaging method to detect a mass, mostly in older infants, is CT.[117] When used in combination with angiography, a better understanding of the vascular structures can be mapped. CT angiography can be part of the planning process for intervention. MRI can be used to demonstrate the location, and the vascular components, including the status of venous drainage. The location and detection of major arterial vessels feeding the fistula are better identified on MRI than CT. Angiography remains the gold standard imaging modality to evaluate and define the architecture of the VGAM, including size, location, arterial feeders, and the dynamic aspect of venous drainage, which helps with decisions regarding intervention.

Management

The management of the patient with significant VGAM manifesting in the neonatal period remains a big challenge. Timing and approach to treatment depend on the patient's age, the severity of congestive heart failure, and the architecture of the lesion at the time of diagnosis.[118] Overall, the management approach, when indicated, is divided into medical, endovascular, or neurosurgical interventions. The main therapy goal is to minimize congestive heart failure using different therapeutic approaches that may include combinations between systemic vasodilators and low-dose dopamine.[119]

Embolization (transvenous or transarterial approach) results in better survival compared to surgical techniques and are thus the preferred approach for intervention.[120] For many years, to evaluate the risks and benefits of interventions, clinicians used the Bicêtre neonatal evaluation score.[93] A Bicêtre score of less than 8 out of 21 is historically associated with a near-fatal prognosis. Hence, these neonates are not considered good candidates for emergent embolization. A score between 8 and 12 characterizes neonates who are most likely to benefit from emergent embolization. A score greater than 12 suggests the infant can be managed medically and does not require embolization. In recent years, many centers have moved away from using Bicêtre score cutoffs as it is possible for some neonates with scores less than 8 to have good outcomes from embolization.

Embolization is considered the main approach to treatment and can be performed by an arterial transarterial approach using liquid adhesive agents or micro coils or by a transvenous approach typically using the umbilical or femoral veins.[89,93,96,102,120,121]

Even though microsurgery is no longer a primary treatment strategy, neurosurgical intervention plays an important role in persistent hydrocephalus, intracranial bleeds, hematomas, or when embolization fails.[90,122,123]

Outcomes

The development and implementation of endovascular interventions have been critical in improving outcomes in patients with VGAM, and despite therapeutic techniques, morbidity and mortality remain high.[90,106,108,124,125] As the treatment evolves and becomes more centralized, the spectrum of impairments for survivors with poor outcomes has to be better characterized. One of the largest, most recent cohorts from the UK ($n = 85$) reported that more than one-third of newborns with a vein of Galen malformation did not survive and that outcome was good in about half of the survivors.[124] Two other meta-analyses described poor clinical outcomes or death in almost one-half of neonates with VGAM.[126,127] Prognosis depends on the size of the malformation, age at diagnosis, the severity of congestive heart failure, the degree of brain injury, and the success of embolization. Neonates with untreated VGAM that survive the neonatal period with medically managed congestive cardiac failure are at increased risk for developmental delays. Later presentations include failure to thrive, seizures, focal neurological deficits, intracranial bleeds, and progressive hydrocephalus.[90,99,101,102,128,129]

Acknowledgment

The authors would like to acknowledge Dr. Ryan McAdams, Christopher Traudt, Jeffery Neil, and Terrie Inder for their work on this topic in the previous edition of this textbook. We would also like to acknowledge Dr. Catherine Amlie-Lefond and Dr. Nina Natarajan for their assistance with this chapter.

Neonatal Neuromuscular Disorders

NIRANJANA NATARAJAN AND CRISTIAN IONITA

KEY POINTS

- Evaluation of neonatal hypotonia includes neuromuscular conditions, and the diagnostic work-up should be approached in a stepwise manner.
- A normal creatine phosphokinase does not completely rule out muscle disease.
- Electromyography is useful in the diagnostic evaluation of hypotonia and weakness.
- Spinal muscular atrophy (SMA) can present in the neonatal period and has time-sensitive treatments. Genetic testing for the commonly found gene deletion in SMA is increasingly available as newborn screen testing in the United States.
- The search for a genetic diagnosis is crucial in patients with neuromuscular disease.

Neonatal Neuromuscular Disorders

Neuromuscular disorders comprise diseases of the muscle (congenital myopathies and muscular dystrophies), neuromuscular junction (myasthenia gravis and congenital myasthenic syndromes), nerves (neuropathies), and anterior horn motor neurons (spinal muscular atrophies). They present in the neonatal period as floppy infant syndrome with or without contractures. Respiratory insufficiency and swallowing difficulties can be in the forefront of the clinical picture and are frequently associated with significant hypotonia and weakness.

This chapter reviews our current knowledge of neuromuscular disorders with neonatal onset and their clinical details alongside pathologic, genetic, and radiologic aspects as applicable. Finally, an approach to the diagnostic evaluation of neonates when a neuromuscular disorder is suspected is discussed.

Primary Muscle Disorders

Historically, neonatal muscle disorders were divided based on histopathologic criteria into (1) congenital muscular dystrophies (CMDs), (2) congenital myopathies (CMs), (3) congenital myotonic dystrophy, and (4) metabolic myopathies. CMDs demonstrate dystrophic changes on muscle biopsy, with disruption of the muscle fiber and its architecture. Congenital myopathies have more subtle changes with preservation of the muscle fiber architecture. While histopathologically and genetically distinct, their phenotypes are often indistinguishable and characterized by congenital onset of muscle weakness and hypotonia. Some distinguishing features of various disorders are apparent at birth, while others become apparent later. Muscle weakness tends to be progressive with CMDs and relatively static in CMs. Improvement in strength has been reported with some congenital myopathies. Involvement of the central nervous system is seen more often with CMDs and congenital myotonic dystrophy and less so with CMs. Creatine phosphokinase (CPK) tends to be elevated with CMDs and normal or mildly elevated with CMs. Many entities are sporadic or inherited in autosomal recessive fashion with few notable exceptions. Congenital myotonic dystrophy type 1 is inherited in autosomal dominant pattern and shows anticipation. Collagen VI- and *RYR1*-related disorders can have both autosomal-dominant and autosomal-recessive inheritance. The genetic advancements of the last decade promised a better understanding of this heterogeneous group of disorders. Instead, it became clear that a pure genetic classification remains impractical for the practicing physician. There are numerous situations where one gene leads to multiple phenotypes and the same phenotype is caused by numerous genes. Recent attempts to classification are based on genetic but also pathologic and clinical data. In the end, a classification that follows a mechanistic approach will likely prove to be most helpful.

Congenital Muscular Dystrophies

CMDs comprise a heterogeneous group of disorders characterized by a dystrophic process on muscle biopsy. Classification schemas alongside diagnostic approaches have been proposed that take into account the recent expansion of knowledge.[1–3] Given the numerous genes discovered, CMDs have most recently been separated into seven subtypes of disorders: merosin-deficient congenital muscular dystrophy, α-dystroglycanopathies, collagen VI-related disorders, *LMNA*-related congenital muscular dystrophy, *SEPN1*-related myopathy, *RYR1*-related myopathies, and CMD without a genetic diagnosis.[2] *SEPN1* and *RYR1*, which are typically considered myopathies, are in this classification scheme secondary to the varying phenotype at presentation.

LAMA2-Related Congenital Muscular Dystrophy (Merosin-Deficient Congenital Muscular Dystrophies; MDC1A)

LAMA2-related CMD is due to autosomal recessive mutations of *LAMA2* gene known to encode the α_2 subunit of merosin. Merosin is an essential component of the extracellular matrix. In the UK, *MDC1A* was the most common form of congenital

muscular dystrophy, followed, as a group, by dystroglycanopathies and collagen VI myopathies.[4] Clinically, *MDC1A* often presents at birth or early infancy with severe hypotonia and diffuse weakness. A weak cry, poor suck and swallow, and respiratory failure are common. Contractures may be present at birth in the more severe cases or develop in time. As opposed to dystroglycanopathies, neonates with *MDC1A* typically have no encephalopathy, and cognitive as well as speech development is normal. On brain MRI, white matter T2 and FLAIR signal abnormalities become apparent in the second half of the first year[5,6] and approximately 20% of patients develop seizures. A mild demyelinating neuropathy is often present, generally not at the forefront of clinical picture. CPK levels in neonatal period and infancy are elevated four to five times above normal limits.[7] Muscle biopsy demonstrates decreased or absent laminin α_2 immunostaining aside from dystrophic features. Care for patients with *LAMA2* mutations is supportive in nature.

Dystroglycanopathies

Dystroglycan complex includes α- and β-dystroglycan and represents one of the transmembrane complexes that link cytoskeleton with extracellular matrix as part of the larger dystrophin-glycoprotein complex. α-Dystroglycan, the extracellular component of the complex, through its heavily glycosylated segment, interacts with several extracellular matrix proteins such as laminin α_2 and agrin. As a receptor for several extracellular matrix proteins, dystroglycan plays a major role in the maintenance of muscle cell structural integrity and synaptogenesis. In the central nervous system, dystroglycan plays an important role in forebrain development, specifically neuronal migration as well as synaptic plasticity and blood-brain barrier integrity.[8,9] Dystroglycan plays important roles in other tissues such as eye and secreting tissues.

Dystroglycanopathies are a phenotypically heterogenous group of disorders that share a common pathophysiologic theme: abnormal interaction of dystroglycan complex with extracellular matrix proteins because of defective α-dystroglycan O-glycosylation. Their phenotype ranges from severe neonatal muscle weakness with early lethality as well as abnormal brain and eye development to asymptomatic hyperCKemia discovered in adult years.

The modern classification of these disorders is based on their genotype and pathophysiology instead of severity. In this classification, dystroglycanopathies are subdivided into primary (due to mutations in *DAG1* gene which encodes the two dystroglycans), secondary (due to mutations in genes known to encode enzymes involved in O-glycosylation of the α-dystroglycan), and tertiary (due to mutations in genes known to encode enzymes and other factors implicated in production of the oligosaccharide building blocks). Primary dystroglycanopathies are the most recent addition to the group and includes a handful of cases, all found in consanguineous families. Their phenotype parallels the more common secondary dystroglycanopathies and includes severe as well as mild forms.[10] Secondary dystroglycanopathies are due to malfunction of various enzymes involved in α-dystroglycan O-glycosylation at the endoplasmic reticulum and Golgi apparatus levels. The number of enzymes involved and their encoding genes have seen significant expansion over the last two decades.

Severe forms, classically labeled as Walker Warburg syndrome" or "Muscle Eye Brain disease", present at birth with severe muscle weakness and hypotonia, as well as often severe brain and eye malformations. Although hypotonia and muscle weakness are severe, the clinical picture is dominated by encephalopathy, brain and eye malformation, and sometimes seizures. CPK is generally elevated. Brain involvement includes one or a combination of the following findings: agyria, lissencephaly (type 2, "cobblestone"), focal pachygyria or polymicrogyria, heterotopia, complete or partial agenesis of corpus callosum, cerebellum abnormalities, brainstem abnormalities including a "kinked" appearance, posterior fossa cyst, occipital encephalocele microcephaly, hydrocephalus, and white matter changes.[11] Eye abnormalities are quite variable as well and can include cataracts, abnormalities of the anterior chamber, abnormalities of the posterior chamber, microphthalmia, microcornea, small lens, retinal abnormalities, optic nerve hypoplasia, coloboma, and glaucoma. Many of these patients have significantly shortened life span and show little psychomotor developmental progress. Milder phenotypes present at birth or soon after with hypotonia and muscle weakness. MRI might show white matter abnormalities starting in the second half of the first year and cognitive disability which first becomes obvious as various degrees of global developmental delay. Yet, milder forms exist with onset as late as adult years. Tertiary dystroglycanopathies is another emerging group which phenotypically is indistinguishable from other dystroglycanopathies.

Collagen VI-Related Disorders

Collagen VI-related disorders are caused by mutations in the genes that encode one of the three subunits of collagen VI (*COL6A1*, *COL6A2*, *COL6A3*) and are classically divided into Ullrich CMD and Bethlem myopathy. Overlaps between the two phenotypes are common though, and the reader is encouraged to think about this group of disorders as a continuum between the two entities.[12] In collagen VI-related disorders there is often a combination of joint laxity and joint contractures in addition to hypotonia and weakness. While Ullrich CMD has a more severe phenotype and onset in utero, often with congenital contractures, Bethlem myopathy tends to be milder and has more variable onset starting in utero and extending into adult life. Ullrich CMD presents at birth with severe muscle weakness, hypotonia, and a combination of marked joint laxity (involving the distal joints) and joint contractures (involving the proximal joints, kyphoscoliosis, and torticollis). Weakness is slowly progressive and respiratory insufficiency is either present at birth or develops later. When it presents in utero or at birth, Bethlem myopathy tends to have a milder phenotype and behaves more like a congenital myopathy. Other useful distinguishing features for collagen VI-related disorders include a prominent calcaneus, hyperkeratosis pilaris on the extensor surfaces, keloid formation, and sometimes congenital hip dislocation. CPK is normal or moderately elevated and muscle biopsy can show both myopathic and dystrophic features. Diagnosis is generally suspected based on clinical grounds and confirmed by targeted genetic testing.

LMNA-Related Congenital Muscular Dystrophy

The *LMNA* gene, which is associated with autosomal dominant form of Emery–Dreifuss syndrome in older children or adults, has been found mutated in neonates and children with CMD.[13–16] *LMNA* encodes for lamin A/C, which is a nuclear envelope protein. The syndrome is classically described as reduced fetal movements, severe hypotonia, and weakness with a "dropped head" appearance because of involvement of the neck muscles.[15]

SEPN1-Related Myopathies

SEPN1-related myopathies straddle the demarcation line between CMDs and CMs, and encodes for selenoprotein N. *SEPN1* is an endoplasmic reticulum glycoprotein preferentially expressed early in the development, and with roles in redox signaling and Ca homeostasis.[17] Most patients with *SEPN1*-related myopathies present at birth or within the first 2 years of life with predominantly axial hypotonia, poor head control, and feeding difficulties. The distinguishing features of *SEPN1*-related myopathies, including spine rigidity, amyotrophy, and respiratory impairment, became apparent in childhood.[17] Despite a relatively well-defined phenotype, the pathologic findings are variable and include dystrophic features, multi-minicore lesions, fiber size disproportion, and desmin inclusions.

Congenital Myopathies

The term congenital myopathies (CMs) refers to muscle disorders that present in neonatal period or early infancy and lack dystrophic changes on muscle biopsy. CMs tend to have a slowly progressive or nonprogressive course. The severity spectrum is wide, starting with severe illnesses often fatal in the first years of life (*MTM1* and severe *ACTA1* disorders), to mild muscle weakness leading to mild gross motor developmental delay. Muscle biopsy shows structural changes at the myofiber level in absence of dystrophic features. The type of structural abnormalities defines the various types of congenital myopathies. Electron microscopy is often very helpful and should always be included when CM is suspected. As with CMDs, genetic advances expanded our understanding of congenital myopathies. We now know that certain genotype might lead to several different histopathologic and clinical phenotypes.[18] The best recognized congenital myopathies are core myopathy, nemaline myopathy, centronuclear myopathy, fiber-type disproportion myopathy, and myosin storage myopathy. In a population study, core myopathies were the most common, representing approximately half of all CMs cases, followed by nemaline and centronuclear myopathies each representing approximately 15% of all CMs cases.[19] Typical neonates present with hypotonia, and weakness. More severe cases have respiratory insufficiency and swallowing difficulties. Elongated and weak face, high-arched palate, and mild ptosis are seen in some of the CMs (nemaline and centronuclear myopathies). Skeletal abnormalities such as hip dislocation, club feet, and pectus excavatum are common. As opposed to congenital muscular dystrophies, CPK may be normal or mildly elevated. Typically, electromyography (EMG) shows myopathic change. EMG can also be normal and even show neurogenic features. Aside from nonspecific myopathic features, muscle biopsy often reveals specific structural abnormalities that define each group of disorders. Genetic testing is often employed first nowadays.

Core Myopathies

Central core and multi-minicore disease together comprise the "core myopathies" and are the most common form of congenital myopathies.[20] Histopathologically, focal myofibrillar disruption with absence of mitochondria leads to formation of single or multiple cores visible on oxidative stains such as Gomori trichrome. The majority of cases are due to autosomal recessive or autosomal dominant mutations in the *RYR1* gene. Clinically, patients with *RYR1*-related central core or multicore myopathies tend to have a milder phenotype with hypotonia and muscle weakness, and often lack facial involvement.[20] The more severe cases, often autosomal recessive, present at birth with contractures, arthrogryposis, and respiratory insufficiency.[21] Serum CPK is often normal or mildly elevated. The *RYR1* gene encodes the ryanodine receptor, a sarcoplasmic reticulum calcium channel with role in excitation-contraction coupling.[22] Mutations in *RYR1* can lead to various phenotypes (nemaline myopathy, congenital myasthenic syndrome),[23] as well as malignant hyperthermia. Malignant hyperthermia precautions are needed every time *RYR1* mutations are a possibility.

Multi-minicore disease is rare in the neonatal period and, when present, is notable for marked axial weakness, myopathic facies, and respiratory failure. Patients may present with arthrogryposis. The two genes most often associated with multi-minicore myopathy are *SEPN1* and *RYR1*. *SEPN1*, discussed previously, accounts for the majority of patients.[24] There is significant phenotypic overlap with rigid spine syndrome.

Nemaline Myopathy

Nemaline myopathy derives its name from "nema," the Greek word for thread. The muscle biopsy shows threadlike rods. The rods stain red on Gomori trichrome, giving its characteristic appearance. Newborns may present with hypotonia with weakness including bulbar involvement. The facial and axial muscles are often involved. Neonates may require respiratory support because of weak respiratory muscles, frequent suctioning, and nutritional support often via gastrostomy tube due to swallowing difficulties. In more severe forms, reduced fetal movements and polyhydramnios occur, and the neonate has severe respiratory failure and feeding difficulties in addition to arthrogryposis.[25]

The most severe cases of nemaline myopathy, often caused by *ACTA1* mutations, have poor prognosis with rare survival past the first year of life. Those with the milder presentation may show improvement and, some achieve independent ambulation. However, many may still require respiratory assistance because of nocturnal hypoventilation and may have failure to thrive or scoliosis. More than 10 genes are associated with nemaline myopathy with *NEB* causing most autosomal recessive cases, and *ACTA1* most autosomal dominant cases.[26]

Centronuclear Myopathy

Centronuclear myopathy is a rare cause of neonatal weakness. The name comes from the histopathologic appearance of centrally located nuclei.[27] Both X-linked as well as autosomal dominant and recessive forms exist as mutations in more than 10 genes, which are associated with this phenotype. The X-linked form caused by mutations in *MTM1* gene is the most common form and often associated with a severe phenotype. Presentation in neonates is notable for severe hypotonia and weakness, associated with bulbar and extraocular muscle involvement, and myopathic facies. Respiratory compromise and need for ventilation are common.[27] Neonates are often macrocephalic, with long, narrow face and may have undescended testes. The *MTM1* gene, encoding for myotubularin, is located on the X chromosome at Xq28, thus resulting in the male predilection for this disease. However, secondary to random X-inactivation, females may be affected.[28]

Autosomal dominant *DNM2* mutations, as well as autosomal recessive *RYR1*, *TTN* mutations, may also lead to neonatal disease.[23]

Congenital Fiber-Type Size Disproportion Myopathy

Congenital fiber-type size disproportion myopathies are characterized by type 1 fibers that are significantly and uniformly smaller than the type 2 fibers. So far, over 10 genes are associated with this pathologic phenotype inherited in both autosomal dominant and recessive fashion. Clinically they share often neonatal onset, with hypotonia, muscle weakness, and variable facial, bulbar, extraocular, and respiratory muscle involvement.

Myosin Storage Myopathy

In addition to several muscle disorders and cardiomyopathy, *MYH7* mutations are also responsible for myosin storage myopathy, also known as hyaline body myopathy. Onset is neonatal with hypotonia and weakness. On muscle biopsy, hyaline bodies are noted predominantly in type 1 muscle fibers on H&E and myosin ATPase stains, and defined as granular material on electron microscopy.

Congenital Myotonic Dystrophy

Myotonic dystrophy is a multisystem, triple repeats disease with wide phenotypic variation dependent, in great part, on the number of cytosine–thymine–guanine (CTG) repeats in the *DMPK* gene. The transcribed CUG RNA repeat has negative impact on expression of *DMPK* as well as other genes such as *SIX5* and splicing of mRNA of the *ClC1* gene. The congenital form is the most severe and is generally associated with CTG repeats higher than 1000.[29] In these cases, pregnancy is usually remarkable for polyhydramnios and reduced fetal movements. Newborns with congenital myotonic dystrophy are often delivered prematurely. At birth, there is marked hypotonia and paucity of movements. Breathing, sucking, and swallowing difficulties are often present and persistent, often leading to gastrostomy tube placement and tracheostomy. Talipes equinovarus is often present. Facial features include facial diplegia with a "carp" mouth appearance and bilateral ptosis. Clinical examination demonstrates hyporeflexia or areflexia and diffuse weakness more severe in distal muscles than proximal ones. Grip and percussion myotonia are not present at this age and develop in childhood. There may be pulmonary hypoplasia. These factors lead to high morbidity in the neonatal period and infancy. The duration and severity of the respiratory muscle weakness and pulmonary hypoplasia are key determinants of outcome. Prolonged mechanical ventilation, defined as greater than 4 weeks in duration, is a negative prognostic factor in these neonates.[30] Some neonates with severe myotonic dystrophy require tracheostomy placement; however, it is not uncommon for older infants or children to be decannulated.

The diagnosis of congenital myotonic dystrophy should be considered when there is a positive family history. The disease is transmitted by mother and shows anticipation. A detailed history and examination of the mother often, but not always, reveals characteristic facial features associated with classical myotonic dystrophy, including frontal balding, ptosis, facial diplegia, temporal wasting, or cataracts. In addition, examination of the mother typically reveals grip myotonia. These symptoms are often subtle, such that the mother is unaware of her diagnosis.

Laboratory evaluation reveals normal to mildly elevated CPK. Muscle biopsy is often remarkable for markedly increased number of internal nuclei. Electrographic or clinical myotonia is absent in the neonatal period. The diagnosis is often suspected on the clinical basis and confirmed by genetic studies. The *DMPK* gene, located at chromosome 19q13.3, contains a CTG trinucleotide repeat in the 3′ noncoding region.[31] Unaffected individuals have between 5 and 27 repeats, while patients with a classical (not congenital) presentation have 50 to 1000 repeats. Just like other triple repeats diseases, myotonic dystrophy exhibits anticipation, resulting in earlier and more severe presentation.

Neonates who survive the neonatal period typically require ongoing respiratory support and can survive into adulthood with close respiratory and cardiac monitoring and with therapy; however, cognitive impairment is frequent and can be severe.[32]

Metabolic Myopathies

Neonatal presentation is not typical for metabolic myopathies except acid maltase deficiency. Other glycogen storage disorders rarely present at this age and when they do, myopathy is associated with other systemic features such as cardiomyopathy and liver involvement. Infantile form of acid maltase disease, also known as Pompe disease, can present at birth with severe and progressive muscle weakness and hypotonia. The majority of patients have cardiac disease, respiratory insufficiency, and a fatal course unless enzyme replacement therapy is initiated early. CPK is usually elevated, and EMG is myopathic with frequent myotonic and complex repetitive discharges. Muscle biopsy shows vacuoles which stain positive with acid phosphatase.

Motor Neuron Disorders

Motor neuron disorders comprise a group of genetic disorders that share involvement of the anterior horn motor neurons. This group is dominated by 5q spinal muscular atrophy (SMA), the most common inherited motor neuron disorder. A substantial number of other rare forms of motor neuron disease are characterized; the more common ones will be mentioned below.

5q Spinal Muscular Atrophy

5q SMA is an autosomal recessive disorder with an incidence of approximately 1 in 10,000 live births, and is the most common form of SMA.[33] Onset and severity fall along a wide spectrum, from very severe cases with intrauterine onset, to mild cases with onset in adult years and mild disability.[34] Given the wide variability, SMA categorized by age of onset and anticipated motor outcome, classically as types 1 to 4, though some recognize "type 0", reserved for those cases with in utero onset.[35] The majority of patients have a homozygous deletion of the *SMN1* gene, survivor motor neuron 1. This gene is expressed in all cell types, and severity of disease is modified by the *SMN2* gene, survivor motor neuron gene 2. The *SMN2* gene is nearly identical to *SMN1* and produces principally a truncated, nonfunctional protein as well as

a small amount of functional protein. Increased copies of *SMN2* modify the severity of disease, with greater copies correlating with the milder phenotype.[36]

Historically, patients undergo a course that includes a decline phase followed by a plateau phase. The decline phase occurs in utero for SMA type 0 newborns affected at birth. For infants whose onset is after birth, a period of normal development is followed by a decline phase that usually lasts for weeks to months.

SMA type 0 neonates have onset of weakness in utero and present with arthrogryposis at birth. Respiratory distress and facial weakness can be present in addition to profound hypotonia and limb muscle weakness. Most of these patients die in the first weeks of life. SMA type 1 or Werdnig–Hoffmann disease presents between birth and 6 months of age. Some of these neonates become symptomatic soon after birth, while others come to medical attention at several months of age in the setting of respiratory or feeding difficulties. Typical patients have profound hypotonia and severe weakness affecting legs more than arms, and proximal more than distal muscles. Usually there are no antigravity movements of the more proximal limb muscles with some movements distally at the level of ankles/wrists or fingers/toes. Deep tendon reflexes are absent, and facial muscles are unaffected. In fact, these infants tend to have a very bright facial expression, however bulbar weakness with dysphagia and poor feeding are often present, as are tongue fasciculations. Various degrees of respiratory insufficiency are present at the time of diagnosis. Because of the disproportionate involvement of the intercostal muscles and relative sparing of the diaphragm, a "bell-shaped" chest conformation is noted. Contractures are not part of the typical initial presentation of SMA, although they can develop after prolonged immobilization. Typically, respiratory function declines over time, with historic cohorts requiring respiratory support by BiPAP or invasive ventilation in the first year of life.[34]

Diagnostic evaluation is often broad initially, beginning with CPK testing, which can be normal to mildly elevated (up to 500 IU/L), however genetic testing is imperative, with testing of *SMN1* and *SMN2* copy number variants. Most cases of 5q SMA are secondary to a homozygous deletion of the *SMN1* gene, and as noted, the copy number of *SMN2* modifies phenotype. In cases where genetic testing is unrevealing, EMG and/or muscle biopsy can be considered to aid in localization and subsequent targeted genetic testing of less common causes of SMA.

Until 2016, treatment for SMA was supportive, without therapeutic options; now, there are three Food and Drug Administration (FDA) approved drugs for the most common cause of SMA, which has altered the landscape for clinical degree of concern, testing, treatment, and outcomes.[37–39]

With the advent of therapeutic options as discussed below, there are moves toward universal newborn screening, given the recognition that early treatment augments outcome. In the United States, SMA is one of the disorders nationally recommended to be on the newborn screen, however implementation is at the state level, with nearly three-fourths of states screening as of May 2021.[40]

Any infant with positive newborn screen for SMA should undergo confirmatory genetic testing of *SMN1* and *SMN2* copy numbers, alongside consultation of neurology. Involvement of the neurologist and pulmonologist can aid in next steps on potential treatment. Consensus guidelines are available for management of the neonate with positive newborn screen findings for SMA.[41,42]

There are currently three FDA-approved medications for SMA: nusinersen (brand name Spinraza), onasemnogene abeparvovec (brand name Zolgensma), and risdiplam (brand name Evrysdi). Nusinersen is an mRNA antisense oligonucleotide, while risdiplam is an mRNA splicing modifier, both acting to increase survival motor neuron protein via the *SMN2* gene. Nusinersen is administered intrathecally, while risdiplam is administered orally. In the sentinel Phase 3 clinical trial, 37 of 73 SMA type I patients who received intrathecal nusinersen gained motor milestones compared to 0 of 37 patients who received sham injections.[43] Providing more hope for presymptomatic treatment was a Phase 2 trial of 25 asymptomatic newborns predicted to have type I or II SMA phenotype based on absence of SMN1 and copy numbers of SMN2, where 22 of 25 patients achieved independent ambulation during the 2.9 years of follow up.[44]

Onasemnogene abeparvovec (AVXS-101) utilizes adeno-associated virus, serotype 9 (AAV9) vector to delivery SMN1 gene. In the sentinel study, 15 patients with SMA type I treated with onasemnogene abeparvovec survived, were event free, defined as not requiring respiratory support for greater than 16 hours continuously for 14 days in the absence of an acute reversible illness or perioperative state at 20 months of life, and gained motor milestones after a single intravenous dose.[45] Onasemnogene abeparvovec is currently approved for those under 2 years of age.[38]

Risdiplam is the most recently approved medication (August 2020) for SMA, and is the only approved oral medication.[39] Like nusinersen, risdiplam is a small molecule, however, it is noted to affect expression of SMN protein in peripheral tissues in addition to the CNS/motor neuron. Based on two open-label studies (ClinicalTrials ID NCT02913482, NCT02908685) FDA approval was given due to clinical improvement. Currently, part 1 outcomes are available, which demonstrated increased SMN protein concentration in the blood.[46]

Non-5q Spinal Muscular Atrophies

Non-5q SMAs comprise a genetically and phenotypically heterogeneous group of disorders that share motor neuron involvement. Different classifications are used, including mode of inheritance and pattern of muscle involvement. Some of these disorders are important entities for neonatologists, while others are not seen in newborns. Although rare, two etiologies that may present in the neonatal period are addressed below.

Spinal Muscular Atrophy With Respiratory Distress

Spinal muscular atrophy with respiratory distress (SMARD) represents a group of motor neuron disorders that present at birth but are notable by a rather sudden and severe respiratory insufficiency that leads to a requirement for ventilatory support as well as predominantly distal weakness and distal contractures. Respiratory insufficiency is less common at birth, but more often noted between 6 weeks and 6 months of life. Diaphragmatic weakness leading to diaphragmatic eventration is characteristic. Clinically, SMARD can be distinguished from 5q SMA by diaphragmatic weakness and eventration with resultant normal thoracic appearance and lack of the "bell-shaped" chest. Distal weakness with contractures can be present, versus the proximal predilection

of 5q SMA. Several genes have been identified, most notably *IDHMBP2* (immunoglobulin μ-binding protein 2), which results in SMARD, type 1.[47]

Current management for SMARD is supportive. Restrictive lung disease is the main cause of morbidity and mortality. Swallowing difficulties, aspirations, and poor caloric intake are also common, leading to gastrostomy tube placement. Cognitive development is believed to be normal. Palliative care is often offered for the more severe cases, while milder cases may benefit from aggressive respiratory and gastrointestinal management. Late-onset forms with a milder phenotype have also been described.

Pontocerebellar Hypoplasia Plus Spinal Muscular Atrophy

Pontocerebellar hypoplasia is a heterogeneous group of inherited disorders that share hypoplasia or atrophy of the cerebellum and pons, with or without other brain or eye abnormalities.[48] Pontocerebellar hypoplasia type 1 can present with features of SMA, with pathologic studies demonstrating anterior horn cell degeneration. Several genes have been implicated, most commonly *EXOSC3*, with increasing knowledge of the genotypic-phenotypic variation in presentation.[49–52] All are inherited in an autosomal recessive pattern. Although the severity and age of onset varies, neonatal presentation includes hypotonia and weakness, contractures, and respiratory distress as well as encephalopathy given pontocerebellar findings. Management is supportive.

Neonatal Neuromuscular Junction Disorders

Transient Neonatal Myasthenia Gravis

Maternal myasthenia gravis is an autoimmune disorder caused by antibodies to acetylcholine receptor (AChR) or to the muscle-specific tyrosine kinase (MuSK). In a subset of mothers with myasthenia gravis, neonates develop transient weakness, often initially presenting as feeding difficulty or bulbar weakness, but can progress to respiratory failure requiring ventilatory support. Most commonly, this is in the setting of AChR receptor antibodies, however there are case reports of involvement in the setting of MuSK antibodies, which can present more severely.[53,54] Interestingly, neonatal disease does not appear to be related to antibody level in the mother, thus requiring all neonates born to mothers with disease to be monitored closely. While neonatal symptoms can occur immediately after birth, they may not develop until a few days after birth. Therefore, newborns of mothers with myasthenia gravis should be observed between 2 and 4 days post birth.[55,56] Affected newborns should receive supportive care such as nasogastric feeds or ventilatory support. Pyridostigmine is indicated in those with maternal AChR antibodies, and intravenous immunoglobulin can be considered in severe cases.[56]

Congenital Myasthenic Syndromes

Congenital myasthenic syndromes (CMS) include a growing number of heterogeneous disorders that are all characterized by the failure of neuromuscular transmission secondary to a genetic defect. A significant proportion of CMS cases present in the neonatal period or early infancy; however, presentation can be subtle, and diagnosis may be delayed by years. The general clinical characteristics include fatigable muscle weakness involving the extraocular, bulbar, respiratory, and limb muscle systems in different combinations.[57]

Certain patterns are unusual enough to deserve special mention. *Dok7* CMS patients can present in the neonatal period with stridor due to bilateral vocal cord paralysis, respiratory distress, and feeding difficulties. Intubation and ventilator support are necessary for some patients.[58] Choline acetyltransferase mutations lead to hypotonia with marked bulbar symptoms and respiratory insufficiency in the neonatal period followed by life-threatening episodes of apnea later in infancy.[59] In a retrospective review of CMS cases presenting in early infancy, 8 out of 11 patients presented at birth in general with severe respiratory distress in addition to hypotonia, weakness, and contractures.[60]

Laboratory evaluation for CMS is usually unremarkable, with normal CPK. Muscle biopsy is either unremarkable or shows mild nonspecific findings. Guidance to diagnosis comes from EMG with repetitive nerve stimulation, which historically has been paramount in the establishment of a neuromuscular junction defect. Increased availability of genetic testing has reduced the necessity of electrophysiologic testing and should be considered in the setting of phenotypic variability in presentation.

Pyridostigmine is the most commonly used medical treatment for CMS. Although a good number of CMS patients respond partially to pyridostigmine, patients with certain types of CMS may worsen. Close observation is needed when pyridostigmine is administered, especially if the exact type of CMS is not known. Other medical treatments may be available, depending on the specific CMS identified; for example, patients with *Dok7* mutations may respond to oral albuterol.[61] Respiratory support remains important though. Noninvasive ventilation is preferred as some patients improve with age. Nutritional support with a gastrostomy tube should be considered.

Peripheral Neuropathies

Hereditary peripheral neuropathies are a rare cause of floppy infant syndrome in the neonatal period. The presentations in the neonatal period can vary from severe hypotonia and weakness with respiratory difficulties, to milder with feet deformities.[62] Electrophysiologic studies will confirm the neuropathy and orient the genetic testing by subdividing them into axonal versus demyelinating. Management is supportive.

Approach to the Hypotonic Newborn

The field of pediatric neuromuscular disorders has exploded following the genetic advances of the last two decades. While the old clinicopathologic classification remains useful, advances in genetics have elucidated the degree of genotypic-phenotypic variability and have implications in the approach to diagnostic evaluation. Hypotonia in the newborn can occur from many reasons, including neurologic, systemic (such as sepsis), and genetic such as trisomy 21 or Prader-Willi syndrome. Neurologic etiologies can originate across the neuroaxis, from central to peripheral (neuromuscular) etiologies. Central causes constitute the majority of cases, accounting for between 60% and 80% of hypotonic newborn.[63,64]

Initial efforts to evaluate hypotonia start with history and physical examination, including a neurologic examination. Historical features include quality of reported fetal movements and complications such as polyhydramnios or previous pregnancy losses. Polyhydramnios suggests poor swallowing ability in utero. Three generations of family history can identify other affected family members, recognizing limitations given intrafamilial variability of neuromuscular conditions. Examination of the neonate's mother for grip myotonia and querying maternal history of easy tripping or muscle stiffness such as hand cramping will help point the clinician toward congenital myotonic dystrophy. This is something that should be done each time a newborn is evaluated for hypotonia; grip myotonia can be tested by asking the mother to squeeze her hand tight and quickly let go, or by testing for percussion myotonia at the thenar eminence or brachioradialis.

Examination of the floppy newborn should include delineation of hypotonia (axial vs. proximal vs. distal vs. diffuse) as well as degree of weakness. Hypotonia is when the tone of the muscle is decreased, whereas weakness refers to decreased muscle strength. Weakness equal to or greater than hypotonia is suggestive of a peripheral etiology and can be further classified as primarily proximal or distal, while weakness that is minor as compared to hypotonia is more suggestive of a central etiology. Weakness can be noted by a newborn's ability to generate strength, even if hypotonic. The presence or absence of deep tendon reflexes, the resting position, and the frequency of spontaneous movements are important.

Central hypotonia is more common than neuromuscular causes, with 60% to 80% of neonatal hypotonia in this category.[63,64] Signs and symptoms suggestive of CNS involvement include, but are not limited to, microcephaly or macrocephaly, hyperreflexia, encephalopathy, seizures, dysmorphic features, history suggestive of hypoxic-ischemic injury, severe hypotonia in a setting of mild weakness, and metabolic derangements. A history of hypoxic-ischemic injury is not mutually exclusive for a neuromuscular condition, as many of these conditions place the newborn at risk for hypoxic-ischemic injury in and of themselves, and thus detailed prenatal and perinatal history obtained in those presenting with presumed hypoxic-ischemic injury should still assess for signs of hypotonia prior to delivery. MRI of the brain should be obtained in newborns with hypotonia. In most neuromuscular conditions, these studies are normal. Pontine and cerebellar hypoplasia will point in the direction of SMA with PCH. Some forms of CMD can often present with significant brain malformations, as mentioned above. The white matter changes described in merosin-deficient CMD are not apparent in the neonatal period.

In addition to the history and physical examination, the tools available to the clinician include the following:

1. CPK
2. EMG with nerve conduction studies
3. Muscle biopsy
4. Genetic testing

Few gestalt diagnoses exist. Congenital myotonic dystrophy presents with typical facial features. If this is combined with maternal myopathic facial appearance and grip myotonia, one may go straight to genetic confirmation. The presentation of SMA in the neonatal period is another situation when gestalt diagnosis is possible for the experienced neonatologist and is increasingly available on newborn screen.

Creatine Phosphokinase

CPK is a rapid test that should be performed when a neuromuscular condition is first suspected. Significantly elevated values (more than five times normal) will point toward a muscle disorder, more likely a CMD. Normal or mildly elevated values can be seen in congenital myopathies and SMA.

Electromyography

Seen as a difficult test to perform in newborns, when performed by experienced electrophysiologists, EMG can be of immense help. The main advantage of EMG is a rapid, on the spot, diagnosis of a neurogenic process versus myopathic process versus neuromuscular junction defect. Given increasing availability of genetic testing, pragmatically, EMG is now often reserved when genetic testing options are limited, or targeted genetic testing is required.

Muscle Biopsy

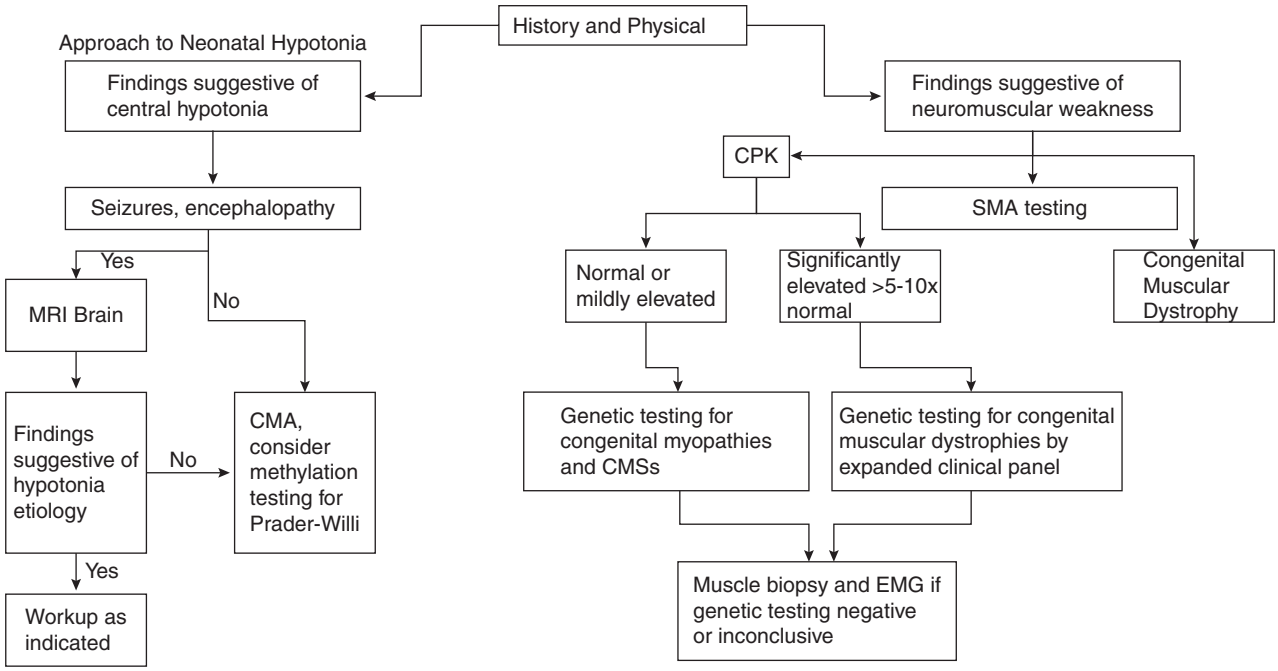
Despite advances in genetic diagnosis, muscle biopsy remains an important tool in the diagnosis of neuromuscular disorders. Its main utility consists in identification of particular types of congenital myopathy or CMD and, as a consequence, directing the genetic testing toward smaller panels of genes. As the pricing of genetic testing is decreasing, it is becoming feasible to start the work-up with genetic testing and employ muscle biopsy only if the first round of genetic tests fails to reveal a genetic abnormality.

Genetic Testing

The availability of genetic testing has increased exponentially in the last decade. A clinicopathologic diagnosis is no longer sufficient, and every effort should be made for genetic confirmation. Single genes as well as panels of genes are now commercially available from multiple commercial laboratories.

In newborns with multiple congenital abnormalities in addition to hypotonia, genetic testing should begin with karyotype and chromosomal microarray (CMA). Microarray may also detect Prader-Willi syndrome, as can methylation testing. Increasingly, whole exome sequencing is available, and is noted to provide diagnoses in 25% to 49% of cases in concerns for pediatric neuromuscular disorders or neurologic disorders.[65–69] Notably, whole exome sequencing has limitations: secondary to technical limitations, it cannot assess for trinucleotide repeats, and thus will not detect disorders with anticipation, such as congenital myotonic dystrophy. Additionally, it may not detect copy number variants, or certain single gene deletions secondary to probe size. Concomitant chromosomal microarray may aid in this detection.

There is increasing interest and availability of whole genome sequencing as well, which has been used to evaluate critically ill neonates using trio technique (e.g., testing the patient, as well as biologic mother and father).[70,71] Limitations currently include availability of this testing, and challenges in interpretations of variants in noncoding regions. A suggested approach to evaluating neonatal hypotonia is presented in Fig. 57.1.



• **Fig. 57.1** Diagnostic approach to neonatal hypotonia. *CMA*, Chromosomal microarray; *CMS*, congenital myasthenic syndrome; *CPK*, Creatine phosphokinase; *EMG*, electromyography; *SMA*, spinal muscular atrophy.

Neonatal Seizures

JENNIFER C. KEENE, NIRANJANA NATARAJAN, AND SIDNEY M. GOSPE JR.

KEY POINTS

- Neonatal seizures are common.
- Clinical assessment alone is insufficient for diagnosis, and EEG evaluation is necessary.
- Seizures are often symptomatic of an underlying cause requiring investigation.
- Confirmed seizures should be treated with antiseizure medications.

Neonatal Seizures

Seizures in the neonate occur in 2 to 4 per 1000 live births and are a cause of neonatal morbidity and mortality.[1–3] Frequently, this onset is a neurologic emergency, requiring prompt and thorough diagnostic investigations and therapeutic interventions. Seizures in the newborn may be transient due to electrolyte abnormalities, the harbinger of underlying brain injury or developmental abnormalities, or the initial presentation of an underlying epilepsy. The clinical appearance of seizures in the neonate differs from that seen in older infants and children. Seizures themselves may be subtle, or without clinical manifestations, and challenging to differentiate from other involuntary movements in the neonate. There are ongoing efforts to determine how aggressively to treat seizures, which medications to use, how long to treat, and the impact of neonatal seizures on neurodevelopmental outcomes.

This chapter discusses the diagnosis, neurophysiologic criteria, etiologic considerations, treatment, and prognosis of neonatal seizures. For the purposes of this chapter, the term *seizure* refers to an *epileptic event*: that is, an event with an electrographic correlate.

Classification of Neonatal Seizures

Seizures in the neonate often are often difficult to clinically differentiate from nonepileptic movements and may present differently than seizures in older infants or children. In 2021, the International League Against Epilepsy (ILAE) published a new framework for the classification of neonatal seizures.[4] The updated classification system emphasizes the need to incorporate electroencephalography (EEG) evaluation (Fig. 58.1), as fewer than 50% of paroxysmal clinical events are correctly identified as seizure versus non-seizure, with poor inter-observer agreement, regardless of the observer's specialty.[5] The ILAE classification system recognizes that approximately 50% to 80% of neonatal seizures are electrographic only and categorizes electroclinical seizures as either (1) motor seizures characterized by abnormal movements, (2) nonmotor seizures characterized by autonomic changes or behavioral arrest, or (3) sequential seizures or unclassified (Table 58.1).[6–9]

Motor Seizure

Automatisms

Neonatal seizures with automatisms are typically manifested as oral–buccal–lingual movements, often with impairment of consciousness. They may be seen in conjunction with other seizure types, such as clonic or sequential seizures. These seizures often appear voluntary and are notoriously difficult to determine clinically. Seizures may have associated vital sign changes, including otherwise unexplained fluctuations in heart rate, blood pressure, or oxygen saturation. As more benign movements may mimic the motor features of these seizures, confirmation with EEG is mandatory.

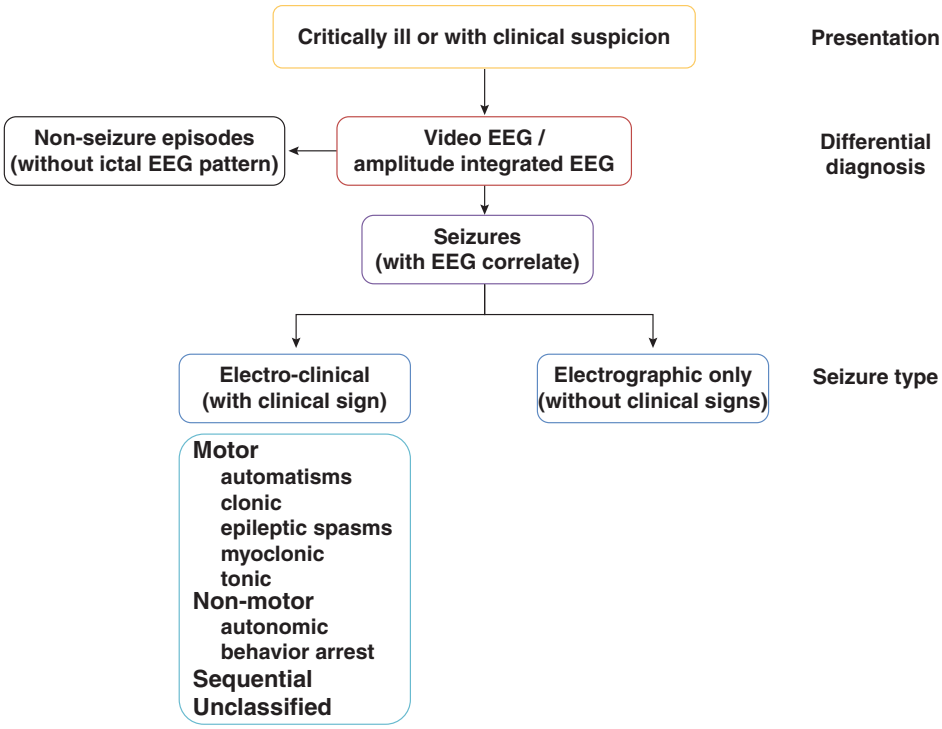
Clonic Seizures

Clonic seizures are characterized by rhythmic movements with a rapid flexor phase followed by a slower extension phase persisting despite flexion of the affected limb. Movements may be symmetric or asymmetric. Clonic seizures can be mistaken for nonepileptic phenomena such as tremor or jitteriness and may be differentiated by the rhythmicity of the event and its ability to be suppressed or altered by changes in positioning.

Focal clonic or hemiclonic seizures can be seen in neonates with injury localized to a specific site, such as a perinatal stroke or another cerebrovascular event.[10–13] Multifocal seizures—clonic seizures that arise, at times, from multiple locations—can be seen in neonates with multifocal or generalized brain abnormalities, such as hypoxic-ischemic encephalopathy.

Myoclonic Seizures

Myoclonic movements are rapid, lightning fast (<100 ms) jerks that can be focal, multifocal, or generalized in nature. Myoclonus can occur at multiple levels of the nervous system: cortical regions, brainstem, and spinal cord. Myoclonus may be epileptic (myoclonic seizures) or nonepileptic, requiring EEG with an electromyography (EMG) channel to differentiate. Myoclonic seizures are most often seen in inborn errors of metabolism and early onset genetic epilepsies.[10,14–17]



• **Fig. 58.1** Diagnostic framework of seizures in the neonatal period including classification of seizures. Neonates present with discrete events suspected to be epileptic seizures or are critically ill (often ventilated, sedated, and treated with muscle relaxants in the neonatal intensive care unit). (From Pressler RM, Cilio MR, Mizrahi EM, et al. The ILAE classification of seizures and the epilepsies: modification for seizures in the neonate. Position paper by the ILAE Task Force on Neonatal Seizures. *Epilepsia*. 2021;62:615–628.)

TABLE 58.1 Seizure Types

Seizure Type	Characteristics	Nonepileptic Differential
Electrographic only	No clear clinical manifestations	None
Motor: Automatisms	Coordinated motor activity, typically oral, often associated with impaired consciousness	Normal behavior
Motor: Clonic	Rhythmic jerking, focal symmetric or asymmetric	Tremor Jitteriness
Motor: Epileptic spasms	Sudden extension/flexion, predominantly involving proximal extremities and trunk, often in clusters	Nonepileptic myoclonus
Motor: Myoclonic	Lightning-fast jerk of a single limb or of multiple extremities	This can be epileptic or nonepileptic
Motor: Tonic	Stiffening of an extremity or hemibody	Provoked bilateral posturing "Brainstem release phenomena" Gastroesophageal reflux
Nonmotor: Autonomic	Paroxysmal alteration of cardiovascular, pupillary, vasomotor, or respiratory function with ictal EEG correlate	Nonepileptic apnea, tachycardia, or autonomic fluctuation
Nonmotor: Behavioral Arrest	Pause in normal activities with ictal EEG correlate	Normal behavioral pause
Sequential	Variable progression of clinical features with ictal EEG correlate	Behavioral movements

Epileptic Spasms

Epileptic spasms in neonates consist of sudden flexion or extension of the proximal and truncal muscles. Duration is longer than myoclonic movements but briefer than tonic seizures and can occur in clusters. Subtle forms can consist of grimacing, head nodding, or eye movements. EEG is required to differentiate from a nonepileptic phenomenon and often requires an EMG channel to differentiate from myoclonus not originating from the central nervous system. These are rare in the neonatal population and classically have been associated with inborn errors of metabolism.[14–23]

Tonic Seizures

Tonic seizures are those with sustained flexion or extension of a muscle group lasting seconds to minutes. Tonic seizures can affect both limbs, eye muscles with sustained eye deviation, or the neck with head version. Neonatal tonic seizures may be focal, unilateral, or bilateral asymmetric and are commonly seen in early infantile onset epileptic encephalopathies.[10,16,23,24]

Nonepileptic bilateral tonic extension not having a correlate on EEG[7] may represent "brainstem release" in the setting of extensive cortical dysfunction. This cortical dysfunction may allow uninhibited subcortical expression to occur. Other movements that may be misidentified as tonic seizures include dystonic posturing and may coexist in neonates with seizures, especially in the setting of brain injury.

Nonmotor Seizure

Autonomic Seizure

Autonomic seizures are defined as paroxysmal onset of alteration in cardiovascular, pupillary, gastrointestinal, vasomotor, or respiratory without alternative explanation and with EEG epileptic correlate. Neonatal seizures with isolated autonomic features are rare with less than 5% of studies obtained for isolated apnea having an ictal correlate,[25] but can be seen in intraventricular hemorrhage, temporal lobe and occipital lesions, and occasionally in early-onset epileptic encephalopathies.[7,18,26,27]

Behavioral Arrest

Ictal behavioral arrest is difficult to ascertain in neonates and is rarely seen in isolation. More commonly, a pause in ongoing activities is seen as part of a sequential seizure.[10,18] EEG is required to differentiate ictal behavioral arrest from nonepileptic behavioral pause.

Sequential Seizure

Neonatal seizures are classified as sequential when there is no single predominant ictal feature, and events instead progress through a series of features with associated EEG changes.[4] The individual features and lateralization may change within or between seizures. This type of seizure was classically associated with KCNQ2 encephalopathy but has been described with other genetic epilepsies.[24,28–31]

Nonepileptic Neonatal Movements

Newborns are prone to a variety of movements that may raise suspicion for seizures but represent other neurologic or nonneurologic entities.[5] Common nonepileptic mimics which can be differentiated from seizures with EEG[32] include tremulousness or jitteriness, nonepileptic myoclonus, dyskinesias, and hyperekplexia.

Tremulousness or Jitteriness

Tremors can be seen frequently in the neonate and can be mistaken for clonic activity. The phenomenology of this movement is flexion and extension, with equal phases and amplitude of both, distinguishing this from clonic activity. Repositioning of the affected limb may often decrease or extinguish the movement, as can flexion. Neonates may be alert or hyperalert, although this may also be present in neonates with somnolence secondary to encephalopathy. Tremors may be asymmetric in nature and of varying amplitudes. Movements can be spontaneous or induced by stimulation.

Tremors, as well as jittery movements, can occur secondary to metabolic derangements such as hypoglycemia or hypocalcemia, as well as in intracranial hemorrhage, newborns with growth restriction, and hypothermia. Exposure to maternal medications such as selective serotonin reuptake inhibitors (SSRIs) or illicit substances including cocaine and marijuana has also been associated with tremulousness.

Jitteriness is common in both healthy and ill neonates, with one study showing mild, moderate, or excessive jitteriness in 44% of healthy term infants. Movements generally decrease with increasing postconceptional age, with a normal neurologic outcome.[33]

Myoclonus Without Electrographic Correlate

Myoclonus is defined as brief shock-like movements caused by sudden involuntary contraction or relaxation of one or more muscles, often occurring as repetitive nonrhythmic movements.[34] Nonepileptic myoclonic movements may originate from multiple levels of the neuroaxis and are more frequent in preterm newborns but also occur in term neonates. It can be benign in some instances, while a harbinger of underlying abnormalities in others.

Myoclonus occurring in an infant with encephalopathy is not typically benign. In this case, myoclonus may be stimulus-induced and occur in the setting of severe brain injury. Myoclonus in the neonate with encephalopathy may also occur in the setting of encephalitis or meningitis, intraventricular hemorrhage, periventricular leukomalacia, or genetic[35] or metabolic disorders such as glycine encephalopathy.[17,20,21,36] In these latter cases, the EEG background is typically abnormal and may have epileptiform discharges, although the myoclonus itself lacks epileptiform correlate.[36]

Midazolam-induced and lorazepam-induced myoclonus are reported in preterm or very low birth weight neonates.[37–39] If medication-induced myoclonus occurs, further use of the offending drug should be limited in the neonatal period where possible. As the response is thought to be developmental, the use of benzodiazepines need not be avoided in infancy or childhood.

Benign neonatal sleep myoclonus is considered a diagnosis of exclusion.[40] Suspicion for this should arise when myoclonus occurs in an otherwise healthy newborn only during sleep, resolves with awakening, and is typically arrhythmic and of varying amplitude. It may increase with attempts of physical restraint or be induced by rocking and occurs in all stages of sleep.[41] This typically resolves by 3 months of age, although some infants may have symptoms until 6 to 12 months of age.[41]

Dyskinesias

Dystonic and dyskinetic movements are frequent and commonly mistaken for seizures. Dystonia is the involuntary sustained or intermittent co-contraction of agonist and antagonist muscles resulting in abnormal posture.[34] This group of movements is associated with dysfunction of the basal ganglia or the extrapyramidal pathways and can occur secondary to acute or chronic injury of these structures. In the neonate, it often represents intrapartum or antepartum injury with severe injury to the basal ganglia.[42] Some inborn errors of metabolism may present with hypertonicity, opisthotonic posturing, or dystonia (e.g., maple syrup urine disease, monoamine neurotransmitter disorders).[43,44] As dyskinetic and dystonic movements are frequent in encephalopathic neonates who may also have epileptic events, the use of continuous video

EEG is imperative to prevent misdiagnosis and inappropriate treatment of either diagnosis.

Hyperekplexia

Hyperekplexia is characterized by an exaggerated startle reflex that does not typically extinguish and is associated with hyperreflexia, and hypertonia. It has predominantly been described as an autosomal dominant disease associated with mutation of the inhibitory glycine receptor gene, although rare cases of autosomal recessive disease have been reported.[45] Hyperekplexia is an important differential for paroxysmal events in the neonate as it is associated with sudden death secondary to apnea and is readily treated with scheduled benzodiazepines.[46,47] The associated apneic spells can be mitigated by the use of the Vigevano maneuver, which utilizes forced flexion of the head and legs towards the trunk.[48]

Evaluation of Neonatal Seizure

Medical providers of various backgrounds have been shown to have difficulty determining whether events represent seizures or not, based on clinical features alone. In an observational study over 70% of events identified as seizures were not found to have an electrographic correlate.[49] When experienced neonatal healthcare providers were evaluated with standardized video clips of neonatal seizures and seizure mimics, seizures were correctly identified approximately 50% of the time.[5] Additionally, since up to 80% of the seizure burden identified in prospective cohorts are electrographic only, identification of seizures by clinical criteria alone underestimates the actual number of seizures.[49,50] With this in mind, it is recommended that all events concerning for seizures be confirmed electrographically.[32] Commonly utilized tools include amplitude-integrated EEG (aEEG) and continuous electroencephalography (cEEG).

Neurophysiologic Diagnosis of Seizure

A standardized definition and characterization of neonatal seizures has been published by the American Clinical Neurophysiology Society.[51] To be considered a seizure, rhythmic activity must last 10 seconds with a minimum of 2 μV peak-to-peak voltage that evolves in quality and subsequently resolves. Events with these characteristics lasting less than 10 seconds are referred to as *brief rhythmic discharges*, and while they are not consistent with seizures, they suggest an increased risk of developing seizures.

Status epilepticus, defined in older children or adults as a seizure lasting greater than 30 minutes, or more than one seizure without a return to baseline in between, is not an appropriate definition in neonates, particularly given the often comorbid encephalopathy and overall challenges in determining true return to baseline. In neonates, the definition of status epilepticus has been established as seizures constituting greater than 50% of an hour-long epoch, which is arbitrarily defined.[51]

Amplitude-Integrated Electroencephalography

Many institutions incorporate aEEG to aid in the detection of seizures. aEEG is a cerebral function monitor widely available as a bedside tool that utilizes 2 to 4 leads, typically placed over the central and parietal regions. The minimum and maximum amplitude during each time epoch are abstracted and typically used to create a single compressed tracing per hemisphere.[52] During a seizure, there is a sudden and sustained increase of the lower and upper margins on aEEG, with raw EEG signal demonstrating a monomorphic waveform consistent with seizure.[53]

Advantages of aEEG include bedside availability and interpretation, as well as reduced cost as compared with continuous EEG monitoring.[53] However, aEEG has well-demonstrated limitations, including challenges in the detection of brief or low-amplitude seizures or seizures that do not occur in the brain regions covered by the aEEG electrode montage.[54] In a concurrent evaluation of aEEG and cEEG in 125 neonates with seizures greater than 34 weeks of age, neonatologists were able to detect on aEEG between 12% and 38% of individual seizures identified on cEEG and correctly identify between 22% and 57% of neonates with seizures.[54] aEEG may also be limited by artifactual signals from movement, high-frequency oscillator ventilation, or extracorporeal membrane oxygenation. In contrasting studies of prospectively evaluated premature infants, aEEG found a seizure incidence of 48%[55] while cEEG evaluation of a similar cohort demonstrated only 5% incidence of seizures,[56] raising concerns that particularly in the preterm population, aEEG may be prone to artifact and misinterpretation. Consequently, it is recommended that aEEG be used as a screening tool where cEEG is limited. However, cEEG should be used when seizures are suspected on aEEG.[57,58]

Continuous Electroencephalography

Continuous EEG is an invaluable tool and the gold standard for neonatal seizure detection. Multiple electrodes are placed in accordance with the international 10–20 system, or with the modified neonatal montage, alongside a single electrocardiogram lead and respiratory belt. Interpretation of cEEG requires mastery of the normal and abnormal patterns of term and preterm wakefulness and sleep. Aid from the EEG technologist or bedside nurse is imperative to note potential events of concern and artifacts (such as nursing care, feeding, etc.).

The American Clinical Neurophysiology Society developed guidelines in 2011 on the use of cEEG monitoring in high-risk neonates.[32] While it is recognized that not all facilities will have the resources necessary to monitor, this guideline provides goals as to how to monitor for seizures in high-risk neonates or which neonates with suspicious events should be evaluated with this technology. Populations in which cEEG use is recommended include acute brain injury secondary to perinatal asphyxia, neonates with clinically suspected seizures, and when neonatal epilepsy is suspected. In some instances, it may be appropriate to continue monitoring after the withdrawal of antiseizure medications (ASMs). Although seizures in the setting of acquired brain injury are not likely to recur shortly after the resolution of the acute injury, those with neonatal epilepsy syndromes or cerebral malformations may deserve monitoring when ASMs are discontinued. It is recommended that neonates remain monitored for a 24-hour period once seizure-free.

Quantitative Electroencephalography

Quantitative EEG (qEEG) is the use of sophisticated algorithmic support to evaluate EEG background trends and seizures in real time. The initial development of seizure detection algorithms focused on older populations and was inaccurate in identifying neonatal seizures.[59] Randomized controlled studies evaluating neonate-specific seizure detection algorithms have

recently demonstrated decreased seizure burden when qEEG is employed in addition to clinician review.[60] Preterm-specific qEEG analysis techniques are being developed to aid in maturational analysis and prognosis, but the burden of artifacts associated with preterm neonatal care remains a significant challenge.[61]

Electroclinical Uncoupling

Administration of ASMs in the setting of electroclinical seizures can result in a phenomenon where electrographic seizures persist while the clinical manifestations resolve. This is termed *electroclinical uncoupling*. One study estimated that 25% of neonates had persistent electrographic seizures after receiving ASMs despite the resolution of clinical seizures.[62] This information suggests that neurophysiologic monitoring is needed after treatment for neonatal seizures, even with an apparent resolution of clinical events.

Interictal Abnormalities

Beyond the determination of seizures, EEG detects interictal findings that aid patient management. The presence of background abnormalities may be serially followed to determine the progression of an encephalopathy.[62] While background findings may not be pathognomonic for particular etiologies, these findings, in conjunction with the remainder of the diagnostic work-up (history, clinical examination, and findings on laboratory and imaging studies), aid in the development of the overall prognosis for a patient.

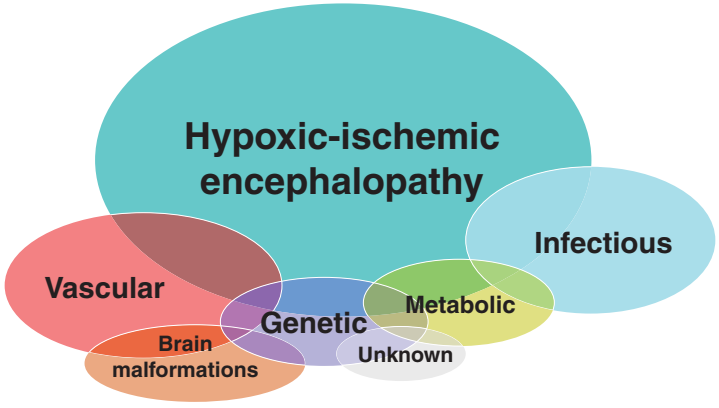
Etiologies of Neonatal Seizures

Once it is determined that a neonate is having seizures, further steps are divided into establishing the etiology of seizures, as well as the treatment of seizures. Neonatal seizures are not disease specific and can occur in a variety of conditions with onset before, during, or after birth. Seizures may occur in the setting of hypoglycemia or electrolyte disturbances such as hypocalcemia or hypomagnesemia and may respond to corrections of these disturbances. Seizures may harken underlying brain injury in the setting of hypoxic-ischemic encephalopathy, perinatal stroke, hemorrhage, trauma, or infection. Metabolic abnormalities, genetic defects, and congenital brain malformations are additional etiologic considerations (Fig. 58.2 and Table 58.2).[6]

TABLE 58.2 Differential Diagnosis of Seizure Etiology

Hypoxic-ischemic encephalopathy	Pre- and peripartum
Metabolic derangement	Hypoglycemia Hypocalcemia Hypomagnesemia Hyponatremia Hypernatremia
Cerebrovascular lesions	Perinatal arterial or embolic stroke Hemorrhage Cerebral sinus venous thrombosis Cortical vein thrombosis Hemorrhagic venous infarction
Infection	Bacterial meningitis Viral encephalitis TORCH infections
Drug exposure/ withdrawal	Includes but not limited to: Methadone Cocaine SSRIs
Congenital brain malformations	Includes but not limited to: Polymicrogyria Hemimegalencephaly
Inborn errors of metabolism	Includes but not limited to: Glycine encephalopathy Aminoacidopathies Urea cycle defects Pyridoxine-dependent epilepsy
Benign neonatal familial seizures	Caused by a mutation in one of the following genes: *KCNQ2* *KCNQ3* *SCN2A*
Progressive epilepsy syndromes	Includes but not limited to mutations in the following genes: *STXBP1* *FOXG1* *CDKL5* *KCNQ2*

SSRIs, Selective serotonin reuptake inhibitors; *TORCH*, toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex.



• **Fig. 58.2** Relative occurrences of common etiologies of neonatal seizures in term infants. (From Pressler RM, Cilio MR, Mizrahi EM, et al. The ILAE classification of seizures and the epilepsies: modification for seizures in the neonate. Position paper by the ILAE Task Force on Neonatal Seizures. *Epilepsia*. 2021;62:615–628.)

Hypoxic–Ischemic Encephalopathy

Hypoxia–ischemia is the most common cause of neonatal seizures. Multiple randomized controlled trials published between 2005 and 2012 establish therapeutic hypothermia as the standard of care[63] for neonates with moderate to severe hypoxic-ischemic encephalopathy (HIE), which is also the population most likely to experience seizures. Further discussion of therapeutic hypothermia is included in Chapter 55 on Neonatal Encephalopathy. Therapeutic hypothermia is geared toward the prevention of secondary energy failure and additional brain injury, and studies, since therapeutic hypothermia has become standard, suggest that this therapy decreases the rate of seizures by approximately half in infants with moderate HIE.[64,65]

In newborns with HIE, it is important to recognize that injury may occur antepartum, intrapartum, or postpartum. Risk factors particularly shown to be associated with seizure include placental lesions consistent with chronic asphyxia stress,[66] intrapartum fever,[67] placental separation, preeclampsia, and cesarean section performed because of hemorrhage, meconium-stained fluid, and shoulder dystocia.[68] Additional seizure risk factors include diabetes mellitus, advanced maternal age over 40 years, and maternal infection.[69]

Cerebrovascular Lesions

Ischemic or hemorrhagic lesions of either arterial or venous origin are associated with a high risk of seizure in the newborn.[70–74] In term neonates with perinatal arterial stroke, seizure is the most common clinical presentation, accounting for between 70% and 90%, followed by hypotonia or feeding difficulties.[75,76] Neonates with cerebral infarction often are otherwise healthy in appearance, with reassuring presentation, not consistent with asphyxia. The use of neuroimaging with magnetic resonance imaging is necessary to demonstrate the focal lesion.[77,78]

In preterm infants, intraventricular hemorrhage is the most common cause of seizures[79,80] and is the etiology of seizures in as many as 45% of EEG-confirmed seizures. Seizures in preterm newborns are thought to be underestimated, as studies prospectively assessing seizure frequency in high-risk preterm neonates find a higher incidence than in those where EEG is obtained in response to a clinical event.[53,79,81]

Cerebral venous infarction may also result in neonatal seizures.[74] This may occur in the setting of systemic infection, dehydration, or poor feeding leading to cerebral venous sinus thrombosis. In preterm infants, venous thrombosis may result in periventricular hemorrhagic infarction within the deep white matter, which may be complicated by seizures.[81]

Infants requiring congenital heart defect repair, with persistent pulmonary hypertension of the newborn, or requiring extracorporeal membrane oxygenation have an increased risk of seizures caused by recurrent hypoxia hypotensive injury and embolic infarction. EEG monitoring following cardiac surgery demonstrates approximately 10% of neonates experience clinical or subclinical seizures[82–86] and in children undergoing extracorporeal membrane oxygenation up to 30% demonstrate seizures.[86,87] The anticoagulation necessary for extracorporeal membrane oxygenation circuit use may convert an ischemic injury to a hemorrhagic one, with a risk of edema or herniation. The presence of seizures is associated with increased inpatient mortality and worsened neurodevelopmental outcomes.[82–84]

Infection

Central nervous system infections antepartum or postnatally can be associated with neonatal seizures.[88] The TORCH infections (toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes virus), as well as other viruses including Zika virus,[89] can produce structural brain changes resulting in a predilection for seizures and encephalopathy. These infections are discussed in detail in other chapters. Neonatal herpes encephalitis is associated with specific EEG findings, with focal or multifocal epileptiform discharges that may be periodic or quasiperiodic in nature.[90,91] Enteroviruses[92–94] and bacterial meningitis may also present with encephalopathy with seizures.[95,96] Some neonates with bacterial meningitis may suffer further complications of arterial stroke or cerebral venous sinus thrombosis, with further neurologic injury.[97] A prolonged course of seizures (>72 hours) or markedly abnormal EEG pattern is associated with poor outcome in this setting.[98,99]

Metabolic Derangements

Hypoglycemia, along with electrolyte disturbances such as hypocalcemia, hypomagnesemia, hyponatremia, or hypernatremia may result in seizures. Repletion of glucose and correction of electrolyte levels is imperative for treatment.

Hypoglycemia

Hypoglycemia is generally accepted as a glucose level less than 47 mg/dL, although the definition remains controversial.[100,101] Hypoglycemia may coexist with hypoxic-ischemic injury or with hypocalcemia, both of which may also result in seizures. Jitteriness, tremors, and abnormal tone may be present in neonates with hypoglycemia, mimicking seizures. Persistent or profound hypoglycemia may result in cerebral injury, classically described as white matter injury or occipital injury.[102,103] Seizures should first be treated by correction of hypoglycemia. Particularly if cerebral injury occurs, seizures may persist despite correction and require treatment with ASMs. Infants with hypoglycemia and cerebral injury may later develop occipital lobe epilepsy, although the severity of the epilepsy varies.[104]

Hypocalcemia

Hypocalcemia is defined as a total calcium level of less than 8.0 mg/dL (2 mmol/L) in term neonates and less than 7.0 mg/dL (1.75 mmol/dL) in preterm neonates or an ionized calcium of less than 4.8 mg/dL (1.2 mmol/L) in term infants and less than 4.0 mg/dL (1 mmol/L) in premature infants.[105] Neonates with hypocalcemia may present with seizures secondary to increased excitability of the cell membrane,[106] thus resulting in exaggerated startles, jitteriness, myoclonic jerks, or seizures.[107,108] Hypocalcemic seizures should be treated with calcium repletion.

Hyponatremia and Hypernatremia

Hyponatremia is a cause of seizures across the life span[106]; however, it is a relatively rare cause in neonates. When present, this may reflect iatrogenic causes, renal failure, a transient or constitutional defect in the mineralocorticoid pathway, or an inappropriate secretion of antidiuretic hormone.[109] Hypernatremic seizures are also rare in neonates but may be secondary to inadequate breastfeeding[110] or iatrogenic from the administration of intravenous solutions with high sodium concentrations.[111]

Drug Withdrawal and Intoxication

Newborns of mothers with prenatal substance use may be at an increased risk of seizures in the neonatal period. Prenatal exposure to opiates can result in neonatal abstinence syndrome, which, in severe cases, can result in seizures.[112] Similarly, perinatal exposure to alcohol intoxication is associated with withdrawal seizures.[113] Cocaine can produce seizures in neonates either secondary to intoxication, from withdrawal,[114,115] or from neonatal stroke, which in turn increases the risk of seizures. Exposure to other stimulants, such as methamphetamine, may be associated with a withdrawal syndrome accompanied by jitteriness, tremor, and exaggerated startle, but seizures have not been typically reported.[116]

Maternal use of SSRIs such as fluoxetine, paroxetine, and sertraline may also result in withdrawal symptoms including tremors, jitteriness, vomiting, diarrhea, and sleep disturbance. In some cases, convulsions may be present as a component of the withdrawal syndrome.[117] EEG remains imperative in diagnosis, however, as many abnormal movements noted may have an EEG correlate.

Congenital Brain Malformations

Approximately 9% of neonates presenting with seizures are found to have brain malformations.[80] These disorders are caused by alterations in stages of induction, segmentation, proliferation, migration, synaptogenesis, and myelination and are discussed in greater detail elsewhere in this text. Encephalopathy is typically present and may coexist or be mistaken for birth asphyxia. Many brain dysgenesis disorders lack specific physical examination findings, but magnetic resonance neuroimaging is appropriate to evaluate for underlying brain malformations. Neonates with brain dysgenesis and seizures in the neonatal period have an exceptionally high likelihood of subsequently developing epilepsy and requiring prolonged use of ASMs.[118]

Inborn Errors of Metabolism

Genetic biochemical abnormalities are rare causes of neonatal seizures, accounting for between 1% and 4% of cases.[119] Although uncommon, consideration of this etiology is imperative, as specific treatments may be available for some causes, based on the enzymatic defect uncovered. In cases where treatment is not available, prognostic implications remain essential. Inborn errors of metabolism causing seizures may be placed in three categories: defects in neurotransmission; disorders of energy production; and metabolic disorders resulting in brain malformation, destruction, or dysfunction.[120] Examples of each are given below, although an extensive review of inborn errors is beyond the scope of this chapter.

Signs suggestive of an inborn error of metabolism include seizures that start prenatally, refractory seizures requiring multiple ASMs, progressive clinical worsening, or deterioration of the EEG.[121] Some neonates may have an initial presentation consistent with HIE, thus a high level of clinical suspicion is necessary in neonates with refractory seizures. Specific neuroimaging may demonstrate characteristic lesions supporting a metabolic etiology.[122]

Defects in neurotransmission include glycine encephalopathy and pyridoxine-dependent epilepsy. Glycine encephalopathy, also known as nonketotic hyperglycinemia, is due to deficiencies in the ability to cleave glycine. Glycine has both inhibitory and excitatory neurotransmitter activities, and glycine encephalopathy presents with apnea, myoclonic seizures, and burst suppression on EEG. In retrospect, mothers will often note that significant hiccups were present in utero, representing fetal myoclonic seizures. Seizures may initially respond to benzodiazepines, but, long term, patients develop early myoclonic encephalopathy, or Ohtahara syndrome.[20,21]

Pyridoxine-dependent epilepsy is an uncommon but treatable cause of neonatal seizures, caused by deficiency of α-aminoadipic semialdehyde dehydrogenase, an enzyme involved in the lysine catabolic pathway. In retrospect, mothers may report paroxysmal in utero movements representing seizures, and newborns may present with seizures, encephalopathy, and hypotonia in the first few days of life.[123,124] In some patients with pyridoxine-dependent epilepsy, lactic acidosis and other biochemical abnormalities may be present, mimicking features of neonatal encephalopathy secondary to hypoxia or ischemia. It is an autosomal recessive condition, caused by a genetic mutation in *ALDH7A1*, and affected patients have elevated levels of α-aminoadipic semialdehyde (AASA) in blood and urine,[123,124] which is the standard screening laboratory evaluation. Recommended treatment and evaluation of neonates with refractory status epilepticus include an empiric trial of intravenous pyridoxine while carefully monitoring EEG for treatment response.

Examples of disorders of energy production and utilization include urea cycle defects and glucose transporter type 1 (GLUT1) deficiency. Urea cycle defects may present with encephalopathy and seizures in the setting of hyperammonemia as toxic breakdown products accumulate. Treatment includes dialysis or exchange transfusion while determining the enzymatic defect. Glucose transport to the brain is mediated by GLUT1. Reduced glucose transport through the blood-brain barrier results in hypoglycorrhachia (cerebrospinal fluid glucose levels less than 45 mg/dL or a ratio of cerebrospinal fluid glucose to serum glucose of <0.4). Patients may present in the first few months of life with significant seizures. Hypoglycorrhachia without alternate explanation should prompt further genetic testing of *SLC2A1*, the major genetic defect found in this disorder.[125] Over the past decade, the phenotype of patients has expanded significantly to include those with movement disorders or early-onset absence epilepsy.[126] Treatment of GLUT1 deficiency is the ketogenic diet, providing an alternative energy source to support brain metabolism.

Metabolic disorders resulting in brain dysgenesis and seizures include peroxisomal biogenesis disorders such as Zellweger syndrome. Infants present with characteristic facial features, hypotonia, and encephalopathy alongside seizures in the first days to weeks of life. Neuroimaging reveals neuronal migration defects such as polymicrogyria, while levels of very long chain fatty acids are elevated. Mutations in the *PEX* gene family have been associated with this group of metabolic disorders.[127]

Neonatal Epilepsy Syndromes

Seizures in the neonatal period are rarely the presentation of a chronic epileptic condition.[128] Affected neonates are more likely to present with myoclonic seizures with early myoclonic encephalopathy, tonic seizures, epileptic spasms, or sequential seizures.[4,10,14–16] These neonatal epilepsy syndromes may be termed *early infantile epileptic encephalopathy* or *Ohtahara syndrome*, and the EEG may demonstrate a suppression-burst pattern or disorganized background. Over the past decade, many genes have been associated with early-onset epileptic encephalopathies, including mutations in *ARX, CDKL5*, and *STXBP1*, among others.[129,130]

In neonates presenting with seizures for whom acute symptomatic causes have been ruled out, a genetic evaluation is

indicated.[131,132] Although there are some presentations with distinct features suggesting a targeted genetic evaluation, many neonatal epilepsy presentations have a high degree of phenotypic overlap. Combined with decreasing cost and increasing availability, this has shifted the testing paradigm towards an early, broad genetic evaluation with whole-exome[133,134] and increasingly whole-genome sequencing.[135]

Benign Familial Neonatal Seizures

A rare form of neonatal epilepsy that is inherited in an autosomal dominant pattern should be considered in newborns with a positive family history[136] or after structural, infectious, metabolic, and toxic causes have been ruled out. In a kindred with benign familial neonatal seizures, often the parents are unaware that they had a seizure in the newborn period until grandparents note this after their grandchild presents with neonatal seizures. Several genes have been implicated, including two potassium channel genes, *KCNQ2* and *KCNQ3*, as well as a sodium channel gene *SCN2A*.[137–139] *KCNQ2* mutations may also result in progressive epileptic encephalopathy; thus, caution should be exercised in counseling regarding prognosis.[140] Infants with benign familial seizures typically have a normal interictal EEG pattern and normal neuroimaging, while those who develop an epileptic encephalopathy tend to have abnormal EEGs with burst suppression, multifocal epileptiform discharges, and basal ganglia hyperintensities.[30] Infants with benign neonatal epilepsies tend to have a good response to ASMs, with reports of sodium channel agents being effective in those with *KCNQ2* mutations.[141]

Management of Neonatal Seizures

Once the diagnosis of neonatal seizures has been made, management is initiated while the determination of an etiology is under way. Rapid initial testing should detect correctable causes of neonatal seizures, such as hypoglycemia, hypocalcemia, or sodium disturbances. Hypoglycemia may be corrected with an infusion of 10% dextrose. Seizures caused by hypocalcemia should be treated with 10% calcium gluconate.[106] Magnesium levels should be checked and repeated if necessary, as hypomagnesemia may coexist with hypocalcemia. Hyponatremia or hypernatremia can be managed dependent on the etiology of sodium dysregulation. Concomitant use of ASMs is typically not needed for hypoglycemia and correctable electrolyte abnormalities.

Antiseizure Medication

Once metabolic derangements are addressed, treatment of seizures is undertaken with ASMs. As neonates may have both clinical and electrographic seizures, and treatment with ASMs may result in electroclinical dissociation, it is recommended that neonates undergoing treatment with ASMs be monitored through cEEG.[32]

Phenobarbital has remained the first-line choice for the treatment of neonatal seizures by most clinicians.[142,143] Phenobarbital is effective in the cessation of seizures in approximately 50% of neonates.[144,145] Phenobarbital is a barbiturate, acting on the γ-aminobutyric acid (GABA) receptor, enhancing GABA activity. Phenobarbital is typically given as an intravenous bolus of 20 mg/kg, with a maintenance dose of 4 to 5 mg/kg/day. The half-life of phenobarbital is quite long in the neonate, ranging between 45 and 200 hours.[146] Therapeutic levels should be assessed as levels above 40 to 60 μg/mL may not have additional therapeutic benefit.[147] Importantly, phenobarbital is known to cause respiratory depression, hypotension[148], and hemodynamic lability and has also been associated with deleterious developmental effects.[149] Due to concerns about suboptimal efficacy and side effects, newer medications are often used off-label by neurologists[150]; a commonly selected ASM is levetiracetam. Levetiracetam has been shown to have minimal adverse side effects in neonates[151–153] and retrospective studies suggested noninferiority of control of seizures relative to phenobarbital.[151] However, a recent prospective randomized trial of phenobarbital versus levetiracetam reported a greater efficacy with phenobarbital in a heterogeneous neonatal population,[154] suggesting that in most settings phenobarbital is likely to remain the first-line ASM of choice.

Treatment choices beyond phenobarbital are variable, with the most common selections being levetiracetam or fosphenytoin.[6,142,143] Fosphenytoin is a water-soluble form of phenytoin that is better tolerated, and the administered doses are expressed as phenytoin equivalents. An intravenous loading dose of fosphenytoin of approximately 20 mg phenytoin equivalents/kg is recommended followed by maintenance therapy.[155] However, phenytoin levels are often difficult to maintain, as the medication is rapidly redistributed to the tissues and follows zero-order kinetics.[156]

Benzodiazepine infusion may also be used to control refractory neonatal seizures. Intravenous midazolam has been studied in neonates for safety and efficacy[157,158] and is the most commonly utilized medication for refractory seizures in the United States.[6] Lidocaine, a sodium channel antagonist, has equal efficacy for refractory seizures when compared with midazolam.[159–161] This medication is used more commonly in Europe than in North America.[142,162]

Other ASMs that have been used in neonates include topiramate[163] and lacosamide.[164] Bumetanide, a loop diuretic, is a neuronal sodium–potassium chloride cotransporter antagonist, and in preclinical studies, it was suggested to be an effective treatment for neonatal seizures.[165] Although a randomized controlled trial was discontinued early due to lack of efficacy and concern for increased hearing loss,[166] a recent randomized controlled pilot study suggested that there may be a role for bumetanide as adjunctive therapy with phenobarbital in some circumstances.[167]

Pyridoxine

Pyridoxine-dependent epilepsy is an important etiologic consideration in the newborn presenting with seizures. Treatment should be undertaken for any infant with unexplained ASM-resistant seizure while awaiting laboratory evaluation. For infants with prolonged clinical and/or electrographic seizures, recommended treatment includes administration of 100 mg intravenous pyridoxine over 5 minutes with close evaluation of EEG response and monitoring for apnea, which can occasionally be seen in pyridoxine responders.[123,124] If a clinical or EEG response is not noted, additional 100-mg doses up to a total of 500 mg may be administered. However, as immediate intravenous responses vary, it is suggested that pyridoxine 100 mg/day (IV or enteral) should be administered until biochemical or genetic testing excludes the diagnosis.[123,168] In a newborn with frequent but relatively short ASM-resistant seizures, pyridoxine 100 mg/day (IV or enteral) should be prescribed, and seizure frequency should be monitored. Patients with pyridoxine-dependent epilepsy should show a resolution of clinical seizures within 3 to 5 days of initiating pyridoxine therapy. As above, biochemical and/or genetic confirmation of the diagnosis should be pursued.[124] If pyridoxine-dependent epilepsy is confirmed, an affected newborn should receive pyridoxine 100 mg/

day and older infants should receive 30 mg/kg/day. A lysine-lowering medical diet should be considered.[123] Some patients with medically intractable epilepsy and unresponsiveness to pyridoxine respond to the administration of pyridoxal phosphate, the active form of vitamin B6. Such a response can be seen in patients with pyridox(am)ine phosphate oxidase deficiency which may be confirmed by evaluation of the *PNPO* gene.[22,169]

Discontinuation of Antiepileptic Drugs

How long to treat a neonate with ASMs after resolution of seizures remains an area of practice variability.[170,171] Commonly used ASMs complicate assessments of arousal, tone, and feeding abilities because of their sedating qualities. Of concern, animal studies show increases in apoptosis after treatment with phenobarbital and phenytoin.[172,173] It is now generally recommended that, when possible, ASMs be discontinued while the baby is still being managed in the neonatal intensive care unit. Both retrospective and more recently prospective cohort studies have demonstrated that there is a low rate of seizure recurrence after early discontinuation of ASMs in acute symptomatic seizures and that a longer length of treatment did not prevent later development of epilepsy.[174–176] However, neonates with congenital brain malformation or genetic epilepsy syndromes have an ongoing risk for seizures and thus would be expected to continue treatment with ASMs.

Outcomes of Neonatal Seizures

Clinicians caring for a patient with neonatal seizures are commonly asked to predict how the newborn will be affected in the near and distant future. Prediction of neurodevelopmental outcomes relies first and foremost on the etiology of seizures and is often dependent on advanced neuroimaging that may elucidate congenital malformations or areas of brain injury. Neurophysiologic data also plays a role in prognostication.[177–179] Those infants with a persistently abnormal EEG pattern, such as burst suppression, are likely to have a poor outcome, especially when this pattern persists on serial EEGs.[179] Neonates with a normal EEG tend to fare better, while those with moderately abnormal EEGs have a variable outcome.[178]

Seizures themselves play an uncertain role in neurodevelopmental outcomes with increasing evidence to suggest independent impact. Animal studies have suggested variable developmental effects of neonatal seizures.[180–182] There are ethical concerns in studying the effects of neonatal seizures rigorously in the human newborn, and thus limited research findings are available. Structural studies have shown that seizure severity is independently associated with brain injury, as measured by magnetic resonance spectroscopy.[183] Research assessing the independent role of clinical seizures in the neonate with HIE has shown mixed results.[184,185] More recent studies evaluating the impact of all seizures, both electroclinical and electrographic only, have shown seizure burden associated with microcephaly, cerebral palsy, and failure to thrive[186] and status epilepticus associated with worse neurodevelopmental outcomes and increased risk of postneonatal epilepsy.[187] A randomized controlled trial prospectively studied neonates with electroclinical and electrographic seizures, treating one group for electroclinical seizures only, while treating all electrographic seizures (including those without a clinical correlate) in the other group. This study found that newborns in whom all electrographic seizures were treated had a lower seizure burden, and, although underpowered, suggested that greater seizure burden was associated with greater injury and lower Bayley Scores of Infant Development-III scores.[188] Other recent studies have similarly supported an association between increased total seizure burden and both short- and long-term negative outcomes.[189,190] Newborns who escape clear impairments in early childhood may still develop more subtle neuropsychological challenges as adolescents or in early adulthood.[191]

Post-neonatal Epilepsy

Newborns with seizures remain at risk for developing epilepsy, defined as recurrent unprovoked seizures, in later life. It is estimated that nearly a quarter of neonates with seizures symptomatic of an underlying cause go on to develop post-neonatal epilepsy.[192–195] Of neonates who later develop epilepsy, approximately two-thirds present with recurrent seizures in the first year of life,[196] although a more recent cohort found later onset and somewhat lower frequency of epilepsy.[197] Typically, there is a latency period between neonatal seizures and the onset of post-neonatal epilepsy. Neonates with refractory seizures requiring multiple ASMs, severe brain injury, or those with persistent interictal epileptiform discharges on EEG have a higher risk of developing post-neonatal epilepsy.[118,192,198]

59 Enteral Nutrition

HEIDI KARPEN AND BRENDA POINDEXTER

KEY POINTS

- Early protein intake is associated with improved growth and neurodevelopmental outcomes in premature infants; achieving adequate intake requires a combined parenteral and enteral approach.
- Mother's own milk (MOM) is the preferred diet for preterm infants; further research is needed to develop evidence-based clinical guidelines to optimize the use of donor human milk when MOM is unavailable.
- For very low birth weight infants, unfortified human milk contains insufficient protein, energy, and many essential micronutrients, requiring supplementation with milk fortifier and/or multivitamin products.
- Postnatal growth failure remains a common complication of preterm birth and is associated with adverse outcomes; optimization of growth outcomes requires attention not only to weight gain but also to appropriate linear growth and body composition both in the neonatal intensive care unit and following hospital discharge.

Providing optimal enteral nutrition to neonates can present a difficult clinical challenge. Nutritional needs in the early neonatal period are greater than at any other time of life. Many infants are born with circumstances that place them at increased risk for nutritional deficits. These "at-risk" infants include the preterm infant, especially those born at less than 28 weeks' gestation or less than 1500 g birthweight. These infants have a high risk of feeding intolerance, necrotizing enterocolitis (NEC), infections, and postnatal growth faltering. Infants with congenital gastrointestinal disorders such as gastroschisis and intestinal atresias often have very disorganized motility and poor barrier function. Term infants with high disease acuity such as congenital heart disease (CHD),[1] disorders such as gastroschisis, congenital diaphragmatic hernia (CDH), and ECMO (extracorporeal membrane oxygenation) also have greatly increased caloric needs and unique feeding challenges. In all of these "at-risk" infants, delayed feeding causes absence of trophic factors, which enhances the complications of abnormal bacterial colonization due to antibiotics and the NICU environment, and makes provision of adequate nutrition difficult.

Preterm infants begin life with limited micro and macro nutrient deposition and often have a high degree of illness which makes the provision of adequate calories and protein immediately after birth extremely urgent. Immature gastrointestinal and endocrine function and critical illness further complicate delivery of adequate nutrition. Despite the lack of evidence, withholding or slowly advancing parenteral protein and fats and fear of NEC if feedings are advanced too quickly may also limit provision of optimal parenteral and enteral nutrition. Late preterm and term infants with CHD and CDH/ECMO quickly descend into a nitrogen and caloric deficit due to high disease acuity, fluid volume limitations, and need for pressor support. Consequently, the "at-risk" infant requires specialized nutritional support to meet their increased nutritional requirements to ensure adequate growth and meet the increased demands from critical illness.

Current recommendations for provision of enteral nutrition to premature infants are based on the elusive goal of duplicating rates of intrauterine accretion of the fetus at the same postmenstrual age. Even when guidelines for nutrient intake are meticulously followed, many preterm infants still experience postnatal growth faltering. Infants who experience one or more major morbidities such as bronchopulmonary dysplasia (BPD), severe intraventricular hemorrhage, NEC, or late-onset sepsis are at the highest risk of growth faltering. The association between suboptimal postnatal growth and poor neurodevelopmental outcomes is especially worrisome and highlights the importance of optimizing nutritional support for premature infants in the neonatal intensive care unit (NICU).

Special considerations regarding nutrient needs of preterm infants arise at birth. Because of limited body stores, increased energy expenditure, severity of illness, and/or immaturity and inability to tolerate enteral feedings, premature infants are given parenteral nutrition immediately after birth. However, to meet nutrient requirements, a combined approach with both parenteral and enteral nutrition is needed to achieve optimal growth outcomes and minimize morbidities such as NEC. This chapter describes the basis of recommendations for enteral nutrient support for high-risk neonates. In addition, evidence regarding the initiation and advancement of enteral feedings in premature infants is discussed. Finally, special considerations for enteral nutrition after discharge from the NICU are reviewed.

Macronutrient Requirements

Protein

When fetal life is interrupted by premature birth, significant protein deficits can occur and may be difficult, if not impossible, to recoup.[2,3] Several observational studies have found an association between early protein intake and postnatal growth in extremely premature infants.[4] In addition, there is increasing evidence that the amount of protein intake early in life correlates with improved neurodevelopmental outcomes. To optimize growth outcomes, particular focus must therefore be given to enteral protein intake, especially as parenteral nutrition is weaned and enteral nutrition is advanced.

The most accepted goal of provision of enteral nutrition to premature infants is to achieve growth comparable with that of the fetus at the same gestational age. Protein losses are inversely related to gestational age, providing an explanation for the higher protein requirements in extremely preterm neonates as compared to their term counterparts. Accretion of protein is dependent on protein quantity and quality, energy intake, and underlying disease states (such as sepsis or surgical stress), as well as concomitant medications (such as systemically acting steroids).

Protein requirements in preterm infants have been estimated with use of a variety of methods, including fetal animal models, the factorial approach, and estimates based on the composition of human milk. Protein and energy needs should be considered together because protein synthesis requires energy. Extremely preterm infants require a higher protein-to-energy ratio for optimal growth (Table 59.1). Protein retention, or balance, is generally a function of protein intake if energy intake is adequate. Enteral protein requirements are calculated to be higher than parenteral ones because only approximately 85% of enteral protein is absorbed. In general, published guidelines for protein intake do not take into consideration requirements for catch-up growth.

Based on currently available evidence and consensus of an expert panel, enterally fed very preterm infants should receive at least 3.5 to 4.0 g of protein/kg/day. If growth faltering is identified, additional protein (up to 4.5 g/kg/day) may be required.[5] Further studies are required to define the upper limit of enteral protein intake in premature neonates to optimize growth and neurodevelopmental outcomes.

Energy

In utero, the fetus utilizes both glucose and amino acids as a source of energy. If energy intake is not adequate, protein utilization is not efficient, resulting in lower retention of nitrogen. Coupled with the inverse relationship between protein requirements and weight, the protein-to-energy ratio required to achieve fetal growth is highest in the most premature infants. The recommended energy intake for enterally fed preterm infants ranges between 110 and 130 kcal/kg/day.[6]

The optimal ratio of enteral protein to energy intake must be defined not only in terms of optimizing weight gain but also by that which achieves optimal body composition. Consequently, attempting to duplicate the intrauterine environment may not be appropriate for extrauterine life, given differences in nutrient supply and metabolism. Changes in body composition in response to energy intake are an important consideration because excessive energy intake can contribute to excessive fat deposition, and recent studies have suggested that rapid weight gain may be associated with adverse outcomes.

The energy needs of the neonate are derived from a computation of the energy expenditure, energy storage, and energy losses. Energy expenditure consists of the energy needed to cover the resting metabolic rate, activity, thermoregulation, and the energy cost of growth. Energy storage consists of the energy (fat and lean mass) deposited for growth. Energy losses are usually due to incomplete absorption of nutrients and are greater in premature infants than in term infants or adults. The largest component of the total estimated energy requirement is that needed for the resting metabolic rate. When nourished parenterally, the preterm infant has less fecal energy loss, generally fewer episodes of cold stress, and somewhat lesser activity. When full parenterally the actual energy needs for growth are lowered to approximately 85 to 95 kcal/kg/day. In the case of chronic disease, such as BPD, the resting energy expenditure rises significantly. Total energy needs in preterm infants with BPD are increased because of greater energy expenditure, activity, and fecal energy losses. It is not surprising to find that these infants may require higher caloric intake to achieve weight gain.

Carbohydrates

The main carbohydrate in human milk is lactose, supplying nearly half of the total calories. Lactase (β-galactosidase) is an intestinal enzyme that hydrolyzes lactose to glucose and galactose in the small intestine. Despite lower levels of intestinal lactase activities in premature infants, they can efficiently digest lactose. Nonetheless, many preterm infant formulas supply glucose polymers. Glucose polymers are digested by α-glucosidases; the activity level of these enzymes approximates adult levels much sooner than does that of β-galactosidase. Theoretically, this makes glucose polymers easier for the premature infant to digest than lactose. Glucose polymers also have an advantage in that they increase caloric density without a rise in osmolality.

Fat

Fat provides a substantial source of energy for growing preterm infants. Preterm infants have low levels of pancreatic lipase, bile acids, and lingual lipase. Human milk, however, supplies a variety of lipases, including lipoprotein lipase, bile salt esterase,

TABLE 59.1 Estimated Protein and Energy Requirements to Achieve Fetal Growth

Weight (g)	Protein (g/kg/day)	Energy (kcal/kg/day)	Protein/Energy (g/100 kcal)
500–700	4.0	105	3.8
700–900	4.0	108	3.7
900–1200	4.0	119	3.4
1200–1500	3.9	125	3.1
1500–1800	3.6	128	2.8
1800–2200	3.4	131	2.6

Based on the factorial method (Ziegler EE. Meeting the nutritional needs of the low-birth-weight infant. *Ann Nutr Metab.* 2011;58[Suppl 1]:8–18).

and nonactivated lipase. The composition of dietary fat affects absorption and digestion. The absorption of fatty acids increases with decreasing chain length and with the degree of unsaturation. Consequently, medium-chain triglycerides (carbon chain length of 6 to 12) are hydrolyzed more readily than long-chain triglycerides. In contrast to formulas designed for term infants, preterm infant formulas supply medium-chain triglycerides. Human milk supplies 8% to 12% of fat as medium-chain triglycerides. The recommended intake for total enteral fat in enterally fed preterm infants ranges between 4.1 and 7.4 g/100 kcal, with medium-chain triglycerides supplying less than or equal to 40% of fat intake. [7]

Micronutrients, Vitamins, Minerals, and Trace Element Requirements

Calcium and Phosphorus

Calcium and phosphorus are primary components of the skeleton. The goal for premature infant nutrition is to achieve a bone mineralization pattern similar to that in the fetus and to avoid osteopenia and fractures. The peak fetal calcium accretion rate occurs in late gestation through active calcium influx.[8] Infants will have greater calcium and phosphorus needs when exposed to diuretics, which increase renal excretion of these minerals. Phosphorus requirements may be greater in the setting of a history of placental insufficiency, and calcium requirements may be greater for infants exposed to steroids.

Preterm human milk contains approximately 250 mg of calcium and 140 mg of phosphorus per liter. Meta-analyses of breast milk content studies reveal calcium and phosphorus levels that are similar in preterm and term milk.[9] The calcium and phosphorus contents of enteral formula products designed for premature infants in the United States are significantly greater. In human milk, calcium and phosphorus exist in ionized and complex forms that are easily absorbed. Thus, in the design of commercial formulas, greater quantities of these minerals are added to compensate for their poorer bioavailability. Therefore, additional supplementation with calcium and phosphorus is generally not necessary in term infants. However, distinct from the term infant, the preterm infant requires significantly greater quantities of calcium and phosphorus than can be provided in human milk.

For the human milk–fed preterm infant, calcium and phosphorus are deficient throughout lactation, and the levels are far below those necessary to achieve respective intrauterine accretion rates. Deficient intakes of calcium and phosphorus are associated with biochemical markers such as low serum and urine phosphorus concentrations, elevated serum alkaline phosphatase activity, and elevated serum and urine calcium concentrations. Usually, serum phosphorus concentrations are the best indicators of calcium and phosphorus status in human milk–fed premature infants, and serum phosphorus concentration below 4 mg/dL should be followed carefully. Monitoring of these laboratory markers should be undertaken during hospitalization of very low birth weight (VLBW) infants.[10] The American Academy of Pediatrics (AAP) Committee on Nutrition issued guidelines that laboratory monitoring of VLBW infants should begin at 4 to 5 weeks after birth. Prolonged deficiency of these minerals tends to stimulate bone resorption to normalize serum calcium concentrations. This bone activity is often correlated with elevated serum alkaline phosphatase activity. It has been reported that most preterm infants who had an elevated serum alkaline phosphatase activity were those fed human milk. Moreover, follow-up evaluations of the same infants at 9 and 18 months noted that linear growth was significantly lower in the group that had the higher serum activity of alkaline phosphatase in the neonatal period. A high alkaline phosphatase value in the neonatal period is a negative predictor of height in 9- to 12-year-old adolescents. Serum alkaline phosphatase levels greater than 600 international units (IU)/L or clinical concern for fractures should lead to a radiographic work-up for rickets. Dual-energy x-ray absorptiometry and quantitative ultrasonography are increasingly used as tools for studying metabolic bone disease in preterm infants but have variable clinical.[11,12] The diagnosis of rickets by neonatologists is most commonly performed by x-ray.[13]

Supplementation of human milk with both calcium and phosphorus not only improves the net retention of both minerals but also increases bone mineral content. Current management of human milk–fed preterm infants emphasizes the need for supplements of both calcium and phosphorus. A linear relationship exists between calcium (or phosphorus) intake and net retention in enterally fed premature infants. Preterm infants receiving unfortified human milk never achieve intrauterine accretion rates for calcium and phosphorus. Daily intakes of calcium at approximately 200 mg/kg/day and phosphorous at 100 mg/kg/day can be achieved with the use of specialized human milk fortifiers (HMFs) and preterm formulas, thus making it possible to meet intrauterine estimates. HMFs contain highly soluble calcium glycerophosphate, promoting calcium retention.[8] However, term infant formulas and specialized (not "preterm") formulas provide inadequate quantities of calcium and phosphorus to meet the needs of growing premature infants.[14] Several factors affect the absorption of calcium and phosphorus, including postnatal age and intake of calcium, phosphorus, lactose, fat, and vitamin D. Calcium absorption increases with a low-pH environment and high-casein, high-lactose formula. Vitamin D, however, is responsible for only a small component of calcium absorption in premature infants.

The time to supply sufficient calcium and phosphorus stores for premature infants is during the initial hospitalization before their discharge. However, because of the need for prolonged parenteral nutrition and the inability to provide "catch-up" quantities of calcium and phosphorus in milk, some infants may benefit from additional calcium and phosphorus after hospital discharge using transitional formulas. Preterm infants discharged on an exclusive breast milk diet may require continued monitoring of biochemical markers of calcium and phosphorus stores.

Magnesium

Approximately 60% of body magnesium is in bone. Magnesium has the highest fetal accretion rate in the third trimester. Preterm human milk contains approximately 30 mg of magnesium per liter. The absorption of magnesium is significantly greater from unfortified human milk than from formula. The needs of preterm infants are 8 to 15 mg/kg/day[8] and net magnesium retention in human milk–fed premature infants meets intrauterine estimates. Hypomagnesemia may be present in infants of diabetic mothers and is frequently transient. Hypomagnesemia may reduce parathyroid hormone secretion and responsiveness. Thus, magnesium correction may be required to achieve normocalcemia.

Trace Elements

Premature infants are particularly susceptible to trace element deficiencies given that most accrual occurs during the last third of

pregnancy. The literature on trace mineral requirements for premature infants is sparse, as are studies to support evidence-based guidelines for provision of these nutrients.[15]

Zinc

Several factors affect the zinc needs of the enterally fed premature infant. Fetal accretion of zinc is approximately 0.85 mg/kg/day. Growth is a major determinant of zinc needs. An enteral zinc intake of 2 to 3 mg/kg/day is recommended for preterm infants (inclusive of zinc supplied in human milk fortifiers).[16] A recent RCT found that higher enteral doses of zinc may reduce mortality and other neonatal morbidities.[17]

The major excretory route of zinc is via the gastrointestinal (GI) tract. Infants with large GI fluid losses may become zinc deficient, and patients with short bowel syndrome may require zinc intake of 400 to 800 µg/kg/day. The classic signs of zinc deficiency include an erythematous dermatitis over mucous membranes, facial areas, and the extremities. Symptomatic zinc deficiency presents with susceptibility to infection, impaired wound healing, and failure to thrive.

Plasma zinc values lower than 50 µg/dL are highly suggestive of deficiency, but this is not a reliable biomarker for marginal deficiency, and levels may be falsely elevated in times of bone remodeling. Zinc levels should be measured in the context of large stool or ostomy losses. A very low activity of serum alkaline phosphatase, a zinc-dependent enzyme, is also suggestive of deficiency. Reports of symptomatic zinc deficiency in unsupplemented human milk–fed preterm infants serve as a reminder of the decline in milk zinc concentration as lactation advances.

Copper

No universally accepted methods exist to assess copper status clinically. Balance study data provide only an estimate of copper retention at one point in time. Premature infants receiving pooled pasteurized human milk (copper intake of approximately 85 µg/kg/day) are in negative copper balance for 30 days postnatally and never meet the intrauterine accretion rate. Copper concentration is high in early breast milk and decreases throughout lactation. Human milk fortifier supplies additional copper. Symptoms of copper deficiency include osteopenia, neutropenia, and hypochromic anemia. Copper retention is negatively correlated to zinc intake and postnatal age.[8] Copper deficiency may also present as metabolic bone disease with osteoporosis, metaphyseal changes, and physeal disruption. Because copper is excreted in bile, cases of severe cholestasis warrant limitation of copper intakes.

Selenium

Selenium is an essential trace element and is actively transported from the mother to the fetus and may have an important role in oxidative damage from organic hydroperoxides. Low maternal selenium status in early gestation may increase the risk of preterm premature rupture of membranes.[18] In randomized controlled trials, the incidence of premature rupture of membranes was lower in a group of pregnant women who received selenium supplementation.[19] Further research is needed to clarify the role of selenium in adverse pregnancy outcomes as most study designs are limited in the ability to determine causal relationships. A Cochrane review of three eligible trials (two of which were done in geographic regions with low population selenium levels) reported an association between selenium supplementation to premature infants and a reduced risk of sepsis.[20]

Iron

The iron needs of the premature infant are determined by birth weight, initial hemoglobin concentration, rate of growth, and magnitude of iron loss and/or volume of transfused blood. Iron endowment may be diminished by growth restriction and placental insufficiency in preterm infants.[21] Optimization of umbilical cord clamping practices results in increased iron stores.[22,23] Postnatal iron metabolism occurs in three phases. In the first phase, there is decreased erythropoiesis. The hemoglobin concentration declines to a nadir, which is at approximately 2 to 3 months of postnatal age. This time represents a physiologic anemia of prematurity. In the second phase, the hemoglobin concentration rises as active red cell production is occurring. In this phase, iron is needed. The third phase is an exhaustion of iron stores, or late anemia of prematurity, observed if iron supplementation is inadequate.

The concentration of iron in human milk declines throughout lactation. Premature infants fed human milk are in negative iron balance, which, in the absence of transfusion, can be corrected with iron supplements which have been shown to decrease the prevalence of iron-deficiency anemia.[24] Iron absorption also appears to be facilitated by a modest degree of anemia. The most recent recommendation from the AAP Committee on Nutrition is to begin enteral iron supplementation of 2 mg/kg/day by 1 month of age in preterm infants fed human milk. Formula-fed preterm infants should receive iron-fortified formula from the onset of milk feeding. Term infants should receive 11 mg/day beginning at 6 months of age.[25]

Iron supplementation may be delayed in preterm and sick term infants, who have received multiple erythrocyte transfusions, as each milliliter of transfused blood delivers 1 mg of elemental iron, leading to risk of excessive iron stores.[12,26] Serum ferritin measurements may be a clinically useful means to gauge timing of enteral iron supplementation in infants who have received multiple transfusions.

Although preterm infants will require iron supplementation, the optimal timing of initiation of supplementation and the duration of use are less clear.[27] There is mixed evidence on the effects of iron supplementation and improved neurodevelopmental outcomes.[24] Dysregulation of the iron ion homeostasis pathway mediating oxidative damage may contribute to the mechanism for retinopathy of prematurity pathophysiology.[28] Latent iron deficiency is associated with abnormal auditory neural maturation in late preterm infants.[29] Early iron supplementation results in a higher nadir of hemoglobin and serum ferritin concentrations but may also result in iron overload.[30]

Sodium and Potassium

Preterm infants generally need more sodium per unit of body weight than is needed by term infants. Historical studies proposed that this increased sodium need was due to immature renal sodium conservation mechanisms, but more recent studies of very preterm infants have revealed defective aldosterone secretion with conserved renal aldosterone sensitivity.[31] Sodium wasting is inversely related to gestational age. A study comparing daily sodium intakes of 2.9 and 1.6 milliequivalent (mmol)/kg in

preterm infants suggested that the former intake provided more appropriate serum sodium concentrations. Hyponatremia also may occur in premature infants primarily fed human milk because the sodium content of preterm milk continues to decline throughout lactation.[32] This can be problematic in the use of donor milk, although studies have revealed that there is a significant increase in the sodium concentration of donor breast milk after 1 year postpartum.[33] Early sodium supplementation prevents hyponatremia in very preterm infants and may enhance weight gain.[34] The need for electrolyte supplementation, particularly potassium, may increase during or after diuretic use. Infants with short gut or ostomies may have increased sodium needs which can contribute to growth faltering. Urinary sodium measurements are a good correlate for growth and may help guide which infants would benefit from supplementation.[35]

Vitamins

The fat-soluble vitamins A, D, E, and K are stored in the body, and large doses may result in toxicity. Water-soluble vitamins—thiamine, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and vitamin C—are not stored in the body, and excess intakes are excreted in the urine or bile (vitamin B_{12}). The intake of water-soluble vitamins should therefore be monitored at frequent intervals to avoid deficiency states. Vitamin A and riboflavin concentrations decline in human milk under conditions of light exposure and after passage through feeding tubes. Because of exposure to air, ascorbic acid concentrations are lower in pooled human milk. Pasteurization of donor breast milk leads to reduction in vitamin D content.[36] Supplementary vitamins are provided in HMFs and in preterm formulas. A multivitamin supplement should be given to preterm infants once feedings change to unfortified human milk or standard formula. Infants with cholestasis and short bowel syndrome often have difficulty absorbing sufficient fat-soluble vitamins. These vitamin deficiencies can have long-lasting effects on retinal development and visual acuity, wound healing and skin integrity, bone density and fracture risk, and clotting abnormalities and neurodevelopmental outcomes.[37] Early assessment and supplementation of vitamins A, D, E, and K are especially vital for these patients.

Vitamin A

The reported vitamin A content of preterm breast milk is variable but is similar to that of term breast milk. The content is highest in colostrum (400 to 600 IU/dL) and in breast milk with a higher fat content and declines in mature lactation (60 to 200 IU/dL). The system of handling of breast milk, including bottle feeding, may decrease the concentration of retinol.[38]

The optimal dosing of vitamin A supplementation needs further study.[39] Meta-analyses reveal that vitamin A supplementation may result in a modest reduction in the risk of BPD or death, as low tissue vitamin A and retinol-binding protein levels are associated with decreased clearance of lung secretions and decreased ability to repair lung tissue.[40] However, these studies are confounded by the use of dexamethasone in preterm infants, which results in a transient rise, then fall, in serum retinol and retinol-binding protein levels. Furthermore, there is evidence of a higher risk of sepsis with vitamin A administration.[41,42] There is emerging evidence that retinoic acid, a vitamin A metabolite, may have a role in prevention of retinopathy of prematurity.[41,43]

Vitamin D

Conflicting guidelines are proposed by different professional organizations regarding the optimal dosing of vitamin D. The AAP Committee on Nutrition issued guidelines establishing the amount of recommended vitamin D as 400 IU/day for infants. The recommendation applies to infants receiving human milk and those who are consuming less than 1 quart of infant formula per day and is based in part on the risk of rickets in exclusively breastfed infants who do not receive supplementation with 400 IU of vitamin D per day. This level of supplementation is sufficient to meet a target plasma 25-hydroxyvitamin D concentration of 50 mmol/L in most infants.[10,44] However, the Endocrine Society recommends that infants may require up to 1000 IU/day to meet a target plasma 25-hydroxyvitamin D concentration of 75 mmol/L for nonskeletal health benefits.[45]

Antiepileptic drugs such as phenytoin and phenobarbital may affect vitamin metabolism. Ethnicity has a role in serum 25-hydroxyvitamin D levels, with Hispanic infants having a lower umbilical cord blood level.[46] Preterm infants are at higher risk of being born with lower 25-hydroxyvitamin D umbilical cord serum levels.[47] Certain vitamin D receptor polymorphisms are associated with increased frequency of BPD.[48] Lower maternal and neonatal serum 25-hydroxyvitamin D levels are associated with BPD in preterm infants.[49,50] Recent studies have revealed that vitamin D supplementation in black preterm infants is associated with more recurrent wheezing.[51]

Vitamin E

A single enteral dose of vitamin E supplementation raises the serum levels of α-tocopherol, the biologically active form, in preterm infants.[52] Colostrum has high concentrations of α-tocopherol in both term and preterm milk.[53] The system of handling breast milk, including bottle feeding, may decrease the concentration of α-tocopherol.[38] There is a high prevalence of vitamin E deficiency in VLBW infants until term-corrected gestational age.[54] Vitamin E supplementation reduces the risk of retinopathy of prematurity and intracranial hemorrhage and increases the risk of sepsis in VLBW infants.[52,55] Long-term (>6 months) α-tocopherol supplementation in extremely low birth weight (ELBW) infants may increase the performance intelligence quotient.[56]

Vitamin K

In the United States, 0.5 to 1.0 mg phytonadione (vitamin K) is routinely administered at birth by intramuscular injection to prevent hemorrhagic disease of the newborn. There are oral dosing regimens reported in the literature, but there is a lack of evidence to support routine alternative use.[57] Genetic polymorphisms in the vitamin K–dependent coagulation system may cause some preterm infants to be at higher risk of developing intraventricular hemorrhage.[58] Proteins induced by vitamin K absence are the most sensitive indicators of vitamin K status, but prothrombin time and coagulation studies are commonly used.

Options for Enteral Nutrition

When clinicians are considering enteral feeding in neonates, there are several basic choices that they must make. First and foremost is the choice of base diet for the infant, with three

options commonly used: maternal milk, donor human milk, or preterm formula. Once this decision has been made, clinicians must decide (1) when to initiate enteral feeding, (2) concomitant medical conditions that may affect feeding, (3) how to advance the feeding volumes, and (4) how to feed the infant, for example, by mouth, by gravity bolus via a nasogastric (NO)/orogastric (OG) tube, or by timed or continuous infusion via NG/OG tube. Because of the specific nutritional needs of preterm infants (primarily the requirement for higher protein and mineral intake than that provided by human milk alone) and critically ill late-preterm/term infants (increased caloric and protein requirements), there is an additional decision to be made, and that is determining when human milk fortification will be initiated, what to fortify the milk with, and how to manage ongoing milk fortification.

Human Milk

Exclusive breastfeeding is recommended for all infants through 6 months of age. Continued breastfeeding for 12 months or beyond is advocated by the World Health Organization (WHO) and the AAP. Not all those who give birth and lactate are female or identify themselves as female. It is therefore appropriate to ask parents what pronouns they prefer when addressing issues surrounding lactation and breastfeeding. Some suggested terms include "lactating person/parent," "mother's own milk," "parent's milk," and "father's milk."[59] The term "mother's own milk" in this chapter refers to any parent's milk belonging to that infant.

Benefits of Human Milk

Human milk (HM) is considered the ideal source of nutrition for all infants.[60] HM feeding has been associated with a greatly reduced incidence of gastroenteritis, otitis media, respiratory illnesses,[61] and allergic and autoimmune disease,[62] and is recommended as the exclusive diet for infants less than 6 months of age.[60] In premature infants, a HM diet has been associated with a decreased incidence of late-onset sepsis, increased intestinal motility and gastric emptying, improved feeding tolerance, and general antiinflammatory effects.[63,64] Most notably, breast milk has been associated with a 6- to 10-fold decrease in the risk of developing NEC than those fed formula).[65–67] Human milk diets have also been associated with a reduction in bronchopulmonary dysplasia with proportionate decrease based on percentage of MBM.[68] Furthermore, HM diets are associated with decreased time to full enteral feeds, decreased hospital length of stay (LOS),[64,68–70] and decreased rates of rehospitalization in preterm infants.[71] These beneficial effects on time to full enteral feeds, LOS, and time on parenteral nutrition have also been shown in late preterm/term infants with surgical intestinal disorders.[72]

Neurodevelopmental Outcome Effects

Longer duration of breastfeeding and greater exclusivity of breastfeeding are associated with better receptive language at age 3 years and with higher verbal and nonverbal IQ (intelligence quotient) at age 7 years,[73] as well as enhanced white matter development in exclusively breastfed infants.[74] In ELBW preterm infants, maternal milk was associated with higher motor, cognitive, and behavioral scores on BSD-II at 18-month and 30-month neurodevelopmental follow-up. This was a dose-dependent response with an estimated increase of 0.5 in IQ for every 10 mL/kg increase in breast milk in the diet.[71] Similarly, there was a dose-dependent increase in hippocampal and gray matter volume, as well as overall intracranial volume for each day VLBW infants were fed greater than 50% mother's own milk (MOM).[75]

Human Milk Nutrient Content

Protein

Human milk is comprised of approximately 70% whey proteins and 30% casein compared to bovine milk, which is predominantly casein with less than 20% whey. The percentage of whey:casein in human milk varies by the stage of lactation, and wanes to 50:50 late in lactation.[76] The inverted ratio of whey:casein in human milk, as compared to bovine milk, lends to a very different amino acid profile. Glutamine is the most abundant free amino acid in human milk and has several key functions, including providing ketoglutaric acid for the Krebs cycle, a key energy source for intestinal epithelial cells and perhaps providing a substrate for neurotransmitters.[77] Glutamine levels rise over 20-fold from colostrum to mature milk. Whey proteins in HM include α-lactalbumin, β-lactoglobulin, serum albumin, immunoglobulins, lactoferrin and peptide hormones such as growth hormone and insulin-like growth factors, epidermal growth factor, b-cellulin, TGF-α and platelet-derived growth factor. Other proteins include lysozyme, casein, lipase and amylase, bifidus factor, folate-binding protein, α_1-antitrypsin, antichymotrypsin, and haptocorrin.[78] The most abundant protein in HM is α-lactalbumin, which functions both as a nutritional protein source for the infant as well as an essential component for lactose synthesis in the mammary gland itself. Several proteins, such as lactoferrin, lysozyme, and immunoglobulins, play a role in innate host defense and are particularly resistant to acid hydrolysis in the GI tract.

Protein content of preterm human milk is higher than that of term milk (2.2 g/dL vs. 1.2 g/dL) and both show a significant decrease in the first month and continued decline over the course of lactation, both leveling out around 0.9 to 1.0 g/dL by 3 months of lactation (Table 59.2).[79]

Colostrum

The protein content of colostrum is very high due in part to the passage of larger bioactive proteins and trophic factors, such as IgA and growth factors, through the mammary epithelium than found in mature milk. Colostrum is also high in cellular content, human milk oligosaccharides (HMOs), lactobacillus, and antioxidant compounds, all of which provide a trophic environment for the newly colonizing neonatal intestine. In the animal model, colostrum and colostrum protein concentrate have been shown to stimulate mucosal growth and increased tight junctions in the epithelium.

Carbohydrate

The two main sources of carbohydrates in human milk are lactose and HMOs. Lactose is a disaccharide comprised of galactose and glucose monosaccharides produced in the mammary gland by the enzyme system lactose synthase, a complex of galactosyltransferase and α-lactalbumin. The transcription of α-lactalbumin, which is essential to human milk synthesis, is regulated by the hormone prolactin, and is only active in the mammary gland during pregnancy and lactation. Unlike protein and fat, lactose content is not influenced by maternal diet, nor does it vary or decline during lactation, and is similar between preterm and term human milk.[80]

TABLE 59.2 Composition of Preterm and Term Human Milk

	Energy (kcal/dL)	Protein (g/dL)	Fat (g/dL)	Lactose (kcal/dL)	Oligosaccharides (g/dL)
Preterm					
Week 1	60 (45–75)	2.2 (0.3–4.1)	2.6) (0.5–4.7)	5.7 (3.9–7.5)	2.1 (1.3–2.9)
Week 2	71 (49–94)	1.5 (0.8–2.3)	3.5 (1.2–5.7)	5.7 (4.1–7.3)	2.1 (1.1–3.1)
Weeks 3–4	77 (61–92)	1.4 (0.6–2.2)	3.5 (1.6–5.5)	6.0 (5–7)	1.7 (1.1–2.3)
Weeks 10–12	66 (39–94)	1.0 (0.6–1.4)	3.7 (0.8–6.5)	6.8 (6.2–7.2)	NA
Term					
Week 1	60 (44–77)	1.8 (0.4–3.2)	2.2 (0.7–3.7)	5.8 (4.2–7.4)	1.9 (1.1–2.7)
Week 2	67 (47–86)	1.3 (0.8–1.8)	3.0 (1.2–4.8)	6.2 (5–7.3)	1.9 (1.1–2.7)
Weeks 3–4	66 (48–85)	1.2 (0.8–1.6)	3.3 (1.6–5.1)	6.7 (5.3–8.1)	1.6 (1–2.2)
Weeks 10–12	68 (50–86)	0.9 (0.6–1.2)	3.4 (1.6–5.2)	6.7 (5.3–8.1)	NA

Human Milk Oligosaccharides

HMOs are complex sugar molecules found in human milk which are unique to each mother. HMOs are comprised of five monosaccharide building blocks: galactose (Gal), glucose (Glc), *N*-acetylglucosamine (GlcNAc), fucose (Fuc), and the sialic acid (Sia) derivative *N*-acetylneuraminic acid (Neu5Ac). All HMOs consist of a lactose backbone (Galb1–4Glc) at the reducing end, which can then be elongated/branched by the addition of a variety of disaccharides. These elongated/branched chains can then be fucosylated or sialylated. HMOs are often classified by the presence or absence of Neu5Ac, which results in either a sialylated (acidic) or nonsialylated (neutral) HMO, both of which can be fucosylated.[81] The presence of fucosylated HMOs is genetically determined by the mother's secretor (expression of Se gene) and Lewis blood group status. One particular HMO, disialyllacto-N-tetraose (DSLNT), seems to confer particular protection against NEC. Although the exact mechanism of this protection remains to be elucidated, it suggests a very structure-specific and potentially host receptor-mediated effect.[81] HMOs in bovine milk are not structurally similar to those found in human milk; hence, formula is not a source of HMOs for the infant.

Colostrum HMO content is higher than in mature milk and can reach up to 20 to 25 g/L. As the milk matures, this concentration declines to 5 to 20 g/L, which still exceeds the total milk protein concentration. HMOs are generally resistant to the stomach's acidic environment and degradation from pancreatic enzymes and arrive at the colon intact.[82]

Roles of Human Milk Oligosaccharides

Prebiotics: Promote the growth of certain but not all *Bifidobacterium*, such as *B. infantis*, which may keep potentially harmful bacteria in check as they compete for limited nutrient supply.[83]

Antiadhesive antimicrobials: HMOs resemble intestinal cell-surface glycan molecules and act as decoy receptors to prevent viral, bacterial, and protozoan pathogen binding.

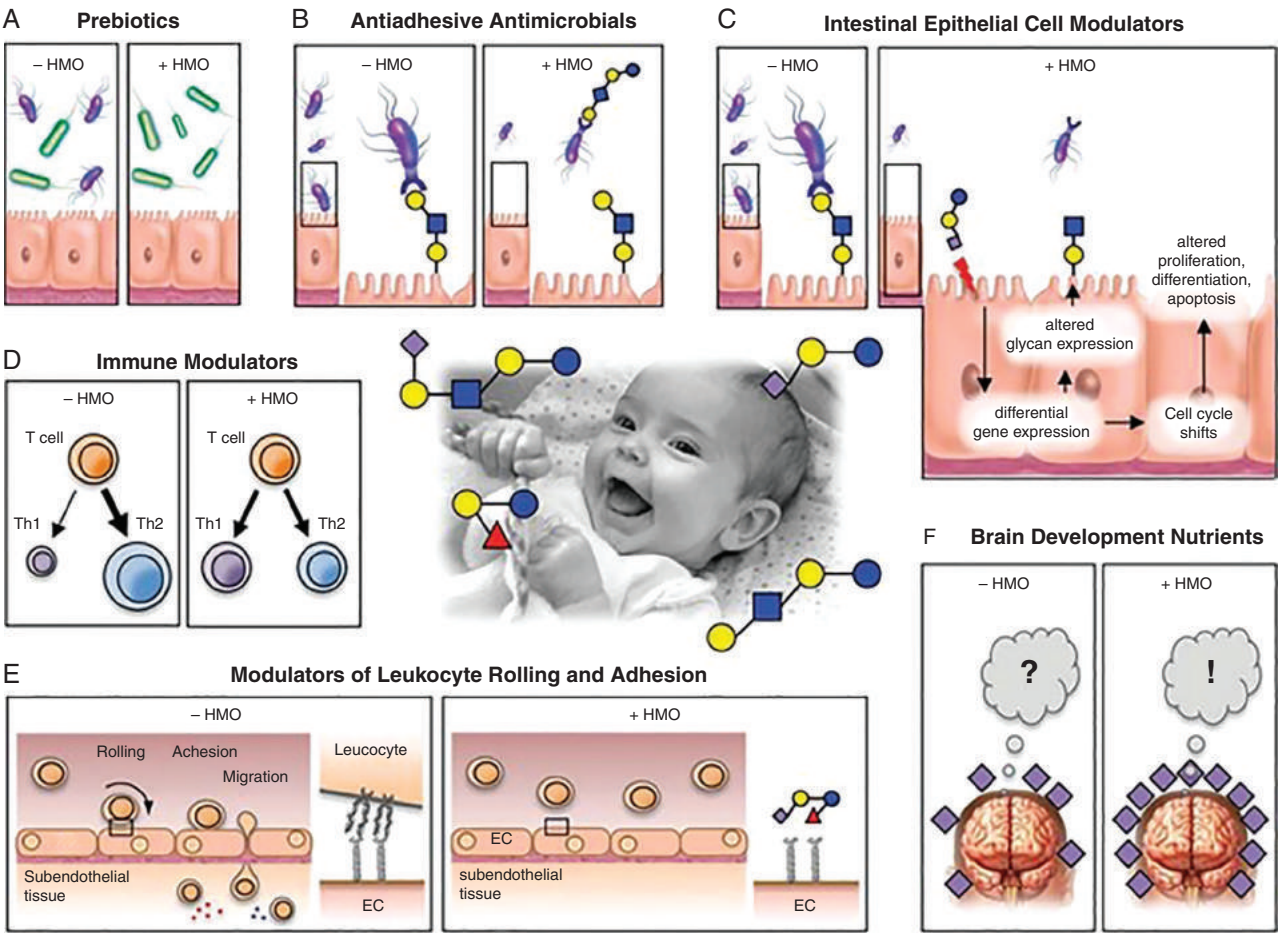
Modulators of intestinal epithelial cell responses: HMOs may also directly modulate host intestinal epithelial cell responses by altering expression of sialylated cell surface glycans which many pathogenic bacteria such as *Escherichia coli* use to adhere to the host's intestinal epithelial cells.

Immune modulators: In addition to local effects of HMOs on mucosa-associated lymphoid tissue, HMOs may also act to modulate the systemic immune response as approximately 1% of HMOs are absorbed into the systemic circulation. Here they have been postulated to influence lymphocyte maturation and enhance the shift towards a more balanced Th1/Th2 cytokine response and decrease production of IL-4 which may contribute toward food allergy prevention (Fig. 59.1).[82]

Fat

Fat provides 50% of the energy in human milk. The lipid system in human milk is structured in a way that facilitates fat digestion and absorption. In human milk, fat exists as organized fat globules containing an outer protein coat and an inner lipid core. The type of fatty acids (high palmitic 16:0, oleic 18:1, linoleic 18:2ω-6, and linoleic 18:3ω-3), their distribution on the triglyceride molecule (16:0 at the 2-position of the molecule), and the presence of bile salt–stimulated lipase are important components of the lipid system in human milk. Fat content of preterm milk is higher than that of term milk in the first 2 weeks (2.2 to 3.5 g/dL in preterm milk vs. 1.8 to 3.0 g/dL in term milk) (see Table 59.2).[9] Fat content of human milk differs among women, changes during the day, rises slightly during lactation, and increases dramatically within a single milk expression. The variability in total fat content is unrelated to maternal dietary fat intake. Because it is not homogenized, the fat separates out of human milk on standing. The separated fat may adhere to collection containers, feeding tubes, and syringes and thus may not be delivered to the infant, compromising energy intake.

The variability in the fat content of human milk may be used to advantage in the premature infant. Most milk transfer during



• **Fig. 59.1** Postulated Human Milk Oligosaccharides *(HMO)* Effects. HMOs may benefit the breast-fed infant in multiple different ways. (A) HMOs are prebiotics that serve as metabolic substrates for beneficial bacteria *(green)* and provide them with a growth advantage over potential pathogens *(purple)*. (B) HMOs are antiadhesive antimicrobials that serve as soluble glycan receptor decoys and prevent pathogen attachment. (C) HMOs directly affect intestinal epithelial cells and modulate their gene expression, which leads to changes in cell surface glycans and other cell responses. (D) HMOs modulate lymphocyte cytokine production, potentially leading to a more balanced Th1/Th2 response. (E) HMOs reduce selectin-mediated cell–cell interactions in the immune system and decrease leukocyte rolling on activated endothelial cells, potentially leading to reduced mucosal leukocyte infiltration and activation. (F) HMOs provide sialic acid as potentially essential nutrients for brain development and cognition. (Bode L. Human milk oligosaccharides: every baby needs a sugar mama. Glycobiology. 2012;22[9]:1147–1162.)

a feeding occurs in 10 to 15 minutes, but continued milk expression yields a milk with a progressively higher fat content. Thus, the "hindmilk" has a higher fat content than the earlier "foremilk." The fat content of hindmilk may be 1.5- to 3-fold greater than that of foremilk. The use of hindmilk in selected cases may provide the infant with additional energy. Hindmilk and foremilk contain similar concentrations of nitrogen, calcium, phosphorus, sodium, and potassium. Copper and zinc concentrations decline by approximately 5% from foremilk to hindmilk.

The differences between foremilk and hindmilk should also be considered in terms of the distribution of calories. Fat and protein account for 42% and 12%, respectively, of the calories in foremilk and 55% and 9% of the calories in hindmilk. The long-term feeding of hindmilk thus could have a negative effect on protein status. A greater proportion of protein calories (10% to 12%) is recommended for premature infants.

Essential Fatty Acids

The essential fatty acids, linoleic and linolenic acids, are present in ample quantities in human milk and commercial formula. Without an adequate intake of these fatty acids, essential fatty acid deficiency (thrombocytopenia, dermatitis, increased infections, and delayed growth) can develop in as little as 1 week. Only 0.5 g/kg/day of essential fatty acids (~4% of total energy intake) will prevent the deficiency. α-Linolenic acid is an important precursor for synthesis of both eicosapentaenoic acid and docosahexaenoic acid (DHA). The very long chain polyunsaturated fatty acids arachidonic acid (AA) (20:4ω-6) and DHA (22:6ω-3) are found in human milk but not bovine milk and are components of phospholipids found in brain, retina, and red blood cell membranes. AA and DHA functionally have been associated with body growth, vision, and cognition. In addition, the fatty acids are integral parts of prostaglandin metabolism. When their diet was supplemented

with polyunsaturated fatty acids, formula-fed premature infants had red blood cell concentrations of DHA paralleling those of similar infants fed human milk. Follow-up studies of such supplemented infants suggest improvements in visual acuity compared with infants that received no supplementation but of similar magnitude to that in infants fed human milk.[84] Improvement in cognitive measures during the first year of life has also been shown. Both AA and DHA are now added to premature formula. The recommended intakes for DHA and AA are 11 to 27 mg/100 kcal and 16 to 39 mg/100 kcal, respectively.[85–87]

Carnitine

Carnitine is synthesized from lysine and methionine and serves as an important effector of fatty acid oxidation in the mitochondria. The provision of carnitine in the diet results in improved fatty acid oxidation. Human milk contains abundant carnitine, and all infant formulas are supplemented with carnitine.

Human Milk Enzymes

Human milk contains enzymes that aid the infant in nutrient digestion. α-Amylase, the enzyme responsible for most of polysaccharide digestion, is not fully developed at birth, even in term infants, who have only 0.2% to 0.5% of adult activity. Mammary amylase is active at the pH of both the stomach and the duodenum and can aid in the digestion of glucose polymers and starches. Although human milk does not contain substrate for α-amylase, this enzyme may aid in digestion of feedings, including infant formula or HMFs that contain complex carbohydrates. Lipases (similar to pancreatic lipase) are present in human milk and aid in digestion of triglycerides such that a significant fraction are broken down into free fatty acids and glycerol before digestion in the small intestine. Bile salt–stimulated lipase, a lipase present in human milk, is highly active because of its wide substrate specificity: it hydrolyzes monoacylglycerols, diacylglycerols, and triacylglycerols, as well as cholesterol esters. This enzyme is also stable in the duodenum and resistant to the low pH of the stomach.[76]

Vitamins and Minerals

Some vitamins and minerals such as thiamine, riboflavin, vitamin B_6, vitamin B_{12}, choline, vitamin A, vitamin C, vitamin D, selenium, zinc, and iodine appear to be rapidly secreted into milk. Maternal dietary intake and states of depletion can substantially affect concentrations of these components in the breast milk. Maternal intake, however, has little effect on concentrations of calcium, magnesium, and iron secreted into breast milk.[80] The vitamin and mineral content of preterm MOM multicomponent human milk fortifiers are shown in Table 59.3.

Preterm Milk

Recent studies of preterm milk analysis show a similar decline in protein content of mother's own milk from ~1.6 to 2.2 g/dL on the first day after delivery to 1.2 to 1.6 g/dL by day 28. This decline was more pronounced in white mothers compared to black mothers.[88] Of note, maternal factors including parity, mode of delivery, prepregnancy body mass index (BMI), previous breastfeeding status, and maternal diet, as well as neonatal factors such as umbilical artery Doppler flows, neonatal AGA or SGA status, gestation, and weight at birth appear to have no impact on the macro- and micro-nutrient content of the breastmilk.[79] Micronutrients such as vitamin D, zinc, calcium, and phosphorus also decline over the first month post-partum and highlight the need for multi-nutrient fortification for preterm infants. Sodium content was significantly lower in milk of mothers of infants born less than 28 weeks' gestation compared to those born greater than 28 weeks' gestation, which can be particularly problematic as the sodium losses for those infants in urine and stool are greater and this can contribute to growth failure.[88]

Special Issues/Contraindications to Mother's Own Milk

Contraindications to breastfeeding and the use of mother's own milk vary throughout the world depending on the risks/benefits to the infant to not breastfeed/receive mother's own milk. In the United States, the following sets of guidelines are generally endorsed (Table 59.4).

Breastfeeding and Substances of Abuse

In addition to the direct risks of contamination of breastmilk by alcohol or drugs, substance use disorders often expose the infant to associated behaviors or conditions that place them independently at higher risk. Although substance use crosses all socioeconomic boundaries, low socioeconomic status, low levels of education, poor prenatal care, food insecurity, and poor nutrition also play a role. Polysubstance abuse is common (drugs, alcohol, tobacco), and adulterants to the drugs, infectious diseases, and mental illness add to the burden of risk to the breastfeeding infant. Despite these multifaceted risks, the proven benefits of human milk and breastfeeding must be carefully considered and weighed.[89] Studies evaluating the outcomes of these risks/exposures are inherently flawed as the infant has already likely been exposed to these circumstances in utero.

Cocaine and phencyclidine hydrochloride (PCP) have both been detected in high concentrations in human milk and have been reported to cause infant intoxication.[90] Other than the drugs discussed below, there is little to no data on other drugs of abuse, as ethical considerations preclude controlled studies.

Opioids

Short courses of most low-dose prescription opioids can be safely used for episodic pain by a breastfeeding mother. Codeine, however, should be used with caution as CYP2D6 ultra-rapid metabolizers may experience high morphine (metabolite) blood levels, potentially placing the infant at increased risk. Information is lacking on the safety of breastfeeding with the use of moderate to high doses of opioids for longer periods of time, nor is there data available for transitioning mothers from short-acting opioids to opioid maintenance therapy while breastfeeding.

Methadone

As the concentration of methadone excreted in human milk is low, women on stable methadone maintenance regimens should be encouraged to breastfeed regardless of their methadone replacement dose. Despite this low excretion rate, provision of breastmilk and breastfeeding have been shown to reduce the severity and duration of neonatal opioid withdrawal syndrome (NOWS)

treatment.[91] Similar results and recommendations apply for buprenorphine treatment for maternal opioid use disorder.

Marijuana

Marijuana is a particularly difficult substance to establish breastfeeding policy for given the differences in legality across state lines, although it currently remains illegal at the federal level. It is also difficult to assess the risk/benefit balance across levels of use from occasional use to heavy use. Δ9-Tetrahydrocannabinol (THC), the psychoactive component found in marijuana, is concentrated up to eight times that found in maternal serum.[92] Once ingested or inhaled, it is rapidly distributed to fat tissues such as adipose and brain, where it may be stored for weeks to months. Because of this long half-life, metabolites may be found in neonatal urine and feces for several weeks, making it extremely difficult to differentiate the occasional versus chronic user, although number of daily uses and time to last use correlate with levels of Δ9-THC in the milk.[93] Also concerning is the increase in potency of marijuana from approximately 3% in the 1980s to 12% in 2012. These

TABLE 59.4 Contraindications to Breastfeeding and the Use of Human Milk

Contraindications to Breastfeeding *and* Use of Expressed Breast Milk

Infant is diagnosed with classic galactosemia.

Mother is infected with the human immunodeficiency virus.[a]

Mother is using an illicit street drug, such as PCP (phencyclidine) or cocaine. *(Narcotic-dependent mothers who are enrolled in a supervised methadone program and have a negative screening for human immunodeficiency virus (HIV) infection and other illicit drugs should be encouraged to breastfeed.)*

Mother has suspected or confirmed Ebola virus disease.

Temporary Restrictions on Breastfeeding *and* Use of Expressed Breast Milk

Mother is infected with untreated brucellosis.

Mother is taking certain medications.[b]

Mother is undergoing diagnostic imaging or treatment with radiopharmaceuticals.

Mother has an active herpes simplex virus (HSV) infection. *(Can breastfeed directly from the unaffected breast if lesions on the affected breast are covered completely to avoid transmission.)*

Temporary Restrictions on Breastfeeding, but *May* Use Expressed Breast Milk

Mother has active, untreated tuberculosis. (*The mother may resume breastfeeding once she has been treated appropriately for 2 weeks and is documented to be no longer contagious.*)

Mother has active varicella (chicken pox) infection that developed within 5 days prior to delivery to 2 days following delivery.

[a]See section on HIV/undetectable viral load for additional considerations.
[b]For the most up-to-date information available on medications and lactation, refer to LactMed.
https://www.cdc.gov/breastfeeding/breastfeeding-special-circumstances/contraindications-to-breastfeeding.html.

issues complicate long-term neurodevelopmental studies. In utero exposure during periods of brain development can have profound effects on brain maturation, leading to long-lasting changes in cognitive function and behavior. Given the long-term neurobehavioral concerns, a mother wishing to breastfeed should be counseled to eliminate or reduce their use/exposure to marijuana.

Alcohol

Alcohol use during pregnancy has been well-documented to be associated with fetal alcohol syndrome, birth defects, preterm birth, spontaneous abortions, and immune dysregulation. Despite the fact that many women reduce or completely eliminate alcohol use during pregnancy, more than half of women in the United States return to consuming alcohol at least occasionally while breastfeeding.[94] Levels of alcohol in human milk parallel those found in maternal serum and effects on the neonate range from somnolence to poor feeding to concern for effects on psychomotor development. Typical recommendations for consumption of alcohol and breastfeeding involve the 2/2/2 rule: no more than 2 (4 oz) glasses of wine or 2 beers, followed by at least a 2-hour waiting period before resuming breastfeeding. A more detailed nomogram based on maternal weight and amount of alcohol consumed has been published and is available online at the Canadian Motherisk program.[95,96]

Human Immunodeficiency Virus/Undetectable Viral Load in Human Immunodeficiency Virus

Breastfeeding in high-income countries (HICs) by women living with human immunodeficiency virus (HIV) remains a contentious issue. There is a dichotomy of advice regarding infant feeding and HIV in the US. The WHO advocates that all new mothers should breastfeed regardless of their status, while the AAP, American College of Obstetricians and Gynecologists, and Centers for Disease Control and Prevention (CDC) continue to recommend formula feeding by mothers living with HIV to eliminate the risk of postnatal transmission.

Approximately 8700 HIV-infected women give birth in the United States in 2006. With current interventions, mother-to-child HIV transmission during pregnancy and labor is very low: under 1%. In the absence of antiretroviral prophylaxis, postnatal infection risk appears to be highest in the first 4 to 6 weeks of life, ranging from 0.7% to 1% per week. The risk continues for the duration of breastfeeding. Two large studies showed that late postnatal transmission risk, after 4 to 6 weeks of age, was 8.9 infections per 100 child-years of breastfeeding (approximately 0.17%/week) and was constant throughout this period. Breastfeeding transmission rates with antiretroviral prophylaxis administered to either the infant or the mother, although low, are still 1% to 5%, and transmission can occur despite undetectable maternal plasma RNA concentrations.

Factors associated with increased risk of HIV transmission via human milk include high maternal plasma and human milk viral load, low maternal CD4+ cell count, longer breastfeeding duration, breast abnormalities (e.g., mastitis, nipple abnormalities), oral lesions in the infant, mixed breastfeeding and formula feeding in the first few months of life (compared with exclusive breastfeeding), and abrupt weaning. Antiretroviral drugs taken by the mother have differential penetration into human milk, with some drugs achieving concentrations much higher or lower than maternal plasma concentrations. The decision to breastfeed with an undetectable HIV viral load is a multifaceted one and requires a thoughtful discussion between the clinician and parent on medication compliance, duration of zero viral load, commitment to

exclusive breastfeeding, and the overall risks/benefits to the infant and mother.

COVID-19

COVID-19 was declared a public health emergency of international concern by the WHO in early 2020 and spread into a worldwide pandemic soon thereafter. Concern for possible transmission of the virus via breast milk led to initial restrictions on breastfeeding and use of MOM.

To date, live, replicatable virus has not been isolated from colostrum or breast milk of mothers positive for SARS-CoV-2 and there has been no convincing evidence for infant infection from breastmilk.[97] The risk of SARS-CoV-2 transmission to the neonate is primarily via contact with infectious respiratory secretions from the mother, caregiver, or other person with SARS-CoV-2 infection. Breastfeeding and provision of breastmilk should continue to be encouraged as the benefits to both the infant and mother outweigh the risks. The CDC has published guidance on safe breastfeeding and handling of breastmilk with COVID-19. Donor milk banks perform extensive screening of their donor mothers for travel and illnesses, including viruses such as COVID-19. In addition, the milk is then pasteurized under conditions which have been shown to kill other viruses such as influenza and SARS-CoV, as cold storage alone is insufficient to kill these viruses.[98,99]

COVID Vaccination

Women receiving SARS-CoV-2 mRNA vaccines have shown robust secretion of IgA, IgM, and IgG antibodies against the virus in their breastmilk for 6 weeks after vaccination.[100,101] The second dose of vaccine further increased levels of IgG in the breastmilk, while IgA remained constant. These antibodies showed neutralizing effects against SARS-CoV-2, providing passive immune transfer to neonates through breastmilk, which may indicate a potential protective effect against infection in the infant. This suggests a critical role for breastmilk IgG in neonatal immunity against SARS-CoV-2 which is similar to the mechanism of protection from several other viral pathogens such as HIV, respiratory syncytial virus, and influenza. The difference in antibody isotype transfer in breastmilk (IgG in vaccine, IgA in natural infection) likely reflects differences in antibody profile programming between naturally acquired SARS-CoV-2 infection (mucosal) versus vaccination (intramuscular).[100] Whether breastmilk IgG or IgA will provide greater neonatal protection remains unclear.

Donor Human Milk

Although MOM is the ideal source of nutrition for at-risk infants, especially the VLBW infant, access to sufficient MOM is often problematic. Admission to an intensive care unit has been shown to impact initiation of pumping, volume of milk pumped per day, and rates of breastfeeding at discharge. A recent study from Children's Hospital of Philadelphia examined these issues in their cardiac ICU. Rates of initiation of pumping were higher among mothers whose babies were inborn (96%) versus mothers who were separated from their infant after birth because of transport to a tertiary care center (67%).[102] Factors that affect provision of maternal milk include separation of mother and infant after delivery, stress of having a critically ill infant, lack of lactation support, and clinician opinion. There is now general consensus from multiple expert panels that pasteurized donor human milk should be provided to VLBW infants as a supplement or alternative to MOM when maternal milk is insufficient in supply.[103,104] Newer data on the advantages of donor milk as a supplement/alternative for MOM in late preterm and term infants with high level of disease severity (CHD, CDH, surgical intestinal disorders) is also evolving.

The majority of donor human milk currently used in NICUs in North America is processed and dispensed from the 31 member banks of the nonprofit Human Milk Banking Association of North America (HMBANA). With expanded criteria for donor milk usage, and the availability for families to buy milk directly from these milk banks for home use, there has been an exponential increase in the amount of milk processed over the past 20 years, from less than 500,000 oz in 2000 to over 7.4 million ounces of milk dispensed in 2019. Human milk processed and dispensed by HMBANA is obtained from healthy donors, most of whom delivered term infants and who undergo extensive screening by HMBANA milk banks, both verbally and in written questionnaires. Donor screenings include detailed inquiries regarding international travel as well as recent illness history including family members in the home. They also require a medical release form to be completed by each donor's licensed healthcare provider. Serologic testing of donors includes human immunodeficiency virus, human T-lymphotropic virus 1 and 2, hepatitis B, hepatitis C, and syphilis. Pooled milk is then processed by a Holder pasteurization, where the milk is heated to 62°C for 30 minutes, allowed to cool, then aliquoted and frozen for shipping. Samples of each batch of pasteurized milk undergo bacteriologic screening. Holder pasteurization is not only highly effective in eliminating all bacterial contamination but eliminates all viruses as well, including members of the SARS (severe acute respiratory syndrome) and MERS (Middle East respiratory syndrome) families. Since the inception of these screening practices in 1985, there has never been an incident of disease transmission or a negative outcome in an infant due to the processing or distribution of pasteurized donor human milk by an HMBANA member bank.

There are several for-profit companies that also supply donor human milk to NICUs and families. Prolacta Bioscience (City of Industry, CA) uses a process similar to Holder pasteurization to process the donated milk. Their screening process is more extensive and, in addition to serologic testing of the mother, the milk is DNA fingerprinted against the mother and tested for drugs of abuse and adulteration. Prolacta is currently the only source of human milk-based fortifiers for both preterm and term infants.

Medolac Laboratories (Lake Oswego, OR) and Ni-Q (Wilsonville, OR) both use a proprietary version of retort processing which exposes the milk to sterilization by heating to 121°C for 5 min, with added pressure of 15 pounds per square inch above atmospheric pressure. This shelf-stable milk does not require refrigeration until after opening and has a shelf life or 1 to 2 years. This milk is an alternative for NICUs that may not have the storage space or volume of usage for a dedicated -80°C freezer and is an option for families who wish to supplement their own milk supply without the use of informal milk sharing.

Differences Between Maternal and Donor Human Milk

Donor human milk has several major differences when compared to mother's own milk. Most milk is donated by mothers of term infants and generally obtained later in the course of lactation. Consequently, donor milk is less calorically dense and contains less protein than mother's own milk from term and preterm infants. Analysis of 415 sequential milk samples from 273 donors showed marked reduction in both energy content and protein. Fat content

was the most variable, leading to a mean energy content of 19 kcal/oz, while 25% of samples were less than 17 kcal/oz and 65% were less than 20 kcal/oz. Processing, container changes, and tube feeding also lead to further decreases in fat content, as human milk fats adhere to the plastics typically used to manufacture these products.[105] Protein content was decreased from estimates of ~1.4 g/dL in mother's own milk to 0.9 to 1.1 g/dL, with over a third of the samples having a protein content of less than 1 g/dL.[106]

A recent metaanalysis by Perrin et al. showed substantial differences between the AAP and American Dietetic and Nutrition published nutritional content values for DHM (donor human milk) and published results from 14 studies. Protein and fat content, as well as total energy, were the most variable between samples, and lower than published norms, and may reflect donor pools and methodological differences in measurements.[107]

Micronutrients such as vitamin D, zinc, calcium, and phosphorus also decline over the first month postpartum and highlight the need for multinutrient fortification for preterm infants. Sodium content was significantly lower in milk of mothers of infants born less than 28 weeks' gestation compared to those born greater than 28 weeks' gestation, which can be particularly problematic as the sodium losses for those infants in urine and stool are greater, and this can contribute to growth failure.[88]

Commercial suppliers of DHM have proprietary processes for balancing macro- and micro-nutrient content between batches and label their products with nutritional content information. Some HMBANA milk banks have pools specifically from mothers who deliver preterm to deliver higher protein content to the smallest infants. Many milk banks also label their pasteurized DHM (PDHM) with total energy and/or nutritional content information.

There are also substantial effects of the pasteurization and sterilization methods on the growth factors and immune components of donor human milk. In both methods, *Lactobacillus* and lymphocytes including B and T cells are destroyed. There is also marked reduction in lactoferrin, erythropoietin, IL-10, IL-1β and IFN-γ. Notably, there is little to no change in electrolytes, vitamins, and iron, as well as lysozyme and HMO integrity, although the composition will be very different to each baby than their MOM. The impact of these differences is highlighted in a recent study by de Halleux et al., in which babies were fed diets of raw MOM, pasteurized MOM (P-MOM), and PDHM and individually fortified, giving equal caloric, protein, and fat content among the groups. The groups fed MOM and P-MOM had substantial increases in weight gain and length and most of that increase was attributable to the raw MOM.[108] These findings raise interesting questions about the effects of noncaloric/macronutrient components of human milk on growth and development.

Donor Milk as a Bridge to Breastfeeding for Term and Late-Preterm Infants

Late preterm infants (LPIs), born between 34 and 36 6/7 weeks. gestational age, are at increased risk of morbidity and mortality, much of which is related to feeding difficulties. They have immature sleep-wake cycles that interfere with their feeding cues, weaker sucks, and early fatigue which lead to poor milk transfer and poor thermoregulation, all of which contribute to hypoglycemia, hyperbilirubinemia, and excessive weight loss that prompts readmission to the hospital and breastfeeding failure. Hospital policies often delineate formula as the only option to supplement breastfeeding and exclude LPIs from receipt of PDHM.[109] A recent study from Mannel et al.[110] examined the type of milk supplementation with LOS and breastfeeding status at discharge in LPIs supplemented with PDHM versus formula. Breastfed infants supplemented with expressed human milk and/or PDHM had a similar LOS to exclusively breastfed infants who required no supplementation. Exclusively formula-fed infants had significant longer LOS. In addition, formula supplementation of breastfed infants led to a 16% decrease in likelihood of breastfeeding at discharge compared to those that received PDHM supplementation. Supplementation with PDHM must be accompanied by robust lactation support in order to produce the desired effect of exclusive breastfeeding success, and policies must evolve to address both of these issues.[111] Meeting the increased demand for PDHM to include this growing population of infants may stress an already limited resource and will need consideration.

Informal Milk Sharing

Wet nursing and cross nursing have existed for thousands of years, being referenced in the Babylonian Code of Hammurabi and ancient Greco-Roman texts. Between the 11th and 18th centuries, the majority of aristocratic infants were fed by wet nurses, as breastfeeding was deemed "indecent." The use of wet nurses declined in the 19th to 20th centuries, as did breastfeeding overall, with the advent of alternate milk sources and formula. With the renewed emphasis on the benefits of breastfeeding for the infant and the mother's health, many families are again exploring the issue of milk sharing through direct wet nursing or cross nursing or attaining donor milk through informal sources such as the Internet or community-based milk sharing groups. Several studies have documented that milk sold for profit on Internet-based sites can pose greater risk than other milk sharing sites. Issues such as milk adulteration (mixing with other substances such as cow's milk to extend the volume), improper storage/freezing methods, bacterial contamination, and lack of transparency of the donor's health, medication, and social histories can greatly increase the risk to the infant.[112,113]

The 2017 Academy of Breastfeeding Medicine Position Statement addresses these concerns and offers recommendations for healthcare providers and families on the strategies to reduce the risk in obtaining milk from informal sources, as well as instructions for home pasteurization. Some HMBANA milk banks and for-profit companies now offer families the opportunity to purchase pasteurized/sterilized donor milk for home use.

Human Milk Fortification

For the term infant, mother's own milk will likely provide adequate protein and energy intake as long as feeding volumes are not restricted and the infant can consume approximately 180 to 200 mL/kg/day. Preterm infants, especially the very low birthweight (VLBW, <1500 g), have several key disadvantages compared to their term counterparts. They are born during what would have been a period of rapid fetal growth in utero and have greatly increased caloric, macro- and micro-nutrient needs to meet this growth potential, as well as contend with severity of illness, after birth. Often respiratory issues and concern for risk of NEC makes larger total daily feeding volumes untenable. Postnatal growth failure is estimated to occur in up to 50% of preterm infants and has been associated with adverse effects on neurodevelopment, renal function, retinopathy of prematurity, BPD, and long-term metabolic function.[113–115] In addition, they have missed much of the

active transport phase of calcium and phosphorus that occurs in the third trimester, placing them at increased risk for metabolic bone disease and fractures.

To meet the nutritional needs of VLBWs, it is standard practice to add a multicomponent fortifier (MCF) to mother's own milk and/or donor milk to provide adequate calories, protein, and minerals. A recent Cochrane review of 18 trials comparing growth in preterm infants fed fortified versus unfortified human milk showed increased gains in head circumference, body length, and weight in those infants receiving fortified feeds while hospitalized. Long-term effects of these fortified feedings on later growth and neurodevelopmental outcome are limited.

MCFs can be divided into two groups: bovine-based (BOV) or human milk-based fortifiers (HMBF). BOV-MCFs provide a hydrolyzed or intact source of bovine protein, as well as added fats and carbohydrate. The BOV-MCFs have evolved from bovine-based powdered packet doses to the newer liquid versions which are designed to provide an increased amount of total protein (1.0 to 1.8 g/100 mL vs. 0.8 to 1.6 g/100 mL) to better approximate the in utero protein accretion and improve linear growth,[116] and are currently the most commonly used in the United States. These liquid MCFs also address the concerns for potential contamination of powdered preparations with *Cronobacter sakazakii*.[117] HMB-MCFs, available for both preterm and at-risk term infants, are produced from PDHM and contain only human milk proteins, fats, and carbohydrates. Both of these fortifier types are enriched with electrolytes, minerals, and vitamins to better meet the needs of the preterm or at-risk infant. The macro- and micro-nutrient content of preterm milk fortified with the most widely used fortifiers are provided in Table 59.3.

Initiation of fortification varies by institution and product used, and range from 20 to 120 mL/kg/day, with little evidence to support differences in practice which are often driven by a balance of concern for NEC and growth restriction at birth. Fortification strategies are typically stratified into standard, adjustable, and targeted, and each is described below.

Standard Fortification

Standard fortification of human milk refers to the addition of fixed amounts of MCFs to HM with the goal of attaining desired caloric and/or protein intakes. This typically results in milk that delivers an estimated 24 kcal/oz, although the total protein intake can range from 3.5 to 5.4 g/kg/day and the micronutrient content vary by product used. The advantages of standard fortification, using either BOV or DMB MCFs, are that it has been shown to be safe and effective and is easy to implement on a large scale.[118,119] A major shortcoming of standard fortification is that it does not account for the differences in protein content and caloric density of the base human milk, especially in the case of DM or as lactation progresses. Preterm infants with in utero growth restriction, increased levels of illness such as BPD, or surgical conditions may require more than the 120 to 130 kcal/kg/day and 3.5 to 4.5 g/kg/day of protein standard fortification provides, so close monitoring is essential.

Adjustable Fortification

Adjustable fortification attempts to achieve optimal protein intake by customizing fortification using blood urea nitrogen (BUN) as a marker of each infant's metabolic response. Although BUN can be affected by hydration status, renal function, sepsis, metabolic, and cardiac disease, it can be a useful marker in the clinically stable, enterally fed infant. BUN is typically targeted to 9 to 16 mg/dL and protein intake is adjusted to attain that target level.[120,121] Modifications of this approach also include targeting both BUN and weight gain with the addition of protein or energy depending on the BUN and growth velocity.[122] When compared with the use of standard fortification, this approach has shown increased short-term growth, as well as higher Bayley Scales of Infant and Toddler Development scores at 18 months.[119,122]

Targeted (or Individualized) Fortification

A major drawback in both standard and adjustable fortification is that the nutrient content of the base HM (MOM or PDHM) is estimated using standard assumptions, which are imprecise at best. Targeted fortification utilizes bedside HM analyzers to more accurately assess the nutrient content of the base HM to which specific amounts of MCF and/or single component nutrients are added to achieve the desired targets for protein, fat, carbohydrates, and overall energy. This method has been shown to produce greater increases in both weight and length, as compared to standard fortification,[123,124] but is more labor and staff intensive, as it requires measurements several times a week for optimal effectiveness.[123] A recent double-blind controlled trial of infants fewer than 30 weeks' gestation, randomized to either standard fortification or targeted fortification using modular protein, carbohydrate, and fat components, showed higher macronutrient intakes, weight gain (~2 g/kg/day), and overall body weight in the intervention group. The impact was most apparent at 36 weeks in the group whose MOM had below-average protein content with significant increases in weight, length, head circumference, fat, and fat-free mass compared to the controls. There were also improved biochemical markers of higher BUN and lower triglycerides and positive effects on feeding tolerance.[124]

Initiation, Mode, and Advancement of Enteral Feedings

The initiation, mode, and rate of advancement of enteral feeding all remain a topic of controversy in neonatology. Substantial variation in the practice of enteral feeding exists among NICUs and, in the absence of standardized feeding protocols, can often vary between clinicians in the same unit. While the fear of necrotizing enterocolitis (NEC) is often cited as the reason for a conservative approach to enteral feeding, standardized feeding protocols have been shown to significantly reduce the incidence of NEC in preterm infants.[125] What is interesting is that, irrespective of the individual components of the feeding protocol, implementation of standardized feeding guidelines not only reduces NEC, but also improves important outcomes such as growth, time to reach full enteral feedings, and duration of parenteral nutrition.

Current evidence supports early initiation of low volume enteral nutrition within the first 48 hours of birth for preterm infants.[126] Low-volume enteral feedings are also referred to as trophic feeding or GI priming. Withholding enteral feeding has been shown to delay gut maturation in preterm infants and results in negative effects. Fasting results in intestinal atrophy, diminished intestinal weight and size (in animal models), delayed maturation of intestinal enzyme function, increase in gut permeability and bacterial translocation, and delay in maturation of the intestinal motor function. Additionally, delay in enteral feeding can extend the duration of parenteral nutrition, with its well-described risks, including metabolic disturbance, direct hyperbilirubinemia and cholestasis, and late-onset sepsis.

Several Cochrane reviews have investigated various aspects of feeding initiation and advancement in preterm infants, with underwhelming results. These issues have been difficult to study in a rigorous manner but have been addressed in a series of Cochrane systematic reviews.[127,128] The primary goal is to determine the optimal feeding regimen that does not increase the incidence of NEC. Comparisons of (1) early (<4 days of age) trophic versus delayed initiation of feeding, (2) early (<4 days) versus delayed progressive feeding advancement, and (3) slow (<24 mL/kg/day) versus faster feeding volume advancement yielded no association between any of these interventions and the incidence of NEC. Early progressive feeding was associated with a 2-day shorter hospital stay, and slow feeding volume advancement was associated with increased risk of invasive infection, not including NEC. They urge caution in interpretation of studies and recommend further randomized trials.[129–131] A recent single center study found that a shorter duration of trophic feeding (less than 3 days) reduced the time to reach full enteral nutrition without an increase in NEC.[132] In addition, the Speed of Increasing Milk Feeds (SIFT) trial conducted in the United Kingdom found that a faster (30 mL/kg) increase in enteral feeding volume (compared to a more standard increment of 18 mL/kg) did not adversely impact the risk of NEC or mortality.[133]

Tube Feeding

Preterm infants are often unable to feed by mouth at the breast or via a bottle at birth because of developmental immaturity. A meta-analysis of small studies suggested that infants with postmenstrual age as low as 28 weeks could safely be exposed to breastfeeding[134] and that introduction of oral feeding can be accomplished at 30 to 31 weeks' postmenstrual age.[135] However, extremely preterm infants may be unable to even begin oral feeding attempts for many weeks after birth and thus are dependent on NG or OG tube feeding. NG/OG feedings may be administered via a timed infusion, with use of an electronic pump, or via gravity bolus. Timed infusions can be periodic, occurring at a specified interval and lasting a specific duration, with a period of rest between feedings, or continuous, in which milk is infused slowly 24 hours a day with no rest period. There are theoretical benefits and risks from both intermittent/bolus and continuous feeding methods, although research is sparse.

Bolus feeding promotes the normal physiologic cyclical surges of GI hormones, which may not only enhance maturation of the preterm GI tract but also increase protein synthesis rates. Immature GI function, including delayed gastric emptying and abnormal intestinal motility, seen not only in preterm infants but also those with GI anomalies and short bowel syndrome, may result in feeding intolerance. With both tube feeding methods, nutrient delivery can be impaired by losses of nutrients that remain in feeding tubes and infusion systems rather than reaching the infant. Fat, particularly, is known to adhere to feeding equipment, decreasing energy delivery, which is worsened with continuous versus intermittent feeding methods.[136]

Infant Nutrition and Growth

A growing body of literature suggests that early nutrition has long-term implications for health and development of all infants and particularly preterm infants. In most scenarios the primary goal of postnatal nutrition for the preterm infant is to, as closely as possible, match expected in utero growth and development. Ideally, this would also optimize long-term developmental outcomes. However, feeding the preterm infant is associated with several challenges. Physiologic weight loss in the first few days after birth sets preterm infants up for "catch-up growth," and it is extremely difficult to provide nutrition (and minerals, in particular) at a rate that matches in utero accretion rates. On the other hand, potential risks of overnutrition may include short-term risk such as increased rates of NEC and longer-term risks such as metabolic syndrome. Most data supporting current nutritional practice in this population are derived from observational studies. The inherent limitations of this type of study design influence the conclusions that can be drawn about the links between nutrition, morbidities, growth, and outcomes.

During the first few weeks after birth, preterm infants may experience weight loss that corresponds to a drop of 0.8 Z score.[137] After this physiologic weight loss and regain of birth weight, it is important to closely monitor growth trajectories, including weight, length, and head circumference. Ideally, preterm infants should track along the percentile they are at after the physiologic contraction of extracellular fluid.

Although postnatal growth failure has historically been defined as body weight or length below the 10th percentile of expected intrauterine growth at the time of hospital discharge, this definition does not adequately account for the growth trajectory during the preterm infant's time in the NICU. The rates of reported growth failure depend on the population studied, and generally increase with decreasing gestational age and birth weight and increase with the severity of illness. Significant variation between hospitals in the degree of postnatal growth failure suggests that this outcome is modifiable and may at least in part reflect differences in nutritional status. Extremely preterm infants with a lower growth trajectory while in the hospital are more likely to have weight, length, and head circumference below the 10th percentile at 18 months' corrected age.[115]

Longitudinal growth is slower in infants with morbidities of prematurity. On the other hand, infants with morbidities such as lung disease or NEC may be fed less aggressively because of their underlying illness. Infants with morbidities of prematurity continue to experience poor growth through at least 2 years, which is only in part explained by the lower growth velocity during the first several months of life.

Extrauterine growth failure among preterm infants has been a target of multiple randomized trials and nutritional interventions in the past several decades. These have led to the current approach to nutrition for very preterm infants, including early intravenous amino acids, trophic enteral feeding—ideally with expressed maternal milk—as soon as possible, and early fortification of human milk feedings. This approach improves energy and nitrogen balance, promotes earlier regain of birth weight, and does not increase the risk of acidosis, NEC, sepsis, or other adverse clinical outcomes. Several studies suggest that lean growth and early catch-up are optimized with a high-protein regimen. In ELBW infants, early enteral provision of protein significantly increases weight, length, and head circumference at least until 36 weeks' postmenstrual age.[138] Shorter duration of dependence on parenteral nutrition is associated with improved longitudinal growth. Nevertheless, "normal" immediate postnatal weight loss is augmented by a suboptimal nutritional state during the first several weeks of life, and growth failure remains common. An observational study demonstrated that postnatal weight loss can be limited to the first few days (and limited to ~8% of birth weight) with optimized early parenteral and enteral nutrition, including a goal of achieving 120 kcal/kg/day and 3.8 g/kg/day of protein by the end of the first week.[139]

Infants with intrauterine growth restriction (IUGR) likely have different metabolic programming and therefore different

nutritional requirements from appropriately grown infants. Term infants born with IUGR have higher rates of adult-onset disease, including hypertension, heart disease, diabetes, and early death.[140,141] Unfortunately, similar data on IUGR preterm infants are not available. Little is known about how to identify or select these infants, and no studies have specifically targeted the nutritional needs of this population. Therefore, the nutrition and growth targets of the IUGR preterm infants are currently similar to those of the appropriate for gestational age preterm infant. The risks of slow growth and persistent small size for age, which are common in the IUGR population, likely outweigh the risks associated with rapid, early catch-up growth. Ultimately, adult weight and risk of long-term metabolic consequences are more likely to be related to parental weight, adult weight, and lifestyle choices than to aggressive early nutrition in the IUGR infant.

While growth failure in the preterm or IUGR infant remains a significant concern, growth that is too rapid in infancy is also associated with adult-onset diseases, including obesity. This phenomenon, in which early "programming" leads to future adverse effects, is commonly termed the Barker hypothesis. In a multicenter study of more than 19,000 term-born American children, growth in the first 4 months was associated with risk of overweight at 7 years.[142] However, it is unlikely these studies of term infants apply to preterm infants, in whom the benefits of brisk early growth may outweigh any potential risks. There is little evidence that current attempts to maximize growth in the NICU "programs" very preterm or critically ill infants for later adverse metabolic consequences. In fact, accelerated or catch-up growth in preterm infants may be associated with improved outcomes.

Assessing Growth and Body Composition in Infants

Infant growth is assessed by anthropometry, in which body weight, length, and head circumference are measured. The use of a length board to accurately measure linear growth is critical. These measurements are compared with established reference data or plotted on a set of growth curves. In general, growth curves for preterm infants are based on expected intrauterine growth. Others are based on postnatal growth data. Several sets of curves have been established for preterm infants; differences are related to population characteristics and sample size, as well as neonatal nutrition practices. In general, curves for both male and female infants allow the clinician to assess growth parameters relative to gestational age and sex-matched norms. Importantly, preterm infants do not always have proportional growth—or proportional growth failure—in the NICU. Linear growth often falters more than weight and may take longer to recover[143] published BMI curves for preterm infants. BMI curves allow the clinician to assess the proportion of weight to length and to distinguish proportionate from disproportionate growth, most commonly when weight increases faster than length. Similar to other growth and body composition parameters, BMI varies with sex and gestational age.

While a preterm infant is hospitalized, growth should be monitored serially and plotted on a set of standardized growth curves. These curves should include weight, length, head circumference, and possibly BMI. Nutrition should be adjusted to target expected intrauterine growth, which is about 15 to 20 g/kg/day for preterm infants with birth weight less than 1500 g.[137]

Changes in body composition over the first months and years of life are associated with nutritional programming of adult morbidities. Assessment of anthropomorphic measures, including BMI, does not inform the clinician about the relative contributions of bone mass, fat mass, and lean mass to body size. Data on the contributions of bone, fat, and lean mass may better reflect the nutritional state of an infant and could potentially inform decisions about appropriate provision of nutrients and goals for growth.

Many preterm infants have poor growth into adolescence, with lower BMI and lower body weight. They have equal fat mass and waist circumference, with an increase in relative abdominal adiposity compared with term-born children. Adiposity may also differ in different groups of preterm infants. For instance, small for gestational age preterm infants have lower fat mass between term-corrected age and 3 months of life but catch up after that point to match appropriate for gestational age born preterm infants.[144] Critically ill preterm infants may have increased central or abdominal adiposity, which is a marker of insulin resistance, versus subcutaneous adiposity. This has unclear implications for short-term and long-term health. Increased abdominal adiposity, rather rapid increases in body weight, or the absolute body weight itself may be the factor that puts some preterm infants at increased risk of adult-onset diseases.[145,146]

Little else is known about the changes in body composition in preterm infants and how to distinguish "normal" from "abnormal." Yet, an understanding of body composition is essential for comparing quality versus quantity of weight gain. An appropriate technique for assessment of body composition must be standardized, valid, reliable, portable, inexpensive, and noninvasive. Ideally, such technology would be used serially to assess response to interventions. Several techniques for assessment of body composition, including dual-energy x-ray absorptiometry and magnetic resonance imaging, are available for research use but cannot practicably be applied in clinical settings, particularly in critically ill neonates. Until additional data on "normal" trajectories of body composition in preterm infants and appropriate technologies for assessment of body composition exist, body composition cannot be used to guide nutrition interventions in the NICU.

Growth and Developmental Outcomes in Preterm Infants

Optimal nutrition is not only essential to match appropriate growth trajectories and minimize risk for adult-onset diseases, early growth and nutrition impact developmental outcomes throughout childhood. The explanation for this long-term impact of infant nutrition is that the first year of life represents a "critical window" of brain growth. In a multicenter cohort study, Ehrenkranz et al. divided ELBW infants into quartiles of in-hospital growth velocity rates.[115] They identified correlations between the quartile of in-hospital growth velocity and the risk of cerebral palsy and developmental outcomes more than 2 standard deviations below the mean at 18 to 22 months' corrected age. These relationships persisted when they were adjusted for multiple potential confounders, such as center and severity of illness.

Postdischarge growth is likely at least as important for developmental outcomes as in-hospital growth. Preterm infants who experience catch-up growth by 8 months' corrected age have better developmental outcomes than those who do not catch up or fail to thrive by 8 months. By 8 to 9 years' corrected age, head growth less than 2 standard deviations below the mean for age at 8 months' corrected age is independently associated with lower intelligence quotient and lower reading, mathematics, spelling, and language scores. In a cohort of 62 VLBW infants followed up prospectively until 24 months' corrected age, poor linear growth

velocity in this period was associated with lower cognitive performance at 24 months.[143]

It remains unknown which specific nutritional interventions in hospital and after discharge would optimize both growth and developmental outcomes in the preterm infant. In two randomized trials of fortified versus term formula at discharge for preterm infants, infants fed fortified preterm formula had improved growth at 18 months.[147] However, there was no difference in developmental scores at 18 months in either trial. Continued research will be essential to establish which growth targets are associated with the best long-term developmental and health outcomes in preterm infants and which nutritional strategies best achieve these targets.

Post-Discharge Nutrition for the Premature Infant

When preterm infants are discharged from the NICU, they have typically accumulated energy, protein, and mineral deficits. In addition, they are often discharged before their original anticipated birth date. Together, these factors lead the preterm infant to have higher nutritional needs after discharge than healthy appropriate for gestational age term infants. Targeting of an appropriate trajectory is essential because postnatal growth through age 1 year in infants born before 32 weeks has a positive relationship with height, weight, and BMI until at least 19 years.[148]

At least one small, randomized trial[149] has demonstrated improved growth among preterm infants fed standard, rather than fortified, formula after discharge. On the other hand, several randomized trials have demonstrated improved growth and mineral accretion among both well former preterm infants and infants with BPD, when fed fortified formula feedings after discharge. However, infants who received the nutrient-enriched formula seemed to have improved proportional growth, because they weighed more at 6- and 12-months' corrected age, were longer at 6 months' corrected age, and had better head circumference growth at term and at 1, 2, 6, and 12 months' corrected age. The nutrient-enriched formula may have been particularly beneficial among infants with birth weight less than 1250 g.

Fewer data are available to support decisions about fortification of maternal milk after discharge of the preterm infant, particularly when families express a goal of nursing rather than bottle feeding their infants. Infants fed unfortified maternal milk have slower growth and lower bone mass than those fed formula after discharge. Fortification of maternal milk is most commonly accomplished by addition of a post-discharge formula to maternal milk to increase energy, protein, calcium, and phosphorus intake. Such fortification improves mineral accretion but may not impact growth in the long term. Nevertheless, on the basis of the existing literature, "fortified" or high-calorie/high-protein milk feeding has become the standard for the preterm infant at discharge, whether feeding is with human milk or formula. Fortification should be continued until at least 6 months' corrected age to optimize catch-up growth. After that time, overly aggressive nutrition may carry an increased risk of adult-onset disease.

Postdischarge formulas supply more energy (22 kcal/oz), protein (2.8 g/100 kcal), calcium, phosphorus, and zinc than term formulas. Compared with term formula, these formulas provide 49% more protein, 10% more calories, 48% more calcium, 62% more phosphorus, and 75% more zinc. Even at intake volumes of up to 200 mL/kg/day, neither maternal milk nor preterm formulas contain the recommended allowance of vitamin D. Thus, vitamin D should be provided as a supplement to all infants both during the hospitalization and after discharge. In infants younger than 1 year, 1 L of vitamin D–fortified infant formula or cow's milk per day will provide sufficient vitamin D to discontinue supplementation.

Post-discharge nutrition should be discussed during the discharge planning process with the families of premature infants. In addition, these plans should be discussed with the primary medical caregiver to ensure a smooth transition to the outpatient setting. Premature infants who are formula fed should be fed nutrient-enriched post-discharge formula for the first year of life. The duration of use will differ depending on the severity of postnatal growth failure, bone health, and proportional growth after NICU discharge. Likewise, growth of preterm infants discharged on human milk should be closely monitored to ensure optimal proportional growth.

Parenteral Nutrition for the High-Risk Neonate

KATIE A. HUFF AND SCOTT C. DENNE

KEY POINTS

- Early use of parenteral nutrition in the very low birth weight (VLBW) neonate minimizes nutrient store losses and improves growth outcomes.
- Initial support goals include glucose infusion of 4 to 8 mg/kg/min, amino acids at 2 to 3 g/kg/day, and lipids at 2 g/kg/day.
- Goal calorie intake for full parenteral nutrition for VLBW infants (1000 to 1500 g) is 90 to 100 kcal/kg/day (3 to 3.5 g/kg/day amino acids, glucose infusion rate 9 to 12 mg/kg/min, and lipids of 3 g/kg/day).
- Goal calorie intake for full parenteral nutrition in extremely low birth weight (ELBW) infants (<1000 g) is 100 to 115 kcal/kg/day (3.5 to 4 g/kg/day amino acids, glucose infusion rate of 9 to 12 mg/kg/min, and lipids of 3 to 4 g/kg/day).
- Complications of parenteral nutrition include parenteral nutrition-associated liver disease (PNALD). Intravenous (IV) lipid emulsions contribute to PNALD development. Fish oil-based lipid monotherapy is now approved for the treatment of PNALD in pediatric patients.

Early, effective nutritional support for the premature and critically ill neonate is largely dependent on parenteral nutrition. In practice, the supply of nutrients to preterm neonates—especially very low birth weight (VLBW) neonates—is often inadequate, and these neonates accumulate major deficits in early postnatal life.[1–3] This inadequate nutritional intake is associated with an increased risk of morbidities in VLBW neonates.[4] In addition, a high proportion of VLBW neonates exhibit poor growth during their neonatal intensive care unit (NICU) stay, with those at the lowest birthweight at greatest risk.[5] However, early use of parenteral nutrition may minimize nutrient losses and improve growth outcomes.[6–9] For example, Genoni et al. found that a change in nutritional protocol to include early, aggressive parenteral and enteral nutrition decreased growth failure.[8] In addition to improved growth outcomes, studies have also noted an association between increased early nutrient intake and improved neurodevelopmental outcomes, including both improved Bayley scores and brain growth.[10,11]

Parenteral nutrition solutions, although still imperfect, have improved markedly from the early days of use, with complications being less common. At present, however, improved outcomes in preterm neonates continue to require a consistent effort at providing parenteral nutrition support, especially in early postnatal life. This means initiating parenteral nutrition as soon as possible after birth, continuing until at least 75% of the total protein and energy requirements are supplied by enteral nutrition, and restarting parenteral nutrition quickly if enteral feeding is suspended.

Components of Parenteral Nutrition

Protein

The initial goal of parenteral nutrition is to minimize losses and preserve existing body stores, particularly for protein. Protein losses are significant if no parenteral amino acids are supplied, with losses being the highest in the most premature neonates. For example, a 26-week gestational age infant loses 1.5 g/kg/day of body protein when provided glucose alone over the first 2 days of life. This is compared to a term infant who loses only 0.7 g/kg/day of body protein over the same time period.[12] Extremely preterm neonates given no amino acid supply lose 1.5% of their body protein per day compared to the fetal accretion rate of 2% per day. After only 3 days of no protein intake, an extremely preterm infant will accumulate a 10% protein deficit compared to the fetus over this same time period.

Fortunately, there is good evidence that early amino acid intake can improve nitrogen balance and help compensate for the high rate of protein loss.[13,14] In addition, high versus low amino acid dosing has been shown to influence the nitrogen balance and decrease the risk for hyperglycemia; the influence on other outcomes, such as growth and neurodevelopment, however, is less clear.[15–19] With regard to the side effects of various amino acid dosing strategies, some studies have found no correlation between blood urea nitrogen (BUN) and early as compared to late amino acid administration.[13,14] Other studies, however, have shown a correlation between increased amino acid dosing and BUN concentrations during the first week of life.[15–17] BUN levels, however, are not only influenced by protein intake but also fluid status and renal function.[20] The available data indicate that providing parenteral amino acids at a rate of 2 to 3 g/kg/day as soon as possible after birth can preserve body protein stores in sick, premature, and VLBW neonates, even when given at low caloric intakes.

It is important to note that even though parenteral amino acid administration is beneficial at low caloric intakes, increasing caloric intake is likely to improve protein accretion. For example, even with a small increase in total calories from 49 to 62 kcal/kg/day over a short period, Vlaardingerbroek et al. demonstrated improved nitrogen balance with lipid supplement

added to parenteral glucose and amino acids.[21] Based on current data, a minimum intake of 30 to 40 kcal per 1 g amino acids is recommended to optimize protein accretion.[22] However, additional energy beyond this amount is necessary to produce appropriate growth.

The ultimate goal of parenteral amino acid administration is to achieve a rate of protein accretion similar to that of the fetus. Based on a variety of studies measuring protein losses and balance, 3 to 4 g/kg/day of amino acids is a reasonable estimate of the parenteral protein requirements of VLBW neonates.[23] Birth weight correlates with parenteral protein needs, with those neonates born less than 1000 g having estimated protein requirements of 3.5 to 4 g/kg/day. Estimates for term neonates are 2.5 to 3 g/kg/day. Parenteral protein intake recommendations for premature neonates are shown in Table 60.1.

The composition of currently available amino acid solutions is shown in Table 60.2. These amino acid solutions were designed to mimic plasma amino acid concentrations in healthy 30-day-old breastfed infants (TrophAmine, B. Braun Medical Inc.) or fetal or neonatal cord blood amino acid concentrations (Primene, Baxter Corporation). No convincing data exists to support the superiority of one neonatal amino acid solution over another.

Although the current neonatal amino acid solutions represent a substantial advance over previous mixtures, these solutions do not contain all amino acids. Glutamine, an amino acid supplied abundantly in breast milk and conditionally essential in premature neonates, is not included in any amino acid solutions due to instability (see Table 60.2). Meta-analysis of multiple studies investigating parenteral glutamine supplementation in premature neonates found no effect on mortality, invasive infection, or necrotizing enterocolitis.[24] Tyrosine, a conditionally essential amino acid in neonates, has limited solubility, so little is included in current amino acid solutions. Some solutions, including TrophAmine and Premasol (Baxter Corporation) contain N-acetyltyrosine, a soluble tyrosine derivative with poor bioavailability. A variety of studies in premature neonates suggest the tyrosine supply may be suboptimal in current amino acid solutions.[25] However, it is also important to note excess tyrosine supplementation should be avoided as elevated levels have been associated with negative neurodevelopmental outcomes.[22] Cysteine, another conditionally essential amino acid in neonates, is not included in most amino acid solutions as it is not stable for long periods. However, a cysteine hydrochloride supplement that can be added to parenteral nutrition solutions prior to delivery is commercially available. Evidence suggests that cysteine hydrochloride supplementation of parenteral nutrition improves nitrogen retention in premature neonates.[22,26] Cysteine supplementation of parenteral nutrition also improves the solubility of calcium and phosphorus. For these reasons, the addition of cysteine hydrochloride (30 to 40 mg/g of amino acids, up to a maximum of 120 mg/kg) is recommended. Cysteine hydrochloride can result in metabolic acidosis, but this can be countered by using acetate in the parenteral nutrition solution.[26]

Energy

The initial goal of parenteral nutrition in early postnatal life is to provide sufficient energy intake to at least match energy expenditure to preserve body energy stores. Estimates of energy expenditure in premature infants over the first few weeks of life range from 30 to 75 kcal/kg/day.[27–29] An early intake of approximately 60 to 70 kcal/kg/day may be a reasonable clinical goal to achieve a neutral or slightly positive energy balance. However, because of glucose and lipid intolerance, this intake may not be achievable for a number of days after birth. Energy expenditure increases with advancing postnatal age, increased calorie intake, sepsis, and stimulant use; it can also be influenced by multiple environmental factors.[30–32] It is important to consider these increases in energy needs as lack of adequate compensation can further worsen energy deficits.

TABLE 60.1 Suggested Daily Parenteral Intake for Infants With Birth Weight Less Than 1000 g and 1000 to 1500 g

Component (units/kg/day unless noted)	<1000 g			1000 to 1500 g		
	Day 0*	Transition†	Growing	Day 0*	Transition†	Growing
Energy (kcal)	40–50	70–80	100–115	40–50	60–70	90–100

To support normal rates of growth, a positive energy balance of 20 to 25 kcal/kg/day must be achieved.[12] This requires parenteral calorie provision of 90 to 100 kcal/kg/day in infants with a birth weight of 1000 to 1500 g and 100 to 115 kcal/kg/day for those infants with a birth weight less than 1000 g (see Table 60.1). For term infants, a parenteral intake of 80 to 90 kcal/kg/day is often sufficient. The majority of parenteral calories is best supplied by a balanced caloric intake of lipid and glucose. Of note, parenteral energy requirements are less than those of enteral requirements as no energy is lost in the stool.

Glucose

Glucose is typically the first parenteral nutrient provided to premature neonates via an IV dextrose solution. IV dextrose should be initiated minutes after birth to maintain normal blood glucose levels and preserve endogenous carbohydrate stores. Although the precise definitions of hypoglycemia and hyperglycemia remain a topic of debate, maintaining glucose concentrations above 40 mg/dL and below 150 to 200 mg/dL is a reasonable goal.[33–35] Hypoglycemia is easily avoided in preterm neonates by maintaining a constant IV glucose delivery. Hyperglycemia, however, is more often problematic, especially in VLBW neonates, with around 75% of these patients having glucose levels greater than 150 mg/dL and around 30% levels greater than 180 mg/dL.[36]

Glucose infusion rates of 4 to 8 mg/kg/min (70 to 120 mL/kg/day of 10% dextrose in water) are appropriate starting points for most neonates. These glucose infusion rates approximate or slightly exceed the rate of endogenous glucose release from the liver in premature and term neonates with the goal to preserve

endogenous stores. Premature infants have higher glucose utilization rates (approximately 6 to 8 mg/kg/min) than term infants, given their increased brain-to-body ratio. In extremely low birth weight infants (ELBW), however, glucose supplementation does not completely suppress endogenous glucose production despite elevated insulin and glucose levels, with glucose production continued at a rate of 2 to 3 mg/kg/min. Concurrent glucose supplementation without suppression of endogenous glucose production increases the risk for hyperglycemia in ELBW infants.[37] Because ELBW infants can have fluid requirements in excess of 100 mL/kg/day, beginning with 5% dextrose may be necessary to maintain appropriate glucose infusion rates and blood glucose levels.

A gradual increase in glucose intake over the first 2 to 7 days of life up to a glucose infusion rate of 7 to 10 mg/kg/min is usually tolerated when the glucose is combined with amino acid supplementation. A reasonable maximum glucose infusion rate of 12 mg/kg/min should be targeted as rates above this level exceed the glucose oxidation capacity.[34] Exceeding glucose oxidative capacity will cause lipid synthesis from glucose, an energy-expensive process. Recommendations for glucose supplementation during parenteral nutrition are provided in Table 60.1.

Some premature infants, especially ELBW infants, have difficulty tolerating glucose supplementation due to their continued glucose production leading to the development of hyperglycemia. This hyperglycemia can typically be treated with a reduction in the glucose infusion rate.[33–35] The use of insulin in this setting is controversial given the contradictory results from several studies. For example, with regard to mortality and insulin use, Zamir et al.[38] showed a decreased mortality rate at 28 and 70 days, while Beardsall et al.[39] noted early insulin therapy was associated with an increased risk for 28-day mortality. Some of this variation may be accounted for by the fact that hyperglycemia itself is associated with an increased risk of mortality.[40] One of the biggest morbidities associated with insulin use is the occurrence of hypoglycemia, highlighting the importance of close glucose monitoring in this setting. Based on current evidence, insulin therapy should be limited to the setting of continued hyperglycemia despite an adequate decrease in the glucose infusion rate.[34]

Meeting the goal of 9 to 12 mg/kg/min of IV glucose supplementation will result in a caloric intake of 45 to 60 kcal/kg/day, which is insufficient by itself to meet total energy needs. IV lipids are necessary to supply the rest of the needed nonprotein calories. A balanced glucose and lipid approach to supplying nonprotein calories has a number of advantages: it better approximates the carbohydrate-to-fat ratio in enteral feedings, it may improve overall protein accretion, and it minimizes energy expenditure.[41,42]

Lipids

IV lipids are composed of triglycerides, phospholipid from egg yolk to aid in emulsification, and glycerol added to achieve isotonicity. IV lipid solutions available in the United States are noted in Table 60.3. Within the last decade, newer generation lipid emulsions containing fish oil have become available, including Smoflipid (Fresenius Kabi) and Omegaven (Fresenius Kabi). With the increased availability of products in the United States, the choice of lipid emulsion for the treatment of the preterm infant has become less clear. A recent meta-analysis found no particular lipid emulsion, with or without fish oil, to be superior for prevention of parenteral nutrition associated liver disease (PNALD), growth, mortality, retinopathy of prematurity, or bronchopulmonary dysplasia (BPD).[43] In the setting of PNALD, this meta-analysis did note less cholestasis associated with fish oil lipid emulsion use as compared to soybean oil lipid emulsion. Despite the lack of convincing evidence regarding lipid superiority, a recent expert consensus noted that fish oil lipid emulsions have advantages over conventional lipid emulsions in infants, including reduced risk of cholestasis, reduced oxidative stress, provision of docosahexaenoic acid (DHA), anti-inflammatory effects, well-balanced ω-6 to ω-3 polyunsaturated fatty acids (PUFA) ratio, and provision of medium-chain fatty acids.[44] In the setting of PNALD, fish oil monotherapy has been shown to reverse cholestasis in pediatric patients in this setting, Omegaven has now been approved in the United States.[45,46]

Supplementation with these various IV lipid emulsions leads to different fatty acid profiles in the infant, with profiles reflecting the fatty acid profile of the individual product given. All available IV lipid products contain long-chain fatty acids, and the mixed emulsion Smoflipid also provides medium-chain fatty acids. The ratio of specific long-chain PUFAs does vary by product, with the fish oil-containing products (Smoflipid and Omegaven) having a decreased ω-6 to ω-3 PUFA ratio as compared to pure soybean oil-based emulsions. Fish oil lipid emulsions also have an increased amount of α-tocopherol (vitamin E) compared to soybean oil lipid emulsions (see Table 60.3). Of note, all the IV lipid products have a fatty acid profile different from that of human milk (Fig. 60.1).[47]

Considering the fatty acid profile of IV lipid products is important when considering dosing. Linoleic acid and α-linolenic acid cannot be synthesized endogenously and are considered essential fatty acids. With less ω-6 PUFA overall, the fish oil-containing lipid emulsions contain less linoleic acid (see Table 60.3). This raises concerns for an increased risk of essential fatty acid deficiency, which has been observed when the fish oil-containing lipid emulsions are given at a dose less than recommended.[48,49] To prevent essential fatty acid deficiency, it is recommended to give preterm infants a minimum dose of 0.25 g/kg/day of linoleic acid.[50] However, despite inadequate linoleic acid content, treatment with fish oil monotherapy at a minimum dose of 1 g/kg/day has been shown to prevent essential fatty acid deficiency.[51] This finding has led to the thought that perhaps the true "essential" fatty acids are the downstream products DHA and arachidonic acid (ARA).[52,53] Additionally, alterations in the DHA and ARA levels have been associated with such outcomes as BPD and late-onset sepsis.[54] Other studies comparing soybean lipid emulsion to the composite emulsion Smoflipid have shown no difference in neurodevelopmental outcomes.[55,56] More information is still needed to fully understand these alterations in neonate fatty acid profiles and outcomes before a clear recommendation can be made regarding lipid use.

After birth, preterm neonates can sustain about 72 hours with no lipid supplementation prior to developing biochemical evidence of essential fatty acid deficiency (triene to tetraene ratio >0.2).[57] There is evidence to show that early IV lipid administration improves growth in ELBW infants and improves nitrogen balance.[21,58] In general, early lipid administration is safe and well-tolerated, and consideration should be given to starting IV lipids at 2 g/kg/day on day 1. Intolerance to lipid infusion is related to the rate of lipid infusion, with better tolerance in preterm infants when lipids are given as a continuous infusion.[50] Elevated triglyceride levels are an indication of lipid intolerance, but given levels of 150 to 200 mg/dL have been noted in enterally fed infants, it is reasonable

to tolerate levels of 250 mg/dL prior to decreasing IV lipid dose.[50] Intolerance to lipid infusion is also related to lipid content. In general, 20% lipid emulsions are better tolerated than 10% lipid emulsions given their lower phospholipid content, which can interfere with triglyceride clearance. For premature infants, 20% IV lipid emulsions are preferred. The clearance of lipids from the blood is dependent on the activity of lipoprotein lipase (LPL). While heparin has been noted to increase the activity of LPL, its routine supplementation in parenteral nutrition for this purpose is not recommended as it has not been shown to improve lipid utilization.

Carnitine aids in the oxidation of lipids by facilitating transport across the mitochondrial membrane. Premature infants receiving parenteral nutrition have low carnitine levels, but the clinical significance of this finding remains uncertain. Meta-analysis of studies evaluating carnitine supplementation in infant parenteral nutrition found no evidence of an effect on ketogenesis, lipid utilization, or weight gain.[59] Despite this lack of evidence, current expert recommendations include using 2 to 5 mg/kg/day of carnitine in parenteral nutrition of infants receiving no enteral source.[60]

IV lipid emulsions undergo peroxidation leading to the formation of free radicals, potentially leading to cellular injury. Light exposure—in particular, phototherapy—greatly increases the amount of lipid peroxidation. Photoprotection of lipid emulsions by shielding the bag and tubing from light can improve outcomes. A recent meta-analysis showed a 50% reduction in mortality for premature infants who received photoprotected lipids.[61] Given this finding, multiple European and American professional societies now recommend light exposure protection of lipid emulsion and parenteral nutrition given to preterm infants.[50,61a]

Electrolytes, Minerals, Trace Elements, and Vitamins

Sodium needs are low in the first few days of life because of expected extracellular fluid contraction and free water diuresis. For VLBW infants, the addition of sodium to the parenteral nutrition may not be necessary until day 3 of life. It is necessary during this time, however, to perform frequent monitoring of serum sodium concentration and an assessment of water balance. After the initial diuresis, 3 to 5 mEq/kg/day of sodium is usually sufficient to maintain serum levels within the normal range (see Table 60.1). However, in VLBW infants, higher levels of sodium supplementation may be needed to compensate for increased renal sodium losses. Potassium requirements are also low in the first few days of life, and supplementation should generally be omitted from parenteral nutrition until renal function in ELBW infants has been clearly established. Potassium intake of 2 to 3 mEq/kg/day is usually adequate to maintain normal serum levels (see Table 60.1).

Chloride requirements follow the same course as sodium, with usual requirements of 3 to 5 mEq/kg/day (see Table 60.1). Excessive chloride supplementation can contribute to the development of metabolic acidosis; however, attempts should be made not to eliminate all chloride supplementation when giving bicarbonate or acetate. The use of sodium acetate as compared to sodium chloride is associated with less metabolic acidosis in VLBW infants.[62]

Supplying adequate calcium and phosphorus in parenteral nutrition is a challenge because of limited solubility. The fetus has average calcium and phosphorus accretion rates of approximately 100 to 120 mg/kg/day and 50 to 65 mg/kg/day, respectively.[63] Presently, in the United States it is not possible to achieve these high rates of calcium and phosphorus supplementation with the solutions available. In other countries, organophosphate preparations are available (e.g., glycerophosphate), allowing for higher rates of supplementation. Precipitation of calcium and phosphorus remains an issue in the United States. However, the solubility is dependent on temperature, type and concentration of amino acids, glucose concentration, pH, type of calcium salt, sequence of addition of calcium and phosphorus to the solution, the calcium-to-phosphorus ratio, and the presence of lipid. As previously noted, adding cysteine to the parenteral nutrition solution lowers the pH and improves calcium and phosphorus solubility. In growing premature infants, intakes of 65 to 100 mg/kg/day (1.5 to 2.5 mmol/kg/day) of calcium and 50 to 80 mg/kg/day (1.5 to 2.5 mmol/kg/day) phosphorus have been recommended (see Table 60.1).[63] A parenteral calcium-to-phosphorus ratio of 1.7 to 1 by weight (1.3 to 1 by molar ratio) is likely optimal for bone mineralization in premature infants, although they seem to be able to tolerate a ratio as low as 0.8.[64,65] In general, calcium and phosphorus should be added to parenteral nutrition early to prevent abnormalities. Magnesium supplementation in parenteral nutrition is also necessary and should be supplied at a dose of 3 to 7.2 mg/kg/day. The timing of magnesium supplementation should depend on infant blood concentration, especially in those infants whose mother received magnesium prior to delivery.

Recommendations for trace element needs in term and preterm infants are derived from recent joint guidelines from multiple European nutritional societies[66] and international expert consensus.[67] It is important to note that selenium and zinc should be included early in parenteral nutrition solutions.[68] Other trace elements may not be needed until after the first 2 weeks of life. The recommended intakes of trace elements for preterm and term infants are shown in Table 60.4.

Multiple individual parenteral products exist to allow for the separate addition of trace elements to parenteral nutrition, including zinc, copper, and selenium. Several combination trace metal solutions are available that include zinc, copper, chromium, and

TABLE 60.4 Recommended Parenteral Intake of Trace Elements for Preterm and Term Infants

manganese, and these solutions are typically given at a dose of 0.2 mL/kg/day. When these trace metal solutions are used, additional zinc is needed to provide the recommended intake for preterm infants, and excess manganese is given. Copper and manganese are excreted via bile and should be used with caution in the setting of cholestasis with levels monitored and supplement discontinued if elevated. In patients with cholestasis, it is now recommended to continue copper supplementation at 20 mcg/kg/day with levels monitored.[66,68] In the setting of renal failure, chromium and selenium levels should be monitored closely. Parenteral iron supplementation is not necessary for short-term parenteral nutrition in infants. For patients on long-term parenteral nutrition, iron status should be assessed using serum iron, transferrin, and ferritin levels prior to initiation of supplementation.

The recommended intakes of vitamins for preterm and term infants on parenteral nutrition are shown in Table 60.5. These recommendations are based on recent updated expert consensus guidelines, although there is still a paucity of data.[67,69] Currently, only two pediatric multivitamin preparations are available. These preparations are meant to approximate the recommended dose for term infants when 5 mL/day is given. However, for preterm infants these preparations provide higher amounts of most B vitamins relative to the recommendations.

TABLE 60.5 Recommended Parenteral Intake of Vitamins for Preterm and Term Infants

Vitamin	Preterm (dose/kg/day)	Term (dose/kg/day)*
Fat Soluble		
Vitamin A (IU)*	700–1500	500–1000 (or 2300 IU/day)

Complications of Parenteral Nutrition

Although a wide variety of complications associated with parenteral nutrition were reported in the early days, most of these are now rare with current parenteral solutions. Many of the modern complications (e.g., electrolyte and glucose abnormalities) can be prevented or corrected by altering the contents of the prescribed solution. The primary complications of parenteral nutrition as currently used include cholestasis and those related to the infusion catheter.

PNALD is hepatic dysfunction with cholestatic jaundice in the setting of parenteral nutrition use with no other identifiable cause. The most common definition of PNALD is a direct or conjugated bilirubin greater than 2 mg/dL. Risk factors for developing PNALD in infants include prematurity, increased length of parenteral nutrition, lower birth weight, and diagnosis (in particular gastroschisis, jejunal atresia, and surgical necrotizing enterocolitis).[70] Historically, PNALD occurs in up to 85% of infants on parenteral nutrition greater than 100 days.[70] Approximately 15% of patients with PNALD progress to end-stage liver disease.[71] Mortality in patients with PNALD is associated with the degree of direct bilirubin elevation.[70,72]

The etiology of PNALD is unknown and may be multifactorial. Parenteral nutrition factors associated with the diagnosis of PNALD include carbohydrate excess, amino acid imbalances (deficiency in taurine or cysteine or excess methionine), manganese excess, and lipid emulsion components.[73] However, current evidence suggests that lipid emulsions play the largest role in the development of PNALD, probably due to their phytosterol content, high concentration of ω-6 PUFAs, and low concentration of antioxidants (i.e., α-tocopherol).[74] As was previously noted, because of these factors a recent expert opinion stated that fish oil-containing IV lipid emulsions have certain advantages over conventional, soybean-based lipid emulsions (see previous "Lipids" section). For treatment of PNALD, pure fish oil monotherapy (Omegaven) is now approved for use in pediatric patients in the United States. In addition to alternate lipid therapies, soybean lipid restriction has been investigated as a means to both prevent and treat PNALD. However, studies investigating this treatment strategy have shown mixed results.[75–77] Given the fundamental role of lipids in supporting caloric needs and brain development, lipid restriction should not be routinely used in ELBW or VLBW infants.

Central line-associated bloodstream infections (CLABSIs) are the most common serious complication associated with central venous catheter use in infants. The most common bacterial pathogen is coagulase-negative staphylococcus. Other organisms found in infants with CLABSIs include gram-negative bacilli and fungi, in particular *Candida*.[78] Risk factors associated with CLABIs include prematurity, duration of central venous access, and the duration of parenteral nutrition. In addition, recurrent episodes of CLABSIs and sepsis in general can contribute to and worsen PNALD. Such strategies as line insertion and maintenance bundles and dedicated line teams have shown success at decreasing the rate of CLABSIs.[79] Other strategies such as antibiotic-impregnated lines, antimicrobial line dressing use, antibiotics at catheter removal, antibiotic locks, and prophylactic antibiotic use have shown promise in some studies regarding a decrease in the rate of CLABSIs.[78,80–83] However, limited data and significant side effects have limited the recommendations for the use of these strategies in neonates at this time. At present, the best strategy to prevent CLABSIs in neonates includes sterile technique use for insertion

and catheter care, although the best agent to carry out this care remains unknown in neonates.[79]

Other catheter-related complications include line-associated thrombosis, line occlusion, and line dislodgement. Life-threatening complications can include extravasation of parenteral nutrition, including pleural effusion and pericardial effusion. In a single-center review of cases, pleural effusions were rare at 0.4 per 1000 line days. All cases, however, were related to migration and malposition of the central venous catheter.[84]

Use of Parenteral Nutrition in the Neonatal Intensive Care Unit: A Practical Approach

The previous portion of this chapter presented the scientific basis for recommendations regarding the provision of parenteral nutrition to neonates. The following section presents a practical approach to administering parenteral nutrition, with particular emphasis on ELBW infants.

Every clinician caring for ELBW infants must recognize the urgent need to start IV amino acids shortly after birth. As noted previously (see "Protein" section), ELBW infants lose 1.5% of total body protein each day amino acid supplementation is withheld. Consequently, the goal of early parenteral nutrition is to limit catabolism and preserve endogenous nutrient stores. Numerous studies have clearly demonstrated both the safety and efficacy of early amino acid supplementation, even at low caloric intakes.

We recommend starting 3 g/kg/day of amino acids on the first day of life. This can be accomplished simply by adding one of the crystalline amino acid solutions designed for use in neonates (Aminosyn-PF, Primene, Premasol, or TrophAmine) to glucose to use as initial maintenance fluid in ELBW infants. We recommend consideration for developing a neonatal amino acid stock solution made in advance by the pharmacy. Our solution contains amino acids in 7.5% dextrose, that when delivered at 60 mL/kg/day, provides 3 g/kg/day of amino acids. Additional fluids with or without electrolytes and varying concentrations of dextrose can also be given to allow for adjustments based on individual fluid, glucose, and electrolyte needs. It is important to note that this stock amino acid solution should not be increased beyond 60 mL/kg/day, and any needed fluid alteration should be via the ancillary fluids. This stock solution can be given via peripheral IV line, umbilical venous line, or another central line, such as a percutaneous central venous catheter. In our unit, strong consideration is given to percutaneous central venous catheter placement in ELBW infants early in their postnatal course.

To meet growth requirements, 3.5 to 4 g/kg/day of amino acids is required. Once administration of amino acids is initiated, intake can be advanced to meet requirements for growth over a short period. We typically advance to an amino acid dose of 3.5 g/kg/day on the second day of life. Given the available data, we also recommend adding cysteine to the amino acid solution (40 mg/g of amino acids, to a maximum of 120 mg/kg). However, we delay adding cysteine until other electrolytes are included in the parenteral nutrition solution in order to add acetate to buffer the acid load of cysteine supplementation.

Glucose supplementation should be supplied at a sufficient dose to maintain normal glucose concentrations. As noted previously, preterm infants have increased glucose utilization rates of 6 to 8 mg/kg/min as compared to term infants at approximately 3 to 4 mg/kg/min. Also previously mentioned, ELBW infants have continued glucose production despite adequate glucose supplementation. Our current practice includes starting dextrose 10% solution at 40 mL/kg/day to give a total glucose infusion rate of 6 mg/kg/min on the initial day of life when combined with the stock amino acid solution. Given their increased risk of excessive fluid losses and hyperglycemia, ELBW neonates may need 5% dextrose supplementation, especially when needing total fluids of more than 120 to 150 mL/kg/day.

Lipids should be started within the first 24 hours. We typically start lipids at a dose of 2 g/kg/day and advance by 0.5 to 1 g/kg/day to a usual maximum goal of 3 g/kg/day while monitoring and maintaining serum triglyceride levels less than 250 mg/dL. Given the previously mentioned advantages, we use 20% lipid emulsions as the first line over 10% solutions. For ELBW infants expected to need parenteral nutrition for a short period of time with normal direct bilirubin levels, we use soybean oil lipid emulsions as the first-line therapy. For those patients who develop persistent cholestasis concerning for PNALD with direct bilirubin greater than 2 mg/dL and have continued need for parenteral nutrition, we consider soybean oil lipid reduction versus the use of composite lipid-containing fish oil (Smoflipid). The initial therapy choice is dependent on caloric needs and the ability to tolerate enteral feeds. If PNALD continues to worsen despite changing to composite lipid-containing fish oil, we consider fish oil monotherapy.

Caloric requirements during parenteral nutrition are lower than with enteral feeds. For optimal protein retention, approximately 70 to 80 kcal/kg/day is a reasonable goal. However, to achieve optimal growth, a goal of 100 to 115 kcal/kg/day for ELBW infants is reasonable once on stable parenteral nutrition. This goal can be achieved using an amino acid intake of 3.5 g/kg/day, lipid intake of 3 g/kg/day, and maximum glucose infusion rate of 12, often with no more than 12.5% dextrose solution.

There is a paucity of data related to laboratory monitoring in the setting of parenteral nutrition and the ELBW neonate. Suggested monitoring is shown in Table 60.6. It is important to

TABLE 60.6 Suggested Monitoring During Parenteral Nutrition

Parameter*	Frequency
Anthropometric Measurements	
Weight	Daily
Length	Weekly
Head circumference	Weekly
Serum Laboratory Monitoring	
Glucose	1× per shift during week 1, then daily
Na, K, Cl, bicarbonate, BUN, Ca	Daily until stable, then 2× per week
Magnesium, phosphorus	2× per week
Triglycerides	2× per week
ALT, AST, alkaline phosphatase, GGT, fractionated bilirubin	Weekly if on parenteral nutrition >2 weeks

*Further laboratory testing would be recommended for patients on prolonged (>3 to 4 weeks) parenteral nutrition including micronutrient monitoring.

ALT, Aminotransferase; *AST*, aspartate aminotransferase; *BUN*, blood urea nitrogen; *Ca*, calcium; *Cl*, chloride; *GGT*, gamma-glutamyl transferase; *K*, potassium; *Na*, sodium.

consider the balance of close monitoring of parenteral nutrition supplementation with the volume of blood needed for this testing. This suggested testing is not comprehensive. More in-depth testing would be needed in patients on parenteral nutrition for greater than 3 to 4 weeks.

The use of parenteral nutrition in ELBW infants should be accompanied by the early initiation of enteral feeds (ideally on the first day). Parenteral nutrition should be continued until enteral feedings are well established. We continue parenteral nutrition until enteral intake is 120 mL/kg/day or approximately 96 kcal/kg/day. As enteral feeds are advanced, delivered parenteral nutrient and fluid supplementation should be weaned to maintain appropriate fluid and calorie intake needs. In addition, with periods of enteral feeding intolerance, prompt reinstitution of parenteral nutrition in the ELBW infant cannot be overlooked.

Structural Anomalies of the Gastrointestinal Tract

KATHERINE T. FLYNN-O'BRIEN AND SAMUEL E. RICE-TOWNSEND

KEY POINTS

- Small inclusion cysts in the oral cavity are common in newborns and almost always resolve without treatment.
- Suspect the diagnosis of esophageal atresia when there is feeding difficulty with an inability to pass a tube from the nose (or mouth) into the stomach.
- In the most common type of esophageal atresia, there is a fistula from the trachea to the distal esophagus (tracheoesophageal fistula [TEF]) that accounts for the air in the gastrointestinal tract (GI) tract seen on radiographs. When no air is seen it suggests that there is only esophageal atresia and no TEF.
- The most important risk factors for mortality in esophageal atresia anomalies are associated prematurity and major congenital heart disease.
- Infants with pyloric stenosis present with nonbilious vomiting of feedings, intravascular volume depletion, and hypochloremic, hypokalemic metabolic alkalosis in the first few weeks of life.
- Bilious vomiting in newborns indicates mechanical obstruction of the GI tract and, specifically, intestinal malrotation with midgut volvulus until proven otherwise.
- Suspected midgut volvulus requires urgent surgical evaluation. It is best to make the diagnosis of volvulus when there are signs of intestinal obstruction and not to wait for signs of intestinal ischemia.
- If there is a concern of intestinal malrotation and midgut volvulus, then an urgent upper GI contrast study should be done to evaluate the position of the ligament of Treitz (the transition point between duodenum and jejunum).
- Failure to pass meconium in the first day of life should raise concerns about distal bowel obstruction.
- The diagnosis of Hirschsprung disease can typically be confirmed or ruled out by suction rectal biopsy.
- In cases of anorectal malformation, associated anomalies in the VACTERL spectrum (Vertebral, Anorectal, Cardiac, TracheoEsophageal, Renal, Limb) should be explored.

This chapter will provide an overview of structural anomalies of the gastrointestinal (GI) tract seen in newborns. Most of the conditions are congenital; however, some are acquired. Although there are an almost limitless number and variety of structural anomalies, we will concentrate on those that are relatively common and those that have important clinical neonatal presentations. The topics will be discussed in anatomic progression, starting from the mouth and ending at the anus. Several important conditions of the GI tract and abdomen such as biliary atresia, necrotizing enterocolitis (NEC), abdominal wall defects, and abdominal tumors are addressed in other chapters.

Disorders of the Oral Cavity

Mouth

Newborns commonly have transient inclusion cysts in the mouth that may be classified into three types: Epstein pearls, Bohn nodules, and dental lamina cysts.[1,2] Epstein pearls are small keratin-filled nodules found in the midline of the palate. They are thought to be epithelial inclusion cysts located at the developmental fusion line of the palate. Bohn nodules are firm white or gray nodules, usually found along the alveolar (dental) ridges and are remnants of developing salivary glands. Dental lamina cysts are small, raised, white papules in the midline of the palate or on the alveolar (dental) ridges. Although at times concerning in appearance, all three types of oral inclusion cysts are benign and usually asymptomatic. Their natural history is to spontaneously rupture and fuse with the oral epithelium within 5 months of birth, thus conservative management is appropriate and treatment is rarely necessary.[1] Oral inclusion cysts may sometimes be confused with an oral cavity tumor such as a small congenital epulis or with the eruption of a neonatal tooth.

Oral cavity tumors are rare in newborns. The two most common oral cavity tumors are congenital granular cell epulis (CGCE) and oropharyngeal teratoma. CGCE is a benign tumor that presents as a smooth, red or pink mass arising most often from the maxillary alveolar (dental) ridge.[3,4] CGCE enlarges prenatally but does not usually grow after birth, is not associated with any syndromes, and has an excellent prognosis.[3]

An oral cavity teratoma arises from the upper jaw or palate and is also known as an epignathus. Teratomas are tumors that arise from fetal germ cells during development and consist of cells and tissues derived from all three germ cell layers (ectoderm, mesoderm, and endoderm). In the newborn, they are commonly found in the sacrococcygeal region but may occur in the gonads or other midline, or near-midline, locations. Symptoms are typically caused by compression of normal structures, although malignant degeneration may occur.

Larger oral cavity teratomas may be seen on prenatal imaging, but granular cell tumors are typically smaller and discovered on physical examination after birth.[5] Granular cell tumors and oral

cavity teratomas vary in size and, when large, their mass effect may cause feeding difficulty and even upper airway obstruction. Most oral cavity tumors require surgical resection. The timing of surgery depends upon the severity or potential severity of the symptoms.[4,6]

Tongue

The tongue is critical for sucking and swallowing, so congenital disorders such as aglossia, ankyloglossia, and macroglossia are usually noted early in life. Aglossia, or congenital absence of part or all the tongue, is a very rare condition caused by failure of tongue embryogenesis in weeks 4 to 8 of gestation. It is usually associated with craniofacial and limb anomalies.[7]

Ankyloglossia is commonly known as "tongue-tie." Several classification schemes exist for ankyloglossia, including the Corylios classification which describes four subtypes based on the location of attachment.[8,9] By far the most common form of tongue-tie is ankyloglossia inferior, which is an abnormally short, thickened, and/or tight inferior frenulum.[10] Ankyloglossia can also be described as anterior or posterior. Anterior ankyloglossia refers to a lingual frenulum that extends to the tip of the tongue or near the tip of the tongue that restricts tongue mobility.[9]

There is significant debate about the degree to which ankyloglossia interferes with tongue movement, feeding, and speech with some classification systems incorporating function in addition to anatomy, that is, Hazelbaker Assessment Tool for Lingual Frenulum Function and the Bristol Tongue Assessment Tool.[8] Overall, most newborns with ankyloglossia have no difficulty breastfeeding; however, if they do have difficulties then lactation evaluation and counseling are the next steps.[9] If feeding difficulties persist, then frenotomy (the surgical division of the frenulum) may improve feeding. While ankyloglossia inferior may impact the articulation of speech, it does not usually delay overall speech and language development.[11] Ankyloglossia superior is a rare but more serious anomaly that refers to a fibrous or osseous connection between the tongue and the hard palate. Ankyloglossia superior is associated with other significant anomalies, such as cleft palate, microglossia, micrognathia, GI malformations, and deformed limbs.[12,13] Ankyloglossia superior can cause difficulty in feeding and even airway obstruction, making early recognition and treatment necessary.[12]

Macroglossia means enlargement of the tongue and is defined as tongue protrusion beyond the teeth or alveolar ridge during resting posture. Macroglossia is seen in 4.63/100,000 live births, with about half being isolated and half syndromic. Macroglossia is more common among female infants and African Americans.[14] Macroglossia may be classified as "true macroglossia" or "pseudomacroglossia."[15,16] True macroglossia can be due to muscle hypertrophy of the tongue, which is usually the result of a genetic abnormality, such as Beckwith–Weidemann syndrome.[15] Tissue infiltration from amyloidosis, infection, hemangiomas/lymphangiomas, or systemic diseases such as hypothyroidism and diabetes can also lead to macroglossia.[15,16] Pseudomacroglossia occurs when the tongue appears large because of a relatively small oral cavity such as in babies with mandibular hypoplasia (micrognathia) or when the tongue is displaced anteriorly.[16] Surgical treatment is needed if there is airway compromise, dysphagia, or dysarthria. Operations for macroglossia aim to reduce the size of the tongue and preserve its function.[15–17]

Salivary Glands

The salivary glands (the parotid, submandibular, and sublingual glands) may be the source of several newborn problems. A ranula is a mucus-filled cyst arising from the sublingual gland. In newborns, a ranula is caused by congenital obstruction of a sublingual gland duct.[18] Ranulas that are entirely intraoral are known as simple ranulas, while those that extend through the floor of the mouth beyond the mylohyoid muscle are known as "plunging" ranulas and present as a submandibular or neck mass.[19] A ranula may be suspected on physical examination, and diagnosis can be confirmed by ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). If physical examination and imaging are not definitive then aspiration of the cyst showing yellow fluid containing amylase and mucin confirms the diagnosis.[20] Ranulas may spontaneously resolve and thus may be observed for up to 6 months before excision or sclerotherapy.[20,21]

Neonatal suppurative sialadenitis and parotitis are rare infections of the salivary and parotid glands, respectively, but should be considered in any newborns presenting with unilateral inflammatory submandibular or parotid swelling.[22–24] Bacterial contamination of the glands is from the oral cavity via the draining ducts or from hematologic spread from transient bacteremia.[23,25,26] Risk factors for these infections include prematurity, prolonged nasogastric feeding, mechanical ventilation, dehydration, and maternal mastitis.[24] *Staphylococcus aureus* is the most common causative organism, though *Streptococcus* species, *Escherichia coli*, and *Haemophilus influenzae* have also been reported. Treatment with broad-spectrum intravenous antibiotics is recommended, including an anti-staphylococcal β-lactam and an aminoglycoside or third-generation cephalosporin.[22–24] Although rare, an abscess can form, causing airway compromise and warranting urgent surgical drainage.[27]

Parotid hemangiomas are the most common salivary gland tumors in newborns.[28] They present as a rapidly growing mass in the preauricular area.[29] They may be segmental, involving structures in the distribution of the V3 (mandibular) branch of the trigeminal nerve, including the parotid gland, the overlying skin, and the airway. Alternatively, they may be focal, located within and involving only the parotid gland.[29] Hemangiomas traditionally have a rapid growth phase in the first months of life followed by spontaneous involution over the next decade. Diagnosis is by physical examination and is confirmed by imaging with Doppler ultrasound and sometimes MRI.[30] Observation alone is appropriate for small, non-disfiguring lesions with no systemic manifestations such as congestive heart failure. Treatment options include intralesional corticosteroids, systemic nonselective β-blocker (i.e., propranolol), endovascular sclerotherapy, and surgical resection with intraoperative facial nerve mapping.[28,29]

Disorders of the Neck

Although most disorders of the neck are not structural anomalies of the GI tract, abnormalities of the developing oropharynx, including branchial cleft and thyroid anomalies, may present as neck masses. The branchial cleft anomalies usually present as lateral neck masses, and thyroid anomalies usually present as midline neck masses. We will consider these topics and other lateral and midline neonatal neck masses briefly before covering disorders of the esophagus in the next section.

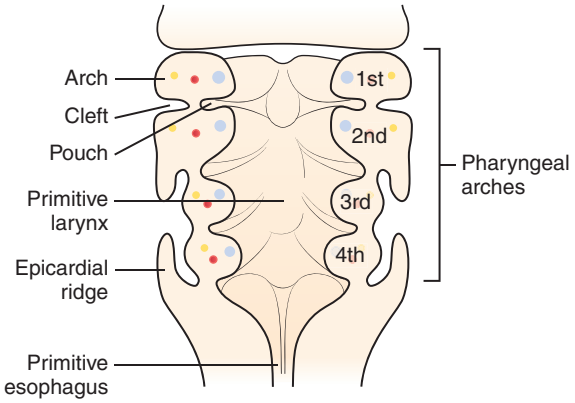
Branchial Anomalies

During early development, the flat, trilaminar embryonic disc forms into a cylindrical body, and in the head, neck, and upper chest this process involves the pharyngeal or branchial (Greek for *gills*) apparatus. (Branchial is the term most used in clinical medicine to describe these developmental structures, so we will use it here.) The branchial apparatus consists of a series of arches that fold and meet in what will be the ventral midline. The arches contain mesoderm and are separated by indentations that on the outer ectodermal surface are called clefts and on the inner endodermal surface are called pouches. The arches and separating clefts and pouches are numbered based on their cranial to caudal embryonic positioning (Fig. 61.1).[31]

Branchial cleft anomalies arise from incomplete obliteration of the embryonic clefts and pouches and result in an epithelial-lined cyst, sinus, or fistula. A cyst has no direct connection from its epithelial inner lining to the normal epithelium of the skin or pharynx. In contrast, a sinus is an abnormal epithelial extension from either the skin or pharynx, and a fistula is an abnormal epithelial connection between skin and pharynx. Most branchial cleft anomalies are cysts, and 95% of the cysts arise from the second branchial cleft. Although they are congenital anomalies present since birth, they often present in older children and adolescents or even adults. They usually present as neck masses on the anterior border of the sternocleidomastoid muscle.[31] These neck masses may be asymptomatic, or they may produce symptoms because of mass effect or infection. Diagnosis of the cyst is made by the characteristic position on physical examination and may be supported by ultrasound, CT, or MRI appearance. A true fistula may be demonstrated by contrast esophagram.[31,32] Treatment of branchial cleft cysts includes initial treatment of any complicating infection and then complete surgical excision when the infection has resolved. Surgical excision is well tolerated with minimal morbidity.[33]

Thyroid

The thyroid may be the source of a neck mass when remnants of its embryologic origin persist and enlarge, when the gland is in an abnormal location, or when it is enlarged in the normal location. During weeks 5 to 7 of gestation the rudimentary thyroid migrates from the foramen cecum (i.e., the base of the tongue) to its final position in the lower neck anterior to the trachea.[34] At the onset of normal migration, the endoderm of the primitive pharynx invaginates and forms the thyroglossal duct with the developing thyroid gland at its inferior aspect. The duct descends to the lower neck and is usually obliterated by week 10 of gestation. Incomplete obliteration of the duct may lead to a thyroglossal duct cyst that presents as a midline neck mass between the hyoid bone and the thyroid gland. Thyroglossal duct cysts have a propensity to become infected, and surgical excision is indicated.[35,36]



• **Fig. 61.1** Branchial Cleft Anomalies.

Simple excision of a thyroglossal duct cyst results in a high rate of recurrence, presumably because of small residual bits of thyroglossal duct tissue not in continuity with the main cyst. Therefore, the operation of choice is the Sistrunk procedure: an en bloc excision of the cyst and its tract, including the middle part of the hyoid bone. Previous infections increase the risk for cyst recurrence after surgery.[35] While rare, when identified later in life, thyroglossal duct cyst carcinoma is reported, with a mean age at diagnosis of 39.5 years.[37]

Disordered thyroid development may result in abnormally located or ectopic thyroid. In general, functional thyroid tissue not located anterior to the second, third, or fourth tracheal rings is considered to be ectopic. Ectopic thyroid tissue can be found anywhere between the foramen cecum and the mediastinum.[38] The most common location for ectopic thyroid is the tongue. Lingual thyroid results from the failure of normal migration of the thyroid during development and presents as a mass in the posterior midline of the tongue. Most patients with a lingual thyroid do not have additional thyroid tissue in the normal position. A large lingual thyroid may cause symptoms of airway obstruction.

A diffusely enlarged, nontender thyroid gland at birth is known as a congenital goiter. It may be associated with hyperthyroidism, hypothyroidism, or a euthyroid state. The diagnosis of congenital goiter can be confirmed with ultrasound. Thyroid function should be assessed to determine the need for thyroid hormone replacement.

Other Neck Masses

Neck masses are often distinguished by their location. As noted, the branchial anomalies usually present as lateral neck masses. The differential for lateral neck masses presenting in the first few weeks of life also includes cystic hygromas and those associated with torticollis.

The "sternocleidomastoid pseudotumor of infancy," or the neck mass associated with congenital muscular torticollis, is a firm, nontender thickening in the lower half of the sternocleidomastoid muscle. The mass is associated with tightness and shortening of the sternocleidomastoid muscle that leads to a characteristic positioning of the patient's head—the face turned away from the side of the lesion with the chin tilted up. The range of motion is reduced. The etiology is unknown, but it is associated with difficult deliveries. The condition is more common in males, more frequent on the right, and generally presents in the first few weeks of life.[39] Diagnosis is by characteristic examination findings. Treatment is directed at improving the range of motion and posture through physical therapy. Surgery is not usually required.

Cystic hygromas are congenital lymphatic malformations. Lymphatic malformations may be defined by the size of the cystic spaces (<2 cm is microcystic, >2 cm is macrocystic), and location is based on the de Serres staging system or the Mulliken/McGill system.[40] Cystic hygromas in the neck are classically macrocystic and located in the posterior triangle, more commonly on the left side. They are present at birth and typically grow with the child but may enlarge suddenly with internal hemorrhage or infection.

Treatment is by surgical excision or sclerotherapy. A systematic review in 2012 did not find conclusive evidence to support the superiority of one treatment modality over the other.[40]

In addition to thyroid anomalies, midline neck masses in newborns include dermoid cysts, teratomas, and, rarely, an undescended thymus. Dermoid cysts are subcutaneous cysts lined by keratinized, stratified, squamous epithelium with appendages such as hair follicles, sweat glands, and sebaceous glands.[41] They commonly occur on the face and scalp at lines of embryonic fusion and can also occur in the midline neck near the hyoid bone and be confused with thyroglossal duct cysts. Dermoid cysts are prone to infection and should be excised. Midline dermoid cysts or those over skull suture lines may connect to the dura, and imaging should be considered in these cases prior to excision. Imaging is not needed in most other cases. Teratomas in the neck are often found in the midline and are biologically the same tumor as oropharyngeal teratomas, described in the earlier section. They usually originate near the larynx and trachea and may cause airway obstruction. Almost all midline neck masses require surgical resection.

Disorders of the Esophagus

Newborns with disorders of the esophagus are challenging patients to manage, particularly if they have associated prematurity or congenital heart disease. This section will focus on esophageal atresia and its common variants and then briefly review related congenital conditions such as laryngotracheal cleft, esophageal stenosis, esophageal duplication cyst, and acquired esophageal perforation.

Esophageal Atresia

Esophageal atresia is the most common congenital anomaly of the esophagus and occurs when the esophagus is congenitally separated into segments that are not in continuity. Esophageal atresia is often associated with a tracheoesophageal fistula (TEF).

Epidemiology

The incidence of esophageal atresia is estimated at approximately 1 in 2500 to 1 in 4500 live births with some variation between regions of the world.[42–44] Esophageal atresia is usually a sporadic disorder, and the recurrence risk for a future sibling is less than 1%.[45]

Etiology and Associated Anomalies

The basic embryology of the foregut and the variants of esophageal atresia and TEF are not understood completely.[46,47] Esophageal atresia may be associated with genetic syndromes such as Down syndrome, Edwards syndrome, CHARGE syndrome (coloboma of the eye, heart defects, atresia of the choanae, retardation of growth and development, and ear abnormalities and deafness), Feingold syndrome, and Fanconi anemia.[48] However, rather than any specific syndrome, esophageal atresia is most often accompanied by additional anomalies in the absence of a known genetic defect or syndrome. These additional anomalies are common in the distribution of VACTERL association (vertebral defects, anorectal malformations, cardiac defects, tracheoesophageal anomalies, renal anomalies, and limb abnormalities).[49] Among 2689 children with esophageal atresia in the United States, 59.1% were found to have associated cardiac defects (most commonly atrial septal defect 46.6% and ventricular septal defect 21.2%). Vertebral, spine, or rib defects were seen in 25.4% of children. Additionally, renal anomalies were associated in 21.8% of children, anorectal malformations in 11.6%, and limb deformities in 6.4%. Approximately one-third of patients had three defects including esophageal atresia, thus qualifying them for a formal VACTERL diagnosis. Duodenal atresia, while not part of VACTERL, was seen in 4.7% of children with esophageal atresia in one study.[50]

Classification

Esophageal atresias with tracheoesophageal malformations occur as a spectrum of anomalies. Several classification systems have been proposed to name the various arrangements[51,52]; however, in a clinical setting it is best to simply describe the anatomic abnormalities. The most important variants are seen in Fig. 61.2.

Diagnosis

Although the diagnosis of esophageal atresia may be suspected prenatally, the diagnosis is usually made after birth. Prenatal ultrasound showing polyhydramnios and an abnormally small stomach may suggest esophageal atresia; however, both findings are nonspecific.[53] If, in addition to polyhydramnios and a small stomach, a dilated esophagus is seen in the neck, a diagnosis of esophageal atresia is more likely.[54] Fetal MRI should be considered if prenatal ultrasound suggests esophageal atresia.[55] Prenatal diagnosis allows an opportunity to counsel parents about the diagnosis, postnatal management, and prognosis.[56]

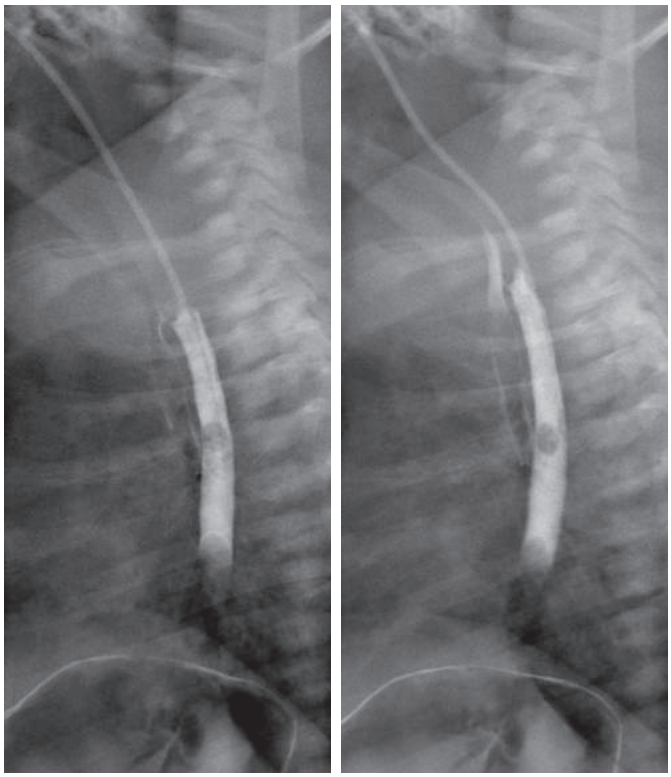
When a neonate is suspected to have esophageal atresia, because of prenatal findings or postnatal clinical symptoms such as excessive drooling, choking, or coughing with feeding, the best way to rule out the diagnosis is to pass a tube into the stomach. A nasogastric (NG) tube that does not pass easily into the stomach, and by x-ray stops or coils in the mid to upper thorax at the 2nd to 4th vertebral body level, is diagnostic of esophageal atresia (Fig. 61.3). A lateral film may demonstrate the tube posterior to the airway, and an air-filled TEF may sometimes be seen. A formal contrast study to outline the pouch is rarely necessary and carries a risk of aspiration.

When esophageal atresia is found, the presence of a distal TEF is confirmed by air in the stomach and intestinal tract (see Fig. 61.3). Absence of air in the abdomen indicates a pure esophageal atresia or an esophageal atresia with an isolated upper pouch TEF (Fig. 61.4). The diagnosis of an isolated TEF without esophageal atresia (i.e., H-type) is often not made at birth because presentation may be subtle. Symptoms can include choking and coughing with feeds and recurrent respiratory infections (caused by aspiration). The abdomen may also appear distended because of excessive air entering the GI tract from the fistula.[57] Since the esophagus is intact, a tube will pass normally into the stomach. The diagnosis may be made by bronchoscopy (Fig. 61.5) or specialized imaging studies such as a "pull-back esophagram" (Fig. 61.6) in which contrast is injected as the NG is slowly withdrawn from the stomach to better demonstrate the fistula.[57]

Management

When esophageal atresia is diagnosed or suspected, the infant should be promptly evaluated by a pediatric surgeon. In the most common situation, when a TEF to the distal esophagus is present, respiratory distress may result from aspiration of contents of the proximal pouch, aspiration of gastric contents into the trachea, loss of ventilation through the TEF, and compression of the lungs by a distended abdomen. Therefore, positive pressure ventilation should be avoided if possible, the patient positioned with the head elevated, and the proximal pouch contents evacuated with a nasoesophageal (NE) tube.

Most commonly, the infant is stable, and there is time before surgery to confirm the diagnosis and to evaluate for associated VACTERL anomalies. The most important investigation is an echocardiogram looking for cardiac defects or great vessel anomalies, which are present in 18% to 35% of cases and can influence the surgical approach.[56,58] The remainder of the VACTERL work-up including renal ultrasound and spinal imaging may be



• **Fig. 61.6** Pull-Back Esophagram.

performed after the operation. Occasionally, the inability to ventilate the infant due to leakage of tracheal air via the fistula into the GI tract forces an urgent operation to ligate the fistula or decompress the abdomen.

The primary goal of the initial operation is to divide and close the TEF. Simple ligation (tying off) of the TEF is not recommended because of the high risk of recurrence. Once the TEF is divided an end-to-end esophageal anastomosis should be performed. In unstable or premature infants, it is often safer to perform a staged repair by performing the esophageal anastomosis later, after the patient has stabilized and grown.[59] A long distance between the proximal and distal esophageal segments may also preclude anastomosis at the initial operation, although a variety of surgical approaches have been utilized in this situation.[60] If no anastomosis is performed, a gastrostomy tube should be placed if possible, at the initial operation for feeding access, until the atresia can be repaired. A chest tube is often placed to identify and evacuate any leakage from the esophageal anastomosis.

The infant should be extubated as soon as safely possible after surgery to reduce the risk of endotracheal tube and positive pressure trauma to the tracheal suture line. Similarly, deep suctioning should not be done, to avoid injury to the tracheal and esophageal repairs. Reintubation, if needed, should be performed with extreme care avoiding significant positive pressure ventilation prior to intubation. Enteral feedings may be given by gastrostomy or by an NG tube if placed across the anastomosis during surgery, or they may be delayed until the anastomosis is judged to be healed and ready for oral feeding or tube placement. A contrast study of the esophagus 7 days postoperatively is commonly performed with removal of a chest tube and commencement of oral feeds; however, practices vary.[56,61,62]

Outcomes

Overall survival from TEF is reported to be 93%, with low birth weight and the presence of major cardiac disease the most important predictors of mortality.[63] Ongoing improvements in neonatal critical care have led to greatly improved outcomes in even the smallest premature infants.[64,65]

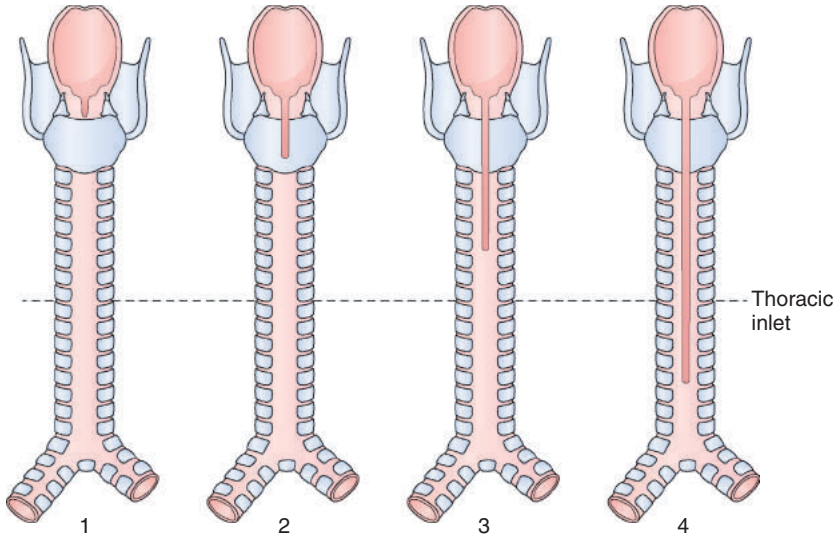
Early complications after repair of esophageal atresia include anastomotic leak and stricture. Leaks occur in up to 20% of cases although most are small, contained, and heal without another operation.[66] Leaks may be detected by observing saliva in the chest drain but are usually discovered in routine postoperative contrast studies. Stricture at the anastomosis is seen in up to one-third of cases and is more common when the anastomosis was created under tension or was complicated by a postoperative leak.[67] Clinically significant strictures usually manifest with feeding difficulty and can often be successfully treated with serial dilations.[68,69]

Patients who have esophageal atresia commonly suffer from gastroesophageal reflux (GER) and tracheomalacia.[70] GER may be more problematic in patients with esophageal atresia because of inherent dysmotility in the distal esophagus.[71] Routine use of gastric acid blockade is recommended to improve symptoms and to decrease the risk of stricture formation because of acid exposure. Many patients go on to require surgical treatment for reflux with fundoplication.[72]

Tracheomalacia is a focal or generalized structural weakness of the trachea leading to airway narrowing or collapse with increasing intrathoracic pressure (e.g., expiration). Patients may have expiratory stridor, a "barking cough," recurrent respiratory illnesses, or acute life-threatening events. The diagnosis of tracheomalacia is made by bronchoscopy, which shows airway collapse during spontaneous breathing. In severe cases, an aortopexy can effectively alleviate the condition by suspending the aorta (and thus the attached anterior wall of the trachea) to the sternum and thus pulling it away from the posterior wall of the trachea.[73,74] Similarly, posterior tracheopexy, a technique to hold and keep the posterior floppy portion of the trachea from collapsing anteriorly, has been used with success.[75]

Laryngotracheoesophageal Cleft

A laryngotracheoesophageal cleft (LC) is a rare congenital connection of variable length between the posterior larynx and trachea and the anterior esophagus resulting from failed midline fusion during development. The cleft starts proximally at the larynx and extends distally. The length of the communication can be as short as a superficial mucosal defect between the arytenoid cartilages or as long as the entire length of the trachea and even into the mainstem bronchi (Fig. 61.7).[76,77] An LC can be associated with Pallister–Hall syndrome, CHARGE syndrome, Opitz G syndrome, or VACTERL association.[78] Approximately 12% of infants with LC also have a more distal TEF[79]; however, among patients with EA/TEF, up to 20% are diagnosed with an LC.[80] Symptoms are related to the length of the connection between the esophagus and trachea and can include cough, stridor, recurrent aspiration and respiratory tract infections, reflux, swallowing difficulty, and even choking and cyanosis with feeds.[81] In long defects, there may an inability to ventilate with severe respiratory distress. It can be difficult to treat the respiratory distress because the endotracheal tube can migrate ("fall") into the esophagus after placement through the vocal cords. Diagnosis is best made by rigid bronchoscopy, which may also assist in placing the endotracheal



• **Fig. 61.7** Diagram of Laryngotracheoesophageal Cleft.

tube beyond the distal aspect of the cleft. Minor defects are often successfully treated with thickened feeds alone though may be repaired endoscopically.[82] Repairs of long defects are major, complex operations of the chest and neck that may require cardiopulmonary bypass.

Congenital Esophageal Stenosis

Congenital esophageal stenosis (CES) is rare, with an incidence of 1 in 25,000 to 1 in 50,000, and is caused by a malformation in the esophageal wall architecture.[83] The malformation may include fibromuscular thickening (53.8%), cartilage from ectopic tracheobronchial remnants in the esophageal wall (29.9%), and/or a membranous web (16.2%).[84] The majority of defects are found in the distal esophagus, most commonly 1 to 2 cm above the gastroesophageal junction. CES is classified by the Ramesh classification: type I is isolated CES, segmental type; type II is isolated CES, diaphragm type; and type III is a combined lesion.[84] CES is usually associated with other anomalies including trisomy 21, duodenal atresia, anorectal malformation, esophageal hiatal hernia, and congenital heart disease.[84] Between 25% and 50% will also have esophageal atresia.[84,85] More than half of cases are diagnosed after the neonatal period. Dysphagia and recurrent vomiting are common symptoms. Diagnosis can be reliably made with a contrast study and confirmed by endoscopy. Diagnosis is also possible in cases associated with esophageal atresia by evaluation of the distal esophagus during and after surgical repair.[83,86] Treatment is dilation or surgical resection.

Esophageal Duplication Cyst

Duplications are congenital malformations of unknown etiology that may form anywhere along the length of the developing GI tract but are most common in the small intestine. Duplications may be cystic or tubular. Esophageal duplication cysts, also known as foregut duplication cysts, are typically covered by a layer of smooth muscle and contain an epithelial lining that can comprise a hybrid histology with elements of respiratory and alimentary tissue within the same lesion.[87] The lumen of the cyst typically does not communicate with the normal foregut lumen.[86]

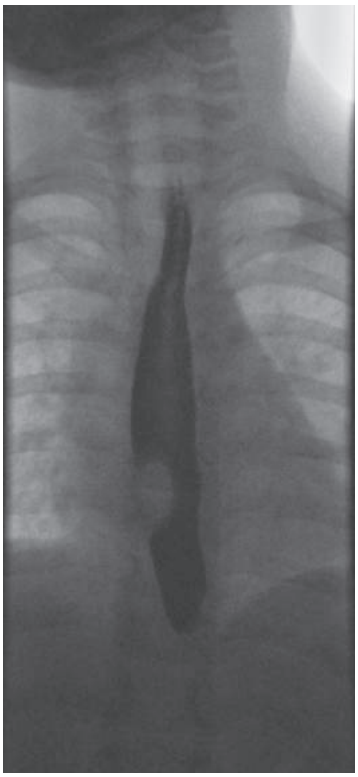
Clinical presentation is often due to compression of adjacent structures in the chest, and symptoms may include cough, wheezing, and dysphagia. Diagnosis is often made on prenatal ultrasound, although can also be made later in childhood.[84,88] Most cases have an abnormal chest x-ray because of mass effect, and contrast studies will demonstrate compression on the esophageal lumen. CT often offers better visualization of the lesions (Fig. 61.8).[89] Tc-99m pertechnetate scintigraphy can identify gastric mucosa in these lesions, and esophagram and endoscopy with or without ultrasound can also be a helpful adjunct to better delineate the lesion.[84] Treatment is via surgical resection.[90]

Esophageal Perforation

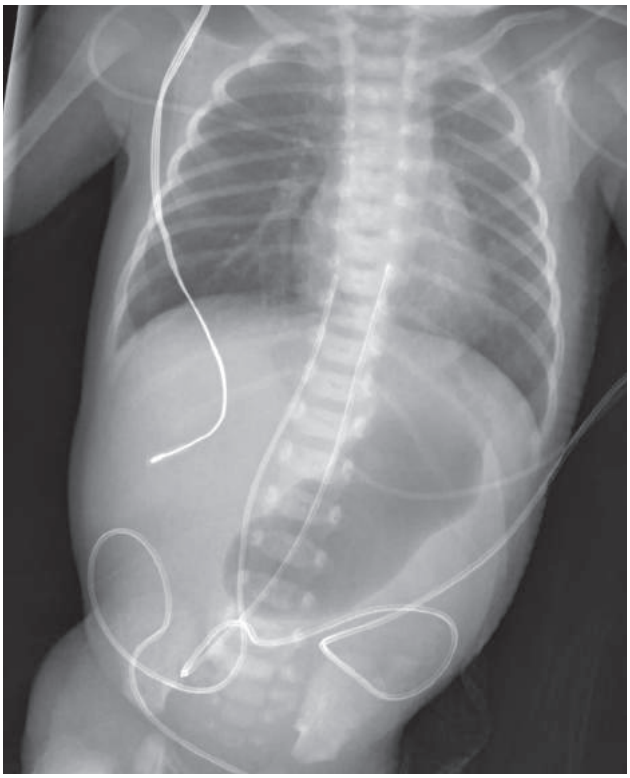
Low birth weight neonates are at higher risk for iatrogenic perforation of the esophagus.[91] In a newborn, the presentation of esophageal perforation can mimic esophageal atresia; in both, there is an inability to pass an orogastric or NG tube into the stomach.[92] When a tube passes beyond the level of the carina but does not enter the stomach, it should raise the possibility of perforation because atresias are almost always at or above the carina (see Fig. 61.8). Treatment depends on the location and severity of perforation. When the perforation is small and the leakage of esophageal contents is contained by surrounding structures in the mediastinum, it may heal without surgical repair. A follow-up contrast study to document healing is important before the initiation of feeds. When the perforation and leak of esophageal contents is larger, especially with contamination of the pleural space, then urgent surgical intervention is indicated.[93]

Disorders of the Stomach

The two congenital malformations of the stomach discussed here, pyloric atresia and gastric duplication, are quite rare and present with vomiting because of partial or complete obstruction. An acquired gastric obstruction, pyloric stenosis, is much more common and also presents with vomiting but not at birth. The last condition reviewed, neonatal gastric perforation, is an acquired condition that presents with respiratory distress, peritonitis, and sepsis.



• **Fig. 61.8** Esophagram of Esophageal Duplication Cyst.

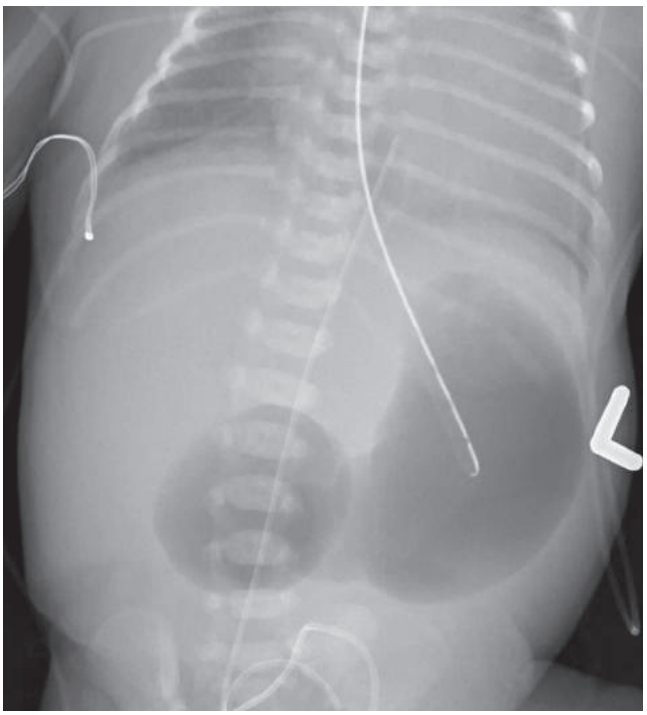


• **Fig. 61.9** Radiograph of Pyloric Atresia in the Setting of Epidermolysis Bullosa.

Pyloric Atresia

Pyloric atresia is a congenital, intrinsic, complete obstruction of the pylorus. It is rare, occurring in 1 in 100,000 live births. There are three distinct anatomic variants of pyloric atresia: (1) a simple membrane (57% of cases), (2) replacement by solid tissue (34% of cases), and (3) a complete separation of the stomach and duodenum (9% of cases).[94]

Prenatally, pyloric atresia leads to polyhydramnios and a dilated stomach, thus prenatal diagnosis is common. Nonbilious vomiting occurs with feeds after birth. Diagnosis is confirmed by abdominal radiographs showing air in a dilated stomach but no air in the GI tract distal to the stomach (Fig. 61.9). The lack of a dilated proximal duodenum on imaging studies distinguishes pyloric atresia from the more common duodenal atresia (Fig. 61.10). Babies with pyloric atresia should be evaluated for epidermolysis bullosa (EB) because of the common association between these two rare conditions.[95] The prognosis of patients with EB and pyloric atresia is poor, although survivors have been reported.[96] Surgical treatment for all forms of pyloric atresia consists of either removing or bypassing the obstruction.



• **Fig. 61.10** Radiograph of Duodenal Atresia Presenting With a "Double Bubble" Sign.

Gastric Duplication

Gastric duplications are similar to esophageal duplication cysts in that they are surrounded by smooth muscle and usually do not communicate with the lumen of the stomach. They are uncommon and comprise only 5% of abdominal duplications.

Gastric duplications are usually located in the distal stomach, and as they enlarge, they cause symptoms of progressively severe gastric outlet obstruction, with vomiting that is usually nonbilious.[88] Approximately one-third of gastric duplications are found in the neonatal period, though they are now also commonly being diagnosed on prenatal ultrasound. The diagnosis may be suspected by palpating an upper abdominal mass, though they are often asymptomatic. They can cause extrinsic compression of the distal

stomach and then be seen on a gastrointestinal series (UGI). Postnatal ultrasounds or CTs are also utilized for diagnosis. Treatment is surgical excision and is recommended even in cases discovered incidentally since most will eventually cause symptoms of gastric outlet obstruction.[88]

Pyloric Stenosis

Pyloric stenosis (or hypertrophic pyloric stenosis [HPS]) is an acquired disorder of hypertrophy of the pyloric muscle at the distal end of the stomach. This hypertrophy narrows the gastric outlet and leads to progressively severe, nonbilious vomiting.

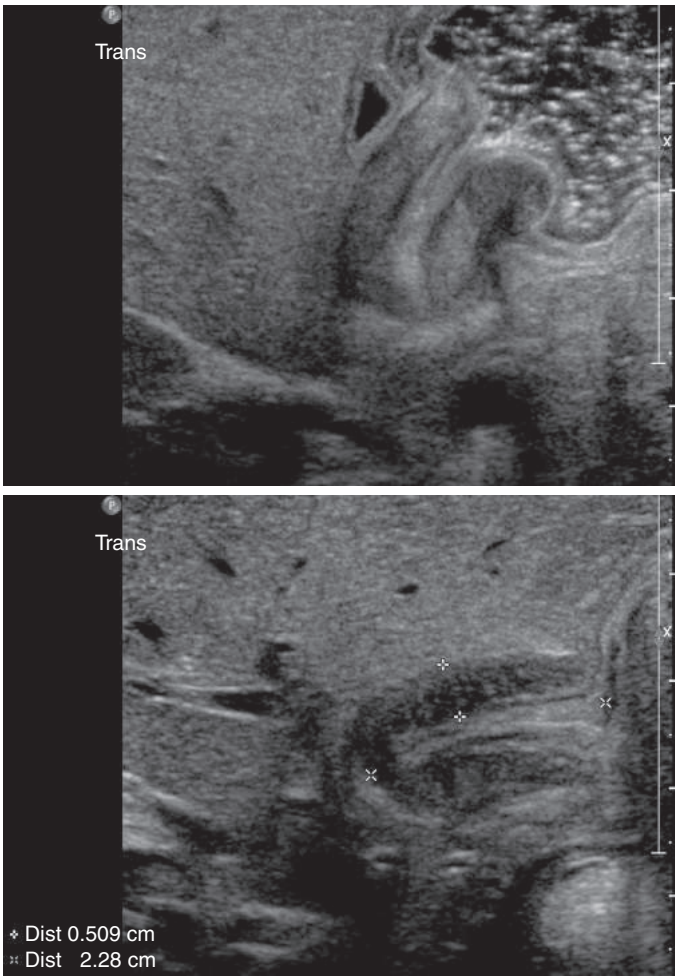
Pyloric stenosis is one of the most common structural problems of the GI tract in infants, with an incidence of 2 to 5 in 1000 live births in the Western population. It occurs almost exclusively between weeks 3 to 8 of life. It is four to five times more common in males than in females, and white infants are more commonly affected than Black or Asian infants. There is a decline in risk with increasing birth order.[97]

The etiology of HPS is unknown. Genetic factors must have a role since there is an increased risk within families: for example, if a baby has pyloric stenosis then the identical twin has an almost 25% chance of having the condition while a nontwin sibling has a 5.8% chance.[97] HPS also occurs more frequently than expected in infants with certain syndromes.[98] Exposure to erythromycin and prostaglandins may also increase the risk of developing HPS.[99] In addition, cesarean section delivery, preterm birth, and bottle-feeding have been found to be associated HPS.[100]

Infants with HPS present with a history of vomiting feedings and gastric contents, similar to patients with reflux or milk protein allergy. Because the pyloric hypertrophy and degree of gastric outlet obstruction are progressive, the vomiting is also progressively more severe. Unlike intestinal obstructions that are distal to the bile duct insertion in the duodenum, the vomiting in HPS is nonbilious, and the loss of gastric contents undiluted by bile and pancreatic secretions leads to a hypochloremic, hypokalemic metabolic alkalosis. The metabolic alkalosis and hypochloremia is due to a loss of hydrogen and chloride ions (HCl) from vomiting gastric contents. The emesis also results in a decrease in extracellular volume, causing contraction alkalosis which stimulates the renin angiotensin aldosterone pathway to reabsorb sodium in exchange for potassium, thereby causing hypokalemia.

The physical examination of a baby with pyloric stenosis may be notable for dehydration, and in some cases, the hypertrophied pylorus may be palpable as a firm, mobile upper abdominal mass known as the pyloric "olive." The diagnosis is usually confirmed with imaging, most commonly an abdominal ultrasound. Ultrasound findings of pyloric stenosis include a pyloric muscle thickness greater than 3 mm and a length greater than 15 mm (Fig. 61.11).[101] Upper GI contrast radiographs can also confirm the diagnosis of pyloric stenosis if ultrasound is not available or uncertain.

After diagnosis, the first step in treatment is to correct intravascular volume depletion as this will permit the correction of any associated hypokalemia and alkalosis. The metabolic alkalosis should be corrected before surgery to prevent alkalosis-induced apnea after general anesthesia. Preoperative protocols for resuscitation and normalization of electrolytes have been published.[102] It may take a day or more to optimize intravascular volume, acid-base balance, and serum electrolytes. To limit the risk of aspiration, the stomach may be evacuated with an NG tube from the time of admission and with a larger red rubber catheter immediately before induction of anesthesia.



• **Fig. 61.11** Ultrasound of Hypertrophic Pyloric Stenosis.

The operative treatment of pyloric stenosis is to incise and split the pyloric muscle layer completely so that the submucosa is exposed from the duodenum to the gastric antrum. This pyloromyotomy can be achieved by an open or laparoscopic approach. The operation is remarkably effective so that feedings can be resumed soon after surgery, and discharge is usually possible within a day or two. Atropine as an alternative to pyloromyotomy has been described but is less effective.[103]

The outcomes of modern management of pyloric stenosis are excellent. Mortality is extremely rare, and there is only a small risk of surgical site infection or wound problems. Other uncommon problems after pyloromyotomy are (1) peritonitis and sepsis from an unrecognized full-thickness mucosal injury and (2) an incomplete myotomy, which can lead to recurrent vomiting (diagnosed by UGI as repeat ultrasound will show postoperative changes). After pyloromyotomy, the pylorus eventually heals, remodels, and appears normal. There are no functional abnormalities of the stomach in the long term.

Gastric Perforation

Similar to esophageal perforations, low birth weight infants are thought to be at higher risk for catheter-associated gastric perforations than term babies. In the absence of obvious trauma, usually from placement of a gastric tube, rupture of the stomach is called "spontaneous," although possible risk factors such as

prematurity, duodenal atresia, mechanical ventilation, or neonatal hypoxia are often identified.[104,105] The mechanism of spontaneous gastric perforation is not known, but it appears to be distinct from necrotizing enterocolitis (NEC) as NEC typically spares the stomach, and the gross and microscopic appearance seen in NEC and spontaneous intestinal perforation are not seen in spontaneous perforations of the stomach.[106] Gastric perforations usually present with large amounts of free air on abdominal x-rays. While decreasing over time, the associated mortality with this condition is still significant.[107] Emergent surgical repair is indicated.

Disorders of the Intestine

Disorders of the intestine reviewed here include intestinal malrotation and midgut volvulus, intestinal atresias, enteric duplications, intussusception, and meconium ileus. These conditions present with intestinal obstruction that may be complicated by intestinal ischemia, necrosis, bleeding, perforation, and/or sepsis. The clinical presentations of these conditions and many other GI tract disorders are usually nonspecific and consist of some combination of signs and symptoms such as pain, feeding intolerance, vomiting, lack of stooling, tenderness, abdominal distention, or mass.

A careful history and physical examination often provide clues to the diagnosis. Pain and tenderness may be caused by visceral distention and/or peritoneal irritation. Typically, nonbilious vomiting is seen with obstruction proximal to the ampulla of Vater (the site of bile drainage into the duodenum), while bilious vomiting results from a more distal obstruction. Abdominal distention in infants is usually the result of diffusely dilated loops of bowel caused by either a functional ileus (intestinal stasis with the accumulation of swallowed air, feedings, and GI secretions) or a true distal obstruction. More-proximal obstructions of the stomach and duodenum usually do not cause significant abdominal distention. Failure to pass meconium in the first 24 hours of life should raise concern for distal GI obstruction.

A clinical concern for intestinal obstruction requires simultaneous supportive care and diagnostic evaluation. Feedings should be stopped, and if there is abdominal distention or signs of intestinal distention on imaging studies, then gastric decompression via an NG or orogastric tube should be done. Intravenous fluids should be given to meet maintenance needs, replace any deficits, and account for any ongoing losses. Antibiotics should be administered when there is a concern for infection.

A directed abdominal examination should be performed to evaluate for distention, tenderness, localized abdominal edema and erythema, hernias, and masses. Abdominal radiographs can help with diagnosis but are rarely definitive. The characteristic imaging findings of specific disorders will be reviewed below. If there are concerns for intestinal obstruction, then a surgical consultation is advised.

Malrotation and Volvulus

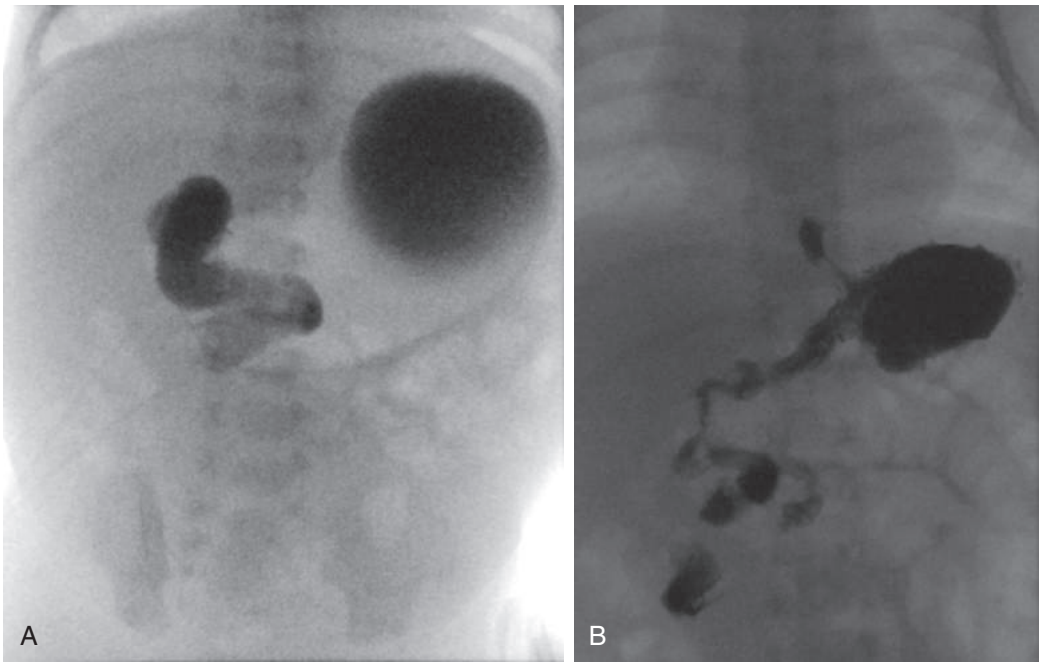
Normal intestinal rotation occurs when the midgut that is herniated outside the abdominal cavity into the umbilical cord early in development returns to the abdominal cavity during weeks 10 to 12 of gestation and fixes to the retroperitoneum in a precise pattern. Normal intestinal rotation results in (1) the duodenum being fixed in the retroperitoneum around the pancreas and transitioning to the intraperitoneal jejunum (visible as the ligament of Treitz) at a point to the left of the spine and above the level of the duodenal bulb, (2) all the small bowel loops floating free in the abdomen, (3) the cecum and ascending colon being attached to the right-lateral posterior body wall up to the hepatic flexure, (4) the descending colon attached to the left-lateral body wall from the splenic flexure to the sigmoid colon, and (5) the blood supply to the entire midgut (jejunum, ileum, and right and transverse colon) attached to the retroperitoneum in a wide pedicle from the ligament of Treitz in the left upper quadrant of the abdomen to the cecum in the right lower quadrant. While a wide spectrum of anatomic abnormalities exists (as a group known as intestinal rotation anomalies),[108] we will focus on classic intestinal malrotation where the duodenum does not cross over the spine, and the other normal attachments to the retroperitoneum do not form, resulting in a narrow mesenteric vascular pedicle. This narrow vascular pedicle supports most of the small and large bowel and is prone to twist which then obstructs blood flow and is called midgut volvulus. Intestinal malrotation may also be accompanied by abnormal retroperitoneal attachments, known as Ladd bands, which can cross the second portion of the duodenum and cause points of obstruction on their own in the absence of volvulus.

The true prevalence of malrotation is difficult to determine for several reasons including symptomatic presentation throughout life and a few children (and even adults) discovered to have asymptomatic variants during imaging studies or operations. Presumably, the more severe anatomic abnormalities are more prone to volvulus and present earlier in life, although life-threatening volvulus can occur in adults.[109] It is believed most malrotation cases, however, present in infancy. Malrotation may occur alone, but it is a regular component of gastroschisis, omphalocele, and congenital diaphragmatic hernia and may accompany intestinal atresia, intussusception (i.e., Waugh syndrome), heterotaxy, and various cardiac defects.

Newborns and infants with midgut volvulus initially present with bilious vomiting, since the twist and resulting intestinal obstruction occur distal to the ampulla of Vater. Early on, there may be abdominal pain, but abdominal tenderness and distention may also be absent. As the twist of the mesentery progresses, the blood supply to the bowel is compromised, and intestinal ischemia and eventually intestinal necrosis and peritonitis set in with resulting pain, tenderness, guarding, abdominal distention, and, eventually, signs of sepsis. Abdominal x-rays may show a gasless abdomen or distended bowel loops, but may also appear normal. A normal appearing x-ray does not rule out volvulus. Furthermore, laboratory studies may also be normal until intestinal ischemia peritonitis and sepsis develop.

Since the entire midgut is potentially at risk for vascular compromise with volvulus, it is essential to make the diagnosis at the onset of symptoms and signs of obstruction before symptoms and signs of intestinal ischemia develop. Midgut volvulus with prolonged ischemia can be a catastrophe either resulting in patient death or leaving a patient with insufficient bowel length to grow without supplemental parental nutrition (i.e., short bowel syndrome). Since early diagnosis is critical, any newborn or infant with bilious vomiting should be considered to have malrotation with volvulus until proven otherwise, and an urgent upper GI series should be obtained. In malrotation, the ligament of Treitz will fail to cross midline to its normal position at the left-sided vertebral body pedicle and will be lower (in the cephalad–caudal axis) than the level of the duodenal bulb (Fig. 61.12). The duodenum should follow a typical path toward the retroperitoneum prior to the transition to the jejunum.

Other imaging findings suggesting malrotation and volvulus include an abnormal position of the cecum by contrast enema



• **Fig. 61.12** (A and B) Upper gastrointestinal series showing malrotation with and without obstruction/volvulus.

and abnormal relationship of the mesenteric vessels by ultrasound. Malrotation can also be diagnosed by CT scan, but CT is rarely indicated in newborns. It is important to emphasize that volvulus in this setting can be associated with a relatively normal-appearing plain film of the abdomen, and thus a high degree of suspicion must be maintained when clinical findings are suggestive.

Midgut volvulus is a surgical emergency. While laparoscopic approaches have been described and may be useful for the evaluation of asymptomatic malrotation, in the setting of acute symptoms an open laparotomy is indicated.[110] The operation of choice is a Ladd procedure that consists of (1) untwisting the volvulized bowel, (2) dividing abnormal bands, (3) broadening of the mesentery, and (4) arranging the bowel so that the midgut mesentery is flat in the retroperitoneum, with the proximal small bowel on the right side of the abdomen and the distal ileum and cecum in the left upper quadrant. The appendix is usually removed since the operation renders its final location unpredictable and diagnosis of appendicitis later in life more difficult (in the developed world with access to modern imaging, the utility of this step is debated). When there is intestinal necrosis, the nonviable bowel is excised. When bowel viability is questionable, "second look" procedures may be performed after a temporary abdominal closure. In neonates with congenital heart defects and asymptomatic malrotation, the American Pediatric Surgery Association (APSA) recommends either observation or postponing the Ladd procedure until after palliation of the congenital heart defect.[108]

Intestinal Atresia

Intestinal atresia is a complete congenital obstruction of the bowel lumen. Atresia is an intrinsic malformation of the bowel and is not a result of extrinsic compression. Esophageal and pyloric atresias are discussed in other sections of this chapter. Duodenal atresia and anorectal atresia are considered separately since each has unique embryology, risk factors, and associated conditions. Jejunal, ileal, and colon atresias, however, have many common features and are considered together here. The process leading to atresia may be incomplete and, in this case, is more correctly called intestinal "stenosis," but the presentation, evaluation, and management are similar, so we will consolidate the discussion of atresias and stenosis together.

Duodenal Atresia

There are several anatomic variations of duodenal atresia including membranous webs, simple occlusions, complete separations of proximal and distal segments, and obstruction associated with annular pancreas, in which abnormal fusion of the ventral and dorsal pancreas lead to the encirclement of the second portion of the duodenum and complete or incomplete obstruction. The exact nature of the developmental abnormality in duodenal atresia is unknown but may be due to a failure of recanalization of the lumen.[111]

The prevalence of duodenal atresia is approximately 1 in 5000 births; however, many studies evaluate all intestinal atresias rather than duodenal atresia specifically.[112] Duodenal atresia is frequently associated with other anomalies including trisomy 21, VACTERL association, cardiac anomalies, intestinal malrotation, anorectal malformations, and biliary tract anomalies, which have important implications for evaluation and management.[113]

Duodenal atresia may be suspected prenatally when other associated anomalies or polyhydramnios are present and by an ultrasound showing a "double bubble." [114] Symptomatic newborns present with vomiting. The vomiting is usually, but not always, bilious since the obstruction is typically distal to the ampulla of Vater. An abdominal x-ray showing a double bubble with no air in the distal GI tract confirms the diagnosis of duodenal atresia (see Fig. 61.10). Duodenal atresia has a characteristic radiographic appearance with a bulbous rounded appearance. Intestinal malrotation and volvulus with complete proximal obstruction in a

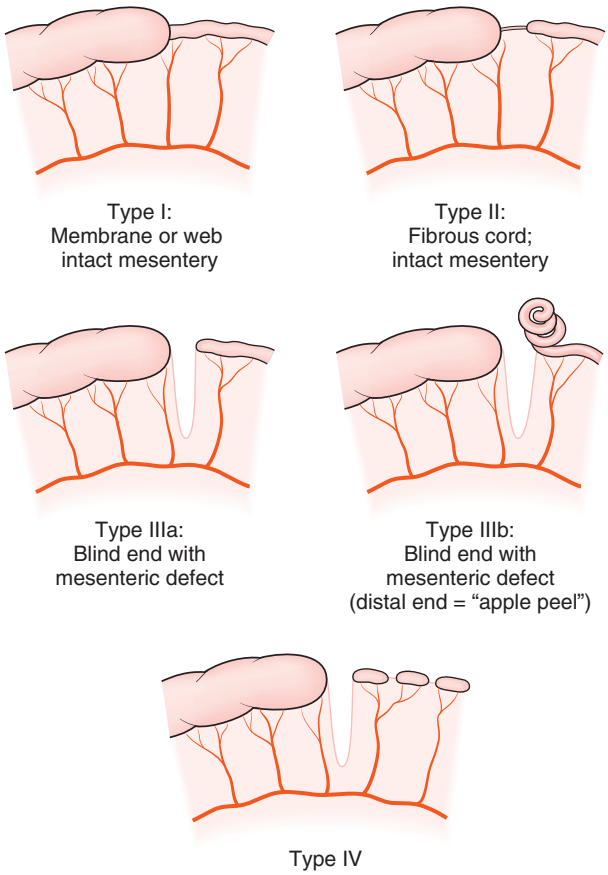
newborn may have an x-ray showing obstruction but usually without typical rounded features of duodenal atresia. If unsure, urgent surgical exploration is warranted. An x-ray with a double bubble sign and air present in the distal GI tract indicates the infant may have duodenal stenosis, but malrotation and volvulus must remain a concern. An upper GI study may be helpful in such cases.

After the diagnosis, initial management includes gastric decompression, fluid resuscitation, and correction of electrolyte abnormalities. Surgical treatment is a bypass of the obstruction with a duodenoduodenostomy. Laparoscopic and open repairs have both been shown to have excellent outcomes; however, gestational age and weight play a role in patient selection.[115] While once a concern, there is now known to be a low incidence of associated intestinal atresias and it is not necessary to "rule out" a distal atresia at the time of laparoscopic repair.[116] Early complications include anastomotic leak and stricture. Potential long-term problems include poor motility of the stomach and duodenum with or without associated megaduodenum.[117]

Jejunoileal and Colonic Atresia

Jejunoileal and colonic atresias are classified based on the anatomic abnormality (Fig. 61.13). The etiology of jejunoileal and colon atresia is thought to be due to a prenatal event associated with mesenteric vascular compromise, for example in utero volvulus. Genetic factors and defective fibroblast growth factor signaling may also play a role in some cases.[111]

The prevalence of small bowel intestinal atresias is approximately 1.6 per 10,000 live births.[118] About one-third of patients with jejunoileal atresia are premature and associated anomalies are less likely, especially compared with patients with duodenal atresia.[119]



• **Fig. 61.13** Types of Intestinal Atresias.

Prenatal ultrasound may show dilated loops of bowel with other loops decompressed. After birth, neonates with jejunoileal and colon atresia present with bilious vomiting, abdominal distention, and failure or delayed passage of meconium; the more proximal the atresia, the earlier the expected onset of signs and symptoms. Abdominal radiographs show dilated loops of bowel with air-fluid levels and an absence of gas in the rectum. After abdominal x-rays, the next step in the evaluation of possible intestinal atresia is typically a contrast enema, which will help differentiate intestinal atresia from meconium ileus, Hirschsprung disease (HD), and small left colon syndrome.[119] A limited upper GI series is sometimes performed as well to confirm normal intestinal rotation and rule out occult volvulus. Contrast enema is helpful to demonstrate the anatomy and patency of the colon, which is important for intraoperative decision-making during which the small bowel is more easily visualized and assessed than the colon.

With atresia, initial management is gastric decompression and fluid resuscitation. An operation is then performed to repair the atresia. The proximal limb of an atresia is typically more dilated than the distal limb, and sometimes significantly so. This creates a technical problem for an end-to-end anastomosis of the bowel in which one end is significantly larger than the other, but also a concern that this chronically dilated segment of bowel may never regain adequate function, leading to stasis and other problems of motility. If the intestine can be spared, it may be removed. When there is a concern for remaining bowel length, the dilated segment may be tapered rather than resected. The distal bowel may be of sufficient length or significantly compromised, raising the possibility for intestinal failure even after correction of the atresia. Early results and long-term outcomes of the operative repair of jejunoileal and colon atresia are good; however, they depend heavily on the total remaining bowel length.[120] Significant loss of bowel can result in short bowel syndrome and in long-term dependence on parenteral nutrition.

Newborns with colonic atresia present similarly to those with more proximal atresia; however, because the obstruction is more distal in the GI tract, the presentation is often delayed until the second or third day of life. Abdominal radiographs show dilated distal bowel and may show a very dilated colon if the ileocecal valve prevents air from refluxing back into the distal ileum. Treatment is similar to jejunoileal atresia, with laparotomy, resection of the dilated colon, and anastomosis. Timely diagnosis and treatment are essential and are associated with a generally excellent outcome, while late diagnosis and treatment (over 72 hours from birth) increase the risk of morbidity and mortality.[121] Colonic atresia can be associated with HD and this should be considered in all cases.[122]

Meconium Ileus

Meconium ileus is an intraluminal obstruction of the terminal ileum by abnormal meconium. Cystic fibrosis (CF) accounts for 90% of patients presenting with meconium ileus, and up to 20% of patients with CF present as newborns with meconium ileus. CF is caused by mutations in the CF transmembrane regulator (CFTR) that alter bicarbonate and chloride transport. These intraluminal fluid changes result in characteristic thickened meconium that adheres to the bowel wall and causes bowel obstruction. Meconium ileus may be "uncomplicated" and result only in bowel obstruction, or it may be "complicated" when the obstruction

leads to twisting and ischemia that may cause ileal atresia and/or intestinal perforation.[123] The term "meconium peritonitis" is a general description of the result of any in utero perforation with meconium spillage into the peritoneal cavity, whether that perforation is caused by meconium ileus or another problem.

Prenatal diagnosis of CF may be suspected when there is a family history of CF or when the parents are carriers of CFTR mutations. CF diagnosis can be confirmed by fetal DNA analysis and, while neither sensitive nor specific, prenatal ultrasound findings of hyperechoic bowel, bowel dilation, and inability to identify the gallbladder have all been associated with meconium ileus.[124]

The newborn clinical presentation of meconium ileus is similar to a jejunoileal atresia with abdominal distention 12 to 24 hours after birth, vomiting, and failure to pass meconium.[125] Abdominal x-rays show dilated loops of bowel suggesting distal intestinal obstruction; however, the appearance is often distinct from other types of bowel obstruction, showing "soap bubbles" in the bowel rather than air-fluid levels. If intrauterine perforation has occurred, abdominal x-rays may show intraabdominal calcifications. When a perforation results in a contained meconium cyst, abdominal distention is often present at the time of birth (rather than several hours later). Abdominal distention at birth should raise immediate concern for this possibility.

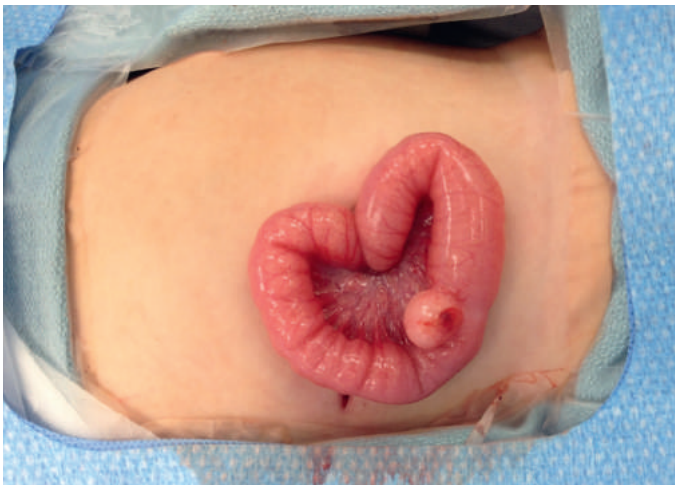
Initial management of babies with meconium ileus is the same as any neonate with bowel obstruction and includes intravenous fluids, correction of electrolyte abnormalities, and gastric decompression. A contrast enema can confirm the diagnosis and offers the chance of nonoperative management of uncomplicated meconium ileus. Instilling water-soluble contrast around and into the abnormal meconium softens it and encourages it to pass out per rectum, thus relieving the obstruction.[124] This can be repeated multiple times in order to relieve the obstruction if the patient is stable and progress is being made.[126] Hyperosmolar solutions have been advocated to draw fluid into the bowel lumen, but they carry the risk of potentially dangerous intravascular fluid shifts. The administration of N-acetylcysteine into the proximal or distal bowel lumen has also been used to help break up the abnormal meconium and relieve the obstruction. Failure of nonoperative measures or the presence of a complicated meconium ileus are indications for surgical intervention.

Operative management of uncomplicated meconium ileus involves laparotomy, opening the small bowel proximal to the obstruction, and irrigation with saline or N-acetylcysteine until the obstructing meconium is cleared. The bowel can often be closed primarily, although sometimes tubes are placed to allow additional irrigation after surgery or ostomies for decompression and potential for distal irrigation. By definition, complicated meconium ileus requires an operation. The goals of surgery are resection of compromised bowel and repair of atresias, often by primary anastomosis, although at times temporary diverting stomas are used.

Long-term GI outcomes after nonoperative or operative management of uncomplicated meconium ileus are generally quite good, although pancreatic insufficiency due to CF, if present, requires lifelong medical management. Any patient diagnosed with meconium ileus must undergo work-up and testing for CF.

Enteric Duplication Cysts

Enteric duplication cysts, often referred to simply as duplications, can occur anywhere in the alimentary tract from mouth to anus.[90,127] Duplications can be cystic or tubular and consist of an inner lining of GI epithelium and an outer layer of smooth muscle. Most duplications occur in the small intestine, especially the distal ileum, and are often on the mesenteric side of the lumen (Fig. 61.14).[128]



• **Fig. 61.14** Intraoperative Photo of a Duplication Cyst.

The overall prevalence of duplications is poorly defined, but a cumulative incidence for all sites and all types is probably around 1 in 4000 to 5000, although any specific duplication type or location is rare. Various theories exist to explain the embryologic etiology for enteric duplications; however, the split notochord theory is generally accepted.[129]

The clinical presentation of an enteric duplication depends on three factors: (1) its location, (2) its relative mass effect, and (3) complications relating to secretions of the involved epithelium.[88] Esophageal and gastric duplication cysts are described in other sections. Only about 4% to 5% of enteric duplications are in the duodenum.[130,131] Duodenal duplications may be connected to biliary or pancreatic ducts. Clinical presentations include asymptomatic masses, GI obstruction, and pancreatitis.[131,132] Jejunal and ileal duplications often present with bowel obstruction or intussusception, sometimes related to segmental volvulus from the weight of the cyst. Colonic and rectal duplications are rare but may present with obstruction or volvulus.[90]

Diagnosis of enteric duplication cysts is made with ultrasound and/or contrast studies, which may show a filling defect. Ultrasound can be used prenatally, leading to early treatment postnatally.[133] CT and MRI may be used to define the location and size of the duplication. Treatment is typically surgical excision; however, the specific location and length of involvement may require an individualized approach.

Intussusception

Intussusception is the telescoping of one portion of bowel into another, usually involving the distal ileum and ascending colon, with a lead point (mesenteric lymph node, Meckel diverticulum, etc.) dragging more proximal bowel into distal bowel. This is a significant source of obstruction and abdominal pain in older infants and toddlers, but it is also a rare cause of intestinal obstruction in neonates.[134] The presenting symptoms of feeding intolerance, vomiting, abdominal distention, and blood in the stool are nonspecific and can delay diagnosis and treatment.[135]

The diagnosis may be made by ultrasound or contrast enema or may be made at the time of operation for intestinal obstruction. Treatment is surgical reduction with resection of bowel if needed, though radiologic enema reduction may be considered in select patients as is standard therapy in older patients.

Disorders of the Colon and Anus

Neonatal Appendicitis

While one of the most common surgical conditions in children, neonatal appendicitis is rare.[136] The clinical presentation usually includes vomiting, abdominal distention and tenderness, and fever.[137] It is unusual to make the diagnosis in the neonate before an operation is performed for peritonitis because of appendiceal perforation. A possible association with HD has been discussed in the literature, and consideration should be given to a suction rectal biopsy in neonates who present with appendicitis.[138] The appendix itself is not a good marker for ganglion cells, and the presence of abnormal ganglion cells or an aganglionic appendix is not diagnostic of HD by itself.

Hirschsprung Disease

HD is characterized by the absence of intrinsic parasympathetic ganglion cells in the submucosal and myenteric plexuses. The condition is caused by premature arrest of the normal craniocaudal migration of neural crest cells in the bowel wall. A segment of abnormal, aganglionic bowel thus exists, extending from the anal canal proximally to the point of arrested migration. HD most commonly involves the rectum and sigmoid colon; however, up to 10% of cases involve the entire colon (i.e., total colon aganglionosis) even extending into the small bowel.[139,140] Aganglionic colon has impaired motility and results in a functional distal bowel obstruction of variable severity. Often depending on the length of involvement, it may present as an intestinal obstruction in the newborn or as intractable constipation in older infants and children if the segment is short. HD may be complicated by enterocolitis, which can cause a clinical picture of marked abdominal distention, pain, tenderness, and systemic manifestations of sepsis. The cause of enterocolitis is unknown; however, it can occur before or after HD is surgically corrected.

The prevalence of HD is estimated to be 1 per 5000 live births. Males are more frequently affected than females (4:1) and Asians, African Americans, and Caucasians (2.8, 2.1, and 1.5 per 10,000 live births, respectively) are more commonly affected than Hispanics (1.0 per 10,000 live births). HD may be an isolated problem; however, almost 20% of cases have chromosomal abnormalities. Although, abnormalities of many genes have been implicated in HD, in most patients the genetic abnormalities have not been defined.[139]

When HD presents in a newborn, the clinical picture is usually of distal bowel obstruction with feeding intolerance, vomiting, and abdominal distention. The diagnosis may be suspected when no meconium is passed in the first 24 hours after birth. An abdominal radiograph may show dilated loops of bowel and a paucity of rectal gas. A characteristic contrast enema will show an abnormally small rectum relative to a larger sigmoid colon, with a calculated rectosigmoid ratio <1 (Fig. 61.15). Diagnosis is confirmed by suction rectal biopsies, which show hypertrophic nerve trunks and a lack of ganglion cells.[141] Suction rectal biopsies cause minimal discomfort and may be performed without sedation at the bedside in the NICU.

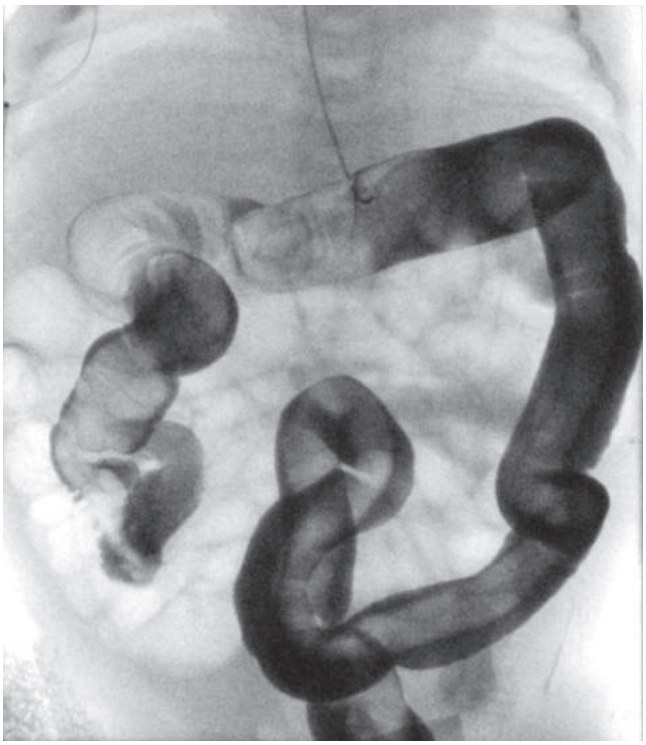
• **Fig. 61.15** Contrast Enema of Hirschsprung Disease.

The surgical treatment of HD involves excision of the abnormally innervated distal colon and a "pull-through" of the normally innervated proximal bowel that is connected to the preserved distal rectum, just above the anal canal. Surgery may be done in multiple stages, with an initial ostomy and then a definitive pull-through done later, or the procedure may be done in a single stage. Surgical approaches include laparoscopic, open, completely via a transanal approach, or with some combination of approaches.

Potential operative complications include anastomotic leak or stricture or damage to nearby structures, including components of the anal sphincter. If the dysfunctional bowel is not completely excised, obstructive symptoms may persist. The functional outcome for any one patient will not be known for years when the child reaches the age of toilet training, but in general, most patients can be expected to achieve social continence and have a good quality of life.[142] It is important to remember that HD is not cured by surgery (every operation leaves behind an abnormally innervated anal sphincter), but a well-done operation can provide excellent palliation, especially with long-term follow-up and management by appropriate specialists.

Meconium Plug

Meconium plug syndrome is the intraluminal obstruction of the colon by abnormal meconium. This contrasts with the intraluminal obstruction of the terminal ileum in meconium ileus. Infants with meconium plug present with delayed passage of meconium, abdominal distention, and perhaps vomiting.[143] Meconium plug is diagnosed by recognition of the passage of abnormal meconium after rectal stimulation, irrigation, or contrast enema (Fig. 61.16). Contrast enema usually resolves the obstruction, and few infants need surgical intervention. Neonates with meconium



• **Fig. 61.16** Contrast Enema of Meconium Plug.

plug syndrome require further evaluation for possible underlying CF or HD.

Anorectal Malformations

Anorectal malformations (ARMs) compromise a spectrum of congenital anomalies in which the anus is either absent or abnormally located outside the normal sphincter muscles. ARMs are often described as "high" or "low" based on where the rectum ends or is suspected to end (e.g., perineum, urethra, or bladder) and relative to the levator muscle component of the anal sphincter muscle complex. However, describing the precise anatomical abnormalities is more valuable and predictive of clinical outcomes (e.g., anorectal malformation with rectoprostatic urethral fistula).[144]

The embryology of ARMs is incompletely understood but results from a disturbance of the complex coordination of the distal GI tract (the hindgut), distal genitourinary structures (especially the bladder, urethra, and vagina), and the musculoskeletal components of the pelvis, spine, and perineum.[145]

The prevalence of ARMs is about 1 in 5000 live births. Associated anomalies are common. Most notable are those of the VACTERL association. In a large multicenter review, of the 4962 children who underwent ARM repair, 31% had vertebral anomalies, 40% had congenital heart disease, 7% had esophageal atresia (EA)/TEF, 34% had genitourinary anomalies, and 7% had limb defects. Thirty-six percent had three or more defined anomalies and thus met the criteria for VACTERL diagnosis.[50] ARMs can also be associated with malrotation, HD, and trisomy 21.[146,147]

Prenatal diagnosis of ARMs is uncommon. After birth, the diagnosis of an ARM is first and foremost dependent upon a good physical examination. Imaging studies are not necessary for initial diagnosis; however, they can assist in determining the level of defect and the existence of fistula. The normal anus is typically halfway between the coccyx and the scrotum or vaginal orifice, and a perineal fistula is typically located anterior to the normal position of the anus and partially or completely outside the sphincter muscle complex. If no anal opening is seen (anal atresia), there may be a blind-ending rectum without a fistula, or the rectum may connect to the urethra, bladder, or inside the vestibule of the vagina (with true rectovaginal fistulae being rare).

The initial management of patients with ARMs includes supportive care for bowel obstruction, evaluation for possible associated anomalies in the VACTERL spectrum, and relief of the obstruction either with dilation of an existing opening or through an operation to create a colostomy. Gastric decompression and intravenous fluids are needed until the bowel obstruction is relieved and enteral feedings are possible. The evaluation for associated anomalies includes a detailed physical examination and imaging studies including echocardiogram, spine radiographs, and renal and spinal ultrasound.[148]

If no anal opening of fistula is present to allow passage of meconium, newborns require surgery for the creation of a colostomy in the first 48 hours of life. Once a colostomy is created, surgical correction of the malformation is often planned for several months later, with the colostomy closed in a staged fashion after this reconstruction has healed. The goal of surgical repair of ARMs is to separate the rectum from other structures and place it into the middle of the muscle sphincter complex. The posterior sagittal anorectoplasty, first described by De Vries and Pena in 1982, is the most common reconstructive procedure performed.[149]

The outcomes of ARMs are related to the severity of the anatomic abnormality and to the presence and severity of associated anomalies. Similar to HD, the surgery for ARMs is more palliative than curative, and functional outcomes take years to accurately assess. Prognosis is suggested by the type of malformation and associated anomalies. A neonate with a perineal fistula and normal sacrum and spine is more likely to achieve voluntary continence than a patient with a rectourethral fistula with sacral agenesis. However, children with even the most severe malformations can still achieve social continence with the help of a long-term bowel management program.

Acknowledgment

This chapter is dedicated to Daniel J. Ledbetter, MD, greatly missed mentor, teacher, and friend.

Abdominal Wall Defects

SHILPI CHABRA, JAMIE E. ANDERSON, AND PATRICK J. JAVID

KEY POINTS

- Gastroschisis is a congenital abdominal wall defect located just to the right of the umbilicus. The bowel that herniates out of the abdomen is not covered by a membrane.
- Fetuses and newborns with a gastroschisis have a low risk of associated anomalies, except for a 10% to 25% risk of intestinal atresia.
- The clinical outcomes of patients with gastroschisis are mainly determined by their intestinal function.
- Surgical options for gastroschisis closure include primary repair via surgical or sutureless bedside approach or delayed repair with temporary silo placement.
- Omphalocele is a congenital midline abdominal wall defect of the umbilical region. The bowel, liver, and other organs that herniate out of the abdomen are covered by a membrane. The umbilical cord inserts into the omphalocele membrane.
- Fetuses and newborns with an omphalocele have a high risk of associated anomalies, especially chromosomal abnormalities and cardiac malformations.
- The clinical outcomes of patients with omphalocele are mainly determined by their associated anomalies.
- Surgical options for omphalocele repair include primary repair or a delayed "paint-and-wait" approach with topical agents that epithelialize the membrane, followed by fascial closure months or years later.

Abdominal Wall Problems

This chapter discusses many of the congenital and acquired abdominal wall problems seen in newborns. It concentrates on gastroschisis and omphalocele, the two most common congenital abdominal wall defects seen in the neonatal intensive care unit (NICU), followed by a review of umbilical cord abnormalities, abdominal wall hernias, and less common congenital abdominal wall defects.

Abdominal Wall Defects

Gastroschisis and omphalocele are the two most common congenital abdominal wall defects that present with herniation of abdominal contents outside the body, requiring reduction of the organs into the abdominal cavity and closure of the abdominal wall defect. However, gastroschisis and omphalocele are distinct conditions with important differences in anatomy and associated conditions that account for their unique management and outcomes (Fig. 62.1).

Gastroschisis

Gastroschisis is a congenital periumbilical abdominal wall defect that is typically located to the right of a normally inserted umbilical cord. The defect results in evisceration of a variable amount of intestine and other abdominal organs outside the abdominal cavity. There is no covering membrane or peritoneum, and the intestine is exposed directly to amniotic fluid prenatally and to the environment after birth (Fig. 62.2). Due to the exposure to amniotic fluid and potential ischemic constriction, there may be secondary bowel damage with thickening and edema (matted bowel) which is covered with fibrinous exudate, often termed the "peel" or "rind." It is unusual for a significant amount of liver to herniate out of a gastroschisis defect. Rarely, the gastroschisis defect is in a mirror image position on the left side of the umbilicus. Left-side gastroschisis has a worse prognosis and is associated with intestinal atresia and extra-intestinal anomalies such as situs inversus, cardiac defects, cerebral arterio-venous malformations, macrocephaly, and scoliosis.[1]

Gastroschisis may be classified as either simple or complicated/complex based on the condition of the bowel and association with intestinal pathologies (atresia, perforation, necrosis, or volvulus). Gastroschisis is considered "simple" when the bowel appears healthy with no intestinal complications and the herniated contents can be easily reduced into the abdominal cavity without underlying anatomic concerns and little post-closure complications. "Complicated" or "complex" gastroschisis includes cases in which there is an associated intestinal atresia, segmental or midgut volvulus, ischemic bowel, intestinal perforation, or the subsequent development of necrotizing enterocolitis.

Complicated gastroschisis has a 7.6× higher mortality than simple gastroschisis.[2] Associated atresias may not be identified initially as the matted bowel can be difficult to fully assess during initial closure. Volvulus, intestinal perforation, or necrotizing enterocolitis may also occur within a few weeks and sometimes up to a few months after closure. In this way, simple gastroschisis at birth can become complicated gastroschisis during the early infant period.

Vanishing or "closing" gastroschisis is a form of complex gastroschisis, in which the gastroschisis fascial defect closes in utero and strangulates the bowel (Fig. 62.3). Babies with vanishing gastroschisis may have little or no viable bowel outside the abdomen and can experience intestinal failure from short bowel syndrome. A new classification scheme for vanishing, or closing, gastroschisis identifies four subgroups[3]:

	GASTROSCHISIS	OMPHALOCELE
		
Location of abdominal wall defect	Right of umbilical cord	Midline, includes umbilical cord
Covering membrane	No	Yes
Umbilical cord insertion	Normal	Into omphalocele membrane
Herniated organs		
Bowel	Always	Common
Liver	Uncommon for more than an edge to be out	Common for large amount of liver to be out
Associated anomalies		
Chromosomal	Rare	Common
Syndromes	Rare	Common
Cardiac	Uncommon, 2%–5%	Common
Bowel atresia	10%–25%	Rare
Major determinant of clinical outcome	Condition and function of bowel	Associated anomalies

• **Fig. 62.1** Gastroschisis Versus Omphalocele.

- Type A (15%): ischemic bowel constricted at the ring but without atresia
- Type B (51%): intestinal atresia with a mass of ischemic, but viable, external bowel
- Type C (26%): closing ring with nonviable external bowel with or without atresia
- Type D (8%) completely closed defect with either a nubbin of exposed tissue or no external bowel.

Epidemiology

The prevalence of gastroschisis in the United States is 4.3 per 10,000 live births.[4] However, in Europe it is reported to be lower at 2.0 per 10,000 births ranging from as low as 0.7 per 10,000 births in Italy to 5.5 per 10,000 births in England.[5] There is no gender predilection in gastroschisis, but the incidence is higher in Hispanic and non-Hispanic white families.[6] For unknown reasons, the incidence of gastroschisis has been reported to be increasing. In the United States, there was an increase in incidence from 4.49 per 10,000 live births in 2004 to 2006 to 5.12 per 10,000 live births in 2010 to 2014,[6] and another recent national inpatient study also reported rising incidence from 4.5 to 4.9/10,000 live births from 2010 to 2014.[7]

The most consistent risk factor for gastroschisis is young maternal age. Mothers under the age of 25 years have a several fold increased risk of carrying a baby with gastroschisis,[4,8–10] and teen fathers have double the risk compared to fathers over 25 years.[11] Numerous other maternal factors have been linked with gastroschisis, including short interpregnancy interval, prior pregnancy loss in mothers younger than age 20, illicit drug use (cocaine, amphetamines), alcohol consumption, prescription opioid use, low body mass index, cigarette smoking, anti-depressants, unmarried status, maternal nativity, and maternal genitourinary infections during gestation.[12–18] Population-based studies also show

• **Fig. 62.2** Gastroschisis Prior to Repair.

• **Fig. 62.3** Vanishing Gastroschisis. Note that the abdominal wall defect has closed.

a higher incidence of gastroschisis in areas where the common agricultural chemical atrazine is used and surface water concentrations of atrazine are elevated.[19,20] However, a more recent study found no correlation of increased risk of gastroschisis in agricultural counties.[21]

Pathophysiology

The embryology of gastroschisis is not completely understood. It occurs early in gestation and although there are rare family case reports, there is no known specific genetic etiology. Its association with young mothers is suggestive of a gene-environment interaction affecting fetuses with either a genetic predisposition or those exposed to unidentified exogenous factors. Pathologically, gastroschisis is a primary midline malformation involving the umbilical ring, with herniation of the intestines (without a covering sac) mostly to the right of the umbilical cord.[22–24] Whether this represents a failure of closure of the primordial umbilical ring before the physiological hernia returns to the abdomen or a rupture of the covering membrane at the ring's edge remains unclear. One theory is that gastroschisis occurs due to a ruptured physiologic hernia and the associated bowel injury is explained by a mesenteric insult.[25]

Unlike omphalocele, extraintestinal anomalies are not common in gastroschisis, although congenital heart disease was reported in 4% of babies with gastroschisis.[26] Anomalies of the intestine are the most common associated malformations in patients with gastroschisis. Nearly all babies with gastroschisis have intestinal malrotation since the bowel is not able to return to the abdominal cavity during fetal development and has no chance for normal rotation and fixation to the retroperitoneum. Intestinal atresia occurs in 10% to 25% of babies with gastroschisis.[27,28]

Clinical Presentation

With routine prenatal ultrasound, about 90% of gastroschisis cases are diagnosed early in pregnancy. Prenatal ultrasound shows extra-abdominal loops of bowel without a covering sac. The maternal alpha fetoprotein level is also elevated.[29] Currently there are no options for fetal intervention, but amnio exchange and fetal repair are being studied as possible future options.[30,31]

Fetuses with gastroschisis have a significant risk of intrauterine growth restriction (IUGR), spontaneous preterm labor, and intrauterine fetal death (IUFD).[32–37] IUGR is a frequent indication for preterm delivery in fetal gastroschisis; however, ultrasound has a low accuracy for diagnosing small for gestational age (SGA) status at birth[38] and the standard formula (that uses the abdominal circumference to calculate fetal growth) has been reported to underestimate the fetal weight.[39] The incidence of IUFD with fetal gastroschisis is approximately 4.5% to 5.2%, which is higher than the reported 2.8% in uncomplicated pregnancies. The mechanisms for sudden fetal death are unclear and possibly related to oligohydramnios, cord compression, vascular compromise, or volvulus.[40,41] Genetic testing of the fetus with gastroschisis is not routinely performed due to lack of specific genetic etiology.

Management

Babies with gastroschisis are best cared for by a multidisciplinary team of maternal fetal medicine specialists, neonatologists, and pediatric surgeons. Prenatal consultation with this group is strongly recommended. Rigorous prenatal surveillance with ultrasounds every 1 to 3 weeks is recommended starting at 24 weeks to evaluate the bowel anatomy, fetal growth, and amniotic fluid volume. Twice weekly nonstress testing (NST) is recommended starting at 32 weeks.

The timing of delivery in gastroschisis remains controversial. Planned preterm delivery is believed by some to reduce IUFD and postnatal complications, but there are no high-quality data to validate this approach, and retrospective studies have conflicting results.[42,43] Two randomized controlled trials failed to show any benefit of elective preterm delivery;[44,45] however, a systematic review reported benefits with decreased neonatal sepsis.[46] A study evaluating the risk of IUFD and neonatal death concluded that mortality can be minimized with delivery at 37 weeks,[41] while another study reported delivery at 38 weeks was associated with decreased risk of stillbirth and a minimal increase in neonatal respiratory morbidity.[47] A literature review concluded that elective delivery at less than 37 weeks is generally not indicated, and delivery should be scheduled between 37 and 38 weeks for uncomplicated gastroschisis.[43] The argument against planned preterm delivery is bolstered by contemporary outcome studies that

consistently demonstrate that preterm delivery is a major source of adverse neonatal outcomes in gastroschisis,[33,48–50] and IUFD did not increase after 35 weeks.[40] Neonates with gastroschisis delivered at less than 37 weeks had longer hospital stays;[51] however, there were no differences in neonatal outcomes between planned delivery at 36 to 37 weeks or at ≥38 weeks.[52] Many centers now advocate for delivery close to term.

There is a stronger consensus regarding vaginal delivery for patients with gastroschisis. Cesarean section seems to offer no benefit to the baby or the mother[53–55] and increases the risk of neonatal respiratory distress.[56] A recent metaanalysis found no difference with elective cesarean section in neonatal mortality or morbidity such as sepsis, short gut syndrome, and duration of hospital stay.[57] Cesarean section is thus not recommended solely for gastroschisis and the delivery mode should be on standard obstetrical indications.[43,58]

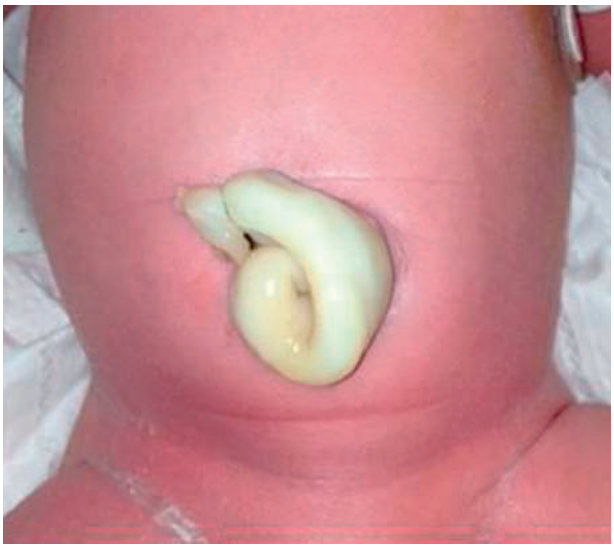
At birth, the umbilical cord should be kept long and clamped at least 30 cm from the baby to preserve the option of primary umbilical closure. Neonatal resuscitation should follow standard protocols, except for placing the baby's lower body, from the nipples to the feet, in a clear plastic bag as a temporary covering over the exposed bowel to minimize evaporative heat and fluid loss. After initial newborn resuscitation measures are performed, the perfusion of the herniated intestinal contents should be carefully evaluated. If bowel ischemia or infarction are suspected, bowel detorsion or emergency enlargement of the gastroschisis defect by a surgeon may need to be performed. An oro- or nasogastric tube is placed to suction to empty the stomach. The baby should be kept warm and dry.

After initial resuscitation and stabilization, the patient is urgently transported to a NICU with pediatric surgical consultation. In the NICU, a peripheral intravenous line is inserted to start intravenous fluids and broad-spectrum antibiotics. Endotracheal intubation is not required unless indicated for respiratory support. Noninvasive positive pressure ventilation is generally avoided to prevent distension of the eviscerated bowel.[59] The baby should be placed with the right side angled slightly down to prevent kinking of the mesentery and maximize blood flow to the bowel. The oro- or nasogastric tube should remain on suction. Bowel perfusion should be visually monitored through the clear plastic bag; opening the bowel bag should be avoided until surgical assessment to avoid further contamination of the bowel.

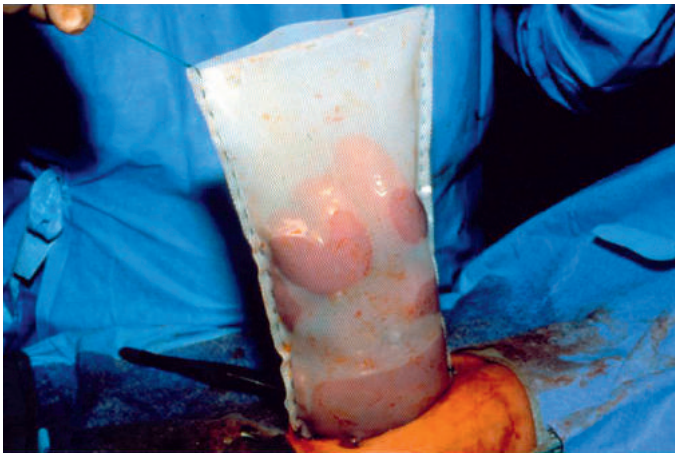
The goal of surgical repair in gastroschisis is safe reduction of the eviscerated contents and closure of the abdominal wall. Multiple surgical options exist to accomplish this goal, and both primary repair and staged repair are acceptable options.

Sutureless abdominal wall closure in gastroschisis uses the patient's own umbilical cord as a biologic dressing to seal the gastroschisis defect without attempting a primary fascial closure.[60,61] The cord is left long at delivery, and the eviscerated contents are reduced into the abdominal cavity while monitoring intra-abdominal pressure. The fascial defect is covered with the coiled umbilical cord that is secured into place with a bandage (Fig. 62.4). In most cases, the gastroschisis defect contracts and the skin heals beneath and around the cord within 14 days. Using sutureless closure, some children will have a persistent umbilical hernia that can be repaired electively at 3 to 4 years of age.[62]

Sutured abdominal wall closure of gastroschisis is now less commonly performed. Sutured closure involves closing the fascial defect with sutures in the operating room under general anesthesia. Intra-gastric or bladder pressure is monitored to ensure the closure does not cause abdominal compartment syndrome. In some cases, a prosthetic patch is required to close the defect. An umbilicoplasty is then performed.



• **Fig. 62.4** Gastroschisis Repair Using Sutureless Umbilical Cord Closure Prior to Application of Dressing.



• **Fig. 62.5** Gastroschisis With Hand-Sewn Silo.

Staged repairs with initial silo coverage of gastroschisis are an accepted surgical strategy that entails delayed reduction of the herniated bowel and closure of the abdominal wall. Silos may be created from silastic or other plastic sheeting and sewn circumferentially to the fascial edges of the gastroschisis defect (Fig. 62.5). Another option is to use a pre-made, spring-loaded silastic silo that is manufactured in different diameters and can be inserted into the gastroschisis defect at the bedside (Fig. 62.6). Once a silo is placed, the bowel gradually reduces over several days into the abdominal cavity by either gravity alone or gentle external pressure. When the reduction takes more than 7 to 10 days, the risk of silo dehiscence from the abdominal wall increases. Delayed sutured abdominal wall closure is performed when the abdominal contents have almost completely reduced into the abdominal cavity. There is also the option of using the sutureless umbilical cord closure technique in a delayed fashion after the bowel has reduced in the silo if the cord is kept moist with dressings. The delayed approach requires close monitoring of the bowel appearance through the silo.

Despite many retrospective studies, database analyses, and meta-analyses, it is unclear which surgical approach is best for any individual baby with gastroschisis.[62–71] Many studies suffer from significant selection bias and do not separately analyze patients with complex gastroschisis, thereby making outcome comparisons difficult. Two randomized, prospective studies to evaluate primary versus delayed fascial closure have not found significant outcome differences between techniques.[72,73] A meta-analysis suggests that delayed primary repair may be associated with improved outcome measures when studies with selection bias are eliminated from the analysis.[74]

The choice of primary fascial closure versus delayed repair using a silo may be less relevant in the era of sutureless abdominal wall closure. Primary sutureless umbilical cord closure is successful in many babies with gastroschisis, may be performed at the bedside, does not always require general anesthesia, and reduces duration of mechanical ventilation.[66,75] In our experience, sutureless umbilical closure is associated with shorter NICU stays and shorter time to initiation of enteral nutrition,[76] as well as decreased hospital costs, ventilator days, and time to goal enteral feeding[77] compared to delayed closure with a silo. One retrospective case control study showed a decrease in mechanical ventilation of 2.8 days and reduction in need for general anesthesia in patients with sutureless versus sutured repair.[78] A multicenter cohort study by the Midwest Pediatric Surgery Consortium reported that sutureless closure was associated with less general anesthetics, antibiotic use, surgical site infections, and decreased ventilator time.[79] In contrast, a single-institution randomized controlled trial comparing sutureless versus sutured primary closure in simple gastroschisis found increased time to full feeds and discharge among patients with primary sutureless closure.[71] Multicenter randomized clinical trials are needed to determine the potential advantages of the sutureless approach.

The gastroschisis prognosis score (GPS) is a validated bedside visual bowel-injury-scoring tool performed after birth. It is helpful for distinguishing low from high morbidity groups and assists in initial counselling.[33] Babies with uncomplicated gastroschisis have average hospital stays of 4 to 6 weeks, which is largely due to their inability to tolerate full enteral feedings. Babies with complicated gastroschisis often have much longer hospital stays.

• **Fig. 62.6** Gastroschisis With Premanufactured Silo.

Outcomes

Outcomes for children born with gastroschisis in high-income countries are excellent. Survival of greater than 95% can be expected in cases of uncomplicated gastroschisis. Infants with complex gastroschisis are at higher risk for overall mortality (2%), need for assisted ventilation (95%), bowel resection (10%), necrotizing enterocolitis (5%), sepsis (9%) and need for home parenteral nutrition after discharge (2%).[3,80] While only a small minority of babies with gastroschisis will need extensive bowel resection, gastroschisis remains a leading etiology of short bowel syndrome in most series of children with intestinal failure.[81,82] In resource-limited settings, mortality remains very high, primarily due to lack of access to total parenteral nutrition, which is required when awaiting return of bowel function.[83] Targeted interventions such as improving prenatal diagnosis and management protocols for earlier enteral feeding, adequate vascular access, and fluid resuscitation have demonstrated improved outcomes in resource-limited settings.[84,85]

Long-term outcomes in gastroschisis are favorable. Most patients will have normal gastrointestinal function and neurodevelopmental outcomes.[86,87] Even though gastroschisis is almost always associated with intestinal malrotation, the risk of midgut volvulus later in life is low (reported at 1%), probably because intra-abdominal adhesions limit the ability of the bowel to twist.[88] These patients may develop hernias at the site of repair. Finally, although boys with gastroschisis commonly have undescended testicles, about 50% of patients will undergo spontaneous testicular descent and not require an operation.

Omphalocele

An omphalocele (known as exomphalos in the United Kingdom) is a midline abdominal wall defect with herniation of bowel and possibly liver and other organs outside the abdomen. Although there is no consensus definition of giant omphalocele, it is often described as omphaloceles with fascial defects greater than 5 cm in diameter or those containing large amounts of liver.[89] The herniated contents are covered with a membrane consisting of peritoneum on the inside, amnion on the outside, and Wharton's jelly between those two layers. The umbilical cord inserts into the membrane rather than the abdominal wall (Fig. 62.7). The

• **Fig. 62.7** Omphalocele.

omphalocele membrane is usually intact, but it occasionally ruptures, resulting in exposure of the herniated visceral contents.

A ruptured omphalocele can be difficult to differentiate from gastroschisis, especially during the prenatal period. Until recently, both omphalocele and gastroschisis shared the same International Classification of Diseases (ICD) code; however, they have since been separated when we submitted a proposal to change the two ICD codes.[90] Ultrasound findings that favor the diagnosis of gastroschisis include a relatively small abdominal wall defect (usually less than 4 cm in diameter), the absence of covering, no liver protruding outside the body wall, and an umbilical cord that is normally inserted into the body wall just to the left of the defect.

Some authors make a distinction between an omphalocele and a hernia of the umbilical cord. In a hernia of the umbilical cord, the umbilical ring is reportedly normal. Since there is only an open umbilical ring and no deficiency of abdominal wall, the surgical repair is much easier. More importantly, unlike newborns with omphaloceles, newborns with a hernia of the umbilical cord reportedly have a low risk of associated anomalies. The clinical differentiation can be difficult, and some physicians refer to a hernia of the umbilical cord as a small omphalocele.[91]

Epidemiology

The incidence of omphalocele is estimated to be 1.5 to 3 per 10,000 births.[4,5,92] The incidence of omphalocele has been stable over time, unlike the incidence of gastroschisis, which is increasing.[92,93] Most cases of omphalocele are sporadic and often associated with chromosomal anomalies, but there are rare familial occurrences.[94]

Risk factors for omphalocele include a maternal age less than 20 years or greater than 40 years, and maternal obesity.[4,95] In contrast to the relatively low risk of associated anomalies in babies with gastroschisis, babies with omphalocele are twice as likely as those with gastroschisis to present with other birth defects. These associated anomalies play a major role in how patients are managed and in their eventual outcome.[96] Chromosomal anomalies such as trisomy 13 and 18 are common, especially in fetuses diagnosed early in gestation.[92,97] In addition, other congenital malformations are frequent, especially congenital heart disease, which may occur in up to 50% of newborns with omphalocele.[93] Finally, omphalocele is a component of several syndromes of congenital malformations, including Beckwith-Wiedemann syndrome, which occurs in 6% of newborns with an omphalocele. Up to 10% to 20% of newborns thought to have an isolated omphalocele have Beckwith-Wiedemann syndrome on prenatal evaluation.[98]

Pathophysiology

Normal development of the abdomen involves the flat, three-layered embryonic disk folding from top, bottom, and both sides to meet at the umbilical ring to form the cylindrical torso during the fourth to fifth week of gestation. The gastrointestinal tract begins to grow very rapidly early in the first trimester, and due to lack of room in the abdominal cavity there is a physiologic bowel herniation through the umbilical ring into the umbilical cord. By 10 to 12 weeks, the bowel returns back into the abdomen in a precise pattern of rotation and fixation to its final position. The embryology of omphalocele is still not clear, and this malformation is thought to occur due to incomplete abdominal wall folding and failure of the intestinal tract to return from the umbilical cord.[99,100] Currently, omphalocele is thought to occur due to the embryonic dysplasia combined with malfunction of the ectodermal placodes.[101]

Clinical Presentation

The prenatal diagnosis of omphalocele may be suspected when maternal serum α-fetoprotein levels are elevated or when there is fetal aneuploidy. The definitive diagnosis is made by prenatal ultrasound. The prenatal ultrasound findings of omphalocele are abdominal organs herniated outside the abdominal cavity and covered with a membrane, and an abnormal insertion of the umbilical cord into the membrane rather than into the abdominal wall.[97] Prenatal ultrasound diagnosis of omphalocele can be reliably made after the first trimester when the bowel returns to the abdominal cavity. The finding of liver outside the abdomen potentially allows an earlier and more accurate diagnosis of omphalocele.[102] It is also important to note the presence or absence of liver within the omphalocele since the presence of liver is associated with a higher risk of other anomalies.[97]

Management

The prenatal management of omphalocele includes evaluation for associated anomalies with imaging for structural anomalies and monitoring of fetal growth because of the risk of IUGR. Because of the high risk of congenital heart disease, fetal echocardiography is indicated. Other specific evaluations for associated pulmonary hypoplasia and the size of the defect, such as fetal MRI, are recommended to provide improved prenatal counseling about the expected hospital course and the long-term prognosis.[103,104]

Obstetric care including the timing and method of delivery is usually determined by traditional maternal and fetal factors rather than by the presence of the omphalocele. Specifically, there is usually no benefit (and there is potential harm) with preterm delivery[105] due to lung immaturity in the setting of possible pulmonary hypoplasia. Cesarean section is indicated only for most fetuses with large defects containing liver (i.e., giant omphaloceles) and is commonly performed in this scenario[55,106] to avoid inadvertent rupture of the sac.

After delivery, the initial evaluation and resuscitation of a baby with an omphalocele follows the same priorities as for all newborns. During the initial resuscitation, a newborn with an omphalocele should be handled carefully to prevent the omphalocele membrane from tearing. After the initial resuscitation, the omphalocele should be inspected to confirm that it is intact and then covered with a nonadherent dressing or bowel bag to protect the sac.

Newborns with omphaloceles, especially large omphaloceles, may have respiratory insufficiency caused by pulmonary hypoplasia and pulmonary hypertension,[107] and they may require respiratory support.[108] In addition, those babies with associated Beckwith-Wiedemann syndrome may have hypoglycemia and require supplemental glucose. An early evaluation for possible associated anomalies, especially congenital heart disease, is required to diagnose conditions that may need further treatment.

The goal of operative treatment of omphalocele is to reduce the herniated organs back into abdomen and close the abdominal wall. Surgical closure of an omphalocele is not an emergency if the omphalocele membrane remains intact. This allows time for the evaluation of associated anomalies and supportive treatment of co-morbidities. If the omphalocele membrane ruptures, it can

sometimes be repaired using suture at the bedside.[109] When a ruptured omphalocele cannot be repaired, the care of the patient and the abdominal wall defect follows a pathway more similar to the care of newborns with a large gastroschisis, although surgical closure is usually more complicated, and both mortality and morbidity are high.[110]

Decisions regarding initial operative versus nonoperative management of the omphalocele depend on whether the membrane is ruptured, the size of the omphalocele including the eviscerated contents, and co-morbidities. When the omphalocele is relatively small and the baby is otherwise stable, an early operation with excision of the omphalocele membrane, reduction of the herniated organs, closure of the abdominal wall muscles, and umbilicoplasty is performed. When the defect is too large to safely reduce the viscera and close the abdominal wall, or if the baby has significant comorbidities, the repair can be staged using a "paint-and-wait" approach if the membrane is intact, or silo placement with delayed surgical repair if the membrane is ruptured.

The "paint-and-wait" delayed approach is accomplished by treating the intact omphalocele membrane with daily application of topical agents that allow the sac to epithelialize, followed by delayed surgical repair months later.[111] A variety of topical agents have been used to treat the omphalocele sac. The agents most commonly used in the United States are silver sulfadiazine cream and povidone iodine solution.[89,112–114] As the sac opacifies and eventually epithelializes, the baby continues to grow with adequate caloric intake. Caloric goals in neonates with omphalocele can generally be reached with enteral nutrition and oral feeds. Prolonged need for parenteral nutrition is rare with uncomplicated omphalocele. The growth of the abdominal cavity allows the herniated abdominal organs to reduce back into the abdomen with gravity alone or with mild external compression. Lung growth over time will also improve the baby's ability to tolerate an operation and an abdominal closure. The eventual repair of the abdominal wall can be done several months or even years later.[115] The "paint-and-wait" approach is especially useful in the management of giant omphaloceles when there is no reasonable chance for early reduction, and in the management of smaller omphalocele in patients with significant congenital cardiac or other disease that precludes an upfront surgical repair.

If the membrane is ruptured, unable to be repaired, and the defect is very large, a staged surgical repair can be performed. The staged surgical repair involves initial silo placement followed by serial reduction of the silo, and finally closure of the abdominal wall. This strategy is almost identical to the staged approach often used for gastroschisis.[111] The early, staged approach is not always successful if the abdominal defect is large and a significant amount of herniated contents need to be reduced into a small abdominal cavity. In addition, reducing the abdominal contents may impair ventilation which can be a significant problem in the setting of underlying pulmonary insufficiency.[116]

Outcomes

The survival and long-term outcomes of newborns with omphaloceles are mainly determined by the severity of associated anomalies.[92,117] After the repair of omphalocele, volvulus occurs in up to 4% of omphalocele cases.[88] Long-term morbidity includes feeding difficulties, failure to thrive, gastroesophageal reflux disease, inguinal hernias, chronic lung disease, and neurodevelopmental and motor delays.[118,119] Babies with giant omphaloceles have increased mortality and morbidity because of the large abdominal wall defect and associated pulmonary hypoplasia and pulmonary hypertension.[103,106,120] Overall survival for liveborn omphalocele infants has improved over the last few decades, and 1-year survival rates have been reported as high as 90% in cases of isolated omphalocele.[92]

Other Abdominal Wall Defects

Body Stalk Anomaly

Body stalk anomaly (BSA), also known as the limb-body wall complex, is a rare, lethal, severe body wall defect of the abdomen and chest in which the abdominal wall does not develop and the peritoneal cavity is left open to the extraembryonic coelom (Fig. 62.8). Prenatal ultrasound can visualize the herniated organs from the chest and abdomen. In addition, a fetus with a body stalk anomaly will usually have scoliosis and other abnormalities including malrotation of the spine and incomplete closure of the pelvis with malrotated limbs and/or club feet. The umbilical cord is either short or absent. If the umbilical cord is absent there are direct vascular connections between the fetus and placenta. It is important to recognize BSA on prenatal imaging so that families can receive appropriate prenatal counseling.[121] Diagnostic criteria for BSA include two of the three anomalies:

1. Exencephaly/encephalocele with facial clefts
2. Thoraco- and abdominoschisis (midline defect)
3. Limb defect (i.e., club foot, polydactyly, oligodactyly, syndactyly, brachydactyly, amelia)

Body stalk anomalies are generally not associated with chromosomal anomalies.[122]

Bladder Exstrophy

Bladder exstrophy is an anomaly of the lower abdominal wall, pelvis, and pelvic organs in which an open bladder makes up the lower part of the anterior abdomen. The open bladder is

• **Fig. 62.8** Body Stalk Anomaly, Also Called Limb Body Wall Complex. (From Plakkal N, John J, Jacob SE, et al. Limb body wall complex in a still-born fetus: a case report. *Cases J*. 2008;1:86. Image under the terms of the Creative Commons Attribution License. https://creativecommons.org/licenses/by/2.0.)

accompanied by a separation of the pubic symphysis. It is a rare anomaly with an incidence of 3 to 5 cases in 100,000 births, and it occurs at least twice as often in boys compared to girls.[123] The etiology is unknown, and it is grouped into the exstrophy-epispadias complex of anomalies. Surgical treatment is required but is not an emergency, so patients can be transferred to specialized centers for definitive care. Early management consists of protecting the exposed bladder mucosa from injury by applying a nonadherent dressing. Evaluation for associated anomalies includes ultrasound for associated upper urinary tract anomalies and an abdominal radiograph to assess the degree of pelvic bone separation.

Cloacal Exstrophy

Cloacal exstrophy is another anomaly grouped into the exstrophy-epispadias complex of anomalies (Fig. 62.9). It is also known as OEIS complex—Omphalocele, Exstrophy, Imperforate anus, Spinal dysraphism—that describes its usual features. Cloacal exstrophy is rare, occurring in about 1 in 100,000 births, and is associated with the 1p36 deletion.[124] Most patients present with an abdominal wall defect that at its cephalic aspect consists of an omphalocele. The omphalocele is in continuity with a more caudal complex exstrophy of two lateral bladder halves joined to a central bowel exstrophy called a cecal plate. This exstrophy complex is accompanied by pubic symphysis diastasis (similar to that seen in bladder exstrophy) and imperforate anus. It may be associated with spinal dysraphism.

Bowel peristalsis and abdominal pressure often lead to prolapse of the terminal ileum and the distal colon/hindgut lumens that are normally attached to the cecal plate. Early management consists of a nonadherent bandage to the exposed bladder and bowel mucosa. Surgical reconstruction is complex and often done in stages. Overall survival is high, but there is substantial long-term morbidity including abnormal function of the anorectal and urinary tracts, and neurologic impairment.[125]

Prune Belly Syndrome

Prune belly syndrome (PBS), also known as Eagle-Barrett syndrome, is a rare condition notable for complete or partial lack of abdominal wall muscle and severe genitourinary abnormalities including bilateral intra-abdominal cryptorchidism, megalourethra, megacystis, hydroureteronephrosis, and renal dysplasia.[126] The cause of PBS is unclear; however, genetic etiology is supported due to 3% of cases being associated with a genomic HNF1β (hepatocyte nuclear factor) mutation, a transcription factor that regulates gene expression for mesodermal/endodermal development.[127] A significant cause of mortality in newborns with PBS is pulmonary hypoplasia, while a major component of long-term morbidity is urinary tract abnormalities, which often result in end-stage renal disease.[128,129] Treatment involves a multidisciplinary team to address urinary tract anomalies, correction of cryptorchidism, and repair of abdominal wall flaccidity. Since bladder dynamics and renal function can change over time, ongoing monitoring of the urinary tract remains crucial.[128] Several reconstruction procedures of the abdominal wall have been described to improve bladder and gastrointestinal function.[130]

• **Fig. 62.9** Cloacal Exstrophy.

Umbilical Abnormalities

Umbilical abnormalities seen in newborns usually present as an umbilical mass or umbilical drainage.

Umbilical Granulomas

The most common umbilical abnormality in infancy is acquired granulation tissue, also described as granuloma formation. Umbilical granulomas are the result of persistence and hypertrophy of the normal granulation tissue present at the base of the umbilicus after the cord separates away from the body wall. Histologically, granulomas are comprised of fibroblasts and capillaries. Granulomas usually present as small (less than 1 cm in diameter), moist, pink or red masses at the umbilicus. They may have serosanguinous drainage or fibrinous exudate that can be confused with the drainage of a soft tissue infection. Most small granulomas will spontaneously dry out and the surrounding skin will contract and heal around the umbilicus.[131,132] Sometimes skin will grow over the granuloma and, as the inflammatory tissue shrinks, eventually result in a skin tag. These skin tags usually become smaller over time. Silver nitrate cauterization of the granulation tissue will eliminate or decrease the size of the umbilical granuloma and allow for the skin to heal. Surgical excision or ligation is usually not necessary unless the lesion persists.[132]

Delayed Separation of the Umbilical Cord

After birth the umbilical cord usually dries out and falls off within a week, but there is considerable variability in the timing of this separation. Some of the variability in umbilical cord separation depends upon how the cord is cared for after birth since bacterial colonization may play an important role in the process. Cords that are treated with more intensive antiseptic regimens typically fall off later than cords that are simply kept clean and dry.[133]

There is no standard definition of delayed separation of the umbilical cord, but in the United States, if cord separation takes more than 2 to 3 weeks, it raises concerns for immune deficiency, urachal anomalies, or infection.[134] Leukocyte adhesion deficiency should be suspected when a newborn presents with delayed cord separation and soft tissue infection around the umbilical stalk.[135] However, most infections associated with the umbilical cord are not associated with immune deficiencies.

Umbilical and Periumbilical Infections

The lack of an epithelial barrier at the unhealed umbilicus, normal bacterial colonization of the skin, and potential contamination of the area during cord care make the umbilicus vulnerable to bacterial invasion. Newborns with unimmunized mothers and improper cord care are at risk for neonatal tetanus, which can be a significant problem in resource-limited countries.[134,136]

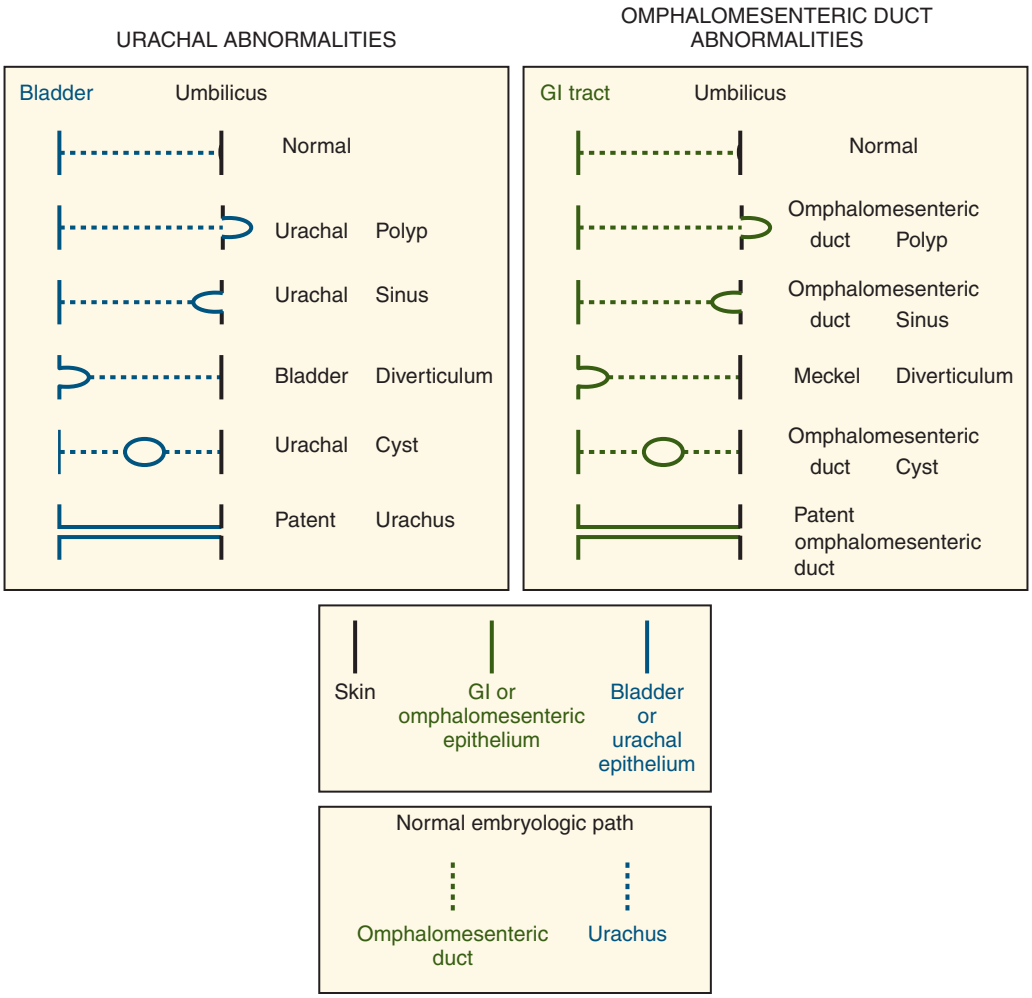
A more common bacterial soft tissue infection of the periumbilical region is omphalitis. Omphalitis ranges in severity from simple cellulitis to necrotizing soft tissue infection of the abdominal wall. The severity of infection depends on host defenses, the virulence of the infecting organism, and the depth of invasion. In high-income countries the incidence of omphalitis is reported at less than 1%, but in resource-limited countries the incidence is much higher.[137] Omphalitis is often a polymicrobial infection with staphylococcus, streptococcus, aerobic gram-negative rods, and anaerobes.[138] Treatment of omphalitis includes broad-spectrum antibiotics and, for invasive infections, surgical debridement of involved tissues. Omphalitis can be a serious infection causing life-threatening systemic sepsis. The infection can also spread up the umbilical vein and cause inflammation and thrombosis of the portal venous system that may evolve into symptomatic portal hypertension years later.[138]

Persistent Remnants of Urachus and Omphalomesenteric Duct

The omphalomesenteric duct and urachus are present during early development but normally regress or obliterate. Persistent remnants of the urachus and omphalomesenteric duct may present with drainage from the umbilicus with or without an umbilical or periumbilical mass. The size and location of the persistent remnant determines the clinical presentation more than the remnant's embryologic origin. The individual pathologic types of remnants are schematically represented in Fig. 62.10 and include polyps, sinuses, fistulae, cysts, and bands. These types may exist alone or in combination.

Umbilical polyps are much less common than umbilical granulomas as a cause of an umbilical mass or umbilical drainage. An umbilical polyp is an epithelial remnant of the omphalomesenteric duct or the urachus that persists at the skin level and presents as a moist, bright red, round mass. The serous exudate or mucous secretions of the epithelium account for the umbilical drainage. Unlike the granulation tissue of an umbilical granuloma, the epithelium of an umbilical polyp will not respond to silver nitrate cauterization, and surgical excision is required.

A partial, persistent remnant of the urachus or omphalomesenteric duct that is open to the skin at the umbilicus is known as



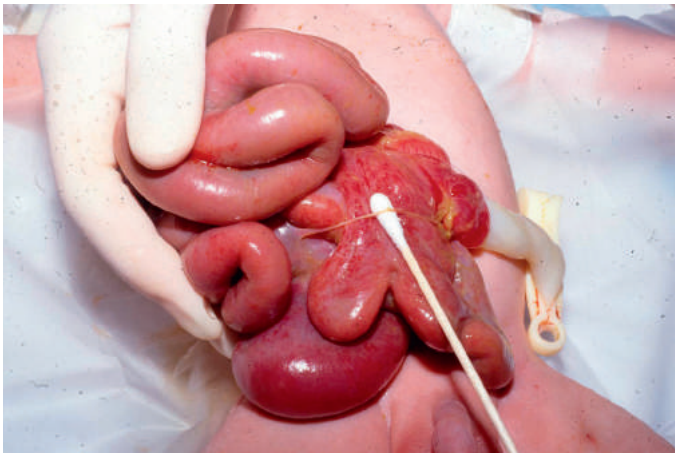
• **Fig. 62.10** Schematic of Urachal and Omphalomesenteric Duct Remnants.

a urachal sinus or an umbilical (or omphalomesenteric) sinus (see Fig. 62.10). Similar to umbilical polyps, sinuses present with umbilical drainage and require surgical excision. A partial, persistent remnant of the urachus or omphalomesenteric duct that is open to the lumen of the bladder or GI tract is known as a bladder diverticulum or Meckel's diverticulum, respectively (see Fig. 62.10). A partial, persistent remnant of the urachus or omphalomesenteric duct that does not connect to the skin or the underlying bladder or bowel lumen is known as a urachal or omphalomesenteric cyst, respectively (see Fig. 62.10), and presents as a midline mass in the abdominal wall at or near the umbilicus. Cysts may also present with increasing size, pain, tenderness, and fever if they become infected. Cysts require excision, although if infected they may first require incision and drainage, and then interval resection.

A complete persistent remnant of the urachus or omphalomesenteric duct results in a fistula between the umbilicus and bladder or bowel respectively (see Fig. 62.10). When the fistula is connected to the bladder it is known as a patent urachus and may drain urine. When the fistula is connected to the GI tract it is known as an omphalomesenteric (or vitelline) duct fistula and may drain stool. When this fistula is obliterated, it may also form an adhesive band, which could be a nidus for bowel obstruction in the future (Fig. 62.11). Treatment for fistulae includes surgical excision and closure of the bladder or bowel respectively using an open or laparoscopic technique.[132]

Abdominal Wall Hernias

A hernia exists when the contents of a body cavity extend through the normal wall of that cavity. Abdominal wall hernias are conditions in which intra-abdominal contents protrude through the normal muscle and fascial layers of the abdominal wall. The congenital abdominal wall defects discussed in the previous section are types of abdominal wall hernias. In contrast to those conditions that present prenatally or immediately after birth, this section will briefly discuss abdominal wall hernias that usually present after birth, although their anatomic cause may be due to an abnormality of development.



• **Fig. 62.11** Omphalomesenteric (or Vitelline) Duct Remnant in a Patient With Gastroschisis.

Inguinal Hernia and Hydrocele

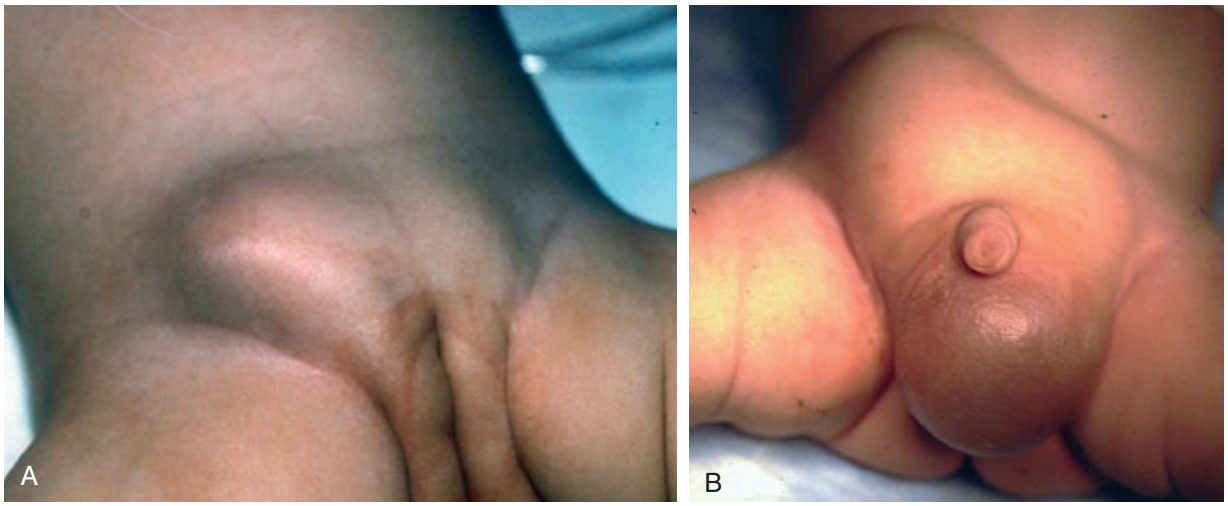
Inguinal hernias are the bulging of intra-abdominal contents through the abdominal wall in the groin (Fig. 62.12). In adults, this may be the result of abdominal wall muscular injury or weakness, but in infants and children the hernia is most commonly the result of a persistent congenital protrusion of the peritoneum through the internal and external ring openings of the abdominal wall muscles. This peritoneal protrusion is known as a patent processus vaginalis. As it crosses the abdominal wall, it is immediately adjacent to the spermatic cord structures in boys, and the round ligament of the uterus in girls. In boys, the processus vaginalis is the path of normal descent of the testis, and it normally closes except for a small pouch around the testis. When it remains open and is large enough, pressure in the abdomen may allow passage of intra-abdominal contents through the abdominal wall, perhaps all the way into the scrotum. When organs or parts of organs protrude it is called a hernia, and when only fluid goes into the processus vaginalis it is known as a hydrocele.[139]

Approximately 1% to 5% of children will have an inguinal hernia. Hernias are more common in boys compared to girls.[140] Hernias are also much more common in premature babies compared to term babies.[141] Unlike umbilical hernias, inguinal hernias do not spontaneously close and tend to enlarge over time. The major risk of an inguinal hernia is the possibility of strangulation of the hernia contents with life-threatening intestinal ischemia. An additional complication may be compression of blood supply to a gonad by the protruding hernia with subsequent loss of testicle or ovary. Strangulation only occurs when hernias are incarcerated; that is, when the contents are not reducible back into the abdomen. Therefore, a nonreducible or incarcerated inguinal hernia requires urgent surgical evaluation. In otherwise healthy infants, inguinal hernias are repaired electively, soon after their diagnosis, since the operation is well tolerated and the risk of anesthesia is low.[142] Premature infants are prone to apnea after general anesthesia, so the ideal timing of operation in this group is controversial.[143,144] A baby who has an inguinal hernia has an increased risk of developing a contralateral hernia later in life, but the risk may not be high enough to justify routine contralateral "prophylactic" hernia repair.[145]

Inguinal hernias present with groin bulges that may extend into the scrotum or labia (see Fig. 62.12). When fluid alone is present in a persistent processus vaginalis it is known as a hydrocele. Hydroceles may be simple collections present at birth in the normally present pouch around the testis, or they may develop after birth along any portion of the path of the processus vaginalis. Hydroceles present at birth may spontaneously resolve, although it may take up to a year. Hydroceles that have an open connection into the abdomen "communicate" across the internal ring will show size fluctuations. Communicating hydroceles are unlikely to resolve, so they are treated as inguinal hernias, although their repair is not urgent. Large hydroceles can be difficult to differentiate from inguinal hernias, especially when hydrocele fluid extends up into the inguinal canal.

Umbilical Hernia

The umbilical ring is the normal fascial layer that surrounds the umbilical cord going through the abdominal wall. It represents



• **Fig. 62.12** Right inguinal hernia in a female (A) and male (B).

the junction of superior, inferior, and lateral body wall folds. An umbilical hernia is a protrusion of bowel or omentum through an open umbilical ring, producing a bulge at the umbilicus. The umbilical ring normally closes after birth, but it may take months or years to become too small for contents to herniate through the abdominal wall.

Umbilical hernias are usually not present in the first few days of life but may become noticeable after a few weeks. They are more common in infants born prematurely and much more common in infants of African descent compared to Caucasian infants. Most umbilical hernias are sporadic, but some families have an increased risk. Umbilical hernias are more noticeable when the intra-abdominal pressure increases with crying or straining, but the hernias usually do not cause pain or distress. The great majority of umbilical hernias close spontaneously before school age, and symptoms including incarceration are uncommon early in life. Surgical repair of an umbilical hernia is usually delayed until 3 to 5 years of age or until symptoms develop.[139] Surgical repair of an umbilical hernia in a child is almost always performed with absorbable suture and mesh is not routinely used.

Epigastric Hernia

Epigastric hernias are small fascial defects in the linea alba, the midline fascia between the rectus abdominis muscles, through which preperitoneal fat can herniate. Because they are typically only a few millimeters in diameter, the fascial defects are often too small to palpate. However, preperitoneal fat can herniate out like a mushroom with only a small stalk traversing the defect and a larger cap in the subcutaneous tissue that may be visible and palpable.[146] Epigastric hernias are usually asymptomatic and surgical repair can be delayed until childhood. Common symptoms include pain at the site with exercise and growth of the hernia lump.

Diastasis Recti

Although diastasis recti is a normal variant and not a hernia, it is often mistaken for an abdominal wall hernia. The central section of a normal anterior abdominal wall consists of the two rectus abdominus muscles that extend from the ribs to the groin. Between the rectus muscles there is an extension of the rectus muscle fascia, known as the linea alba, that joins the two rectus muscles and creates a solid abdominal wall. A visible separation of the rectus muscles with an intact linea alba fascia is known as diastasis recti or rectus abdominis diastasis. The body wall musculofascial layer is intact, but the midline bulge of the linea alba fascia between the xiphoid process and the umbilicus when the abdominal muscles contract is often mistaken for a hernia. Imaging studies are not indicated. The condition is not pathologic and will typically be less noticeable after normal growth. Surgical treatments may be performed in adults for cosmetic reasons but are not indicated in infants and children.[147]

Umbilical Cord Abnormalities

As the direct connection between the placenta and the fetus, the umbilical cord normally consists of an umbilical vein and two umbilical arteries encased in a gelatinous matrix, known as Wharton's jelly, that is covered with a layer of amnion. Even when umbilical cord abnormalities are not problematic, they are often associated with other pathologic conditions that result in poor fetal and neonatal outcomes. Therefore, when abnormalities of the umbilical cord are found, it usually warrants further investigation for chromosomal abnormalities and structural malformations. In addition, many fetuses with umbilical cord abnormalities will need more frequent evaluations of fetal well-being.[148] Common umbilical cord abnormalities are summarized in Table 62.1, although many more have been described.

Acknowledgment

We would like to acknowledge the contributions of Dr. Daniel J. Ledbetter's work on this chapter in the last edition and his devotion to children with surgical problems over many years.

TABLE 62.1 Umbilical Cord Abnormalities

Cord Anomaly	Description	Incidence	Associations	References
Non-coiled or hypo-coiled cord	Umbilical coiling index is based on gestational age is used to quantify degree of umbilical cord coiling.	5%	IUGR, preterm labor, fetal distress during labor and delivery, meconium-stained amniotic fluid, stillbirth, chromosomal anomalies.	149–150
Single umbilical artery	One umbilical artery as opposed to the normal two.	0.5%–1%	Stillbirth, IUGR, multiple gestations, stillbirth, risk of genitourinary malformations and chromosomal anomalies.	131,152–154
Umbilical vessel dilations	Includes dilations of the umbilical vein (umbilical vein varices); dilations of umbilical artery (umbilical artery aneurysms).	Rare	Associated with fetal and chromosomal anomalies, increased risk of adverse fetal outcomes.	155,156
Umbilical cord cyst or pseudocyst	Cyst: Epithelial-lined remnants of vitelline (or omphalomesenteric) duct or allantois (which forms urachus). Pseudocyst: due to degeneration of Wharton's jelly, pooling of cord edema, or liquefaction of umbilical cord hematoma.		Large cysts may lead to compression of umbilical cord blood flow and may require aspiration. Pseudocysts that persist into second trimester are associated with fetal aneuploidy and malformations.	157–159

IUGR, Intrauterine growth restriction.

Neonatal Gastroesophageal Reflux

ERIC C. EICHENWALD

KEY POINTS

- Gastroesophageal reflux (GER) is almost universal in neonates.
- It is a physiologic process secondary to frequent spontaneous transient lower esophageal sphincter relaxation, relatively large volume liquid diet, and age-specific body positioning.
- Preterm infants have relative immaturity of neural control of the gastrointestinal tract, leading to delayed gastric emptying and slow gut motility.
- The diagnosis of GER in the neonatal intensive care unit (NICU) is frequently made based on behavioral signs (irritability, back arching, discomfort with feedings) which most often are not temporally associated with documented reflux.
- Multichannel intraesophageal impedance monitoring combined with lower esophageal pH measurement is the best diagnostic test for GER in infancy.
- Treatment of GER involves both nonpharmacologic and pharmacologic management, but drug therapy of GER is associated with the potential for several adverse outcomes.

Gastroesophageal Reflux

Epidemiology

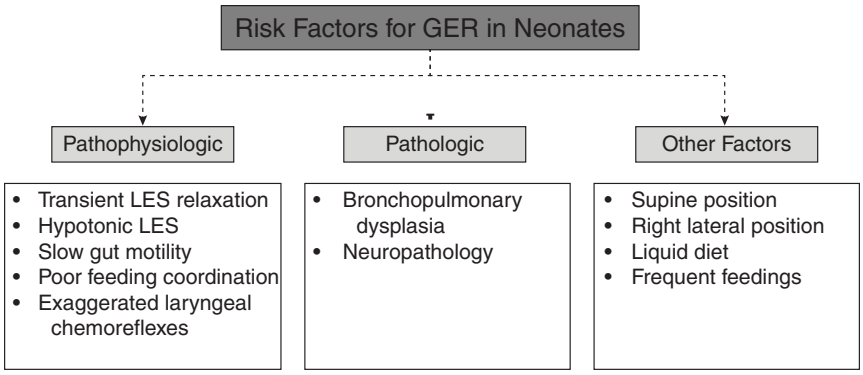
Gastroesophageal reflux (GER) is defined as the retrograde movement of gastric contents into the esophagus with or without regurgitation. Uncomplicated GER is a normal physiologic process in infants, in part due to relatively large liquid volumes ingested during feedings and supine positioning which places the gastroesophageal junction in a liquid environment. Preterm infants are at particular risk for reflux due to gastrointestinal dysmotility and delayed gastric emptying affected by immaturity. Uncomplicated GER should not prompt further investigation or treatment. However, when reflux of gastric contents is associated with troublesome clinical symptoms or signs, it is called gastroesophageal reflux disease (GERD). In clinical practice, since "troublesome signs" in neonatal patients are most often nonspecific and subjective, it is difficult to differentiate GER from GERD in the neonatal intensive care unit (NICU); as a result, these terms are frequently used interchangeably by medical professionals and parents alike.

The difficulty in making a diagnosis of GERD in neonatal patients can lead to its overdiagnosis and treatment, as well as significant practice variation. In one study of 33 academic children's hospital NICUs, there was a 13-fold variation (2% to 26%) in the diagnosis and treatment of GERD in NICU patients.[1] In this study, patients with a GERD diagnosis had longer hospital stays and higher costs than infants without this diagnosis. In addition, infants discharged from the NICU on antireflux medications frequently remain on treatment for many months after discharge, making it an important clinical entity in the NICU and beyond.[2] This chapter will discuss the physiology, diagnosis, and therapy of GER in nonsurgical patients in the NICU.

Pathophysiology

There are many pathophysiologic mechanisms which increase the risk of GER in the neonatal period (Fig. 63.1). The lower end of the esophagus is defined anatomically by the junction of the esophagus with the stomach, and functionally by the junction of the inferior border of the high-pressure area of the lower esophageal sphincter (LES) with the lower pressure in the stomach. The LES is comprised of smooth muscles organized in two layers, with circular and longitudinal muscle fibers separated by a myenteric plexus. The gastroesophageal junction is functionally augmented by the diaphragmatic crural fibers, the intra-abdominal esophagus, and sling fibers of the stomach, which together form the principal barrier to GER. Extrinsic innervation of the esophagus involves neurons in both the brainstem and spinal cord. The LES is innervated by both parasympathetic (vagus) and sympathetic (primarily splanchnic) nerves. The LES is tonically active and functionally closed. The vagal pathways are the central neural pathway for reflex relaxation of the LES. Parasympathetic vagal nerve pathways, coordinated through the dorsal motor nucleus and nucleus tractus solitarius, trigger periodic reflex relaxation induced by swallows and esophageal dilatation to facilitate bolus transit from the upper esophagus. These mechanisms of swallow-related relaxation of the LES and tonic activity of the LES to maintain esophagogastric competence are present even in extremely preterm infants.[3]

In addition to reflex relaxation of the LES related to swallowing, the LES also spontaneously relaxes without stimulation. These events are termed "transient lower esophageal sphincter relaxation" events, or TLESR. TLESR is an abrupt reflex decrease in LES pressure to levels at or below intragastric pressure unrelated to swallowing and is the primary mechanism for GER in infants. TLESR appears to use the same efferent neural pathway as the swallow reflex, whereas afferent pathways may originate in the pharynx, larynx, or stomach. In contrast to swallow-related LES relaxation, TLESRs are generally longer in duration and at lower LES pressures.



• **Fig. 63.1** Risk Factors for Gastroesophageal Reflux (GER) in Neonatal Intensive Care Unit (NICU) Patients. LES, Lower esophageal sphincter. (Adapted from Gulati IK, Jadcherla SR. Gastroesophageal reflux in the neonatal intensive care unit: who needs to be treated and what approach is beneficial? *Pediatr Clin N Am*. 2019; 66:461–473.)

The normal function of TLESR is to prevent gastric bloating by periodically releasing gas from the stomach. As such, gastric distention after a meal stimulates stretch receptors in smooth muscle in the stomach wall, stimulating a vasovagal response with resultant TLESR. The number of TLESR events per day in neonates appears to decrease with maturity, so that preterm infants have dozens of episodes per day, many of which are associated with GER.[3] GER and regurgitation is very common in neonates, induced by a reflex TLESR associated with gastric distention after a feeding. As such, physiologically, some degree of subclinical or clinically apparent reflux is a normal phenomenon in neonates. In neonates, GER is exacerbated by a pure liquid diet and age-specific body positioning.[4] Newborns spend most of their sleeping time in the supine position because of its known protective effect on the incidence of sudden infant death syndrome (SIDS).

Infants positioned supine and in the right-side-down lateral position have more episodes of TLESR and GER compared with the left-side-down lateral position, despite more rapid gastric emptying in the right lateral position.[5,6] Prone position decreased episodes of GER versus the supine position, likely due to a more optimal positioning of the LES relative to the liquid-filled stomach rather than a decrease in TLESR events.[5]

Impaired gastric motility and delayed emptying do not appear to play a contributory role in GER in infancy, in that infants with symptomatic GER do not have delayed gastric emptying compared with other infants.[7] However, the composition of gastric contents does affect the rate of gastric emptying, which may influence the frequency of GER. Increased caloric density feeding, especially with fats, frequently fed to preterm infants, slows gastric emptying, whereas expressed breast milk empties at almost double the rate of formula.[8]

Preterm infants, especially those with intrauterine growth restriction, are at a higher risk for gut dysmotility, causing feeding intolerance which may be assessed as a sign of GER.[9] The motility of the small intestine is less organized in preterm compared with term infants, due in part to intrinsic immaturity of the enteric nervous system that slows intestinal transit. In growth-restricted infants, prolonged periods of intrauterine hypoxia can produce injury to the bowel, which modulates the development of motor, secretory, and mucosal functions after birth, and may result in a higher risk for dysmotility and stasis.[10]

Mechanisms to protect the esophagus and airway from GER appear to be intact even in the most preterm infants. These include reflex antegrade peristalsis of the esophagus in response to esophageal dilatation with gastric contents, and closure of the upper esophageal sphincter to prevent refluxate from reaching the pharynx. Despite this, if refluxed material does reach the upper esophagus, the upper esophageal sphincter will reflexively open to allow the material into the pharynx to protect the laryngeal structures, resulting in episodes of "spitting" or emesis frequently seen in infants.

Evaluation

Several different methods to diagnose reflux in infants are currently utilized and are comprehensively reviewed in a joint clinical practice guideline published by the North American and European Societies of Gastroenterology.[11] These include contrast fluoroscopy, lower esophageal pH monitoring, direct laryngoscopy and bronchoscopy to assess airway inflammation, and multichannel impedance (MII) monitoring combined with pH measurement.

Contrast fluoroscopy will demonstrate if reflux occurs and can determine the height in the esophagus reached by the refluxate, but it cannot differentiate between clinically significant and insignificant GER. As such, it is not generally recommended as a sole methodology to diagnose GER.[11]

Continuous monitoring of pH over several hours using a probe placed in the lower esophagus has been used to diagnose GER in older children and adults, since reflux of acidic stomach contents will result in transient periods of acidic pH in the lower esophagus. A scoring system developed by gastroenterologists may be used to determine if a study is "normal" or "abnormal." Measurements include the total number of reflux episodes during the recording period, the longest duration of acidification recorded, and a "reflux index (RI)" defined as the percentage of the total recording time with an esophageal pH < 4. In pH studies in older children and adults, an RI $> 7\%$ is considered abnormal, an RI $<3\%$ normal, and an RI between 3% and 7% indeterminant.[11,12] However, the measurement of esophageal pH is not a sensitive method to detect GER in newborns and in early infancy because of a higher baseline stomach pH in part due to frequent milk feedings and the fact that the stomach pH is rarely below 4.[12]

A potentially less invasive diagnostic technique investigated in infants is to measure salivary pepsin levels as an extra-esophageal biomarker of GER.[13] In one small study, 44.5% of infants with suspected GER had salivary pepsin detected, as compared to 29% of control infants.[13] However, this measurement has limited sensitivity and specificity in part due to a lack of normative values for salivary pepsin in infants and is not routinely used outside of research studies.[11]

Otolaryngologists have developed a "reflux finding score" for airway inflammation suspected to be caused by GER, which is assessed by direct laryngoscopy and bronchoscopy. It is frequently used to recommend antireflux medical treatment.[14] However, in one prospective cross-sectional cohort study of children with reflux-like symptoms, there was no correlation between the reflux finding score and other confirmatory tests of reflux such as pH and MII measurements.[14] The authors concluded that airway examination in children could not predict GERD and should not be used as a basis for prescribing therapies. Although not systematically studied, this is likely to be true in infancy as well.

The most accurate way to detect GER in infants is multichannel esophageal impedance (MII) monitoring, combined with simultaneous measurement of pH.[11] As used in infants, MII tracks the movement of fluids and air in the esophagus through measurement of changes in electrical impedance between electrodes spaced along an esophageal catheter. It can detect whether a fluid bolus in the esophagus is antegrade, as in a swallow, or retrograde, as in a reflux episode, as well as determine the height of the reflux event. When combined with a pH probe, it can also determine if the episode of GER is acidic, mildly acidic, or alkaline. Normative data collected by MII suggest that healthy preterm infants mostly have mildly acidic reflux events which occur more frequently after a feeding.[15] Although somewhat invasive and technically difficult, MII/pH measurement is the recommended evidence-based way to correlate presumptive symptoms and signs of GER with actual measured reflux events during infancy.[11]

TABLE 63.1 Signs and Symptoms Frequently Attributed to Gastroesophageal Reflux in the Neonatal Intensive Care Unit

Gastrointestinal

- Regurgitation
- Spitting
- Abdominal distention
- Nipple aversion

Aerodigestive

- Swallowing problems
- Feeding intolerance
- Choking
- Coughing
- Stridor

Cardiorespiratory

- Apnea
- Bradycardia
- Desaturation events
- Respiratory distress

Behavioral

- Irritability
- Back arching
- Crying
- Grimace

Adapted from Gulati IK, Jadcherla SR. Gastroesophageal reflux in the neonatal intensive care unit: who needs to be treated and what approach is beneficial? *Pediatr Clin N Am.* 2019;66:461–473.

Clinical Presentation

Many clinicians continue to diagnose GER, particularly in preterm infants, based on nonspecific behavioral signs (Table 63.1). Other clinical signs often attributed to GER include feeding intolerance (i.e., abdominal distention, spitting), poor growth, frequent apnea, and desaturation episodes, as well as worsening lung disease in infants with evolving bronchopulmonary dysplasia (BPD).[16]

Behavioral and Feeding Issues

Infants in the NICU frequently display nonspecific behavioral signs which clinicians often ascribe to GER. These behavioral signs include arching, irritability, and apparent discomfort associated with feedings, as well as other feeding difficulties, such as frequent spitting and nipple aversion. Data to support the relationship between these signs and GER are sparse in otherwise healthy infants as well as those who are clinically suspected as having GER. Most studies which examined the correlation of the timing of these behavioral signs with documented reflux as measured by MII/pH show no temporal relationship, and infants frequently display behaviors ascribed to GER unrelated to documented GER episodes.[17–19]

Apnea, Bradycardia, and Desaturation

There are several physiological reasons to suspect that GER may precipitate apnea, bradycardia, and desaturation events in preterm infants. Because preterm infants possess a hyperactive laryngeal chemoreflex response to liquid stimulation which induces apnea as an airway protective mechanism, some clinicians believe that apnea spells in preterm infants may be caused or worsened by the frequent GER events.[16] However, studies which examined the timing of reflux episodes in relation to apnea, bradycardia, or desaturation events have found that they are rarely temporally related,[20,21] and the measured GER does not prolong or worsen apneic events.[22] In contrast, it does appear that spontaneous apneic events can result in a reflex relaxation of the LES (and resultant GER), presumably due to vagal stimulation.[23] Other studies of empiric treatment of clinically diagnosed GER with agents which decrease gastric acidity or promote faster gastric emptying have no effect on the incidence and severity of apnea or bradycardia in preterm infants.[24,25]

Respiratory Disease

It remains unclear whether GER causes clinically silent microaspiration in ventilated infants that worsens lung disease, particularly in infants with developing or established BPD. Infants with BPD may be at a higher risk for GER due to greater respiratory symptoms causing increased intra-abdominal pressure swings and use of medications which could influence LES tone, such as caffeine and albuterol.[26] Small studies have reported a high frequency of the recovery of measurable levels of pepsin in tracheal aspirates of ventilated preterm infants, higher levels of pepsin in tracheal aspirates of infants who developed BPD,

and an association of higher concentrations of pepsin in tracheal aspirates with the severity of BPD, leading to speculation that chronic microaspiration may contribute to the development and severity of BPD.[27,28] However, these results have not been replicated in larger studies, and there remain questions whether the measured pepsin is of gastrointestinal origin. Other studies have examined whether infants with BPD have a higher frequency or severity of GER events compared with infants without BPD using esophageal pH only, or MII/pH monitoring with negative results.[18,29] Infants with BPD also are frequently assessed to have behavioral signs ascribed to GER, but similar to other preterm infants, these behavioral signs are infrequently temporally associated with either acidic or nonacidic reflux as measured by MII/pH monitoring.[18] Despite the lack of evidence that GER is a worse pathologic problem in infants with BPD, infants with BPD are more likely to be clinically diagnosed and receive pharmacologic therapy for GER.[30]

Management

Infants in the NICU frequently receive both nonpharmacologic and pharmacologic therapies for clinically diagnosed GER, though there remains little data about the effect of treatment on either symptom burden or long-term outcomes.[2,31] The lack of randomized placebo-controlled trials of GER therapies in infants in the NICU also makes it impossible to assess the effectiveness of therapy versus the natural history of GER improving with maturity.[24]

Nonpharmacologic Approaches

Changes in body positioning are widely used as a management strategy in infants clinically diagnosed with GER. These include placing babies in a head-up angle, using the left lateral position after feeding, and prone versus supine positioning which may enhance gastric emptying and reduce episodes of TLESR. These maneuvers, while perhaps benign, have not been shown to reduce behavioral manifestations of presumptive reflux, such as frequent crying or irritability.[32]

Changes in feeding strategy and approach are also frequently prescribed for infants with suspected GER. If GER is precipitated in part by gastric distention with large bolus feedings, smaller volume, more frequent feeding might in theory decrease GER. Some evidence supports this hypothesis, although whether a decreased incidence of GER has a beneficial effect on other outcomes is unknown.[33,34] Continuous transpyloric feedings as opposed to intragastric are also prescribed in infants, particularly those with BPD.[35] However, in one small cohort of infants with severe BPD, trans-pyloric feedings were associated with an increased frequency of intermittent hypoxemia events when compared to gastric feedings in an *N* of 1 crossover trial.[36]

Another feeding strategy used is to thicken feedings with several different agents including xanthan gum, starch, or rice cereal.[37] Commercially available formula products that thicken upon acidification in the stomach are also available. Neither of these approaches is recommended for use in preterm infants. One systematic review of randomized-controlled trials of thickened formulas in term infants with GER showed that these agents reduced episodes of spitting and regurgitation but did not reduce the frequency of acidic GER.[38] Elemental or extensively hydrolyzed protein formulas increase gastric emptying and reduce gastrointestinal transit time, and may reduce symptoms of GER in term infants.[39]

Pharmacologic Management

Pharmacologic management of GER in infants includes prokinetic agents, and medications which decrease gastric acid production. Prokinetic agents used in infants include metoclopramide and erythromycin. These drugs work to improve gastric emptying and appear to enhance LES tone and are occasionally used for other functional motility disorders in preterm infants, including delayed gastric emptying causing frequent regurgitation, and slow gut motility which may prevent feeding volume advancement in extremely premature infants. Erythromycin has been studied as both a prophylactic as well as rescue drug for feeding intolerance in preterm infants.[40,41] Erythromycin is a competitive motilin agonist, which mimics the effects of motilin on the proximal gastrointestinal tract enhancing contraction of gut smooth muscle that produces forward propulsion of nutrients in the small bowel. The timing of erythromycin's use, its dose (high or low dose), administration (intravenous or enteral), and the most appropriate patient population remain poorly studied.[40,41] Metoclopramide has not been shown to reduce GER symptoms in preterm infants.[24,42] Caution should be exercised in their use, since they carry a potential for significant adverse effects, including a higher risk of infantile pyloric stenosis (erythromycin), cardiac arrythmia (erythromycin), and neurologic side effects (metoclopramide).

Acid-reducing agents include histamine$_2$ (H_2) receptor blockers and proton pump inhibitors (PPI). H_2 receptor blockers (e.g., ranitidine, famotidine) compete with histamine for the H_2 receptor in parietal cells in the stomach, thereby decreasing hydrochloric acid secretion and increasing gastric pH. PPIs (e.g., omeprazole, lansoprazole) block the gastric proton pump, with a resultant decrease in both basal and stimulated parietal cell acid secretion. Since clinicians often equate the suspected clinical signs of GER (irritability, crying, and discomfort after feeding) with acidic irritation of the lower esophagus, these agents were frequently prescribed to infants with a clinical diagnosis of GER.[2,16] However, no studies have assessed the efficacy of acid blockade on the symptom profile of infants with clinically suspected GER. Acid-reducing agents may be associated with a higher rate of adverse events, especially when used long term, including a higher risk of infection and pneumonia.[43,44] Because of an increased recognition for the potential for serious complications associated with their use, prescriptions of acid blockade agents have become less commonplace in NICUs.[45–47]

Necrotizing Enterocolitis and Short Bowel Syndrome

GREGORY KEEFE, TOM JAKSIC, AND JOSEF NEU

KEY POINTS

- What we have termed "necrotizing enterocolitis" (NEC) is not a discrete entity but, rather, a manifestation of different forms of intestinal injury that can lead to intestinal necrosis. To make progress in terms of prevention, a better delineation of these forms of injury is critical.
- The pathophysiology of the classical form of NEC involves an interaction of factors that include an immature bowel and a dysbiotic microbiota that induces intestinal mucosal inflammation, leading to intestinal necrosis.
- Medical treatments are not evidence based but include the use of broad-spectrum antibiotics, bowel rest, close observation, and frequent diagnostic testing.
- Surgical interventions include placement of primary peritoneal drainage or laparotomy with direct inspection and resection. The decision as to when and which procedure to use is not based on clear criteria.
- Future studies should focus on delineation of the different entities under the umbrella of NEC, including an evaluation of multiomics and predictive analytics for biomarker development used to guide prevention and treatment.
- NEC is the most common cause of pediatric short bowel syndrome (SBS). Outcomes in SBS have dramatically improved in the past 20 years. Hallmarks of successful management include preservation of maximal intestinal length, hepatoprotective parenteral nutrition, and multidisciplinary intestinal rehabilitation programs.

Necrotizing Enterocolitis

Epidemiology

In the past several decades, a pattern of intestinal injuries has been referred to as necrotizing enterocolitis or "NEC." This set of entities affects approximately 2000 to 4000 newborns in the United States each year.[1–5] Of these, 10% to 50% die, approximating the childhood death rate from leukemia or meningitis. Long-term consequences often include short bowel syndrome (SBS), discussed later in this chapter, and neurodevelopmental disorders.[6]

To understand NEC, a brief historical perspective is in order. Prior to the emergence of neonatal intensive care in the 1960s, an entity affecting preterm infants that caused intestinal necrosis in neonates was rarely mentioned in the literature. Sparse references are made to a disease resembling NEC in the 19th and early 20th centuries.[7,8] In the 1960s and early 1970s issues of Schaffer and Avery's *Diseases of the Newborn*, very little mention is made of NEC. During these same years, with the precipitous emergence of neonatal intensive care and survival of less mature infants, the high prevalence of NEC also materialized. Thus, even though this is a disease of progress (in terms of greater survival of low birthweight infants), not much progress has been made in its prevention or treatment in the past 50 years. One of the most distressing issues is that we have yet to "define" this disease, which is difficult because what we are referring to likely represents more than one entity.[9]

This chapter will present some of the major issues surrounding NEC and why it has become such an enigma in terms of prevention and treatment. We will provide some of the current thinking about the different entities that have been termed NEC and will discuss epidemiology, diagnosis, pathophysiology, treatment, and prevention. There will also be a discussion of how we might proceed with future studies to improve our understanding of the processes that have been placed under the umbrella of NEC, how we differentiate them, and target our preventative and therapeutic measures with greater precision. In this chapter, we will also emphasize what is currently thought of as the "classic" form of NEC, its diagnosis, treatment (medical and surgical), sequelae in terms of SBS, and intestinal rehabilitation methods.

Defining Necrotizing Enterocolitis: A Conundrum

It is evident that what we have termed NEC is not a discrete entity. This lack of a clear phenotypic and pathophysiologic description thwarts progress. The underlying reasons are multifactorial and include:

1. Greater emphasis and support for the smallest, most preterm infants who have the highest propensity to develop intestinal injury.
2. Intestinal injury seen in the smallest, most immature infants occurs at a different time after birth than in more mature infants.
3. Many different forms of intestinal injury in the neonate are consolidated under the all-encompassing term NEC; however, preventative and therapeutic procedures are not specifically aimed at these subentities of intestinal injury.
4. Animal models used in studies of pathophysiology and preclinical preventative and treatment strategies do not accurately reflect the disease in preterm infants.

5. Multifactorial pathophysiology of these individual-specific injuries placed under the umbrella of NEC has not been clearly elucidated.

If progress is to be made in the prevention and treatment of the various forms of intestinal injuries termed NEC,[9] a better classification system is in order. Numerous retrospective observational studies have suffered from classifying different pathophysiologic entities as NEC. Because of this, databases include infants with spontaneous intestinal perforations (SIPs), ischemic bowel disease secondary to cardiac anomalies, congenital intestinal abnormalities, and food protein intolerance enterocolitis syndrome (FPIES). These all have different pathophysiologic features. Furthermore, the staging system for NEC, developed about five decades ago, has less current utility due to the greater degree of immature infants seen in today's intensive care setting.

NEC Stages

Variants of a staging system originally developed in the 1970s by Dr. Martin Bell have been relied upon to guide the management of NEC.[10] These have been incorporated into databases such as the Vermont Oxford Network (VON), but it is becoming clear that this system has numerous pitfalls and may cause considerable confusion and not be as useful as intended.[11] Numerous previous chapters have listed these stages, but we will not because they lead to confusion and, in the authors' opinion, should no longer be used. For example, in stage 1 NEC, intestinal necrosis is implied but not validated. Many of the symptoms and signs in this stage are seen in extremely low birthweight (ELBW) infants without any clear bowel pathology. Stage 2 is largely dependent on radiographic diagnosis, which provides no clear evidence for necrosis of the bowel and can be misread. Stage 3 largely depends on stronger evidence of bowel injury, which is optimally diagnosed by direct examination of the bowel by intraoperative inspection and/or histologically. However, when reliance for the diagnosis of stage 3 NEC is placed on radiographic diagnosis of pneumoperitoneum and is treated with surgical drain placement without direct visualization, the differentiation between true bowel necrosis and SIP, a distinct entity, is not possible. This matters in terms of most appropriate treatment.[12,13]

Newly emerging artificial intelligence technologies such as machine learning may help us better differentiate these entities and provide a more accurate definition of NEC.[1,2]

Pathology/Pathophysiology

The pathologic findings of NEC have been described by examination from severely affected infants. Gross anatomic exam reveals predominantly terminal ileum and proximal colon involvement. However, in severe cases ("NEC totalis"), the entire bowel from the stomach to the rectum may be involved. Histology reveals mucosal edema, hemorrhage, coagulation necrosis, and mucosal ulceration. The pathophysiology of NEC is discussed as follows.

Animal Models

In the early years of NEC research, hypothermia, severe hypoxia, and infection were considered to be stressors that led to NEC.[14] These stressors were associated with difficult birth. However, studies have shown that low Apgar scores, when corrected for prematurity, are not associated with NEC.[15] Furthermore, in the most preterm infants, in whom NEC occurs most frequently, the disease tends not to develop until several weeks after birth,[16] hence undermining hypoxia and ischemia as significant pathophysiologic triggers for classic NEC.[17] Despite these caveats, the most common animal model used to study NEC[18] involves some combination of inducing hypoxia, exposing the animal to a cold environment, infusing pathogenic bacteria or proinflammatory bacterial components such a lipopolysaccharide (LPS), and feeding the animals with a formula that is very different than the milk provided by the mother.[19] It is highly unlikely that this model is relevant to NEC seen in the human preterm baby.

Piglets have been used as models for NEC largely because the porcine gastrointestinal (GI) tract shares similarities to that of humans, but there are also important differences. In contrast to the human neonate, one critical difference is that piglets require mother's colostrum or infusion of immunoglobulin G (IgG) to prevent death from a sepsis-like syndrome.[20]

One rodent model uses a chemical inhibitor of intestinal Paneth cells and ingestion of pathogenic *Klebsiella* during the later stages of preweaning.[21] Whether this model expresses fidelity to the disease seen in humans is unlikely because it uses damage to a single cell type to induce disease, whereas it is more likely that true inflammatory NEC involves a multifactorial pathophysiologic cascade.[22]

"Classic" Necrotizing Enterocolitis Pathophysiology

As we discuss what is considered the most "classic" form of NEC, it is critical to remember that some of our knowledge is derived from patient databases that are diluted with "imposters" as well as animal and cell culture studies that may not accurately simulate the disease seen in human preterm infants. The focus on single pathophysiologic pathways may also be misleading because this disease involves multifactorial predispositions along with pathophysiologic cascades culminating in intestinal necrosis that may best be understood using rapidly developing systems network-based illustrations.

One of the forms of intestinal injury that has been termed NEC involves acute antecedent inflammation but is also associated with several other factors.[12,16–19] Factors that are associated with this inflammatory injury include characteristics associated with intestinal immaturity: intestinal barrier immaturity, immature immune response, and an immature regulation of intestinal blood flow.

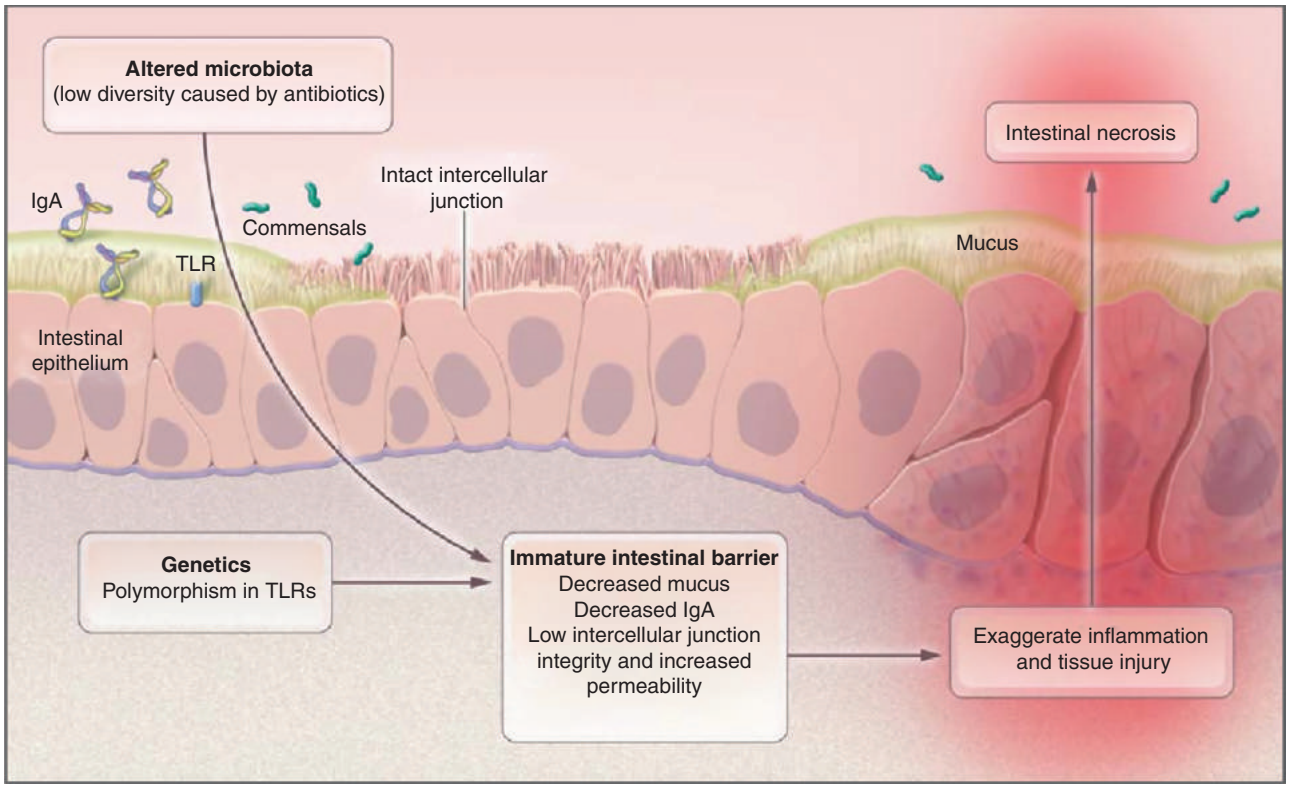
Based on observations of concordance in twins, there is suggestion that there is a genetic component to the pathogenesis of this form of intestinal injury. However, genome-wide association studies (GWAS) and exome-sequencing based studies are limited by the lack of adequately powered replication cohorts to validate the accuracy of these discoveries.[23]

Intestinal Microbiota, Mucosal Immune System, and Vascular Immaturities

The environment affects the taxonomy and function of intestinal microbiota. Although a precise pathophysiologic cascade has not been based on solid mechanistic evidence, an overall likely scenario has been envisioned (Fig. 64.1).

Intestinal Mucosal Immune System

An in-depth review of intestinal mucosal immune system development is beyond the scope of this chapter. The reader is referred to more comprehensive reviews of this topic.[24] Here we will summarize some of the main components as they are related to development of NEC.



• **Fig. 64.1** Conceptualization of Intestinal Injury, Which Could Be Termed "Classic Necrotizing Enterocolitis (NEC)." Etiopathogenesis of inflammatory intestinal injury in the preterm neonate. Acting in concert with host immaturities, a dysbiosis disposes to disruption of the intestinal mucosal surface via increased permeability of tight junctions between epithelial cells. This in turn allows for greater interaction of the intraluminal microbes and antigens that incite an inflammatory response that can lead to a cycle of further intestinal injury. (From Neu J, Walker WA. Necrotizing enterocolitis. *N Engl J Med*. 2011;364:255-264.)

Although most attention is paid to the developing intestinal immune system after birth, it is becoming obvious that there is considerable development that occurs prior to parturition in the fetus, and this is a largely unexplored area. The development of the intestinal mucosal immune system is programmed to develop in different phases. These phases can be disrupted by various environmental circumstances, which we will discuss after our brief summary of some of the main components of the intestinal mucosal immune system.

The first layer of defense encountered by a pathogen or foreign antigen is the acidic environment of the stomach.[25,26] Although primarily designed for digestive processes, these enzymes also are able to destroy many pathogens and immunogenic proteins. On the small intestinal surface, there are additional defense mechanisms. These defense mechanisms include production of mucus by goblet cells, which hinders microbial adherence in concert with polymeric secretory immunoglobulin A (sIgA) that binds luminal antigens. Peristalsis is key because it keeps the antigen-antibody complexes moving aborally to be subsequently eliminated in the stool.[27] Paneth cells from the bottom of the crypts secrete antimicrobial peptides (AMPs).[28] Interepithelial junctions contain various intercellular proteins that maintain junctional integrity and keep the epithelial cells in close proximity to prevent paracellular passage.[29,30] Cell types such as dendritic cells, undifferentiated and differentiated T cells, and plasma cells interact in a manner that depends on the type of stimulatory milieu present in the intestine for the incitement of proinflammatory and antiinflammatory responses, as well as providing a homeostatic balance between these processes. Dendritic cells are of the macrophage-monocyte lineage that capture luminal antigens, process inflammatory signals, and then migrate to secondary intestinal lymphoid organs to interact with T-cell lymphocytes.[24]

Intestinal epithelial cells, macrophages, and other intestinal cells carry both cell membrane and intracellular receptors involved in inflammatory responses; the best known of these being the Toll-like receptors (TLRs). TLRs recognize and bind to highly conserved and specific pathogen-associated molecular patterns (PAMPs) or microbe-associated molecular patterns (MAMPs). TLR4, one of the receptors that has been provided considerable attention in the pathogenesis of NEC,[31] is preferentially expressed by enterocytes within crypts. The intracellular pathway commonly associated with TLR4 and some of the other TLRs includes activation of nuclear factor kappa B (NF-κB), which is a critical transcription factor inciting inflammatory responses in the developing intestine.[32]

The fetus and preterm infant usually respond to luminal microbial stimuli with inflammation.[33] This response can be beneficial.[34] However, an abnormal intestinal microbial profile associated with an excessive immature inflammatory response is a critical pathophysiologic component of the "classic" form of NEC (see Fig. 64.1). When in proper balance, they contribute to innate immunity by maintaining a healthy epithelial barrier.[24] However, imbalances may occur. Specific microbial components such as LPS stimulate the production of proinflammatory cytokines and

initiate a downstream signaling cascade that may upset the balance of proinflammatory and tolerizing mechanisms. These intestinal mucosal interactions are complex and require additional investigation to attain clinical diagnostic and therapeutic relevance. Antibodies in the intestinal tract are also of importance. Studies of secretory IgA appear to play a role in prevention of intestinal injury in both humans and animal models.[35,36]

Microbial Colonization and Dysbiosis

It is becoming increasingly recognized that the microbial environment of the intestine plays an important role in inflammatory bowel injury in preterm infants.[37] Microbes harbor various agonists that interact with the aforementioned intestinal receptors, which incite an inflammatory response. Of interest, these same inflammatory agonists can also induce tolerance and produce various metabolites that may be either injurious or protective to the intestine depending on dose and presence of other mediators.[24]

Over the past two decades, research stemming from the Human Microbiome Project has allowed for molecular identification of many microbes that are difficult to culture when using conventional techniques. Evaluation of fecal microbiota from infants in whom NEC was diagnosed and compared with control samples suggests that NEC is associated with altered intestinal microbial taxa prior to the development of the disease.[16] From these studies, an imbalance in microbes with differing inflammatory and metabolic potentials is associated with pathogenesis. The microbial ecology of the intestine appears to be an important feature that predisposes to intestinal inflammatory injury such as that seen in NEC. However, to develop preventative approaches, we need a better understanding of how these microbes and their metabolites interact with the developing intestine. Such studies should use newly emerging multiomic approaches integrated with prospective randomized studies exploring different environmental conditions, as will be discussed next.[38]

Antibiotics

Antibiotics are routinely prescribed in very low birthweight (VLBW) neonates after birth due to fear that preterm delivery is secondary to infection. This is despite the low incidence of culture-positive, early-onset sepsis. There is considerable evidence showing that antibiotics in the early perinatal and neonatal period, even when provided for short periods, are associated with intestinal dysbiosis,[39–43] which has been linked to short-term adverse outcomes that include bronchopulmonary dysplasia, late-onset sepsis, NEC, and retinopathy of prematurity.[16,44–56] On the other hand, one large observational study suggests a lower incidence of NEC after early antibiotic use.[57] Whether or not such routine antibiotic use is warranted can be at least partially addressed with a prospective, randomized, multicenter, appropriately powered trial.[58] Such a trial should take into account not only clinical outcomes but also multiomic features, which will provide an improved mechanistic framework for pathogenesis and prevention.

Human Milk

It is very difficult to perform controlled randomized studies between human milk (especially that derived directly from the infant's own mother) versus formula. Nevertheless, studies in human infants comparing the relation of type of diet to intestinal barrier function have demonstrated increased intestinal permeability in those receiving formula. This suggests either a compromise in intestinal barrier function[59] from the cows' milk or intestinal protection from the human milk. Infants fed predominantly breast milk also have a reduced incidence of infections[60] and are less likely to develop NEC compared with infants fed formula.[61] The numerous bioactive factors present in fresh breast milk include live microbes, immunoglobulins, cells, enzymes, growth factors, oligosaccharides, and IgA, to name a few, all of which may play a protective role against NEC and other intestinal injuries.

Clinical Presentation

The most typical initial signs and symptoms of NEC in a preterm infant include feeding intolerance, bloody and/or mucus-containing stools, periumbilical erythema, and abdominal distention (Fig. 64.2), usually occurring at a peak of 29 to 32 weeks' corrected gestational age.

Evaluation

Ultrasound and Radiographs

Bowel ultrasound is a modality that is becoming of major interest in the evaluation of bowel injury in neonates. Fig. 64.3 shows the appearance of NEC on abdominal radiographs, and Fig. 64.4 shows some of the salient features on ultrasound in preterm infants diagnosed with NEC.

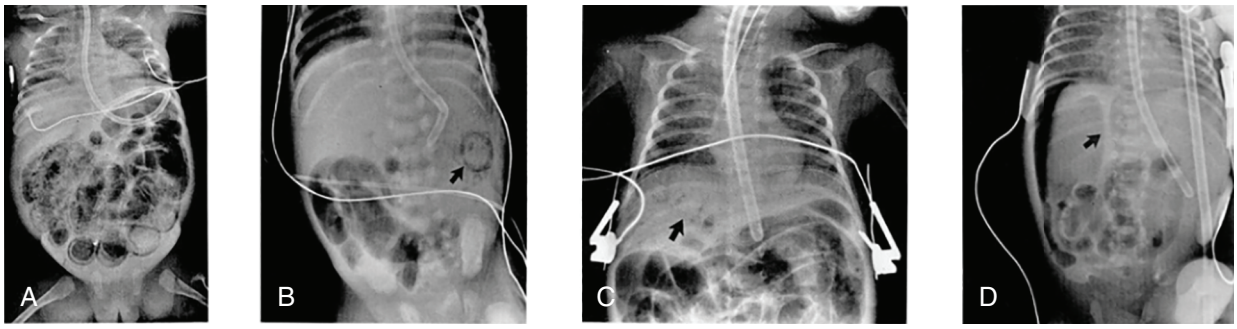
Laboratory Findings

Several biomarkers, including C-reactive protein, white blood cell, and platelet counts, are often used to help establish the diagnosis of NEC but of themselves are not of sufficient sensitivity, specificity, or accuracy to be of high diagnostic value. We need better biomarkers that accurately predict the full expression of NEC.[62]

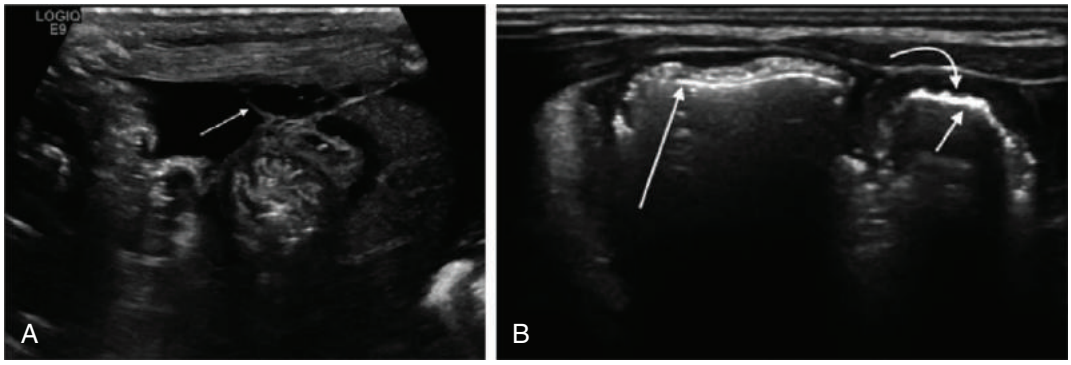
Differential Diagnosis

As seen in Table 64.1, there are several forms of intestinal injury in the neonate ("imposters") that have been called NEC. There have been recent strides to establish a more accurate definition for NEC based on the fact that these are different pathophysiologic entities.[9,63] Here we discuss the other forms of intestinal injury that are sometimes labeled an "NEC."

• **Fig. 64.2** Preterm Infant with Abdominal Distension and Necrotizing Enterocolitis. (Courtesy Dr. David Kays, Department of Pediatric Surgery, University of Florida.)



• **Fig. 64.3** (A–D) Radiologic Findings of Necrotizing Enterocolitis (NEC). Findings used to diagnose NEC using abdominal radiography are pneumatosis intestinalis, portal venous gas, or both. Extraluminal air ("free air") outside the bowel can be a sign of advanced NEC or spontaneous intestinal perforation. (A) Several dilated air-filled loops of bowel in the right lower quadrant indicate a focal ileus. The arrow points to submucosal air in the splenic flexure. (B) Film of the chest and abdomen shows massive air-distended bowel with diffuse intramural air. (C) Air in the portal system *(arrow)*. (D) Left lateral decubitus film of the abdomen shows free intraperitoneal air from a bowel perforation. Free air is shown on both sides of the falciform ligament *(arrow)*. (From Neu J. Necrotizing enterocolitis: the search for a unifying pathogenic theory leading to prevention. *Pediatr Clin North Am*. 1996;43(2):409–32.)



• **Fig. 64.4** (A, B) Ultrasound Findings of Necrotizing Enterocolitis (NEC). Focal fluid collection with septations *(arrow)* indicating bowel perforation. (From Alexander KM, Chan SS, Opfer E, et al. Implementation of bowel ultrasound practice for the diagnosis and management of necrotising enterocolitis *Arch Dis Childhood Fetal Neonatal Edition* 2021;106:96–103.)

TABLE 64.1 Stages of Necrotizing Enterocolitis and Some Examples of "Imposters" of Necrotizing Enterocolitis

Name of Entity	Major Diagnostic Criteria	Treatment	Pitfall
Stage 1 NEC	Clinical signs in baby: feeding intolerance, vomiting, abdominal distension, gastric residuals.	Observation, but often NPO, antibiotics, frequent blood monitoring, radiographs.	Seen very commonly in extremely preterm infants, those on nasal or mask ventilation, being monitored for gastric residuals.
Stage 2 NEC	Clinical signs can be similar to those above but also include radiographic criteria such as pneumatosis intestinalis and/or hepatic portal venous gas.	NPO, gastric suction, antibiotics for 7–10 days, frequent lab and radiographic monitoring.	Benefits of antibiotics and length of antibiotic treatment unknown. Radiographic signs can be misleading, especially a bubbly appearance in the bowel where a radiographic reading is "cannot rule out NEC."
Stage 3 NEC	Abdominal distension, pneumoperitoneum on radiograph, necrosis diagnosed at laparotomy or autopsy.	Usually surgical emergency, with drain placement and/or exploratory laparotomy with resection of diseased bowel.	May be readily confused with spontaneous intestinal perforation or congenital bowel disease if bowel is not directly visualized. This is common when only a drain is placed without direct examination of the bowel.
Spontaneous Intestinal Perforation (SIP)	As above with Stage 3 NEC but minimal bowel necrosis.	Surgical emergency with drain placement and/or exploratory laparotomy. Resection usually not required.	As above—often confused with surgical NEC, but treatment and prognosis are different. Pathophysiology is also different high level of inflammation.

Continued

TABLE 64.1 Stages of Necrotizing Enterocolitis and Some Examples of "Imposters" of Necrotizing Enterocolitis —cont'd

Name of Entity	Major Diagnostic Criteria	Treatment	Pitfall
Ischemic Bowel due to Cardiac Anomalies	Abdominal distension. Most commonly associated with low left ventricular output such as seen in hypoplastic left heart, aortic atresia, interrupted aortic arch.	As with Stage 2 or 3 NEC.	Complexities associated with heart disease may cause hesitation to do abdominal surgery.
Variants of Food Protein Intolerance Syndrome (FPIES)	Abdominal distension can be seen but not pathognomonic. Often presents with bloody stools, may have eosinophilia.	Responds well to highly elemental diet.	Does not have good biomarkers to differentiate from other intestinal injuries.

NEC, Necrotizing enterocolitis; *NPO*, nil per os.

Data from Lure AC, Du X, Black EW, et al. Using machine learning analysis to assist in differentiating between necrotizing enterocolitis and spontaneous intestinal perforation: a novel predictive analytic tool. *J Pediatr Surg*. 2021;56:1703–1710; Lueschow SR, Boly TJ, Jasper E, et al. A critical evaluation of current definitions of necrotizing enterocolitis. *Pediatr Res*. 2022;91:590–597.

Cardiogenic Intestinal Ischemia

One form of intestinal injury, sometimes incorrectly called "NEC," is secondary to ischemia of the intestine caused by a low blood flow state, most commonly associated with heart diseases in human infants. These cardiac defects include hypoplastic left ventricle, interrupted aortic arch, or other etiologies that lead to inadequate perfusion of the intestine, thereby not providing adequate oxygen delivery. This form of intestinal injury should be classified as a different entity and receive a name such as cardiogenic ischemic intestinal necrosis.[22]

Spontaneous Intestinal Perforation

SIP is associated with several risk factors, including severe prematurity, early postnatal steroid or indomethacin exposure, as well as a combination of the two.[64] Chorioamnionitis and the stress-related elevated cortisol that accompanies it are risk factors for SIP. Antenatal indomethacin may also be a risk factor when given close to the time of birth, especially when there is coexposure to antenatal steroids.[65,66] SIP is most often seen in extremely preterm, low birthweight infants within the first week after birth. The pathophysiology of SIP remains poorly understood. Histopathologic evaluation in SIP reveals focal perforations and necrosis of the muscularis externa without clear signs of ischemia.[64] The factors associated with the onset of SIP suggests attenuation of the muscularis in the ileum.[67] Whether this is causally related to antenatal steroids, indomethacin, or the combination remains unclear, but studies in rodent models suggest that steroids may induce intestinal atrophy.[68]

Food Protein Intolerance Enterocolitis Syndrome

FPIES is a hypersensitivity to food antigens that is non–IgE mediated. FPIES was previously thought to occur in infants only in the first months after birth outside of the neonatal period. However, a small case series of neonatal intensive care unit (NICU) patients with FPIES and clinical features comparable with typical NEC has been reported.[69] Signs and symptoms of FPIES are similar to NEC and include vomiting, diarrhea, hematochezia, or lethargy with exposure to a triggering antigen. The gold standard for FPIES diagnosis is a positive response to an oral food challenge. Studies suggest that certain laboratory trends are common to these patients but, by themselves, do not confirm the diagnosis. Leukocytosis with an eosinophil predominance, thrombocytosis, hemoccult positive stools, anemia, hypoalbuminemia, and radiographic findings of pneumatosis intestinalis may be seen with FPIES. Recent studies have shown that patients who subsequently develop FPIES have relatively high eosinophil counts in their cord blood.[70] More recent evidence suggests that the pathogenesis of FPIES relates to marked activation of innate immune and neuroendocrine pathways, but how these relate to specific recognition of antigens in foods remains poorly understood.[71] Clinically, differentiating FPIES from NEC is challenging. Eosinophilia is more likely to be present in FPIES, and babies with FPIES show tolerance to feeding with hydrolyzed or amino acid–based formulas.

Importantly, the treatment of FPIES and NEC is quite different. Intravenous antibiotics and bowel rest is recommended for NEC. However, for FPIES, a change in the diet to a protein hydrolysate is usually most appropriate.[72]

Medical Management

NEC is a very difficult disease to treat because no therapy or intervention definitively slows or stops the progression of the disease process. Usual therapy consists of immediate initiation of broad-spectrum antibiotics, cessation of feedings, and gastric decompression. Specific antibiotic regimens for treating NEC are not data driven but include broad-spectrum antibiotics that cover typical enteric flora, including gram-negative and anaerobic coverage. In patients who require surgical intervention, intraoperative cultures may help guide antibiotic therapy. The length of antibiotic therapy also is not data driven, but 7 to 10 days is a common length of treatment. Some centers may use inflammatory markers such as C-reactive protein to guide length of therapy.

Once these measures are incorporated, close observation of the patient's clinical status is used to guide therapy. If the patient is stable or improving with these measures, these medical measures are continued until there is improvement of the abdominal examination, radiographs, and/or ultrasound findings. Once the clinical course has stabilized for several days, antibiotics are discontinued, and if that baby no longer requires gastric decompression, enteral feedings are carefully resumed.

If the patient deviates from a stable clinical course with signs and symptoms such as hemodynamic instability, respiratory compromise from abdominal distention, thrombocytopenia, anemia, or disseminated intravascular coagulation, this should prompt strong consideration for surgical intervention.

Surgical Management

Multicenter cohort analyses show that approximately 50% of VLBW neonates diagnosed with NEC receive laparotomy, primary peritoneal drainage (PPD), or both.[73,74] Widely accepted indications for surgery are intestinal perforation or continued clinical deterioration despite maximal medical management.[75] The goals of surgical intervention include controlling enteric soilage and, if laparotomy is performed, the resection of frankly necrotic bowel.[76] NEC is the most common cause of pediatric SBS; hence it is important to preserve as much viable small intestine as possible.[77] In cases of extensive NEC, "second look" laparotomies, usually done within 24 to 48 hours of the initial procedure, may be necessary to better differentiate viable from nonviable bowel. If there is concern for abdominal compartment syndrome, a silo closure is a useful temporizing measure.

Laparotomy Versus Primary Peritoneal Drainage as Initial Therapy for NEC

Surgical therapy for NEC classically consists of exploratory laparotomy, resection of segments of necrotic bowel, and creation of ostomies.[78] In selected cases of minimal NEC, primary repair may also be effective.[79,80]

Bedside PPD under local anesthesia was first reported as a stabilizing modality for small or very ill neonates with severe NEC.[81,82] Interestingly, approximately 30% of surviving patients treated in this manner recovered intestinal function without the need for further surgery.[74,82] Over time there has been greater utilization of PPD for the treatment of NEC.[83] A multicenter analysis found that the use of PPD as the initial surgical therapy for NEC in VLBW neonates born in the United States has increased in frequency from 23% to more than 45% between 2006 and 2017.[73]

A Cochrane review of two relatively small randomized controlled trials[84,85] failed to show a statistically significant difference in 90-day mortality between initial PPD versus initial laparotomy treated neonates with NEC.[86] Due to sample size restrictions, no definitive recommendations were possible. A large cohort study confirmed that the frequency of subsequent laparotomy in initially PPD treated neonates with NEC approaches 50%.[74]

One recent randomized control trial compared outcomes of neonates with NEC or SIP treated with initial laparotomy vs. PPD and found no difference in mortality or neurological impairment at 18-22 months' corrected age. However, on Bayesian analysis, it appears that preoperative diagnosis of NEC vs. SIP modifies the effect of initial treatment. Overall, there is need for further investigation to fully elucidate the differences between PPD and laparotomy as initial surgical interventions for NEC.[85a]

Outcomes

Mortality

In VLBW neonates, the mortality of medical NEC declines linearly as birthweight increases.[74] Surgical NEC mortality is significantly higher than medical NEC for each birthweight range and tends to maintain a plateau of 30% even in patients with birthweights from 1000 to 1500 g.[74] The overall mortality of laparotomy-confirmed NEC in VLBW neonates is 38% as compared with a significantly reduced mortality of 19% for laparotomy-confirmed SIP.[12] The ischemic bowel, with or without pneumatosis, that is sometimes loosely referred to as "NEC" in term babies with severe congenital heart disease has an associated mortality of 23% if abdominal surgery is required and only 8% if the bowel injury can be managed medically.[87] In 5% of gastroschisis patients, pneumatosis is demonstrated, and it is often, somewhat confusingly, also termed NEC, although the pathogenesis is likely quite different than that found in VLBW neonates. The mortality of gastroschisis-associated "NEC" is 5%, whereas the baseline mortality of gastroschisis without "NEC" is 2%.[88]

The VON has recently completed a 12-year multicenter cohort analysis examining changes in the mortality of NEC in VLBW infants. That study found that mortality decreased significantly year over year during the study period, from 20.6% to 16.5% for medical NEC and from 36% to 31% for surgical NEC.[73] Of note, this improved survival was observed despite a concomitant decline in median birth weights. Interestingly, the decrease in surgical mortality was similar for both the initial PPD and initial laparotomy groups.[73]

Necrotizing Enterocolitis-Associated Strictures

The development of intestinal strictures is the most common delayed surgical complication of NEC patients. Clinically significant strictures usually manifest with feeding intolerance and abdominal distension 4 to 8 weeks after the initiation of feeds. Their presence is confirmed with contrast studies, and the majority require an operation to resolve the obstruction.[89] It is estimated that the incidence of medical NEC-related strictures is upwards of 15%, with the colon being the most common site.[89–91] In the absence of obstructive symptoms, routine contrast studies are not needed. Asymptomatic strictures incidentally found on diagnostic imaging do not require surgical intervention.

Neurodevelopmental Disability

There is little question that surgical NEC is associated with an increase in adverse neurologic outcomes. A VON follow-up of ELBW neonates indicated that 38% of those with surgical NEC had severe neurodevelopmental disability at approximately 2 years of age, which was significantly higher than baseline.[92] Early descriptive studies comparing PPD to laparotomy suggested possibly improved neurodevelopmental outcomes in patients undergoing initial laparotomy versus PPD.[93–95] Unfortunately, all of these studies were confounded by selection bias, with a tendency for PPD to be reserved for ELBW and severely ill neonates. In contradistinction, a VON cohort of ELBW neonates did not show any difference in neurologic outcomes between initial PPD versus initial laparotomy, and with risk adjustments there was, in fact, an indication that the PPD group may have had less neurologic impairment.[96]

Prevention

Currently, there are very few preventative strategies for NEC, but provision of baby's own mother's milk appears to be protective. Beyond the evidence for protection by human milk, there are several notions not based on clear evidence regarding the prevention of NEC. These include very slow feeding advancement, holding feedings during transfusion, and not feeding infants treated with certain vasoactive drugs. None of these is substantiated with clear evidence.

Prebiotics, probiotics, postbiotics, and synbiotics are proposed for the prevention of NEC. Metaanalyses of numerous studies suggest benefit to the routine use of probiotics as a group. However, in the United States, probiotics are categorized as nutritional supplements and thus are not regulated by the US Food and Drug

Administration (FDA). Hence no commercially available probiotics have been approved by the FDA.[97]

Not all probiotics are the same, and there are no adequately powered randomized controlled prospective trials that show both safety and benefit in the prevention of NEC. Thus little guidance is available in terms of which probiotics should be used, their dosage, which age group should be most appropriately targeted, and what kind of feedings should be used as an adjunct (prebiotics). If used routinely, any such agent should undergo rigorous prospective evaluation for safely and efficacy along with regulatory guidance.[98] In a 2021 Clinical Report from the American Academy of Pediatrics (AAP), the AAP Committee on Fetus and Newborn[99] stated that, given the lack of FDA-regulated pharmaceutical-grade products, conflicting data on safety and efficacy, and potential for harm in a highly vulnerable population, the current evidence does not support the routine administration of probiotics to preterm infants, particularly those with a birthweight of less than 1000 g.

The Future of Necrotizing Enterocolitis

To make progress in the field of NEC, it is important to understand that prevention is the best strategy. We first need to have a better definition and understanding of the different entities that are called NEC, and they need to be clearly differentiated in the various databases that are analyzed for research in this field. In addition, there are likely different pathophysiologies and treatments for these entities. Using multiomic and artificial intelligence technologies, we are on the verge of considerably more accurate predictive analytics which will guide our therapies.[38,100]

Short Bowel Syndrome

Epidemiology

Pediatric intestinal failure (IF) may be defined as a reduction in functional gut capacity with an inability to meet nutrient, fluid, and electrolyte requirements, ultimately manifesting as growth failure. This is an umbrella diagnosis that includes actual bowel loss which is termed SBS, motility disorders (i.e., pseudo-obstruction), and congenital mucosal disorders (i.e., microvillus inclusion disease). SBS is the most common form of IF in children, and NEC is the most frequent cause of SBS in the pediatric population.[101] Other frequent etiologies of childhood SBS include complicated gastroschisis, intestinal atresia, and midgut volvulus.

Animal models use an 80% to 90% small bowel resection model to create SBS.[102] However, a simple functional definition of SBS in children is intestinal loss resulting in a parenteral nutrition (PN) requirement of at least 90 days.[103,104] The achievement of independence from PN or "enteral autonomy" is a strong predictor of survival in SBS.[105,106] Therefore the overarching goal in the management of SBS is to attain enteral autonomy, and if that is not possible, to maintain normal growth using both enteral and intravenous means while mitigating the negative effects of long-term PN.

Management

The optimal management of SBS requires coordinated interdisciplinary care and has resulted in the formation of regional intestinal rehabilitation centers. These programs integrate the work of pediatric surgeons, pediatric gastroenterologists, neonatologists, dieticians, nurses, pharmacists, social workers, and feeding team specialists. Such efforts have resulted in a substantive survival benefit for children with SBS.[107,108]

Enteral Autonomy

There are various factors that can influence a patient's ability to attain enteral autonomy. First, the intestine has an innate ability to adapt and maximize its absorptive potential. Various mechanical and humoral factors have been implicated in intestinal adaptation, which often results in some bowel dilation as well as increased villous height and crypt depth.[101,109–111] In SBS patients, persistently dilated bowel seen on plain abdominal x-rays is sometimes mistaken as a sign of a distal obstruction or stricture. Another major factor that aids in achieving PN independence is that neonatal protein and energy needs markedly decrease on a per kilogram basis as patients age.[101] Quantitatively, there is a four- to fivefold reduction in macronutrient requirements from the neonatal period to late adolescence. Other considerations associated with a higher likelihood of achieving enteral autonomy include greater residual small bowel length, the presence of an intact colon, and the absence of intestinal dysmotility. The presence of an ileocecal valve is not consistently associated with enhanced weaning from PN, and this may be secondary to variable amounts of terminal ileum associated with a preserved valve. The terminal ileum has unique functional properties including the absorption of fat-soluble vitamins, zinc, and vitamin B_{12}. The underlying diagnosis causing pediatric SBS also affects the likelihood of attaining enteral autonomy with NEC patients having the highest success rate of weaning from PN.[105,112]

Parenteral Nutrition

PN is a lifesaving therapy for SBS patients and is necessary for adequate growth. Although vital, PN is associated with complications including intestinal failure–associated liver disease (IFALD), central line–associated bloodstream infections (CLABSIs), and deep vein thrombosis (DVT).[101]

The development of IFALD is likely multifactorial, including PN composition, lack of enteral stimulation, the presence of prematurity, and recurrent sepsis. The replacement of the standard soybean-based lipid emulsion in PN with fish oil–based lipids, which are omega-3 rich and low in phytosterols, leads to improvement of IFALD.[113,114] In addition, restriction of intravenous soy-based lipid to a total allotment of 1 g/kg per day can both prevent and reverse IFALD in pediatric patients with SBS.[115] Many centers now routinely treat infants who have significant direct hyperbilirubinemia with lipid emulsions low in soy or lipid restriction to avoid the complications of IFALD. A balancing factor in neonates treated with relatively low lipid allotments is the need for high glucose infusion rates.

Enteral Nutrition

The goal of intestinal rehabilitation is to wean PN support while maximizing enteral intake. Enteral nutrition effectively improves IFALD[116] and eventually eliminates the need for central venous access. Even SBS children with established cirrhosis have a 95% long-term transplant-free survival if they are successfully transitioned to full enteral nutrition.[106]

The prompt initiation of enteral feeding after bowel resection has a favorable impact on achieving enteral autonomy.[103] Utilizing breast milk appears to augment intestinal adaptation in neonatal SBS and is linked to a decrease in the number of PN days required.[117] If human milk is not available, amino acid–based formulations are often favored as they manifest enhanced enteral tolerance compared with hydrolyzed formulas.[118–120] Amino acid formulas also minimize the risk of allergic enteritis.

The theoretic advantage of bolus feeding compared with continuous feeding is its cyclical nature, which more closely simulates the normal release of GI hormones.[121] However, some studies have shown that continuous feeding is more easily tolerated and is associated with improved nutrient absorption and growth.[122–124] The usual progression of enteral nutrition in SBS consists of low-rate continuous feeds that are slowly increased with respect to volume while paying close attention to weight gain, stool output, and signs of feeding intolerance. Suitable patients are further transitioned to bolus feeds (ideally oral) during the day and receive continuous feeds overnight to help maximize absorption. Oral aversion is a common sequela of SBS. With this in mind, it is important to introduce oral feeding, even if it is nonnutritive, to help encourage oral-motor development.[118,125]

Medical Management

The prevalence of micronutrient deficiencies is high in pediatric SBS.[126] The segments of intestine that are missing as well as the absorptive capacity of the remaining bowel influence the micronutrient deficiency states that are present. It is important to carefully monitor micronutrient levels and provide appropriate supplementation. For patients with high stool output, antimotility agents such as loperamide are of benefit and help prolong transit time and absorption.

Children with gastric dysmotility may benefit from prokinetic agents such as erythromycin (motilin receptor agonist).[127] SBS patients with massive bowel resections have been shown to have gastric hypersecretion, for which histamine (H_2) blockers and proton pump inhibitors are helpful for amelioration. However, this increase in gastric output is transient, and the protracted administration of acid suppressive agents has been linked to an elevated risk of infections and bacterial overgrowth.[101,128]

In general, patients with SBS have an increased capacity for developing small bowel bacterial overgrowth (SBBO). This is, in part, due to the altered intestinal microbiome, lack of enteral stimulation, as well as the presence of dilated and dysmotile segments of intestine that can foster bacterial colonization. Symptoms of SBBO include poor growth, decreased enteral tolerance, and occasional D-lactic acidosis. SBBO can be treated with empiric enteral antibiotic regimens, and if this is unsuccessful, endoscopically obtained duodenal aspirate cultures can more precisely direct therapy.[129] The use of probiotics tends to be avoided in SBS patients with central venous catheters in situ. This is due to the risk of CLABSIs from probiotic seeding of the line or translocation of gut bacteria.[130]

Glucagon-like peptide 2 (GLP-2) is a hormone with a significant effect on intestinal adaptation. It stimulates proliferation of the small bowel epithelium and delays gastric emptying.[131] Teduglutide, a substituted GLP-2 analogue with a prolonged half-life, has been shown to increase villous height and crypt depth, thereby increasing intestinal absorptive capacity.[132] As found in adults, a recent randomized control trial of teduglutide administration in pediatric patients with SBS demonstrated a reduction in PN support, increase in enteral nutrition, and higher serum citrulline levels (a biomarker of intestinal mucosal mass).[133]

Studies examining the safety and efficacy of teduglutide are restricted to patients older than 1 year of age and greater than 10 kg. Hence, at this time, teduglutide is not an intervention recommended for neonates. Long-term teduglutide therapy does potentially increase the risk of developing GI neoplasms and may cause bowel obstructions, so careful follow-up is required.

Surgical Management

The hallmark of the surgical management of SBS is the preservation of as much viable small intestine as possible. Colonic salvage is also important to promote fluid homeostasis and enhance the absorption of some nutrients.[134] In addition, the establishment of bowel continuity with prompt stoma closure optimizes intestinal absorptive surface area.

Surgical bowel lengthening and tapering operations are considered for select SBS patients with bowel dilation. Indications for surgery are failure to advance enteral feeding despite full medical management, severe SBBO resistant to enteral therapy, and neonatal bowel obstruction with very limited residual small bowel length. Techniques for bowel lengthening include the longitudinal intestinal lengthening and tapering (LILT) procedure[135] and now the more commonly used serial transverse enteroplasty (STEP).[136] The International STEP Data Registry reported that, after STEP, about half of children reached enteral autonomy and two-thirds demonstrated enhanced enteral tolerance.[137]

Transplantation is used as a salvage strategy for SBS patients with progressive IFALD, loss of venous access, recurrent life-threatening CLABSIs, and complete mesenteric thrombosis and in some individuals with extremely short residual bowel length resulting in a lifelong dependence on PN. The 5-year patient survival for isolated intestinal transplantation is 75% and 62% if both liver and intestine are transplanted.[138]

The long-term patient and graft survivals in pediatric intestinal transplantation have improved.[139] Coincident with development of multidisciplinary intestinal rehabilitation programs, there has been a reported 25% reduction in the number of intestinal transplants performed in the United States.[139]

Outcomes

Advances in the care of patients with SBS over the past two decades have led to multidisciplinary teams now reporting long-term transplant-free survivals of greater than 90%.[104] This improvement extends to children with "ultrashort" bowel, which is defined as having less than 20% of expected small bowel length. A study evaluating outcomes in patients with ultrashort bowel secondary to midgut volvulus found that long-term survival in the context of multidisciplinary IF care was 91%. Remarkably in this cohort, greater than 50% of patients who did not have concomitant gastroschisis were able to achieve enteral autonomy without transplantation.[140] Similarly, children discharged from the NICU with severe NEC, defined as having residual small bowel lengths of less than 30 cm, had a 93% survival with a median follow-up of 8 years in a multidisciplinary setting.[141] Those weaning completely from PN had a median small bowel length of only 22 cm. Given these findings, the dated term "NEC totalis" is perhaps best abandoned. A precise determination of residual small bowel length is more appropriate when assessing prognosis and goals of care in the neonatal setting.

Cycled home PN allows children with SBS to lead relatively normal lives where attending school, exercise, and outside activities are all possible. However, SBS can negatively impact the quality of life of both patients and their families.[142] There are ongoing investigations to quantify and improve the quality of life of these children. Furthermore, as patients with pediatric SBS are now routinely living to adulthood, additional longitudinal studies to evaluate pubertal development, childbearing potential, and neurodevelopmental sequelae are required.[104]

Disorders of the Liver

MOHAMMAD NASSER KABBANY AND KAREN F. MURRAY

KEY POINTS

- Early onset (<24 hours of age) or new jaundice is never normal and should be investigated.
- Initial evaluation of a jaundiced infant should always include conjugated and unconjugated bilirubin levels.
- Infants presenting with jaundice secondary to conjugated hyperbilirubinemia should undergo expedient evaluation for potentially life-threatening and treatable causes of cholestasis and then for other causes.

Neonatal Liver Disease

The liver is the largest abdominal organ and serves as the body's main location of energy production, metabolism, protein synthesis, and detoxification. Embryologically, the liver is derived from an endodermal outgrowth from the foregut into the septum transversum. There are multiple cell types within the liver parenchyma, including hepatocytes, cholangiocytes, stellate cells, endothelial cells, and cells of the innate immune system. The key roles of the hepatocyte include protein synthesis, fatty acid synthesis and oxidation, formation of lipids, cholesterol and bile salts, bilirubin metabolism, gluconeogenesis, glycogen synthesis, urea cycle and production of ammonia, and detoxification. The hepatocyte is the only cell in the body that manufactures albumin, fibrinogen, and prothrombin clotting factors. In the setting of significant liver injury, loss of normal hepatocyte synthetic function often results in the development of coagulopathy and hypoalbuminemia.

Bile is primarily composed of bile acids, bilirubin, cholesterol, and phospholipids, which are manufactured in the hepatocyte, secreted into the canaliculus, transported into the biliary ducts, and, ultimately, secreted into the intestine or stored within the gallbladder. Bile is critical for solubilizing dietary fats and fat-soluble vitamins (A, D, E, and K) to make them available for absorption. Disruption of this process at any level results in cholestasis. Cholestasis refers to obstruction of the normal excretion of bile from the liver resulting in the abnormal accumulation of bile components within the liver and serum. While cholestasis is not synonymous with jaundice from conjugated hyperbilirubinemia, serum conjugated bilirubin level is the most clinically useful marker of cholestasis.

Like the lungs, the liver is unique in that it has a dual blood supply: nutrient-rich venous blood from the portal vein, and oxygen-rich arterial blood from the hepatic artery. Venous drainage of the liver occurs through the hepatic veins. In the fetus, the umbilical vein delivers oxygenated blood to the liver via the left portal vein and the ductus venosus, which then joins the left hepatic vein as it drains into the inferior vena cava. The ductus venosus closes spontaneously at birth. Congenital anomalies of the portal vein or thrombosis associated with umbilical vein catheter placement may lead to portal vein obstruction and portal hypertension. Portal hypertension describes a pathologic increase in venous pressure in the portal venous system and occurs when the portal pressure rises above 10 mmHg. Portal hypertension may be prehepatic (portal vein), intrahepatic (cirrhosis), or posthepatic (hepatic venous) in etiology. Signs and symptoms of portal hypertension include splenomegaly, ascites, and gastrointestinal bleeding secondary to bleeding varices.

Neonates with liver disease may present with an array of clinical signs ranging from asymptomatic jaundice to acute liver failure. Clinical evaluation and management differ depending on underlying etiology. Clinical signs suggestive of underlying liver disease include ascites, hepatomegaly with or without splenomegaly, coagulopathy, elevated transaminases, hyperammonemia, hypoglycemia, and cholestasis. The initial evaluation of suspected liver disease must include a careful physical examination, laboratory evaluation, and imaging. The initial laboratory evaluation for suspected liver disease includes an assessment of hepatocellular injury and function, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP), gamma-glutamyl transpeptidase (GGT), conjugated and unconjugated bilirubin levels, prothrombin time/international normalized ratio (INR), and albumin levels. Elevations in serum ALT and AST indicate hepatocellular injury; however, they are not specific to the liver and may be found in other tissues such as red blood cells and skeletal muscle. An elevation in ALP and GGT may indicate biliary obstruction or inflammation; however, care must be taken in children, as elevated ALP is also indicative of normal bone growth and metabolism. ALP can be particularly elevated in preterm infants with osteopenia of prematurity. As stated previously, an elevation in transaminases (AST, ALT) indicates hepatocyte injury, whereas an elevation in prothrombin time/INR and hypoalbuminemia indicates a loss of normal hepatocyte function and most likely a greater degree of hepatocyte injury. The most appropriate initial imaging modality is abdominal ultrasound (US) with Doppler, which can detect anatomic or vascular anomalies, thrombosis, or suggest underlying portal hypertension.

Liver disease in the neonate frequently presents with new or persistent jaundice. Infants presenting with new jaundice deserve an urgent evaluation, as this is never normal. Term infants with jaundice persisting beyond 14 days and preterm infants with jaundice beyond 21 days of life deserve expedient evaluation.[1,2] In any jaundiced infant, it is necessary to determine whether jaundice

is due to conjugated versus unconjugated hyperbilirubinemia. Although the differential of potential causes will vary by the type of predominant bilirubin, it is prudent to prioritize the evaluation to identify conditions where early intervention is associated with improved outcome.

Elevated unconjugated hyperbilirubinemia is often seen secondary to breast milk jaundice, sepsis, hemolysis secondary to blood group incompatibility (ABO and rhesus) or red blood cell dyscrasia, and, more rarely, Crigler–Najjar syndrome. While physiologic jaundice and breast milk jaundice are common, jaundice secondary to unconjugated hyperbilirubinemia should still be investigated if it is of very early onset (within 24 hours of life), prolonged beyond 14 days, or at high levels. Breast milk jaundice is the most likely etiology of unconjugated hyperbilirubinemia if the serum level is downtrending; there is no evidence of hemolysis, infection, abnormal thyroid function, or elevated serum aminotransferases; and the child is clinically well. However, if unconjugated hyperbilirubinemia persists or is rising, or the child is ill, disorders influencing bilirubin conjugation and hemoglobin metabolism should be investigated.

The presence of conjugated hyperbilirubinemia (defined as conjugated bilirubin level ≥15% of the total) should raise concern for underlying liver disease. An initial approach to the evaluation of neonatal conjugated hyperbilirubinemia is shown in Fig. 65.1. Specific etiologies of neonatal cholestasis are reviewed below and summarized in Table 65.1. Idiopathic neonatal hepatitis is a term historically applied to infants presenting with neonatal cholestasis or hepatitis in whom no specific etiology can be identified. Liver biopsies in these infants often demonstrate nonspecific intrahepatic cholestasis and giant cell transformation of hepatocytes (Fig. 65.2).[3] Currently, it is recognized that multinucleated giant cells represent a stereotypical response by the immature liver to many etiologies of hepatocellular injury, including infection, biliary obstruction, and metabolic disease. Today, with advancements in next generation DNA sequencing, the number of identifiable etiologies of neonatal cholestasis and hepatitis has increased dramatically, further reducing the frequency and utility of the idiopathic neonatal hepatitis diagnosis.

Cholestatic Liver Disease

Cholestasis refers to obstruction of the normal excretion of bile from the liver, resulting in abnormal accumulation of bile salts, bilirubin, and lipids in the blood. In infants, cholestasis may present as asymptomatic jaundice, pruritus, unexplained fat-soluble vitamin deficiency, or acute liver failure. The presence of acholic stools suggests functional or anatomic biliary obstruction. The following sections review the most common etiologies of neonatal cholestasis and discuss the corresponding disease-specific evaluation and clinical management.

Nutritional management is critical and central to the care of infants with chronic cholestasis. Growth failure commonly occurs secondary to malabsorption from inadequate bile flow, intestinal congestion from portal hypertension, and increased caloric needs in the setting of chronic liver inflammation. The estimated daily caloric intake for infants with chronic cholestasis may approach 150% of that of healthy infants.[4] In addition, malabsorption of fat-soluble vitamins (A, D, E, and K) can result in progressive coagulopathy and pathologic fractures. While enteral nutrition is preferable, some infants go on to require nutritional optimization with total parenteral nutrition. The general principles of nutritional management in cholestatic infants include assurance of adequate absorbable calories and nutrients, monitoring levels of and supplementation with fat-soluble vitamins, and preparation to escalate the nutritional support and supplementation in infants who cannot sustain adequate intake for growth orally, with

Nutritional

Total parenteral nutrition

supplemental enteral feeds via nasogastric tube, or initiation of parenteral nutrition in situations of failure to grow or gain weight adequately with maximal enteral nutrition. The selection of formula should consider medium-chain triglyceride (MCT) content, as this fat source is directly absorbed into the portal venous system and does not require emulsification by bile acids or active transport that is disrupted in cholestasis. Children with portal hypertension and ascites also benefit from sodium restriction.

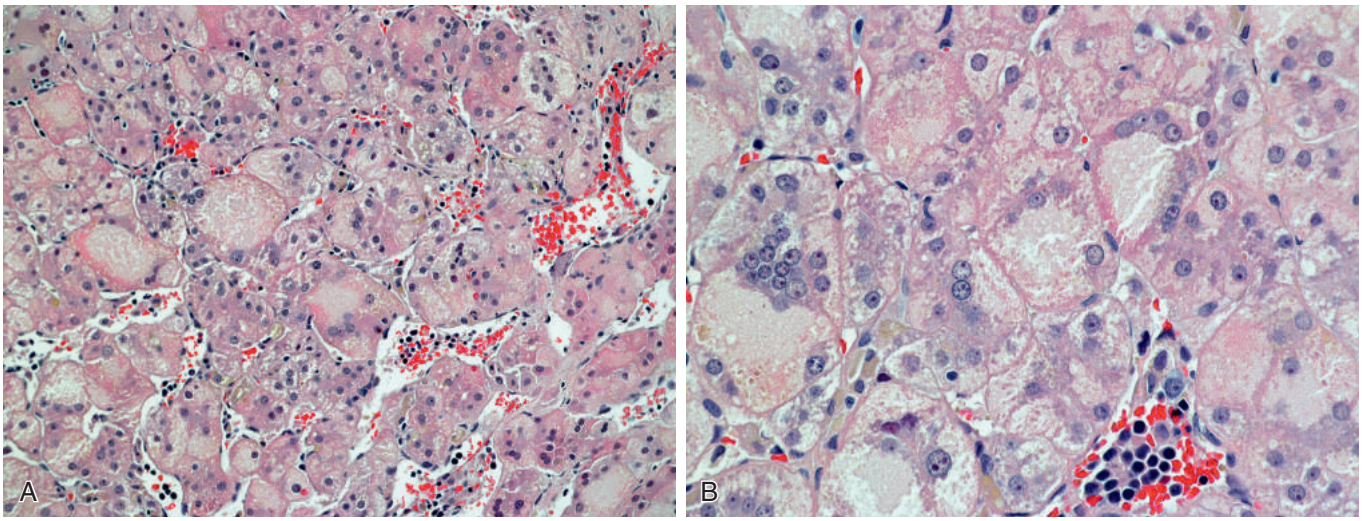
Biliary Atresia

Biliary atresia (BA) is an idiopathic hepatobiliary disorder of infancy characterized by inflammation and progressive fibrosis resulting in the obliteration of the extrahepatic biliary ducts within weeks of birth.[5,6] As the disease progresses, the end result is variable destruction and obliteration of the intrahepatic bile ducts with subsequent biliary cirrhosis. BA is the most common cause of infantile chronic liver disease and the most frequent indication for liver transplantation in the pediatric population. The reported incidence of BA is 0.5 to 3.2 per 10,000 live births but varies based on ethnicity and geography with higher incidence in the Far East and Oceania. Babies with BA generally present between 2 and 5 weeks of age. Without rapid intervention the natural history of BA is uniform fatality by 2 years of age.

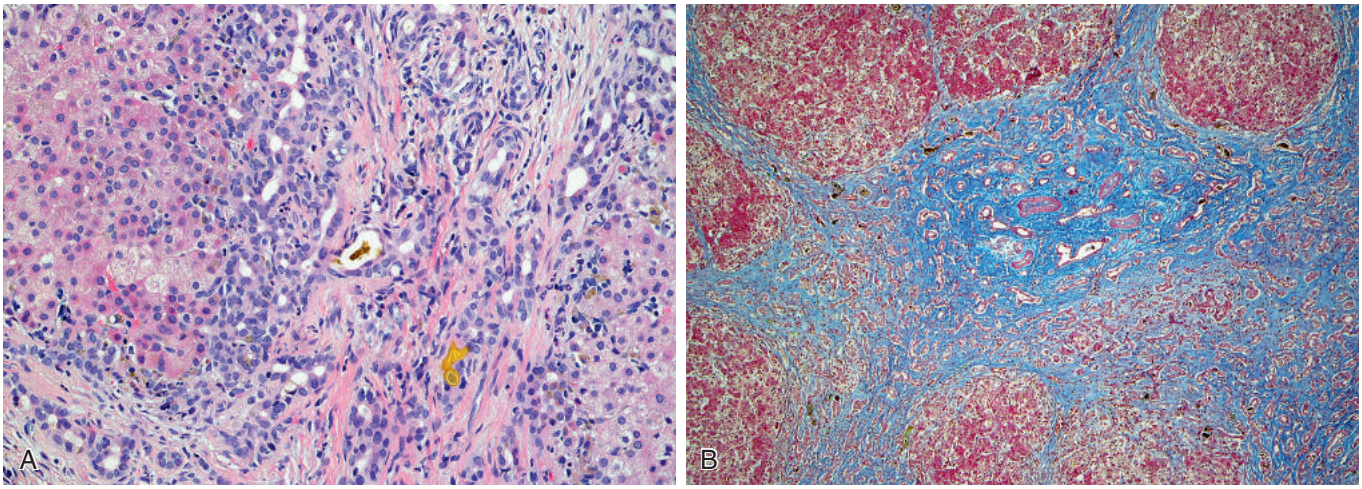
Biliary atresia generally presents in one of two broad clinical phenotypes: sporadic/nonsyndromic, which is the more common form (85% to 90%) and is not typically associated with other congenital anomalies; and embryonic/syndromic/congenital form, which accounts for 10% to 15% of the cases, and is associated with non-hepatic anomalies. The embryonic/syndromic/congenital form is commonly associated with non-hepatic congenital anomalies such as situs inversus, polysplenia or asplenia, vascular and cardiac malformations, and intestinal malrotation. In a large North American multicenter study, the latter group was further divided into two distinct subgroups based on the presence of laterality defects. The group with at least one major malformation, but without laterality defects, has a higher incidence of genitourinary defects like cystic kidney and hydronephrosis. The other group is syndromic with laterality defects.[7]

BA typically presents with cholestatic jaundice and hepatosplenomegaly between 2 and 5 weeks of age. Acholic stools suggest biliary obstruction and are frequently present, but onset is commonly well after the onset of jaundice. If the infant also had a preceding history of physiologic jaundice, the cholestatic jaundice may not be recognized as new; this highlights the importance of evaluating any prolonged or new jaundice in infants. Although splenomegaly is commonly present at diagnosis, other signs of portal hypertension such as ascites generally occur later in the course of disease. As chronic inflammation and cholestasis lead to malabsorption, many infants with BA present with inadequate weight gain.

Expedient differentiation of BA from other causes of neonatal cholestasis is critical, as surgical intervention before 2 months of age has been shown to improve surgical success and outcome.[8,9] If early laboratory evaluations are suggestive of BA, consultation with a pediatric hepatologist is mandatory. Laboratory evaluation early in the course of disease typically demonstrates conjugated hyperbilirubinemia between 2 and 7 mg/dL and total bilirubin levels between 5 and 12 mg/dL.[4] Elevations in ALT, ALP, and GGT are generally seen.[4] Abdominal US is recommended as the first-line imaging modality and may demonstrate absence of the gallbladder after adequate fasting or a fibrotic remnant of extrahepatic bile duct. However, the presence of the gallbladder does not necessarily exclude BA. In the porta hepatis, a triangular or tubular echogenic cord of fibrous tissue representing the biliary remnant may be described as "triangular cord sign." The reported sensitivity of this sonographic finding is 80%.[10] As a follow-up to abdominal US, hepatobiliary scintigraphy with technetium-labeled iminodiacetic acid derivatives (HIDA scan) may be used to assist in the differentiation between obstructive and nonobstructive causes of neonatal cholestasis.



• **Fig. 65.2** Neonatal Hepatitis Histology. (A) Low power of a hematoxylin and eosin stain from a liver biopsy demonstrating hepatocytes with giant cell transformation and ballooning. Some cholestasis is evident. (B) Higher power of same biopsy shows the hepatocytes with giant cell transformation as well as a focus of extramedullary hematopoiesis.



• **Fig. 65.3** Biliary Atresia Histology. (A) Hematoxylin and eosin stain of a liver biopsy from a 3-month-old girl demonstrating a proliferation of bile ductules. Bile plugs are present. (B) Masson trichrome stain from a liver transplant specimen from the same girl at 8 months of age. This specimen has diffuse cirrhosis with fibrous expansion of portal tracts. The portal triads lack bile ducts, but there is a marked bile ductule reaction, many containing bile plugs.

In BA, radionucleotide scans demonstrate rapid update of tracer but absence of excretion into the bowel at 24 hours. The sensitivity of the HIDA scans may be increased by pretreatment with oral phenobarbital (5 mg/kg/day) for 5 days. Care must be taken, however, to not delay definitive diagnosis by awaiting scan results and recognition that functional causes of cholestasis (such as hypothyroidism) can also result in a nonexcreting HIDA scan. Percutaneous liver biopsy is helpful in excluding alternate causes of cholestasis. Histopathologic findings supportive of a diagnosis of BA demonstrate bile ductular proliferation and bile duct plugging (Fig. 65.3). Given the progressive nature of BA, the histologic findings will vary with the point in progression. Matrix metalloproteinase-7 (MMP-7), a protease involved in tissue remodeling, was found to have good accuracy in BA diagnosis. However, more studies are needed to further validate its use in clinical practice.[11]

Failure to exclude BA after the above evaluation is complete necessitates surgical exploration with intraoperative cholangiogram. The diagnosis of BA may be made or confirmed at the time of laparotomy with the observation of an atretic biliary tree and intraoperative cholangiogram demonstrating lack of patency in the biliary ductal system. If BA is confirmed, surgical intervention with a Kasai hepatic portoenterostomy is recommended. The Kasai is a surgical procedure that works to restore the normal flow of bile by excising the obstructed bile ducts and creating an anastomosis of a jejunal limb of a Roux-en-Y with the liver at the porta hepatis, the area of the liver from which the bile ducts become extrahepatic. Restoration of bile flow may prevent or delay progression of disease, worsening of fibrosis, and development of end-stage liver disease. However, despite Kasai portoenterostomy, most children progress to cirrhosis and portal hypertension and ultimately require liver transplantation.

Choledochal Cysts

Choledochal cysts are congenital dilations of the biliary ducts which can impede bile flow, leading to liver injury. The incidence of choledochal cysts is high in the Asian population with a female predominance. Choledochal cysts can present at any age, including infancy. However, 80% of choledochal cysts are diagnosed in the first decade of life, with cholestasis being the most common sign in infants, and cholangitis or pancreatitis being less common. Choledochal cysts are associated with increased risk of choledocholithiasis, ascending cholangitis, and liver cirrhosis. There are five types of choledochal cysts based on the location of biliary dilation. The most common forms are type I (spherical or fusiform dilation of the extra hepatic biliary tree) followed by type IV (includes multiple cysts that can involve intrahepatic and extrahepatic biliary tree). The pathogenesis of choledochal cyst formation is not entirely clear. However, anomalous pancreaticobiliary union may play a role by causing reflux of pancreatic secretions into the bile duct. Diagnosis is usually made with abdominal ultrasound. Choledochal cysts need to be excised surgically, and in their entirety whenever possible. Continued surveillance for malignancy (cholangiocarcinoma and squamous cell carcinoma) is warranted after excision due to increased risk over the general population. Although not well defined for pediatric ages, screening should include regular biochemical evaluation and imaging (ultrasound or cross-sectional CT).[12,13]

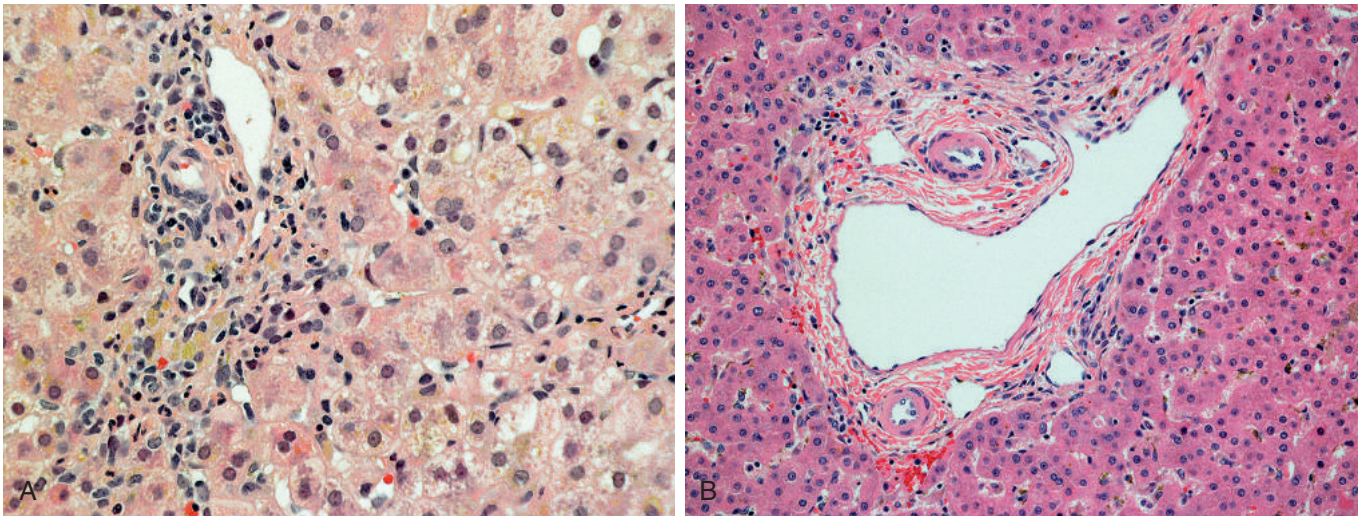
Alagille Syndrome (Arteriohepatic Dysplasia)

Alagille syndrome (ALGS) is an autosomal dominant or sporadic de novo genetic disorder with variable penetrance, characterized by chronic, progressive cholestasis secondary to a paucity of intralobular bile ducts. The estimated prevalence is 1 in 30,000 live births.[2] The majority (more than 90%) of children with ALGS carry a mutation in the gene *JAG1*, located on chromosome 20.[14–16] The product of *JAG1* is a ligand in the Notch signaling pathway that plays a key role in embryogenesis and the pathogenesis of the disorder. A small number of infants with ALGS have mutations in *NOTCH2*.[17,18]

ALGS is a multisystem syndrome characterized by cholestatic liver disease, stereotypical facial features, congenital heart disease, ocular abnormalities (most commonly posterior embryotoxon which represents prominence of Schwalbe line), skeletal abnormalities (butterfly vertebrae and rib abnormalities), and renal disease. Other features include short stature, as well as vascular and dental abnormalities. Most infants with ALGS present within the first 3 months of life with cholestasis; however, those with severe extrahepatic manifestations (usually caused by associated congenital heart disease) may present at birth or even be identified by prenatal US. Although many forms of congenital heart disease have been associated with ALGS, the most common is peripheral pulmonary stenosis. The characteristic facial features are frequently difficult to appreciate in the neonatal period but include a prominent forehead and pointed chin, giving the face a triangular appearance, deep-set eyes with hypertelorism, and a saddle nose.

When cholestatic jaundice occurs in the first 6 weeks of life, care must be taken to discriminate ALGS from alternate etiologies of neonatal cholestasis, particularly BA and other treatable etiologies for which timely initiation of treatment may change the outcome. Initial evaluation for ALGS should include serum biochemistries, abdominal US, and echocardiogram when a heart murmur is identified. In ALGS, the conjugated hyperbilirubinemia is associated with elevated serum aminotransferases and GGT, reflective of the biliary involvement. If there is clinical concern for ALGS, a spinal radiograph should be obtained to evaluate for hemivertebra or butterfly vertebra, and an ophthalmologic evaluation for posterior embryotoxon is recommended.

Although a liver biopsy is not required for the diagnosis of ALGS when other stereotypical syndromic features are present, biopsy should be performed when the diagnosis is in question. The histopathology in ALGS is characterized by bile ductular paucity; however, this is not pathognomonic. In the preterm infant the number of bile ducts is normally diminished, and hence care must be taken to not incorrectly make the diagnosis of pathologic paucity (Fig. 65.4).[19] In term infants and older children, the normal bile duct to portal tract ratio ranges from 0.9 to 1.8; ratios less than 0.9 are suggestive of paucity. Given the normal



• **Fig. 65.4** Alagille Syndrome Histology. (A) Hematoxylin and eosin stain of a liver biopsy from a 3-month-old boy demonstrating loss of bile ducts in a portal triad. This bile duct paucity is accompanied by hepatocanalicular cholestasis. The hepatocytes also demonstrate swelling. (B) At 10 months of age, another boy was transplanted for Alagille syndrome. On hematoxylin and eosin stain, his liver demonstrated paucity of bile ducts in the portal triads. Mild hepatocanalicular cholestasis is also present in this biopsy.

developmental progression of the biliary system in infancy and the importance of excluding BA, infants with cholestatic jaundice and elevated GGT usually require liver biopsy and hepatobiliary scintigraphy. Additionally, an intraoperative cholangiogram to verify patency of the extrahepatic biliary system may be required.

Metabolic bone disease is especially striking in ALGS. Elevated ALP commonly reflects abnormal bone metabolism in addition to the biliary disease. Serum bile salt levels can be extremely elevated, even in the absence of jaundice, leading to intractable and refractory pruritus. Hypercholesterolemia and hypertriglyceridemia can lead to the development of xanthomas, most prominent on extensor surfaces and areas of minor trauma, including the diaper area and plantar surfaces of feet, abdomen, and neck.

Treatment of ALGS is directed at improving or maintaining adequate nutrition, treating the complications if there is cholestasis, and supporting the cardiovascular health. The introduction of this section has details regarding nutritional management of cholestatic infants. About 21% to 31% of patients who fail medical therapy will require liver transplantation.[20]

α-1 Antitrypsin Deficiency

α-1 Antitrypsin (A1AT) deficiency is the most common genetic cause of liver disease and affects approximately 1 in 2000 live births.[21–23] It is an autosomal codominant disorder that results in a reduction in α-1 antitrypsin, a serine protease produced in the liver whose role is to inhibit other proteases and elastases that can lead to cellular destruction. The genetic defect results in a single amino acid substitution within the A1AT protein, resulting in abnormal molecular folding, and inability of the protein to be processed beyond the Golgi apparatus. Excessive hepatic accumulation of the abnormal A1AT protein results in hepatocellular injury.

The clinical phenotype of A1AT deficiency includes both liver and pulmonary manifestations. Pulmonary disease generally manifests in adulthood, whereas liver involvement commonly presents in neonates. Liver disease in A1AT is most often characterized by cholestatic jaundice, which can develop in 10% of infants with PI ZZ genotype. Hepatosplenomegaly and ascites can also be seen in the most advanced cases.[24]

A1AT deficiency is diagnosed by serologic testing and liver histology. The most specific serum test is A1AT phenotyping (Pi type). While commonly used as a less costly and widely available screening test, the serum levels of A1AT can be falsely elevated into the normal range in times of systemic inflammation or infection and so should not be used in the diagnosis of A1AT. A1AT variants are named according to their electrophoretic migration pattern.[25] The normal protein is designated M, and the S and Z variants are the most common, leading to a reduction in serum A1AT. The homozygous PiZZ is named because it has the slowest gel migration and causes the most severe disease phenotype. Generally liver disease manifests only in PiZZ, PiSZ, or, rarely, PiMZ variants.[26]

The classic, but not pathognomonic, histologic finding in A1AT deficiency is periodic acid-Schiff (PAS)-positive diastase-resistant eosinophilic globules within the hepatocytes. These globules represent the accumulated abnormal protein trapped within the endoplasmic reticulum. Liver histology may also demonstrate bile duct destruction, proliferation, and, potentially, bile duct paucity, making it important to exclude BA and ALGS.

Although recombinant A1AT has been used for the treatment of the pulmonary manifestations, management of the associated liver disease is primarily supportive, as there are no specific or targeted therapies currently available. As in all disorders resulting in cholestasis, fat malabsorption is common with A1AT deficiency. Cholestatic infants usually benefit from MCT-rich formula to aid the fat absorption and supplementation with fat-soluble vitamins as needed. Additionally, ursodeoxycholic acid may be utilized to improve bile flow; however, no study has demonstrated clear benefit. Historically, breastfeeding was thought to be of some benefit. However, in a study comparing formula-fed with breastfed infants, no benefit was found.[27,28] To prevent acceleration of pulmonary manifestations, including early emphysema, avoidance of smoking and environmental pollution is critical.

For infants and children with end-stage liver disease, liver transplantation is indicated. As most A1AT is manufactured in the liver, the recipient assumes the donor's Pi phenotype and, posttransplant, experiences normal serum levels of the functional protein, decreased risk of pulmonary disease, and no chance of recurrent disease in the transplanted organ.

Cystic Fibrosis Liver Disease

While cystic fibrosis (CF) is common, affecting approximately 1 in 2500 births in North America, CF-related liver disease is uncommon in the neonatal period. It is estimated that less than 2% of infants with CF present with cholestasis.[29] Given the low incidence of CF-related liver disease in neonates, testing for CF beyond state-mandated newborn screens should be reserved for those infants in whom alternate causes of cholestasis have been excluded or in infants with other typical features of CF, including meconium ileus or inadequate weight gain despite theoretically adequate caloric intake.

Disorders of Bile Acid Synthesis

There are several steps in the synthesis of bile acids that may be disrupted, leading to an accumulation of hepatotoxic bile acid intermediates. Bile acid synthesis disorders are rare autosomal recessive disorders, with a prevalence of 1 in 50,000 in the general population. In the neonatal period, phenotypes of bile acid synthetic disorders include acute hepatitis, acute liver failure, persistent cholestasis, and progressive chronic hepatitis.

Cholic acid and chenodeoxycholic acid are the primary bile acids in humans, and disruption at any step in their synthesis results in the accumulation of toxic intermediate metabolites. Liver injury associated with disorders of bile acid synthesis occurs secondary to direct hepatocellular injury from accumulation of toxic intermediates or secondary to the accumulation of cholesterol, drugs, and other toxins within the liver from abnormal bile excretion.

The age at presentation with a disorder of bile acid synthesis is variable, ranging from early infancy to adulthood. The most common clinical presentation includes neonatal jaundice, failure to thrive, hepatosplenomegaly, metabolic bone disease, and bleeding early in childhood. Pruritus is usually absent. Some disorders are associated with progressive neurologic disease, manifesting with seizures, developmental delay, deafness, blindness, and neuromuscular weakness.

Laboratory testing in infants with bile acid synthetic disorders demonstrates normal or low serum bile acid levels, elevated serum aminotransferases, normal GGT, and complications of fat malabsorption, including fat-soluble vitamin deficiency. If serum bile acids are found to be low, urinary bile acids should be measured

for identification of the particular synthetic defect. Liver biopsies are generally nonspecific and can demonstrate canalicular bile plugging, inflammation without bile duct proliferation, and sometime a picture similar to those observed in idiopathic neonatal hepatitis such as giant cell transformation.[30,31]

Treatment of inborn errors of bile acid synthesis focuses on supporting normal growth and supplementation of fat-soluble vitamins. Treatment with cholic acid is a preferred therapy for the most common disorders of primary bile acid synthesis because cholic acid suppresses the production of the toxic bile acid intermediates. Ursodiol is not indicated as it does not suppress production of abnormal bile acid intermediates.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is a group of autosomal recessive disorders characterized by defective bile export leading to cholestasis. This group of disorders is classified based on the genetic mutation, and they are named PFIC 1, PFIC 2, and PFIC 3. Liver disease in PFIC results from accumulation of bile salts within the hepatocytes leading to profound cholestasis, fat-soluble vitamin deficiency, and intractable pruritus.

PFIC 1, also known as Byler disease, is caused by a mutation in the gene *ATP8B1* on chromosome 18q21-22, which encodes for a protein flippase (FIC 1) that facilitates the flipping of aminophospholipids from the outer to inner canalicular membrane. As the gene is also expressed in many extrahepatic tissues, affected individuals may also have short stature, deafness, pancreatitis, and persistent diarrhea.

PFIC 2 results from a defect in the bile canalicular bile salt export pump (BSEP) caused by a mutation in the gene *ABCB11* on chromosome 2q24. BSEP is responsible for transporting bile acids from inside the hepatocyte to the canaliculus. Disruption of BSEP results in accumulation of bile acids within the hepatocyte resulting in severe cholestasis and rapid progression to end-stage liver disease. PFIC 2 presents earlier and is a more rapidly progressive liver disease than PFIC 1. Children with PFIC 2 have an increased risk of developing hepatocellular carcinoma, a risk that persists even after liver transplantation.

PFIC 3 is caused by a mutation in the gene *ABCB4* on chromosome 7q21, which encodes for multidrug resistance–associated protein 3 (MDR3) and mediates flopping of aminophospholipids from the inner to outer canalicular lipid bilayer. Rather than a deficiency in bile acid export, patients with PFIC 3 have a deficiency in phospholipid export. The resultant bile lacks phospholipids, making the micelles unstable and toxic to bile ducts, leading to a progressive intrahepatic cholangiopathy. In contrast to PFIC 1 and 2, only a third of children with PFIC 3 present with cholestasis during infancy, with most presenting in later childhood and adolescence. When infants with PFIC 3 do present with liver disease, they commonly have cholesterol gallstones complicating their intrahepatic cholestasis.

Infants with PFIC generally have markedly elevated serum bile acid levels with only mildly elevated serum bilirubin. The characteristic biochemical markers of PFIC 1 and 2 are a normal or low GGT, normal serum cholesterol, and only mild transaminitis; however, specific diagnosis requires genetic testing. PFIC 3 presents with an elevated GGT in the absence of extrahepatic biliary obstruction. The intrahepatic cholestasis that is commonly seen in PFIC often progresses to end-stage liver disease. Liver biopsy shows canalicular cholestasis and biliary plugs. More pronounced hepatocyte injury and giant cell hepatitis is noted in PFIC 2.[32]

Treatment for PFIC initially focuses on the nutritional management of cholestasis because of insufficient absorption of fat and fat-soluble vitamins. Most dietary fat should be provided from MCT oil, which does not depend on bile salts for absorption. Additionally, aggressive treatment of debilitating pruritus with ursodiol, antihistamines, cholestyramine, rifampin, and opioid antagonists is often required. In refractory cases, treatment may include partial biliary diversion, interruption of the enterohepatic circulation by surgical ileal exclusion, and liver transplantation.[33]

Congenital Hepatic Fibrosis

Congenital hepatic fibrosis (CHF) is a hereditary malformation of the bile ducts resulting from failure of remodeling during embryogenesis. It is an autosomal recessive disorder that may present in isolation but is more often seen as a feature of several syndromes, including Ivemark, Berdet-Biedl, Caroli, and Joubert syndromes; autosomal recessive polycystic kidney disease (ARPKD); and disorder of glycosylation type 1b.

Caroli syndrome is characterized by CHF and ductal ectasia with cystic dilation of intrahepatic ducts. Infants with CHF most commonly present with portal hypertension and splenomegaly, although some present with cholestasis caused by cholangitis. Characteristically, CHF is associated with normal transaminases and intact synthetic function despite advancing portal hypertension. When complicated with cholangitis, transient elevation of GGT and conjugated bilirubin are typically seen. Diagnosis of Caroli syndrome may be made by imaging with abdominal US with Doppler or magnetic resonance imaging (MRI) of the liver with magnetic resonance cholangiopancreatography. When associated with ARPKD, CHF can be diagnosed clinically, but if in isolation, histologic diagnosis is necessary.

Treatment of CHF is aimed at treating complications of portal hypertension and preventing and treating cholangitis. Portosystemic shunting is commonly required to decompress advanced portal hypertension. In Caroli syndrome, focal cystic dilation may be amenable to liver lobectomy, but, if diffuse, liver transplantation is required.

Infections

Congenital or perinatal infections and sepsis are common causes of neonatal liver cholestasis, hepatitis, and sometimes liver failure. A careful history and physical examination may suggest infection as an etiology of neonatal liver disease. For ill-appearing infants with cholestasis, a rapid evaluation for bacterial infection (such as sepsis or urinary tract infection) is recommended. Judicial selection of antimicrobials must be considered, as several are known to exacerbate cholestasis by displacing bilirubin from albumin (e.g., ceftriaxone) or cause direct hepatotoxicity (e.g., sulfamethoxazole/trimethoprim and fluconazole).[2] In addition to common bacterial infections, TORCH infections (toxoplasmosis, rubella, cytomegalovirus, herpes, and syphilis), as well as infections with hepatitis B, parvovirus B19, adenovirus, or echoviruses, can result in neonatal cholestasis and hepatitis. For more detail regarding diagnosis and specific treatments for congenital or neonatal infections, please refer to Part IX of this text, Immunology and Infections.

Parenteral Nutrition–Associated Liver Disease

Parenteral nutrition–associated liver disease (PNALD) is an important and common cause of hepatitis, cholestasis, and

liver-related morbidity in the neonatal period. It is estimated that between 33% and 85% of premature infants who receive parenteral nutrition for more than 7 days develop PNALD.[34,35] The primary phenotypic manifestation of PNALD in infants is cholestasis. When total parenteral nutrition (TPN) is utilized for a short duration, generally less than 2 weeks, the transient liver inflammation generally completely resolves. However, prolonged use increases the risk for irreversible and severe liver disease, which may ultimately result in liver failure.[36,37] PNALD often presents as hepatic steatosis with elevated serum aminotransferases, cholelithiasis, and cholestasis. Several risk factors have been identified that contribute to the development of PNALD, including prematurity, low birth weight, lack of enteral feeding, sepsis, short gut syndrome, and necrotizing enterocolitis.[38,39] The diagnosis of PNALD in an infant receiving TPN is suggested by the presence of a serum conjugated bilirubin level less than 2 mg/dL and ALT greater than two times the upper limit of normal.

Management of PNALD includes early initiation and continuation of enteral feeding, lipid minimization to less than 1 g/kg/day, and prevention of infection. Ursodiol at a dose of 20 to 30 mg/kg/day in divided doses may be utilized to improve or stimulate bile flow.[40–42] Additionally, the use of omega-6 fatty acid or fish oil–based, rather than soy-based, lipid formulations have been shown to be effective at resolving cholestasis.[2] Recognition and early intervention are required to prevent irreversible liver damage, which can progress to end-stage liver disease.

Metabolic Liver Disease

Inborn errors of metabolism often present with elevated serum aminotransferases, hepatomegaly, or metabolic derangements. There are several clinical phenotypes of metabolic liver disease, including acute liver failure, encephalopathy, cholestasis, and isolated hepatomegaly. Tables 65.2 and 65.3 summarize the clinical phenotypes of neonatal metabolic liver disease and etiologies of acute neonatal liver failure.

Disorders of Carbohydrate Metabolism

Galactosemia

Galactosemia results from an inability to metabolize galactose secondary to a deficiency in one of the following: galactokinase, galactose-1-phosphate uridyl transferase (Gal-1-PUT), or uridine diphosphate galactose-4-epimease. Classic galactosemia is caused by gal-1-PUT deficiency. This is the most common cause of galactosemia and results in the inability to metabolize galactose into glucose-1-phosphate. It is an autosomal recessive disorder with an incidence of 1 per 60,000 live births.[43] Abnormal galactose metabolism results in accumulation of toxic metabolites in the liver, brain, kidney, and eye lens.

Classically, galactosemia presents within the first few weeks of life after infants ingest breast milk or milk-based formulas that contain lactose. Presenting symptoms may include failure to thrive, jaundice, vomiting, and diarrhea. Occasionally, infants may present acutely, with *Escherichia coli* sepsis with severe acidosis, jaundice, and coagulopathy. Additional clinical findings may include hepatomegaly, ascites, bleeding, hemolysis, renal tubular acidosis, hypotonia, edema, and bulging fontanelle. Although affected infants will spill reducing sugar in their urine (positive urine reducing substances) while still ingesting galactose, the gold standard of diagnosis is demonstration of a complete absence of Gal-1-PUT activity via a quantitative red blood cell (RBC) assay.

TABLE 65.2 Common Clinical Presentations of Metabolic Liver Diseases in the Neonatal Period

Clinical Presentation	Metabolic Disorder	Laboratory Investigation
Acute liver failure	Galactosemia	Erythrocyte galactose-1-phosphate uridyl transferase activity, DNA mutational analysis
	Tyrosinemia	Urine—succinylacetone
	Hereditary fructose intolerance	Screen—urine reducing substances Genetic testing Enzyme activity analysis
	Mitochondrial defects	Serum lactate, pyruvate
	Fatty acid oxidation defects	Fibroblast enzymatic assay, acyl carnitine profile, genetic testing
	Gestational alloimmune liver disease	Ferritin, liver biopsy with C5b-9 staining
Encephalopathy	Fatty acid oxidation defects	As above (ferritin, liver biopsy with C5b-9 staining)
	Organic acidemias	Urine organic acids
	Urea cycle defects	Serum ammonia level, serum amino acid profile
Cholestasis	Peroxisomal disorders	Specialized screening for urine metabolites such as very long chain fatty acids, pipecolic acid, phytanic acid, pristanic acid
	Lysosomal storage disorders	Liver biopsy, leukocyte glucocerebrosidase activity, genetic mutational analysis
Hepatomegaly	Glycogen storage diseases	Liver or fibroblast enzymatic assay, genetic testing

Many newborn screens may identify variants of the disease, resulting in varying activity of Gal-1-PUT. Patients with clinical variants typically have 1% to 10% enzyme activity, and biochemical variant patients (also known as Duarte variant) show 15% to 35% enzyme activity. It should be noted that, because the assay is of RBC enzyme activity, analysis post-RBC transfusion will give unreliable results. Diagnosis can be established by genetic analysis as well.[44]

Treatment of galactosemia centers on the immediate stabilization of the critically ill infant as well as urgent restriction of galactose from the diet. Treatment is generally supportive and involves intravenous fluids with glucose, vitamin K, antibiotics, and initiation of a soy-based (nongalactose-containing) formula. As infants graduate to solid food, continued avoidance of lactose-containing foods is recommended. Despite treatment, many children with galactosemia will have some degree of developmental delay necessitating close neurocognitive follow up. Referral to ophthalmology is recommended at diagnosis. Infants with "Duarte variant" have initially diminished gal-1-PUT enzyme activity which improves

after few months. Those patients generally have normal development and can tolerate unrestricted diet.

Galactokinase deficiency results in cataract without other features of classic galactosemia. Cataract results from accumulation of galactitol within the lens. Diagnosis is suspected based on newborn screen or the presence of infantile cataract. Dietary galactose restriction is highly effective if diagnosis is done early. UDP-Galactose-4-Epimerase Deficiency (GALE Deficiency) presentation is a spectrum that varies between asymptomatic to severe symptoms similar to classic galactosemia depending on organs affected.

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder characterized by a deficiency in fructose-1-phosphate aldolase (aldolase B), which is important in both glycolysis and gluconeogenesis, and plays a critical role in the metabolism of fructose. The incidence is approximately 1 per 20,000 live births.[43] Approximately 75% of dietary fructose is metabolized by the liver, with the remainder metabolized by the kidneys and small bowel. The deficiency in aldolase B leads to a toxic accumulation of fructose-1-phosphate and traps phosphate in an unusable form, thus depleting adenosine triphosphate (ATP) stores and, in turn, inhibiting normal gluconeogenesis and glycogenolysis.

Most infants with HFI are healthy until ingestion of fructose or sucrose (disaccharide of glucose and fructose). Upon ingestion of fructose they begin accumulating the toxic metabolites, developing metabolic derangements that lead to vomiting, hepatomegaly, and failure to thrive. Diagnosis may be suspected after a careful dietary history is obtained, and laboratory evidence of acute liver failure, hypoglycemia, and proximal renal tubular acidosis is found. Urine can be tested for the presence of reducing substances, as fructose in the urine will give a positive test, but this is not specific. Definitive diagnosis requires confirmation with genetic testing for mutations in the *ALDOB* gene, located at 9q22.3, or enzyme analysis from liver tissue.

Treatment of HFI requires prompt removal of dietary fructose and sucrose. Complete elimination is seldom achievable, and there are no established thresholds of required restriction. Additionally, as the severity of the enzyme deficiency is heterogeneous, some patients may develop chronic symptoms despite treatment.[45] Fortunately, with nearly complete dietary restriction of fructose and sucrose, most children with HFI display normal growth and development.

Glycogen Storage Diseases

Glycogen is a glucose polymer that is primarily stored in the liver and muscle and is required for glucose homeostasis during fasting. There are 12 recognized glycogen storage diseases (GSD), but only types I, III, and IV primarily manifest as neonatal liver disease.

GSD type I, also known as von Gierke disease (named after its discoverer, Edgar von Gierke), is a rare autosomal recessive disease with an incidence of approximately 1 per 100,000 live births.[43] There are several defects that lead to the clinical manifestation of GSD type I; however, the end result is absence or decreased activity of glucose-6-phosphatase. Infants with GSD type I generally present with hepatomegaly and fasting hypoglycemia, often first noted when children begin to sleep more than 4 hours. Lactic acidosis, hyperuricemia, hyperlipidemia, hyperphosphatemia, neutropenia (specific to GSD type Ib), and bleeding secondary to platelet dysfunction are other clinical manifestations experienced by those affected with GSD type I.

Diagnosis of GSD is confirmed by DNA mutational analysis of the potentially affected genes. GSD Ia accounts for 80% of cases and results from mutation of *G6PC*, the gene for glucose-6-phosphatase, located on chromosome 17q21. GSD Ib represents less than 20% of cases and results from mutations of the gene *G6PT1*, the G6P transporter. Prenatal diagnosis is possible via chorionic villus sampling.

Treatment in infancy consists of maintaining euglycemia with frequent feedings, and continuous enteral feeds overnight with a high-glucose, low-fat formula. In older infants and children, a carbohydrate-balanced diet and frequent feedings that include the addition of cornstarch are recommended. Cornstarch provides a long-lasting source of glucose because it is slowly degraded by α-amylase and hence negates the need for hourly glucose intake. With adequate metabolic and glycemic control, children generally grow and develop normally.

GSD type III (Cori or Forbes disease) is an autosomal recessive disease that results from deficiency of the glycogen debranching enzyme, amylo-1,6-glucosidase, and occurs in 1 in 100,000 live births. The disease has two subtypes: Type IIIa, the most common form, affects both the liver and muscle. Type IIIb only affects the liver. The presentation in infancy is similar to that of GSD type I,

although the hypoglycemia is not usually as rapid and severe, and failure to thrive may be more prominent. In type IIIa, the skeletal muscle (hypotonia) and cardiac manifestations (cardiomyopathy) occur later in childhood. Diagnosis is made by directly measuring the activity of amylo-1,6-glucosidase in the liver or, more recently, doing mutational analysis on the associated gene, *AGL*. Treatment mirrors that of GSD type I, with efforts to maintain euglycemia. The difference in GSD type III is the ability to use protein as a source of glucose since gluconeogenesis in intact.[46]

GSD type IV (Andersen disease) is an autosomal recessive disorder caused by a mutation in the *GBE1* gene, resulting in deficiency of glycogen branching enzyme; it affects roughly 800,000 individuals worldwide and accounts for 3% of the cases of GSD. GSD type IV may present prenatally with hydrops or postnatally with hypotonia, heart failure (secondary to cardiomyopathy), contractures, and muscle atrophy. Diagnosis is based upon the absence of branching enzyme activity in skin fibroblasts or detection of mutations in the *GBE1* gene. Treatment consists of liver transplantation when progression to end-stage liver disease has occurred (usually in the third decade of life); however, care must be taken in patient selection as extrahepatic manifestations may be life-limiting.

Disorders of Amino Acid Metabolism

Tyrosinemia Type 1

Tyrosinemia is an autosomal recessive disorder with an incidence of 1 in 100,000 live births. It results from deficiency of fumarylacetoacetate hydrolase (FAH), the enzyme responsible for the final step of tyrosine degradation.[43] Tyrosinemia generally presents acutely in the neonatal period and should be included in the differential of fulminant neonatal liver failure. Failure to thrive, vomiting, ascites, coagulopathy, hypoglycemia, and hyperbilirubinemia may be the initial presenting signs and symptoms. In older infants and children, a more chronic presentation typified by growth failure, Fanconi syndrome, and neurologic manifestations may develop. Children with tyrosinemia type 1 carry a long-term risk of developing hepatocellular carcinoma. Serum tyrosine level is not a sensitive or specific screening tool. Blood succinylacetone, a more sensitive marker, is now being used in many newborn screening protocols. Diagnosis is confirmed by measuring elevated succinylacetone in urine or blood.[47] Molecular testing for FAH can be done to confirm the diagnosis but should not delay the treatment.

Treatment in the neonatal period consists of correcting metabolic derangements, treating sepsis, and correcting coagulopathy, followed by the restriction of dietary tyrosine and phenylalanine using specific formulas. Treatment with diet alone, however, results in less than 40% survival at 1 year of age.[48–50] Treatment with NTBC (2-(2-nitro-4-trifluromethylbenzoyl)-1,3-cyclohexanedione, nitisinone) has been demonstrated to improve survival to greater than 85% at 1 year of age, and is now the standard of care in the treatment of tyrosinemia.[51] NTBC works by reversibly inhibiting 4-hydroxyphenylpyruvate dioxygenase, hence preventing the formation of maleylacetoacetic acid and fumarylacetoacetic acid, the precursors to the hepatotoxic compound succinylacetone. Dietary changes and NTBC should be initiated as soon as the diagnosis is made.[47]

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD), like other rare disorders of amino acid metabolism, is autosomal recessive and screened for on routine newborn screening tests throughout the United States. MSUD is caused by the deficiency in the branched chain α-ketoacid dehydrogenase complex. The disease results in accumulation of the branch chain amino acids and their toxic ketoacids. Most infants with MSUD present with vomiting, acidosis, and evolving neurocognitive dysfunction or intermittent altered mental status. The disorder is named from the particularly sweet odor, reminiscent of maple syrup, which emanates from the urine of affected infants. Laboratory analysis may reveal mildly elevated transaminases, hypoglycemia, and hyperammonemia. The diagnosis of MSUD is made by the identification of excessive branched chain amino acids (valine, leucine, and isoleucine) in the serum. Treatment is dietary, with restriction of branched chain amino acids by limiting protein intake, supplementation with specialized formula, and care not to induce catabolism. The clinical course and natural history of MSUD and other disorders of amino acid metabolism are characterized by intermittent episodes of metabolic crises, including ketosis, acidosis, and hyperammonemia, which may be treated with intravenous glucose administration, arginine, and, rarely, dialysis. Liver transplantation may be considered for those patients in whom severe metabolic crises are threatening to cause developmental delays.

Disorders of Organic Acid Metabolism

The autosomal recessive methylmalonic acid, isovaleric acid, and 3-hydroxy-3-methylglutaryl (HMG)-coenzyme A (CoA) lyase deficiencies are rare and make up disorders of organic acid metabolism. Most are screened for during routine newborn screening in the United States but are confirmed with the identification of a particular pattern of organic acids in the urine. Clinically, they all present with metabolic crises, similar to MSUD. Treatment is largely by avoidance of catabolism and by tailored diets.

Fatty Acid Oxidation Defects

Fatty acid oxidation (FAO) is responsible for the production of the cellular energy that is required for normal cardiac and skeletal muscle function and glucose homeostasis. FAO largely occurs within mitochondria. The end result of FAO is the production of ketones, which serve as a critical energy source when glucose stores are depleted. Fatty acid oxidation defects are autosomal recessive diseases that include medium-chain acyl-CoA dehydrogenase deficiency (MCADD), long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHADD), HMG-CoA synthase deficiency, and carnitine-acylcarnitine translocase (CACT) deficiency.

MCADD is an autosomal recessive disorder that affects the metabolism of medium-chain fatty acids and results in fasting hypoglycemia and accumulation of toxic acyl-CoA. The clinical presentation is generally recurrent lethargy, emesis, coma, and even death secondary to life-threatening hypoglycemia. Laboratory evaluation reveals hypoglycemia, hepatitis, hyperammonemia, hypoketosis, and hyperuricemia. Confirmation of diagnosis is made by fibroblast enzymatic assays or genetic testing. Treatment is avoidance of hypoglycemia, but infants are at risk of sudden death due to metabolic derangements, and many develop significant developmental delays.

LCHADD is an error of fatty acid metabolism that affects the mitochondrial trifunctional complex, the primary function of which is to metabolize long-chain fatty acids (found in oils and milk). The classic presentation of a neonate with LCHADD is acute onset of poor feeding in the newborn period, accompanied by lethargy, hypotonia, and hypoketotic hypoglycemia. Older

children may go on to develop neuropathy and retinopathy. LCHADD in a fetus predisposes the mother to develop *he*molysis, *l*iver dysfunction, *l*ow *p*latelets (HELLP) syndrome and acute fatty liver of pregnancy. Diagnosis is suggested by newborn screening and confirmed by measuring LCHADD activity in fibroblasts or muscle or mutational analysis. Treatment is largely dietary, with a low-fat, high-carbohydrate diet and supplementation with MCTs. Morbidity is high, despite dietary intervention.

HMG-CoA synthase deficiency results in the failure to form ketones in times of stress, resulting in hypoketotic hypoglycemia. Infants may present with hepatomegaly, encephalopathy, or coma in the setting of acute illness or fasting. Generally, serum aminotransferases are normal, as is serum lactate. Diagnosis is suggested by the absence of urinary ketones with normal acyl carnitine profile and confirmed by molecular testing. Treatment is largely avoidance of fasting.

CACT is necessary to transport long-chain fatty acids from the cytosol into the mitochondrion, which supports the production of ATP. Most patients with deficiency in CACT present in the neonatal period with hypoketotic hypoglycemia, hepatic dysfunction, cardiomyopathy, and seizures. Laboratory investigation often reveals hypoketosis, hypoglycemia, hyperammonemia, elevated creatinine kinase, elevated serum aminotransferases, low carnitine levels, and abnormal acyl carnitine profile. Diagnosis is confirmed by genetic testing. Treatment is dietary and involves a low-fat diet with supplementation of MCTs and carnitine. Morbidity and mortality are high in the presence of cardiomyopathy.

Urea Cycle Defects

One of the primary functions of the liver is ureagenesis, to detoxify ammonia, which is the end product of amino acid metabolism. The accumulation of ammonia and glutamine lead to hepatocellular and central nervous system dysfunction. The most common disorders of ureagenesis include ornithine transcarboxylase deficiency, carbamoyl phosphate synthase, and citrullinemia. These disorders generally present in the first few days of life with hyperammonemia and, potentially, cerebral edema. The clinical presentation may be confused with sepsis. Diagnosis is suggested by the presence of hyperammonemia with low serum blood urea nitrogen and typical patterns of abnormal elevations in serum amino acids. Diagnosis is confirmed by molecular genetic testing. Treatment should be directed by a metabolic specialist and largely focuses on maintaining serum ammonia within normal range, preventing catabolism, and utilizing a protein-restricted formula with one-half of the protein content as essential amino acids. Liver transplantation may be considered in patients with severe recurrent episodes of metabolic crises with hyperammonemia.

Mitochondrial Hepatopathies

Mitochondrial hepatopathies secondary to respiratory chain complex deficiencies may present in the neonatal period as acute liver failure. Additionally, mitochondrial disorders should be suspected in neonates who present in the first week of life with hypoglycemia, hypotonia, seizures, and evolving hepatic synthetic dysfunction. Diagnosis is suggested by elevated lactate and specifically with lactate-pyruvate ratios greater than 30. With evolving mitochondrial DNA mutational analysis some disorders may be identified; however, few targeted therapies are available. Liver transplantation may be considered if additional comorbidities do not suggest poor posttransplant survival.

Lysosomal Storage Disorders

Lysosomal storage disorders generally present with hepatosplenomegaly as well as an array of systemic symptoms. The most common lysosomal storage disorders are Gaucher disease, Niemann-Pick disease type C (NPD-C), and lysosomal acid lipase deficiency.

Gaucher disease is an autosomal recessive genetic disease that results from the deficiency of a lysosomal enzyme, glucocerebrosidase, leading to an accumulation of glycolipids within lysosomes. The incidence is approximately 1 per 75,000 live births but is more prevalent in infants of Ashkenazi Jewish descent.[43] Clinical suspicion should be raised in infants who present with hepatosplenomegaly and normal to mildly elevated liver enzymes. Diagnosis is supported by liver biopsy, which demonstrates macrophages filled with lipid, also known as Gaucher cells. However, the diagnosis is confirmed by reduced glucocerebrosidase activity in leukocytes or by mutational analysis. Prenatal diagnosis is available by chorionic villus sampling or amniocentesis. Targeted treatment with enzyme replacement therapy with recombinant glucocerebrosidase is recommended for symptomatic children.

NPD-C is autosomal recessive and caused by mutations in *NPC1* and *NPC2*. These mutations result in impaired processing and transport of low-density lipoprotein (LDL) cholesterol, which clinically manifests as hepatosplenomegaly and progressive neurocognitive degeneration with dystonia, seizures, dysphagia, and ataxia. Laboratory findings characteristic of NPD-C include decreased high-density lipoprotein, hypertriglyceridemia, and increased LDL. Diagnosis is confirmed by fibroblast cell culture and genetic testing. Treatment is largely supportive, as bone marrow transplantation, liver transplantation, and lipid-lowering medications have not been shown to confer survival benefit.

Lysosomal acid lipase deficiency results in two distinct phenotypes: Wolman disease and cholesteryl ester storage disease (CESD). Both occur secondary to abnormal lysosomal accumulation of cholesteryl esters, triglycerides, and other lipids. Phenotype severity depends on the extent of reduction in lysosomal acid lipase activity. Wolman disease is the most severe manifestation of lysosomal acid lipase deficiency. Infants typically present in the first few weeks of life with failure to thrive, steatorrhea, hepatosplenomegaly, and jaundice. Death generally occurs within the first year of life. Diagnosis is suggested by calcifications of adrenal glands, cholestasis, elevated transaminases, liver synthetic dysfunction, and a normal plasma lipid profile. Liver biopsies have a characteristic orange-yellow appearance secondary to lipid and fat accumulation. CESD generally presents in older children or even in adulthood. Treatment is largely supportive, although trials of recombinant lysosomal acid lipase are available with promising results in early and late-onset disease.

Gestational Alloimmune Liver Disease

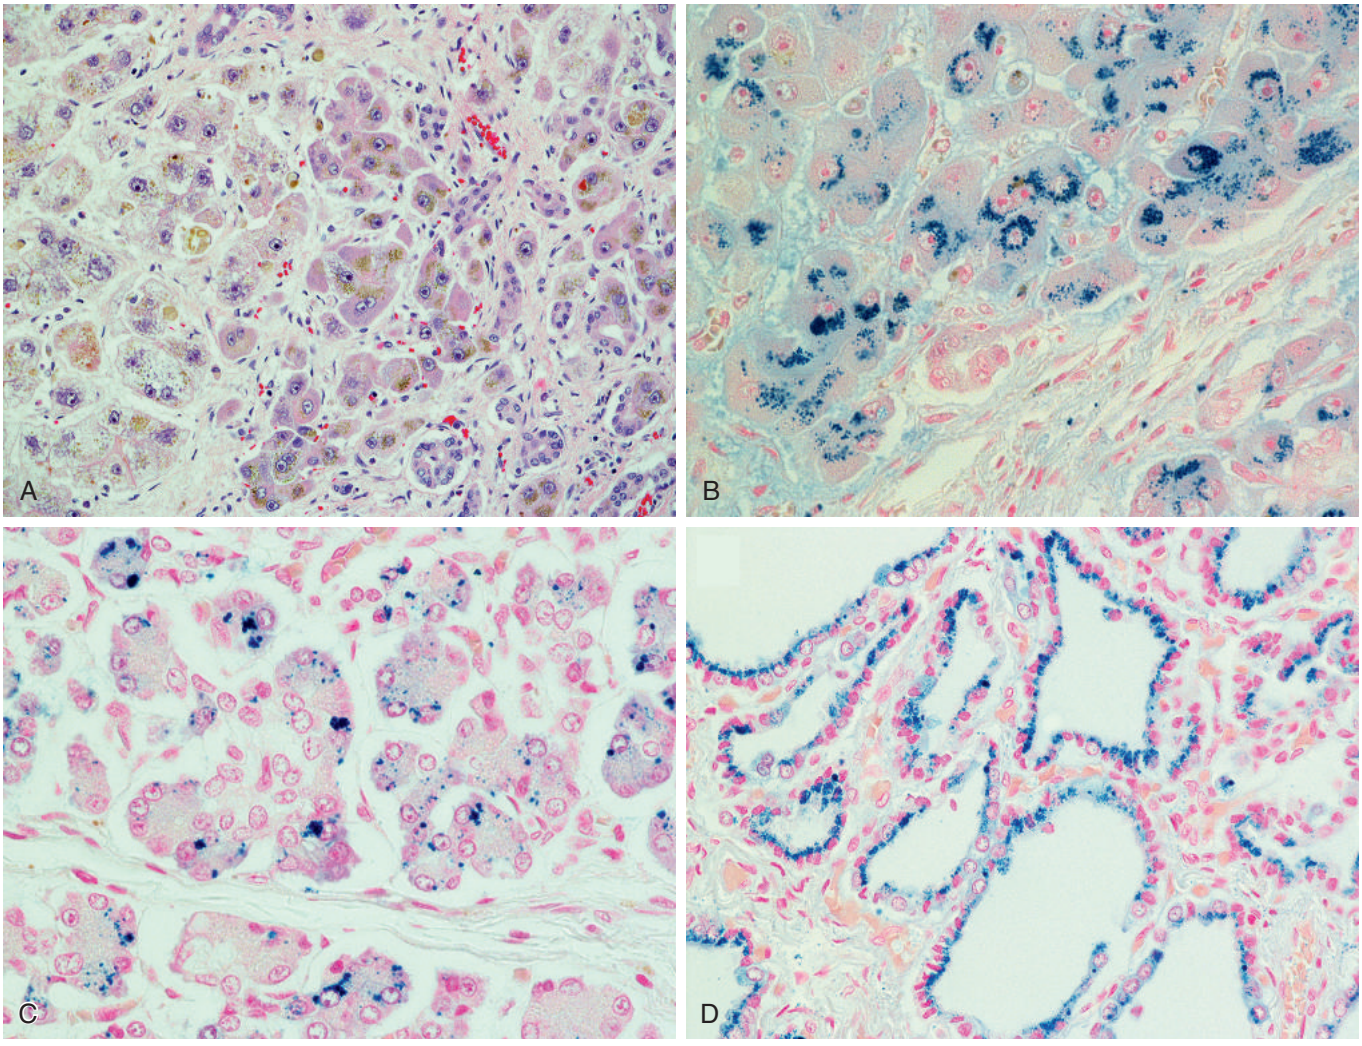
Historically, gestational alloimmune liver disease (GALD) was referred to as neonatal hemochromatosis, a term used to describe the clinical phenotype of severe neonatal liver disease resulting from an inborn error of iron metabolism, causing hepatic and extrahepatic siderosis. Recently, advances in understanding of the pathogenesis debunk earlier suppositions that GALD results from primary iron overload. Evidence now suggests that iron overload is the phenotype that results from GALD.[52–54] While nearly all nonhematopoetic iron overload is due to GALD, there are a few rare associations other than GALD which include trisomy 21, mitochondrial DNA depletion syndrome, bile acid synthetic defects, GRACILE (growth

retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death syndrome), myofibromatosis, Martinez-Frias syndrome, and tricho-hepato-enteric syndrome.[55]

The pathogenesis of GALD stems from complement-mediated hepatocyte injury and alloimmunity activated by maternal immunoglobulin G (IgG) (the only immunoglobulin that freely crosses the placenta). Once sensitization has occurred, maternal anti-fetal hepatocyte IgG binds to fetal liver antigen. Subsequently, complement-mediated destruction of fetal hepatocytes results in a neonatal liver mass that is 10% to 25% less than normal. The unaffected fetal liver normally produces hepcidin to regulate placental iron delivery,[52] but in GALD the drastically reduced amount of hepcidin fails to appropriately regulate iron influx, resulting in increased iron transport through the placenta and iron overload in extrahepatic tissues including pancreas, salivary glands, heart, and thyroid gland.[56]

GALD typically presents at birth but can present anytime between 18 weeks gestation up to 3 months of age. GALD should always be suspected in infants who manifest prenatal or neonatal liver disease, especially liver failure. Infants with GALD are typically sick at birth. In the fetal period, oligohydramnios or intrauterine growth restriction are common. Affected newborns generally present in the neonatal period in acute liver failure with hypoglycemia and coagulopathy or, more rarely, with cirrhosis. Cholestasis generally evolves over time and is not present at birth. Laboratory findings may include normal to slightly elevated ALT, elevated ferritin levels (generally >800 ng/mL but commonly exceeding 15,000 ng/mL), alpha fetoprotein greater than 80,000 ng/mL but typically greater than 300,000 ng/mL, and iron saturation greater than 90%. Imaging may demonstrate extrahepatic siderosis effecting the pancreas, myocardium, thyroid, and salivary glands. Patients are typically extremely coagulopathic. Generally the reticuloendothelial system, including the spleen, bone marrow, and lymph nodes, is spared.[55]

The diagnosis of GALD is suggested by liver biopsy demonstrating reduced hepatocyte volume and the presence of C5b-9 complex on immunohistochemistry.[57] Biopsies may also show hepatocyte collapse, fibrosis, and siderosis (Fig. 65.5). However, demonstration of extrahepatic siderosis is necessary to confirm the diagnosis. This may be accomplished by tissue biopsy



• **Fig. 65.5** Gestational Alloimmune Liver Disease Histology. (A) Hematoxylin and eosin stain of a liver demonstrating pericellular fibrosis. Many hepatocytes contain pigment, some of which is hemosiderin, and some of which is bile. (B) The corresponding Gomori iron stain shows iron deposition within hepatocytes. (C) Iron stain demonstrating iron deposition in the pancreas acinar epithelial cells. (D) Iron stain demonstrating iron deposition in thyroid follicular cells.

or T2-weighted MRI. Generally, it may be preferable to obtain mucosal tissue (submucosal glandular biopsy). This may be followed by MRI if the biopsy is negative, and diagnosis is still suspected. Unfortunately, GALD is often diagnosed at autopsy where extrahepatic siderosis is observed. Diagnosis also should be considered in cases of fetal demise and stillbirth.

Treatment attempts to block existing antibody action by administration of high-dose intravenous immunoglobulin (IVIG) (1 g/kg) as well as to remove existing antibody with double-volume exchange transfusion. This regimen has been shown to improve survival to between 75% and 80% without liver transplantation.[58] Before this treatment regimen, outcomes were very poor with older medical therapies such as iron chelation and antioxidants, which have no role in current treatment recommendations. GALD remains a common indication for liver transplantation in the neonatal period. However, transplantation in these patients is complicated by small infant size and multiorgan failure. Transplant adverse outcomes (graft loss and death) are high; however, they are comparable to those of transplantation for other indications of neonatal acute liver failure.[59]

Because of the rapid progression and high mortality associated with GALD, if it is suspected, an infant should receive a dose of IVIG immediately, even before the diagnostic work-up is complete. Side effects of IVIG are minimal, and IVIG has minimal impact on the natural history of alternate causes of neonatal liver failure. If diagnosis is confirmed, then the double-volume exchange transfusion should be employed followed by a second dose of IVIG. It may take 4 to 6 weeks for INR to normalize depending on existing liver damage.

The probability of GALD diagnosis in each subsequent infant born to a mother whose previous child was born with GALD is greater than 90%.[60,61] However, GALD is thought to be congenital and familial but not hereditary.[62] Evidence for prevention of GALD is evolving. Given the high risk of subsequent infants developing GALD following an index birth of an affected infant, all mothers should be treated during pregnancy with recurring infusions of IVIG at 14 weeks gestational age, 16 weeks, and weekly from 18 weeks until delivery.[63]

Vascular Malformations

Vascular malformations of the liver generally present in the neonatal period if they are associated with cutaneous malformations or result in significant systemic shunting of blood. Types of shunts may include hepatic artery to hepatic vein, hepatic artery to portal vein, or from portal vein to systemic circulation (portosystemic shunts).

Arteriovenous Malformations

Arteriovenous malformations that shunt large volumes of blood may present in the neonatal period with anemia, heart failure, portal hypertension, or hepatomegaly, depending on the vascular involvement. Treatment includes embolization, surgical ligation, or resection. Liver transplantation is reserved for those lesions that are not amenable to more limited surgical intervention and that result in life-threatening complications.

Congenital Portosystemic Shunts

Congenital portosystemic shunts allow for intestinal venous blood to bypass the liver and shunt directly into the systemic venous system. They may be either intrahepatic or extrahepatic in origin (Figs. 65.6 and 65.7). Extrahepatic portosystemic shunts are known as "Abernathy malformations" (Fig. 65.8). Persistence of fetal circulation with a patent ductus venosus may allow for intrahepatic shunting from the left portal vein to a hepatic vein.

Portosystemic shunts are most commonly identified incidentally on abdominal imaging in individuals with portal hypertension or other vascular malformations. If diverting significant portal blood flow past the liver, they may lead to elevated serum ammonia. Portal hypertension is not usually seen with portosystemic shunts.

Treatment of congenital portosystemic shunts varies and depends on the severity of clinical sequelae. Several may close spontaneously; however, those that are contributing to encephalopathy and subsequent developmental delay or cardiopulmonary compromise should be considered for closure. Techniques may include embolization, surgical ligation, or, rarely, liver transplantation.[64,65]

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disease characterized by mucosal and cutaneous telangiectasias, and visceral vascular malformations. The visceral organs most commonly affected include the lungs, liver, intestine, and brain. The prevalence is estimated to be approximately 1 per 10,000 live births. Diagnosis of HHT is based on fulfilling greater than three of four clinical criteria and genetic testing. The clinical criteria include spontaneous, recurrent epistaxis, multiple cutaneous and oral cavity telangiectasias, the presence of visceral vascular lesions, and a first-degree relative with HHT.

Most infants with HHT will present with high-output heart failure and potentially portal hypertension secondary to arterioportal shunting. An ischemic cholangiopathy may result if hepatic arterial blood shunts away from bile ducts.

As with all liver-associated vascular lesions, diagnosis is accomplished by Doppler-enhanced US of the abdomen. In the case of HHT, US most commonly demonstrates a dilated hepatic artery with elevated hepatic artery flow and intrahepatic vascularity. On computed tomography (CT), the presence of multiple telangiectasia leads to heterogeneous enhancement of the liver. Liver biopsy carries high risk of bleeding.

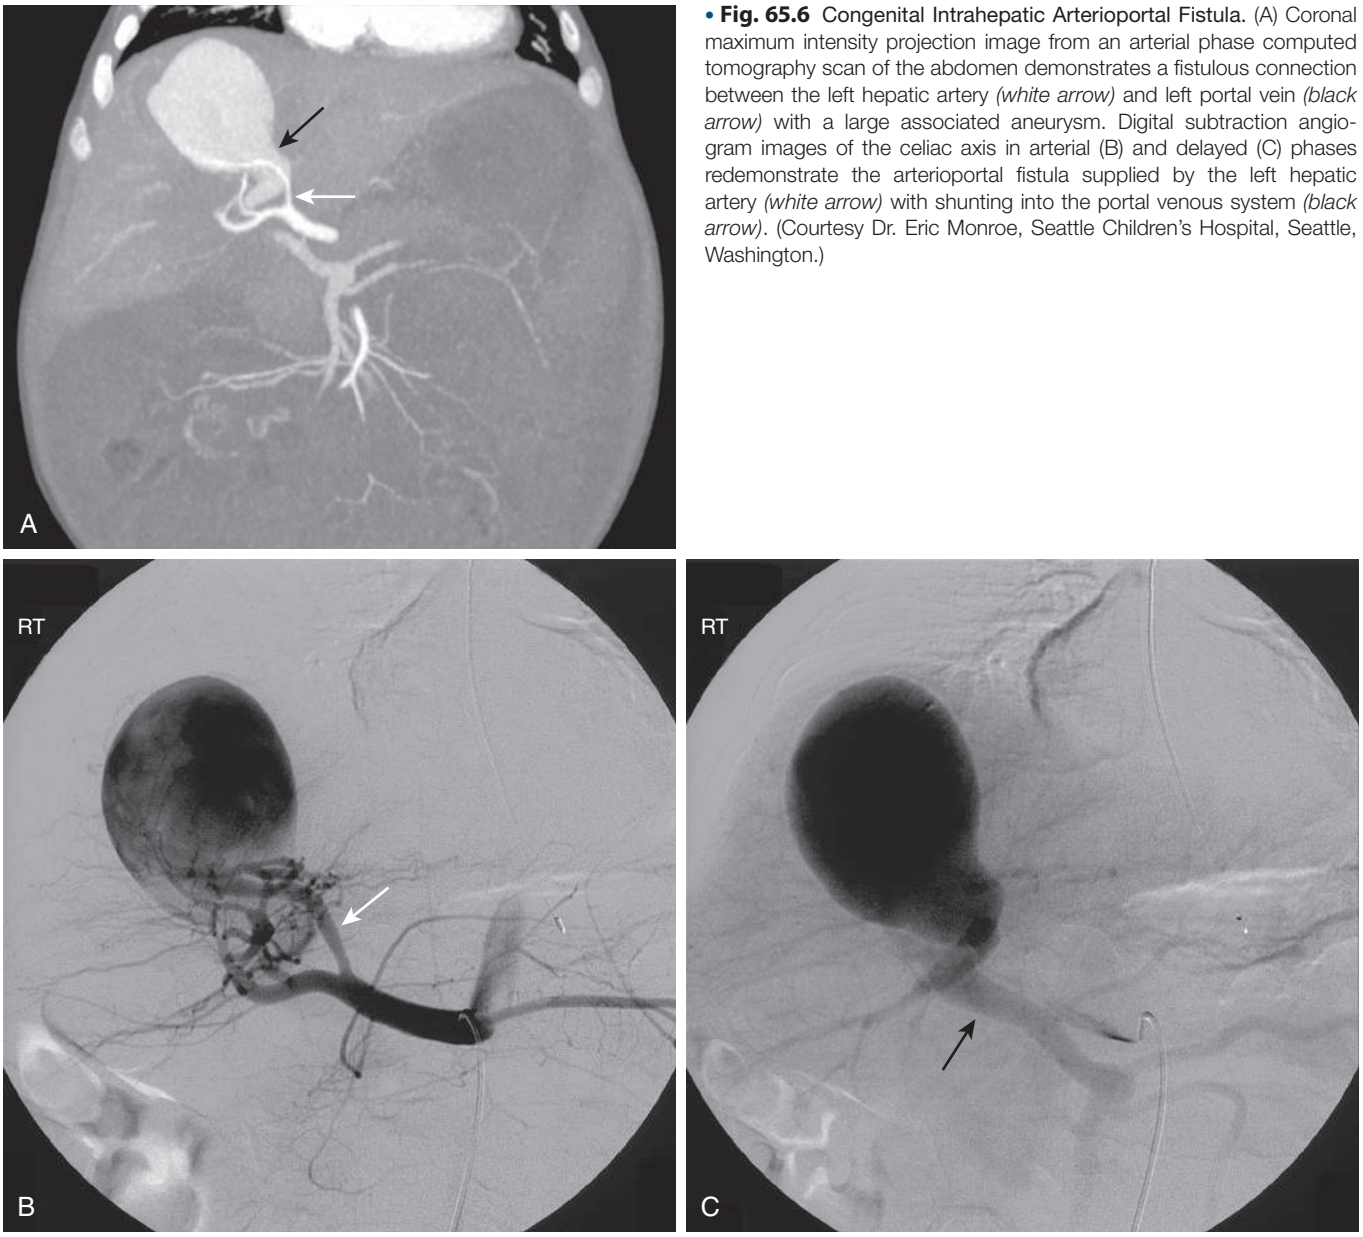
Liver transplantation may be considered in the setting of heart failure, biliary ischemia, or severe portal hypertension.

Infantile Hepatic Hemangiomas

Infantile hepatic hemangiomas (IHHs) are the most common benign tumor of infancy and the most common pediatric tumor of the liver, affecting as many as 1% to 2% of newborns and upwards of 10% of infants by 1 year of age.[66] Most infants present with associated cutaneous or subcutaneous lesions; however, many present with isolated vascular lesions of the liver, brain, and lungs. IHH should be suspected in infants with five or more cutaneous hemangiomas, and this physical finding should prompt investigation for visceral involvement.

IHH may be characterized as focal, multifocal, or diffuse. Most infants with IHH present before 6 months of age and experience initial progression of the size of lesions from birth to 12 months, followed by a period of regression and involution by about 2 to 10 years of age.

Focal IHH is usually incidental and may be initially seen on prenatal US. They are not associated with cutaneous findings and are typically asymptomatic; larger lesions may lead to high-output



• **Fig. 65.6** Congenital Intrahepatic Arterioportal Fistula. (A) Coronal maximum intensity projection image from an arterial phase computed tomography scan of the abdomen demonstrates a fistulous connection between the left hepatic artery *(white arrow)* and left portal vein *(black arrow)* with a large associated aneurysm. heart failure. Diagnosis is by US imaging, identifying a hyperechoic or hypoechoic lesion with heterogeneous echotexture with vascular flow on Doppler interrogation. On MRI, lesions are noted to be hypointense on T1-weighted images, and hyperintense on T2-weighted scans with centripetal enhancement with gadolinium contrast.

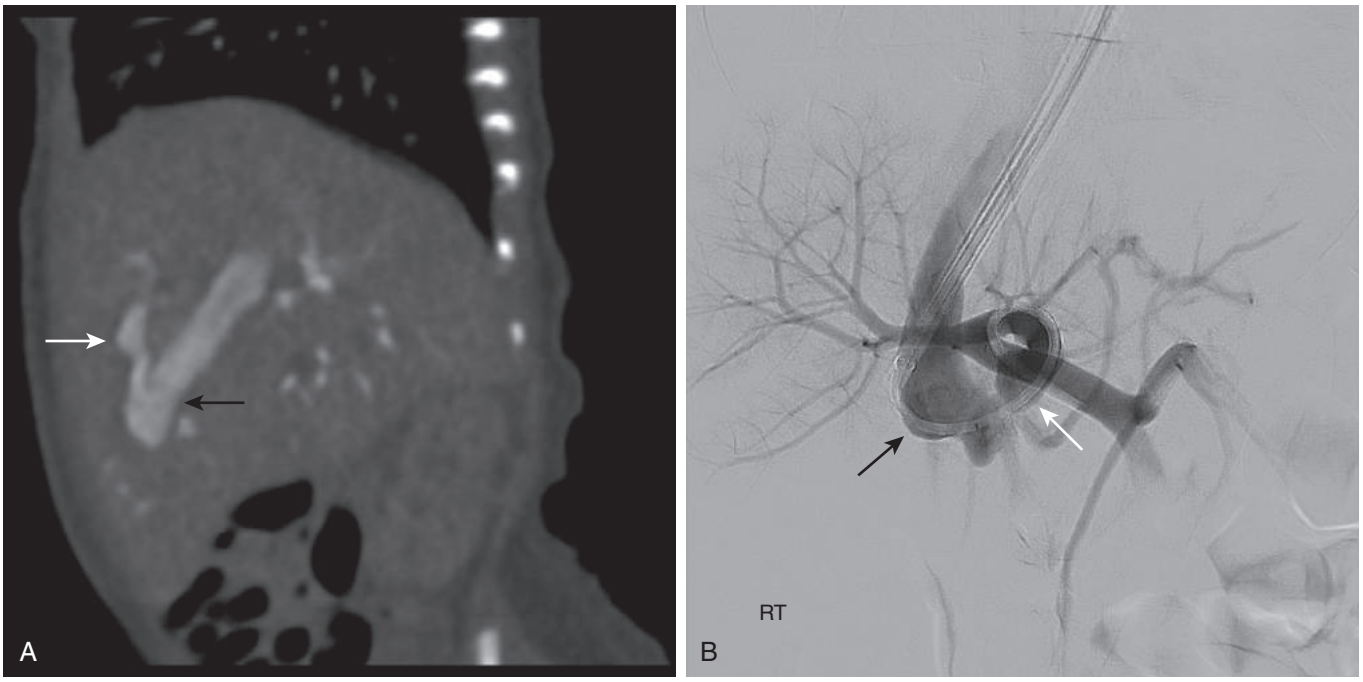
Multifocal and diffuse IHH are associated with multiple cutaneous hemangiomas. Multifocal IHH is typically not apparent at birth but presents within the first few weeks of life when the hemangiomas become more prominent. Symptomatic infants present with hepatomegaly, heart failure, anemia, and occasionally thrombocytopenia secondary to consumption, hemorrhage, or thrombosis within the hemangioma. Rarely, hemangiomas may stimulate inactivation of thyroxine, resulting in hypothyroidism. Occasionally, rupture of hemangiomas may result in intraperitoneal hemorrhage. US and MRI imaging are similar to that of focal IHH but with more numerous lesions. Treatment is reserved for symptomatic infants. Asymptomatic infants may be observed and followed with serial imaging. Medical therapy employs propranolol at a dose of 1 to 3 mg/kg/day, continued until the proliferation phase is completed around 9 to 12 months of age. Second-line treatments for propranolol failures include steroids, vincristine, and alfa 2a interferon.[67,68] Embolization or surgical resection may be utilized if medical therapy fails or in the setting of significant organ dysfunction. Liver transplantation has been performed in critical clinical circumstances without other options.[69,70] Rarely, multifocal IHH may be associated with hepatic angiosarcoma.

Liver Masses

Hepatoblastoma

While many solid and cystic tumors of the liver may present in the neonatal period, the most common malignant tumor is hepatoblastoma. Risk factors for the development of hepatoblastoma include prematurity, low birth weight, familial adenomatous



• **Fig. 65.7** Congenital Intrahepatic Portosystemic Shunt. polyposis, trisomy 18, GSD Ia, Beckwith-Wiedemann syndrome, and Li-Fraumeni syndrome. Hepatoblastoma most commonly presents as an abdominal mass associated with weight loss, abdominal pain, and decreased oral intake. Diagnosis is made by typical radiologic findings, including a well-defined but heterogeneous mass that may have areas of necrosis, hemorrhage, or calcification. MRI is the preferred mode of imaging. Biopsy to differentiate epithelial subtype (fetal, embryonal, macrotrabecular, and small cell undifferentiated) is required. AFP is usually elevated in most hepatoblastoma patients. AFP in a full-term infant can be as high as 100,000 ng/mL, making interpretation difficult; however, in unaffected infants the value rapidly decreases over time. AFP is a

valuable prognostic marker after therapy. Treatment consists primarily of resection and is augmented by chemotherapy. When not resectable, liver transplantation may be considered.

Congenital Hepatic Cysts

Congenital hepatic cysts are one of the most common benign liver masses of infancy. With modern imaging techniques, simple hepatic cysts are frequently diagnosed prenatally by US. There is a wide spectrum of pathologies resulting in simple hepatic cysts. Simple cysts are generally thought to develop from aberrant bile ducts and are not generally associated with cystic lesions of other organs.[71] They are characterized by a layer of cuboidal or columnar epithelium surrounding a collection of serous fluid. Congenital hepatic cysts are more common in females and can be solitary or multiple.[72] Most cysts are incidental, asymptomatic, do not require intervention, and may shrink or resolve over time. It is recommended that periodic, serial US be utilized to survey for interval growth or resolution. Indications for surgical intervention include interval growth, large size, which may cause compression of nearby structures or cause risk for rupture, or those that become symptomatic.[71]

66 Developmental Hematology

SANDRA E. JUUL AND ROBERT D. CHRISTENSEN

KEY POINTS

- Pluripotential stem cells sustain hematopoietic function throughout a person's lifetime; the fate of developing cells is influenced by the microenvironment.
- The site of erythropoiesis changes over development, progressing from the yolk sac to the aortogonadomesonephron, to the liver, and then to the bone marrow. Erythropoietin (Epo) is the principal factor regulating secondary erythropoiesis.
- Hemoglobin tetramers change over development. Oxygen affinity decreases as hemoglobin switches from embryonic to adult forms.
- While the optimal hematocrit or hemoglobin trigger for transfusion of preterm infants is not known, it has now been established that hemoglobin thresholds of 11 to 13 g/dL for critically ill or ventilated infants and 7 to 10 g/dL for stable infants can be safely used.
- The need for transfusions in the neonatal intensive care unit can be reduced by delayed cord clamping or cord milking, reducing phlebotomy-related losses, and using erythropoiesis-stimulating agents (Epo or darbepoetin).
- Most platelet transfusions given in the neonatal intensive care unit are prophylactic, meaning they are given to nonbleeding neonates with low platelet counts. For nonsurgical preterm infants less than 32 weeks of gestation, allowing the platelet count to reach 25,000/μL prior to transfusion is safe. Including metrics in addition to the platelet count, such as the "platelet mass" (platelet count × mean platelet volume), and the immature platelet fraction, might provide a better transfusion trigger than the platelet count alone. In general, 10 to 20 mL of single donor platelets per kilogram should raise the platelet count by more than 100,000/μL. The use of volume-reduced or pooled platelets should be avoided because processing results in platelet activation and decreased function.

Introduction to Embryonic Hematopoiesis

Hematopoiesis is the process by which self-renewing multipotential stem cells give rise to all the differentiated blood cells (Fig. 66.1). This process involves the coordinated expression of growth factors, some of which act on primitive progenitors that can give rise to multiple cell lineages and others that support clonal maturation of lineage-committed multipotential hematopoietic stem cells (HSCs). Hematopoiesis begins in the embryo, with the first lymphoid progenitors emerging within the embryo and yolk sac before stem cell detection at embryonic day 7.5.[1] By day 10, HSCs are present in the aortogonadomesonephron, and activity then shifts to the liver and finally to the bone marrow.[2] Each cell lineage undergoes developmental changes that are unique and specific.[3]

Stem Cell Biology

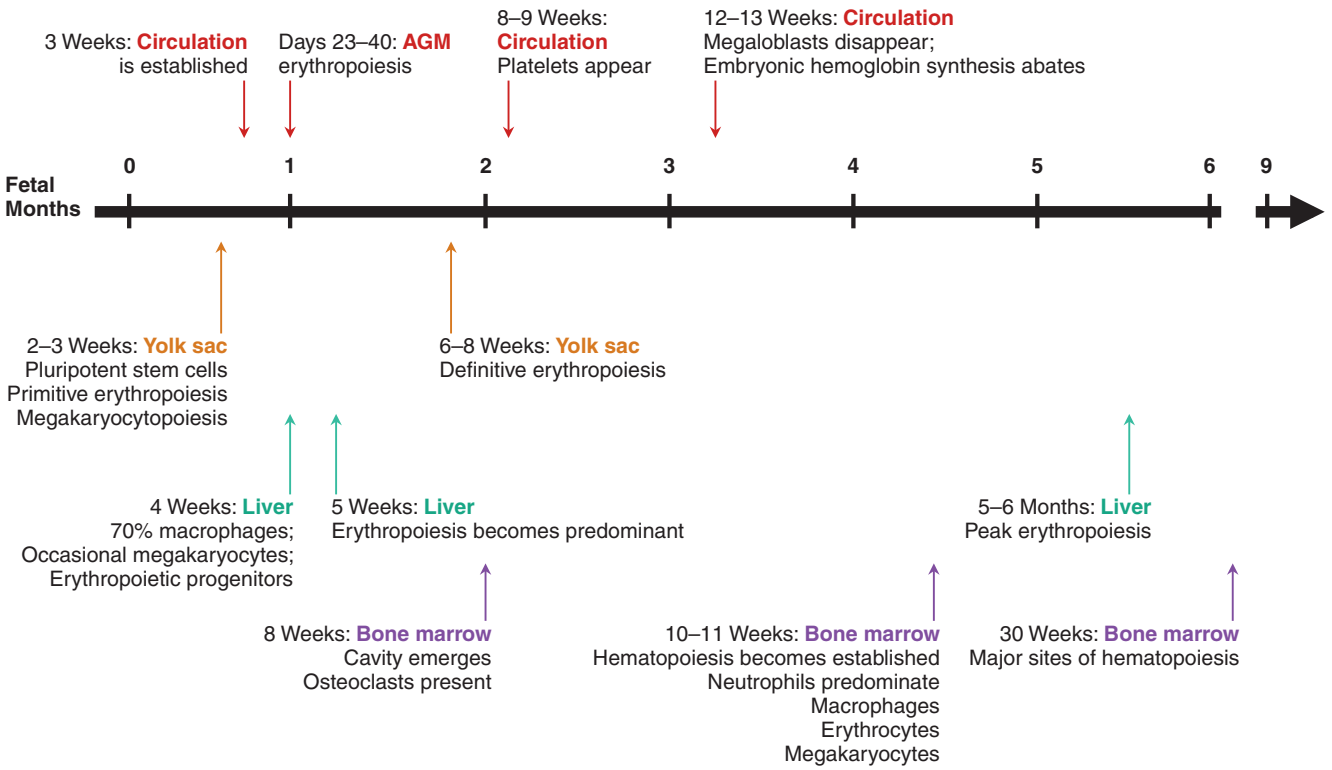
Pluripotential stem cells sustain marrow function throughout a person's lifetime. A unique characteristic of these cells is that their direct offspring include at least one identical daughter cell, thus perpetuating the population. In contrast, progenitor cells are more differentiated and give rise only to cells more differentiated than themselves. The fate of any particular developing cell is determined in large part by its microenvironment.

The developmental changes in the number, function, and location of HSCs are of interest to transplantation biologists and gene therapists. The proliferative capacity of HSCs differs with the anatomic source of the cells and with the age at which the cells are harvested. The sensitivity of these cells to recombinant cytokines also changes with age. Improving the understanding of the ontogeny of these cells may be helpful in optimizing their clinical use.

Embryonic and fetal HSCs are capable of repopulating adult organisms.[4] In contrast, transplanted adult stem cells have a lower capacity for self-renewal, sometimes resulting in late graft failure. This might be because stem cells harvested from adults continue to express the adult differentiation program, even if transplanted into a neonatal environment, indicating an irreversible change in gene expression.[5] Other explanations for the decrease in proliferative potential may have to do with DNA damage over time and loss of telomere repeats with each stem cell division, limiting the replicative potential.[6]

Ongoing research focuses on optimizing stem cell harvesting techniques. Cell-surface markers, which are dependent on cell maturity and gestational age, are often used to identify and separate HSCs with the use of monoclonal antibodies and fluorescence-activated cell sorting analysis. For example, CD34, a cell-surface sialomucin, is an antigen commonly used to select HSCs and early erythropoietic progenitor cells. Combining CD34 positivity with the absence of lineage-specific markers allows the selection of a population highly enriched for cells desired for transplant. Research is also focused on optimizing stem cell harvest sites. Both bone marrow and umbilical cord blood (UCB) are rich in stem cells and have long been used as sources of progenitor cells. The collection of stem cells from peripheral blood by stimulated apheresis, with ex vivo expansion of select populations, is now also an option.[7]

UCB can be harvested as a source of HSCs and used for transplant in patients with marrow failure, malignancy, or immunodeficiency.[8,9] Hematopoietic progenitor cells in UCB tend to have



• **Fig. 66.1** Changing Sites of Hematopoiesis During Human Gestation. Fetal gestation is shown in months along the *central horizontal arrow*. The timing of significant events during hematopoiesis is shown, beginning with primitive erythropoiesis and megakaryocytopoiesis in the yolk sac and ending with definitive hematopoiesis in the bone marrow during late gestation. *AGM*, Aortogonadomesonephron.

a high proliferation index compared with cells harvested from adult marrow.[10] Because of the immaturity of the UCB cells, HLA matching is less stringent for UCB, allowing more efficient donor unit identification compared with a bone marrow registry.[11] This feature also allows the improved matching ability for patients in minority ethnic populations since bone marrow registry matches are frequently in short supply. Promising strategies to increase cells available for transplant include combining multiple units of UCB[12] and ex vivo expansion of UCB units.

The first successful use of UCB for HSC transplant purposes was in 1989, between HLA-identical siblings, for severe aplastic anemia from Fanconi anemia.[13] Since then, thousands of UCB transplants have been performed to treat malignancies such as acute lymphoblastic leukemia, acute myeloid leukemia, and chronic myeloid leukemia; bone marrow disorders such as Fanconi anemia; immunodeficiencies such as severe combined immune deficiency; metabolic disorders; and hemoglobinopathies.[9]

UCB can be stored in public or private commercial banks. Donation of harvested cells to public UCB banks allows storage in a central repository available to all individuals in need of a transplant.[14] Private banking is expensive and less standardized. Banked cells are available for future use by individuals or a family, but there is a low likelihood of any one individual needing an autologous UCB transplant.[15]

Delaying umbilical cord clamping by 60 seconds increases the blood volume of the neonate and increases the endowment of iron. In theory, this practice might result in insufficient UCB remaining for banking. However, the Canadian Task Force on Preventive Health Care suggests that delayed cord clamping has significant benefits for the neonate and that sufficient blood typically remains in the umbilical cord and placenta after delayed clamping for UCB banking. The task force suggests that both techniques can generally be accomplished.[16]

Developmental Aspects of Erythropoiesis

Erythropoiesis is the process of perpetual production of red blood cells (RBCs). Serial adaptations occur throughout development to meet the changing oxygen demands of the embryo, fetus, and neonate. The type of cells produced, the locations in which they are produced, and the microenvironments within these locations change as development proceeds (see Fig. 66.1). The molecular mechanisms involved in instituting, regulating, and maintaining these adaptations are complex.

Primitive and Definitive Erythropoiesis

During development, two types of RBCs are formed: primitive and definitive erythrocytes. The liver is the primary organ of hematopoiesis during fetal life, but primitive RBCs are first formed in the yolk sac.[17] Large primitive RBCs are produced in blood islands of the yolk sac days after implantation of the embryo. These cells enter the newly formed vasculature of the embryo, where they continue to divide and differentiate for several days. This process is only minimally responsive to Epo.[18] Primitive erythroblasts are large (>20 μm), nucleated, CD34 negative, and contain predominantly embryonic hemoglobin. Hemoglobin synthesis continues until cell replication ceases.[19] In mice, a transition to definitive erythropoiesis occurs at embryonic day 13.5 (full gestation is 21 days). Definitive erythropoiesis is characterized by smaller (<20 μm) CD34-positive erythroblasts, which produce fetal and adult hemoglobins, extruding their nuclei when mature.

Unlike primitive erythropoiesis, this process is dependent on Janus kinase signal transduction and Epo stimulation.[20] Primitive erythroblasts normally undergo apoptosis, becoming extinct during fetal life, whereas definitive erythroblasts are able to self-renew.[21]

Switch of the Primary Site of Erythropoiesis

Humans have four main sites of embryonic and fetal erythropoiesis—yolk sac, aorta (ventral aspect), liver, and marrow. In rodents, the spleen is also an important site of hematopoiesis, but there is no evidence for this in healthy humans.[22] Studies using an in vitro embryonic stem cell differentiation system showed that endothelial cells, primitive hematopoietic cells, and definitive blood-cell colonies arise from a common fetal, liver, kinase-1 (Flk-1)-expressing progenitor.[23] Between embryonic day 8 and embryonic day 11.5, runt-related transcription factor 1 is required for the formation of HSCs and their progenitors. Primitive progenitor cells first develop in the yolk sac, followed by the rise of definitive progenitors, also in the yolk sac.[24] Another source of the early definitive progenitors is the ventral aspect of the embryonic aorta.[24,25] Once circulation is established, progenitors from all lines are detected in the blood, then in the liver, and finally in the marrow.[26]

Yolk Sac

The yolk sac is an extraembryonic structure that can be subdivided into the primary and secondary yolk sac. The primary yolk sac is transient and has no known hematopoietic function. In humans, it forms by proliferation and differentiation of primitive endodermal cells 7 to 8 days after conception. These endodermal cells give rise to mesodermal precursors (intermediate cells). The primary yolk sac then collapses into small vesicles, and the secondary yolk sac is formed from its remnants 12 to 15 days after conception. By 16 to 19 days, primitive erythropoiesis is found in the human yolk sac.[27,28] The secondary yolk sac is an active site of protein synthesis, nutrient transport, and hematopoiesis.[29] Primitive hematopoietic cells, adherent to surrounding endothelial cells, are first observed on day 16 in the mesodermal layer. These hematopoietic–endothelial cell masses have been described as *blood islands*. As maturation proceeds, these blood islands migrate toward each other, merging to form a network of capillaries. Small clusters of undifferentiated cells, the hemangioblasts, and clusters of primitive erythroblasts are observed in the small vessels present at this developmental stage.[29] As differentiation proceeds, endothelial and hematopoietic cell lineages emerge. These cell types share common molecular markers and responsiveness to a cohort of growth factors and, depending on the microenvironment, can be derived from a common stem cell in culture.[23,30,31]

After the sixth week after conception, definitive erythroblasts are found in the yolk sac. A decline in yolk sac hematopoiesis is observed after the eighth week.[29] Yolk sac–derived hematopoietic cells have more restricted potential in vivo, as only RBCs and macrophages are present in the yolk sac,[32] while progenitor cells in the liver develop into the full spectrum of hematopoietic cells. However, when yolk sac–derived stem cells are cultured in vitro or are transplanted, they are multipotent, illustrating the importance of the microenvironment in the development of committed cell lineages.

Aortogonadomesonephron

Another site of early erythropoietic activity in the developing human embryo is the ventral aspect of the aorta in the periumbilical region.[25] At around the 23rd postconceptional day in humans, the multipotent hematopoietic progenitor cells in this region are more numerous than in the yolk sac or the liver. By day 40 of gestation, hematopoiesis in this site is concluded.

Liver

A short time after the onset of blood circulation (week 4 to week 5 of gestation), erythropoiesis begins in the liver.[27] As in the yolk sac, primitive erythroblasts initially predominate. However, over the next 4 weeks, definitive erythrocytes become the predominant RBC form. During this time, the liver mass increases 40-fold, with hematopoietic cells constituting 60% of the liver from week 11 to week 12.[33.] Meanwhile, other hematopoietic cell types are also produced in the liver. Early in this process (5 weeks), macrophages predominate, with approximately one granulocyte to every nine macrophages.[34] In contrast to the yolk sac, during the period of peak hepatic hematopoiesis (week 6 to week 18), production of all hematopoietic cell lines (erythrocytes, macrophages, megakaryocytes, granulocytes, and lymphocytes) occurs. Between 18 and 21 weeks of gestation, hematopoiesis in the liver diminishes, but the liver continues as an erythropoietic organ until term.

Bone Marrow

As hepatic hematopoiesis diminishes, the bone marrow becomes the primary site of erythropoiesis and remains so throughout postnatal life. The process of erythropoiesis in marrow begins at about 8 weeks with primitive erythrocytosis.[27] Over the next few gestational weeks, a switch to definitive erythropoiesis occurs, and by 14 weeks, only definitive erythroblasts are present. As with the liver, the production of all hematopoietic cells occurs in the bone marrow. Erythropoietic cells constitute a maximum of 35% of total bone marrow cells at week 12 of gestation, falling to between 20% and 30% thereafter.[35]

Factors Influencing the Sites of Erythropoiesis

The microenvironment at each site of hematopoiesis influences the type and timing of hematopoietic development. The microenvironment includes hematopoietic growth factors and cytokines, as well as the extracellular matrix in which the cells proliferate.

Growth factors are thought to act mainly as permissive and/or selective signals, allowing already committed cell types to proliferate and differentiate. Growth factors important for definitive erythropoiesis include Epo, stem cell factor, interleukin (IL)-3, thrombopoietin (TPO), and possibly insulin and insulin-like growth factor I, both of which act as nonessential survival factors for $CD34^+$ cells.[36] These growth factors work in concert to promote definitive erythropoiesis. However, Epo is the primary growth factor: in the absence of Epo signaling, as in the case for both Epo-null and Epo receptor–null mutations, definitive erythropoiesis does not occur. Null mutations of either Epo or its receptor are lethal at 13.5 days of gestation in the mouse because of severe anemia.

Extramedullary Hematopoiesis

Extramedullary hematopoiesis can occur after the bone marrow has been established as the primary site of erythropoiesis. Diseases inducing this occurrence include hemolytic conditions, congenital rubella, cytomegalovirus infection, and parvovirus B19 infection.

Extramedullary hematopoiesis can occur in the liver, spleen, adrenal glands, pancreas, thyroid, endocardium, testes, uterus, skin, or brain.[37] When the skin is involved in a neonate, the classic "blueberry muffin" rash is seen, typical of congenital rubella or cytomegalovirus infection.

Ontogeny of Erythrocytes

The earliest precursor cells specific to the erythroid lineage are the burst-forming unit–erythroid (BFU-E) cells. BFU-E cells have low numbers of Epo receptors[38] and respond to Epo, as well as a granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3. As these cells mature into erythroid colony-forming units–erythroid and proerythroblasts, they become highly dependent on Epo, which is reflected by the high density of Epo receptors on the cell membrane (up to 1000 per cell).[39] Mature erythroblasts have fewer Epo receptors and are less sensitive to Epo stimulation, and reticulocytes and erythrocytes have no Epo receptors and are unresponsive to Epo. The principal functions of mature erythrocyte metabolism are to maintain adequate adenosine triphosphate (ATP) stores, to produce reducing substances to act as antioxidants, and to produce 2,3-diphosphoglycerate (2,3-DPG), which modifies the oxygen affinity of hemoglobin. Recent studies have identified a previously unappreciated role for RBCs in immune regulation. The role of RBCs in the modulation of response to bacterial and viral infection, immune tolerance, tumor surveillance, and RBC effects on the microbiome is reviewed by Yang and Lewis.[40]

Important developmental changes occur in hematocrit, reticulocyte count, RBC morphology, membrane content, deformability, life span, and metabolism. Over the course of gestation, there is an expected rise in hematocrit, from (36 ± 3)% at 18 to 20 weeks of gestation (fetal samples) to (61 ± 7)% expected at term birth. To maintain this increase in hematocrit and blood volume (up to 7 mL/day during the last trimester), the production of approximately 50×10^9 erythrocytes per day is required. During this same period of fetal development, erythrocyte size (the mean cell volume) decreases from 134 ± 9 femtoliters (fL) to 119 ± 9 fL.[41] At term, the mean cell volume is larger than that of normal healthy adults and drops postnatally, reaching a nadir at 4 to 6 months. It then increases to reach adult values (88 ± 8 fL) by approximately 1 year.

Reticulocytes are near mature erythrocytes released from the bone marrow into circulation. Although the nucleus has been extruded, they retain cytoplasmic organelles such as ribosomes, mitochondria, and Golgi bodies for approximately 24 hours. These newly released cells can be differentiated from mature RBCs by staining with new methylene blue or brilliant cresyl blue, which stains the nucleic acid within the cells. They can also be enumerated using flow-cytometric gaiting of cells that are larger and contain more nucleic acid than mature RBCs. The reticulocyte count can be used to assess the level of erythrocyte production because high values indicate active erythropoiesis, while low numbers indicate low levels of erythropoiesis. At birth, reticulocyte counts in preterm infants tend to be higher than in term infants (400,000/μL to 550,000/μL vs. 200,000/μL to 400,000/μL).[42] Absolute reticulocyte counts, reticulocyte percentage of total RBCs, and corrected reticulocyte counts can be obtained. In general, when neonates are being evaluated, the absolute reticulocyte count is the most helpful.[43]

RBC morphology is quite heterogeneous in preterm and term infants as compared with adults. Irregularly shaped cells such as poikilocytes, acanthocytes, schistocytes, and burr cells are common in the blood smears of neonates. This reflects developmental changes in cell membrane deformability and flexibility. The neonatal RBC has a life span of approximately 70 to 80 days as compared with 120 days for the adult RBC.

Developmental Changes in the Regulation of Erythropoiesis

The principal growth factor that regulates erythropoiesis is Epo. This 30.4-kDa glycoprotein contains 165 amino acids and is extensively glycosylated, with 40% carbohydrate content. Epo maintains RBC production during fetal, neonatal, and adult life by inhibiting apoptosis of erythroid progenitors and by stimulating their proliferation and differentiation into normoblasts.[44] Since very little Epo crosses the placenta, the Epo concentrations measured in the fetus reflect fetal synthesis.[45,46] Epo production begins early in fetal life, and Epo has been identified in extraembryonic coelomic fluid and amniotic fluid.[47] The primary site of Epo production during fetal life is the liver, with the transition to the kidney postnatally.[48] This transition is mediated in part by the expression of *GATA4*.[49] Production of Epo is stimulated by hypoxia via hypoxia-inducible factor (HIF) 1 and 2 pathways.[50–54] HIF is a DNA-binding complex composed of two subunits: HIF-1β, which is not oxygen responsive and is constitutively expressed, and either HIF-1α or HIF-2α, which are highly oxygen sensitive. The HIF complex is, in turn, regulated by prolyl hydroxylase domain enzymes 1–3.[55] Elevated Epo concentrations (up to 8000 mU/mL) have been reported in pathologic states such as fetal hypoxia, anemia, placental insufficiency, and in infants of diabetic mothers.[56]

During fetal development, circulating Epo concentrations range from 4 mU/mL at 16 weeks of gestation to 40 mU/mL at term.[57,58] An unhealthy intrauterine environment can result in increased Epo production, reflecting fetal hypoxemia.[59,60] In healthy term infants, serum Epo concentrations decrease after birth to reach a nadir between the fourth and sixth week of age.[60] By 10 to 12 weeks, they reach adult concentrations (approximately 15 mU/mL).[61] These changes in Epo concentrations are consistent with the changes in hemoglobin and hematocrit are seen following term birth (physiologic anemia). In premature infants, the anemia is more severe and persists longer, leading to anemia of prematurity. Epo concentrations in these infants are inappropriately low, forming the rationale for recombinant human Epo therapy.

Ontogeny, Organization, and Structure of Hemoglobins

Hemoglobin is a tetrameric molecule comprising two pairs of polypeptide subunits. As development proceeds, various hemoglobins are constructed by a combination of two α-like globins (ζ or α) with two β-like globins (ε, γ, δ, or β) to form hemoglobin tetramers. These tetramers include the embryonic hemoglobins, hemoglobin Gower 1 ($\zeta_2\varepsilon_2$), hemoglobin Gower 2 ($\alpha_2\varepsilon_2$), and hemoglobin Portland 1 ($\zeta_2\gamma_2$), fetal hemoglobin (hemoglobin F) ($\alpha_2\gamma_2$), and the adult hemoglobins A ($\alpha_2\beta_2$) and A_2 ($\alpha_2\delta_2$). Their expression and proportion depend on gestational age but can be modified by external mechanisms. The basic function of the various hemoglobins is similar, but their oxygen affinity differs. As the hemoglobins switch from embryonic to fetal to adult forms, oxygen affinity decreases. Thus the switch from embryonic to fetal to adult hemoglobin synthesis is a major mechanism by which

the developing fetus adapts from the relatively hypoxic intrauterine environment to the relatively oxygen-rich extrauterine environment.[62]

Changes in Hemoglobin Synthesis With Development

The genes within the α-globin and β-globin families are expressed according to a strict ontogenetic schedule, and the quantitative expression of the genes from each of these families is strictly balanced and coordinated.[63] Hemoglobin synthesis begins around 14 days after conception, with the synthesis of ζ-globin and ε-globin chains. These are replaced by the synthesis of α-globin and γ-globin chains by the fifth to the seventh week of gestation (hemoglobin Gower 2, hemoglobin Portland 1, and hemoglobin F become predominant).[64] By 12 weeks of gestation, hemoglobin F ($\alpha_2\gamma_2$) accounts for almost all hemoglobin produced.[65] After the 20th week of gestation, no ε-globin chains are produced, but the production of the ζ-globin chains can persist through the last trimester in pathologic conditions such as homozygous α-thalassemia. Expression of the γ-globin gene peaks during midgestation and declines rapidly during the last month of fetal gestation. β-Globin synthesis, required for hemoglobin A, starts at the sixth week of gestation, increasing as γ-globin synthesis declines, a transition that continues to the sixth month of life.[66] Thus, hemoglobin A synthesis quantitatively increases first after the 30th week of gestation. At the end of the last trimester, a rapid switch from the synthesis of fetal hemoglobin to adult hemoglobin occurs, falling from 85% at 34 weeks of gestation to 60% to 80% at birth.[67] The synthesis of δ-globin chains, required for hemoglobin A_2 ($\alpha_2\delta_2$), begins at the 34th to 35th week of gestation. After birth, a rapid increase in hemoglobin A and hemoglobin A_2 synthesis occurs.

Red Blood Cell Transfusion

RBCs can be transfused to anemic patients to simultaneously increase the recipient's blood volume and RBC content, thereby increasing oxygen-carrying capacity. The technical ability to store blood for future transfusion was developed in the early 1900s.[68] In the early years, RBCs were kept viable in a citrate and glucose solution, but current solutions make it possible to store cells for up to 42 days in solutions such as citrate–phosphate–dextrose, citrate–phosphate–dextrose–adenine, and various additive solutions, which may contain additional dextrose, mannitol, and adenine.[69] The hematocrit of "packed RBCs" typically ranges from 55% to 80%. During storage, RBCs undergo metabolic and structural changes. 2,3-DGP, antioxidant, and ATP contents decrease, glycolysis decreases, osmotic fragility increases, and deformability decreases.[70] ATP-dependent membrane pumps become dysfunctional, and extracellular potassium content increases at a rate of 1 milliequivalent per day, which can be dangerous when large volumes are transfused quickly. Oxidative damage occurs in lipids and proteins during storage and irradiation.[71] Proinflammatory compounds accumulate during the storage of blood, particularly if it is not leukoreduced. After an RBC transfusion, the mean life span of the RBC is about 70 days with a mean half-life of 30 days.[72,73]

The risks of RBC transfusion may be due to the storage process, the transfusion itself, and the association with oxidative damage. Because of the storage process and increasing age of the stored blood, RBC transfusion exposes the recipient to high levels of potassium, glucose, hydrogen, inflammatory mediators, and lactic acid; the clinical significance depends on the age of the blood and the volume and speed of transfusion.[71] However, it is not clear that transfusion of recently donated RBCs decreases transfusion risks.[74] Although rare, transfusion-transmitted bacterial infections can occur because of bacterial contamination of stored blood.[75] Other risks of RBC transfusion include viral infections, transfusion-related acute lung injury, graft-versus-host reaction, and, potentially, an increased risk of neurodevelopmental impairment.[76,77] Multiple RBC transfusions in the absence of significant phlebotomy-related loss may also put the patient at risk of iron overload and oxidative injury.[78] There is 200 mg of iron in a 420-mL unit of whole blood, which is then processed into 250-mL units of packed RBCs,[79] so a unit of blood with a hematocrit of 60% has an iron content of 0.7 mg/mL, which becomes available as the cells turn over. There is increased unbound iron in stored blood, which may increase the amount of reactive oxygen species.[80] Studies comparing restrictive with liberal transfusion practices in premature infants have not demonstrated a substantial and lasting benefit to maintaining higher hemoglobin levels.[81–84]

Preterm infants are at high risk of receiving red blood cell (pRBC) transfusions during their initial hospitalization (range from 0 to >10 transfusions).[83–87] In retrospective and observational studies, increased numbers of RBC transfusions have been associated with the development of bronchopulmonary dysplasia (BPD),[88] necrotizing enterocolitis (NEC),[89–92] retinopathy of prematurity (ROP),[93,94] diuretic use,[85] and poorer neurodevelopmental assessments[77,95] and therefore are to be avoided if possible. Transfusions can be prevented or decreased by combining several approaches: use of and adherence to restrictive transfusion guidelines, delayed cord clamping,[96] use of a cord or placental blood for initial laboratory studies,[97] minimized phlebotomy draws, ensured availability of adequate iron for erythropoiesis, and use of erythropoiesis-stimulating agents (ESA) such as erythropoietin (Epo)[98] or darbepoetin (Darbe) when reticulocytosis is inadequate.[99–101]

Bilirubin Metabolism

The primary source of bilirubin in the fetus and neonate is the metabolism of heme derived from hemoglobin in circulating erythrocytes. The rate-limiting step in heme breakdown is the formation of biliverdin, a process controlled by heme oxygenase.[102] After heme breakdown, the iron is recycled, carbon monoxide is liberated and exhaled, and biliverdin is reduced to bilirubin IXα by biliverdin reductase. In utero, unconjugated bilirubin is processed by the mother after placental transfer. Exhaled carbon monoxide can be quantified to assess the heme breakdown rate.[103] Unconjugated bilirubin is lipophilic and tightly bound to circulating albumin. The conjugation of bilirubin results in a relatively polar, water-soluble molecule, bilirubin diglucuronide, which can be excreted. This process occurs in the liver and is dependent on ligandin, a transfer protein, and the enzyme uridine diphosphoglucuronyl transferase. The conjugating ability of the fetus and newborn is impaired relative to that of older individuals because of reduced transferase activity and low levels of uridine diphosphoglucuronic acid.[104]

Developmental Aspects of Megakaryocytopoiesis

Megakaryocytopoiesis is the process by which megakaryocytes, and ultimately platelets, develop. Platelets are small (7.5 fL) anucleated fragments of megakaryocytes that circulate as relatively

smooth disks when unactivated. The normal circulating life span of a platelet is 10 days. Platelets provide hemostasis when a breach of the vascular endothelial lining occurs, and they activate and adhere to the exposed subendothelium. Activated platelets generate mediators, including the potent vasoconstrictor thromboxane A_2 and adenosine diphosphate, both of which further contribute to hemostatic plug formation.[105]

Sites of Megakaryocyte Production

As with erythropoiesis, the sites of megakaryocytopoiesis change during embryonic and fetal development; in mouse development, megakaryocytes are found in the early yolk sac.[106] These cells, when cultured in the presence of stem cell factor, IL-3, IL-6, Epo, TPO, and granulocyte colony-stimulating factor (G-CSF), produce not only BFU-E cells but also megakaryocyte colonies. Megakaryocyte progenitors share a common progenitor with primitive hematopoietic cells.[106] In humans, electron micrograph studies have shown megakaryocytes present in the liver and circulatory system as early as 8 weeks after conception.[107]

Megakaryocyte Precursors

Megakaryocytopoiesis begins with the pluripotent HSCs, which give rise to myeloid progenitor cells (colony-forming unit–spleen cells), then burst-forming unit–megakaryocyte cells, followed by colony-forming unit–megakaryocyte cells (Fig. 66.2). Further maturation brings these small mononuclear cells that are largely indistinguishable from monocytes to large polyploid cells, which are easily recognized on the basis of their phenotype. The process of megakaryocyte differentiation has been separated into four stages. Stage I cells, or megakaryoblasts, are the smallest and most immature. As cells mature through stage II (promegakaryocytes), stage III (granular megakaryocytes), and stage IV (mature megakaryocytes), the nucleus becomes multilobed; the cytoplasm becomes increasingly eosinophilic by Wright–Giemsa staining, and cellular size increases from 6 to 24 μm up to 50 μm. The presence of granules increases steadily until, in the mature cells, they become organized into "platelet fields." Unlike in other cell lines, as the nucleus of megakaryocytes matures, it undergoes endomitosis or endoreduplication, a process by which cell ploidy is increased in the absence of cell division. Megakaryocytes from adults typically have a modal ploidy of 16 *N*, while comparable samples from preterm or term infants have a significantly lower ploidy of less than 8 *N*.[108] Megakaryocytes from newborns are also typically smaller than those in adults, although they manifest features of mature megakaryocytes.[109] Adult-size megakaryocytes appear by 2 years of age. Typically, smaller cells with lower ploidy produce fewer platelets than larger cells with higher ploidy. Despite this, the platelet counts of fetuses are only slightly lower than those of adults.[110]

Control of Megakaryocytopoiesis

Platelets serve the primary function of hemostasis but also participate in the antimicrobial defense and tissue repair.[111] Multiple cytokines participate in the process of megakaryocytopoiesis; however, TPO is the principal one. Stem cell factors, IL-3 and IL-6, increase ploidy and the size of megakaryocytes. IL-11 also stimulates the proliferation of megakaryocyte progenitors and induces megakaryocyte maturation, while still other growth factors such as Epo, stem cell factor, GM-CSF, IL-1, basic fibroblast growth factor, platelet-derived growth factor, and interferon-γ have a less clearly defined role. Some cytokines inhibit thrombopoiesis,

including transforming growth factor β and platelet factor 4.[112] The magnitude of the influence of these growth factors changes with development.

Thrombopoietin

The presence of a growth factor regulating platelet formation was hypothesized in the 1950s but was not realized until 1994 when the protein was isolated.[113] TPO is composed of 332 amino acids and contains two domains. The amino terminal is the active domain (153 amino acids) and bears marked homology to Epo. TPO is produced primarily by the liver, although other tissues express small amounts. It acts as a potent stimulator of all stages of megakaryocyte development by binding to its specific cell-surface receptor, c-myeloproliferative leukemia (MPL). In TPO- and c-MPL-knockout models, platelet production is 10% to 15% of that of controls, confirming that TPO is the primary regulator of platelet production but also indicating that alternative pathways exist for megakaryocytopoiesis. TPO is bound to the surface of platelets by its receptor, thereby reducing megakaryocyte exposure to the hormone.[113] Serum TPO concentrations tend to be lower in preterm infants than in older infants and children, and the TPO response to thrombocytopenia is less robust as gestational age decreases. This is counterbalanced by an increased sensitivity of megakaryocyte precursors to TPO.[114]

Early clinical trials of recombinant TPO administration to patients with immune thrombocytopenia showed significantly increased platelet counts, but the development of antibodies in a few patients, which cross-reacted with endogenous TPO, resulted in a halt to further clinical trials of recombinant TPO. In 2008 the US Food and Drug Administration (USFDA) approved the first TPO receptor agonist, molecularly and structurally unrelated to TPO but nevertheless capable of activating the TPO receptor and resulting in increased platelet production. This TPO agonist was originally called AMG531 but is now known as Romiplostim.[115]

In 2018 Romiplostim was approved by the USFDA to manage ITP in children 1 year of age or older, where safety and efficacy are reported to be good.[116] Only two case reports have been published describing the use of Romiplostim to decrease platelet transfusions in neonates with severe and prolonged thrombocytopenia. Both neonates were platelet-transfusion dependent[117,118] until Romiplostim treatment was begun, after which further platelet transfusions were not needed. No adverse effects of the medication were observed in either case.

Developmental Changes in Platelet Count

Fetal platelet counts increase with gestation. At 15 weeks, the average platelet count is 187,000/μL, increasing to 274,000/μL at term. Overall, preterm infants have slightly lower platelet counts than do adults with a broader range of normal (100,000/μL to 450,000/μL).[42,110]

Platelet Transfusions

Clinical practice regarding platelet transfusion of neonates has been inconsistent until very recently because no evidence-based guidelines were available.[119] In a 2005 Web-based survey of neonatologists in the United States and Canada, wide variations in practice were noted, with platelet transfusions frequently administered to nonbleeding neonates with platelet counts greater than 50,000/μL. This practice was particularly common during indomethacin treatment, before or after procedures or operations, or after diagnosis of intraventricular hemorrhages.[120] This is concerning because several studies show a correlation between the number of platelet transfusions received by hospitalized neonates and the mortality rate.[121,122] In a study of 1600 thrombocytopenic NICU patients, those who received platelet transfusions had higher mortality rates: 2% for those with no transfusions, 11% for those with 1 or 2 transfusions, 35% for those with more than 10 transfusions, and 50% with 20 or more transfusions.[122] This was partially due to the underlying illness that required the infant to be transfused. However, since transfusion practices differ so widely, some of the increased mortality could statistically be ascribed to the harmful effects of multiple platelet transfusions. In an attempt to create a reasonable yet safe approach to platelet transfusions, two guidelines were prospectively compared: one based on platelet count and the other based on platelet mass (platelet count times mean platelet volume). Fewer patients were transfused when platelet mass was used as a transfusion trigger.[123,124] The authors recommended that prophylactic transfusions of platelets be avoided after the first week of life unless the platelet count falls below 30,000/μL. During the first week of life, they recommend a transfusion trigger of 50,000/μL for preterm infants. For patients with platelet counts greater than 50,000/μL, transfusions should be reserved for those with active serious bleeding. Another controversy concerns the preparation of platelets: single donor, multiple donors, single unit, or volume-reduced multiple unit preparations. In general, 10- to 20-mL single donor platelets per kilogram should raise the platelet count by more than 100,000/μL. In the absence of consumption, some of the donor platelets should remain in the recipient's circulation for 1 week. The use of volume-reduced or pooled platelets should be avoided because processing results in platelet activation and decreased function.

The recently published multicentered platelet transfusion trial by Curley and collaborators[119] involved 660 premature neonates with a birth weight averaging 740 g and gestational age averaging 26.6 weeks. If the platelet count fell below 50,000 per cubic millimeter, they would either receive a platelet transfusion (randomized to the high threshold group) or do not receive a platelet transfusion unless their platelet count subsequently fell below 25,000 per cubic millimeter (the low threshold group). Outcomes were worse in those randomized to the high threshold group, who obviously received more platelet transfusions but somewhat paradoxically had fewer subsequent bleeding episodes. Thus, it is clear that platelet transfusions can have deleterious effects on preterm neonates, and the evidence from this trial strongly suggests a lower threshold for platelet transfusion is better in this population.

Subsequent to the study of Curley et al., a further analysis was performed of a subgroup of those study neonates who had a high baseline risk of death. Those also were found to have better outcomes if they had been randomized to the lower threshold platelet transfusion group. This suggests that a platelet transfusion threshold of 25,000 is better than one of 50,000, even for the smallest and most ill preterm infants.[125]

Developmental Aspects of Granulocytopoiesis

Early hematopoiesis is characterized almost exclusively by erythropoiesis, although a small number of macrophages are produced in the yolk sac. After circulation begins in the fourth to the fifth week of gestation, macrophages appear in the liver, brain, and

lungs. During the fifth week, hematopoiesis begins in the liver, and the first hematopoietic cells to appear are macrophages.[27] Whether Kupffer cells originate in the yolk sac and migrate to the liver or arise de novo in the liver is unknown. The marrow space begins to develop around the eighth week after conception, and as occurs in the liver, the first hematopoietic cells to appear in the bones are phagocytes.[27,34] These phagocytic osteoclasts seem to core out the marrow space. When hematopoiesis is established in the marrow at 10 to 11 weeks after conception, primarily neutrophils are produced, in contrast to the liver, where primarily macrophages are present.[126]

The thymus appears around 8 weeks after conception. T-cell progenitors are thought to migrate from the fetal liver to the thymus at 8 to 9 weeks after conception,[127] and by the 10th week, lymphoid cells constitute 95% of this organ, with granulocyte precursors and macrophages making up the remainder. B-cell precursors first appear in the omentum and the fetal liver 8 weeks after conception. B-cell production in the omentum occurs transiently from 8 to 12 weeks,[128] while production continues in the fetal liver. Regulatory T cells are found in the thymus and secondary lymphatic organs in the early second trimester and are proposed to be involved in self-reactivity and immune tolerance.[129,130]

The spleen is an important secondary lymphatic organ in humans. The human spleen does not have intrinsic granulocytopoiesis and erythropoiesis activities or produce hematopoietic growth factors,[22] and lymphocytes appear to migrate there through fetal blood. Lymphocytes begin to appear in the spleen around 11 weeks after conception. By the 22nd week, 70% of the cells are lymphocytes.

Hematopoietic Cytokines

Hematopoietic growth factors can be classified into two groups: those responsible for the regulation of myeloid and erythroid growth and differentiation, called *colony-stimulating factors*, and those concerned with immunity, called *lymphokines*. Once sequenced, lymphokines are assigned IL numbers. There is a great deal of functional overlap between hematopoietic growth factors (redundancy), and each growth factor has a multiplicity of biological actions (pleiotropy). Thus more than one cytokine controls cells in any cell lineage, and most factors affect cells in more than one lineage.[131]

Epo, GM-CSF, and G-CSF belong to a family of hematopoietic cytokines that share a tertiary structure and function by binding to specific cell-surface receptors. Specific ligand binding results in allosteric changes in the receptor molecules, which, depending on the type of receptor, results either in protein kinase activation, as with macrophage colony-stimulating factor,[132] or in a cascade of intracellular signaling via the Janus kinase two mechanisms, as is characterized by Epo.[133]

Many of the hematopoietic cytokines were discovered on the basis of their growth-promoting effects on hematopoietic cells or their specific immune functions. It was initially assumed that their effects were specific to the hematopoietic system. This view was incomplete. Functional receptors are expressed by other nonhematopoietic cells, with clear nonhematopoietic functions as reviewed by Li et al. and Juul and Pet.[134,135] For example, both glia and neurons produce many of the cytokines once thought to be restricted to the hematopoietic system. Furthermore, they express receptors for these peptides, indicating the capability of both paracrine and autocrine interaction. Epo and G-CSF are both available in recombinant form and are approved by the USFDA for clinical use.

Neonatal Bleeding and Thrombotic Disorders

MATTHEW A. SAXONHOUSE AND ASHLEY P. HINSON

KEY POINTS

- Acquired or inherited coagulation disorders should be considered in any neonate that suffers significant hemorrhage.
- Treatment for specific coagulation disorders should be provided in consultation with pediatric hematology and based on the most current guidelines.
- Thromboembolism (TE) is a significant problem affecting both term and preterm neonates.
- Most neonates that experience a significant TE event have acquired risk factors and/or a prothrombotic disorder.
- Proper imaging is essential for accurately identifying neonatal TE events.
- The use of central venous/arterial catheters significantly increases a neonate's risk for thrombosis.
- Recommendations for treatment for neonatal TE events are based on expert opinion and data from case studies/series.
- Care for neonates with coagulation disorders or significant TE events should occur in a tertiary referral center that has appropriate subspecialty support.

Neonatal bleeding and thrombotic disorders may present a diagnostic challenge to the caregiver. Excess and/or deficiencies of certain coagulation/anticoagulation proteins coupled with multiple acquired and/or prothrombotic risk factors and/or thrombocytopenia can result in a hemorrhagic or thromboembolic (TE) emergency in the neonatal period. The timely diagnosis of a congenital hemorrhagic disorder can potentially avoid significant long-term sequelae, while the lack of randomized clinical trials addressing the management of neonatal thromboses can leave a neonatologist guessing on what the optimum treatment strategy should be. In this chapter, we briefly review the neonatal hemostatic system. Neonatal hemorrhagic disorders are presented with a discussion of current treatment options. Congenital and acquired risk factors and common sites for neonatal thromboses are reviewed. Finally, suggested evaluations for neonates with TE emergencies as well as the latest treatment options are presented.

The Neonatal Hemostatic System

Blood vessel injury causes clinical bleeding, which can be severe. Hemostasis refers to the process in which bleeding is controlled at the site of damaged endothelium.[1] The process of hemostasis involves the interaction between endothelium, subendothelium, platelets, circulating cells, and plasma proteins. Blood vessel injury leads to an immediate, local response of both plasma and cellular components. Thrombosis is confined to the area of injury, leading to eventual tissue repair. A model of hemostasis combining the vascular, platelet, and plasma phases is presented in Video 67.1. The result is a localized, firm thrombosis, leading to cessation of bleeding. The thrombosis then serves as a scaffold for tissue repair, leading to complete restoration of the endothelial lining.[2] Fibrinolysis must then occur for blood vessel repair and return of blood flow (Video 67.2).

Hemostatic processes are regulated by natural anticoagulants (Video 67.3), whose job is to contain these processes to the site of injury and to prevent these reactions from becoming systemic and pathologic.[2] Deficiencies in natural anticoagulant proteins, as well as decreased fibrinolysis in neonates, may lead to the formation of pathologic thromboses during the neonatal period, and these disorders are described later. The complex interaction of the hemostatic, fibrinolytic, and anticoagulant components of the hemostatic system results in a well-balanced machine that allows for hemostasis to occur at the site of injury and for fibrinolysis to follow, facilitating a localized tissue repair process.

Developmental Hemostasis

The neonatal hemostatic system differs significantly from that of older children and adults.[3] The concentrations of the procoagulant, anticoagulant, and fibrinolytic proteins, compared with adults', are shown in Table 67.1, and age-related normal values should be referenced when assessing for bleeding or clotting abnormalities. Essentially, all the procoagulant proteins, except for fibrinogen, factors V and VIII, and von Willebrand factor (vWF), are lower. These lower levels are balanced by lower levels of anticoagulant proteins, except for alpha2-macroglobulin, which is the only anticoagulant protein that is elevated during the neonatal period. All the fibrinolytic proteins are reduced. These differences place a neonate in a "relative" prothrombotic state, but other factors balance the system and prevent a term or "well" premature neonate from experiencing spontaneous thrombosis. However, many acquired (Table 67.2) and/or prothrombotic risk factors (Box 67.1) may disrupt this balance, shifting the neonate into a prothrombotic state.

The exact reasons for the differences in the fetal and neonatal hemostatic systems, compared with adults, are unclear but

TABLE 67.1 Neonatal Coagulation/Anticoagulation/Fibrinolytic Protein Levels Compared With Adult Levels

	Protein Levels Elevated Compared With Adult Values	Protein Levels Decreased Compared With Adult Values
Procoagulant	Fibrinogen Factor V* Factor VIII vWF	Factors II, VII, IX, X, XI, XII, XIII† Prekallikrein High-molecular-weight kininogen
Anticoagulant	Alpha2-macroglobulin	Antithrombin III Heparin cofactor II Protein C Protein S
Fibrinolytic	Tissue plasminogen activator Plasminogen activator inhibitor	Plasminogen α_2-antiplasmin

*Factor V levels are low on day of life 1 but reach adult values within days after birth.[3]
†Levels are 50% of adult values.[3]
vWF, von Willebrand factor.

TABLE 67.2 Acquired Risk Factors for the Development of Neonatal Thromboses

Maternal Risk Factors	Delivery Risk Factors	Neonatal Risk Factors
Infertility	Emergent cesarean section	Central venous/arterial catheters*
Oligohydramnios	Fetal heart rate abnormalities	Congenital heart disease
Prothrombotic disorder	Instrumentation	Sepsis
Preeclampsia	Meconium-stained fluid	Meningitis
Diabetes		Birth asphyxia
Intrauterine growth restriction		Eosinophilia
Chorioamnionitis		Respiratory distress syndrome
Prolonged rupture of membranes		Dehydration
Autoimmune disorders		Congenital nephritic/nephrotic syndrome
Fetal thrombotic vasculopathy		Necrotizing enterocolitis
		Polycythemia
		Pulmonary hypertension
		Surgery
		Extracorporeal membrane oxygenation
		Medications (steroids)

*Greatest risk factor for thrombosis with a significant risk if present ≥14-days.
From Saxonhouse MA, Manco-Johnson MJ. The evaluation and management of neonatal coagulation disorders. *Semin Perinatol.* 2009;33:56; with permission. Data from the following references 58,60,62,73,75,78,87,90,123,135,162–169.

supported by recent theories surrounding overall fetal development.[4] In the fetus, the lower levels of antithrombin III (ATIII) are balanced by elevated concentrations of alpha2-macroglobulin, allowing for unrestricted angiogenesis during intense growth while maintaining an effective anticoagulant pathway.[5,6] Lower levels of vitamin K during fetal growth may reduce the synthesis of osteocalcin, preventing premature fetal cartilage maturation.[7]

Despite having a balanced hemostatic system at birth, neonatal prothrombin time (PT) and activated partial thromboplastin times (APTT) are elevated when compared with adults. Elevated tissue factor (TF) in neonates compensates for the lower levels of tissue factor pathway inhibitor (TFPI) and ATIII. Some aspects of decreased platelet aggregation in neonates are compensated with higher levels of vWF and factor VIII (FVIII). Therefore, despite the lower levels of coagulation proteins, neonates can form effective thromboses.

The neonatal hemostatic system undergoes numerous changes over the first 6 months of life, and many of the lower protein levels reach adult values during this time.

Bleeding Disorders in the Neonate

When faced with either an actively bleeding infant or one that has suffered a significant hemorrhage, acquired or inherited, coagulation defects must be considered, especially if the neonate has a normal platelet count. Laboratory diagnostic criteria for the bleeding newborn are shown in Table 67.3. Inherited and acquired coagulation defects and the most common symptoms associated with their presentations in the neonate are shown in Table 67.4. It is important to obtain a detailed family and delivery history for any neonate experiencing significant bleeding, as information gained may allow the clinician to perform a quicker, more focused approach.

Laboratory Investigation

The first approach (initial screen) to any neonate with a suspected bleeding disorder should be a complete blood count (CBC) and coagulation screen (PT, APTT, and fibrinogen). More specific testing can then be performed to make the correct diagnosis. It is important to remember that the method of sample collection may affect sample results. For example, heel-stick samples should

never be used for coagulation screening, and they may result in platelet clumping, which will produce a falsely low platelet count. Elevated hematocrit levels greater than 55% may result in prolonged diluted coagulation times. In addition, the collection of blood samples through heparinized arterial or venous lines will prolong the APTT, unless the specimen has the heparin absorbed and/or adequate blood is removed from the line before sample collection to clear heparin from the line. When interpreting values from coagulation screening and more detailed testing, values should be interpreted using age-adjusted normal ranges based on gestational age and days of life; these are published elsewhere.[8–10]

• BOX 67.1 Prothrombotic Disorders Implicated in the Development of Neonatal Thromboembolism

Factor V Leiden mutation (most common)
Factor II *G20210A* gene mutation (1%–2% of Caucasians)
Increased apolipoprotein(a)
Methylenetetrahydrofolate reductase gene mutation (*MTHFR C677T*) genotype
Hyperhomocysteinemia
Protein C deficiency
Protein S deficiency
Antithrombin III deficiency
Heparin cofactor II deficiency
Dysfibrinogenemia
PAI-1 4g/5G gene mutation
Increased levels of factors VIIIC, IX, XI, or fibrinogen
Antiphospholipid antibodies (including anticardiolipin antibodies, lupus anticoagulant)
Chromosome 2q
Chromosome 2q13 deletion

Hemophilia

The most common congenital bleeding disorders are hemophilia A (FVIII deficiency) and hemophilia B (factor IX deficiency), both being inherited as X-linked recessive. The incidence of hemophilia A is 1 per 5000 males and for hemophilia B is 1 per 20,000 males.[11] Approximately one-third of cases will occur in the absence of a positive family history.[12] Heterozygous females may have mild hemophilia as a result of nonrandom X-chromosome inactivation.[2] The severity of hemophilia is determined by the type of mutation and the part of the protein that is affected, with severity of bleeding phenotype inversely proportional to the infant's factor level.[2] The lower the factor level, the greater the potential for more severe early onset bleeding. With the absence of either FVIII or factor IX, there is reduced thrombin formation on the surface of activated platelets, resulting in a thrombosis with poor structural integrity that is more susceptible to fibrinolysis, and as a result, bleeding occurs. Approximately 70% of patients with hemophilia are diagnosed during the first month of life, with the mean age of patients with hemophilia having their first bleed by 28.5 days.[12,13] The most common presentation of hemophilia in the neonate is excessive bleeding, either after circumcision or surgery; but these infants can also present with severe intracranial hemorrhage. Further classifications of hemophilia A and B, based on factor activity level, and the types of bleeding that neonates may present with are shown in Table 67.4.

TABLE 67.3 Laboratory Diagnostic Criterion for the Bleeding Newborn*

Disorder	PT	APTT	Platelets	Fibrinogen
Hemophilia A	Normal	↑↑↑	Normal	Normal
Hemophilia B	Normal	↑↑↑	Normal	Normal
Hemophilia C	Normal	↑↑	Normal	Normal
Factor XIII deficiency	Normal	Normal	Normal	Normal
Factor II, V, and X deficiency	↑↑	↑↑	Normal	Normal
Hemorrhagic disease of the newborn	↑↑↑	Normal/↑†	Normal	Normal
DIC‡	↑↑↑	↑↑↑	Low	Low
Liver disease‡	↑↑↑	↑↑↑	Low	Low
vWD	Normal	Normal/↑	Normal	Normal
Hypofibrinogenemia	↑↑↑	↑↑↑	Normal	Low
Dysfibrinogenemia	↑↑↑	↑↑↑	Normal	Normal/Low

*A complete blood count and coagulation screening test should be performed for any bleeding infant.
†APTT values may be prolonged but not as severe as the elevated PT value.
‡To differentiate between DIC and liver disease, a factor VIII value should be obtained. Factor VIII values will be normal in infants with liver disease but low in infants with DIC.
APTT, Activated partial thromboplastin time(s); *DIC*, disseminated intravascular coagulation; *PT*, prothrombin time(s); *vWD*, von Willebrand disease.

TABLE 67.4 Acquired and Inherited Bleeding Disorders in Neonates

Inherited	Classification	Symptoms
Hemophilia A (FVIII) Hemophilia B (FIX)	Severe (<1%) Moderate (1%–5%) Mild (>5%)	Bleeding after circumcision and/or blood draws, ICH, extracranial hemorrhage, excessive bruising, muscle hematomas, bleeding after surgery
Fibrinogen deficiency	Decreased levels (heterozygote): hypofibrinogenemia Absent levels (homozygote): afibrinogenemia Dysfunctional Dysfibrinogenemia	Prolonged bleeding from umbilical stump, bleeding after circumcision, ICH, or mucocutaneous bleeding
Factor II (prothrombin) Factor V	Commonly associated with congenital anomalies, particularly cardiac defects	Mucocutaneous bleeding, ICH, prolonged bleeding from umbilical stump, bleeding after procedures
Factor VII Factor X	Levels do not correlate well with bleeding phenotype	
Factor XI	Levels do not correlate well with bleeding phenotype	
Factor XIII		Umbilical cord stump bleeding, ICH, bleeding after procedures

Acquired	Classification	Symptoms
DIC Liver disease		Prolonged bleeding after venipuncture/heel sticks, jaundice, pulmonary hemorrhage
Vitamin K deficiency	Early <24 hours	Cephalohematoma, umbilical stump bleeding, ICH
	Classical 1–7 days	GI bleeding, umbilical stump bleeding, mucocutaneous, circumcision, ICH
	Late ≥2 weeks	ICH, mucocutaneous, GI bleeding

DIC, Disseminated intravascular coagulation; *FVIII*, factor VIII; *FIX*, factor IX; *GI*, gastrointestinal; *ICH*, intracranial hemorrhage.

References 2,22,170.

Most symptomatic infants with hemophilia A and B will have significant prolongation of their APTT; however, if the diagnosis is suspected, specific factor levels should always be obtained. If there is a strong family history for hemophilia, factor levels may be screened from cord blood samples at birth, but severity of disease should always be confirmed from samples obtained after the infant is born. Infants suspected to have hemophilia, or with known family histories, should have strategies employed to reduce the risk of bleeding, such as subcutaneous vitamin K at birth, applied pressure to an intramuscular injection site for 5 minutes, use of smallest possible needles and lancets for venipunctures, and avoidance of arterial punctures.[14]

Because FVIII levels are increased during the neonatal period, the diagnosis of mild hemophilia A may be difficult, and confirmatory testing should be done at 6 to 12 months of age. In addition, lower levels of factor IX at birth may also make the diagnosis of mild hemophilia B difficult, and testing should also be repeated at 6 to 12 months of life.

Treatment for bleeding episodes is replacement of the specific factor and should be done as quickly as possible and in consultation with pediatric hematology, as there are a number of factor concentrates that are commercially available for both FVIII and factor IX deficiency (Table 67.5).[2] Many neonates do not require treatment during the neonatal period, as they may not manifest any bleeding symptoms. Adjuvant therapies for hemophilia, such as desmopressin, may increase factors to hemostatic levels, and can be useful for management of minor bleeding or procedures in patients with mild factor VIII deficiency. Desmopressin should be used with caution in infants, and only in conjunction with pediatric hematology, as use carries a risk of symptomatic hyponatremia.[2] Fresh frozen plasma (FFP) should only be used in the instance of acute hemorrhage when confirmatory testing is not yet available.[15,16] Any infant with concern for hemophilia and intracranial bleeding should receive immediate factor replacement as this can be life-threatening if not treated rapidly and appropriately.

von Willebrand Disease

The primary plasma protein required for platelet adhesion, vWF, also has a role in platelet aggregation and serves as the carrier for FVIII.[2] Absence, reduction, or abnormal function of vWF results in defects in platelet adhesion and aggregation, increasing one's risk for bleeding. The effectiveness of vWF as an adhesive protein relies on multimerization of the protein, resulting in very

TABLE 67.5 Treatment for Congenital/Acquired Bleeding Disorders

Factor	Replacement Therapy
Hemophilia A	Factor VIII concentrate
Hemophilia B	Factor IX concentrate
Fibrinogen	Fibrinogen concentrate FFP or cryoprecipitate if concentrate unavailable
Factor II	Prothrombin complex concentrate (if available) FFP if concentrate unavailable
Factor V	FFP
Factor VII	Recombinant factor VIIa or prothrombin complex concentrate (if available)
Factor X	Factor X concentrate (if available) FFP if concentrate unavailable
Factor XI	Factor XI concentrate (if available; use with caution) FFP if concentrate unavailable
Factor XIII	Plasma derived and recombinant (only for A subunit deletions) FXIII concentrate Cryoprecipitate if concentrate unavailable
Early vitamin K deficiency Classical vitamin K deficiency Late vitamin K deficiency	Parenteral vitamin K Prothrombin concentrates for active bleeding Recombinant factor VIIa for severe active bleeding
DIC*	FFP and cryoprecipitate, platelets
Liver disease*	Cryoprecipitate, FFP, prothrombin complex concentrates, platelets, vitamin K, recombinant factor VIIa

*Therapies for bleeding patients, not abnormal laboratory testing.
DIC, Disseminated intravascular coagulation; *FFP*, fresh frozen plasma; *FXIII*, factor XIII.

large molecules comprising what are known as high-molecular-weight multimers.[2] Neonates have higher plasma concentrations of vWF and an increased proportion of high-molecular-weight vWF multimers than older children or adults. As a result, presentation of von Willebrand disease (vWD) during the neonatal period is rare.[17]

The spectrum of vWD is presented in Table 67.6. Suspicion for vWD in a neonate requires specialized testing. Coagulation testing may demonstrate an isolated prolonged APTT and prolongation of epinephrine and ADP closure times as measured by the PFA-100. Further testing would evaluate the levels of vWF (vWF antigen assay), platelet-binding function (ristocetin cofactor assay), and FVIII-binding function (FVIII activity).[18,19] Assistance by a pediatric hematologist should occur if a diagnosis is suspected.[2]

The management of type 3 vWD should consist of factor replacement using an intermediate purity FVIII concentrate containing the high-molecular-weight multimers of vWF. Desmopressin should be reserved for those patients with type 1 vWD but, as noted above, should only be used after consultation with a pediatric hematologist, as it carries a risk of symptomatic hyponatremia in infants.[2]

TABLE 67.6 Spectrum of Neonatal von Willebrand Disease

Type	Description	Clinical Findings
1	Quantitative	Reduced amounts of vWF due to decreased production/secretion of vWF or increased clearance
3		Complete absence of vWF due to severe gene mutations*
2A	Qualitative	Defects in multimerization resulting in absence of large and medium-sized multimers
2B		Mutation that leads to increased binding of the high-molecular weight multimers to platelets
2M		Mutation leading to inability of vWF to bind to platelets
2N		Affects vWFs ability to bind to FVIII

*Highest potential for presentation during the neonatal period
vWD, von Willebrand Disease; *vWF*, von Willebrand factor; *FVIII*, factor VIII.

Other Rare Inherited Coagulation Disorders

There are other rare factor deficiencies, inherited as autosomal recessive, in 1 in 500,000 to 1 in 2,000,000 live births, representing 3% to 5% of all coagulation disorders.[20,21] A complete listing of the disorders and their potential symptoms are displayed in Table 67.4. Severe deficiencies of fibrinogen, factor VII, factor X, and factor XIII are the most likely (of the rare coagulation disorders) to present during the neonatal period. The majority of these deficiencies will present with an abnormality in the coagulation screen (see Table 67.3). Further testing for the specific abnormality will then confirm the diagnosis.[22] One must remember that newborn levels of many of these factors are lower at birth, and therefore diagnosis may be difficult and must be confirmed by 6 to 12 months of life. Treatment for the various deficiencies is shown in Table 67.5.

Factor XIII is composed of two subunits and cross-links with fibrin to stabilize clots. Factor XIII deficiency is extremely rare, with an incidence of one per 1 to 3 million people but can cause a range of bleeding symptoms in the neonatal period from skin or umbilical cord bleeding, to severe intracranial hemorrhage.[23] Low levels of factor XIII do not prolong the PT or APTT. Therefore, any neonate with concerns for a coagulation disorder that has a normal platelet count, normal fibrinogen levels, and normal PT and APTT values should be screened for factor XIII deficiency via a quantitative assay. Treatment of factor XIII deficiency is shown in Table 67.5.

Acquired Coagulation Disorders

Vitamin K Deficiency

Vitamin K is found in leafy green vegetables as vitamin K_1 (phytonadione) and is synthesized as vitamin K_2 in intestinal bacteria.[24]

It is an essential cofactor for the γ-carboxylation process of procoagulant factors II, VII, IX, and X and anticoagulant proteins C and S.[22] Insufficient bacterial colonization of the colon at birth, inadequate dietary intake in solely breastfed infants, poor intestinal absorption of vitamin K, and poor transfer across the placenta place neonates at risk for vitamin K deficiency bleeding (VKDB). Further, preterm infants are at higher risk for VKDB than term infants, due to hepatic and gut flora immaturity. The different forms of VKDB and their clinical presentation are shown in Table 67.4. Treatment is shown in Table 67.5.

Early VKDB may be due to maternal malabsorption disorders or maternal ingestion of oral medications which inhibit vitamin K such as warfarin, anticonvulsants, and antituberculosis agents. These agents cross the placenta and interfere with vitamin K metabolism. Classical VKDB occurs because of a physiologic deficiency in vitamin K at birth combined with a sole breast milk diet (low vitamin K in breast milk), inadequate vitamin K prophylaxis at birth, or inadequate feeding. Late VKDB presents in an infant that is either solely breastfed who receives an inadequate dose of vitamin K (none or one oral dose) or has an associated disease process that interferes with the absorption or supply of vitamin K such as diseases of malabsorption or cholestasis like diarrhea, cystic fibrosis, α_1-antitrypsin deficiency, biliary atresia, hepatitis, and celiac disease.[25,26] In the absence of vitamin K prophylaxis, the incidence of late VKDB is 4 to 10 per 100,000 births.[27] When intramuscular (IM) vitamin K prophylaxis is provided, the incidence of late VKDB decreases to 0.24 to 3.2 per 100,000 live births.[28]

If VKDB is suspected, coagulation screening should be performed and will usually demonstrate isolated prolongation of the PT, followed by prolongation of the APTT. The prolongation of the PT is usually out of proportion to the elevation of the APTT. Fibrinogen concentration and platelet counts will be normal. In addition, decreased concentrations of factors II, VII, IX, and X will occur. An alternative is to obtain an undercarboxylated or abnormal coagulation factor II measurement.[29] This factor is released into the bloodstream in the very early stages of vitamin K deficiency, and it can be detected well before changes in the PT become manifest. The adoption of this single test in clinical practice may improve the early diagnosis of VKDB, resulting in decreased incidences of intracranial hemorrhage (ICH).

When presented with a patient with suspected VKDB, parenteral treatment (intravenous, IM, or subcutaneous injection) with vitamin K should immediately occur. Improvement of the PT and APTT 2 to 6 hours after the administration of parenteral vitamin K will confirm the diagnosis. However, if a patient suspected of having VKDB presents with severe hemorrhage, additional therapy with prothrombin complex concentrates (contain all the vitamin K-dependent factors; not available at every institution; use FFP if not available) aimed at immediate correction of factor deficiencies should occur.[2] Additionally, recombinant factor VIIa can be used in the treatment of severe intracranial hemorrhage due to vitamin K deficiency.

Common practice in the United States is to provide all infants 1.0 mg (0.3 mg/kg for infants <1000 g and 0.5 mg for infants >1000 g but <32 weeks' gestation) of IM vitamin K on the first day of life.[24] This single dose has been found to prevent both classical and late VKDB, even in infants with cholestatic jaundice.[30,31] The safety of IM vitamin K has been questioned because of the reported association between IM vitamin K administration in newborns and an increased incidence of childhood cancer.[32,33] Further studies have concluded no association between IM vitamin K and childhood leukemia or other cancers.[34] Further research has suggested a prenatal origin of childhood leukemia, further weakening the plausibility of a causal relationship between IM vitamin K and cancer.[35]

Proper oral administration of vitamin K has been shown to have an efficacy similar to that of IM vitamin K in the prevention of early and classical VKDB.[36,37] However, cases of late VKDB began to increase and surveillance data from four countries revealed oral prophylaxis failures of 1.2 to 1.8 per 100,000 live births,[38] with higher rates of 2 to 4 per 100,000 cases when incomplete oral dosing was observed. More recent data have demonstrated that weekly or daily oral dosing of vitamin K until 3 months of age protects almost all babies from VKDB, and late VKDB remains confined to breastfed infants who received no vitamin K or just one oral dose. [39,40]

A more recent study evaluated the association of VKDB in breastfed infants with unrecognized biliary atresia and oral versus IM dosing of vitamin K.[41] Of 91 breastfed infants diagnosed with biliary atresia, 25 received a 2-mg IM dose after birth compared with 55 and 11 infants receiving 25-μg and 150-μg oral daily dosing, respectively; 4% of the infants that received IM dosing experienced vitamin K deficiency bleeding compared with 82% (both groups) of the infants that received only oral dosing. More importantly, 0% of the infants who received IM dosing experienced ICH compared with 40% and 27%, respectively, in the oral dosing groups.[41] Thus, a single dose of IM vitamin K at birth remains standard of care for preventing vitamin K deficiency bleeding; but repeated oral vitamin K until 3 months of age is an option for those who decline or refuse the IM dose.

Disseminated Intravascular Coagulation

A complex process involving the activation and dysregulation of the coagulation and inflammatory systems, disseminated intravascular coagulation (DIC), results in massive thrombin generation with widespread fibrin deposition and consumption of coagulation proteins and platelets, ultimately leading to multiorgan damage and hemorrhage.[12] DIC always occurs as a secondary event, and many perinatal and neonatal problems are associated with its development. These include birth asphyxia, respiratory distress syndrome, meconium aspiration syndrome, infection, necrotizing enterocolitis, hypothermia, severe placental insufficiency, homozygous protein C/S deficiency, and thrombosis.[12]

The diagnosis of DIC is made in an ill neonate with supporting laboratory parameters (see Table 67.3). The most important aspect of treatment for DIC is to treat the underlying disorder. However, once DIC is established, it can be difficult to control.[12] The focus of acute management in the neonate is to support adequate hemostasis to reduce the risk of spontaneous hemorrhage. This is usually achieved with platelet transfusions, FFP, and/or cryoprecipitate.[42] Another option is to inhibit the activation of the coagulation system using heparin. However, trials in neonates have not been conclusive, and the risk of bleeding may be increased, so this is generally not advised.[43,44]

Liver Disease

Acute liver disease is rare in the neonatal population. Illnesses that can lead to acute liver failure include congenital heart disease with low cardiac output, birth asphyxia, extrahepatic biliary atresia, inborn errors of metabolism, hemophagocytic syndromes, and viral hepatitis. Mechanisms contributing to hemostatic abnormalities include decreased synthesis of coagulation factors, activation of the coagulation and fibrinolytic systems, poor clearance of activated hemostatic components, loss of coagulation proteins into ascitic fluid, thrombocytopenia, platelet dysfunction, and vitamin

K deficiency.[44] The diagnosis of acute liver disease in the neonate should include elevated liver enzymes, direct hyperbilirubinemia, prolonged PT and APTT, thrombocytopenia, elevated ammonia concentrations, decreased fibrinogen levels, and decreased concentrations of factors VII and V (see Table 67.3). A normal FVIII concentration, reflecting extrahepatic synthesis, can help distinguish primary liver disease from DIC.[44] Treatment, in addition to treating the underlying cause of liver disease (if able), includes prothrombin complex concentrates (if available),[2] cryoprecipitate (if fibrinogen is low), FFP, recombinant factor VIIa (for severe bleeding not responsive to platelets and plasma products), platelets, and vitamin K.

Neonatal Thrombosis

Epidemiology

Neonatal TE is becoming an increasingly recognized condition due to improved diagnostic modalities and the survival of the smallest and sickest neonates. The exact incidence of neonatal TE varies with the most recent centers reporting 6.9 to 15 per 1000 NICU admissions.[45] Thromboses occur in both term and preterm infants, with a slight predominance in male neonates.[45] The majority of venous thromboses in neonates are associated with central venous catheters (CVCs).[46] The recurrence rate for neonatal TE remains low and ranges from 3.3% to 7%.[47]

Risk Factors for Neonatal Thromboembolism

Hypercoagulability, disturbances in blood flow, and endothelial damage/disruption (Virchow triad) all pertain in some degree to neonates admitted to the NICU.[2] Therefore, it is understandable that neonates have the highest rate of TE events among pediatric patients. As demonstrated in Table 67.1, neonates, particularly premature neonates, are deficient in the anticoagulant proteins, especially protein C and protein S. Prothrombotic disorders may also be present, shifting the neonate into a hypercoagulable state. Hypovolemic, septic, or cardiogenic shock may affect an ill neonate, resulting in hypotension and thus disrupting blood flow to vital organs. Polycythemia or certain cardiac lesions may also result in sluggish blood flow and/or hyperviscosity, increasing the risk for thrombosis. However, the presence of CVC and arterial catheters is by far the greatest acquired risk for the development of TE in neonates.[46] Insertion, infusion of hyperosmolar substances, and length of time that a catheter remains in place may disrupt the endothelium, increasing the risk for thrombosis. The effects of different types of catheter materials, catheter design, and lumen number have been evaluated. These reviews have demonstrated that fewer thrombotic complications were associated with end-hole umbilical arterial catheters (UACs).[48–51] Risk factors that have been implicated in neonatal TE are shown in Table 67.2.

Prothrombotic Disorders: Pathophysiology and Their Role in Neonatal Thromboembolism

A genetic mutation resulting in the complete absence or severe deficiency of an inhibitor of hemostasis, the production of an inhibitor of hemostasis that has inadequate function despite normal levels, or an overproduction of a procoagulant protein or cofactor greatly increases a neonate's risk for TE. The more severe the mutation, the greater the risk for the development of severe thrombosis. Homozygous prothrombotic disorders, such as severe protein C, protein S, or ATIII deficiency, usually present in newborns with severe clinical manifestations, mainly purpura fulminans.[52] The inheritance of a heterozygous prothrombotic mutation and a neonate's risk for symptomatic TE is less well defined.[53] Despite having a heterozygote prothrombotic mutation, a neonate may never experience a symptomatic TE event, thus demonstrating that the inheritance of a prothrombotic trait does not guarantee a symptomatic TE event. Other acquired risk factors (see Table 67.2) are usually present. Prothrombotic disorders that have been associated with neonatal TE are shown in Box 67.1.

Neonatal registries have demonstrated that greater than 80% of neonates with symptomatic thromboses have acquired risk factors present (see Table 67.2).[53,54] Therefore, it appears that the combination of acquired factors, and the presence of a prothrombotic mutation, may represent the perfect storm for neonatal TE.[54] Registry data and other case studies have demonstrated that the majority of symptomatic neonatal TE events stem either from the association of multiple prothrombotic defects or the combination of prothrombotic defects and environmental or clinical conditions.[55–61] It is therefore currently recommended that pediatric patients, including neonates, with thrombosis (regardless of other acquired risk factors), be tested for prothrombotic traits (see Box 67.1).[62,63] A more detailed laboratory approach is presented later.

The most common prothrombotic disorder is the factor V Leiden mutation, which reduces the inactivation of activated factor V by its regulator, activated protein C.[64] Heterozygous mutations affect about 5% of the Caucasian population, and confer a 5-fold increased TE risk in adults.[65] The presence of the prothrombin 20210 mutation has the potential to increase circulating concentrations of prothrombin by 15% to 30%.[66,67] The exact role regarding mutations in the methylenetetrahydrofolate reductase (MTHFR) enzyme and risk for neonatal TE remains unclear.[68] The mutation results in a defect in the remethylation of homocysteine into methionine, with the end result being hyperhomocysteinemia. Increased levels of homocysteine have been speculated as an increased risk for premature vascular disease and arterial thrombosis.[61,69] However, most studies have associated an increased risk for thrombosis because of elevated homocysteine levels (kidney damage) and not with the genetic mutation. Thus, the *MTHFR* gene mutation and the risk of neonatal arterial thrombosis remain controversial.[70,71]

The activated protein C system, consisting of protein C plus protein S and factor V as cofactors, cleaves and inactivates factors V and VIII. Mutations that affect the quantity or quality of these proteins may contribute to an increase in neonatal venous thrombosis. ATIII, when bound to heparin sulfate, inhibits thrombin and activated factors IX, X, and XI. Mutations may result in deficiencies in ATIII production, increasing thrombosis risk.[72] Elevations in lipoprotein(a) (reduces fibrinolytic capacity) have been implicated as a significant risk factor for both venous and arterial thrombosis in the German and Dutch registries; however, generalizing these findings to all populations remains unclear.[73,74] Lupus anticoagulant, anticardiolipin antibody, anti-β_2-glycoprotein-I antibodies, and other maternal antiphospholipid antibodies may play a role in neonatal TE, especially neonatal stroke. These antibodies either lead to thromboses in the placenta or are transported across the placenta and may serve as a nidus for thrombosis formation.[75–77] A recent review of 16 infants with a history of maternal antiphospholipid antibodies and perinatal thrombosis found that 13/16 had arterial thromboses, with 8/16 presenting as strokes. Therefore, mothers of and/or infants with

significant arterial or venous TE events should be screened for the presence of antiphospholipid antibodies.[78]

Locations of Neonatal Thromboses, Imaging Modalities to Diagnose Them, and Management Guidelines for Specific Thromboses

Neonatal TE events may occur in a variety of locations and are usually identified by proper imaging modalities (Table 67.7). Difficult intravenous access, desire to limit radiation exposure, lower glomerular filtration rates, and inaccessibility to perform specific testing at the bedside limit neonatal use of many of the gold standard techniques used in adults and children.[79] Therefore, doppler ultrasonography is the most widely and safely used modality. The small diameter of certain vessels, low pulse pressure, and the presence of a CVC at the site of thrombus may limit interpretation of the results.[79]

Arterial Thromboses

Neonatal Arterial Ischemic Stroke

The majority of neonatal arterial TE events are represented by neonatal arterial ischemic stroke (NAIS). Neonatal stroke (NS) refers to a cerebrovascular incident causing interruption of blood flow that presents in the first 28 days postnatally and is confirmed by neuroimaging or pathological studies.[80] The subcategories of neonatal stroke and their presenting symptoms are displayed in Table 67.8.[81,82] Arterial stroke in neonates is referred to as NAIS for the remainder of the chapter (cerebral sinovenous thromboses are presented later). NAIS refers to a condition with acute encephalopathy, seizures, or neurologic deficits presenting in the term or preterm infant before the 29th postnatal day, with brain imaging confirming a parenchymal infarct in the appropriate arterial territory (Fig. 67.1).[82,83] NAIS is responsible for 22% to 70% of congenital hemiplegic cerebral palsy in neonates,[75,84,85] as well as other neurologic comorbidities, including seizure disorders, delayed language development, and behavioral disorders.[86]

TABLE 67.7 Locations of Neonatal Thromboses and the Best Imaging Modalities to Diagnose Them

Vessel	Type of Thromboses *(Vessels Potentially Involved)*	Imaging Modality
Arterial	Perinatal arterial ischemic stroke *(Left middle cerebral artery, anterior cerebral artery, posterior cerebral artery)*	Diffusion-weighted MRI/MRA
	Iatrogenic *(Abdominal aorta, radial artery, renal artery, mesenteric artery, popliteal artery)*	Doppler ultrasound
	Spontaneous *(Iliac artery, left pulmonary artery, aortic arch, descending aorta, renal artery)*	
Venous	Iatrogenic/spontaneous vessel occlusion *(SVC, IVC, hepatic vein, subclavian vein, abdominal veins, peripheral veins)*	
	Renal vein	
	Portal vein	
	Cerebral sinovenous *(Superior sagittal sinus, transverse sinuses of the superficial venous system, straight sinus of the deep system)*	Diffusion-weighted MRI w/ venography
	Congenital heart disease related *(Right/left atria, right/left ventricle, SVC, IVC)*	Echocardiography

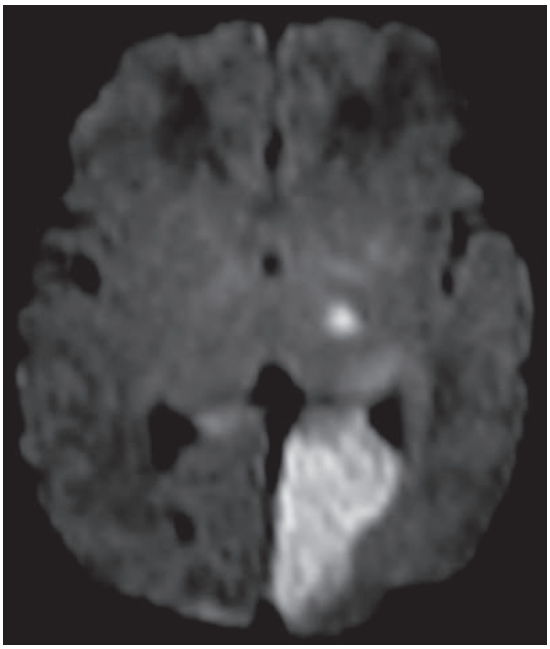
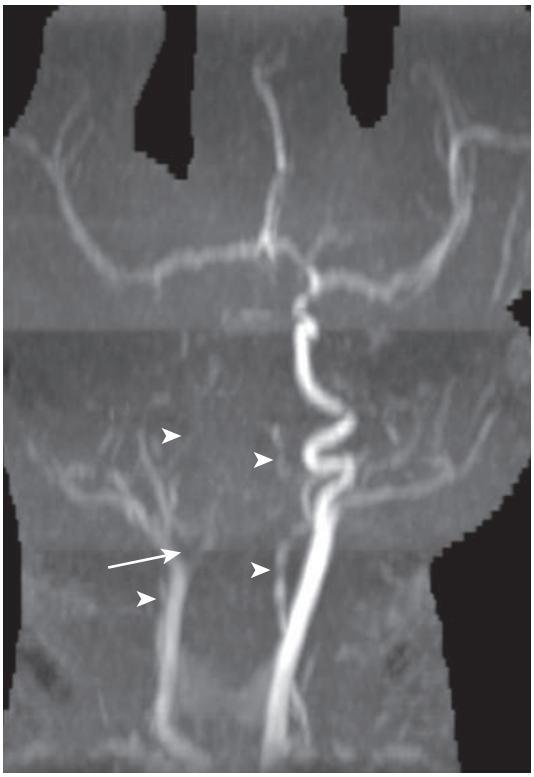
TABLE 67.8 Subcategories of Neonatal Stroke

Subcategory	Description	Symptoms
Neonatal arterial ischemic stroke	Occurs after birth but before 29th day of life	Seizures (focal), apnea, chewing or bicycling movements, persistent feeding difficulties
Perinatal arterial ischemic stroke	Difficult to establish whether stroke occurred before, during, or after childbirth but occurs from 20 weeks' gestational age until birth	
Neonatal hemorrhagic stroke	Predominant signal intensity is blood with no underlying vascular lesion or bleeding abnormality	
Neonatal cerebral sinovenous thrombosis		Seizures, apnea, lethargy, irritability, poor feeding, jitteriness, thrombocytopenia, anemia, changes in muscle tone

References 75,81,82,87,93,176,177.



• **Fig. 67.1** Axial diffusion-weighted MRI demonstrating areas of high signal in bilateral frontal and parietal lobes, left occipital lobe, left thalamus, and left pons.



• **Fig. 67.2** Three-dimensional (3D) maximum intensity projection image from 3D time-of-flight MRA demonstrates occlusion of the right internal carotid artery at its origin *(arrow)*. The vertebral arteries are diminutive *(arrowheads)*, and the basilar artery is not visualized.

The incidence of NAIS ranges from 25 to 35 per 100,000 live births.[81,87] Most abnormalities occur in the left hemisphere within the distribution of the middle cerebral artery, with anterior and posterior cerebral artery lesions being less common.[75,88] The origin of the left carotid artery from the aorta allows a more direct vascular route to the brain as a corridor for cardiac emboli. Rarely, multifocal cerebral infarctions can occur, and these tend to be embolic in origin (Fig. 67.2). Many potential risk factors have been implicated in the etiology of NAIS (see Table 67.2).

Placental pathology is a major risk factor for NAIS. Maternal/fetal conditions that may result in decreased placental reserve, thromboinflammatory processes leading to placental blood vessel thrombosis, and sudden catastrophic events may result in emboli that break off from the placental circulation and enter the fetal circulation, passing through a patent foramen ovale with a predilection to enter the left middle cerebral artery.[89]

Prothrombotic disorders (see Box 67.1) may have a role in NAIS as results have varied in population-based studies.[81,90] In a study of 91 full-term neonates with NAIS, prothrombotic risk factors, most commonly lipoprotein(a), were identified in 68% of these neonates compared with 25% in controls.[91] A more recent study of 27 neonates with NAIS did not identify any prothrombotic disorders.[81]

There are no randomized clinical trials addressing the management of neonates with NAIS. Current guidelines from the American College of Chest Physicians recommend anticoagulation for neonates with NAIS if there is an ongoing cardioembolic source or if there is evidence of recurrent NAIS. Otherwise, supportive care is recommended.[92,93] Treatment, if necessary, ultimately depends on the acute clinical situation and the specific hemorrhagic risks for that neonate.

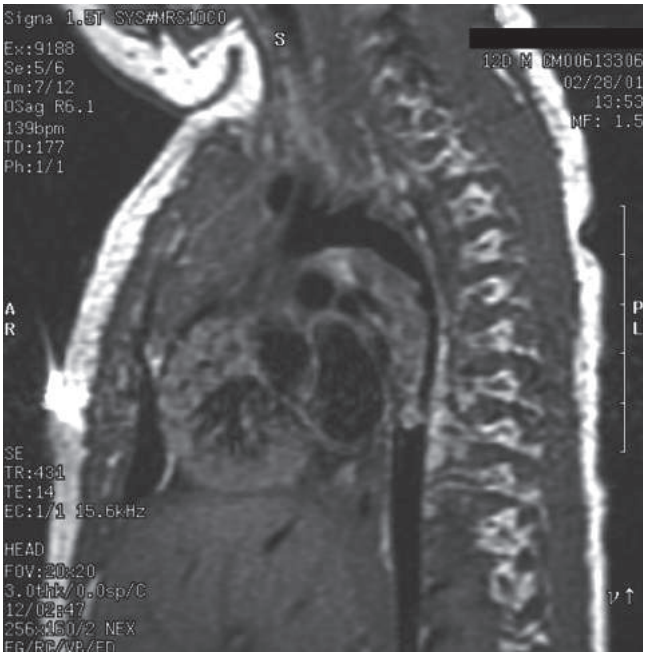
Magnetic resonance imaging (MRI) with diffusion-weighted imaging (DW MRI) is the most sensitive technique for the early detection of NAIS.[94] This technique allows for the detection of cerebral edema, which is an early sign of cerebral ischemic damage.[95,96] Angiography allows for the detection of thromboses if there is a history of instrumentation/difficult delivery. Although cranial ultrasound (CUS) is the least-invasive method for diagnosing NAIS, it is also the least sensitive. One study found that 75% of cases of neonatal NAIS were missed when CUS was used.[97] Therefore NAIS should never be excluded in any neonate based on negative CUS results.

Iatrogenic/Spontaneous Arterial Thromboses

Used for continuous monitoring of arterial blood pressure and blood gases, umbilical arterial catheters (UACs) and peripheral arterial lines (PALs) are frequently used in ill neonates admitted to the NICU. Approximately 10% to 64% of newborns admitted to the NICU require placement of a UAC.[4] Femoral arterial catheters are used less frequently but are more commonly used in neonates with congenital heart disease or those requiring extensive surgery. Despite their important role, one must remember that complications from arterial catheters can occur and range from line dysfunction/infection to limb-/organ-threatening ischemia, as demonstrated in Figs. 67.3–67.5.

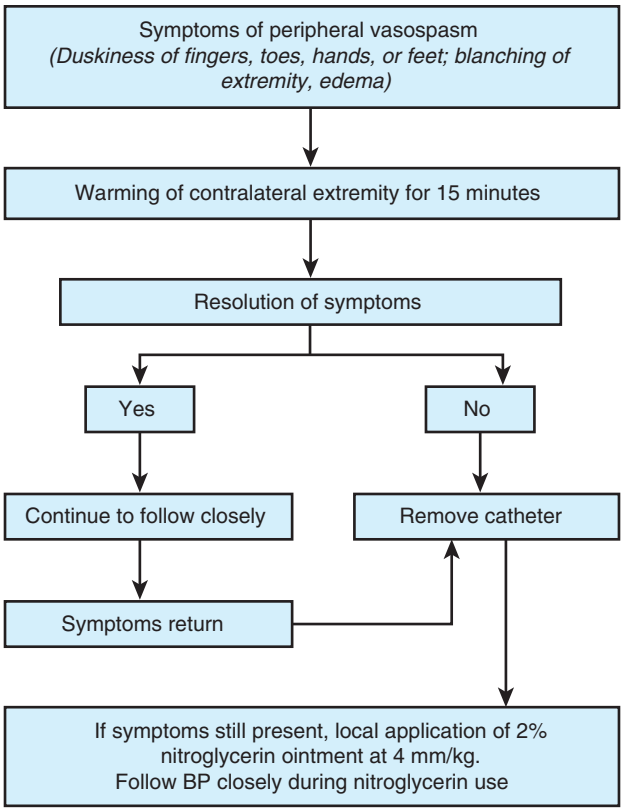
The incidence of arterial thromboses from UACs based on autopsy reports has ranged from 9% to 28%,[98] whereas the incidence of PAL-related thromboses is unknown. Potential short-term and long-term complications of UACs include mesenteric ischemia, hypertension, renal dysfunction/failure, limb loss, and congestive heart failure.[99,100] High UAC positioning (T6-9) has been found to have fewer clinical complications,[51] while low-dose continuous heparin infusion at 1 U/mL prolongs catheter patency but does not reduce the risk of thrombosis.[50] Clinical signs of PAL-related thrombosis include limb ischemia, pale or cold extremities distal to the cannulation site, weak or absent pulse, and decreased

• **Fig. 67.3** Arterial thrombosis with skin necrosis.



• **Fig. 67.4** Aortic thrombus diagnosed by MRI.

• **Fig. 67.5** Arterial thrombosis of digital artery.



• **Fig. 67.6** Management of peripheral vasospasm. Current recommendations for the evaluation and management for neonates with peripheral vasospasm caused by complications from peripheral arterial lines and umbilical arterial catheters. Nitroglycerin dosing is provided. *BP*, Blood pressure.

or immeasurable blood pressure (see Fig. 67.5).[101] Catheter material, duration of placement, and solutions infused influence the risk for both UAC-related and PAL-related thrombosis.

Suspicion or confirmation of an arterial thrombosis should warrant immediate removal of the arterial catheter. Vascular spasm may occur, and removal of the catheter may simply resolve symptoms. If symptoms of spasm persist, further actions are needed. An approach to the neonate with vascular spasm is shown in Fig. 67.6. If thrombosis is suspected, the most sensitive method to diagnose an arterial catheter-related thrombosis is contrast angiography,[102] but because of its risk in neonates, it is generally reserved for older children and adults. As a result, Doppler ultrasound is mainly employed in neonates.

Management options for neonates with a UAC and peripheral arterial catheter or femoral arterial catheter-related TE event are to (1) remove the catheter and provide supportive care, (2) administer anticoagulation following catheter removal if there are non-limb-threatening symptoms, or (3) attempt thrombolysis if there are limb-threatening symptoms.[92]

Venous Thrombosis

The biggest risk for the development of venous thromboses in neonates admitted to the NICU is the presence of a CVC. Additional risk factors (see Table 67.2) combined with the presence of a CVC further increase this risk.

Catheter-Related Venous Thrombosis (Umbilical Venous Catheters and Peripherally Inserted Central Venous Catheters)

Premature and sick newborns greatly benefit from CVCs. Infusion of life-saving medications and enhanced nutrition lead to better outcomes, but risks for thrombosis, infection, malfunction, and death exist. Those caring for neonates admitted to the NICU must weigh the benefit versus the risk every day that a CVC remains in place, and the catheter should be removed as soon as necessary. Damage to blood vessel walls during insertion, disrupted blood flow, infusion of substances that damage endothelium, and thrombogenic catheter materials are the main reasons that thromboses develop.[103,104]

Neonates, especially very low birth weight infants (<1500 g), routinely have umbilical venous catheters (UVCs) placed during the first few days of life as peripheral access may be difficult to secure. Despite their clinical importance, UVCs represent the most common cause for thrombosis in premature infants.[79] Appropriate catheter position is vital to avoid severe complications.[105] The exact incidence of UVC-related thrombosis varies, but reports have ranged from 21% to 71% (dependent on how aggressive centers screened for asymptomatic thrombosis) and include portal vein, renal vein, and inferior vena cava (IVC) thrombosis.[103] Autopsy studies have estimated that 20% to 65% of infants who die with a UVC in situ have microscopic evidence of TE.[106,107] Intracardiac thrombosis from UVC placement ranges from 1.8% to 5.3%.[103]

Clinical signs and symptoms suggestive of a UVC-related thrombosis include persistent infection, persistent thrombocytopenia, line dysfunction, and bilateral lower limb edema (Fig. 67.7).[92] The Centers for Disease Control and Prevention recommend that use of UVCs be limited to 14 days.[108] A randomized trial comparing long-term UVC (up to 28 days) use with short-term (7 to 10 days) use followed by peripheral central venous line placement demonstrated that 4% of neonates in the short-term group, compared with 7% of neonates in the long-term group, developed significant thromboses (detected by echocardiogram). However, all of the thrombi were at the site of the UVC tip, and none of the neonates required treatment.[109] Most centers remove UVCs within 7 days of placement, but malpositioned lines should be removed as soon as possible.

To enhance nutrition, and to administer long-term parenteral medications, peripherally inserted central venous catheters (PCVCs), or surgically placed CVCs, are routinely placed in preterm and ill neonates. These lines tend to remain in place for weeks until treatment is finished or an infant reaches full enteral feedings. Clinical signs of PCVC and surgically placed CVC-related thrombosis include unilateral limb swelling/pain/discoloration, superior vena cava syndrome, chylothorax, chylopericardium, intracardiac thrombosis, unresolving sepsis, thrombocytopenia, and cardiac failure.[55,79,110]

• **Fig. 67.7** Femoral deep vein thrombus. Note the swollen leg, with venous congestion pattern on the skin.

The gold standard for diagnosing venous TE is MR (magnetic resonance) venogram; however, this modality is difficult to perform in neonates.[102] Ultrasound is therefore the most widely and safely used modality. False-negative results often occur when evaluating for thromboses in the upper central venous system because of obstruction of the distal subclavian veins by the clavicles. In addition, compression of veins in a central location by the probe is not feasible because of the neonate's rib cage.[44]

Long-term complications of venous TE include chronic venous obstruction with prominent cutaneous collateral circulation, chylothorax, portal hypertension, and embolism. More children are now presenting with postthrombotic syndrome who had a previous history of a neonatal venous TE.

Management options for CVC-related thromboses are displayed in Table 67.9 and depend on whether the CVC is vital for patient care and/or the neonate is symptomatic. If anticoagulation is used, it should continue until there is resolution of the thrombus. Treatment may last from 2 weeks to 3 months, depending on the size, location, and symptoms of the thrombus.[92]

Intracardiac Thromboses and Thromboses in Infants With Complex Congenital Heart Disease

The placement of a CVC into the right atrium may lead to damage of the endocardium, inducing either pericardial tamponade and/or the development of intracardiac thrombi. The development of intracardiac vegetations secondary to CVC infections may expose an infant to prolonged infection and dissemination of septic emboli. Thrombus formation in the right atrium and superior vena cava has been associated with a high endocarditis risk, sepsis persistence, pulmonary artery obstruction, ventricular dysfunction, acute hemodynamic compromise, and death.[56,111–113]

Thrombosis is a common complication reported in neonates undergoing repair for complex congenital heart disease.[114,115] Less is known about neonates undergoing initial palliative procedures for single ventricle physiology. A retrospective review of neonates who underwent palliative repair found that in patients who died and had autopsies available, 33% of deaths were attributable to thrombosis.[116] A more recent review of 22 neonates who underwent palliative repair between 1 and 11 days of life found evidence of thrombi in five infants (23%).[115]

A recent case-control study performed at a high-level referral NICU demonstrated an incidence of intracardiac thrombosis of 22.5 cases per 1000 admissions.[113] Many of these infants were critically ill and had complex congenital heart disease. Major risk factors from this study included prematurity, maternal history of gestational diabetes/diabetes mellitus, surgical cut-down technique to place a CVC, and *Staphylococcus epidermidis* infection. In addition, almost one-quarter of these infants died despite receiving treatment for the thrombosis.[113]

Echocardiography is the preferred modality for diagnosing either right atrial thrombus formation, intracardiac vegetations, or thrombus formation in infants with single ventricle physiology. Signs suggestive of an atrial thrombus include new-onset murmur, persistent sepsis, persistent thrombocytopenia, and cardiac failure. A surgical approach to remove the thrombus in neonates

TABLE 67.9 Recommendations for Central Venous Catheter-Related Thromboses

	Vital for Patient Care*	Symptomatic	Worsening	Recommendation
CVC	Yes	Yes	No	Initiate anticoagulation; no removal of the catheter
	Yes	Yes	Yes	May remove catheter vs continue to use catheter but anticoagulation should have already been initiated
	No	Yes	N/A	Initiate anticoagulation for 3–5 days prior to removal of the catheter
	No	No	N/A	Immediate removal of the catheter

*Assumed that catheter is still functioning; if not functioning, considered nonessential.

TABLE 67.10 Management of Renal Vein Thrombosis (RVT), Portal Venous Thrombosis (PVT), and Cerebral Sinovenous Thrombosis (CSVT)

TE		Clinical Description	Treatment/Monitoring
RVT	Unilateral or bilateral (symptomatic)	Normal renal function	Anticoagulation
		Renal failure	Initial thrombolytic therapy with rt-TPA, followed by anticoagulation
PVT		Nonocclusive thrombus and no evidence of portal hypertension	Observation with repeat US in 10-days
		Occlusive thrombus (extension into the IVC, RA, and/or RV)	Anticoagulation *rTPA with UFH may be considered if there is evidence of end-organ compromise*
CSVT		Evidence of CSVT and infant symptomatic	Anticoagulation Repeat MRI and MRV in 6 weeks for vessel recanalization. If complete, stop therapy. If not, consider 6+ weeks of treatment

IVC, Inferior vena cava; *MRI*, magnetic resonance imaging; *MRV*, magnetic resonance venography; *RA*, right atrium; *rt-TPA*, recombinant tissue type plasminogen activator; *RV*, right ventricle; *TE*, Thromboembolism; *UFH*, Unfractionated heparin; *US*, ultrasound.

is not feasible, especially the premature infant. There have been case reports using recombinant tissue type plasminogen activator (rt-TPA) for thrombolysis of catheter-related atrial thrombus in the neonate.[111,117–120] rt-TPA has also been used successfully in the management of premature infants with infective endocarditis.[121]

Renal Vein Thrombosis

The renal vein is the most common location for spontaneous venous TE in neonates,[56] with most cases presenting during the first month of life.[122,123] The most recent population-based cohort study demonstrated an annual incidence of 2.6 per 100,000 live births.[124] Reviews of neonatal renal vein thrombosis (RVT) cases have demonstrated that 70% were unilateral, with 64% of these involving the left kidney, and males were more frequently affected.[123,125,126] The classic triad of signs and symptoms suggesting RVT are macroscopic hematuria, a palpable abdominal mass, and thrombocytopenia, although varying numbers of neonates presenting with these exact three symptoms varies.[45,125] Other symptoms include oliguria, proteinuria, acute renal failure, and hypertension. Risk factors (shown in Table 67.2) are frequently found in RVT cases, with prematurity and perinatal asphyxia being the most common.[125] Prothrombotic risk factors have been found in varying numbers of neonatal cases of RVT, with studies finding at least one prothrombotic risk factor in 17% to 67% of cases.[123,125,127,128] Because of the potential association of prothrombotic disorders and RVT, an evaluation for an inherited thrombophilia is warranted.

The diagnosis of RVT is usually made via Doppler ultrasound. Radiographic criteria for RVT include presence of echogenic clot, venous distention secondary to the presence of a thrombus, or absence of flow.[125]

The treatment for RVT is controversial, as there are no large randomized clinical trials addressing the issue. However, complications of RVT are serious and include adrenal hemorrhage, extension of the clot into the IVC, renal failure, hypertension, and death.[123] A recent cohort study demonstrated a 12.3-fold increased risk of chronic kidney disease or death and a 15.7-fold increased risk for hypertension.[124] The most recent treatment recommendations based on observational and case series and expert opinion are shown in Table 67.10.[129]

Portal Vein Thrombosis

The two main risk factors for the development of portal vein thrombosis (PVT) in neonates are sepsis/omphalitis and UVC use.[130] Most cases of PVT are isolated to the left portal vein, but some involve the right or main portal vein and extend into the inferior vena cava.[130] PVT tends to be clinically silent, making the diagnosis difficult. Incidences vary (because of aggressiveness of imaging in asymptomatic patients following UVC use) between 1% and 75%.[130–133] Ultrasound is the preferred modality for diagnosis, and findings of cavernous transformation of the portal vein with subsequent splenomegaly and reversal of portal flow are used to document its severity.[130] Spontaneous resolution of asymptomatic PVT is relatively common, but the detection of PVT, even in asymptomatic patients, warrants close observation to follow for signs of portal hypertension.[45] This complication may manifest itself up to 10 years after the neonatal period.[130,134] Management options, based on limited clinical data, are provided in Table 67.10.[129,130]

Cerebral Sinovenous Thrombosis

Cerebral sinovenous thrombosis (CSVT) represents a subcategory of neonatal stroke[81] with symptoms being like those with NAIS (see Table 67.8).[81,135] Anemia and/or thrombocytopenia may accompany these symptoms. The incidence of CSVT ranges from 3 to 12 per 100,000 live births.[136,137] A review of neonates with CSVT demonstrated that 90% of children who presented with CSVT had predisposing risk factors (see Table 67.2 and Box 67.1), with 16% of these patients having multiple risk factors.[90,135] The most common risk factors were infections (40%), perinatal complications (25%), and prothrombotic traits (13%).[135] More recent studies have reported CSVT in neonates following therapeutic hypothermia[138] and cardiac surgery.[139]

The superficial and lateral sinuses are the most frequently involved vessels,[75] and up to 30% of cases have reported venous infarction with subsequent hemorrhage.[140] Impaired or absent venous drainage in one of the cerebral sinuses leads to increased venous pressure, vasogenic edema, and secondary infarction. Intraventricular hemorrhages (especially in term neonates) and hemorrhages within the caudate nucleus and thalamus are associated with thrombosis of the deep cerebral venous sinuses. Therefore, the presence of an intraventricular hemorrhage or thalamic hemorrhage in a term or late preterm infant warrants exclusion of CSVT.[140] Diagnosis of CSVT is best made through diffusion MRI with venography.[63,79,92,141]

Neonatal CSVT mortality rates have ranged from 2% to 24%.[142] Long-term follow-up of neonates diagnosed with CSVT has demonstrated neurologic deficits, consisting of cerebral palsy, epilepsy, and cognitive impairments in 10% to 80% of infants.[142,143]

The role of anticoagulation for CSVT remains controversial, and recommendations for management are not based on clinical trials.[129,143] Current treatment recommendations are shown in Table 67.10. Surgery is reserved for those with hydrocephalus or large intracerebral hematomas with mass effect.

Evaluation of Neonatal Thromboses

The question remains whether every neonate diagnosed with a clinically significant thrombosis should have a full evaluation for a prothrombotic disorder (see Box 67.1). Does the presence of acquired risk factors (see Table 67.2) provide enough risk to avoid searching for a possible prothrombotic trait? Does a critically ill neonate with a CVC-related venous thrombosis warrant a full prothrombotic evaluation?[102,144,145] Definitive answers to these questions remain unknown, but based on the current evidence from data registries, case series, case reports, and expert opinion, a stepwise investigation for a prothrombotic disorder should be performed based on the type and severity of the thrombosis and the number of acquired risk factors. Timing of the evaluation is important, with certain aspects being performed immediately following an acute event, and other aspects being performed at 3 to 6 months of life. Key points and a comprehensive laboratory evaluation based on acquired risk factors are listed in Table 67.11 and Box 67.2. The clinician may choose to add or delete tests based on the presentation, family history, or timeframe of the event.

The large amount of blood that traditionally has been required to perform this evaluation has always been a criticism; therefore, the evaluation should take place at an experienced tertiary care center that has the ability to perform these tests.[120] This approach dramatically reduces the amount of blood required, as it is specifically designed for neonates. Although anticoagulation treatment is not usually started based on a prothrombotic evaluation, the identification of a disorder may help prevent future thromboses during childhood and adolescence. Anticoagulation before certain medical or surgical procedures may help to avoid the development of a significant thrombosis and truly be beneficial to the future health of the patient.

Management of Arterial and Venous Thromboses

The use of anticoagulant/fibrinolytic therapy in the NICU carries the significant risk for bleeding, especially ICH. Many clinicians are hesitant to start therapy, even when the benefits outweigh the risks. Specific neonatal formulations for antithrombotic agents are limited, making accurate and reproducible weight-adjusted dosing difficult.[92,129]

The majority of recommendations and dosing regimens for anticoagulant/fibrinolytic therapy in neonates are based on case series, cohort studies, and expert opinion. The goals for fibrinolysis are restoration of blood flow, preserving organ function, and preventing catastrophic long-term complications, including death. The goals for anticoagulation are prevention of recurrent thromboses and serious sequelae from embolism.[146] Before initiating any therapy, serious complications must be considered, and the treatment's benefits must outweigh its risks, especially in the premature infant. Family discussions highlighting the risks and goals for treatment must be documented before initiating any therapy. Treatment should occur at a tertiary care center that has proper laboratory, blood bank, pharmacy, pediatric radiological subspecialty, pediatric hematological subspecialty, and pediatric surgical support.[92,120] The clinician should refer to the most recent guidelines,[46,129] or may use the service 1-800-NO CLOTS to receive up-to-date management guidance. Before initiating any treatment, absolute and relative contraindications to antithrombotic therapy should be reviewed (Table 67.12).

Unfractionated Heparin

The use of unfractionated heparin (UFH) should be limited to clinically symptomatic thromboses that are not life or limb threatening. UFH achieves its main anticoagulant effect by binding to antithrombin, catalyzing its ability to inactivate thrombin and factor Xa.[147] The dosing of UFH in neonates is affected by

TABLE 67.11 Evaluation for Prothrombotic Disorder

Laboratory Testing If Other Acquired Risk Factors Present	Laboratory Testing If Other Acquired Risk Factors Not Present

*May be performed from maternal serum during first few months of life.
†Protein-based assays are affected by the acute thrombosis and must be repeated at 3 to 6 months of life, before a definitive diagnosis may be made. Therefore, recommend that complete evaluation (excluding DNA-based assays) be performed at 3 to 6 months of life.[140,164] If anticoagulation is being administered, then these assays should be obtained 14 to 30 days after discontinuing the anticoagulant. Lipoprotein(a) levels may need to be repeated at 8 to 12 months of life.

• BOX 67.2 Key Points Regarding the Laboratory Evaluation for a Prothrombotic Disorder

- Because of many of the pro/anticoagulation protein levels being lower than adult values, the diagnosis of a coagulation disorder may be difficult in the immediate neonatal period.
- Certain protein-based assays may aid in treatment during the neonatal period (antithrombin III and plasminogen assays) and may be performed during the neonatal period.
- DNA-based assays are accurate and may be obtained at any time.
- Lipoprotein(a) concentrations increase during the first year of life and should be repeated at 8–12 months of life if values obtained at 3–6 months are low, especially in Caucasian individuals.
- The different evaluations listed below are based on the presence of acquired risk factors, type of thrombosis, severity of thrombosis, and treatment regimen.
- Baseline complete blood count, prothrombin time, activated partial thromboplastin time, and fibrinogen levels should be obtained shortly after the acute event.
- Antiphospholipid antibody panels should be obtained from the mother and may warrant coordination with obstetrics.
- Placental pathology, especially in cases of perinatal arterial ischemic stroke, should be requested.

Data from references 92,102,141,157,168.

many factors, including lower AT levels, increased binding of UFH to plasma proteins, and faster clearance in neonates compared with adults.[148–150] These differences explain why neonates tend to require a higher infusion rate to reach therapeutic levels than do adults.[151,152] Current dosing guidelines for neonates are provided in Table 67.13. Routine use of AT-replacement therapy

TABLE 67.13 Recommended Dosing for Anticoagulant and Thrombolytic Therapy in Neonates

Gestational Age	UFH*	LMWH†	rTPA‡
≤32-weeks	15 units/kg/h	1.5 mg/kg SQ q 12 h	For both age groups: 0.03 mg/kg/h Dose escalation up to 0.3 mg/kg/h may be considered, but must be done slowly with continuous monitoring of the patient (see Box 67.3) Supplementation with plasminogen (FFP at 10 mL/kg) prior to commencing therapy is recommended to ensure adequate thrombolysis Infuse UFH at 10 units/kg/h during rTPA treatment
>32-weeks	28 units/kg/h	2 mg/kg SQ q 12 h For both age groups: Prophylactic dosing 0.75 mg/kg SQ q 12 h	

Complete blood count, platelet count, and coagulation screening (including aPTT, PT, and fibrinogen) should be performed prior to starting anticoagulation/thrombolytic therapy.
Monitoring for UFH: Maintain anti-Xa UFH assay level of 0.3 to 0.7 U/mL. Levels should be checked 4 to 6 h after initiating therapy. If loading dose provided, check level 4 to 6 h after loading dose provided. If need to make changes in dosing, check levels 4 to 6 h after each change in infusion rate.
Bolus dosing for UFH should be performed only if there is a significant risk or evidence of thrombus progression. Otherwise, avoid bolus dosing in neonates. If bolus dosing is recommended: ≤32-weeks 25 U/kg IV over 10-min; >32-weeks 50 U/kg IV over 10-min.
If infant with renal dysfunction, dosing should be discussed with pharmacy.
FFP, fresh frozen plasma; *UFH*, Unfractionated heparin.
*Dosing applies also to post-conceptional age (GA + weeks of life).
†**Monitoring for LMWH**: Maintain anti-Xa LMWH assay level of 0.5–1.0 U/mL. Check level 4-h after the 2nd or 3rd dose. If therapeutic, repeat level within 24- to 48-hours. If remain therapeutic, then may check weekly.
‡Dose titrations for rTPA may be made every 12 to 24 h and are as follows: 0.06 mg/kg/h → 0.1 mg/kg/h → 0.2 mg/kg/h → 0.3 mg/kg/h. Max dose is 0.3 mg/kg/h.
Data from references 92,120,141,155,156,158,159,178.

is not recommended in neonates receiving UFH for standard anticoagulation.[129]

The most recent review of UFH dosing in neonates does not recommend a loading dose.[146] A loading dose is not recommended because of increased bleeding risk and low risk for recurrent thrombosis. Additionally, there is no evidence suggesting that recurrent thromboses are due to subtherapeutic antifactor Xa levels during the first 24 hours of anticoagulation.[146] Loading doses should be reserved for neonates with significant risk or evidence for thrombus progression.

Proper laboratory monitoring of UFH therapy is crucial to reducing bleeding complications (see Table 67.13). Guidelines for adjusting UFH therapy are presented elsewhere.[92]

Therapy is usually limited to 2 to 14 days, but data to support this recommendation are lacking.[92] Bleeding is the most significant complication of UFH therapy in neonates with concerns for IVH in preterm neonates. Therefore, CUS should be performed before and during treatment. Treatment of hemorrhage usually only requires cessation of the infusion because of UFH's short half-life. Other complications such as heparin-induced thrombocytopenia, although common in adults and children, rarely occurs in neonates.[153,154]

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH), specifically enoxaparin, has become the neonatal anticoagulant of choice because of a low risk of hemorrhage, subcutaneous (SQ) dosing, and reduced monitoring requirements.[155–157] LMWH specifically acts against factor Xa, and its administration can be achieved either through SQ injection or the use of an indwelling SQ catheter (Insuflon; Unomedical, Birkerod, Denmark).[141,156] The use of the SQ catheter reduces the number of needle sticks from 14 per week to 1 per week. However, case reports and reviews of SQ catheter usage in neonates have reported that greater than 50% of neonates experience minor adverse events, including induration, leakage, and bruising.[158] Other case reports have reported major adverse events caused by SQ catheters in three infants and one case of an infected hematoma.[156–159]

Recommended dosing and monitoring for infants less than 2 months of age are provided in Table 67.13. Guidelines for adjusting LMWH therapy are presented elsewhere.[92]

Maintaining therapeutic levels in neonates may be a challenge. Lack of pediatric formulations and rapid growth rates in premature infants are the main reasons.[141] A recent review evaluating enoxaparin use in 240 neonates found that the mean maintenance dose of enoxaparin ranged from 1.48 to 2.27 mg/kg every 12 hours for all infants, but was higher for preterm neonates at 1.9 to 2.27 mg/kg every 12 hours.[158,159] These findings have influenced current recommended dosing (see Table 67.13).[159]

LMWH therapy has been effective in the NICU with centers reporting either partial or complete resolution of TE events in 59% to 100% of neonates treated.[158,159]

Recombinant Tissue Type Plasminogen Activator

Fibrinolytic agents, specifically recombinant tissue type plasminogen activator (rt-TPA), convert plasminogen to plasmin, which cleaves fibrinogen to fibrin and fibrin degradation products. rt-TPA use in neonates should *only* be considered for limb-threatening or organ-threatening thromboses and acute atrial thrombi.[76,92,118,129] Treatment in neonates is affected by low baseline plasminogen levels.

The safety and efficacy of rt-TPA treatment in neonates have been reported in case series and cohort studies demonstrating complete or partial clot lysis in 84% to 94% of cases.[118,120,160] Based on limited data, recommended dosing is provided in Table 67.13, with very careful laboratory and radiologic monitoring required, and these recommendations are provided in Table 67.14. rt-TPA treatment does not inhibit clot propagation or directly affect hypercoagulability; therefore, simultaneous infusion of UFH at 10 U/kg per hour is recommended.[118,141] Once the clot is adequately lysed, rt-TPA therapy should be discontinued, with anticoagulants, preferably LMWH, started (Box 67.3).

Surgery

The use of microsurgical techniques, and combined microsurgical and thrombolytic regimens, has the potential to rapidly restore

TABLE 67.14 Monitoring Recommendations for Thrombolytic Therapy in Neonates

Testing	When Performed	Levels Desired (If Applicable)
Imaging of thrombosis	Before initiation of treatment Every 12–24 h during treatment	
Fibrinogen level	Before initiation of treatment 4–6 h after starting treatment Every 12–24 h	Minimum of 100 mg/dL Supplement with cryoprecipitate
Platelet count	Before initiation of treatment 4–6 h after starting treatment Every 12–24 h	Minimum of 50–100 × 10^4/μL, dependent upon bleeding risk
Cranial imaging	Before initiation of treatment Daily during treatment	
Coagulation testing	Before initiation of treatment 4–6 h after starting treatment Every 12–24 h	
Plasminogen	Before initiation of treatment 4–6 h after starting treatment Every 12–24 h	Adequate to achieve thrombolysis Supplementation with plasminogen (FFP) before commencing therapy is recommended to ensure adequate thrombolysis
Line associated or mucosal oozing	At all clinical assessments	Topical thrombin as needed

FFP, Fresh frozen plasma.

• BOX 67.3 Key Points Regarding rTPA Therapy in Neonates

- When using for arterial thrombi, reimage at 12-hour intervals.
- When using for venous thrombi, reimage at 12- to 24-hour intervals.
- If repeat imaging reveals clot lysis <50%, *increase* infusion to next dosing level and repeat imaging in 12–24 h.
- If repeat imaging reveals clot lysis 51%–94%, continue same dose of infusion and repeat imaging in 12–24 h.
- If repeat imaging reveals clot lysis >95%, stop infusion, and initiate anticoagulation protocol.
- If no clot dissolution occurring 12–24 h after starting infusion and/or d-dimers are not increasing, may also give additional 10 mL/kg of FFP to provide plasminogen to increase efficacy of rTPA.
- Maintain fibrinogen levels >100 mg/dL (provide Cryo if <100) and platelet counts >50,000 during rTPA treatment.
- rTPA infusion should not be used for >96 h unless deemed appropriate by neonatology and hematology staff taking care of baby.
- When starting rTPA therapy, please have the staff place a sign at the bedside alerting all caregivers that the patient is you.

blood flow, avoiding tissue loss, without major bleeding complications, especially in patients with peripheral arterial occlusion.[161] One center's experience of 11 patients with arterial vascular access–associated thrombosis, secondary to PAL complications, described 5 patients that required arteriotomy, embolectomy, and subsequent microvascular reconstruction.[161] When faced with a significant arterial thrombosis, especially one from a PAL, surgery may be entertained, but should only take place at an experienced institution.

Neonatal Platelet Disorders

EMÖKE DESCHMANN AND MARTHA SOLA-VISNER

KEY POINTS

- The most common cause of mild to moderate, early-onset thrombocytopenia in well-appearing neonates is placental insufficiency, frequently manifesting as small-for-gestational status at birth. This thrombocytopenia resolves spontaneously, usually within 10 days, and carries good prognosis. Thrombocytopenia in sick infants is usually associated with sepsis or necrotizing enterocolitis (NEC) and requires prompt intervention.
- Neonates with platelet counts $<50 \times 10^9$/L in the first day of life, particularly if well appearing, should be screened for neonatal alloimmune thrombocytopenia (NAIT). Random donor platelet transfusions (± IVIG) are the first line of therapy for these infants, unless HPA-1b1b and 5a5a platelets are immediately available for use (as is the case in some European countries, or if a prior child was affected). In those cases, these platelets are the preferred first line treatment.
- The risk of bleeding in thrombocytopenic neonates is multifactorial and is not related to the severity of the thrombocytopenia. Gestational age <28 weeks, postnatal age <10 days, and a diagnosis of NEC are more important predictors of bleeding than the platelet count.
- Historically, there has been significant variability in platelet transfusion thresholds used in the NICU. The recently published large multicenter PlaNeT-2 trial found a *higher* incidence of death or major bleeding among neonates randomized to receive platelet transfusions for platelet counts $<50 \times 10^3$/mcL compared to those transfused only for platelet counts $<25 \times 10^3$/mcL, supporting the hypothesis that platelet transfusions might be harmful to neonates.
- A subsequent risk stratification analysis of neonates enrolled in PlaNeT-2 demonstrated that infants with a high baseline risk of bleeding and mortality benefit from the low platelet transfusion threshold as much as (or more than) low-risk neonates.
- Most platelet function defects seen in the NICU are acquired, and are related to medications, medical conditions (i.e., uremia), or medical interventions (i.e., ECMO, therapeutic hypothermia). The most severe platelet function defects, which can present with bleeding in neonatal life, are Bernard-Soulier syndrome, caused by deficiency of glycoprotein Ib (the vWF receptor), and Glanzmann thrombasthenia, caused by a deficiency of glycoprotein IIb/IIIa (the fibrinogen receptor) on the platelet surface.

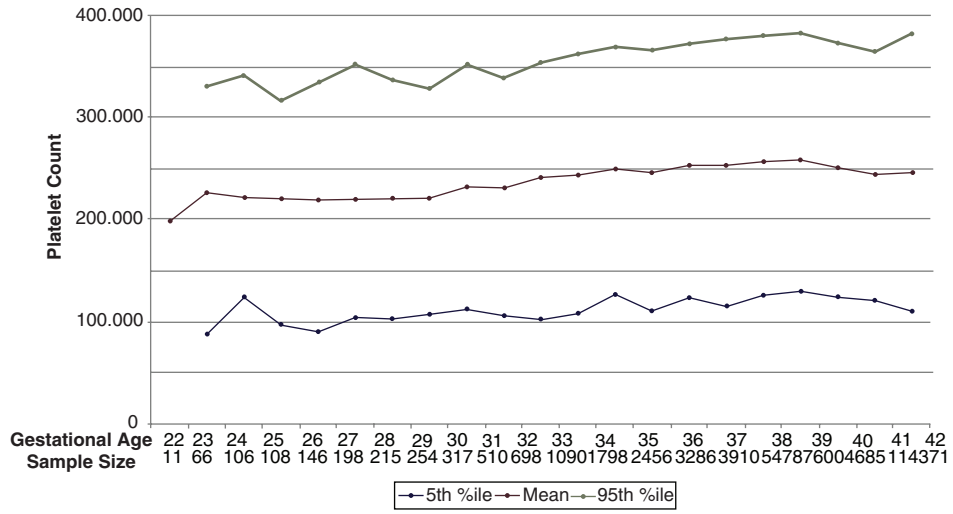
Fetal and Neonatal Platelet Production

A mounting body of evidence arising over the last decade has clearly demonstrated that there are substantial morphological and biological differences between fetal/neonatal and adult megakaryocytes and platelets. Developmental stage-specific differences are ontogenetically important because they allow the fetus to maintain stable platelet counts while the blood volume is rapidly expanding in a time characterized by exceptionally rapid growth. The complex process of platelet production can be represented as consisting of four main steps: (1) the production of thrombopoietic factors, mainly thrombopoietin (TPO), (2) the proliferation of megakaryocyte progenitors, (3) the differentiation and maturation of megakaryocytes through a unique process of endomitosis, and finally (4) the production and release of platelets into the circulation.

Studies culturing megakaryocyte progenitors derived from term and preterm umbilical cord blood, fetal blood (18 to 22 weeks' gestation), or fetal bone marrow have documented that fetal/neonatal megakaryocyte progenitors proliferate at a significantly higher rate as compared to their adult counterparts. Additionally, fetal and neonatal megakaryocytes are substantially smaller and have lower ploidy levels than adult megakaryocytes. Contrary to adult megakaryocytes, which mature as their ploidy level increases, neonatal megakaryocytes are fully mature and capable of platelet production despite their small size and low ploidy. This dissociation between proliferation, polyploidization, and cytoplasmic maturation is a hallmark feature of neonatal megakaryopoiesis. The net result of this process is the production of large numbers of low-ploidy but highly mature megakaryocytes, with which fetuses and neonates populate their rapidly expanding bone marrow space and blood volume, while maintaining normal platelet counts. As developmental processes are easily disturbed, however, sick neonates, and particularly very low birth weight infants (birth weight <1500 g), are at high risk of thrombocytopenia.

Platelet Counts During Development and Reference Ranges

In 2009, Wiedmeier et al. published the largest study on neonatal platelet counts conducted to date, which included approximately 47,000 infants delivered between 22 and 42 weeks' gestation.[1] This study showed that platelet counts at birth increased with advancing gestational age (Fig. 68.1) by approximately 2×10^9/L for each week of gestation. Importantly, while the mean platelet count was $\geq 200 \times 10^9$/L even in the most preterm infants, the 5th percentile was 104×10^9/L for those ≤32 weeks' gestation, and 123×10^9/L for late-preterm and term neonates (see Fig. 68.1).[1] These findings suggested that different definitions of thrombocytopenia should be applied to preterm infants. In that regard, however, it is important to emphasize that the reference ranges in that study were generated by eliminating the top 5% and the bottom 5% of all available values, rather than excluding values based on diagnoses. Thus, these should be considered "epidemiological reference



• **Fig. 68.1** First recorded platelet counts, obtained in the first 3 days after birth, in neonates born at 22 to 42 weeks' gestation. Mean values are indicated by the red line, and the 5th and 95th percentiles are shown in the blue and green lines, respectively. (From Wiedmeier SE, Henry E, Sola-Visner MC, et al. Platelet reference ranges for neonates, defined using data from over 47,000 patients in a multihospital healthcare system. *J Perinatol*. 2009;29:132.)

ranges" rather than "normal ranges." Nevertheless, these data suggest that platelet counts between 100 and 150 × 10^9/L might be more frequent among otherwise healthy extremely preterm infants than among full term neonates or older children/adults.

Thrombocytopenia in neonates (as in adults) has traditionally been defined as a platelet count <150 × 10^9/L and has been classified as mild (100 to 150 × 10^9/L), moderate (50 to 99 × 10^9/L), and severe (<50 × 10^9/L). However, consistent with the data by Wiedmeier et al., platelet counts in the 100 to 149 × 10^9/L range are more common among healthy neonates than adults. The incidence of thrombocytopenia in neonates varies significantly, depending on the population studied. Based on the traditional definitions, large studies in unselected populations of live-births (including healthy and sick neonates) established an overall incidence of neonatal thrombocytopenia of 0.7% to 0.9%.[2,3] However, when focusing on neonates admitted to the NICU, the incidence of thrombocytopenia is much higher, ranging from 18% to 35%.[4–6] The incidence of thrombocytopenia is also inversely correlated to the gestational age, so that the most immature neonates are the most frequently affected: platelet counts <150 × 10^9/L were found at least once during the hospital stay in 70% of infants with a birth weight <1000 g.[7]

Platelet Function and Primary Hemostasis

Multiple studies evaluating platelet adhesion, aggregation, and activation have shown that neonatal platelets are hyporesponsive in vitro to most agonists compared with adult platelets,[8,9] and this low level of reactivity is more pronounced in preterm infants.[10,11] Platelet aggregation studies demonstrated that platelets from neonatal (full term) cord blood were less responsive than adult platelets to agonists such as adenosine diphosphate (ADP), epinephrine, collagen, thrombin, and thromboxane analogues.[12] Similar results were obtained in flow cytometric platelet activation studies, which showed decreased expression of surface activation markers in neonatal platelets stimulated with thrombin, ADP, and epinephrine.[10,12] Different mechanisms account for the hyporeactivity of neonatal platelets to various agents: (1) the hyporesponsiveness to epinephrine is due to fewer α2-adrenergic receptors, the binding sites for epinephrine[13]; (2) the reduced response to collagen likely results from impaired calcium mobilization,[14] although recent studies also showed a mildly reduced expression of GPVI (the collagen receptor) coupled with an intracellular signaling defect[15]; (3) the decreased response to thromboxane results from differences in signaling downstream from the receptor in neonatal platelets[8]; and (4) the decreased responsiveness to thrombin is related to reduced expression of PAR-1 and PAR-4 in neonatal platelets.[16] Recently, developmental differences have also been described in regard to platelet *inhibitory* pathways, specifically a hypersensitivity of neonatal platelets to the inhibitory effects of prostaglandin E1 (PGE_1) during ADP- and collagen-induced platelet aggregation.[17]

Surprisingly, while the hypofunctional platelet phenotype in vitro would predict a bleeding tendency, healthy full-term neonates have normal to *enhanced* primary hemostasis, compared to older children or adults. Bleeding times (BTs) in healthy term neonates are shorter than bleeding times in adults.[18] Similarly, studies using the Platelet Function Analyzer (PFA-100, an in vitro test of primary hemostasis that measures the time it takes to occlude a small aperture, or Closure Time) found that cord blood samples from term neonates exhibited shorter closure times (CTs) than samples from older children or adults.[19,20] The results of these studies suggest that there is an enhanced platelet/vessel wall interaction in full-term neonates, likely related to their higher hematocrits, higher mean corpuscular volumes, and higher concentrations of von Willebrand factors (particularly its ultralong polymers),[18] all factors that, when combined, effectively counteract the neonatal platelet hyporeactivity. Taken together, the available evidence strongly suggests that the in vitro platelet hyporeactivity of healthy full-term infants is an integral part of a carefully balanced and well-functioning neonatal hemostatic system, rather than a developmental deficiency.

These compensatory mechanisms might be less well developed in preterm infants, whose platelets are also more hyporeactive than those of full-term infants, leading to longer BTs[21] and therefore a less balanced and probably more vulnerable hemostatic system. Specifically, BTs performed on the first day of life were longer in preterm compared with term infants, with neonates <33 weeks' gestation exhibiting the longest BTs.[21] Saxonhouse et al. found that PFA-100 CTs from non-thrombocytopenic neonates were inversely correlated to gestational age in both cord blood and

neonatal peripheral blood samples obtained on the first day of life.[22] Importantly, however, while these BTs and CTs were longer in preterm compared to term neonates, they were still near or within the normal range for adults, suggesting that healthy preterm neonates also have adequate primary hemostasis. Data regarding how disease processes perturb this delicate system, particularly in the preterm neonate, are lacking.

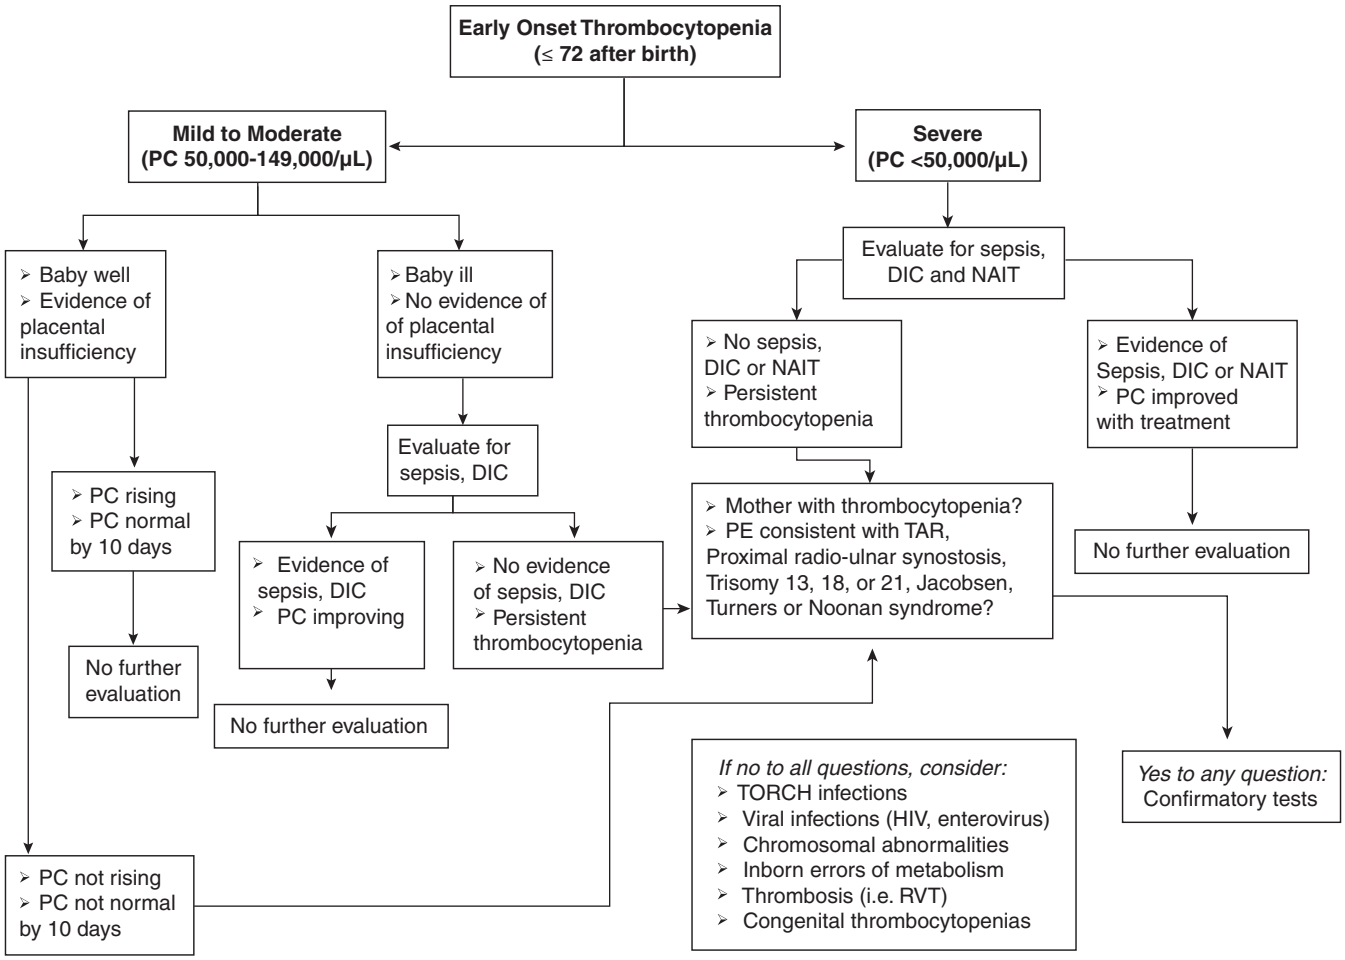
In vitro studies using flow-cytometry or the cone and platelet analyzer showed that the neonatal platelet function improves significantly and nearly normalizes by 10 to 14 days, even in preterm infants.[10,11,23] Consistent with this, Del Vecchio et al. found that, by day of life 10, all infants had shorter BTs than at birth, and early gestational age-related differences had disappeared. Moreover, little or no further shortening of BTs occurred between days 10 and 30.[21] While no causal association has been demonstrated, this period overlaps with the period of highest risk of bleeding among preterm NICU patients, namely during the first 10 days of life.[24]

Neonatal Thrombocytopenia

When evaluating a thrombocytopenic neonate, the first step to narrow the differential diagnosis is to classify the thrombocytopenia as either early onset (within the first 72 hours of life) or late onset (after 72 hours of life), and to determine whether the infant is clinically ill or well. Importantly, infection/sepsis should always be considered near the top of the differential diagnosis (regardless of the time of presentation and the infant's appearance), as any delay in diagnosis and treatment can have life-threatening consequences.

Early-Onset Thrombocytopenia (Fig. 68.2, Table 68.1)

The most frequent cause of early-onset thrombocytopenia in a well-appearing neonate is placental insufficiency, seen in infants born to mothers with pregnancy-induced hypertension/preeclampsia, and in those with intrauterine growth restriction (IUGR).[25] This thrombocytopenia is always mild to moderate, presents immediately or shortly after birth, reaches a nadir on day of life 4, and resolves within 10 days. In a recent large cohort study, approximately one third of small for gestational age (SGA) infants had thrombocytopenia ($<150 \times 10^9$/L) during the first week of life, compared to only 10% of non-SGA gestational age-matched infants. This type of thrombocytopenia was associated with low mortality (2%), as long as there was no identified cause for the SGA other than placental insufficiency (i.e., genetic syndrome or congenital infection).[26] If an SGA otherwise non-dysmorphic



• **Fig. 68.2** Guidelines for the evaluation of neonates with early onset thrombocytopenia (≤72 h of life). *DIC*, Disseminated intravascular coagulation; *NAIT*, neonatal alloimmune thrombocytopenia; *PC*, platelet count; *PE*, physical exam; *TAR*, thrombocytopenia absent radii; *RVT*, renal vein thrombosis. (From Cloherty JP, Eichenwald EC, Stark AR. *Manual of Neonatal Care*, 8th ed, Chapter 47: Neonatal Thrombocytopenia.)

TABLE 68.1 Classification of Neonatal Thrombocytopenia By Time of Presentation

Early-Onset Thrombocytopenia

Chronic fetal hypoxia (hypertension/preeclampsia, diabetes)—IUGR/SGA
Immune-mediated thrombocytopenia (NAIT, autoimmune thrombocytopenia)
Early-onset sepsis (GBS, *Escherichia coli*)
Congenital viral/parasitic infection (HIV, CMV, toxoplasma, enterovirus)
Birth asphyxia
Renal vein thrombosis
Polycythemia
Chromosomal anomalies (trisomy 21, 18, 13)
Congenital thrombocytopenia (thrombocytopenia-absent radii [TAR], amegakaryocytic thrombocytopenia with proximal radio-ulnar synostosis [ATRUS] syndrome, Wiskott-Aldrich syndrome)
Congenital leukemia

Late-Onset Thrombocytopenia

Late-onset infection/sepsis (bacterial, fungal)
NEC
Viral infection (HSV, acquired CMV, enterovirus, adenovirus)
Thrombosis (catheter related)
Drug-induced thrombocytopenia (antibiotics, heparin)
Fanconi anemia

Can Present Both Early and Late

Sepsis/DIC
Inborn errors of metabolism (Gaucher disease, methylmalonic acidemia)
Kasabach-Merritt syndrome

ATRUS, Amegakaryocytic thrombocytopenia with proximal radio-ulnar synostosis; *CMV*, cytomegalovirus; *DIC*, disseminated intravascular coagulation; *IUGR*, intrauterine growth restriction; *NAIT*, neonatal alloimmune thrombocytopenia; *NEC*, necrotizing enterocolitis; *TAR*, thrombocytopenia-absent radii syndrome; *TORCH*, toxoplasmosis, other, rubella, cytomegalovirus, herpes simplex virus infection complex.

infant with mild to moderate thrombocytopenia remains clinically stable and the platelet count normalizes within 10 days, no further evaluation is necessary. However, if the thrombocytopenia becomes severe and/or persists >10 days, further investigation is indicated.

Severe early-onset thrombocytopenia in an otherwise healthy infant should trigger suspicion for an immune-mediated thrombocytopenia, either autoimmune (if the mother is also thrombocytopenic) or alloimmune (if the mother has a normal platelet count). These varieties of thrombocytopenia are discussed in detail below. Early-onset thrombocytopenia of any severity in an *ill-appearing* term or preterm neonate should prompt evaluation for sepsis, congenital viral or parasitic infections, or disseminated intravascular coagulation (DIC). DIC is most frequently associated with sepsis but can also be secondary to birth asphyxia.[27]

In addition to these considerations, the affected neonate should be carefully examined for any radial and thumb abnormalities (suggestive of thrombocytopenia-absent radii [TAR] syndrome, amegakaryocytic thrombocytopenia with radio-ulnar synostosis, or Fanconi anemia). The inability to rotate the forearm on physical examination, in the presence of severe early-onset thrombocytopenia, suggests the rare diagnosis of congenital amegakaryocytic thrombocytopenia with proximal radio-ulnar synostosis (ATRUS). Dysmorphic features on physical exam should warrant investigation for other genetic disorders associated with early-onset thrombocytopenia, most commonly trisomy 21, trisomy 18, trisomy 13, Turner syndrome, Noonan syndrome, and Jacobsen syndrome.

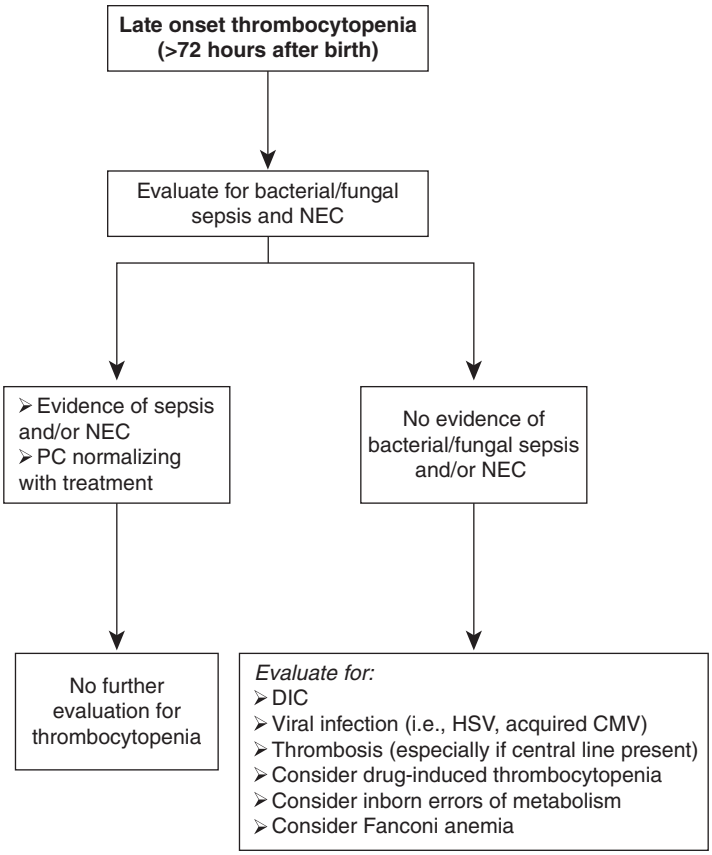
The presence of hepato- and/or splenomegaly is suggestive of viral infection, although it can also be seen in hemophagocytic syndrome and liver disease from different etiologies. Other diagnoses, such as renal vein thrombosis, Kasabach-Merritt syndrome, and inborn errors of metabolism (mainly propionic acidemia and methylmalonic acidemia) should be considered and evaluated for based on specific clinical indications (i.e., hematuria in renal vein thrombosis, presence of a vascular tumor in Kasabach-Merritt syndrome).

Late-Onset Thrombocytopenia (Fig. 68.3, see Table 68.1)

The most common causes of thrombocytopenia of any severity presenting after 72 hours of life are sepsis (bacterial or fungal) and necrotizing enterocolitis (NEC). Affected infants are usually ill-appearing and have other signs suggestive of sepsis and/or NEC. However, it is important to keep in mind that thrombocytopenia can be the first presenting sign of these processes and can precede clinical deterioration. Appropriate treatment (i.e., antibiotics, supportive respiratory and cardiovascular care, bowel rest in case of NEC, and surgery in case of surgical NEC) usually improves the platelet count in 1 to 2 weeks, although in some infants the thrombocytopenia persists for several weeks. The reasons underlying this prolonged thrombocytopenia are unclear.

If bacterial/fungal sepsis and NEC are ruled out, viral infections such as herpes simplex virus, cytomegalovirus (CMV), or enterovirus should be considered. These viral infections are frequently accompanied by abnormal liver enzymes. If the infant has or has recently had a central venous or arterial catheter, thromboses should be part of the differential diagnosis, although thromboses typically only cause thrombocytopenia if the thrombus is enlarging or is infected. Finally, drug-induced thrombocytopenia, while rare in neonates, should be considered if the infant is clinically well, other potential etiologies have been ruled out, and he/she is receiving heparin, antibiotics (penicillins, cephalosporins, metronidazole, vancomycin, or rifampin), indomethacin, famotidine, cimetidine, phenobarbital, or phenytoin, among others.[28,29] Other less common causes of late-onset thrombocytopenia include inborn errors of metabolism and Fanconi anemia (rare).

Novel tools to evaluate platelet production, which aid in the evaluation of thrombocytopenia of unclear etiology, have been recently developed, and are likely to become widely available to clinicians in the near future. Among those, the immature platelet fraction (IPF) measures the percentage of newly released platelets (<24 hours). The IPF can be measured in a standard hematological cell counter (Sysmex 2100 XE Hematology Analyzer) as part of the complete cell count, and can help differentiate thrombocytopenias associated with decreased platelet production from those with increased platelet destruction, in a manner similar to the use of reticulocyte counts to evaluate anemia.[30] Thus, an elevated IPF would suggest platelet consumption (as in neonatal alloimmune thrombocytopenia [NAIT] or DIC), while a decreased IPF would be consistent with a hyporegenerative thrombocytopenia, as in bone marrow suppression or failure.



• **Fig. 68.3** Guidelines for the evaluation of neonates with late-onset thrombocytopenia (>72 h of life). *CMV*, Cytomegalovirus; *DIC*, disseminated intravascular coagulation; *HSV*, Herpes simplex virus; *NEC*, necrotizing enterocolitis; *PC*, platelet count. (From Cloherty JP, Eichenwald EC, Stark AR. *Manual of Neonatal Care*, 8th ed, Chapter 47: Neonatal Thrombocytopenia.)

Reference intervals for the IPF% and the absolute IPF (also known as the immature platelet count, or IPC) have been evaluated in healthy adults and full term neonates, using umbilical cord blood samples (Table 68.2),[31] as well as in nonthrombocytopenic NICU patients (IPF% = 4.1 ± 1.8).[32] In the largest IPF study published to date, MacQueen et al. examined 24,372 platelet counts and IPFs from 9172 term and preterm neonates 0 to 90 days old. Data from nonthrombocytopenic infants in this cohort were used to generate age-specific reference intervals for IPF% and IPC (calculated as IPF% × platelet count) (Fig. 68.4).[33] As seen in the figure, the IPF at the time of birth was higher in preterm infants and decreased through gestation until 32 weeks, at which time it stabilized at full-term values (similar to adult values). Postnatally, the IPF increased progressively over the first 2 weeks of life and returned to baseline by 1 month in infants of all gestational ages. This study also assessed IPF percentages in neonates with thrombocytopenia, and found significantly higher values in neonates with consumptive etiologies compared to those with thrombocytopenia secondary to decreased production (Table 68.3). Thus, when available, the IPF can help differentiate rare congenital thrombocytopenias (usually low) from NAIT or other consumptive disorders (usually elevated). Other studies have shown the usefulness of the IPF to predict platelet recovery in neonates.[32,34] In patients with NEC and severe thrombocytopenia, a low absolute IPF has also been associated with a poor prognosis and high mortality.

Immune Thrombocytopenia

Immune thrombocytopenia occurs due to the passive transfer of antibodies from the maternal to the fetal circulation. There are two distinct types of immune-mediated thrombocytopenia: (1) NAIT and (2) autoimmune thrombocytopenia.

Neonatal Alloimmune Thrombocytopenia

Epidemiology

NAIT is the most common underlying cause of early-onset severe thrombocytopenia, with an incidence among liveborn neonates of 0.5 to 1.5 per 1000 births.[35] The true incidence of the disease is likely higher, however, since the milder cases might go undetected and the most severe cases lead to intrauterine death. Intrauterine death or intracranial hemorrhage (ICH) may occur as early as at 14 to 16 weeks of gestation, resulting in a relatively high incidence of intrauterine ICH (>10%).[35] The overall incidence of ICH (prenatal and postnatal) is particularly high in this population, affecting up to 20% of infants with NAIT and potentially leading to lifelong consequences. ICH may occur during the first pregnancy and has a recurrence risk close to 100% in subsequent pregnancies in the absence of prenatal treatment.[36]

Pathophysiology

In NAIT, the antibody is produced in the mother against a specific human platelet antigen (HPA) present in the fetus but absent in the mother. The antigen is inherited from the father of the fetus. The antigens responsible for NAIT are caused by single nucleotide polymorphisms on any of the main glycoproteins located on the platelet surface, particularly GPIIb/IIIa. The first platelet antigen was identified in 1959 by von Loghem et al. and was designated Zw-a (later PLA1).[37] The initial nomenclature for these antigens came from the name of the patients, leading to confusion in the field. In 1990, a simplified system for HPA nomenclature was described, in which each antigen was given a HPA number.[38] Antigens were numbered chronologically, according to the date of their initial report. The bi-allelic antigens were given an alphabetic designation of "a" or "b" in the order of their frequency (higher frequency for "a"). Thus, the Zw-a/PLA1 antigen was named HPA-1, with its two serological forms designated as HPA-1a for the common form, and HPA-1b for the less common form (the latter corresponding to PLA2). Currently, there are at least 33 HPA antigens identified. The frequency of each antigen varies within ethnic groups: in Caucasians, antibodies to HPA-1a are the

major cause of NAIT, followed by HPA-5a and, less frequently, HPA-9b, HPA-3a and b, and HPA-15. Antibodies to HPA-4b are the predominant cause of NAIT in the Japanese population.[39]

The anti-HPA antibody produced in the maternal serum crosses the placenta and reaches the fetal circulation, leading to platelet destruction, apoptosis of early megakaryocyte progenitors (therefore decreased platelet production),[40] and thrombocytopenia.

Clinical Presentation

NAIT should be considered in any neonate who presents with severe thrombocytopenia at birth or shortly thereafter, particularly in the absence of other risk factors, clinical signs, or abnormalities in the physical exam. In a study of more than 200 neonates with thrombocytopenia, using a platelet count $<50 \times 10^9$/L in the first day of life as a screening indicator identified 90% of the patients with NAIT.[41] Based on this observation, it is currently recommended that all neonates with platelet count $<50 \times 10^9$/L in the first day of life be screened for NAIT. In addition, the combination of severe neonatal thrombocytopenia with a parenchymal (rather than intraventricular) ICH is highly suggestive of NAIT.

Evaluation

When NAIT is suspected, blood should be collected from the mother and father and submitted for testing. The initial antigen screening should include HPA-1, 3, and 5. This evaluation should identify approximately 90% of cases of NAIT. However, if the diagnosis is strongly suspected and the initial evaluation is negative, further testing should be undertaken for HPA-9 and 15 (and HPA-4 if the parents are of Asian descent).[42] If positive, these tests will reveal an antibody in the mother's plasma directed against the specific platelet antigen in the father. If blood cannot be collected from the parents in a timely fashion, neonatal serum may be screened for the presence of antiplatelet antibodies. However, a low antibody concentration in the neonate, coupled with binding of the antibodies to the infant's platelets, can lead to false-negative results. It is still unclear if there is any correlation between the affinity of the antibodies and the severity of disease.[43] Due to the complexity of testing, evaluations should be performed in an experienced reference laboratory that has a large number of typed controls available for antibody detection, and the appropriate DNA-based technology to type multiple antigens. In rare cases, antibodies may be hard to detect in samples drawn at the time of delivery; therefore, when the clinical diagnosis is most likely NAIT, follow-up serology tests should be performed.

Brain imaging studies (beginning with cranial ultrasound) should be performed as soon as NAIT is suspected, regardless of the presence or absence of neurologic manifestations, because findings from these studies will dictate the aggressiveness of the treatment regimen for the affected infant and for the mother's future pregnancies. The clinical course of NAIT is short in most cases, often resolving almost entirely within 2 weeks. However, to confirm the diagnosis, it is imperative to follow the platelet count frequently until a normal count is documented.

Management

The management of NAIT differs depending on the specific clinical scenario: suspected NAIT (unknown pregnancy); known case of NAIT; or antenatal management of pregnant woman with previous history of NAIT.

Management of the Neonate With Suspected NAIT (Unknown Pregnancy)

Based on recent data demonstrating that a large proportion of infants with NAIT respond to random donor platelet transfusions, this is now considered the first line of therapy for infants in whom NAIT is suspected.[44] If the patient is clinically stable and does not have an intracranial hemorrhage, platelets are usually given when the platelet count is $<30 \times 10^9$/L, although this is arbitrary. In addition to platelets, if the diagnosis of NAIT is confirmed or strongly suspected, intravenous immune globulin (IVIG) (1 g/kg/day for up to 2 consecutive days) may be administered to increase the patient's own platelets and potentially to protect the transfused platelets.[39] Because in NAIT the platelet count usually falls after birth, IVIG may be given when the platelet count is between 30 and 50×10^9/L in a stable neonate, to try to prevent a further drop.

If the patient has evidence of an ICH, the goal is to maintain a platelet count $>100 \times 10^9$/L. However, this may be challenging in the setting of NAIT. In all scenarios, it is important to keep in mind that some infants with NAIT fail to respond to random donor platelets and IVIG. For that reason, the blood bank should be immediately alerted about any infant with suspected NAIT, and arrangements should be made to secure a source of antigen-negative platelets (either from HPA-1b1b and 5a5a donors, which should be compatible in >90% of cases, or from the mother) as soon as possible, so they are available if there is no response to the initial therapies. If maternal platelets are used, they need to be concentrated to decrease the amount of antiplatelet antibodies, which are present in the mother's plasma, infused into the infant. Platelets can also be washed to eliminate the plasma, although this induces more damage to the platelets than concentrating them.[45] Of note, in some European countries, HPA-1b1b and 5a5a platelets are maintained in the blood bank inventory and are immediately available for use. In those cases, these are preferable to random donor platelets and/or IVIG, and should be the first line of therapy.

Management of the Neonate With Known NAIT

When a neonate is born to a mother who had a previous pregnancy affected by confirmed NAIT, genotypically matched platelets (e.g., HPA-1b1b platelets) should be available in the blood bank at the time of delivery, and should be the first line treatment if the infant is thrombocytopenic.

Management of Pregnant Women With Previous History of NAIT

Mothers who previously delivered an infant with NAIT should be followed in high-risk obstetric clinics during all future pregnancies as the reoccurrence rate is high, reaching 100% if the father is homozygous dominant for the causative HPA. However, in all cases fetal genetic testing should be performed. Non-invasive methods have recently become available through cell-free DNA testing from the mother's plasma. The intensity of prenatal treatment will be based on the severity of the thrombocytopenia and the presence or absence of ICH in the previously affected fetus. This is particularly important to assess the risk of developing an ICH in the current pregnancy, and to minimize this risk. Current recommendations involve maternal treatment with IVIG (0.5 to 2 g/kg/week) ± steroids (0.5 to 1 mg/kg/day prednisone), starting at 12 or at 20 to 26 weeks of gestation, depending on whether the previously affected fetus

suffered an ICH, and if so, at what time during pregnancy.[45] Most recent studies showed that the combination of IVIG and steroids is the most efficient treatment.[35] Regarding mode of delivery, elective cesarean section is recommended in most countries to avoid ICH, regardless of ICH status in previous and current fetus.[43]

Autoimmune Thrombocytopenia

Epidemiology

The diagnosis of neonatal autoimmune thrombocytopenia should be considered in any neonate who has early-onset thrombocytopenia and a maternal history of either immune thrombocytopenic purpura (ITP) or an autoimmune disease (with or without thrombocytopenia). A retrospective study of obstetric patients who had ITP (including a high number of mothers who had thrombocytopenia during their pregnancies) demonstrated a relatively high incidence of affected babies: 25% of neonates had thrombocytopenia at birth, the thrombocytopenia was severe in 9%, and 15% received treatment for it.[46] Other large studies confirmed an incidence of severe neonatal thrombocytopenia in this population ranging from 8.9% to 14.7%, with ICH occurring in 0% to 1.5% of affected neonates.[47–49]

Pathophysiology

In autoimmune thrombocytopenia, the antibody is directed against an antigen on the mother's own platelets (autoantibody) as well as on the infant's platelets. The maternal autoantibody crosses the placenta (both passively and actively transported), resulting in destruction of fetal platelets and thrombocytopenia.

Evaluation

We recommend that all neonates born to mothers who have autoimmune diseases undergo a screening platelet count at or shortly after birth. If the platelet count is normal, no further evaluation is necessary. If the infant has mild thrombocytopenia, however, the platelet count should be repeated in 2 to 3 days, since this type of thrombocytopenia usually reaches the nadir between days 2 and 5 after birth. If the platelet count is $<30 \times 10^9$/L, IVIG (1 g/kg, repeated if necessary) is the first line of therapy. Random donor platelets, in addition to IVIG, should be provided if the infant has evidence of active bleeding, although some experts recommend them in addition to IVIG when the platelet count is $<30 \times 10^9$/L, and provide IVIG alone for platelet counts between 30 and 50×10^9/L. Cranial imaging should be obtained in all infants with platelet counts $<50 \times 10^9$/L, to evaluate for ICH. Importantly, neonatal thrombocytopenia secondary to maternal ITP may last for weeks to months and requires long-term monitoring and sometimes a second dose of IVIG at 4 to 6 weeks of life. This is unlike NAIT, which usually resolves within 2 weeks. Recently, it has been reported that the transfer of antiplatelet antibodies (IgA type) from mothers with ITP through breastfeeding can be associated with persistent neonatal thrombocytopenia.[50]

Management

Even if the mother has severe ITP, it appears that fetal hemorrhage in utero is very rare, compared with the small but definite risk of such hemorrhage in alloimmune thrombocytopenia. Because of that, treatment of ITP during pregnancy and delivery is mostly based on the risk of maternal hemorrhage.[51] A small prospective randomized trial of low-dose betamethasone failed to prevent thrombocytopenia in newborns.[52] IVIG given prenatally to the mother with ITP has also not been clearly shown to affect the fetal platelet count.

There is in general little correlation between fetal platelet counts and maternal platelet counts, platelet antibody levels, or history of maternal splenectomy. Attempts to measure the fetal platelet count before delivery are not recommended, due to the risk associated with such attempts. The only reliable predictive measure of neonatal thrombocytopenia in a mother with ITP is a history of neonatal thrombocytopenia in a previous pregnancy.[53] In regard to the mode of delivery, there is no evidence that cesarean section is safer for the fetus with thrombocytopenia than uncomplicated vaginal delivery. Given this fact, combined with the difficulty predicting severe thrombocytopenia in neonates and the very low risk of serious hemorrhage, the 2010 International Consensus Report on the Investigation and Management of Primary Immune Thrombocytopenia concluded that the mode of delivery in ITP patients should be determined by purely obstetric indications.[51] However, interventions that increase the risk of bleeding in the fetus should be avoided, such as vacuum extraction or forceps delivery.

Congenital Thrombocytopenias

Congenital thrombocytopenias are rare conditions which most often present at birth and are therefore classified as early-onset thrombocytopenias. This is a heterogeneous group of diseases with variable clinical manifestations. Often, but not always, patients with congenital thrombocytopenia have dysmorphic features and associated abnormalities as part of a genetic syndrome. If a neonate presents with radial abnormalities, the differential diagnosis includes thrombocytopenia-absent radii (TAR) syndrome, amegakaryocytic thrombocytopenia with radio-ulnar synostosis, and Fanconi anemia. Although thrombocytopenia associated with Fanconi almost always presents later (during childhood), few isolated neonatal cases have been reported.[54] In patients with neonatal Fanconi anemia, thumb abnormalities are frequently found, and chromosomal fragility testing is nearly always diagnostic. If the infant has radial abnormalities with normal appearing thumbs, TAR syndrome should be considered.[55] The platelet count is usually $<50 \times 10^9$/L and the white cell count is elevated in >90% of TAR syndrome patients, sometimes exceeding 100×10^9/L and mimicking congenital leukemia. Infants with TAR syndrome that survive the first year of life generally do well, since the platelet count then spontaneously improves to low-normal levels that are maintained through life.[56] The inability to rotate the forearm on physical examination, in the presence of severe early-onset thrombocytopenia, suggests the rare diagnosis of congenital amegakaryocytic thrombocytopenia with proximal radio-ulnar synostosis (ATRUS). Radiologic examination of the upper extremities in these infants confirms the proximal synostosis of the radial and ulnar bones.[57] Most (but not all cases) of ATRUS are associated with Hox-A11 mutations,[58,59] and require bone marrow transplantation. Other genetic disorders associated with early-onset thrombocytopenia include trisomy 21, trisomy 18, trisomy 13, Turner syndrome, Noonan syndrome, and Jacobsen syndrome. Cases of Noonan syndrome presenting with mild dysmorphic features and very severe neonatal thrombocytopenia (mimicking congenital amegakaryocytic thrombocytopenia

[CAMT]) have been described, so genetic testing should be performed in children who present with a CAMT-like picture and no mutations in the *C-mpl* gene.[60]

In non-syndromic cases of congenital thrombocytopenia, there is usually a history of chronic thrombocytopenia in family members. These conditions belong to a heterogeneous group of diseases and due to diverse clinical manifestations and laboratory findings, the diagnosis is challenging. Often the size of the platelets helps in the differential diagnosis (Table 68.4). Myosin heavy chain-9 (MYH-9) related disorders (May-Hegglin anomaly, Fechtner syndrome, Sebastian syndrome) are inherited in autosomal dominant fashion and present with macrothrombocytopenia.[61] Other congenital thrombocytopenias presenting with large platelets include Bernard-Soulier syndrome (with autosomal recessive inheritance) and X-linked macrothrombocytopenia. Wiskott-Aldrich syndrome, in contrast, should be suspected in male neonates with severe thrombocytopenia and small platelets, particularly if they develop eczema. The diagnosis of congenital amegakaryocytic thrombocytopenia (CAMT) is challenging as it presents with normal sized platelets and may not be diagnosed in the newborn period (when it is usually confused with alloimmune thrombocytopenia) due to lack of other clinical features. A summary of congenital thrombocytopenias and their associated features is provided in Table 68.5.[62] These conditions are often paired with platelet dysfunction as well.

TABLE 68.4 Classification of Congenital Thrombocytopenias by Platelet Size

Small Platelets	Normal-Sized Platelets	Large Platelets
Wiskott-Aldrich syndrome (X-linked microthrombocytopenia)	Congenital amegakaryocytic thrombocytopenia (CAMT)	MYH9-associated thrombocytopenia (May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, Epstein syndrome)
	Thrombocytopenia-absent radius (TAR) syndrome	Bernard-Soulier syndrome
	Thrombocytopenia associated with trisomies (13, 18, 21)	X-linked macrothrombocytopenia

Management

Platelet Transfusions

Platelet transfusion is the primary modality of treatment for neonatal thrombocytopenia. Several studies have shown great variability in neonatal transfusion practices in the U.S. and worldwide.[24,63–65] To a large extent, this was attributed to the absence of scientific evidence in the field and the high incidence of bleeding in this population. Indeed, until recently, there was only one randomized trial that compared different platelet transfusion thresholds in neonates. This trial was limited to very low birth weight (VLBW) infants in the first week of life, and excluded patients with severe thrombocytopenia (platelet counts $<50 \times 10^9$/L).[66] The investigators found no differences in the incidence or severity of intraventricular hemorrhages (IVHs) between a group of neonates transfused for any platelet count $<150 \times 10^9$/L and a group transfused only for counts below 50×10^9/L or for clinical bleeding. Based on these findings, the investigators concluded that transfusing VLBW infants with platelet counts $>50 \times 10^9$/L does not reduce the risk of IVH.

In 2019, the much larger PlaNeT-2 multicenter trial was published. This trial randomized 660 thrombocytopenic neonates with a median gestational age of 26.6 weeks and a median birth weight of 740 g to receive platelet transfusions at a platelet count threshold of $<50 \times 10^9$/L (<50 group) or $<25 \times 10^9$/L (<25 group). Infants were randomized at any time during their NICU hospitalization when the platelet count fell below 50×10^9/L. The primary outcome was a composite of death or new major bleeding within 28 days of randomization.[67] Ninety percent of infants in the <50 group and 53% in the <25 group received at least one

platelet transfusion. Unexpectedly, infants in the <50 group had a significantly *higher* rate of mortality or major bleeding within 28 days of randomization, compared to those in the <25 group (26% vs. 19%, respectively; odds ratio 1.57, 95%CI 1.06 to 2.32). Among secondary outcomes, infants in the liberally transfused group also had a higher incidence of bronchopulmonary dysplasia. While these findings might have seemed surprising, they were consistent with a number of prior observational studies describing a poor association between severity of thrombocytopenia and bleeding risk, a lack of effectiveness of platelet transfusions to prevent bleeding in neonates, and an association between number of platelet transfusions and neonatal mortality and morbidity.[68,69]

The question of whether the benefits of the lower transfusion threshold would be limited to clinically stable infants with a low risk of bleeding and/or death was largely addressed in a secondary analysis, in which a multivariable logistic regression model was developed (incorporating factors known to influence neonatal bleeding risk and mortality) and used to predict the baseline bleeding/mortality risk of neonates enrolled in PlaNeT-2.[70] Based on their model-predicted baseline risk, 653 neonates from PlaNeT-2 were divided into four quartiles (very low, low, moderate, and high risk) and the absolute risk difference between the <50 group and the <25 group was assessed within each quartile. Interestingly, the lower transfusion threshold was associated with an absolute risk *reduction* in all four groups, varying from 4.9% in the lowest to 12.3% in the highest risk group. These results suggested that using a lower ($<25 \times 10^9$/L) prophylactic platelet transfusion threshold might be particularly beneficial in high-risk neonates, although some uncertainties remain. First, 39% of infants in PlaNeT-2 received one or more platelet transfusions prior to randomization, for unknown reasons and at non-specified platelet counts. This raises the question of whether these transfusions were given during the first few days of life, the highest risk period for IVH in preterm neonates. Second, the study required obtaining a head ultrasound within 6 hours of randomization and excluded infants with a significant IVH for 72 hours (after which they could be randomized). Thus, by design, PlaNeT-2 did not assess the effects of a restrictive versus liberal platelet transfusion threshold on the potential extension of an existing IVH. Nevertheless, the currently available evidence strongly supports the hypothesis that platelet transfusions can be harmful to neonates, and that restrictive transfusion thresholds can be safely used in the great majority of neonates. Based on this evidence, we currently recommend administering platelet transfusions to neonates according to the criteria shown in Table 68.6.

TABLE 68.6 Proposed Platelet Transfusion Recommendations

Platelet count ($\times 10^3$/mcL)	Recommendations
<25	*Transfuse all*
25–49	*Transfuse if:* Major hemorrhage in last 72 h (i.e., grade 3 or 4 IVH) Prior to surgical procedure
50–100	*Transfuse if:* Active bleeding NAIT with intracranial hemorrhage Before major neurosurgical procedures

Regarding the platelet product that should be transfused, neonates should receive 10 mL/kg of a standard platelet suspension, either a platelet concentrate ("random-donor platelets") or apheresis platelets. Each random-donor platelet unit has approximately 50 mL of volume and contains approximately 10×10^9 platelets per 10 mL.[71] There is no need to pool more than one random-donor unit for a neonatal transfusion, a practice that only increases donor exposures and induces platelet activation, without any benefit. Two additional important considerations in neonatology are the prevention of transfusion-transmitted CMV infections, and graft versus host disease (GVHD). Most blood banks provide either CMV-negative or leuko-reduced products to neonates, both of which significantly reduce (but do not completely eliminate) the risk of transfusion-transmitted CMV. Transfusion of CMV-negative and leuko-reduced blood products completely prevented transmission of CMV to VLBW infants.[72] GVHD is prevented by irradiating cellular blood products prior to transfusion. Of note, most neonatal cases of GVHD have been reported in neonates with underlying immunodeficiencies, receiving intrauterine or large volume transfusions (i.e., double exchange transfusions), or receiving blood products from a first-degree relative. Thus, these are all absolute indications for irradiating blood products.[71]

When making platelet transfusion decisions, it is important for neonatologists to be aware of the risks associated with these transfusions. In the case of platelet suspensions, the risk of bacterial contamination is higher than the combined risk of all viral infections for which platelets are routinely tested. This is because platelet suspensions are stored in the blood bank at room temperature for up to 5 days, which increases the risk of bacterial growth. In addition, platelet transfusions can induce transfusion-associated lung injury (TRALI), a process characterized by the onset of hypoxemia and bilateral pulmonary infiltrates within 6 hours of a transfusion.[73] Given that neonates have frequent episodes of respiratory decompensation due to variable causes, TRALI is likely to be under-recognized in the NICU.

Alternative Tests to Guide Platelet Transfusions

While currently platelet transfusions are administered based on platelet counts, the evidence strongly suggests that factors other than the degree of thrombocytopenia determine the bleeding risk. The PFA-100 is an *in vitro* test of primary hemostasis that provides a quantitative measurement of platelet adhesion, activation, and aggregation in whole blood.[74] Since PFA-100 closure times (CTs) represent global measurements of primary hemostasis, they are particularly attractive in neonates, in whom many factors contribute to a finely balanced hemostatic system. Two recent studies found that the CT-ADP (closure time in response to collagen and ADP) was correlated with bleeding severity in preterm neonates,[75,76] while the platelet count was not. Furthermore, changes in the CT-ADP (but not in platelet count) correlated well with changes in bleeding score.[77] Fustolo-Gunnink and collaborators recently developed a dynamic model to predict major bleeding in preterm neonates at any time-point during the first week after the onset of severe thrombocytopenia, which incorporated the variables gestational age, post-natal age, intrauterine growth retardation, NEC, sepsis, platelet count, and mechanical ventilation.[78] While not yet prospectively validated, this is a promising approach to making individualized transfusion decisions in this population.

Non-Transfusional Therapies

While severe thrombocytopenia resolves within 14 days in 80% of affected neonates, in approximately 10% it persists for

>30 days,[79] resulting in multiple platelet transfusions (>20).[80] In 2008, two thrombopoietin (TPO) mimetics, romiplostim and eltrombopag, were approved by the FDA for the treatment of adults with chronic immune thrombocytopenic purpura and, more recently, eltrombopag was approved for use in other varieties of chronic thrombocytopenia (i.e., chronic hepatitis C, aplastic anemia). In 2015,[81] eltrombopag was approved by the FDA for use in children with symptomatic chronic immune thrombocytopenia. Recent publications have reported the use of eltrombopag in adult and pediatric patients with various hematological disorders, including inherited thrombocytopenia associated with MYH9 mutations,[82,83] Wiskott-Aldrich syndrome,[84] and aplastic anemia.[85,86] Thus, it is plausible that eltrombopag would also be considered as a therapeutic alternative in neonates, infants, and children in the first year of life with different varieties of thrombocytopenia. Both agents, romiplostim and eltrombopag, begin to raise platelet counts 4 to 6 days after the initiation of the treatment, and reach peak platelet counts at 10 to 14 days. Because of these characteristics, they would only be appropriate for selected infants with thrombocytopenia expected to last longer than 10 to 14 days and severe enough to warrant treatment. Difficulties in predicting the duration of thrombocytopenia in neonates have hampered the use of any TPO mimetics in neonates and infants <12 months, which so far has been limited to sporadic reports.[87] It is likely that only a very small subset of thrombocytopenic neonates would be acceptable candidates for treatment with these medications.

Outcomes

The outcomes for patients with congenital thrombocytopenia are variable depending on the specific disorders. Patients with CAMT often develop bone marrow failure and pancytopenia and require bone marrow transplant. The thrombocytopenia in TAR patients is severe at birth, but improves over time, often reaching platelet counts >100 × 10^9/L. The hematologic outcome of MYH-9 related disorders is good, although they frequently develop nephritis, hearing loss, and cataracts later in life.

Platelet Function Disorders

Pathophysiology

Platelets play a major role in hemostasis, both by supporting the cellular structure for the primary platelet plug, and also by providing a phospholipid surface on which the plasma elements involved in coagulation can bind. Thus, a decrease in the platelet count and/or poor platelet function can result in bleeding symptoms. Platelet function disorders can be broadly categorized as congenital or acquired.

Most platelet function defects seen in the NICU are acquired, and can be due to medications, medical conditions, or medical interventions. The list of medications that can affect platelet function is extensive, but the most common medications resulting in platelet dysfunction include aspirin and other non-steroidal anti-inflammatory drugs (indomethacin and ibuprofen), prostacyclin, certain anticonvulsants (valproic acid in particular), and some antibiotics (beta-lactams). Among the medical disorders associated with platelet dysfunction, the most common and best described is uremia. Although the exact mechanism by which the platelets are affected is not clear, a prevailing theory is that the accumulation of certain substances associated with uremia disrupts the platelet phospholipid surface. Last, certain medical procedures are associated with platelet dysfunction, with the most common being the use of extracorporeal circuits (ECMO) and cardiopulmonary bypass. Therapeutic hypothermia, currently the standard of care for infants with hypoxic-ischemic encephalopathy, also causes transient platelet dysfunction.[88]

Congenital platelet function disorders occur as a result of defects or deficiencies in any of a multitude of components (functional, structural, and regulatory proteins) required for normal platelet function. The most severe platelet function defects, which can present in neonatal life, result from deficiency or absence in the glycoproteins (GP) located on the platelet surface: Bernard-Soulier syndrome, caused by deficiency of GPIb (the vWF receptor), and Glanzmann's thrombasthenia, caused by a deficiency of GPIIb/IIIa, the fibrinogen receptor.[89] Both have been reported to present with bleeding in neonatal life, although they most frequently present later in childhood.

Most of the other inherited platelet function defects are mild, and very rarely present in the newborn period. Secretory platelet disorders have defective platelet granules, and cause mild to moderate bleeding. These include δ-storage pool defects (including the common ADP secretion defect and the less common absence of dense bodies associated with Hermansky-Pudlak syndrome), and α-granules defects (gray platelet syndrome). Over the last decade, the availability of better genetic tools has led to the identification of the genetic causes of many of these platelet functional defects (i.e., mutations in NBEAL2 cause gray platelet syndrome), and of novel mutations associated with platelet dysfunction and bleeding. A thorough review of these disorders is outside of the scope of this chapter, particularly because the degree of bleeding associated with most of these conditions rarely leads to manifestations in the neonatal period.

Clinical Presentation

Patients with platelet function disorders present similar to thrombocytopenia with bleeding signs, including mucocutaneous bleeding (nose, mouth, gastrointestinal tract, genitourinary tract) and bruising. The extent, location, and nature of the bruises are generally related to birth trauma and invasive procedures. Bernard-Soulier syndrome patients present with mild thrombocytopenia, giant platelets on the blood smear (macrothrombocytopenia), and mucosal type bleeding due to platelet dysfunction. Patients with Bernard-Soulier present with gastrointestinal bleeding, bleeding after circumcision, and bleeding after cardiac catheterization in a patient with DiGeorge syndrome.[90] Glanzmann thrombasthenia is a rare autosomal recessive platelet function disorder, caused by a deficiency or abnormality of GPIIb–IIIa expression on the platelet surface. In neonates, the most common manifestations of Glanzmann thrombasthenia are generalized purpura or bleeding after circumcision, although more serious hemorrhages have also been described.[91]

Evaluation

The diagnosis of platelet function disorders in neonates is problematic, because many of the traditional tests require a large amount of blood (platelet aggregation studies), or lack reference values for neonates. The traditional assay of platelet function is platelet aggregometry. This assay uses a set concentration of platelet-rich plasma and assesses platelet aggregation via light transmission after addition of a variety of platelet agonists (ADP, epinephrine,

ristocetin, arachidonic acid, collagen, and thrombin-related activation peptide). Neonates have reduced platelet aggregation compared to older children and adults (based on cord blood values), and therefore the interpretation of this test in neonates is difficult. The amount of blood required for platelet aggregometry is 20 to 30 mL, depending on the platelet count and how many agonists will be tested. Recently, whole blood aggregometry assays have been developed and are becoming increasingly available. These assays require significantly less blood than traditional platelet aggregometry, thus making them accessible to neonates. However, the lack of neonatal reference ranges has hampered the wider use of aggregometry in this age group.

There are two other tests that can screen for platelet function disorders; however, both have significant limitations. The original screening test is the bleeding time, a test that is difficult to perform, particularly in neonates, and is rarely offered clinically. The PFA-100 is a widely used laboratory assay available in most coagulation laboratories and is a useful screening assay to evaluate for disorders of primary hemostasis. Normal ranges for the PFA have been established in cord blood,[92] and in neonatal blood.[22] The blood volume required for this test is much less than for aggregometry, and thus it can be used in neonates. Patients with severe platelet function defects such as Bernard-Soulier and Glanzmann's thrombasthenia typically have significantly abnormal results. The PFA is also often abnormal in the milder disorders such as the common ADP secretion defects; however, its sensitivity for these disorders is not sufficient to allow such defects to be ruled out if the results are normal. The PFA-100 is also abnormal in patients on aspirin and clopidogrel and ticlopidine (the collagen/ADP cartridge). Neonates on indomethacin, ibuprofen, or certain antibiotics can also have a prolonged PFA-100. The effects of other medications known to affect platelet function are not clear. Thus, the PFA is a useful screen for the platelet function defects. However, it cannot be performed when the patient is on certain medications, and it cannot rule out milder platelet function defects.

In general, it is reasonable to start with a complete blood count and a review of the peripheral blood smear. The combination of mild thrombocytopenia and large platelets (macrothrombocytopenia) is suggestive of Bernard-Soulier syndrome. Bernard-Soulier can be confirmed using flow cytometry to evaluate for the presence of GPIb on the platelet surface. Similarly, GPIIb/IIIa surface expression can be assessed to evaluate for Glanzmann's thrombasthenia. This evaluation can be done in a small blood volume and is accurate in neonatal life. Some platelet function defects also lead to easily identifiable ultrastructural changes in the platelets that can be visualized by electron microscopy. In particular, a deficiency or absence of dense bodies (δ-storage pool deficiency) or α-granules (gray platelet syndrome) can be demonstrated by electron microscopy.

More recently, a high-throughput sequencing platform targeting 63 genes relevant for bleeding and platelet disorders was generated, which allows the efficient molecular diagnosis of bleeding and platelet disorders, avoiding the need for multiple sequential tests to narrow the diagnostic possibilities. This DNA-based diagnostic platform will likely become the new approach to patients with suspected inherited platelet function disorders.[93]

Management

The management of congenital platelet function defects relies on several medications, and platelet transfusions in dire situations when the medications or local measures are ineffective. In acquired conditions, reversal of the condition that led to the platelet dysfunction will reverse the platelet defect, but this is not always possible. In such situations, the approach to management of bleeding is mostly based on platelet transfusions.

Several medications have nonspecific mechanisms whereby they can enhance hemostasis when platelet function is abnormal. These include desmopressin, antifibrinolytic agents, and recombinant activated FVII (rFVIIa). Desmopressin improves platelet function in many congenital disorders, in uremia, and during cardiopulmonary bypass. However, desmopressin is generally not used in children <2 years of age, because it can lead to vasodilatation, resulting in reductions in blood pressure sufficient to lead to clinical signs, but mostly because it is an analogue of antidiuretic hormone and can induce hyponatremic seizures. Neonates are at a particularly high risk for this complication; thus, desmopressin is not recommended in this age group.

Recombinant FVIIa was developed for the management of bleeding in patients with hemophilia and inhibitors; however, it has been shown to also be effective for managing severe bleeding in patients with severe platelet function defects. It is licensed in Europe for the management of bleeding in patients with Glanzmann thrombasthenia who are refractory to platelet transfusions. The major risk of rFVIIa is the risk of thrombosis. Thus, it is suggested that rFVIIa be used only for patients with severe bleeding in whom standard therapeutic measures have failed. The use of this agent in neonates has been reported, and it appears that neonates are at increased risk for thrombosis from this agent compared with older children.[94] There is no consensus, however, since another study evaluating the risk of thrombotic events associated with rFVIIa use in neonates showed a prevalence of 7.5% in bleeding and/or coagulopathic neonates, which was similar to those neonates who received FFP.[95] Antifibrinolytic agents might also be helpful, particularly later in life, for epistaxis and menorrhagia.

For severe bleeding that has not responded to the measures just described, a platelet transfusion should be given to provide normally functioning platelets. Although most platelet function defects are mild enough that this will never be required, for the more severe disorders such as Bernard-Soulier and Glanzmann's thrombasthenia, a platelet transfusion may be lifesaving. The risks associated with a platelet transfusion are no different from those for other patients, with one important exception: patients with Bernard-Soulier and Glanzmann thrombasthenia are at risk for alloimmunization, resulting in the formation of antibodies to GPIb and GPIIb/IIIa, respectively. Once these antibodies develop, future platelet transfusions are likely to be ineffective. Thus, it is imperative to withhold platelet transfusions for these patients except in life-threatening hemorrhage, because it may be possible to use this therapy only once in a patient's lifetime. Last, local measures are extremely important in the management of bleeding.

Neonatal Erythrocyte Disorders

KATIE CARLBERG

KEY POINTS

- Erythropoiesis occurs in stages or waves during embryonic development, initiating in the yolk sac, migrating to the liver, and finally to the bone marrow. The sites of erythropoietin production also transition during development from the neuronal cells to the fetal hepatocytes, and ultimately to the renal fibroblasts.
- Fetal red blood cells (RBCs) have higher mean corpuscular volumes and mean corpuscular hemoglobins, different hemoglobin composition, and a higher oxygen affinity than adult RBCs.
- Anemia and polycythemia must be defined during the neonatal period in accordance with reference intervals appropriate for gestational and postnatal age. Anemia in the fetus or neonate can be categorized kinetically as the result of underproduction, hemorrhage, or hemolysis. Polycythemia in the fetus or neonate similarly can be attributed to either increased production or hypertransfusion.
- Areas of controversy include the use of cytomegalovirus-negative products and liberal versus restrictive transfusion thresholds for various neonatal populations.

Normal Erythrocyte Physiology in the Fetus and Newborn

Fetal Erythropoiesis

Embryonic and fetal hematopoiesis is a complex system, simultaneously adapting to and supporting the ever-changing anatomy and milieu within which it develops. Fetal erythropoiesis occurs sequentially during embryonic development in three different sites: yolk sac (extra-embryonic hematopoiesis), liver, and bone marrow.[1] The initial waves of cells originate in blood islands within the yolk sac and serve to meet the immediate needs of the growing embryo. The first types of blood cells produced are morphologically distinct, large nucleated erythrocytes[2] which have been termed "primitive erythrocytes." The yolk sac is also the source of the first wave of "definitive erythrocytes" or erythro-myeloid progenitors (EMPs) which ultimately seed the liver where they differentiate. Yolk sac formation of red blood cells (RBCs) is maximal between 2 and 10 weeks of gestation as the developing fetal liver does not become the predominant source of erythrocytes and other hematopoietic cells until after the first trimester. Bone marrow production of RBCs begins around week 18. Slowly, the liver's function transitions from hematopoiesis to metabolic and by the 30th week of fetal life, bone marrow is the major erythropoietic organ. At full term gestation, almost all RBCs are produced in the bone marrow, although a low level of hepatic erythropoiesis persists through the first few days of life. Sites of fetal erythropoiesis occasionally are reactivated in older patients with hematologic disorders such as myelofibrosis, aplastic anemia, and severe hemolytic anemia.

The growth factors and cytokines that regulate embryonic hematopoiesis remain areas of controversy,[3,4] and animal work suggests that they differ from those that regulate proliferation and differentiation of stem cells in later life.[5] RBC production in extrauterine life is controlled in part by erythropoietin (EPO), a humoral erythropoietic-stimulating factor produced primarily by the kidney. The role of erythropoietin in the developing fetus has not been completely defined, but EPO is not thought to influence the earliest stages of yolk sac erythropoiesis. Within the past decade, neural crest cells have been determined to be the first site of EPO production.[4] As production within the neural crest and neuroepithelial cells begins prior to circulation, delivery to the yolk sac does not occur until roughly day 20, with the first heartbeats. Drive of primitive erythropoiesis (prior to day 20) is therefore EPO-independent. As the sites of early hematopoiesis transition, so too do the sites of EPO production from the neuronal EPO-producing cells to the fetal hepatocytes in late embryonic stages where EPO acts in a paracrine manner, and finally a gradual transition to the fibroblasts of the kidneys (renal erythropoietin-producing cells) beginning at week 30 of gestation.

EPO is detected in fetal blood and amniotic fluid during the third trimester of pregnancy. The concentration of this hormone increases directly with the period of gestation, and thus, EPO levels in term newborns are significantly higher than in premature infants. This difference may reflect some degree of fetal hypoxia during late intrauterine life. Increased EPO titers also are seen in placental dysfunction, fetal anemia, and maternal hypoxia.[6] Fetal RBC formation is not influenced by maternal EPO. Animal studies have demonstrated that EPO does not cross the placenta.[7] In humans, transfusion-induced maternal polycythemia which decreases maternal EPO levels has no effect on fetal erythropoiesis.[8] Additionally, maternal nutritional status is not a significant factor in the regulation of fetal erythropoiesis, because iron, folate, and vitamin B_{12} are trapped by the fetus irrespective of maternal stores, to a point. Studies have demonstrated that women with severe iron deficiency bear children with normal total body hemoglobin content.[9]

The placenta has been the focus of much of the research in maternal-fetal iron homeostasis and indeed has revealed a tightly

TABLE 69.1 Mean Red Blood Cell Values During Gestation

Weeks of Gestation	Hb (g/dL)	Hct (%)	RBC (10^6/mm^3)	MCV (fL)	MCH (pg)	MCHC (g/dL)	Nucleated RBCs (% of RBCs)	Reticulocytes (%)	Diameter (μm)

regulated system of placental iron transport mechanisms. In the setting of maternal iron deficiency, the expression of various placental proteins is increased and include but are not limited to divalent metal transporter 1 (DMT1),[10] transferrin receptor 1 (TFR1), and ferroportin (FPN) in more severe iron deficiency.[11] Despite this intricate dance, recent studies suggest that the placental acquisition of iron is prioritized over fetal endowment.[11] This is not surprising given the well described correlation between maternal iron deficiency and adverse neonatal outcomes such as preterm birth, low birth weight, impaired immune function, and numerous neurobehavioral effects.[12–14] Additionally, parameters such as cord blood hemoglobin and cord blood ferritin may not accurately reflect the neonate's total body stores. Neonatal iron has been shown to preferentially be used for heme synthesis which maintains normal total body hemoglobin content while sacrificing brain iron endowment.[15]

Hemoglobin, hematocrit, and RBC count increase throughout fetal life (Table 69.1). Extremely large RBCs (mean corpuscular volume [MCV] of 180 fL) with an increased hemoglobin content (mean corpuscular hemoglobin [MCH] of 60 pg/cell) are produced early in fetal life. The size and hemoglobin content of these cells decrease throughout gestation, but the mean corpuscular hemoglobin concentration (MCHC) does not change significantly. Even at birth, the MCV and MCH are greater than those in older children and adults. Many nucleated RBCs and reticulocytes are present early in gestation, and the percentage of these cells also decreases as the fetus ages.

Hemoglobin production increases markedly during the last trimester of pregnancy. The actual hemoglobin concentration increases, but, more important, body weight, blood volume, and total body hemoglobin triple during this period. Fetal iron accumulation parallels the increase in total body hemoglobin content. The neonatal iron endowment at birth, therefore, is directly related to total body hemoglobin content and length of gestation. Term infants have more iron than premature infants.

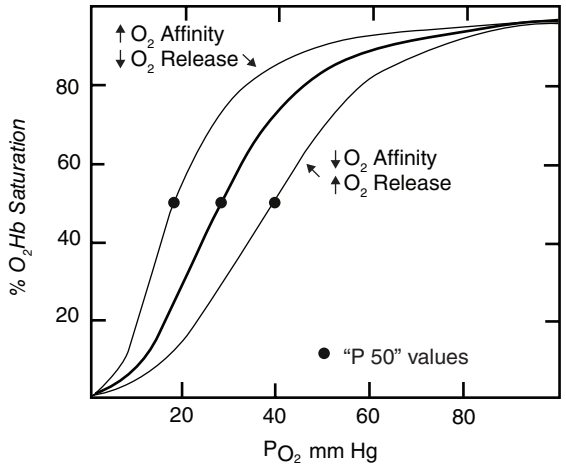
Red Blood Cell Physiology at Birth

In utero, the PO_2 in blood delivered to the tissues is only one third to one fourth the value in adults. This relative hypoxia may be responsible for the increased content of erythropoietin and signs of active erythropoiesis (nucleated RBCs, increased reticulocytes) seen in newborns at birth. When lungs become the source of oxygen, hemoglobin-oxygen saturation increases to 95% and erythropoiesis decreases. Within 72 hours after birth, erythropoietin is undetectable, nucleated RBCs disappear, and by 7 days, reticulocytes decrease to less than 1%.

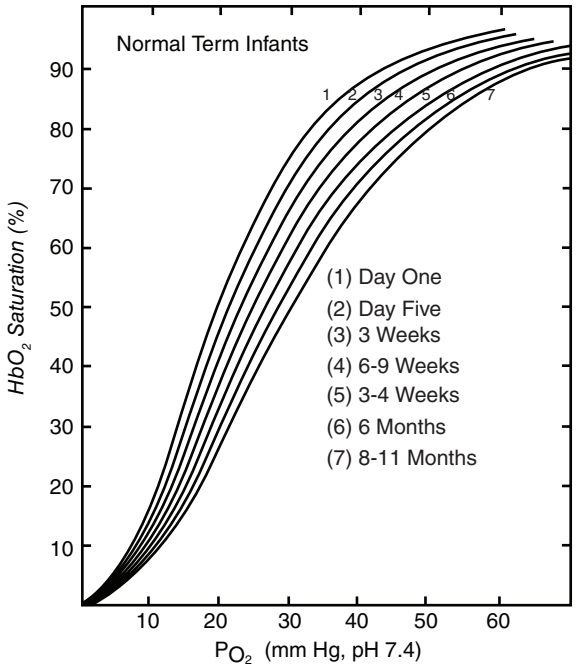
The concentration of hemoglobin during the first few hours of life increases to values greater than those in cord blood. This is both a relative increase caused by a reduction in plasma volume[16] and an absolute increase caused by placental blood transfusion.[17] The umbilical vein remains patent long after umbilical arteries have constricted, and thus transfusion of placental blood occurs when newborns are placed at a level below the placenta. The placenta contains approximately 100 mL of fetal blood (30% of the infant's blood volume). Approximately 25% of placental blood enters the newborn within 15 seconds of birth, and by one minute, 50% is transfused. The time of cord clamping is thus a direct determinant of neonatal blood volume. The blood volume in term infants (mean of 85 mL/kg) varies considerably (50 to 100 mL/kg) because of different degrees of placental transfusion.[17] These differences are readily apparent when the effects of early versus delayed cord clamping are compared at 72 hours of age: 82.3 mL/kg (early clamping) versus 92.6 mL/kg (delayed clamping).[17] These changes are largely the result of differences in RBC mass, 31 mL/kg (early clamping) versus 49 mL/kg (delayed clamping).[17] The blood volume in premature infants (89 to 105 mL/kg) is slightly greater than that in term infants, but this difference is due in large part to an increased plasma volume.[18] The RBC mass in premature infants, expressed in milliliters per kilogram, is the same as in term newborns.

Fetal and Neonatal Hemoglobin Function

A variety of hemoglobins are present during fetal and neonatal life. Fetal hemoglobin (hemoglobin F) is the major hemoglobin in utero, whereas hemoglobin A is the normal hemoglobin of extrauterine life. A single RBC may contain both hemoglobin F and hemoglobin A in varying proportions, depending on gestational



• **Fig. 69.1** The oxygen dissociation curve for normal adult hemoglobin *(bold line)*. The percent oxygen saturation (ordinate) is plotted for arterial oxygen tensions between 0 and 100 mm Hg (abscissa). As the curve shifts to the right, more oxygen is released at any given P_{O_2}. Conversely, as the curve shifts to the left, more oxygen is retained on hemoglobin at any given PO_2. The "P 50" refers to that PO_2 in which hemoglobin is 50% saturated with oxygen. This term is useful in comparing the oxygen affinities of different hemoglobins. (From Oski FA, Delivoria-Papadopoulos M. The red cell, 2,3-diphosphoglycerate, and tissue oxygen release. *J Pediatr*. 1970;77:941–956.)



• **Fig. 69.2** The oxygen affinity of blood from term infants at birth and at different postnatal ages. The gradual rightward shift of the oxygen saturation curve indicates increased oxygen release from hemoglobin as infants get older. This decreased oxygen affinity is due to a decrease in hemoglobin F and an increase in hemoglobin A. (From Oski FA, Delivoria-Papadopoulos M. The red cell, 2,3-diphosphoglycerate, and tissue oxygen release. *J Pediatr*. 1970;77:941–956.)

and postnatal age. One major difference between hemoglobins A and F is related to oxygen transport.

The transport of oxygen to peripheral tissues is regulated by several factors, including blood oxygen capacity, cardiac output, and hemoglobin-oxygen affinity. Oxygen capacity is a direct function of hemoglobin concentration (1 g hemoglobin combines with 1.34 mL oxygen). Compensatory changes in cardiac output can maintain normal oxygen delivery under conditions in which oxygen capacity is significantly reduced. The oxygen affinity of hemoglobin also influences oxygen delivery to tissues. Hemoglobin A is 95% saturated at an arterial PO_2 of 100 mm Hg, but this decreases to 70% to 75% saturation at a venous PO_2 of 4 mm Hg. The difference in O_2 content at arterial and venous oxygen tensions reflects the amount of oxygen that can be released. Changes in hemoglobin affinity for oxygen can influence oxygen delivery (Fig. 69.1).[19] At any given PO_2, more oxygen is bound to hemoglobin when oxygen affinity is increased. Stated in physiologic terms, increased hemoglobin-oxygen affinity reduces oxygen delivery, whereas decreased hemoglobin-oxygen affinity increases oxygen release to peripheral tissues.

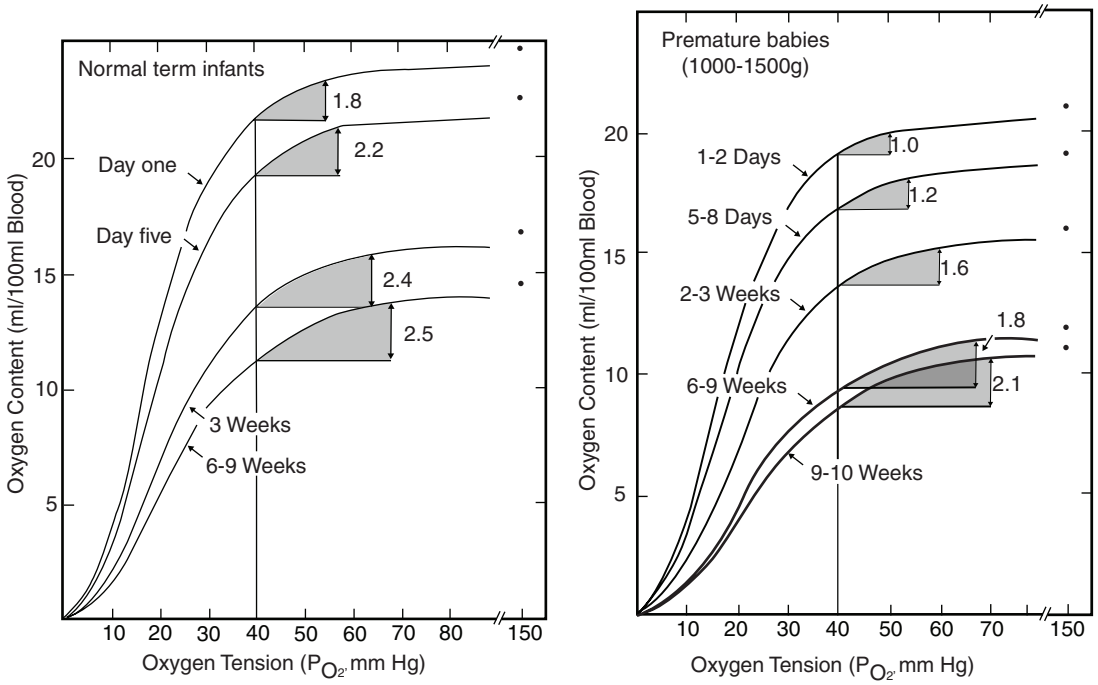
The oxygen affinity of hemoglobin A in solution is greater than that of hemoglobin F. Paradoxically, however, whole blood from normal children (hemoglobin A) has a lower oxygen affinity than that of neonatal blood (hemoglobin F).[20] This difference is related to an intermediate of RBC metabolism, 2,3-diphosphoglycerate (2,3-DPG). This organic phosphate compound interacts with hemoglobin A to decrease its affinity for oxygen, thereby enhancing O_2 release. Fetal hemoglobin does not interact with 2,3-DPG to any significant extent[21]; consequently, cells containing hemoglobin F have a higher oxygen affinity than those containing hemoglobin A. The increased oxygen affinity of fetal RBCs is advantageous for extracting oxygen from maternal blood within the placenta.

A few months after birth, infant blood acquires the same oxygen affinity as that of older children (Fig. 69.2). The postnatal decrease in oxygen affinity is due to a reduction in hemoglobin F and an increase in hemoglobin A (which interacts with 2,3-DPG). Oxygen delivery (the difference in arterial and venous O_2 content) increases while oxygen capacity (hemoglobin concentration) decreases during the first week of life (Fig. 69.3). This enhanced delivery is largely a reflection of the decreased oxygen affinity of infant blood.[22] The oxygen affinity of blood from premature infants is higher than that of term infants, and the normal postnatal changes (decrease in oxygen affinity, increase in oxygen delivery) occur much more gradually in premature infants (see Fig. 69.3).

Another role of the fetal erythrocyte that has only relatively recently been appreciated is maternal immune tolerance. In a mouse model, the immunosuppressive role of CD71+ erythroid cells both on the maternal side as well as the fetal side has been demonstrated. In pregnant mice as well as pregnant women, a higher proportion of peripheral CD71+ erythroids was found compared to their non-pregnant counterparts. This upregulation was also present locally, at the fetomaternal interface (placental tissue).[23] Through regulation of L-arginine levels and site-specific expression of PDL-1, the work of Delyea et al. suggests that fetal CD71+ erythroid cells play an integral role in the immune tolerance which is essential for a successful allogeneic pregnancy.

Anemia in the Fetus and Newborn

The cause of anemia frequently can be ascertained by medical history and physical examination. Particular focus should be given to family history (anemia, cholelithiasis, unexplained jaundice, splenomegaly), maternal medical history (especially infections), and obstetric history (previous pregnancies, length of gestation,



• **Fig. 69.3** Oxygen delivery in normal term and premature infants. Oxygen content (a function of total hemoglobin) is on the ordinate. Oxygen tension is on the abscissa. Oxygen delivery is measured by the difference in oxygen content at arterial (100 mm Hg) and venous (40 mm Hg) oxygen tensions. For both term and premature infants, oxygen delivery *(shaded areas)* increases with age. This occurs despite a decrease in oxygen content. (From Delivoria-Papadopoulos M, Roncevic NP, Oski FA. Postnatal changes in oxygen transport of term, premature, and sick infants: the role of red cell 2,3-diphosphoglycerate and adult hemoglobin. *Pediatr Res*. 1971;5:235–245.)

TABLE 69.2 Differential Approach to Anemia in the Newborn Period

Hemoglobin	Reticulocytes	Bilirubin	Direct Antiglobulin (Coombs) Test	Clinical Considerations
Decreased	Normal/decreased	Normal	Negative	Physiologic anemia of infancy and prematurity Hypoplastic anemia
Decreased	Normal/increased	Normal	Negative	Hemorrhagic anemia
Decreased	Normal/increased	Increased	Positive	Immune-mediated hemolysis
Decreased	Normal/increased	Increased	Negative	Acquired or hereditary red blood cell defects Enclosed hemorrhage with resorption of blood DAT-negative ABO incompatibility

method and difficulty of delivery). The age at which anemia becomes manifest also is of diagnostic importance. Significant anemia at birth is generally due to blood loss or alloimmune hemolysis. After 24 hours, internal hemorrhages and other causes of hemolysis are more common. Anemia that appears several weeks after birth can be caused by a variety of conditions, including abnormalities in the synthesis of hemoglobin beta chains, hypoplastic RBC disorders, and the physiologic anemia of infancy or prematurity.

Infants with anemia resulting from chronic blood loss may appear pale, without other evidence of clinical distress. Acute blood loss can produce hypovolemic shock and a clinical state similar to severe neonatal asphyxia. Newborns with hemolytic anemia frequently show a greater-than-expected degree of icterus. In addition, hemolysis often is associated with hepatosplenomegaly, and in cases resulting from congenital infection, other stigmata may be present.

Evaluation of Anemia

A simple classification of neonatal anemia based on physical examination and basic laboratory tests is presented in Table 69.2. More extensive RBC testing is discussed elsewhere.[24]

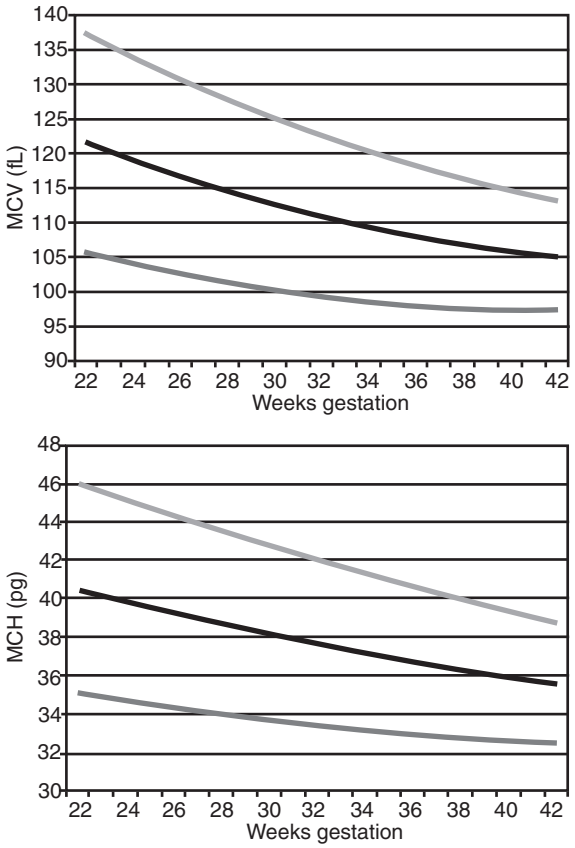
Red Blood Cell Count, Hemoglobin, Hematocrit, and Red Blood Cell Indices

RBC values during the neonatal period are more variable than at any other time of life. The diagnosis of anemia must therefore be made in terms of "normal" values for gestational and postnatal ages. The mean cord blood hemoglobin of healthy term infants ranges between 14 and 20 g/dL (Table 69.3). Shortly after birth, however, hemoglobin concentration increases. This increase is both relative (owing to a reduction of plasma volume) and absolute (owing to placental RBC transfusion).

TABLE 69.3 Red Blood Cell Values in Term and Premature Infants During the First Week of Life

	Hb (g/100 mL)	Hct (%)	Reticulocytes (%)	Nucleated RBCs (Cells/1000 RBCs)
Term				
Cord blood	17.0 (14–20)	53.0 (45–61)	<7	<1.00
Day 1	18.4	58.0	<7	<0.40
Day 3	17.8	55.0	<3	<0.01
Day 7	17.0	54.0	<1	0
Premature (Birthweight <1500 g)				
Cord blood	16.0 (13.0–18.5)	49	<10	<3.00
Day 7	14.8	45	<3	<0.01

Hb, Hemoglobin; *Hct*, hematocrit; *RBC*, red blood cell.



• **Fig. 69.4** Reference ranges for MCV *(upper panel)* and MCH *(lower panel)* for neonates on the first day after birth. The lower line shows the 5th percentile values, the middle line shows the mean values, and the upper line shows the 95th percentile values. (From Christensen RD, Henry E, Jopling J, Wiedmeier SE. The CBC: reference ranges for neonates. *Semin Perinatol*. 2009;33:3–11.)

Failure of hemoglobin to increase during the first few hours of life may be the initial sign of hemorrhagic anemia. RBC values at the end of the first week are virtually identical to those seen at birth. Anemia during the first week of life is thus defined as any hemoglobin value less than 14 g/dL. A significant hemoglobin decrease during this time is suggestive of hemorrhage or hemolysis. For example, a hemoglobin of 14.5 g/dL at 7 days of age is abnormal for a term infant whose hemoglobin was 18.5 g/dL at birth. A slight hemoglobin reduction normally occurs in premature infants during the first week of life. Beyond the first week, however, the hemoglobin concentration decreases in both term and premature infants (see Physiologic Anemia of Infancy and Anemia Prematurity, later).

The electronic equipment used for blood counts also gives statistical information regarding erythrocyte size (MCV) and hemoglobin content (MCH). The normal MCV in older children ranges from 75 to 90 fL. MCV values of less than 75 fL are considered microcytic, whereas those over 100 fL indicate macrocytosis. Normal infant RBCs are large (MCV 105 to 125 fL), and not until 8 to 10 weeks of age does cell size approach that in older children. Neonatal microcytosis is defined as an MCV of less than 95 fL at birth. The RBC hemoglobin content of neonatal cells (MCH 35 to 38 pg/cell) is greater than that seen in older children (MCH 30 to 33 pg/cell). Neonatal hypochromia is defined as an MCH of less than 34 pg/cell. Hypochromia and microcytosis generally occur together and are due to hemoglobin production defects. Neonatal hypochromic microcytosis is seen with iron deficiency and thalassemia disorders (alpha and gamma thalassemias). Both the MCV and MCH are higher in preterm infants as shown in Fig. 69.4.[25]

The site from which blood is obtained is important, because hemoglobin and hematocrit are higher in capillary blood than in simultaneously obtained central venous samples (up to 20%). This difference can be minimized by warming an extremity to obtain "arterialized capillary blood."[26] In the face of acute hemorrhage, however, central venous samples must be obtained because of marked peripheral vasoconstriction.

Reticulocyte Count

The normal reticulocyte count in children and older infants is 1% to 2% of the circulating red cells. The reticulocyte count in term infants ranges between 3% and 7% at birth, but this decreases to less than 1% by 7 days of age (see Table 69.3). In premature infants, reticulocyte values at birth are higher (6% to 10%) and may remain elevated for a longer period of time. Nucleated RBCs are seen in newborn infants, but they generally disappear by the third day of life in term infants and in 7 to 10 days in premature infants. The persistence of reticulocytosis or nucleated RBCs suggests the possibility of hemorrhage or hemolysis. Hypoxia, in the absence of anemia, also can be associated with increased release of reticulocytes and nucleated RBCs.

Peripheral Blood Smear

Examination of the peripheral blood smear is an invaluable aid in the diagnosis of anemia. The smear is evaluated for alterations in the size and shape of RBCs as well as abnormalities in leukocytes and platelets. Erythrocytes of older children are approximately the size of a small lymphocyte nucleus, whereas those of newborns are slightly larger. RBC hemoglobinization (e.g., hypochromia)

is estimated by observing the area of central pallor, which is one third the diameter of normal RBCs and more than one half the diameter of hypochromic cells. Spherocytes are detected by the complete absence of central pallor. The degree of reticulocytosis can be estimated, because these cells are larger and have a bluish coloration.

Direct Antiglobulin Test

Most cases of neonatal hemolytic anemia are due to isoimmunization. The direct antiglobulin test (DAT), previously known as the direct Coombs test, detects the presence of antibody on RBCs. The indirect antiglobulin test, previously known as the indirect Coombs test, detects anti-RBC antibodies in the plasma.

Management of Anemia

A hemoglobin of 14 g/dL corresponds to an RBC mass of 31 mL/kg. Thus, an RBC transfusion of 2 mL/kg will increase the hemoglobin concentration by approximately 1 g/dL. Packed RBCs (hematocrit approximately 67%) contain 2 mL of RBCs/3 mL of packed RBCs. Thus, the transfusion of 3 mL of packed RBCs/kg increases hemoglobin concentration by approximately 1 g/100 mL.

Packed RBCs are the product of choice when transfusion is necessary for simple anemia, as occurs in hemolysis. If anemia is accompanied by hypovolemia from acute blood loss, volume expansion must be achieved promptly, using packed RBCs and normal saline or a colloid such as 5% serum albumin (infused separately). The previously common practice of reconstituting RBCs with fresh frozen plasma to make "whole blood" is no longer acceptable because the increased donor exposure increases the risk of transmitting infectious disease. When packed RBCs need to be diluted to facilitate nonurgent transfusion, isotonic saline is the preferred diluent. Although fresh blood less than 2 days old is ideal because there is a reduced risk of hyperkalemia, this is not usually available. An acceptable substitute is packed RBCs less than 4 to 5 days old. These packed RBCs provide adequate oxygen delivery; hyperkalemia can be prevented by washing the RBCs once in saline and then reconstituting with normal saline. Washing is not required for the usually small, simple transfusions of packed RBCs, because the small volume of plasma minimizes any toxic effect of increased concentration of potassium in the plasma.

Blood currently available in most blood banks is anticoagulated with citrate-phosphate-dextrose (CPD), CPD-adenine (CPDA-1), or adenine-saline (AS-3), with a shelf life of 21, 35, or 42 days, respectively. Hematocrit usually ranges between 65% and 80% for packed RBCs. Near-normal 2,3-DPG levels are maintained for up to 12 to 14 days, which is advantageous in transfusing infants with acute hypoxia or those receiving large volumes of blood. Hematocrits range from 55% to 65%, thus facilitating flow during infusion. The newest of these preparations, AS-3, is well tolerated by newborns even after up to 42 days of storage, so long as only small-volume transfusions are given at any one time.[27] However, when larger-volume (≥20 mL/kg) transfusions are required, the theoretical concern is for fetal/neonatal renal and hepatic exposure to potentially toxic levels of the additives within these products such as adenine, mannitol, sodium chloride, dextrose, citrate, and phosphate. To date, there have been no trials assessing the safety of these additive solutions when transfusion needs increase, and many institutions utilize them in certain situations. A survey conducted in 2015 of 21 facilities across the US found that for large-volume transfusions in neonatal patients, 43% of responding centers used AS-3 RBC units, 29% used AS-1 RBCs, and 28% used CPD or CPDA RBC units.[28] Risks were mitigated using fresh units or re-washing previously radiated units so as to decrease the chance of hyperkalemia.

It is important to adopt practices that limit donor exposure in order to reduce the risk of transfusion-associated infections. Splitting and aliquoting a single red cell donation for multiple use by one neonate, using a unit through its outdate, the use of restrictive transfusion thresholds, and larger transfusion volumes are all effective ways to limit exposures.[29–32]

Preterm infants born weighing less than 1250 g are uniquely susceptible to potentially serious cytomegalovirus (CMV) infection from transfused blood, particularly if they lack immunity because their mothers are seronegative. Practices to prevent CMV infection have involved utilizing blood products from seronegative donors[33] but because approximately 40% to 60% of adults are seropositive, there is limited availability of seronegative donors. Alternatively, because CMV resides mainly in leukocytes, removal of such cells also can prevent transmission of the virus, and the use of high-efficiency leukocyte depletion filters[34] has proven effective. A potential disadvantage of using CMV-seronegative blood in CMV-positive infants receiving large amounts of blood is dilution of infant's antibody level, resulting in increased susceptibility to nursery-acquired CMV infection. Currently, a majority of neonatal services utilize leukocyte-reduced red cell products rather than relying on CMV-negative products to prevent CMV infection.[35] Although the efficacy of using leukoreduced and CMV-seronegative products was demonstrated in a recent prospective cohort study of 539 infants,[36] there remains quite a bit of controversy in terms of which products should be utilized for which patient populations. This ambiguity was highlighted when in 2016, the American Association of Blood Banks Clinical Transfusion Medicine Committee decided not to issue guidelines regarding the use of such products to reduce the risk of transfusion-transmitted CMV.[37] This controversy plays out in practice as was depicted in a US practice survey which was conducted in 2015 and published in 2018.[38]

Graft-versus-host (GVH) reaction rarely follows transfusion and occurs mainly in certain newborns at risk. For this to occur, viable lymphocytes in cellular blood products must be able to engraft and react against foreign antigens on tissues of the recipient. Infants at risk include those with congenital or acquired defects of cellular immunity, those who as fetuses received intrauterine transfusion of RBCs or platelets, newborns receiving exchange transfusion following intrauterine transfusion,[39,40] and infants receiving directed blood donations from first-degree relatives (whose genetic similarity may increase the likelihood of engraftment). Irradiation of RBCs and platelets with a minimum of 1500 rads has proved effective in preventing GVH reaction. Reports of GVH reaction after RBC transfusion in very premature infants without known risk factors[41,42] have prompted most neonatal services to irradiate all RBC blood products.[35]

Causes of Fetal and Neonatal Anemia

Hemorrhagic Anemia

Anemia frequently follows fetal blood loss, bleeding from obstetric complications, and internal hemorrhages associated with birth trauma (Box 69.1). Iatrogenic anemia due to repeated removal of blood for laboratory testing is common in premature infants. The clinical presentation of anemia depends on the magnitude and acuteness of blood loss.

BOX 69.1 Causes of Hemorrhagic Anemia in Newborns

Fetal Hemorrhage
Spontaneous fetomaternal hemorrhage
Hemorrhage following amniocentesis
Twin-twin transfusion
Nuchal cord

Placental Hemorrhage
Placenta previa
Abruptio placentae
Multilobed placenta (Vasa previa)
Velamentous insertion of cord
Placental incision during cesarean section

Umbilical Cord Bleeding
Rupture of umbilical cord with precipitous delivery
Rupture of short or entangled cord

Postpartum Neonatal Hemorrhage
Bleeding from umbilicus
Cephalohematomas, scalp hemorrhages
Hepatic rupture, splenic rupture
Retroperitoneal hemorrhage
Diffuse alveolar hemorrhage

Infants with anemia from moderate hemorrhage or chronic blood loss are generally asymptomatic. The only physical finding is pallor of the skin and mucous membranes. Laboratory studies can range from a mild normochromic normocytic anemia (hemoglobin 9 to 12 g/dL) to a more severe hypochromic microcytic anemia (hemoglobin 5 to 7 g/dL). The only therapy required for asymptomatic children is supplemental iron (3 to 4 mg elemental iron/kg once a day for 3 months). RBC replacement is indicated only if there is evidence of clinical distress (tachycardia, tachypnea, irritability, feeding difficulties). In most cases, increasing the hemoglobin to 10 to 12 g/dL removes all signs and symptoms associated with anemia. Because severely anemic infants are frequently in incipient heart failure, however, these children should be transfused very slowly (2 mL/kg/h). If signs of congestive heart failure appear, a rapid-acting diuretic (furosemide, 1 mg/kg intravenously) should be given before proceeding with the transfusion. An alternative approach is to administer a partial exchange transfusion with packed RBCs to severely anemic infants. This approach increases the hemoglobin concentration without the danger of increasing blood volume and precipitating congestive heart failure.

Infants who rapidly lose large volumes of blood appear to be in acute distress with pallor, tachycardia, tachypnea, weak pulses, hypotension, and shock. This presentation is distinct from that seen in neonatal respiratory asphyxia. Infants with respiratory problems demonstrate a marked improvement with assisted ventilation and oxygen, whereas there is little change in anemic newborns. Cyanosis is not a feature of severe anemia because the hemoglobin concentration is too low (for clinical cyanosis to be apparent, there must be at least 5 g/dL of deoxygenated hemoglobin). The hemoglobin concentration immediately after an acute hemorrhage may be normal, and a decreased hemoglobin may not be seen until the plasma volume has reexpanded several hours later. Thus, the diagnosis of acute hemorrhagic anemia is based largely on physical findings and evidence of blood loss. It is important to recognize these clinical features because immediate therapy is required. Treatment is directed at rapid expansion of the vascular space (20 mL fluid/kg) by rapid infusion of either isotonic saline or 5% albumin, followed by either type-specific, cross-matched packed RBCs. In infants in whom anemia and hypoxia are severe, non-cross-matched group O, Rh-negative RBCs are an acceptable alternative to cross-matched RBCs. Infants with hypovolemic shock caused by acute external blood loss usually show marked clinical improvement after this treatment. A poor response is seen in newborns with ongoing internal hemorrhage.

Fetal Hemorrhage

Significant bleeding into the maternal circulation occurs in approximately 8% of all pregnancies and thus represents one of the most common forms of fetal bleeding. Small amounts of fetal blood are lost in most cases, but in 1% of pregnancies, fetal blood loss may exceed 40 mL.[43] Fetomaternal hemorrhage occasionally follows amniocentesis and placental injury,[44] although anemia is seen only after unsuccessful amniocentesis or when there is evidence of a bloody tap.[45] For this reason, infants born to mothers who have had amniocentesis should be observed closely for signs of anemia. The effects of anemia resulting from fetomaternal hemorrhage are variable. Large acute hemorrhages can produce hypovolemic shock, whereas slower, more chronic blood loss results in hypochromic microcytic anemia resulting from iron deficiency. Some newborns with severe chronic fetal anemia (hemoglobin levels as low as 4 to 6 g/dL) may have minimal symptoms.

An examination of maternal blood for the presence of fetal cells is necessary to diagnose fetomaternal hemorrhage. Two techniques are available. The Kleihauer-Betke preparation involves examination of a stained specimen of maternal blood by microscopy following differential elution of hemoglobin A but not hemoglobin F from the red cells. Alternatively, flow cytometry–based techniques are probably more accurate but are less widely available. These approaches use antibodies against fetal hemoglobin (sometimes combined with antibodies against carbonic anhydrase) or against the D antigen to distinguish fetal RBCs from adult cells.[46–48]

Approximately 50 mL of fetal blood must be lost to produce significant neonatal anemia. This volume is greater than 1% of the maternal blood volume, and therefore fetal cells within the maternal circulation may be detected readily. Tests that depend on the presence of fetal hemoglobin are not valid when a maternal hemoglobinopathy with increased hemoglobin F levels coexists, such as sickle cell anemia, beta thalassemia, and hereditary persistence of fetal hemoglobin (HPFH). In addition, fetomaternal ABO incompatibility may cause rapid removal of fetal RBCs, thus obscuring any significant hemorrhage. For this reason, it is important to obtain a sample of maternal blood as soon as anemia from fetal hemorrhage is suspected.

Twin-Twin Transfusion

Transfusion of blood from one monozygous twin to another can result in anemia in the donor twin and polycythemia in the recipient. Significant hemorrhage is seen only in monochorionic monozygous twins (approximately 70% of all monozygous twins). The most common form, chronic twin-to-twin transfusion (TTTS), is seen in 10% to 15% of monochorionic pregnancies.[49,50] Bleeding occurs because of vascular anastomosis in monochorionic placentas. The anemic donor twin is usually smaller than the polycythemic recipient, with a greater than 20% difference in birthweight. Polyhydramnios is frequently seen in the recipient

twin and oligohydramnios is seen in the donor. TTTS is diagnosed when there is evidence of twin oligohydramnios (<2 cm)/polyhydramnios (>8 cm) sequence in the absence of other disorders which may lead to discordant amniotic fluid volumes. These volume thresholds differ depending on gestational age. The high rate of intrauterine mortality (approximately 63% with conservative management) has spurred attempts at fetal therapy, including decompression amniocentesis, laser coagulation of vascular anastomoses, interfetal septal disruptions, and selective feticide.[51,52]

Since first described in 1990,[53] laser coagulation for this purpose has undergone a series of technical modifications and is now considered the best option for treatment of most cases of TTTS. A systematic review from 2015 described perinatal survival of at least one twin after laser therapy in 81% to 88% of pregnancies and survival of both twins in 52% to 54% of pregnancies.[54] Despite impressive advancements made over the last 25 years, complications following laser therapy are not uncommon. Recurrent TTTS has been reported in up to 16% of cases,[55] twin anemia-polycythemia sequence (TAPS) in 2% to 13% of cases,[56] and preterm premature rupture of membranes (PPROM) in 17% to 40% of cases.[57–59]

Placental Blood Loss

Placental bleeding during pregnancy is common, but in most cases hemorrhage is from the maternal aspect of the placenta. In placenta previa, however, the thinness of the placenta overlying the cervical os frequently results in fetal blood loss. The vascular communications between multilobular placental lobes also are very fragile and are easily subjected to trauma during delivery. Vasa previa is the condition in which one of these connecting vessels overlies the cervical os and thus is prone to rupture during delivery. Abruptio placentae generally causes fetal anoxia and death, although some infants survive but can be severely anemic. Bleeding also follows inadvertent placental incision during cesarean section,[60] and thus the placenta should be inspected for injury following all cesarean sections.

Umbilical Cord Bleeding

The normal umbilical cord is resistant to minor trauma and does not bleed. The umbilical cord of premature infants, however, is weak and thus vulnerable to rupture and hemorrhage.[61] In cases of precipitous delivery, a rapid increase in cord tension can rupture the cord, causing serious acute blood loss. Short or entangled umbilical cords and abnormalities of umbilical blood vessels (velamentous insertions into the placenta) are also vulnerable to rupture and hemorrhage. Bleeding from injured umbilical cords is rapid but generally ceases after a short period of time, owing to arterial constriction. The umbilical cord should always be inspected for abnormalities or signs of injury, particularly after unattended, precipitous deliveries.

Hemorrhage After Delivery

Hemorrhagic anemia due to internal bleeding is occasionally associated with birth trauma. Characteristically, internal hemorrhages are asymptomatic during the first 24 to 48 hours of life, with signs and symptoms of anemia developing after this time. Cephalhematomas can be sufficiently large to cause anemia and hyperbilirubinemia secondary to the resorption of blood. Subgaleal hemorrhages are seen infrequently, sometimes occurring after vacuum extraction is used during delivery. In contrast to cephalhematomas, subgaleal bleeding can be extensive because hemorrhage is not limited by the periosteum. Adrenal and kidney hemorrhages occasionally follow difficult breech deliveries. Splenic rupture and hemorrhage occur most commonly in association with splenomegaly, as in erythroblastosis fetalis. Hepatic hemorrhages are generally subcapsular and may be asymptomatic. Rupture of the hepatic capsule results in hemoperitoneum and hypovolemic shock. Hepatic hemorrhages are suspected when a previously healthy infant goes into shock with clinical manifestations of an increasing right upper quadrant abdominal mass, shifting dullness on percussion, and evidence of free fluid on abdominal radiographs. In contrast to newborns with acute blood loss from fetomaternal or umbilical vessel bleeding, infants with hepatic hemorrhage generally demonstrate a poor clinical response to blood replacement. Diffuse alveolar hemorrhage is a rare but life-threatening cause of neonatal anemia, the etiology of which can be broadly divided into three categories: immune disorders, cardiovascular causes, and non-immune, non-cardiovascular origins.[62] The impact of iatrogenic blood loss has been well described, especially in premature neonates as the phlebotomy requirements are noted to increase with decreasing gestational age and increasing illness severity. The total blood volume removed from a preterm infant over the first weeks to months of life frequently exceeds their total blood volume.[63]

Hemolytic Anemia

RBCs from children and adults normally circulate for 100 to 120 days. Erythrocyte survival in newborns is shorter at 70 to 90 days in term infants, and 50 to 80 days in premature infants.[64] Hemolytic anemia, which further shortens RBC survival, may arise for many reasons (Box 69.2). Red cell destruction can occur by macrophage recognition of abnormal RBC membrane properties (extravascular hemolysis) or, alternatively, RBC destruction can occur by direct damage of the RBC in the circulation with the resultant release of hemoglobin (intravascular hemolysis). In most cases some degree of both types of hemolysis occurs.

In older infants and children, the usual response to increased RBC destruction is enhanced erythropoiesis, and there may be little or no anemia if the rate of production matches the accelerated rate of destruction. In these cases of well-compensated hemolysis, the major manifestations are due to increased erythrocyte destruction (hyperbilirubinemia) and augmented erythropoiesis (reticulocytosis). During the early neonatal period, however, the

BOX 69.2 Causes of Hemolytic Anemia During the Newborn Period

Immune Disorders

Isoimmune: Rh and ABO incompatibility
Maternal immune disease: autoimmune hemolytic anemia, systemic lupus erythematous
Drug-induced: penicillin

Acquired Red Blood Cell (RBC Disorders)

Infection: cytomegalovirus, toxoplasmosis, syphilis, bacterial sepsis
Disseminated and localized intravascular coagulation, respiratory distress syndrome

Hereditary RBC Disorders

Membrane defects: hereditary spherocytosis, hereditary elliptocytosis
Enzyme abnormalities: glucose-6-phosphate dehydrogenase, pyruvate kinase
Hemoglobinopathies: α-thalassemia syndromes, γ/β-thalassemia

increased oxygen-carrying capacity of blood (see Physiologic Anemia of Infancy and Anemia Prematurity, later) may blunt any compensatory erythropoietic activity in cases of mild hemolysis. Consequently, hyperbilirubinemia in excess of normal neonatal levels may be the only apparent manifestation of hemolysis. In most cases of significant hemolysis, however, some degree of reticulocytosis is usually present.

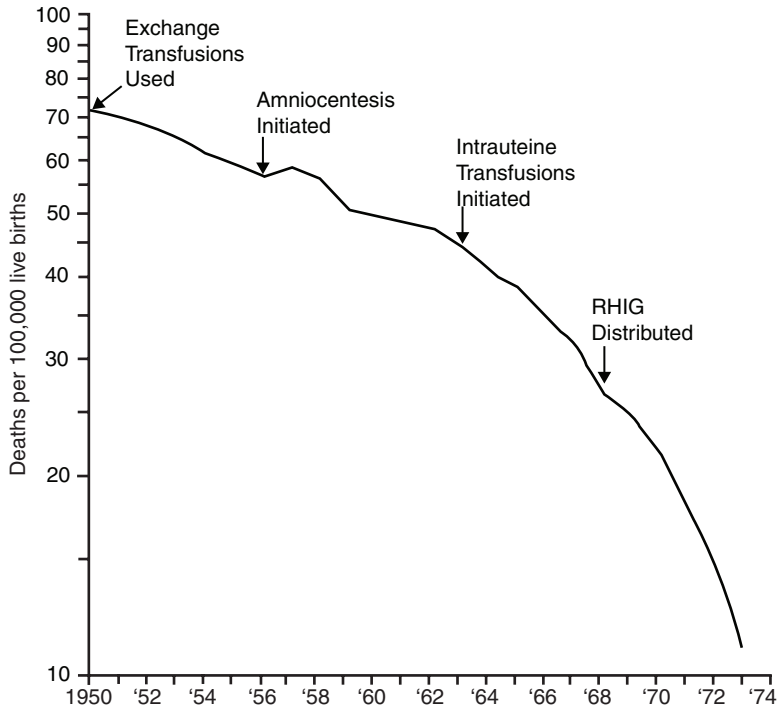
Immune Hemolysis

Placental transfer of maternal antibodies directed against fetal RBC antigens is the most common cause of neonatal hemolysis. This phenomenon is a consequence of maternal sensitization to fetal RBC antigens inherited from the father. Hemolysis occurs only in the fetus. The spectrum of clinical problems ranges from minimal anemia and hyperbilirubinemia to severe anemia with hydrops fetalis. At one time, before effective prevention of Rh sensitization was available, hemolytic disease of the newborn was responsible for more than 10,000 deaths annually in the United States.[65] In 1968, IgG and anti-Rh(D) gained regulatory approval and licensure for routine postpartum prophylaxis in RhD-negative women. Globally, this shift led to a decrease in the rate of RhD alloimmunization from 16% to roughly 2%[66] and ultimately to <0.5% upon additional antenatal administration in 1977 (Fig. 69.5).[67,68] Nevertheless, Rh incompatibility still occurs in areas where immune prophylaxis is not readily available. In the United States, most cases of alloimmune hemolysis are due to ABO maternal-fetal incompatibility with a smaller fraction resulting from sensitization to Kell, Duffy, Kidd, and other Rh antigens such as c and E.

Rh Hemolytic Disease: Erythroblastosis Fetalis

The role of Rh antibodies in classic erythroblastosis fetalis was first elucidated by Levine and Katzen in 1941.[69] There are over 50 (serologically defined) antigens within the Rh blood group, all of which are encoded by *RHD* and *RHCE*. These two genes are located on chromosome one, share 92% nucleotide sequence homology and 96% amino acid sequence similarity, and are organized in opposite orientation.[70–72] The *RHCE* gene encodes both the C/c and E/e proteins and their variants while the *RHD* gene encodes the RhD protein and its variants. The most common isoforms are D, C, c, E, and e. Rh-positive RBCs are those that possess the D antigen. This phenotype may result from homozygosity (DD) or heterozygosity (Dd) for the D antigen. In Rh-positive whites, approximately 44% are homozygous (DD) and 56% are heterozygous (Dd). There is no separate isoform for this antigen (as there is for C, c, E, and e), but rather a lowercase d is used to denote the absence of D, or Rh-negative status. As there is no "d" antigen, no "anti-d" serum has been identified. The majority of people with an Rh-negative phenotype have the *RHD* gene deleted from both chromosomes. The frequency of Rh negativity varies in different ethnic groups. It is high in whites (15%), lower in blacks (5%), and virtually nonexistent in Asians.[73] Interestingly, the genotype of Rh negativity also varies by ethnicity. In black populations, only 18% of RhD-negative individuals are homozygous for the deletion. Instead, *RHD* variants are more common which either lead to the expression of an incomplete or hybrid D antigen (*RHD* pseudogene) or complete lack of expression (phenotypically D-negative). The former can result in "weak D" (previously "D^u positive") antibody testing.[74] These are relevant scenarios for obstetrical care as the genotype can predict which women can be treated as D-positive versus those that should be managed with anti-D immunoglobulin.[72,75,76]

The pathophysiology of alloimmune hemolysis resulting from Rh incompatibility includes the following: an Rh-negative mother, an Rh-positive fetus where the D antigen is expressed on fetal RBCs as early as 38 days of gestation,[77] leakage of fetal RBCs into maternal circulation, maternal sensitization to D antigen on fetal RBCs, production and transplacental passage of maternal anti-D antibodies into fetal circulation, attachment of maternal antibodies to Rh-positive fetal RBCs, and



• **Fig. 69.5** Infant death rates from hemolytic disease of the newborn, United States, 1950 to 1973.

destruction of antibody-coated fetal RBCs. Rh hemolytic disease occurring during the first pregnancy is rare (occurring in 1% of cases) but increases significantly with each subsequent pregnancy. Significant hemolysis occurring in the first pregnancy indicates prior maternal exposure to Rh-positive RBCs. On occasion the sensitization may be a consequence of an earlier transfusion in which Rh-positive RBCs were administered by mistake or in which some other blood component (e.g., platelets) containing Rh(D) RBCs was transfused. Small volumes of fetal RBCs enter the maternal circulation throughout gestation, although the major fetomaternal bleeding responsible for sensitization occurs during delivery[44] with certain factors increasing the volume of hemorrhage at that time such as cesarean delivery, multifetal gestation, bleeding placenta previa or abruption, manual removal of placenta, etc. Fetomaternal bleeding resulting from various other antepartum events such as abortion (spontaneous or induced), invasive procedures, maternal abdominal trauma, ectopic pregnancy, etc. account for only 1% to 2% of Rh alloimmunization.[78]

Once sensitization has occurred, reexposure to Rh(D) RBCs in subsequent pregnancies leads to an anamnestic response, with an increase in the maternal anti-D titer. In this circumstance, anti-D immune globulin is no longer effective at preventing or reducing the severity of consequent hemolysis in the fetus. If future pregnancies are desired, a woman has three options which allow for utilization of her own gamete: use of a gestational carrier, preimplantation genetic testing where an RHD negative embryo is selected and fertilized in vitro if the father is heterozygous for RHD, and insemination with sperm from a D-negative donor if the father is homozygous for RHD.

The major factor responsible for the reduced death rate related to Rh alloimmunization is the development of Rh immune globulin to prevent maternal sensitization. Important early observations were that fetomaternal RBC transfer (and thereby sensitization) occurs primarily during delivery and that the frequency of Rh immune hemolytic disease was much lower in ABO-incompatible pregnancies (maternal RBC type O, fetal RBC type A or B). The apparent beneficial effect of ABO incompatibility is because maternal anti-A and anti-B antibodies recognize the corresponding A and B fetal RBCs, leading to their destruction before sensitization can occur.

It is recommended that all women have their blood typed (ABO and Rh) along with an antibody screen at their first prenatal visit. For women who are Rh negative with a fetus that is or could be Rh positive, it is recommended that they receive anti D-immune globulin at 28 weeks' gestation, within 72 hours of delivery of a D positive baby, as well as after an antepartum event which could increase the risk of fetomaternal bleeding (see above). The antibody screen should be repeated at 28 weeks, prior to receiving immune globulin given the risk, albeit small, that the mother has become sensitized in that window. Although commercially available and highly sensitive (99.3%) and specific (98.4%),[79] noninvasive methods which utilize fetal cell free DNA in maternal plasma is not yet accepted as standard of care for determining the fetal Rh status. Prior to administering the anti D-immune globulin at delivery, a rosette test is done to determine if the routine dose is sufficient.[80] This test screens for excessive fetomaternal bleeding and if positive, should be followed by a quantitative test such as the Kleihauer-Betke test[81] or flow cytometry. In suspicious cases (e.g., with placental abruption or neonatal anemia), the volume of fetal hemorrhage can be quantified using the Kleihauer-Betke procedure.

As noted previously, pregnant Rh-negative women previously sensitized to Rh(D) should not receive anti D-immune globulin. In this circumstance, if the fetus is indeed at risk (Rh positive), the transplacental passage of maternal anti-D leads to a positive DAT on Rh(D) fetal RBCs. Depending on the amount of anti-D absorbed, a variable degree of fetal hemolysis occurs, thereby leading to anemia, hepatosplenomegaly, and increased bilirubin formation. In utero, bilirubin is removed by transfer across the placenta into the maternal circulation; therefore, hyperbilirubinemia is not a problem until after delivery, when levels may increase because of immaturity of hepatic conjugating enzymes as well as increased enterohepatic circulation. The major threat to the fetus is severe anemia leading to hydrops fetalis and intrauterine death. Typically, maternal anti-D titers are followed serially until they reach a "critical titer" at which point the fetus is felt to be at risk for these outcomes. As this is only a screening test and can actually increase even in cases where the fetus is Rh negative, once the critical titer is reached, the presence of fetal anemia can be assessed with various methods such as the middle cerebral artery peak systolic velocity (MCA-PSV).

Mild hemolytic disease is most common, manifested by a positive DAT with minimal hemolysis, little or no anemia (cord blood hemoglobin greater than 14 g/dL), and minimal hyperbilirubinemia (cord blood bilirubin less than 4 mg/dL). Aside from early phototherapy, these newborns generally require no therapy unless the postnatal rate of rise in bilirubin is greater than expected. Infants who do not become sufficiently jaundiced to require exchange transfusion are at risk of development of severe late anemia associated with a low reticulocyte count, usually at 3 to 6 weeks of age; thus, it is important to closely monitor hemoglobin levels after hospital discharge.

Moderate hemolytic disease is found in a smaller proportion of affected infants. This form is characterized by hemolysis, moderate anemia (cord blood hemoglobin less than 14 g/dL), and increased cord blood bilirubin levels (greater than 4 mg/dL). The peripheral blood may reveal numerous nucleated RBCs, decreased numbers of platelets, and occasionally a leukemoid reaction with large numbers of immature granulocytes. Infants with Rh disease also may exhibit marked hepatosplenomegaly, a consequence of extramedullary hematopoiesis and sequestration of antibody-coated RBCs. The risk of development of bilirubin encephalopathy is high if these neonates do not receive treatment. Thus, early exchange transfusion with type O, Rh-, and S-negative fresh RBCs (less than 5 days old) is usually necessary, in conjunction with intensive phototherapy. This approach has been responsible for the favorable outcome for most infants with moderate alloimmune hemolysis. Exchange transfusion is a procedure with which fewer and fewer providers have familiarity given the successful implementation of anti-Rh(D) prophylaxis in RhD-negative women. Significant complications of an exchange include infectious, catheter-related, metabolic, cardiovascular, and hematologic.[82–84] It is common for newborns who receive exchange transfusion to demonstrate a lower-than-normal hemoglobin concentration at the nadir of their "physiologic" anemia. Therefore, follow-up evaluation of hemoglobin for at least 2 months is important. The decrease in hemoglobin may be due in part to persistence of some anti-D antibody and destruction of the patient's own Rh(D)-positive RBCs. Also, this low hemoglobin measurement may reflect the decreased oxygen affinity and enhanced oxygen delivery of adult RBCs used for the exchange process, thereby blunting the expected erythropoietic response to hypoxia. Some studies suggest that the administration of recombinant human erythropoietin (rHuEPO) may

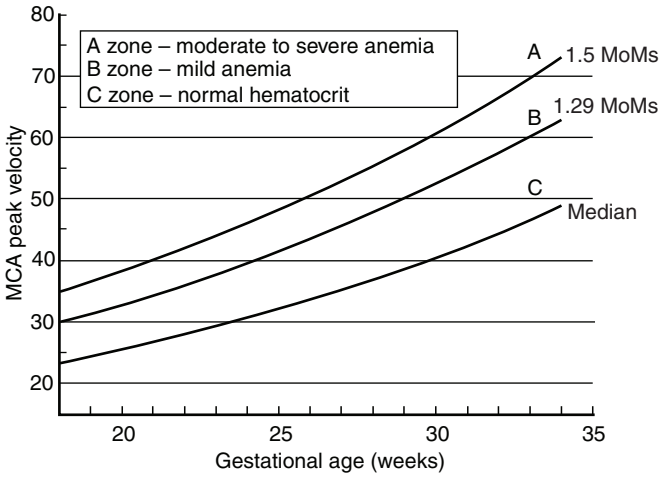
minimize this late anemia of Rh hemolytic disease,[85,86] although it is not always effective.[87]

Severe hemolytic disease is seen in approximately 25% of affected infants, who are either stillborn or hydropic at birth. Understanding of hydrops fetalis, originally attributed to high-output cardiac failure secondary to severe anemia, is incomplete. Two other consequences of anemia also may contribute to the edema of hydrops. One of these is low colloid osmotic pressure resulting from hypoalbuminemia, a consequence of hepatic dysfunction. The second is a capillary leak syndrome secondary to tissue hypoxia. Management of seriously affected fetuses is directed at the prevention of severe anemia and death. To accomplish this, it first is necessary to identify those fetuses at risk. An increase in the maternal anti-D titer in a previously sensitized Rh-negative woman is a good serologic measure of a fetus in potential jeopardy. Moreover, a previous history of neonatal hemolytic disease resulting from anti-D antibodies suggests that the current fetus also may be at risk. In this regard it may be useful to know the fetal Rh blood type because this identifies those Rh-negative infants who are not at risk. In many cases this can be accomplished by direct Rh typing of fetal RBCs obtained via cordocentesis. Alternatively, molecular biologic techniques can be used to determine the Rh genotype in DNA obtained from amniocytes, chorionic villus samples, or cell free fetal DNA in maternal circulation.[88–90] When the fetus is found to be Rh-negative, no further maternal monitoring or fetal blood studies are necessary.

An increase in the maternal titer of immunoglobulin G (IgG) anti-D indicates maternal sensitization but does not accurately predict the potential severity of fetal hemolysis. Previously, when the indirect antiglobulin test exceeded a critical threshold level (1:16 to 1:32), amniocentesis was done to perform spectrophotometric estimation of bile pigment in amniotic fluid as measured by the deviation in optical density (OD) at 450 nm. Plotting the "ΔOD450nm" against fetal age provided a good correlation with the severity of fetal hemolysis during the third trimester, and the trend of two or more values is a more reliable predictor of severity of fetal disease.[91]

Efforts have been made to use noninvasive detection of fetal anemia. Ultrasonography signs of hydrops fetalis represent a relatively late sign of fetal anemia, often not developing until Hgb values are more than 7 g/dL below gestational age norm. However, Doppler assessment of peak velocity in the fetal MCA, reflecting the lower viscosity associated with more severe anemia, has become the standard of care at most centers. MCA Doppler has been compared to the previous gold standard of the amniocentesis for "ΔOD450nm."[92] In one study, 45% of infants had severe anemia at cordocentesis, defined as a hemoglobin level at least five standard deviations below the mean for gestational age. The MCA Doppler was both more accurate than the ΔOD450nm (85% as compared with 76%) and more sensitive (88% as compared with 76%). It was suggested by the authors that more than 50% of invasive procedures might be avoided using this technique.

In severely affected fetuses, hydrops may occur as early as 20 to 22 weeks' gestation. Measurement of the peak MCA Doppler can begin as early as 18 weeks but more commonly is initiated at approximately 24 weeks, then repeated every 1 to 2 weeks, with adjustment in normal velocity with advancing gestation age to define the risk of severe anemia (Fig. 69.6). When the MCA Doppler exceeds 1.5 multiples of the median (A Zone) between 24 and 35 weeks' gestation, cordocentesis is required for direct determination of hematocrit as well as fetal blood type, DAT, reticulocyte count, and total bilirubin.[93] The rate of fetal trauma and morbidity associated with cordocentesis is less than



• **Fig. 69.6** Middle cerebral artery (MCA) Doppler graph based on gestational age. (From Moise KJ. Management of rhesus alloimmunization in pregnancy. *Obstet Gynecol*. 2008b;112:164–176.)

2%.[94,95] Cordocentesis should be performed with blood available for intravascular intrauterine transfusion if necessary. Such blood should be type O, RhD and S negative, cytomegalovirus negative, and less than 72 hours from collection; extended crossmatch is often performed with maternal blood type. Irradiation is mandatory, and many centers also perform leukoreduction. The transfusion is generally administered at approximately 20 mL/kg estimated fetal weight with a target of 40% to 50% hematocrit. Beyond 35 weeks, amniocentesis to determine both fetal lung maturity and the ΔOD450nm should be performed. Induction of delivery should be considered if the lungs are mature in order to decrease the risk of needing subsequent intrauterine transfusion with their attendant risks, or postnatal exchange transfusion for hyperbilirubinemia. For a full discussion and algorithm for management of pregnant patients with RhD alloimmunization, see Moise, 2008.[93]

Hyperbilirubinemia (with elevation of the conjugated fraction) often develops in newborns who have received intrauterine RBC transfusions and often predicts the need for exchange transfusions. This hyperbilirubinemia reflects the severity of hemolysis and its effects on the fetal liver. In some cases, anemia may be minimal or absent, and the DAT may be negative if the Rh-negative RBCs transfused prenatally still predominate. In such cases the infant may not require exchange transfusion. Neonatal exchange transfusion, amniocentesis, selective early induction of delivery, and intrauterine fetal blood transfusions all have contributed to the declining neonatal death rate from Rh incompatibility.

ABO Incompatibility

Hemolysis associated with ABO incompatibility is similar to Rh hemolytic disease in that maternal anti-A or anti-B antibodies enter the fetal circulation and react with A or B antigens on the erythrocyte surface (Table 69.4). In persons with type A and type B blood, naturally occurring anti-B and anti-A isoantibodies largely are IgM molecules that do not cross the placenta. In contrast, the alloantibodies present in persons with type O blood also include IgG antibodies that can traverse the placenta.[96] For this reason, ABO incompatibility is largely limited to type O mothers with type A or B fetuses. The presence of IgG anti-A or anti-B antibodies in type O mothers also explains why hemolysis caused

TABLE 69.4 Clinical and Laboratory Features of Immune Hemolysis Due to Rh Disease and ABO Incompatibility

	Rh Disease	ABO Incompatibility
Clinical Features		
Frequency	Unusual	Common
Pallor	Marked	Minimal
Jaundice	Marked	Minimal to moderate
Hydrops	Common	Rare
Hepatosplenomegaly	Marked	Minimal
Laboratory Features		
Blood type		
Mother	Rh(−)	O
Infant	Rh(+)	A or B
Anemia	Marked	Minimal
Direct antiglobulin test	Positive	Frequently negative
Indirect antiglobulin test	Positive	Usually positive
Hyperbilirubinemia	Marked	Variable
Red blood cell (RBC) morphology	Nucleated RBCs	Spherocytes

by ABO incompatibility frequently occurs during the first pregnancy without prior "sensitization." ABO incompatibility is present in approximately 12% of pregnancies, although evidence of fetal RBC sensitization (i.e., positive result on DAT) is found in only 3% of births, and less than 1% of live births are associated with significant hemolysis.[44,97] The relative mildness of neonatal ABO hemolytic disease contrasts sharply with the findings in Rh incompatibility. In large part, this is because A and B antigens are present in many tissues besides RBCs; consequently, only a small fraction of anti-A or anti-B antibody that crosses the placenta actually binds to erythrocytes, the remainder being absorbed by other tissues and soluble A and B substances in plasma.

Although hemolytic disease resulting from ABO incompatibility is milder than Rh disease, severe hemolysis occasionally occurs. In suspected cases of ABO incompatibility, it is essential to exclude other antibodies and other nonimmune causes of hemolysis such as glucose-6-phosphate dehydrogenase (G6PD) deficiency or hereditary spherocytosis. In most cases, pallor and jaundice are minimal (see Table 69.4). Hepatosplenomegaly is uncommon. Laboratory features include evidence of minimal to moderate hyperbilirubinemia and, occasionally, some degree of anemia. The DAT sometimes is negative, although the indirect antiglobulin test (neonatal serum plus adult group A or B RBCs) more commonly is positive. This paradox is related to the fact that fetal RBCs, compared with adult erythrocytes, have less type-specific antigen on their surface.[98] The peripheral blood smear is characterized by marked spherocytosis that is indistinguishable from that seen in hereditary spherocytosis (see Hereditary Spherocytosis, later).

Hemolysis in ABO incompatibility is usually mild, presenting with some degree of hyperbilirubinemia. Some infants with ABO incompatibility may be discharged home from medical establishments before clinical jaundice is evident. It is critical that infants with ABO incompatibility be monitored closely for evolving jaundice and hyperbilirubinemia in the first few days of life. In most cases, hyperbilirubinemia is readily controlled by phototherapy. In the minority of cases not controlled by phototherapy, exchange transfusion with group O, Rh-, S-compatible RBCs is utilized. Additional follow-up at 2 to 3 weeks of age to check for anemia in these infants is essential.

Minor Blood Group Incompatibility

With the sharp decline of hemolytic disease caused by Rh incompatibility, the proportion of cases caused by Rh c, Rh E, Kell, Duffy, and Kidd incompatibility has increased from the previous estimates of 1% to 3%, to as high as 20% for Kell sensitization.[99,100] The pathophysiology of these disorders is similar to that of Rh and ABO incompatibility. The infrequency of minor group incompatibility is primarily a reflection of the lower antigenicity of these RBC antigens. Diagnosis of minor group incompatibility is suggested by hemolytic anemia with a positive DAT in the absence of ABO or Rh incompatibility and with a negative maternal DAT. Definitive diagnosis requires identification of the specific antibody in neonatal serum or an eluate from neonatal RBCs. This is readily accomplished by testing maternal serum against a variety of known RBC antigens. With some antibodies such as Kell, antibody titer and amniocentesis findings may underestimate the severity of fetal hemolysis.

Immune Hemolytic Anemia Due to Maternal Disease

Maternal autoimmune hemolytic anemia or lupus erythematosus during pregnancy may be associated with passive transfer of IgG antibody to the fetus. The diagnosis is suggested by the presence of neonatal hemolytic disease, a positive DAT, absence of Rh or ABO incompatibility, and antiglobulin-positive hemolysis in the mother. Treatment with prednisone in the mother may reduce both maternal hemolysis and the risk of neonatal morbidity. As in other cases of neonatal hemolysis, treatment is focused on prevention of severe hyperbilirubinemia and kernicterus.

Nonimmune Acquired Hemolytic Disease

Infection

Cytomegalic inclusion disease, toxoplasmosis, syphilis, and bacterial sepsis all can be associated with hemolytic anemia. In most of these conditions, some degree of thrombocytopenia also exists. Generally, hepatosplenomegaly is present. In cases of bacterial sepsis, both the direct and indirect bilirubin levels may be elevated. The mechanism of hemolysis associated with infection is not clearly defined. Documentation of infection as the cause of hemolysis is made by the presence of other clinical and laboratory evidence of neonatal infections. Hemolysis caused by infections may present early in the neonatal period, or it can be delayed for several weeks.

Coronavirus-2019 (COVID-19) infection has been associated with anemia. The anemia seen with COVID-19 is multifactorial but in large part can be attributed to immune destruction. Autoimmune hemolytic anemia has been described in asymptomatic patients,[101] symptomatic patients with severe acute respiratory syndrome, as well as in children with multisystem inflammatory syndrome (MIS-C). Both warm[101] and cold[102] agglutinin disease

have been described.[103] Neonatal infection is thought to occur in one of three ways: transplacental hematogenous spread or viral particles in the amniotic fluid, intrapartum transmission after exposure to maternal infected fluids (secretions or feces), and postpartum transmission from an infected contact (any caregiver). When postpartum transmission from an infected mother is suspected, the mode is felt more likely to be respiratory secretions rather than breast milk[104,105] and various organizations including the American Academy of Pediatrics and World Health Organization have strongly supported and encouraged the protection of breastfeeding during the pandemic in various forums.[106] Anemia in the neonate infected with COVID-19 has not been widely described but one case report describes an 8-week-old who developed MIS-C with diarrhea and anemia after having been exposed to a positive family member at 2 weeks of age.[107] Other causes of anemia in neonates with COVID-19 may be more related to the conservative management employed by providers in the early stages of the pandemic such as mother-infant separation, early cord clamping, etc. that may have predisposed the infant to iron-deficiency anemia.

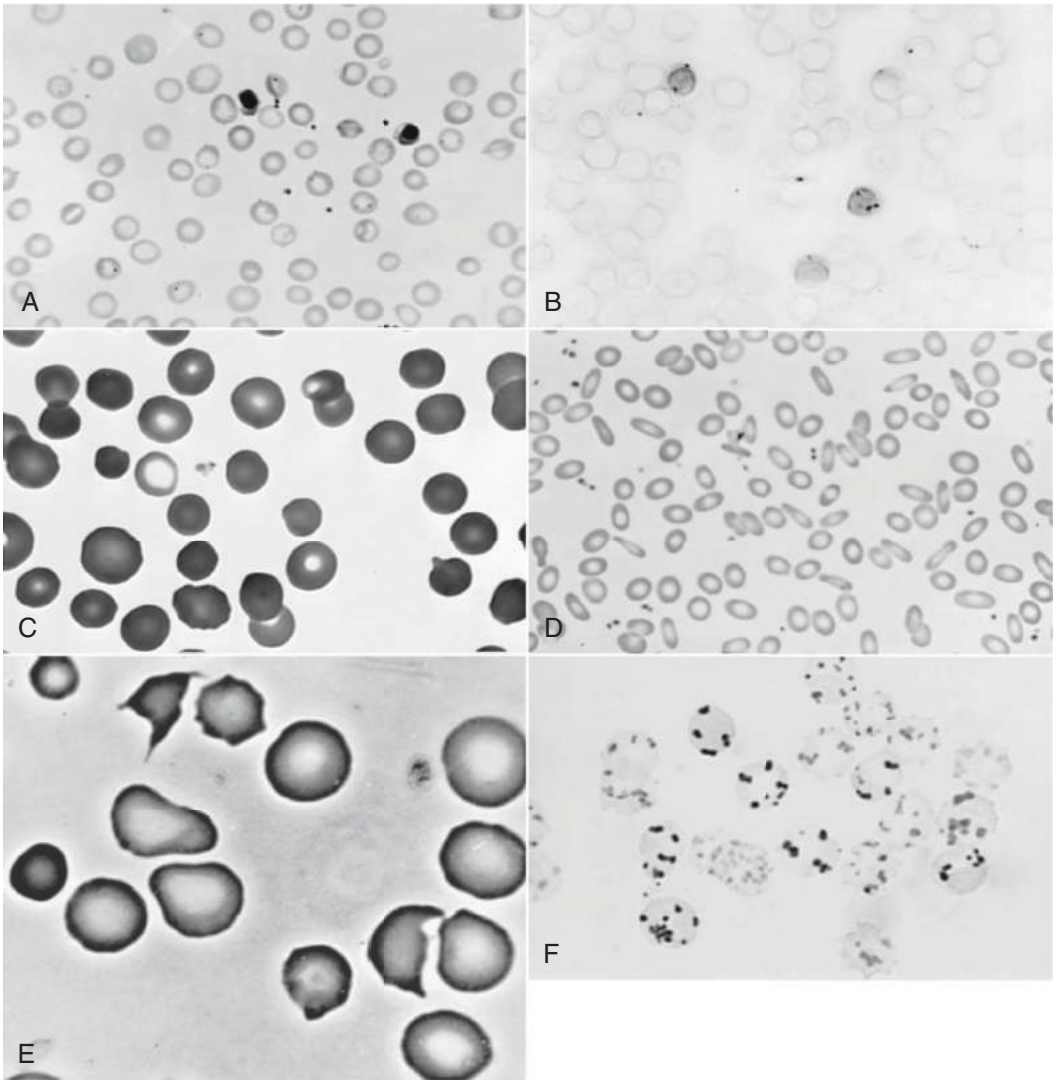
Schistocytic Anemias

Disseminated intravascular coagulation (DIC) is discussed elsewhere in this text. The hemolytic component of this disorder is secondary to the deposition of fibrin within the vascular walls. When erythrocytes interact with fibrin, fragments of RBCs are broken off, producing fragile, deformed RBCs, or schistocytes. Abnormalities of the placental microcirculation or macrovascular anomalies such as an umbilical vein varix are rare causes of congenital schistocytic anemia.[108]

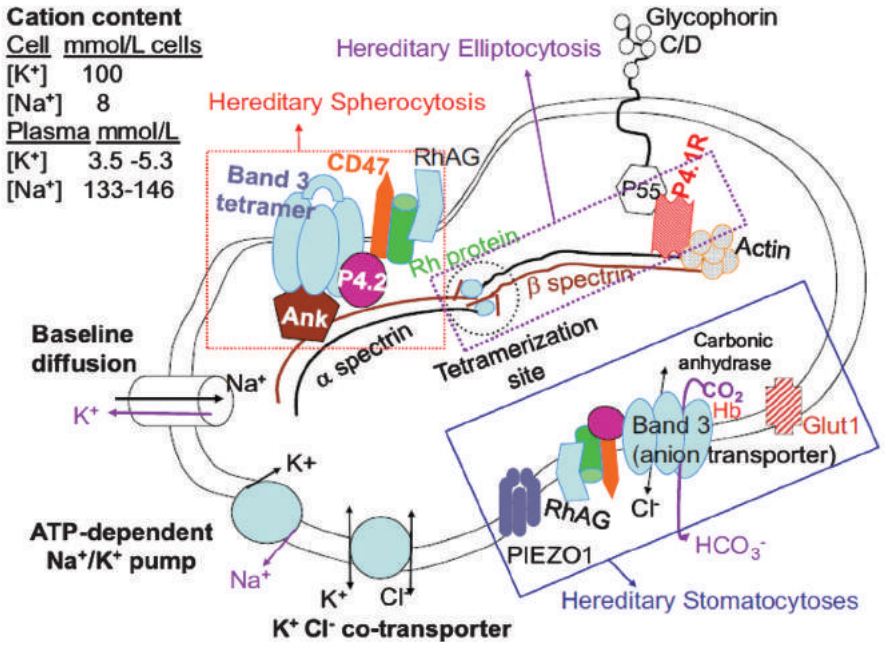
Hereditary Red Blood Cell Disorders

Membrane Defects

Common findings in RBC membrane disorders are the presence of dominant inheritance and abnormal RBC morphology (Fig. 69.7). The ultrastructure of the RBC is critical to its function and deformability and is dependent upon both structural support of the lipid bilayer as well as the maintenance of a cation gradient between the RBC and its environment which establishes the RBC



• **Fig. 69.7** (A) Hypochromic-microcytic red blood cells (RBCs) secondary to chronic fetal blood loss. (B) Fetal RBCs in the maternal blood after a fetomaternal hemorrhage (acid-elution technique). (F) Heinz bodies from a patient with G6PD-deficient hemolysis (stained with supravital dye).



• **Fig. 69.8** Structural organization and functions of various red cell membrane proteins in health and disease. (From King MJ, Garcon L, Hoyer JD, et al. ICSH guidelines for the laboratory diagnosis of nonimmune hereditary red cell membrane disorders. *Int J Lab Hematol*. 2015;37[3]:304–325.)

surface-to-volume ratio (Fig. 69.8).[109] Disorders which alter the membrane structural organization such as hereditary spherocytosis, hereditary elliptocytosis, hereditary pyropoikilocytosis, and Southeast Asian ovalocytosis or the membrane transport function such as overhydrated hereditary stomatocytosis, dehydrated hereditary stomatocytosis or xerocytosis. familial pseudohyperkalemia, and cryohydrocytosis therefore result in deviation from the typical biconcave shape, and ultimately, to hemolysis. Aside from hereditary spherocytosis, these disorders are uncommon.

Hereditary Spherocytosis

The hallmark of hereditary spherocytosis (HS) is the presence of spherocytes in the peripheral blood smear (see Fig. 69.7). Causal mutations have been identified in six genes which encode the vertical components of the membrane cytoskeleton: spectrin, ankyrin, band 3, or band 4.2. A large majority of these mutations are autosomal dominant. The phenotype manifests when, because of either quantitative or qualitative defects in these proteins, the stability of the interactions between the cytoskeleton and the membrane lipid bilayer is weakened, promoting vesiculation and loss of bits of the bilayer, thus leading to progressive loss of membrane surface area.[110] As RBCs become more spherical, they lose flexibility and become vulnerable to entrapment in the spleen and attack by macrophages, leading to hemolysis. Removal of the spleen after 5 years of age allows spherocytes to have a near-normal life span despite their cytoskeletal defects and abnormal shape.

The clinical manifestations of HS in neonates range from the very rare presentation of hydrops fetalis with fetal death[111] to fully compensated, lifelong hemolysis marked by reticulocytosis but no anemia. Anemia at birth (Hgb < 15 g/dL) is present in 28% to 43% of infants.[112] Neonatal hemolysis or hyperbilirubinemia appears in approximately half of all affected infants.[113] It is often the exaggerated neonatal hyperbilirubinemia that raises the suspicion of HS. In many cases, other family members are affected in a pattern consistent with autosomal dominant inheritance. In 20% to 30% of cases, recessive inheritance is noted, but only homozygotes express the clinical features of spherocytosis. Occasionally, the appearance of a new case of spherocytosis in a previously unaffected family is due to spontaneous mutation.

The diagnosis of HS is suspected when spherocytes are seen on the blood smear of an infant with hyperbilirubinemia or other laboratory evidence of hemolysis. Spherocytes also are seen in ABO incompatibility. Blood typing and a DAT may support the diagnosis of ABO incompatibility, but the DAT occasionally can be negative and thus misleading. In this situation, evaluation of the family for other persons affected with spherocytosis may point to a hereditary rather than an acquired cause. Historically, it had been necessary to wait until the infant was at least 3 months of age to obtain a definitive laboratory diagnosis of HS, because, by this age, the confounding effects of maternal antibody and fetal RBCs are no longer present and for many years, the "gold standard" for testing had been the osmotic fragility test. More recently, flow cytometric analysis of eosin-5′-maleimide (EMA)-labeled RBCs has become the preferred diagnostic test. EMA binds various RBC membrane proteins, including band 3 and Rh-related proteins. The fluorescence levels in patients with hereditary spherocytosis is typically two thirds that found in normal controls.[114,115] For the neonate, the advantages of this test are its short turnaround time, the fact that it can be performed on a small amount of blood (a few microliters), ability to run the test even after a patient has received a blood transfusion,[116] and that results are reliable even within the newborn period as long as they are compared to samples from age-matched controls. The test has a high sensitivity and specificity at 96.4% and 94.2%, respectively[117] but false positives can occur in the presence of other inherited RBC disorders such as hereditary pyropoikilocytosis, Southeast Asian ovalocytosis, and congenital dyserythropoietic anemia type II as well as in cases of autoimmune hemolytic anemia.[117]

The mainstay of treatment of HS during the newborn period is directed toward management of hyperbilirubinemia, which often is present and may not peak until the infant is several

days of age. Occasionally, RBC transfusions are required in the neonatal period for management of symptomatic anemia.[111] A common occurrence is the appearance of a transient but severe anemia during the first 20 days of life due to underproduction of erythropoietin in the face of continuing hemolysis.[118] Careful monitoring of affected infants after discharge from the nursery is warranted. Splenectomy is the definitive treatment for HS, but this is not recommended before 5 years of age because of the increased risk of overwhelming sepsis with encapsulated organisms such as *Streptococcus pneumoniae*[119] that occurs following splenectomy in infants and young children. Guidelines regarding the indications for total or partial splenectomy have been reviewed.[120,121]

Hereditary Elliptocytosis

Hereditary elliptocytosis is an autosomal dominant, clinically heterogeneous group of disorders that are caused by mutations of the RBC membrane cytoskeletal proteins, usually spectrin or protein 4.1, that weaken skeletal protein interactions and increase RBC mechanical fragility.[110] Heterozygotes usually exhibit elliptocytes on the blood smear, but in most instances hemolysis is absent. Homozygotes or compound heterozygotes may have sufficient weakening of the cytoskeleton to cause significant hemolysis accompanied by striking abnormalities in RBC morphology such as homozygous hereditary elliptocytosis or hereditary pyropoikilocytosis.

Transient poikilocytosis and hemolysis may occur during the newborn period in infants destined ultimately to have asymptomatic elliptocytosis.[122] RBC membrane mechanical fragility is strikingly abnormal in these infants, probably as a consequence of the destabilizing influence of large amounts of free intraerythrocytic 2,3-DPG, a byproduct of the presence of fetal hemoglobin.[123] As fetal hemoglobin levels decline postnatally in affected infants, membrane mechanical fragility lessens, hemolysis disappears, and RBC morphology undergoes a transition from poikilocytosis to elliptocytosis. Without knowledge of the membrane protein mutations present in the infant and the infant's family, it is difficult to predict at birth who will have transient poikilocytosis with ultimate recovery and who is destined to have lifelong pyropoikilocytosis with hemolysis. A practical approach to this problem is to wait 4 to 6 months to see if common HE evolves or chronic hemolysis with abnormally shaped RBCs persists.

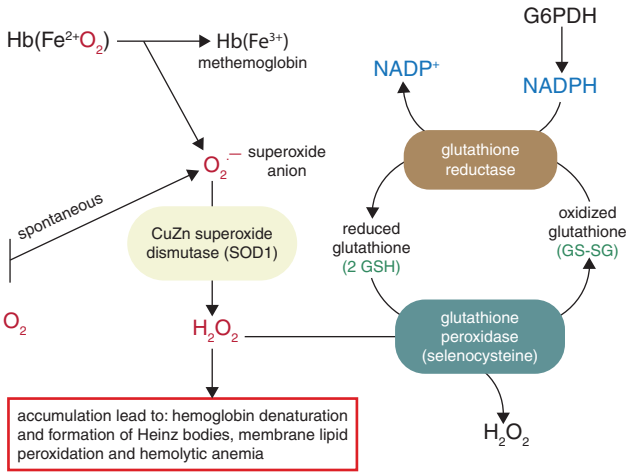
Red Blood Cell Enzyme Abnormalities

Hyperbilirubinemia, anemia, and hydrops fetalis can be the result of inherited RBC enzymopathies. The two most encountered red cell enzyme disorders are glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase (PK) deficiency. Overviews of these two disorders, as well as other more esoteric enzyme deficiencies, are available elsewhere,[110,124] and the special features of RBC enzymopathies in the newborn period have also been summarized.[125]

Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is a sex-linked disorder that affects millions of people throughout the world, particularly in Mediterranean countries, the Middle East, Africa, and Asia. Like sickle cell trait and thalassemia, G6PD deficiency is thought to have become common because it provides a measure of protection against malaria.[126–128] In most G6PD-deficient persons, hemolysis and anemia are present only episodically. Precipitating factors can include infection, exposure to medications that are potent oxidants, or to other agents such as fava beans, naphthalene, or certain petrochemical-derived substances. Rarely, hemolytic anemia is chronic rather than episodic and is present even in the absence of obvious exposure to oxidant stress. Over 400 variants have been identified within *G6PD*, not all of which are clinically significant. The WHO has developed a classification system based on the degree of enzyme deficiency and the severity of hemolysis. Most mutations are missense point mutations that lead to altered enzyme function.[129,130] Normal RBCs contain abundant amounts of reduced glutathione (GSH), a sulfhydryl-containing tripeptide that serves as an intracellular antioxidant, neutralizing oxidant drug metabolites and activated oxygen species released during phagocyte activation. Because of the enzyme deficiency, G6PD-deficient RBCs have a limited capacity to regenerate GSH from oxidized glutathione (Fig. 69.9).[131] In the absence of GSH,[131] RBCs are vulnerable to oxidant injury of hemoglobin. Denatured globin precipitates termed *Heinz bodies* bind to the cell membrane, unfavorably altering its structure and function. Membrane lipid peroxidation may contribute to altered function. The ultimate result of these insults is hemolysis.

The variant G6PD A− is responsible for nearly all the G6PD deficiency seen in Africans and is present in approximately 10% of African Americans. G6PD A− was previously considered to be a single biochemical disorder but is now known to be due to three different genotypes and are classified as class III variants. G6PD A− affects the stability of the enzyme, causing an accelerated decline in activity during the life span of the RBC. Only in the oldest RBCs does enzyme activity reach low enough levels to create vulnerability to oxidant hemolysis. For this reason, hemolysis, if it occurs, is usually mild and self-limited. In contrast, in Asians and persons of Mediterranean or Middle Eastern descent, G6PD deficiency decreases the enzyme activity in young and old RBCs alike. Hemolysis is usually more severe and can be life threatening. G6PD variants found throughout the Mediterranean and Middle East, once thought to be biochemically different, are now recognized to be due to one common single genotype. In these ethnic groups, some G6PD-deficient persons are susceptible to severe and even fatal episodes of hemolysis following exposure to fava beans (favism). The pathophysiology of favism has been elucidated[132] and reviewed elsewhere.[133] Formation of reactive oxygen species results from high concentrations of divicine and isouramil in the fava bean. Favism is only very rarely seen in African Americans



• **Fig. 69.9** Pentose phosphate pathway and G6PD deficiency. (Used with permission of themedicalbiochemistrypage.org. From Harcke SJ, Rizzolo D, Harcke HT. G6PD deficiency: an update. *JAAPA*. 2019;32:21–26.)

with G6PD A−.[134] For pregnant and lactating women, some inciting agents can be transmitted to the fetus across the placenta or to the neonates via breast milk and cause hemolysis in an affected fetus or neonate.[135,136]

The gene for G6PD is located on the X chromosome. All of the RBCs of G6PD-deficient males are affected by the enzyme deficiency, whereas a variable fraction of RBCs of G6PD-deficient females is enzyme deficient, depending on the degree of lyonization.[137] Because of these differences, hemolysis due to G6PD deficiency occurs mainly in males and is much less common in females.

The diagnosis of G6PD deficiency is suggested by the appearance of a DAT-negative hemolytic anemia in association with infection or the administration of drugs. Cells that appear as if a bite had been taken from them as a result of splenic removal of Heinz bodies are occasionally seen on the peripheral blood smear. Supravital stains of the peripheral blood with crystal violet may reveal Heinz bodies during hemolytic episodes. Although screening tests are available, they are not as sensitive as direct assay of RBC G6PD activity. Measurement of enzyme activity may not reveal the deficiency in African Americans immediately after a hemolytic episode, because the population of enzyme-deficient RBCs has been eliminated. Repeating the assay later is often necessary. Identification of specific G6PD mutations by DNA analysis is available, but rarely used for diagnostic purposes.[129,130]

In the neonatal period the major manifestation of G6PD deficiency is hyperbilirubinemia. There usually is more jaundice than anemia, and the anemia is rarely severe. Also, in contrast to classic Rh-related neonatal hyperbilirubinemia, neonatal jaundice due to G6PD deficiency rarely is present at birth, with clinical onset usually occurring between days 2 and 3.[138] Most infants with hyperbilirubinemia due to G6PD deficiency are of Mediterranean, Middle Eastern, or Asian descent.

In most cases of neonatal hyperbilirubinemia due to G6PD deficiency, there is no obvious exposure to external oxidants. The degree of hyperbilirubinemia reflects both the increased bilirubin load presented to the liver by hemolysis of G6PD-deficient RBCs and the presence or absence of the variant form of UGT responsible for Gilbert syndrome.[139] The relative importance of the latter is underscored by the observations that most jaundiced G6PD-deficient neonates are not anemic and that often, evidence for increased bilirubin production secondary to hemolysis is lacking.[140,141]

The severity of jaundice in G6PD deficient varies widely, from being subclinical to causing kernicterus if not treated.[142] Data from the USA Kernicterus Registry from 1992 to 2004 indicate that more than 30% of kernicterus cases were associated with G6PD deficiency. These observations have raised the question of whether testing for G6PD deficiency should be included in newborn screening programs worldwide.[143] Neonatal screening for G6PD deficiency has been very effective in reducing the incidence of favism later in life in Sardinia[144] and in other regions where this potentially fatal complication is common. Currently, in the United States only the District of Columbia and Pennsylvania require newborn screening for G6PD deficiency.

Therapy for neonatal hemolysis and hyperbilirubinemia resulting from G6PD deficiency includes (1) phototherapy or exchange transfusion to prevent kernicterus, (2) RBC transfusion for symptomatic anemia, (3) removal of potential oxidants that may be contributing to hemolysis, and (4) treatment of infections using agents that do not themselves initiate hemolysis. In infants known to be G6PD deficient, prevention of severe hyperbilirubinemia by administration of a single intramuscular dose of tin-mesoporphyrin, an inhibitor of heme oxygenase, has been advocated.[145,146]

Pyruvate Kinase Deficiency

Pyruvate kinase (PK) deficiency is an autosomal recessive disorder that occurs in all ethnic groups. Although it is the most common of the Embden-Meyerhof glycolytic pathway defects, it is rare in comparison with G6PD deficiency. Hundreds of cases, mostly in northern Europeans, have been described in the literature, although many more unpublished cases also occur.[147] PK is one of the two enzymes that generate adenosine triphosphate (ATP) in RBCs. Because nonerythroid tissues have alternative means of generating ATP, clinical abnormalities in PK deficiency are limited to RBCs. The number of pathogenic variants is continuously growing and currently is well over 290.[148,149] Reflecting this genetic diversity, the hemolytic anemia that characterizes PK deficiency varies considerably in severity from family to family. Most patients are diagnosed within the first months of life with approximately 90% of PK-deficient babies experiencing hyperbilirubinemia and 46% requiring exchange transfusions.[150] Death or kernicterus may occur. Severe intrauterine anemia and hydrops fetalis have been reported.[147] In two cases, newborns with PK deficiency presented with neonatal cholestasis and developed progressive liver dysfunction leading to fatal hepatic failure.[151]

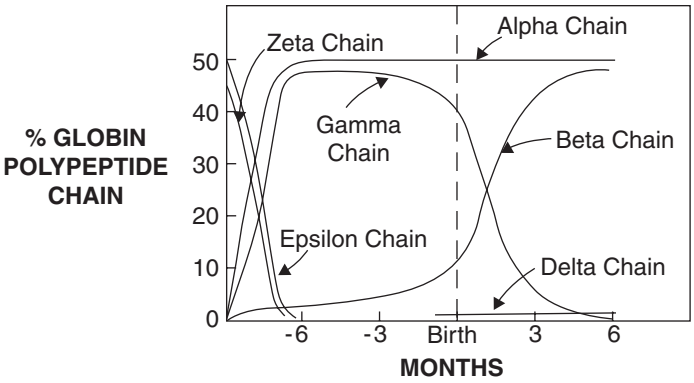
The diagnosis of PK deficiency should be considered in a jaundiced newborn with evidence of nonimmune hemolysis in the absence of infection or exposure to hemolytic agents. Hemoglobinopathies and membrane disorders should be ruled out by examination of the blood smear and other appropriate diagnostic tests before proceeding to assay of RBC PK activity. RBC morphology is normal in PK deficiency, although a few dense cells with irregular margins (echinocytes) are occasionally seen. PK heterozygotes are clinically and hematologically normal but usually have roughly half the normal amount of RBC PK activity. When infants have been transfused before confirmation of diagnosis, the determination of RBC PK activity in parents may detect the heterozygous state and help lead to the diagnosis.[152]

Treatment of hyperbilirubinemia by phototherapy and exchange transfusion if necessary is usually the only therapy necessary in the newborn period. RBC transfusions for anemia occasionally are required. Splenectomy may reduce the rate of hemolysis but should be avoided in infancy and early childhood because of the high risk of infection after splenectomy.

Treatment has been largely supportive with many patients requiring RBC transfusions and splenectomy. Data from a large cohort demonstrated that 84% of 250 patients had received at least one transfusion while roughly 50% (25 of 52) patients 5 years or younger received regular transfusions.[150] Transfusion dependence lessens and can even resolve with age. Complications are related to iron overload secondary to ineffective erythropoiesis and RBC transfusions as well as chronic hemolysis.

To date 18 patients have been reported in the literature to have received hematopoietic stem cell transplantation (HSCT), the indications protocols and outcomes for 16 of whom are described by van Straaten et al.[153]

AG-348 is an oral allosteric activator of PKR which acts by increasing PK activity and ATP levels. Phase II studies have demonstrated a hemoglobin response (rise in hemoglobin from baseline of greater than 1 g/dL) in a large majority of the patients with PK deficiency.[154] Further investigation has shown that clinical response is, at least to some degree, genotype dependent.[155] A lentiviral vector for delivery of a wild type *PKR* has demonstrated



• **Fig. 69.10** Fetal and neonatal hemoglobin production.

successful correction of the disease phenotype in a murine model,[156] and phase II gene therapy study is underway.[157]

Hemoglobin Disorders

Beyond infancy the predominant hemoglobin tetramer is hemoglobin A (Hb A), composed of two alpha globin chains and two beta globin chains (α2β2). To appreciate the hemoglobinopathies that occur in newborns, however, it is necessary to understand the normal developmental changes that occur in globin synthesis during fetal and neonatal life (Fig. 69.10). Embryonic hemoglobins are composed of zeta (alpha-like) and epsilon (beta-like) chains. Gower1 ($\zeta_2\varepsilon_2$), Gower2 ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$) comprise 50%, 25%, and 25% of embryonic hemoglobin, respectively (Table 69.5). Under normal circumstances, the transitions from zeta to alpha globin chains and epsilon to gamma globin chains are complete by the end of the first trimester. Epsilon chain expression wanes and is replaced by gamma chain expression, allowing fetal hemoglobin, Hb F (α2γ2), to become the predominant hemoglobin in the fetus by 8 weeks of gestation. Hb F percent peaks at 90% by 28 weeks' gestation, after which point it slowly trends downward as beta globin expression is induced. At birth, roughly 75% of the hemoglobin is Hb F. As RBCs made before birth are replaced postnatally, the percentage of Hb F declines rapidly such that by 6 months of age it has typically fallen to 1% to 5% (Fig. 69.11).

Only trace amounts of the minor adult hemoglobin, hemoglobin A2 (α2δ2), and Hb Barts (γ4) are present in cord blood. Hb Barts quickly disappears, whereas the hemoglobin A2 level increases gradually to the adult level of 2% to 3% by 1 year of age.

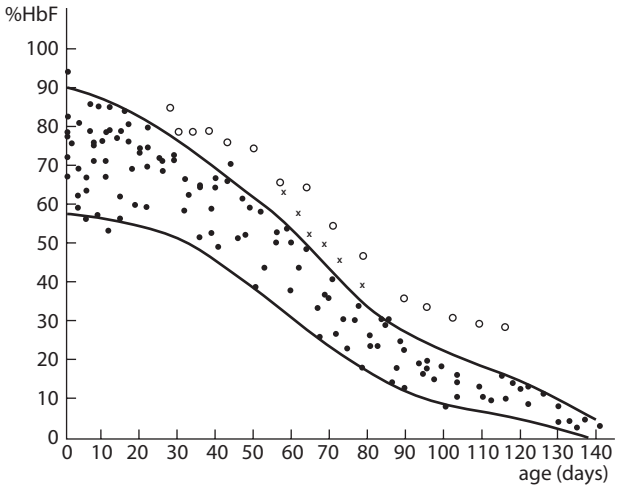
Beta globin disorders such as sickle cell disease or beta thalassemia major are not clinically apparent until several months of age, when the switch from Hb F to Hb A synthesis reveals the defect. In contrast, gamma globin mutations are most evident in fetal and neonatal life and then disappear by approximately 3 months of age as gamma globin synthesis wanes. Alpha globin disorders are evident at all stages of development from fetal to adult.

Thalassemia Syndromes

Thalassemias are due to absent or deficient synthesis of one or more of the normal globin chains, leading to a relative excess of the complementary or partner chain. For example, alpha thalassemias are due to diminished synthesis of alpha globin chains, leading to an excess of beta chains (or, in the fetus, of gamma chains). The excess beta chains form tetramers (β4 or hemoglobin H) that are unstable and can lead to hemolysis beyond infancy. The excess gamma chains also form tetramers, Hb Barts (γ4), that have

TABLE 69.5 Hemoglobin Composition of Cord Blood

	Hemoglobin	Globin Polypeptides	% in Cord Blood
Embryonic	Gower-1	Zeta-2, Epsilon-2 ($\zeta_2\varepsilon_2$)	0
	Gower-2	Alpha-2, Epsilon-2 ($\alpha_2\varepsilon_2$)	0
	Portland	Zeta-2, Gamma-2 ($\zeta_2\gamma_2$)	0
Fetal	Barts	Gamma-4 (γ_4)	<1%
	Hgb F	Alpha-2, Gamma-2 ($\alpha_2\gamma_2$)	60%–85%
Adult	Hgb A	Alpha-2, Beta-2 ($\alpha_2\beta_2$)	15%–40%
	Hgb A_2	Alpha-2, Delta-2 ($\alpha_{2\delta2}$)	<1%



• **Fig. 69.11** Decreasing concentration of fetal hemoglobin after birth. (From Garby L, Sjöhn S, Vuille JC. Studies of erythro-kinetics in infancy. II. The relative rates of synthesis of haemoglobin F and haemoglobin A during the first months of life. *Acta Paediatr*. 1962;51:245–254.)

an increased affinity for oxygen but do not cause hemolysis. In beta thalassemia, excess alpha globin chains accumulate, forming aggregates that injure the cell membrane, leading to hemolysis. In addition, the decrease in overall production of hemoglobin produces small RBCs (microcytosis) that are often filled with less than the normal amount of hemoglobin (hypochromia).

In the United States, changing immigration patterns have markedly increased the numbers of infants born with significant hemoglobinopathies. In California, analysis of newborn screening results between 1998 and 2006 demonstrated clinically significant hemoglobin genotypes in 0.05% of newborns; of these, the prevalence of alpha and beta thalassemia syndromes combined (28%) was almost as high as the prevalence of sickle cell disease (32%).[158]

Alpha Thalassemia

Alpha thalassemia is of particular importance to neonatologists because its clinical manifestations are present in utero and at birth. The molecular basis for alpha thalassemia is usually deletion of one or more of the four alpha globin genes as opposed to point mutations which are more commonly seen in the pathologic variants in beta thalassemia. A thalassemic hemoglobinopathy involving the abnormal hemoglobin Constant Spring also may behave functionally as a mild form of alpha thalassemia. Clinical severity is dictated by how many alpha globin genes are absent or nonfunctional. An infant can inherit no, one, or two variants or deletions from each parent, giving rise to the following four clinical syndromes:

1. *Silent carrier state*. Deletion or nonfunction of a single alpha globin gene is not accompanied by any clinical or hematologic abnormalities.
2. *Alpha thalassemia trait*. Deletion or nonfunction of two alpha globin genes, in *cis* (more common in people of Asian descent) or *trans* (more common in people of African descent), is associated with mild microcytic anemia, without hemolysis or reticulocytosis.
3. *Hemoglobin H disease*. When three of four alpha globin genes are deleted or nonfunctional, a mild to moderate hemolytic anemia is found, often aggravated by oxidant stresses just as in G6PD deficiency. The RBCs are hypochromic and microcytic and contain inclusions of hemoglobin H when appropriate staining is performed. Hemoglobin H Constant Spring (two deletions in cis in combination with the non-deletional variant, Constant Spring, on the other chromosome) can be a particularly severe syndrome, with up to one third requiring regular transfusions.[159,160]
4. *Hemoglobin Barts Hydrops Fetalis (alpha thalassemia major)*. Lack of all four alpha globin genes is associated with a severe intrauterine hemolytic anemia and hydrops fetalis, with massive hepatosplenomegaly, and, in most instances, fetal demise. The RBCs are very hypochromic, fragmented, and bizarre in shape. Erythroblastosis is present.[161] Timing of fetal loss depends upon the size of the causative deletions. For the larger deletions (i.e., FIL and THAI), not only are the alpha genes deleted, but so too are the embryonic, alpha-like genes which encode zeta globin. When this is the case, the pregnancy is typically lost around 6 to 8 weeks' gestation as there are no alpha-like globin chains with which the epsilon or gamma chains can bind to form functional tetramers, whereas when the deletion leaves the zeta globin gene intact (i.e., SEA), a low level of zeta globin gene expression continues in definitive erythroid cells which can combine with gamma chains and produce small amounts of Hb Portland ($\zeta_2\gamma_2$). Unlike the Hb Barts ($\gamma 4$), Hb Portland is a functional form of hemoglobin that allows the fetus to survive up to the second or third trimester. Untreated, however, all affected individuals die at these stages of development.

No treatment is needed for the silent carrier state or for alpha thalassemia trait, but studies to determine the thalassemia status of other family members, particularly those in their reproductive years, are recommended so that genetic counseling and prenatal diagnosis if indicated can be provided. Parents of infants who have hemoglobin H disease should be instructed to avoid oxidant agents that can cause hemolysis (the same list that is given to patients with G6PD deficiency). Although these infants are usually only mildly anemic, they may experience severe episodes of hemolysis during infections or with exposure to oxidant agents.

The diagnosis of the alpha thalassemia syndromes is easily made during the newborn period by correlation of the clinical and hematologic appearance of the child with the amount of Hb Barts (γ_4) present in the RBCs (Table 69.6).[162] Screening of all newborns for hemoglobin H disease is justified in populations with a substantial number of at-risk pregnancies.[158,162]

The large amount of Hb Barts found in the RBCs of patients with Hb H or alpha thalassemia major contributes to the clinical severity of the syndrome because the increased oxygen affinity of this hemoglobin impairs oxygen release to the tissues. DNA-based diagnostic tests are available for prenatal diagnosis which is often carried out when a pregnancy at risk for a fetus with alpha thalassemia major is identified.[161] DNA samples for fetal testing historically have been obtained via invasive methods such as chorionic villus sampling (between 10 and 12-weeks' gestation) or amniocentesis (after 15 weeks' gestation). There exists proof of concept and principal for noninvasive methods involving cell free fetal DNA circulating in maternal plasma, but validation of this testing is ongoing.[163]

Aside from the less invasive nature of such testing, with the technology and methodology currently in use, a diagnosis made from maternal plasma can be made earlier in gestation compared to traditional invasive methods. Earlier diagnosis creates a new, earlier therapeutic window into which various novel therapies may be implemented. Over the last decade, much attention has been given to the concept of in utero HSCT for hemoglobinopathies. Utilizing maternal cells, the goal of infusing haploidentical stem cells is to induce fetal tolerance, not necessarily to achieve donor engraftment or cure. The thought is that curative transplant could then be pursued postnatally without the need for myeloablative conditioning. This elegant concept has been successfully achieved in animal models and clinical trials in humans are underway.[164,165]

In the meantime, for families who chose to continue a pregnancy with a fetus diagnosed with alpha thalassemia, intrauterine RBC transfusions may be administered at a regular interval in order to support the growing and developing fetus. Transfusions must then be continued postnatally. The long-term outcome of these survivors has been a topic of much debate. Some reports depict favorable neurocognitive outcomes[166] while others raise concern about growth retardation and neurodevelopmental delays.[167] The largest study to date includes 69 individuals with alpha thalassemia who survived until birth either naturally ($n = 28$) or with intrauterine interventions such as straight transfusions, exchange transfusions, or hematopoietic stem cell infusions ($n = 41$). Thirty-nine of the 69 were over 5 years of age at the time of data collection. The authors concluded that although intrauterine interventions had some positive impact during the neonatal period such as prolonged gestation, improved Apgar scores, and

TABLE 69.6 Alpha Thalassemia Syndromes

		Anemia	Hemolysis	α:β Chain Synthesis	Abnormal Hemoglobins	
					Cord Blood	Adult Blood
Normal	α/α α/α	None	None	0.95–1.10	0%–1% γ_4	—
Silent carrier	α/— α/α	None	None	0.85–0.95	1%–2% γ_4	—
Alpha-thalassemia trait	—/— α/α	Mild hypochromic Microcytic	None	0.72–0.82	5%–6% γ_4	—
Hemoglobin "H" disease	—/— α/—	Moderate hypochromic Microcytic	Moderate	0.30–0.52	20%–40% $\gamma_4$0%–5% β_4	20%–40% β_4
Homozygous alpha-thalassemia ("hydrops")	—/— —/—	Severe hypochromic Microcytic	Severe	0	70%–80% $\gamma_4$15%–20% $\beta_4$0%–10% $\zeta_2\gamma$	

shortened duration of neonatal mechanical ventilation, the risks for later adverse outcomes such as growth retardation and neurodevelopmental delays were not entirely obviated.

Beta Thalassemia

Like alpha thalassemia, beta thalassemia is found in regions of the world where malaria was formerly endemic: Southeast Asia, India, Africa, and the Mediterranean basin. Although deletions of the beta globin locus occasionally cause beta thalassemia, most cases are caused by point mutations that affect transcription, messenger RNA (mRNA) processing, or translation.[168–170] Two general types of beta thalassemia are recognized. In beta0 thalassemia, no beta globin is produced by the thalassemic locus, whereas in beta+ thalassemia, there is reduced but measurable output of beta globin. The severity of homozygous beta thalassemia (formerly beta thalassemia major) is greatest when two beta0 thalassemia genes are inherited; clinical disease usually is much milder when two beta+ thalassemia genes are inherited. By contrast, the inheritance of one thalassemia gene (beta thalassemia trait) is characterized by a mild microcytic anemia that needs to be distinguished from alpha thalassemia and iron deficiency. Severe beta thalassemia is associated with lifelong hemolytic anemia, dependence on regular RBC transfusions for survival, and the gradual development of transfusion-associated hemosiderosis.[170] Survival has improved, however, with improvements in iron chelation and with the use of HSCT for patients with available matched donors.[171,172]

The clinical abnormalities of beta thalassemia are not evident at birth and first manifest only after 3 months of age, when beta globin normally becomes the dominant form of non-alpha globin synthesized. Although affected newborns appear clinically normal, the diagnosis of beta0 thalassemia can be made at birth by detecting a complete absence of Hb A, using hemoglobin electrophoresis or similar techniques. Definitive diagnosis of beta+ thalassemia by these techniques, however, is not possible in the newborn period, because the reduced amount of Hb A produced overlaps the range for normal babies. Direct identification of beta thalassemia mutations by DNA diagnostic techniques is increasingly available and allows the identification at birth of all infants with more severe beta thalassemias. These techniques, however, are more commonly used for prenatal diagnosis of beta thalassemia syndromes. DNA may be obtained using the same methods as for alpha thalassemia, allowing families to make informed decisions regarding termination of pregnancy.[173] The implementation of a strategy of carrier detection, genetic counseling, and prenatal diagnosis in countries where beta thalassemia is common has led to a striking reduction in the number of births of infants with beta thalassemia major.[174] More recent advances have included preimplantation genetic diagnosis[175] and noninvasive prenatal testing.[163]

Hemoglobin E/Beta Thalassemia

Hb E is a structurally abnormal hemoglobin that results from an amino acid substitution (lysine for glutamine) at the number 26 amino acid of beta globin, counting from the N terminus. Because this mutation also adversely affects mRNA processing, there is reduced output of beta globin mRNA. Hb E trait is therefore an example of a thalassemic hemoglobinopathy. Hb E carriers are microcytic but not anemic. Even those who are homozygous for Hb E have little or no anemia. However, coinheritance of Hb E trait and beta0 thalassemia trait can give rise to a transfusion-dependent form of beta thalassemia.[176] As with other types of transfusion-dependent beta thalassemia, clinical abnormalities are not seen until the infant is 3 to 6 months of age. However, the presence of Hb E is easily detected at birth by hemoglobin electrophoresis or related techniques. Infants found to have Hb E need careful follow-up evaluation to exclude the possibility of Hb E/beta thalassemia. DNA-based detection of the Hb E mutation is feasible[177] and has been applied to both prenatal and neonatal diagnosis. Infants born to mothers with Hb E/beta thalassemia have a higher risk of preterm birth, low birthweight, and fetal growth restriction.[178]

Other Variants Within the Hemoglobin Beta Gene Cluster

Many other variants within the hemoglobin beta (HBB) gene cluster exist and include large deletions as well as gene rearrangements

which result in fusion proteins. These variants result in phenotypes which are broadly and commonly referred to as deletional and non-deletional hereditary persistence of fetal hemoglobin (HPFH), delta-beta thalassemia, gamma-delta-beta thalassemia, or fusion proteins (i.e., hemoglobin Lepore). The clinical phenotype of heterozygous individuals is typically quite mild, appearing similar to a beta thalassemia trait. However, the picture becomes quite complicated with potentially severe morbidity for those who are homozygous or compound heterozygous, depending on the genes affected and oftentimes the amount of Hb F. The variability in clinical and laboratory findings of hemoglobin fractions and RBC indices depend not only on the thalassemic genotype but also on quantitative trait loci, various epigenetic factors (regulatory regions, enhancers, etc.), and possible co-inheritance of alpha thalassemia. These complexities emphasize the need for molecular characterization of the underlying defect(s) in those patients for whom a more obvious diagnosis does not seem to fit.

Sickle Cell Disease

The sickling hemoglobinopathies are beta globin mutations that, as with beta thalassemia, do not become clinically evident until the infant reaches several months of age. Sickle cell anemia, the most severe of the sickle cell diseases (SCDs), is the result of inheritance of two betaS mutations (substitution of valine for glutamic acid at the sixth amino acid on the beta globin chain), one from each parent. Sickle/beta0 thalassemia, phenotypically identical to sickle cell anemia, is caused by inheritance of one betaS and one beta thalassemia mutation. A third common form of sickle cell disease, hemoglobin S-C disease, is somewhat milder than sickle cell anemia or sickle-beta0 thalassemia. It is the consequence of inheritance of one betaS mutation and one betaC mutation (the substitution of lysine for glutamic acid at the sixth amino acid on the beta globin chain). Although no clinical abnormalities are present at birth, early diagnosis is important, because two potentially fatal but largely preventable complications may occur during the first year of life. The first is the splenic sequestration crisis, an unpredictable pooling of large numbers of RBCs in the spleen, which leads to a rapid decrease in hematocrit and, in the most severe cases, cardiovascular collapse and death. The second is overwhelming septicemia, usually caused by *S. pneumoniae*. The unusually high susceptibility to infection with encapsulated organisms such as *S. pneumoniae* is the consequence of functional asplenia, which commonly appears by 1 year of age in infants with sickle cell anemia or sickle-beta0 thalassemia and later in persons with hemoglobin S-C disease. Prompt treatment of splenic sequestration with RBC transfusions is lifesaving, so parents are taught to recognize early manifestations such as splenic enlargement, lethargy, and pallor. Overwhelming sepsis can be prevented in most instances by early immunization with *Haemophilus influenzae* and conjugated pneumococcal vaccines, and by institution of daily prophylactic penicillin at a dose of 125 mg twice daily,[179] beginning at 2 months of age. The need to institute these prophylactic measures within the first 1 to 2 months of life provided compelling rationale for neonatal screening and diagnosis of the sickling disorders. Data regarding the impact of these interventions have confirmed a 68% reduction in mortality from sickle cell disease for children ages zero to three, between 1983 and 1986 and between 1999 and 2002.[180] With this, the National Heart, Lung, and Blood Institute within the NIH formally recommended universal newborn screening for SCD in 1987. In 2006, with the publication of the Recommended Uniform Screening Panel (RUSP), New Hampshire became the last of the 50 states to adopt newborn sickle cell screening. An excellent overview of issues related to newborn screening for sickle cell disease has been published by Wethers et al.[181] The importance of early meetings with an experienced SCD clinician cannot be overstated and should occur between 6 and 8 weeks of life. The goal of these meetings should be to provide care givers vital information regarding management of vaso-occlusive episodes (VOEs), fever plan, spleen palpation, penicillin prophylaxis, immunization, results of blood counts, genetic counselling, and possible complications of the disease.

For infants who have inherited SCD, the reported age of first VOE is quite varied and is thought to depend on factors such as genotype, coinheritance of alpha thalassemia or other RBC abnormalities such as G6PD, environmental (altitude, nutrition, etc.), and provider awareness. In one large, multinational cross-sectional retrospective questionnaire, over 50% of patients had their first VOE before the age of 5.[182] Hydroxyurea remains one of the only disease-modifying agents for patients with SCD and was approved by the FDA for use in this patient population in 1998. It has been shown to have significant effect on rates of VOE, acute chest syndrome, stroke, transfusion needs, and overall survival, among others. Since 2014, NHLBI has recommended it for children down to 9 months of age, rather than waiting to start therapy until symptoms develop. The safety and efficacy of this approach was provided in large part by the BABY HUG study.[183] More recently studies, looking at personalized, PK-based dosing, suggest extending the age of initiation down to 6 months.[184,185]

Infants without a hemoglobinopathy born to mothers with SCD present more of a clinical problem during gestation and the neonatal period than is the case with infants who have SCD. In a large systematic review and meta-analysis of observational studies, looking at greater than 26,000 pregnancies in women with SCD, the odds ratios for stillbirth, preterm delivery, and small for gestational age were 4.0, 2.2, and 4.0, respectively, for women with hemoglobin SS disease.[186] These problems may in part be attributed to the increased metabolic demands and physiologic hypercoagulability of pregnancy which, in the setting of SCD, result in abnormalities of the placenta such as small size, infarction, and an increased incidence of placenta previa and abruptio placentae. These problems are not caused by the presence of the sickle trait, beta thalassemia trait, or hemoglobin C trait in the infant, because no hematologic disease is associated with the carrier state for these mutations, even in adult life when they are fully expressed, except under conditions of extreme hypoxia. One caveat regarding sickle trait blood is that blood from an adult donor who has sickle trait should not be used for exchange transfusions in the newborn, particularly if hypoxemia is present, because use of sickle trait RBCs in this setting may contribute to a fatal outcome.[187]

Hypoplastic Anemia

Hypoplastic anemias in the neonatal period can be caused by inherited disorders, infections, and drugs. This section will focus primarily on the hereditary causes which are likely to present within this timeframe. As bone marrow failure syndromes are rare, a high index of suspicion is oftentimes needed for the correct diagnosis to be made. Critical to the workup is an assessment of any congenital anomalies (skeletal, renal, cardiac, craniofacial, etc.), obtaining a thorough family history of any cancers, hearing disorders, renal dysfunction, etc., and various high yield labs (reticulocyte count, CBCd, eADA, sometimes Hgb F).

Diamond-Blackfan Anemia

The two major causes of RBC aplasia in children are Diamond-Blackfan anemia (DBA) and transient erythroblastopenia of childhood (TEC). The latter condition, TEC, is a disease that rarely occurs before 6 months of age,[188,189] and most children with this disorder are older infants or young children. In contrast, many infants with DBA are anemic at birth or become so in the first months of life with the median age of diagnosis being 2 months.

Originally termed congenital hypoplastic anemia, DBA is a red cell aplasia characterized by the absence of recognizable erythroid precursor cells in the bone marrow.[190] It is a disorder of ribosome biogenesis[191] that results in profound erythroid hypoplasia because erythroid progenitors and precursors are highly sensitive to apoptotic cell death. Although many cases are sporadic, familial, autosomal-dominant DBA is estimated to account for up to 45% of cases.[192] Over 220 distinct, pathologic mutations have been described, most of which occur within the genes encoding one of 19 (of the 79 total) ribosomal proteins.[193] *RPS19* and *RPL5* are the most commonly affected genes, variants within which account for roughly 25% and 9% to 21% of cases, respectively.[193] Recently, causative mutations have also been found in *GATA1*, *TSR2*, *ADA2*, and *EPO*.[194] Accumulation of p53 and consequent cell cycle arrest has been shown to be erythroid lineage-specific, sparing the myeloid and megakaryocyte lineage and accounting for the phenotype of DBA.[195,196] Apoptosis follows cell cycle arrest and ultimately leads to anemia. Some of the ribosomal proteins have extra-ribosomal functions which are thought to contribute to the various other manifestations of DBA including poor growth and congenital malformations.

Anemia in DBA is lifelong, but the onset of the disease is variable. Penetrance is incomplete and expressivity is widely variable, even for members of the same family. Many affected infants are severely anemic in the newborn period, and pallor at birth or soon thereafter has been a feature of the disease in most cases. Pre- and postnatal growth failure, thumb abnormalities, or other congenital anomalies including craniofacial, ophthalmologic, as well as structural renal and heart defects are seen in half of patients,[197] which can be helpful when considering the differential in a neonate with hypoplastic anemia. The diagnosis of DBA is suggested by anemia and reticulocytopenia appearing in the first 6 months of life. Certain unusual features of the RBCs such as macrocytosis, elevated fetal hemoglobin, and increased erythrocyte adenosine deaminase activity (eADA) may assist in diagnosis but may be difficult to interpret in the newborn period and can be confounded by RBC transfusion. eADA is elevated in 80% of patients with DBA and has high sensitivity and specificity of 84% and 95%, respectively.[198] Other disorders which can also be associated with elevated eADA include cartilage-hair hypoplasia, myelodysplastic syndromes, paroxysmal nocturnal hemoglobinuria, and acquired immunodeficiency syndrome. The role for genetic testing is increasing, with various next-generation sequencing panels identifying upwards of 70% of cases.[199]

Many patients achieve durable remissions from anemia when treated with corticosteroids. Those who do not respond to corticosteroids require chronic RBC transfusions and are at risk of transfusion hemosiderosis. Transfusion-dependent DBA can be cured by allogeneic bone marrow transplantation from an HLA-matched donor with overall survival as high as 91% in patients less than 10 years of age.[200] The risk of malignancies in patients with DBA is increased, with a cumulative incidence of 13.7% by 45 years of age and a median age of presentation of 35 years (11 to 70).[197] There is an overrepresentation specifically of myelodysplastic syndrome, acute myeloid leukemia, colon carcinoma, and osteogenic sarcoma.

Deficiency of Adenosine Deaminase 2

First described in 2014,[201,202] deficiency of adenosine deaminase 2 (DADA2) is an autoinflammatory disorder with a highly variable presentation, classically including early onset vasculitis, mild immunodeficiency, marrow failure, and systemic inflammation. It is an autosomal recessive, monogenic disease involving *ADA2* (previously *CECR1*). Given the heterogeneity and rarity of the disease, the differential often includes autoimmune lymphoproliferative syndrome (ALPs), combined variable immunodeficiency (CVID), Castleman syndrome, DBA, and polyarteritis nodosa (PAN), among others. 24% of patients are diagnosed before the age of one and 77% before the age of 10.[203] Patients as young as 2 months have been reported.[204] Hematologically, one review described 4% of patients presenting with a pure red cell aplasia while other hematologic abnormalities include anemia (13%), thrombocytopenia (6%), lymphopenia (16%), neutropenia (7%), and pancytopenia (4%). Diagnosis requires a high degree of suspicion, and patients who present with red cell aplasia may have protracted diagnostic journeys after failing initial DBA therapies.[205]

Historically, immunosuppressive agents were considered first-line therapy in DADA2, especially for patients presenting with PAN and recurrent strokes. Flares, however, were frequently encountered when tapers were attempted. Azathioprine, cyclosporine, tacrolimus, cyclophosphamide, methotrexate, and various others have also been utilized in this patient population without much success.[203] Currently, the mainstay of treatment is anti-tumor necrosis factor agents (etanercept, infliximab, adalimumab). Now with over 3000 cases reported to date,[204] patients have seemed to fall into one of three groups defined by their predominant clinical manifestation—CVID, early-onset stroke, or bone marrow failure. These groupings have seemed to predict responsiveness to various therapies. Specifically, patients with red cell aplasia and marrow failure have proven to be more refractory to TNF inhibitors.[206] Therefore, treatment for this subgroup more often involves hematopoietic stem cell transplantation with 14 patients having been cured (median follow-up of 18 months) to date.[203] In patients with documented hypogammaglobulinemia and a clinical immunodeficiency, immunoglobulin substitution and the use of prophylactic antibiotic and antivirals are standard of care antibiotic, and antiviral treatments have been used routinely.[203]

Pearson Marrow-Pancreas Syndrome

Pearson syndrome (Pearson marrow-pancreas syndrome) is a rare multisystem mitochondrial disorder characterized by a transfusion-dependent anemia with variable other cytopenias, endo- and exocrine dysfunction of the pancreas, and proximal tubular insufficiency, among others. Patients present in infancy but can also present at birth.[207,208] The phenotype evolves from one in which the hematologic manifestations dominate to one of muscle dysfunction and severe neurological symptoms. Anemia, however, was present in all patients in one report,[209] with the median age of diagnosis of 5 months. The cytopenias do not tend to respond to growth factors but spontaneously resolve over time if the patient survives. Most patients die in infancy,

however, secondary to metabolic derangements or infections. Allogeneic HSCT has been utilized in this patient population with mixed outcomes.[208,210–212]

The classic bone marrow findings include vacuolization in myeloid and erythroid progenitors, ringed sideroblasts, and global hypocellularity. An unremarkable bone marrow exam, specifically within the first month of life, however, does not rule out the diagnosis,[207] underscoring the importance of mtDNA analysis as the phenotype may vary and correlates with mtDNA gene mutation load.[213,214]

Congenital Dyserythropoietic Anemia

There are four main types of congenital dyserythropoietic anemia (CDA) with type I being the most likely one to present in the newborn period. The disease manifests with an anemia (macrocytic in roughly 70% of cases), ineffective erythropoiesis, and iron overload as well as occasional skeletal anomalies (hand, feet, frontal bossing, scoliosis).[215] There have been occasional cases where the diagnosis was made in utero.[216] A report of 45 patients with CDA diagnosed within the neonatal period described small for gestational age, hepatosplenomegaly, early jaundice, persistent pulmonary hypertension, and transient thrombocytopenia as other manifestations aside from the anemia. Within this cohort, 80% of them ($n = 36$) required blood transfusion during the first month of life.[217] The erythroid morphology on bone marrow studies is markedly abnormal with erythroid hyperplasia with megaloblastic changes, basophilic stippling, Howell-Jolly bodies, and a small proportion of multi-nucleated erythroblasts. The pathognomonic morphologic feature for this disease is internuclear chromatin bridges.[218,219] 90% of patients with type I CDA are homozygous or compound heterozygous for mutations in one of two genes: *CDAN1* on chromosome 15q15 or *C15ORF41* on chromosome 15q14.[220,221] Aside from supportive therapy (transfusion, chelation, etc.), specific treatment depends on the type of CDA. Therapies for type I include alpha-interferon[222,223] and HSCT.[224–226] Of note, splenectomy has not been shown to be of any benefit in patients specifically with type I CDA.[227]

Osteopetrosis

Infantile malignant osteopetrosis (IMO) is a rare, autosomal recessive, genetically diverse disorder of early childhood. Anemia within the first month of life can be one of the first manifestations, especially for those patients who lack a family history.[228] Ablation of normal marrow space with pathologically increased bone density (dysfunctional osteoclasts lead to failure of bone resorption) leads to hypoplastic anemia secondary to decreased hematopoietic capability. However, given the subsequent extramedullary hematopoiesis, sequestration and increased destruction of RBC have also been cited as contributing factors to anemia in these patients. Hepatosplenomegaly has been described as a prominent feature.[229–231] Other manifestations include hypocalcemia, dental anomalies, cranial nerve dysfunction (from encroachment of nerve foramina in the skull), and gross motor delays. If untreated, overall survival at 6 years of age is roughly 30%, primarily due to complications from bone marrow failure.[228] As osteoclasts are hematopoietically derived, HSCT has been used as a curative therapy.[230–232] The application of gene therapy has recently led to the first clinical trial employing lentiviral-mediated delivery of T-cell immune regulator 1 gene (*TCIRG1*), the affected gene in roughly 50% of patients with IMO.[233]

Congenital Infections

Various maternal infections have been associated with red cell aplasia in the fetus. These include, but are not limited to rubella, CMV, Epstein-Barr virus adenovirus, hepatitis A, B, and C, human immunodeficiency virus, and perhaps the most well-known, parvovirus B19. The majority of adults have been exposed and express antibodies to B19. However, for women lacking antibodies, primary infection during pregnancy leads to a 30% risk of vertical transmission.[234] In the largest prospective study of 1018 pregnant women with acute infection,[235] fetal death was reported in 6.3% of pregnancies. The rate of fetal loss decreased as infection occurred later in gestation; 13%, 9%, and 0% occurring in the first, second, and third trimester, respectively. Red cell aplasia in parvovirus B19 infection can be explained by the narrow cellular tropism. P blood group antigen is its cellular receptor and is present in high concentrations on RBCs and their precursors.[236] Productive infections therefore occur only in CD36 human erythroid progenitor cells. In the same large study,[235] hydrops occurred in 3.9% of pregnancies and similarly decreased in frequency when the maternal infection occurred later in gestation (4.4% vs. 0.8% when ≤32 weeks vs. >32 weeks, respectively). When trying to determine the etiology of non-immune hydrops, fetal infection can be confirmed either with PCR testing of amniotic fluid or detection of B19 IgM in fetal blood. For affected pregnancies, management is typically expectant. However, if anemia is suspected, MCA Doppler assessment for fetal anemia should be obtained. Supportive intrauterine transfusions should be administered if severe anemia is detected. Of note, a complete blood count should also be obtained to assess for concomitant thrombocytopenia which has been appreciated in roughly one third of parvovirus-infected fetuses with hydrops.[237,238] Thrombocytopenia may lead to complications during fetal procedures if not recognized and addressed with platelet transfusion as well.

Physiologic Anemia of Infancy and Anemia Prematurity

At birth, the mean hemoglobin of term infants (17 g/dL) is slightly greater than in premature infants (16 g/dL). The hemoglobin concentration in term infants subsequently decreases to a nadir at which it remains throughout the first year of life (Table 69.7). Termed *physiologic anemia of infancy*, this anemia characterized by low (relative to adult values) hemoglobin is a normal part of development and has no adverse clinical effects. A similar process, called *anemia of prematurity* occurs in premature infants, but the hemoglobin decreases more rapidly and reaches a lower nadir. After 1 year of age, there is little difference between the hemoglobin values of term and premature infants.

Physiologic Anemia of Infancy

With the onset of respirations at birth, considerably more oxygen is available for binding to hemoglobin, and the hemoglobin-oxygen saturation increases from approximately 50% to 95% or more. Furthermore, the normal developmental switch from fetal to adult hemoglobin synthesis actively replaces high-oxygen-affinity fetal hemoglobin with lower-oxygen-affinity adult hemoglobin, which can deliver a greater fraction of hemoglobin-bound oxygen to the tissues. Therefore, immediately after birth the increase

in blood oxygen content and tissue oxygen delivery downregulates erythropoietin production; consequently, erythropoiesis is suppressed. In the absence of erythropoiesis, hemoglobin levels decrease because there is no replacement of aged RBCs as they are normally removed from the circulation. Iron from degraded RBCs is stored for future hemoglobin synthesis. The hemoglobin concentration continues to decrease until tissue oxygen needs are greater than oxygen delivery. Normally, this point is reached between 6 and 12 weeks of age, when the hemoglobin concentration is 9.5 to 11 g/dL. This physiologic hemoglobin decrease does not represent anemia in the true sense of the term; rather, it is a normal adjustment reflecting the presence of excess capability for oxygen delivery relative to tissue oxygen requirements. It is unnecessary to administer iron during this period because it does not prevent the physiologic decrease in hemoglobin, and any iron administered is added to stores for future use. As hypoxia is detected by renal or hepatic oxygen sensors, erythropoietin production increases and erythropoiesis resumes. The iron previously stored in reticuloendothelial tissues can then be used for hemoglobin synthesis and is typically sufficient for hemoglobin synthesis, even in the absence of dietary iron intake, until approximately 20 weeks of age. In fact, the American Academy of Pediatrics recommendation that any cow milk or soy formula used to supplement breast milk be iron fortified has the goal of preventing the late iron deficiency that can occur when the shift is made to the typical cow's milk–based, iron-poor diet of later infancy and toddlerhood.[239]

Anemia of Prematurity

The anemia seen in preterm infants is more profound and occurs earlier (see Table 69.7). Because symptoms may occur, the anemia of prematurity is considered nonphysiologic. The cause of anemia is multifaceted. The lower hemoglobin may be in part a physiologic response to the lower oxygen consumption in premature infants compared with that in term infants, a consequence of their diminished metabolic oxygen needs.[240] An important component in the first few weeks of life is blood loss due to sampling for the many laboratory tests necessary to stabilize the clinical status of these infants, particularly those with cardiorespiratory problems. The erythropoietic response to anemia also is suboptimal, a significant problem because demands on erythropoiesis are heightened by the short survival of the RBCs of premature infants (approximately 40 to 60 days instead of 120 days as in adults) and the rapid expansion of the RBC mass that accompanies growth. The basis for suboptimal erythropoiesis in prematurity appears to be inadequate synthesis of erythropoietin in response to hypoxia. Fig. 69.12 illustrates the magnitude of the deficiency, which, as shown by Stockman et al.,[241] is greatest in the smallest, least mature infants. Because the liver is the predominant source of erythropoietin during fetal life, it has been proposed that relative insensitivity of the hepatic oxygen sensor to hypoxia explains the blunted erythropoietin response seen in premature infants.[242] The spontaneous resolution of the anemia that occurs by approximately 40 weeks' gestational age is in keeping with a developmental switch from the relatively insensitive hepatic oxygen sensor to the renal oxygen sensor, which is exquisitely sensitive to hypoxia, because by this time the predominant site of erythropoietin synthesis has shifted to the kidneys. The problem does not lie with altered sensitivity of erythroid progenitors to erythropoietin because this has been shown to be normal.[243]

TABLE 69.7 Hemoglobin Changes During the First Year of Life

Week After Birth	Term	Premature (1.2–2.5 kg)	Premature (<1.2 kg)
0	17.0 (14.0–20.0)*	16.4 (13.5–19.0)	16.0 (13.0–18.0)
1	18.8	16.0	14.8
3	15.9	13.5	13.4
6	12.7	10.7	9.7
10	11.4	9.8	8.5
20	12.0	10.4	9.0
50	12.0	11.5	11.0
Lowest hemoglobin: mean (range)	10.3 (9.5–11.0)	9.0 (8.0–10.0)	7.1 (6.5–9.0)
Time of nadir	6–12 wk	5–10 weeks	4–8 weeks

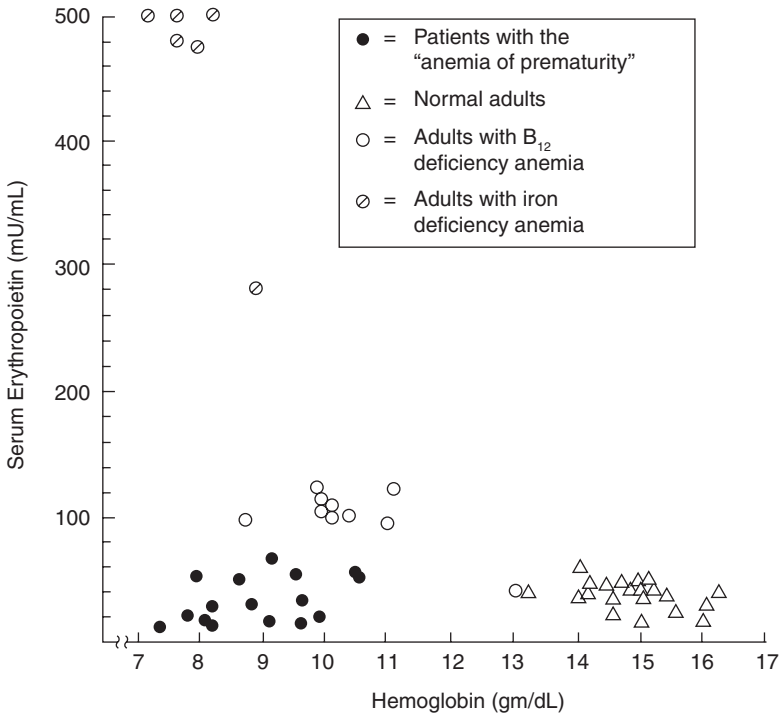
The anemia of prematurity occurs even in nutritionally replete infants, but it may be heightened by deficiencies of folate, vitamin B12, or vitamin E.[244] Premature infants are endowed at birth with significantly less vitamin E than is present in term infants, and unless supplemental vitamin E is provided, this deficiency state persists for 2 to 3 months. Vitamin E is an antioxidant compound vital to the integrity of erythrocytes, and in its absence, these cells are susceptible to lipid peroxidation and membrane injury. One clinical consequence of vitamin E deficiency is that hemolytic anemia can occur in small premature infants weighing less than 1500 g at 6 to 10 weeks of age.[245,246] This hemolytic anemia, which is characterized by reduced vitamin E levels and increased RBC peroxide hemolysis, rapidly disappears following vitamin E administration. A logical conclusion is that vitamin E deficiency might contribute to the anemia of prematurity in a more general sense. In fact, premature infants given daily vitamin E (15 units/day) had higher hemoglobin levels and lower reticulocyte levels than a control group not given the vitamin.[245] However, more recent studies found no hematologic benefit for the administration of 25 or 50 international units of vitamin E daily to premature infants.[247,248] A Cochrane review of the use of vitamin E in preterm infants suggested that routine vitamin E supplementation increased the hemoglobin concentration by a significant but small amount.[249] In very low-birthweight infants, there was a decreased risk of retinopathy and blindness but increased risk of sepsis. This review concludes that the routine use of high-dose intravenous vitamin E, or to achieve tocopherol levels greater than 3.5 mg/dL, is not supported by evidence. Although it has become standard practice to administer vitamin E to all premature infants, the hemoglobin nadir in these babies is still lower than that in term newborns, indicating that anemia is largely caused by other factors such as erythropoietin deficiency.

The optimum management of anemia of prematurity requiring intervention beyond nutritional and vitamin support remains controversial.[250–252] Primary questions include the role of erythropoietin and the application of liberal versus restrictive transfusion thresholds.



• **Fig. 69.12** Hemoglobin levels and corresponding serum erythropoietin levels. Values are from infants with the anemia of prematurity, normal adults, adults with vitamin B_{12} deficiency anemia, and adults with iron deficiency anemia. (From Ross MP, Christensen RD, Rothstein G, et al. A randomized trial to develop criteria for administering erythrocyte transfusions to anemic preterm infants 1 to 3 months of age. *J Perinatol*. 1989;9:246–253.)

Treatment of Anemia of Prematurity With Recombinant Human Erythropoietin

Because a relative deficiency of erythropoietin is present in the anemia of prematurity, a number of studies have evaluated the safety and efficacy of recombinant human erythropoietin (rHuEPO) therapy in this setting. The optimal timing for initiation of rHuEPO therapy and the optimal dose have yet to be determined. Trials have used two different timing strategies: early treatment (before 8 days of age) and "late" treatment. The former has the goal of preventing anemia of prematurity, whereas the latter aims to treat anemia of prematurity and decrease transfusions after the acute stage. Although many studies have shown a modest decrease in RBC transfusion with either approach, there have not been significant differences between these two practices.[253,254] Although infants require relatively high doses of rHuEPO/kg compared to adults because of more rapid clearance and higher volume of distribution, a trial of high dose (1500 units/kg/week) as compared to low dose (750 units/kg/week) resulted in no difference in transfusion requirement.[255] Even in very small premature infants less than 1300 g birthweight with the highest likelihood of needing a transfusion, the effects are minimal, except in infants with birthweight <1000 g.[256] To optimize response to rHuEPO, infants must have adequate protein intake, receive vitamin E, and receive iron supplementation. To achieve the best results, supplemental oral iron at a dose of at least 6 to 9 mg/kg/day needs to be administered. It may be possible to use parenteral iron supplements, particularly in young very low-birthweight infants who are not able to take oral iron[257] or as a supplement to oral iron.[258]

A metanalysis of 21 prospective controlled trials of rHuEPO treatment of the anemia of prematurity was published.[259] Although there was considerable variation between studies, in general the efficacy of rHuEPO in reducing the need for red cell transfusions was modest. The authors concluded that it was premature to recommend rHuEPO for standard therapy for the anemia of prematurity. More recently, Juul et al. published data from the multicenter PENUT (Preterm Erythropoietin Neuroprotection Trial) which enrolled 941 neonates between the ages of 24 and 27 weeks' gestation, randomized to either erythropoietin treatment (1000 units/kg q 48 hours ×6 doses and then 400 units/kg three times a week as maintenance dosing through a postmenstrual age of 32 weeks) or placebo (sham injections) at the same interval. This study demonstrated a relative rate (RR) of transfusions of 0.66 (95% CI, 0.59 to 0.75) and RR of donor exposure of 0.67 (95% CI, 0.58 to 0.77) in the treatment versus the placebo arms.[260] They go further to suggest that the historical lack of demonstrable benefit from erythropoietin therapy is likely related to the following differences between studies: targeted populations, dosing, duration of treatment, and iron supplementation. Despite this elegant work, there remains wide variation in the use of rHuEPO for very low-birthweight infants in the United States,[252] and there is disagreement regarding the cost-benefit ratio of rHuEPO therapy.[261–264]

Although studies in adults have raised questions about the safety of rHuEPO and have led to reductions in its use in patients with malignancy and with renal insufficiency, there are no definitive data supporting safety concerns in premature infants. Previous questions regarding neutropenia and retinopathy of prematurity have not been borne out as significant.[265] In fact, interest in potential neuroprotective effects of rHuEPO has led to careful testing of three different high doses of rHuEPO in extremely low-birthweight infants ≤1000 g and ≤28 weeks of age.[266] Erythropoietin treatment may have a particularly important role to play in the management of infants whose parents refuse to allow blood transfusions on religious grounds.[267]

Red Blood Cell Transfusion Therapy in Premature Infants

It has been estimated that of the infants born weighing less than 1500 g in the United States each year, 80% received multiple RBC transfusions.[268,269] Most transfusions given in the first several weeks of life are to replace losses from phlebotomy required for laboratory monitoring during ventilator support and other intensive care measures. After the first few weeks of life, most transfusions are given to treat the symptoms of anemia of prematurity. The risks associated with use of allogeneic RBC transfusion in premature infants include exposure to viral infections, graft-versus-host disease, electrolyte and acid-base imbalances, exposure to plasticizers, hemolysis when T antigen activation of RBCs has occurred, and immunosuppression.[268,270] Many strategies to reduce the need for allogeneic RBC transfusion in premature infants have been developed and have resulted in a marked decrease in the number of transfusions and number of donor exposures for most premature infants. Reducing phlebotomy losses by use of noninvasive monitoring techniques has been of only limited usefulness.[268] Donor exposures can be reduced by assigning a specified bag of adult donor blood to a sick neonate for multiple transfusions,[30] particularly because it has been shown that blood stored for up to 35 days in CPDA-1[271] or AS-3[27,29] is safe for use in this setting. Defining strict criteria for RBC transfusions also can reduce the number of donor exposures in routine nursery practice.[272,273]

Lachance et al.[274] measured oxygen consumption, myocardial function, resting energy expenditure, and other physiologic variables before and after RBC transfusions. They concluded that in asymptomatic anemic premature infants, oxygenation was well maintained without RBC transfusions when the hemoglobin level was 6.5 g/dL or more. Nelle et al.[275] studied a similar group of asymptomatic anemic premature infants and found that RBC transfusion improved systemic oxygen transport as well as transport in the cerebral and gastrointestinal arteries. When clinical features of hypoxia are absent or findings are equivocal, an elevated blood lactate level may predict a need for transfusion,[276] but in the experience of Frey and Losa[277] it adds little value to the decision-making process in the individual patient. A more recent modality of measuring cerebral oxygenation by near-infrared spectroscopy (NIRS) has accumulated some promising data[278–281] but requires further clinical validations before it can be widely applied.

Traditionally, RBC transfusions have been given to replace phlebotomy losses or in the presence of symptoms thought to reflect hypoxia (e.g., tachycardia, tachypnea, dyspnea, apneic spells, poor feeding).[282,283] However, studies to validate such practices have yielded conflicting results.[241,284–288] A more recent retrospective chart review of 52 ELBW infants admitted to a NICU over the course of 1 year assessed transfusion rates as well as both short- and long-term effects of transfusion.[289] Of these neonates, 90% received at least one RBC transfusion. In this cohort, the outcomes of those transfused were worse (increased risk of bronchopulmonary dysplasia [BPD], necrotizing enterocolitis [NEC], and diuretic use) without any clinical benefit (no improvement in weight gain, heart rate, apnea, or ventilatory/oxygen needs). Although the numbers are small, this experience demonstrates the controversy and underscores the need for further study and guidelines.

Universal guidelines for the optimal approach to the transfusion of preterm infants have yet to be developed. One of the elusive outcomes which continues to drive much of the research is the effect of various transfusion strategies on neurodevelopmental outcomes (NDOs). To date, there have been four randomized control trials addressing these questions.[290–293] Perhaps laying the groundwork for these studies were the Iowa[294] and the PINT[295] studies.

The Iowa study enrolled 100 preterm infants with birth weights between 500 and 1300 g. Infants were enrolled between December 1992 and June 1997. Each infant was assigned to a transfusion algorithm with either high or low hemoglobin thresholds. The thresholds varied within each group depending on weight and level of required respiratory support. Outcomes included the number of RBC transfusions, number of donors, survival to discharge, occurrence of patent ductus arteriosus, germinal matric or intraventricular hemorrhage (IVH), periventricular leukomalacia, retinopathy of prematurity (ROP), BPD, duration of assisted ventilation, duration of supplemental oxygen therapy, number, frequency, and severity of apneic episodes, time to regain birth weight, time to double birth weight, and length of hospitalization. Only 10% to 12% of patients required transfusions. The restrictive group received fewer transfusions (3.3 ± 2.9) as compared to the liberal group (5.2 ± 4.5), but the number of donor exposures was similar (2.8 ± 2.5 for liberal group, 2.2 ± 2.0 for restrictive group). There was more apnea in the restricted transfusion group. In addition, although the study was not designed to detect a difference in CNS outcome, there was a higher rate of grade IV intraventricular hemorrhage (IVH) and periventricular leukomalacia in the restricted group.

The PINT study enrolled 451 extremely low birth weight (ELBW) infants between January 2000 and February 2003. Each infant was assigned within 48 hours of birth to a transfusion algorithm with either high or low hemoglobin thresholds. The thresholds varied within each group depending on postnatal age, blood sampling method (capillary vs. central), as well as whether the baby was receiving respiratory support. Their primary outcome was death before home discharge or survival with any of the following: severe retinopathy, BPD, or brain injury on cranial ultrasound. Secondary outcomes included hemoglobin level, number of RBC transfusion, numbers of donor exposures, rate of growth, and serum ferritin change. Although their study was not powered to assess them, other parameters recorded included NEC, apnea requiring treatment, culture proven infections, time in oxygen, time to extubation, and time to discharge. Their conclusion was that a more liberal strategy increased the number of infants receiving transfusion (89% in the restrictive group vs. 95% in the liberal) but that there was little obvious clinical benefit. Post hoc analysis, however, was suggestive of an increased risk of cognitive delay when infants were treated per the more restrictive algorithm.

These findings spurred the four subsequent studies looking at neurodevelopmental outcomes.[290–293] The findings of these randomized control studies along with other observational studies[296,297] suggest discordant effects on short- and long-term NDOs. The short-term NDOs (<2 years) appear to favor a more liberal approach whereas the longer-term NDOs (school age and older) appear to favor the restrictive approach.[298] The current theory behind this phenomenon lies in the neuroprotective role of erythropoietin.[260,265,299–303] When using a more liberal transfusion threshold, endogenous EPO production is suppressed.[287,294,304] These data from McCoy as well as the others are reassuring especially given the increased rates of periventricular leukomalacia and IVH in the restrictive group.[294]

Despite controversies, there is agreement that the optimum approach to the anemia of prematurity includes delayed clamping of the umbilical cord (at least 30 seconds);[305] limiting blood loss

by phlebotomy; use of dedicated RBC units to minimize donor exposure; optimizing nutrition including protein, iron, folate, vitamin B12, and vitamin E; and use of standardized transfusion guidelines.[306]

Polycythemia

Neonatal polycythemia is observed in 0.4% to 4% of neonates and is usually caused by one of two conditions: increased intrauterine erythropoiesis or fetal hypertransfusion (Table 69.8).[307] Other causes seen in older children, such as arterial hypoxemia (cyanotic heart disease and pulmonary disease), abnormal hemoglobins, or hypersecretion of erythropoietin by tumors, are rare, and primary polycythemia or polycythemia vera is virtually nonexistent. In normal term infants, delayed clamping of the cord leading to an increased transfer of placental blood to the infant is the most common cause of polycythemia. In the setting of acute intrapartum hypoxia, increased placental transfusion also may account for the observed increase in fetal RBC mass, according to animal studies by O et al.[308] Placental insufficiency and chronic intrauterine hypoxia, as seen typically in small-for-gestational-age infants, most commonly underlie increased intrauterine erythropoiesis.

TABLE 69.8 Etiology of Neonatal Polycythemia

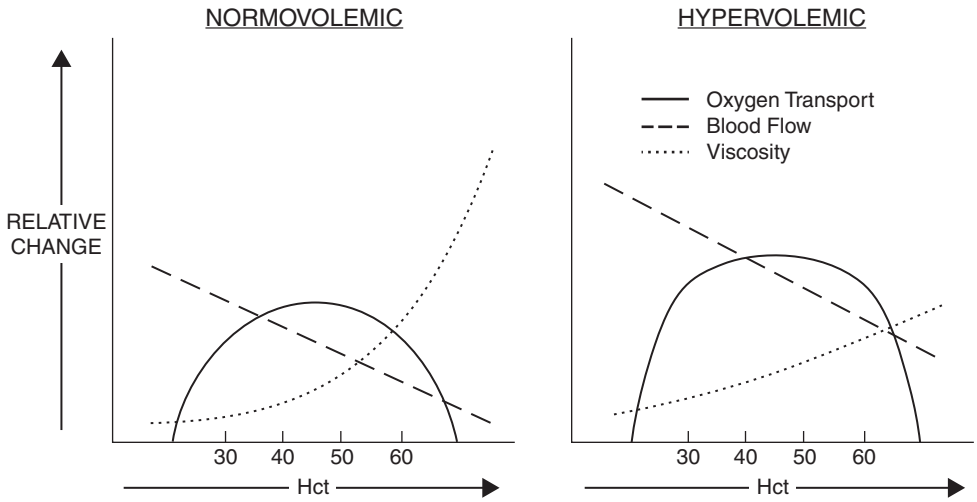
Active (Increased Intrauterine Erythropoiesis)	Passive (Secondary to Erythrocyte Transfusions)
Intrauterine hypoxia	Delayed cord clamping
Placental insufficiency	Intentional
Small-for-gestational-age infant	Unassisted delivery
Postmaturity	Maternofetal transfusion
Toxemia of pregnancy	Twin-twin transfusion
Drugs (propranolol)	
Severe maternal heart disease	
Maternal smoking	
Maternal diabetes	
Neonatal hyperthyroidism or hypothyroidism	
Congenital adrenal hyperplasia	
Chromosome abnormalities	
Trisomy 13	
Trisomy 18	
Trisomy 21 (Down syndrome)	
Hyperplastic visceromegaly (Beckwith syndrome)	
Decreased fetal erythrocyte deformability	

Data from Oski FA, Naiman JL. *Hematologic Problems in the Newborn.* 3rd ed. Philadelphia: Saunders; 1982.

As the hematocrit increases, blood viscosity increases exponentially (Fig. 69.13). Blood flow is impaired by hyperviscosity at hematocrits of 60% or more. Oxygen transport, which is determined by both hemoglobin levels (i.e., oxygen-binding capacity) and blood flow, is maximal in the normal hematocrit range. At low hematocrits, oxygen transport is limited by reduced oxygen-binding capacity, whereas at higher hematocrits, reduction in blood flow secondary to hyperviscosity may similarly limit oxygen transport. At any given hematocrit, expansion of the blood volume beyond the normal level (hypervolemia) distends the vasculature, decreases peripheral resistance, and increases blood flow and, ultimately, oxygen transport. These physiologic observations have implications for therapy of polycythemia.

Most polycythemic infants have no symptoms, particularly if the polycythemia becomes apparent only on routine neonatal screening. Symptoms, when present, usually are attributable to hyperviscosity and poor tissue perfusion or to associated metabolic abnormalities such as hypoglycemia and hypocalcemia. Common early signs and symptoms include plethora, cyanosis (resulting from peripheral stasis), lethargy, hypotonia, poor suck and feeding, and tremulousness. Serious complications include cardiorespiratory distress (with or without congestive heart failure), seizures, peripheral gangrene, NEC, renal failure (occasionally resulting from renal vein thrombosis), and priapism. Because the elevated RBC mass increases the catabolism of hemoglobin, hyperbilirubinemia is common and gallstones occasionally occur.

In the symptomatic infant, a venous hematocrit of 65% or more (or a hemoglobin greater than 22 g/dL) confirms the presence of polycythemia. In screening apparently healthy newborns for polycythemia, however, account must be taken of a number of physiologic variables that influence the hematocrit during the first 12 hours of life:



• **Fig. 69.13** Effect of hematocrit on viscosity, blood flow, and oxygen transport.

1. Time of cord clamping—immediate clamping (within 30 seconds) minimizes placental transfusion.
2. Age at sampling—values increase from birth to a peak at 2 hours, gradually decreasing to cord levels around 12 to 18 hours.[309,310]
3. Site of sampling—values from blood extracted by the heel stick method exceed those from venous blood (the difference can be minimized by prewarming the heel).
4. Method of hematocrit determination—spun values are higher than those obtained by electronic cell counter and show better correlation with blood viscosity.[311]

One way to standardize and simplify screening for polycythemia is as follows: At birth, clamp the cord at about 30 to 45 seconds; at 4 to 6 hours of age, obtain a blood sample from a warmed heel stick and perform a spun hematocrit determination. If the result is greater than 70%, repeat the test on a venous sample. A venous hematocrit of 65% or more indicates polycythemia. By this approach, 1% to 5% of newborns are polycythemic; the range largely reflects differences in altitude at which the study population resides. Because the hematocrit is lower with increasing prematurity, polycythemia is seen less frequently in preterm infants than in term babies.

Following diagnosis, an attempt should be made to determine the cause of polycythemia (see Table 69.8). The condition is particularly common in infants of diabetic mothers or those with Down syndrome[312] and may also occur in the setting of maternal hypertension[313] or, rarely, fumaric aciduria.[314] However, no apparent cause is found in most cases. Studies to determine the effects of polycythemia are dictated by the clinical findings but should usually include serum bilirubin, glucose, calcium, urea nitrogen, and creatinine levels.

Treatment by isovolumetric partial exchange transfusion (PET) is recommended to reduce the RBC mass without inducing hypovolemia. However, the precise indications for PET and the impact of the procedure on outcome remain controversial, without any clear guidelines in place. In a review of randomized or quasirandomized studies of infants with symptomatic or asymptomatic polycythemia,[315] there was no evidence of difference in either long-term neurodevelopmental outcome or short-term neurobehavioral scores. There was a trend toward an earlier improvement in symptoms, but an apparent increase in risk of NEC (RR 8.68, 95% CI 1.06 to 71.1), although several of the studies used fresh frozen plasma. The general finding that polycythemic infants have a poorer outcome than concurrent infants without polycythemia has been thought to be related to the underlying cause of the polycythemia; in one study, perinatal risk factors other than polycythemia were best correlated with outcome and thought to underlie both the polycythemia and the developmental delay.[316] A small randomized control trial compared treatment with 25 mL/kg NS over 6 to 8 hours to no treatment in a group of 55 neonates >34 weeks' gestation with hematocrits between 65% and 75%.[317] Both groups received maintenance fluids. Their primary outcome was need for PET, the rate of which did not differ between the two groups: 22.2% in the treatment group versus 28.6% in the group that did not receive extra fluids.

Many neonatal intensive care units use PET for symptomatic infants with hematocrits greater than 60% to 65%, and for asymptomatic infants with hematocrits greater than 65% to 70%. However, the Committee on the Fetus and Newborn of the American Academy of Pediatrics acknowledged in their 1993 statement that "there is no evidence that exchange transfusion affects long term outcome… Universal screening for polycythemia fails to meet the methodology and treatment criteria and also, possibly the natural history criterion." Thus, Schimmel et al.[318] made the following recommendations based on the available evidence, until such time as systematic studies can be conducted directly measuring blood viscosity to allow development of objective criteria for PET in polycythemia:

- In symptomatic patients with hematocrit >65%, PET with normal saline should be used to reduce possible ongoing injury to tissues by enhancing blood flow.
- In asymptomatic polycythemic infants with presumed normal or increased blood volume, careful monitoring (glucose, cardiorespiratory) is adequate.
- In infants with presumed reduced plasma or blood volume status, treat with early feeding or intravenous fluids.
- For asymptomatic polycythemic infants with presumed normal blood and plasma volume, consider PET only if repeated venous hematocrits are >75%.

A retrospective cross-sectional analytical study utilizing similarly restrictive management for 190 polycythemic infants revealed no increased risk of short-term complications in the following three groups:[319]

1. Hematocrit 65% to 69%: treated as healthy neonates
2. Hematocrit 70% to 75% and asymptomatic hydrated with D10 solution at 100 mL/kg/day and NPO for at least 24 hours or until hematocrit decreased to <70%.
3. Symptomatic polycythemic neonates, regardless of their degree of polycythemia and those with hematocrit >75% were administered PET using NS solution either through umbilical or peripheral vascular access.

Of note, they considered infants symptomatic if in addition to polycythemia at least one of the following was present: hypoglycemia (glucose <40 mg %), thrombocytopenia (<150 × 10^9/L), or respiratory distress requiring oxygen treatment.

Systematic reviews of several studies comparing the use of crystalloid or colloid for PET have concluded that crystalloid solutions are as effective as colloid solutions.[320,321] Thus, normal saline, as an inexpensive product that carries no risk of transfusion-associated infection or reaction to plasma proteins, should be used. Withdrawal of blood for a PET is most easily done using an umbilical artery catheter. Any vessel may be used for blood withdrawal, and all but arterial lines can be used to infuse volume. An umbilical venous catheter inserted into the right atrium also provides acceptable access, but if correct placement cannot be achieved, the catheter should be inserted just far enough into the vessel to allow blood to be withdrawn. Calculation of the total volume of blood to be exchanged for diluent uses the following formula[282]:

$$\text{Exchange volume} = \frac{\text{observed Hct} - \text{desired Hct} \times \text{BV}\left(\frac{\text{mL}}{\text{kg}}\right) \times \text{weight (kg)}}{\text{observed Hct}}$$

where blood volume (BV) usually is 100 mL/kg but in infants of diabetic mothers may be lower (80 to 85 mL/kg).

Example: A 3-kg dyspneic infant with an 80% hematocrit requires a partial exchange transfusion.

$$\text{Blood volume} = 3\,\text{kg} \times 100\frac{\text{mL}}{\text{kg}} = 300\,\text{mL}$$

$$\text{Exchange volume} = \frac{\text{observed Hct} - \text{desired Hct}}{\text{observed Hct}} = \frac{80 - 55}{80} = 0.31$$

Therefore, volume of exchange = 300 mL × 0.31 = 93 mL.

Because coexisting hypoglycemia is an important determinant of adverse neurologic outcome, careful monitoring and maintenance of adequate glucose levels and hydration are essential.

Methemoglobinemia

Methemoglobin (metHb) is an oxidized derivative of hemoglobin in which heme iron is in the ferric (Fe^{3+}) or oxidized state rather than the ferrous (Fe^{2+}) or reduced state. Methemoglobinemia adversely affects oxygen transport, shifting the oxygen dissociation curve to the left in two ways. First, ferric hemes of methemoglobin are unable to bind oxygen and second, the remaining ferrous hemes within the tetramer have increased oxygen affinity. Small amounts of methemoglobin normally are formed daily, associated with the release of oxygen from hemoglobin (auto-oxidation). MetHb that is formed rapidly is reduced through the action of the RBC enzyme cytochrome b5 reductase (Cyb5R) so that in normal persons, levels of metHb seldom exceed 1%. A second methemoglobin reductase, nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase, also is present in RBCs. This enzyme has little function under normal physiologic conditions, but it is greatly activated by the presence of certain redox compounds such as methylene blue, forming the basis for the clinical treatment of methemoglobinemia.

Acquired methemoglobinemia can occur in normal individuals following exposure to chemicals that oxidize hemoglobin iron. Newborns are particularly susceptible because fetal hemoglobin is more readily oxidized to the ferric state than is hemoglobin A and because RBC Cyb5R activity is only 50% to 60% of normal adult levels during the first 4 months of life.[322] Merely marking the diapers of newborns with aniline dyes has caused methemoglobinemia. Drugs such as prilocaine, administered before birth to provide local anesthesia, can produce methemoglobinemia in both mother and infant. Although in most infants, no increase in methemoglobin levels follows the use of lidocaine-prilocaine cream (Emla cream) to provide analgesia during circumcision,[323] a few case reports of visible cyanosis due to methemoglobinemia in infants treated with this cream have appeared.[324,325] Perhaps the best-known agent that may cause methemoglobinemia is nitrite, either present de novo in ingested material or generated by administering nitric oxide to term babies in high concentrations for treatment of persistent pulmonary hypertension.[326] Nitrates can be converted to nitrite by the action of intestinal bacteria. It is for this reason that well water or foods with a high nitrate content (e.g., cabbage, spinach, beets, carrots) can produce methemoglobinemia in infants.[327] Accumulation of nitrate in the intestinal tracts of infants with diarrhea and acidosis[328,329] or symptomatic dietary protein intolerance[330] is thought to underlie the transient methemoglobinemia that occurs in these conditions.

Congenital methemoglobinemia is most commonly due to inherited disorders of hemoglobin structure or to a Cyb5R deficiency. The inherited abnormalities of hemoglobin structure that give rise to methemoglobinemia, known collectively as the hemoglobin M disorders, are rare autosomal-dominant defects caused by point mutations that alter a single amino acid in the structure of normal globin. The altered conformation that ensues favors the persistence of the ferric rather than the ferrous form of heme iron. The normal methemoglobin reductive capacity of the RBC cannot compensate for such instability of ferrous heme. There are three variants affecting the α chain (Hb M Iwate, Hb M Boston, Hb M Yantai), three variants affecting the β chain (Hb M Saskatoon, Hb M Milwaukee, Hb M Hyde Park), and six variants affecting the γ chain (Hb FM Osaka, Hb FM Fort Ripley, Hb FM Circleville, Hb F Cincinnati, Hb FM Toms River, Hb FM Viseu).[331] Only the alpha and gamma globin chain mutations are associated with neonatal methemoglobinemia, because these are the globins that form hemoglobin F. Neonatal methemoglobinemia is transient when produced by one of the six gamma chain mutations, because the normal developmental switch from fetal to adult hemoglobin eliminates all but a trace of the mutant hemoglobin.[332] Hemoglobin M heterozygotes inheriting alpha or beta globin mutations have lifelong cyanosis, but they are usually asymptomatic. No therapy is needed. The homozygous state is incompatible with life. Diagnosis of the hemoglobin M disorders is made by special tests in RBC diagnostic laboratories.

Cyb5R deficiency is an autosomal recessive disorder of which there are two phenotypes. Type I affects the soluble RBC-specific isoform and accounts for roughly 90% of Cyb5R disease. Type I defects are caused by missense mutations which give rise to enzymatically active but unstable proteins.[333] Type II affects the membrane-bound isoform of Cyb5R which plays a larger role in non-RBCs leading to methemoglobinemia along with microcephaly, developmental delay, intellectual disability, and failure to thrive. Type II defects are typically full stops or deletions leading to absent protein expression or expression of an enzymatically inactive protein.[334] Heterozygotes with type I are asymptomatic and do not have methemoglobinemia under normal circumstances. However, if challenged by drugs or chemicals that cause methemoglobinemia, they may become cyanotic and symptomatic at doses that have no effect in normal persons. Homozygotes have lifelong methemoglobin levels of 15% to 40% and are cyanotic but otherwise asymptomatic unless exposed to toxic agents. Patients with homozygous or compound heterozygous mutations for type II have methemoglobin levels ranging from 10% to 42% (mean ± SEM: 20.7% ± 3.2%).[335] Diagnosis of Cyb5R deficiency is by assay of RBC enzyme activity, a procedure available only in specialized hematology laboratories.

Cytochrome b5 deficiency is the rarest cause of congenital methemoglobinemia, having been described only in a few families.[336–340] These cases describe individuals in whom their methemoglobinemia is clinically inapparent, with only mildly elevated levels (6.1% to 8.5%). The males described in the literature presented with 46,XY disorder of sex development. This phenotype is thought to be related to Cyb5a role in facilitating CYP17A1 reduction and ultimately the production of dehydroepiandrosterone (DHEA), the principal androgen precursor.

The cardinal clinical manifestation of methemoglobinemia is cyanosis not resulting from cardiac or respiratory disease. Cyanosis present at birth suggests hereditary methemoglobinemia, whereas that appearing suddenly in an otherwise asymptomatic infant is more consistent with acquired methemoglobinemia (Box 69.3). The blood is dark and, unlike deoxygenated venous blood, does not turn red when exposed to air. Rapid screening for methemoglobinemia can be done by placing a drop of blood on filter paper and then waving the filter paper in air to allow the blood to dry. Deoxygenated normal hemoglobin turns red, whereas methemoglobin remains brown. Methemoglobin levels of 10% or more can be detected.[341] More accurate determination of methemoglobin levels is accomplished in the blood gas laboratory by co-oximetry or in the clinical laboratory using a spectrophotometer. It is important to recognize that cyanosis and symptoms resulting from methemoglobinemia do not necessarily correlate directly. Cyanosis is first clinically evident when the total amount of methemoglobin (not the percentage) reaches approximately 1.5 g/dL. This occurs

BOX 69.3 Approach to Infants with Cyanosis and Methemoglobinemia

Cyanosis With Respiratory and Cardiac Abnormalities

Blood turns red when mixed with air
Decreased arterial PO_2
Consider pulmonary, cardiac, or central nervous system disease

Cyanosis With or Without Respiratory or Cardiac Abnormalities

Blood turns red when mixed with air
Normal arterial PO_2
Consider polycythemia syndromes

Cyanosis Without Respiratory or Cardiac Abnormalities

Blood remains dark after mixing with air
Normal arterial PO_2
Consider methemoglobinemia syndromes

1. With rapid clearing of methemoglobin following methylene blue:
    a. Consider toxic methemoglobinemia (look for environmental oxidants)
    b. Consider NADH-methemoglobin reductase deficiency (perform enzyme assay)
2. With reappearance of methemoglobinemia after initial response to methylene blue:
    a. Consider NADH-methemoglobin reductase deficiency
3. With no change in methemoglobin following methylene blue:
    a. Consider hemoglobin M disorders (perform hemoglobin electrophoresis)
    b. Consider associated glucose-6-phosphate dehydrogenase deficiency (perform enzyme assay)

at methemoglobins of 10% in an individual with a total hemoglobin of 15 g/dL, where it will be delayed until the methemoglobin percentage reaches 15 in an individual with a total hemoglobin of 10 g/dL. In this way, individuals with erythrocytosis will develop cyanosis at lower methemoglobin percentages while anemia can mask cyanosis. Symptoms attributable to hypoxemia and diminished oxygen transport develop at varying levels and depend on a number of factors including the acuity of the methemoglobin accumulation as well as the underlying cause. Typically, however, symptoms do not appear until levels increase to 30% to 40% of total hemoglobin. Death occurs at levels of 70% or greater. Methemoglobinemia is not associated with anemia, hemolysis, or other hematologic abnormalities.

Treatment with intravenous methylene blue (1 mg/kg as a 1% solution in normal saline) is indicated when methemoglobin levels are greater than 15% to 20%. Doses greater than 1 mg/kg should be avoided, because they may be toxic.[342] The response to methylene blue is both therapeutic and diagnostic. Methemoglobin levels decrease rapidly, within 1 to 2 hours, if methemoglobinemia is caused by a toxic agent or by a deficiency of Cyb5R. In contrast, the hemoglobin M disorders do not respond to methylene blue. Reappearance of methemoglobinemia after an initial response to methylene blue suggests a deficiency of Cyb5R or the persistence of an occult oxidant. A poor response to methylene blue also is seen in G6PD-deficient persons because this disorder is characterized by suboptimal generation of NADPH, a required cofactor in the reduction of methemoglobin by methylene blue in deficient persons. Cases have been described in which treatment with methylene blue in patients with G6PD led to severe hemolysis.[343–345] Ascorbic acid can be used instead. In general, most infants with hereditary methemoglobinemia are asymptomatic and require no therapy.

Acknowledgment

I would like to acknowledge Dr. Dana Matthews who was the original author of this chapter in the ninth edition of *Avery's Diseases of the Newborn*. Dr. Matthews' wisdom and thoughtfulness have left an indelible mark on the world of hematology and many aspiring hematologists.

70
Neonatal Transfusion

RAVI MANGAL PATEL AND CASSANDRA D. JOSEPHSON

KEY POINTS

- Recent multicenter randomized trials support more conservative transfusion approaches with the use of lower hemoglobin and platelet count thresholds.
- Two multicenter clinical trials did not show improvement in survival without neurodevelopmental impairment or other important outcomes with the use of higher hemoglobin thresholds for red blood cell transfusion in preterm infants. Given the lack of benefit, these data generally support the use of a lower hemoglobin threshold in most clinical circumstances for routine transfusions, although the safety of thresholds below those studied in clinical trials to date is uncertain and not generally recommended.
- One multicenter trial comparing higher (50×10^9/L) versus lower (25×10^9/L) thresholds for prophylactic platelet transfusion showed an increased risk of death or serious bleeding among infants randomized to a higher threshold. These data suggest that a lower threshold should be used in most clinical circumstances for prophylactic platelet transfusions, although they do not apply to actively bleeding infants.
- There is wide variation in the use of hemoglobin and platelet thresholds among centers in the United States, highlighting an opportunity for patient blood management.
- Prophylactic plasma transfusion is likely to have a minimal effect on prevention of intracranial bleeding in preterm infants, and newer measures such as thromboelastography may provide more precise data to guide the administration of plasma transfusion.
- Delaying clamping of the umbilical cord and minimizing phlebotomy-related blood losses are important strategies to minimize red blood cell transfusions and improve outcomes.

Overview

Blood transfusion is essential to modern neonatal intensive care and can be lifesaving, particularly for critically ill neonates or infants undergoing surgery. Blood components are necessary to carry and deliver oxygen to tissues, provide adequate preload to the heart to support cardiac output, and maintain a balance between hemostasis and coagulation to prevent both bleeding and thrombosis. In this chapter, specific blood component therapy and special circumstances in neonatal transfusion medicine will be reviewed.

Red Blood Cell Transfusion

Components of Red Blood Cell Transfusion

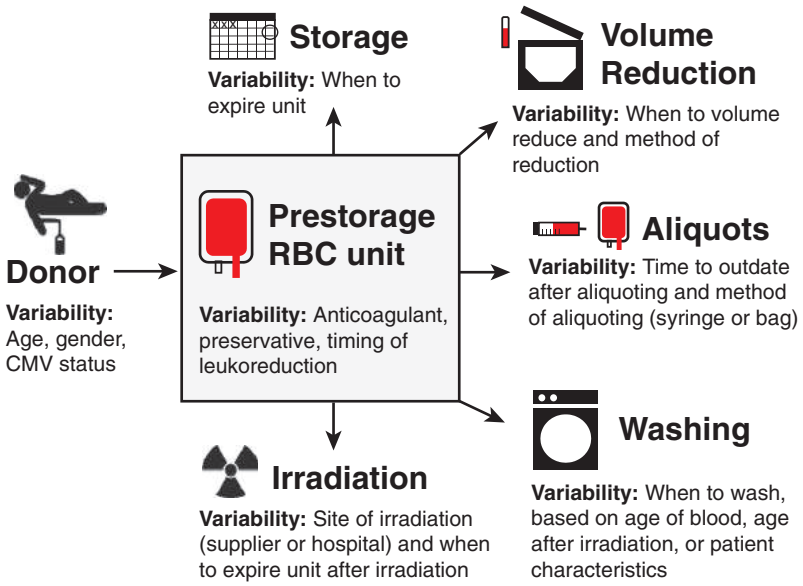
Red blood cells (RBCs) are the most commonly transfused component of whole blood. They are produced by centrifugation from whole blood or, less frequently, acquired directly from a donor by apheresis. Various storage solutions, such as citrate–phosphate–dextrose–adenine (CPDA-1) and additive–glucose–mannitol (e.g., AS-1, AS-3), containing anticoagulants and preservatives are used to maintain RBCs at 4°C during storage. AS-1 and AS-3 units contain mannitol and adenine, which are associated with diuresis and renal toxicity, respectively. Therefore, RBCs stored in AS-1 and AS-3 should not be used for large-volume (≥20 mL/kg) transfusions.

Preparation of Red Blood Cell Transfusion

Preparation of RBCs for transfusion begins with donor assessment and ends with transfusion into the neonate. The goal is to assure blood safety and maximize efficacy and response to transfusion. Accurate RBC component and recipient identification are imperative for safety. More than 300 blood group antigens, from 35 blood group systems, have been discovered on RBCs.[1] Among these, the ABO and D (also known as rhesus [Rh]) blood groups are the most important in determining the compatibility of allogenic RBC transfusion. Infants can have four ABO blood types containing the corresponding A or B antigens on the RBC surface: group A, group B, group AB, or group O (no A or B antigens). In addition, infants can be D antigen positive or D antigen negative. Testing of the plasma or serum from either the infant or the mother must include ABO and D typing of their RBCs and a screen for unexpected RBC antibodies (indirect antiglobulin test). Before non–group type O RBCs are issued, the infant's plasma or serum is tested to detect passively acquired maternal anti-A or anti-B isohemagglutinins, which usually do not develop until more than 4 months of age. Importantly, crossmatch compatibility testing and repeated ABO and D typing, as is required for all patients older than 4 months, may be omitted during any hospitalization for an infant younger than 4 months, as long as any of the following criteria are met:

1. Antibody screen is negative
2. Transfused RBCs are group O, ABO identical, or ABO compatible
3. RBCs are either D negative or the same D type as those of the patient

Testing for the isohemagglutinins must also include the antiglobulin phase of testing at 37°C (body temperature). In the presence of an immunoglobulin G (IgG) antibody, crossmatched, ABO-compatible RBCs are administered until the acquired antibody is no longer detected. Once RBC units have been properly



• **Fig. 70.1** Vein-to-Vein Processing of Red Blood Cells. Variability among centers and blood banks in processing of red blood cells, from donation to preparation before transfusion into the neonate. *CMV*, Cytomegalovirus. (From Patel RM, Meyer EK, Widness JA. Research opportunities to improve neonatal red blood cell transfusion. *Transfus Med Rev*. 2016;30:165–173.)

selected, sterile aliquots from the parent unit are produced to more accurately provide volumes of RBCs dosed based on the patient's weight. This can reduce the risk of transfusion-associated circulatory overload and also limit donor exposure–related infectious risks by repeatedly using the same RBC unit.[2] Data suggest that 20 mL/kg transfusions in very low birth weight (VLBW) infants, compared with 10 mL/kg transfusions, lead to a greater increase in hematocrit without respiratory compromise.[3] Although the optimal dose and duration of RBC administration are not known, transfusions should not run for longer than 4 hours. There is substantial variability in how blood centers and blood banks prepare RBCs (Fig. 70.1). This includes strategies to prevent cytomegalovirus (CMV) transmission,[4,5] how and when RBCs are irradiated,[6,7] when RBCs are washed,[8] and what age of RBC units are used.

The exclusive use of RBC transfusions from CMV-seronegative donors in VLBW infants has been associated with a very low risk of transfusion-transmitted CMV infection: between 0.0% and 0.3% per unit of CMV-seronegative and leukoreduced blood.[5] Historically, the risk of transfusion-transmitted CMV (TT-CMV) infection from leukoreduced transfusions from CMV-untested donors has been reported to be higher than that from approaches using both CMV-negative donors and leukoreduction.[9] In the opinion of the authors, the safest approach for transfusion of VLBW infants is to use leukoreduced RBCs from CMV-negative donors. However, given the low risks of TT-CMV infection with improvements in modern leukoreduction techniques, use of leukoreduced blood from CMV-untested donors is an acceptably safe and low-risk alternative.[10,11] Importantly, RBC transfusion should not be delayed if CMV-negative blood is unavailable, and CMV-untested blood should be used given the relatively low risk of TT-CMV infection.

Many centers limit the storage time of RBCs transfused into neonates and infants.[7,12] The maximum storage duration depends on the type of storage solution, with 35 days for CPDA-1 units and 42 days for AS-1 and AS-3 units. Recent randomized trials have provided high-level evidence regarding the safety of using stored, older RBC units. The Age of Red Blood Cells in Premature Infants (ARIPI) trial randomized VLBW infants to receive fresh blood (mean 5 days) versus standard issue blood (mean 15 days) and found no difference in a composite of mortality or morbidity between groups.[13] Similar trials in adults and children have produced concordant findings.[14–16] However, the age of RBC units may not account for other donor RBC characteristics, such as storage solutions and irradiation.[6] A recent observational study suggests that characteristics of blood donors may influence outcomes in transfused VLBW infants, with red cell transfusions from older female blood donors associated with the lowest risk of adverse short-term outcomes, although additional study is needed before selection of donors based on age and sex can be recommended.[17]

Indications for Red Blood Cell Transfusion

Common indications for RBC transfusion include anemia, bleeding, and cardiorespiratory compromise. Extremely preterm infants are among the most highly transfused populations in medicine, with 64% of extremely low birth weight infants weighing 1000 g or less at birth receiving at least one RBC transfusion during their neonatal intensive care unit (NICU) stay.[18]

Studies of RBC transfusion approaches in preterm infants suggest it is safe to practice a conservative approach. Four clinical trials enrolling at least 100 subjects each have compared the efficacy of RBC transfusion using liberal (high hemoglobin threshold) versus conservative (low hemoglobin threshold) transfusion strategies (Table 70.1).[19–22] In the Prematures in Need of Transfusion (PINT) trial, a lower hemoglobin transfusion threshold resulted in a nonsignificant increase in neurodevelopmental impairment at 18 to 21 months (odds ratio [OR] 1.74, 95% confidence interval [CI] 0.98 to 3.11), which was significantly higher in a post hoc analysis with a more inclusive measure of neurodevelopmental impairment.[23] The Transfusion of Prematures (TOP) trial enrolled 1824 infants and found that a higher hemoglobin threshold, compared to a lower threshold, did not improve survival without

TABLE 70.1 Red Blood Cell Transfusion Thresholds for Preterm Infants in Randomized Trials

Thresholds		Iowa Trial[19]	PINT Trial[20]	TOP Trial[21]	ETTNO Trial[22]
Liberal transfusion thresholds*	Upper	15.3	13.5	13.0	13.7
	Lower	10.0	8.5	10.0	9.3
Restrictive transfusion thresholds*	Upper	11.3	11.5	11.0	11.3
	Lower	7.3	7.5	7.0	7.0

*Thresholds are hemoglobin values in grams per deciliter, and differences between upper and lower thresholds within each transfusion arm reflect the range based on an infant's respiratory illness severity and postnatal age. See the text for additional information on the trials.
ETTNO, Effect of transfusion thresholds on neurocognitive outcome of extremely low birth weight infants; *PINT*, prematures in need of transfusion; *TOP*, transfusion of prematures.

neurodevelopmental impairment at 22 to 26 months (relative risk 1.00; 95% CI 0.92 to 1.10).[21] In addition, there was no difference in survival or other common morbidities. Similar findings were reported in another multicenter trial from Germany, where no difference in death or disability at 24 months was noted between more liberal (higher) versus restrictive (lower) thresholds for RBC transfusion (risk difference 1.6%; 95% CI −4.8% to 7.9%).[22] Both of these more recent trials support use of RBC thresholds within the ranges studied and favor the use of lower hemoglobin thresholds, given the lack of benefit with more liberal thresholds. However, the safety of thresholds below those evaluated in the aforementioned trials is uncertain and should be avoided.

RBC transfusions are sources of parenteral iron, and fewer RBC transfusions using lower hemoglobin transfusion thresholds without appropriate enteral iron supplementation may increase the risk of iron-deficiency anemia. Iron-deficiency anemia is associated with adverse long-term neurodevelopmental outcomes[24,25] and higher amounts of enteral iron supplementation is associated with better cognitive outcomes at 2 years of age.[26] Recent trends suggest an increasing use of conservative transfusion thresholds to decrease RBC exposure,[27,28] mirroring patient blood management approaches in adults designed to minimize blood exposure.[28] However, there is wide variation in pretransfusion thresholds among US centers.[18]

For more mature preterm and term infants, transfusion approaches are largely based on expert opinion, owing to the lack of randomized trials. In select populations of infants, such as those undergoing surgery, hematocrit values of 40% or higher may be desired.[29] By contrast, asymptomatic preterm infants may tolerate a hematocrit of 21% before needing RBC transfusion (see Table 70.1). In neonates without an ongoing source of blood loss, iron supplementation or erythropoiesis-stimulating agents may be sufficient to help restore RBC volume. However, a multicenter trial of high-dose erythropoietin did not show a reduction in death or severe neurodevelopmental impairment at 2 years of age with the use of erythropoietin (relative risk 1.03; 95% CI 0.81 to 1.32).[30] Additional studies are needed to guide appropriate thresholds in term infants, particularly among neonates undergoing surgery,[29] including cardiac surgery[31] and those receiving extracorporeal membrane oxygenation support, given the association between higher transfusion rates and increased mortality in this population.[32]

Risks of Red Blood Cell Transfusion

The risks of blood component therapy, specifically RBC transfusion, are reviewed here. However, many of the immunologic and nonimmunologic risks discussed are based on studies in adult transfusion recipients and have not been adequately studied in the neonatal population.

TABLE 70.2 Risk of Transfusion-Transmitted Infections in the United States

Infection	Estimated Risk per Unit*
HIV	1 in 2 million
Zika	None reported in United States (<1 in 3 million)
CMV	Historically estimated risk up to 1%–3% for leukoreduced RBC transfusions from CMV-untested donors, although likely substantially lower.[47] For RBC products from CMV-negative donors, estimated risk of 0% (95% CI 0.0%–0.3%)[5]
Hepatitis B	1 in 2 million
Hepatitis C	1 in 2 million
HTLV-I/II	<1 in 3 million
West Nile virus	<1 in 3 million
Malaria	<1 in 3 million
Chagas disease	<1 in 3 million

*Unless specified, estimates are from Busch et al.[33]
CI, Confidence interval; *CMV*, cytomegalovirus; *HIV*, human immunodeficiency virus; *HTLV-I/II*, human T-lymphotropic virus I/II; *RBC*, red blood cell.

Immunologic Complications

Historically, the primary risk of blood transfusion has been infection. However, current estimates of the risk of transfusion-transmitted infections suggest that modern donor selection and post-donation diagnostic testing strategies reduce the risk to below 1 in 2,000,000 for most infections (Table 70.2).[33] Acute immunologic complications of transfusion include hemolytic transfusion reactions, immune-mediated platelet destruction, febrile nonhemolytic reactions, allergic reactions, anaphylaxis, and transfusion-related acute lung injury (TRALI).[34] Formation of antibodies to ABO blood group antigens (anti-A and anti-B IgM and IgG types) typically occurs after 3 to 4 months of age.[35] Therefore, transfusion reactions related to ABO blood group incompatibility are less likely to occur in neonates. Delayed immunologic complications include delayed hemolytic

reactions, alloimmunization to white blood cells, RBCs, and platelet antigens in blood components, posttransfusion purpura, and transfusion-associated graft-versus-host disease. Transfusion-related immunomodulation (TRIM) is a potential entity described in adults that involves immunosuppressive effects of blood transfusion, which may be beneficial in solid-organ transplant but also can potentially increase the risk of infection and malignancy.[36] However, many of the studies on TRIM were done in an era before leukoreduction, and TRIM has not been investigated in neonates.

Transfusion-Related Acute Lung Injury

Although transfusion-related acute lung injury (TRALI) has not been well studied in neonates and infants, it is one of the most severe complications of blood component transfusion in other populations. TRALI is largely caused by substances in plasma and platelet components but can also occur after RBC transfusion. The causes of TRALI are grouped into immune and nonimmune types. In adults, immune TRALI is estimated to occur in 1 per 5000 transfusions, with case–fatality rates of 6% to 9% among those affected.[37] However, the incidence and risks of TRALI in neonates are unclear. Immune TRALI is suspected to be due to substances within transfused blood products that elicit an immune response, such as HLA and granulocyte-binding alloantibodies. Nonimmune TRALI is thought to occur following stored platelet and RBC transfusions. Nonimmune TRALI is more benign than immune TRALI and is thought to be mediated by biologically active lipids.

Transfusion-Related Acute Gut Injury

Transfusion-related acute gut injury (TRAGI), in which necrotizing enterocolitis (NEC) occurs within a short (e.g., 48 hours) time period after RBC transfusion, has been suggested as a possible transfusion-related adverse event.[38,39] However, the association between RBC transfusion and NEC has only been reported in some observational studies,[40] with a more recent metaanalysis reporting highly heterogeneous findings among studies with no overall association.[41] Other studies suggest that anemia may be the underlying risk factor for NEC[42] and gut injury,[43] or that both anemia and subsequent RBC transfusion are necessary to elicit gut injury.[44] However, no difference in the incidence of NEC was observed in randomized trials comparing higher versus lower transfusion thresholds (see Table 70.1). Therefore, there remains uncertainty about whether RBC transfusion causes NEC.

Nonimmunologic Complications

Infection

Viral, bacterial, parasitic, or prion infections are possible from blood transfusion. Donor screening by history questionnaire, infectious testing, and donor deferral substantially reduces the risk of these infections but does not eliminate them. Additionally, there is the potential for yet undiscovered infections to be transmitted through transfusion, as occurred with human immunodeficiency virus (HIV) among hemophilia patients in the 1980s.[45] Donor screening based on guidance from the Food and Drug Administration (FDA)[46] involves testing the donor's ABO group and Rh type, including testing for a weak D antigen. Infectious testing is based on FDA-licensed tests and involves screening patients for HIV, hepatitis B virus, hepatitis C virus, Human T-lymphotropic virus I/II, West Nile virus, syphilis, and *Trypanosoma cruzi*, the cause of Chagas disease.[33] Donors can also be screened for CMV. CMV rates are much higher in southern geographic locales as compared to temperate and cooler regions. This causes a wide variation in seroprevalence of donors of 40% to 80% in different regions of the United States. This circumstance leads to variation among blood centers in the use of a CMV donor testing strategy to prevent CMV transmission, given the low risks of transmission.[47]

Emerging pathogens such as Zika virus and Ebola virus highlight the residual risk of infections,[48] including those that are yet to be identified. This is particularly relevant given global travel and the effect of epidemics such as dengue[49] and chikungunya[50] on transfusion medicine. Pathogen reduction offers an alternative that has the potential to increase the safety of the blood supply and has been recently approved by the FDA in the United States for use with plasma and platelet transfusions.[51] Clinical trials evaluating pathogen-reduction technologies for whole blood and RBCs are ongoing.[51]

Pathogen inactivation works by combining ultraviolet irradiation with photosensitizers, such as psoralen, that damage pathogen nucleic acids, preventing replication and host infection. This can work for a wide range of viruses, bacteria, parasites, and other pathogens. In addition, this technology can be used to reduce the risk for emerging infections, particularly when donor testing strategies are not available or fully implemented. However, pathogen reduction does not inactivate all pathogens, such as hepatitis A virus and hepatitis E virus. In addition, pathogen reduction is contraindicated for infants treated with certain phototherapy devices, because of the potential reaction between the psoralen additive and ultraviolet light from phototherapy that can lead to skin erythema.[46]

Transfusion-Associated Circulatory Overload

Large-volume (>20 mL/kg) RBC transfusions may place the infant at risk of transfusion-associated circulatory overload (TACO) that can lead to congestive heart failure and pulmonary edema. Patients with severe anemia without acute bleeding may require slow correction of anemia with RBC transfusion to reduce the risk of TACO. Additionally, certain subsets of neonates, such as those with fetal anemia and hydrops fetalis, may need isovolumetric RBC transfusion using an exchange transfusion. In this procedure, RBCs without whole blood reconstitution with plasma are administered, and whole blood is removed from the patient. Whole blood exchange transfusion for hemolytic disease of the fetus and newborn is discussed later in this chapter.

Hypothermia

Large-volume RBC transfusions can increase the risk of hypothermia because RBC units are stored at 4°C. Thus, blood warmers in the setting of large-volume or massive transfusion are indicated. The possibility of hypothermia resulting from transfusion should also be monitored in operative transfusions, when patients may have acute bleeding requiring rapid large-volume transfusions, coupled with potential cold stress from the operating room environment.

Metabolite Derangements

Electrolyte abnormalities can occur following RBC transfusion. Additive solutions in donor RBCs include mannitol (AS-1), a diuretic, and citrate (CPDA-1, AS-3), a calcium chelator, which can lead to hypocalcemia. This is particularly of concern in infants receiving massive transfusion or exchange transfusion. Additional risks include changes in pH and hyperkalemia or hypokalemia, particularly among patients with impaired renal function in the

setting of massive transfusion. Washing of RBCs may reduce the risk of hyperkalemia.

Transfusion-Related Death

Although rare, fatal reactions can result from any of the complications previously discussed and should be reported to the FDA. Historically, acute hemolysis from ABO-incompatible transfusions was the leading cause of deaths from blood transfusion.[52] Such reactions are now uncommon because of improvements in blood banking practices. Fatal hemolytic reactions are especially rare in neonates due to the lack of antibodies to blood group antigens in the first few months of life.[35] Currently, TRALI is the most frequent cause of acute transfusion fatality among all blood recipients, accounting for 37% of deaths. However, there is uncertainty if this complication occurs in neonatal patients.[53] Transfusion-transmitted bacterial sepsis is the third most common cause of reported transfusion-related fatalities, with more than two-thirds of infections caused by gram-negative organisms. Although a number of organisms have been reported, *Klebsiella pneumoniae, Escherichia coli*, and *Staphylococcus epidermidis* are the three most common organisms, and all attributed to platelet transfusion.[54,55]

Platelet Transfusion

Component of Platelet Transfusion

Two types of platelet units are available in the United States, platelet concentrates (known as *random-donor* or *whole blood–derived platelets*) and apheresis platelets, known as *single-donor platelets*. Platelet concentrates are produced from whole blood drawn from a donor, whereas single-donor platelets are collected via an apheresis technique that returns the remaining whole blood components to the donor. These two methods of platelet collection yield distinctly different numbers of platelets per unit. One platelet concentrate contains approximately 7×10^{10} platelets, in contrast to one single-donor apheresis platelet concentrate with 3 to 6×10^{11} platelets per unit. Pooling of five to eight platelet concentrates from different donors is required to equal the same number of platelets in an apheresis platelet unit. Platelets have a short shelf life (limited to 5 days) and are stored at room temperature and preserved with constant, gentle agitation.

Indications for Platelet Transfusion

Platelet transfusions, typically dosed at 10 to 15 mL/kg, are nearly always administered prophylactically in the setting of thrombocytopenia, defined as a platelet count of less than 150,000/μL, or in response to severe bleeding. Thrombocytopenia is a common occurrence in neonates requiring intensive care, affecting an estimated 18% to 35% of neonates on NICU admission and close to 70% of extremely low birth weight infants.[56] However, only a fraction of these infants receive platelet transfusions. Platelet transfusions are estimated to be used in 5% to 9% of infants cared for in US NICUs. There is considerable debate as to the appropriate prophylactic platelet transfusion thresholds for neonates, with wide variation in practices.[18,57,58]

Three randomized trials in preterm infants have evaluated the use of more liberal versus conservative platelet transfusion thresholds (Table 70.3),[59–61] the largest of which reported a significant increase in the risk of death or severe bleeding with the use of a more liberal threshold for prophylactic platelet transfusions.[60] Findings from this trial were consistent across subgroups of infants with higher and lower baseline risks of bleeding or mortality.[62] Multicenter observational studies among US NICUs report wide variation in platelet thresholds for transfusion. In one study, thresholds ranged from less than 10,000/μL to more than 150,000/μL. In that study, platelet transfusion was not associated with a lower risk of intraventricular hemorrhage (IVH) after controlling for the severity of thrombocytopenia.[56] Another multicenter study reported the median pretransfusion platelet count was 71×10^9/L for neonates, with the 10th to 90th percentile ranging from 26 to 135×10^9/L. Complicating the assessment of platelet threshold and risk of bleeding are contributors to platelet dysfunction, such as nonsteroidal anti-inflammatory medications, acidosis, or concomitant coagulopathy.[63] Functional assays, such as closure time following stimulation with collagen and adenosine diphosphate, may be more important than platelet count in determining bleeding risk.[64]

TABLE 70.3 Platelet Transfusion Thresholds for Preterm Infants in Randomized Trials

Thresholds	Andrew et al.[59]	Curley et al.[60]	Kumar et al.[61]
Year published	1993	2019	2019
Liberal transfusion thresholds*	150	50	100
Restrictive transfusion thresholds*	50 or bleeding	25	20
Summary	No significant difference in new intracranial hemorrhage (28% vs. 26%, $P = .73$)	Increase in death or severe bleeding with higher threshold (OR 1.57; 95% CI 1.06–2.32)	No significant difference in closure of a patent ductus arteriosus (adjusted hazard ratio 1.4; 95% CI 0.57–3.47)

*Platelet transfusion thresholds are reported as 10^9/L.
CI, Confidence interval; *OR*, odds ratio.

Risks of Platelet Transfusion

One of the major risks of platelet transfusions is bacterial sepsis, although this is relatively uncommon, with an estimated occurrence of 1 in every 100,000 platelet transfusions.[33] Approximately 1 in every 2000 to 3000 platelet units contains clinically relevant bacteria concentrations.[33,51] Currently, in the United States, it is recommended that all blood banks employ bacterial risk control strategies. Pathogen inactivation is one approach to decrease this residual risk even further, although the effects of this approach on transfusion of platelets into immature neonates require additional study given the relatively low risks of platelet transfusion–associated sepsis and concerns about platelet refractoriness.[65]

Plasma and Cryoprecipitate Transfusion

Components of Plasma and Cryoprecipitate Transfusion

Plasma is the aqueous, acellular portion of whole blood and includes albumin, the most abundant of the plasma proteins, along with complement (predominantly C3), enzymes, transport molecules, Igs (γ-globulins), and coagulation factors. The coagulation factors in plasma include (1) fibrinogen, (2) factor XIII, (3) von Willebrand factor, (4) factor VIII, primarily bound to its carrier protein von Willebrand factor (~100 ng/mL), and (5) vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X. Plasma products, fresh frozen plasma (FFP), or F24 plasma is mainly produced from whole blood and less frequently from plasmapheresis collections. FFP is frozen within 6 to 8 hours of collection, while F24 plasma is frozen within 24 hours of collection.

Cryoprecipitate is an insoluble precipitate that is formed by the thawing of FFP and then refreezing it in 10 to 15 mL of plasma within 1 hour. This produces a product with high concentrations of factor VIII (80 to 150 U/unit), von Willebrand factor (100 to 150 U/unit), fibrinogen (~250 mg/unit), factor XIII (150 to 250 U/unit), and fibronectin (~2 mg/mL). Cryoprecipitate can be stored at temperatures of −18°C or lower and can be maintained for up to 1 year.

Indications for Plasma and Cryoprecipitate Transfusion

Plasma transfusions are used in NICU patients for a variety of indications, most often to treat or prevent bleeding in the setting of coagulopathy or disseminated intravascular coagulation.[66] Additionally, plasma transfusion may be used as a colloid to increase intravascular volume, including situations in which low plasma oncotic pressure is suspected or patients have not responded to crystalloid therapy. The incidence of plasma transfusion varies widely based on the degree of prematurity, need for surgery, and presence of a comorbid condition.[18] The wide variation in plasma transfusion may be related to variation in the assessment of coagulation and treatment of abnormal coagulation function studies.[67] Evidence suggests that increasing coagulation testing is associated with more frequent use of plasma transfusion.[68]

Plasma transfusion is often used in preterm infants to treat abnormal coagulation tests. However, there is no evidence to support an association between abnormal coagulation values in the first week of birth and serious hemorrhage, including IVH.[69] No contemporary clinical trials exist to guide the use of plasma transfusion in neonates, particularly as it relates to the prevention of bleeding. The most common INR associated with plasma transfusion in neonates is 1.7, with the 10th and 90th percentiles 1.2 and 2.8, respectively.[18] One randomized trial compared the prophylactic use of plasma compared with dextrose infusion or gelatin plasma (Gelofusine) and found no beneficial effect of early plasma transfusion with regard to death or cranial ultrasound scan abnormality.[70]

Cryoprecipitate is used to treat or prevent bleeding in infants with acquired hypofibrinogenemia (fibrinogen level <100 or 150 mg/dL) or as part of a massive transfusion protocol (discussed later in this chapter). A single unit of cryoprecipitate usually contains 15 to 20 mL, although there is a paucity of data to guide optimal dosing, with infants typically transfused 5 to 10 mL/kg (or corresponding unit dose such as 0.5 units depending on weight). Of note, a full unit of cryoprecipitate may be too high a dose for most infants.

Risks of Plasma and Cryoprecipitate Transfusion

The risks of plasma transfusions include TRALI, as mentioned previously, and infection. In addition, two studies have reported an increased risk of thrombosis among neonates[71] and children[72] who received plasma transfusion. In the study by Maruyama et al.,[71] a total dose of FFP of more than 50 mL/kg in the first 5 days after birth was associated with an increased risk of venous thrombosis (adjusted OR of 5.9, 95% CI 1.1 to 41.8). Potentially, the use of thromboelastography, which measures multiple aspects of clot formation, strength, and fibrinolysis, may provide a more precise measure of coagulation to better guide the use of plasma transfusion in neonates.[73]

Special Circumstances

Massive Transfusion

Massive transfusion may be required in neonates with large-volume blood loss. On the basis of evidence from adults and children, the use of massive transfusion protocols with balanced ratios of blood products (RBCs, plasma, platelets, cryoprecipitate) may decrease the adverse effects of massive transfusion, particularly on the ability of the neonate to maintain hemostasis.[74] In addition, the risks of transfusion previously discussed, such as metabolic complications or TACO, are increased in massive transfusion and require close monitoring. The appropriate ratio of blood products is uncertain, but studies[74,75] have suggested use of a 1:1 ratio of RBCs and FFP, with additional alternating use of platelet and cryoprecipitate transfusions. In adults, the use of whole blood among trauma patients requiring massive transfusion has been evaluated and may be associated with better outcomes,[76] but this has not been sufficiently evaluated in preterm infants. The use of fresh whole blood for cardiopulmonary bypass priming has no advantage over the use of a combination of products during surgery for congenital heart disease, with whole blood priming associated with an increased length of stay and more fluid overload.[77]

Exchange Transfusion

The indications for exchange transfusion include severe hyperbilirubinemia, often in the setting of hemolytic disease of the fetus and newborn with ABO or Rh incompatibility or other minor RBC antigen–antibody incompatibilities with the mother, as well as anemia with fluid overload (e.g., hydrops fetalis) or hemochromatosis. Exchange transfusion is a relatively uncommon treatment following the introduction of Rh_0(D) immune globulin prenatally administered to the mother and intensive phototherapy for the infant. In one series, only 5 of 111,009 infants in a cohort from California NICUs received exchange transfusion for severe hyperbilirubinemia (bilirubin level >30 mg/dL),[78] and more recent data estimate this may be as low as 1.9 per 100,000 live births.[79]

For infants with severe hyperbilirubinemia, exchange transfusion is the most effective method of removing bilirubin rapidly, while simultaneously removing and diluting the offending antibody and RBC antigen target for the antibody. Typically, a double-volume exchange transfusion is recommended.[80] This involves removing twice the estimated amount of circulating blood volume (70 to 80 mL/kg for term infants, 90 to 100 mL/kg for preterm infants) and replacing it with

RBCs reconstituted with plasma over 1 to 3 hours, to a target hematocrit of the infant. The RBCs should be leukoreduced, and, if they are going to a fetus for intrauterine transfusion, they should be irradiated. Small volumes, 5 mL/kg or less, with absolute aliquot volumes ranging from 5 to 20 mL, are exchanged serially, with each exchange occurring in several minutes. This procedure replaces approximately 85% of native circulating RBCs.

The most common risks following exchange transfusion are hypocalcemia (estimated to occur in 29% to 38% of infants), thrombocytopenia (38% to 44%), and infection.[81] Less common risks include catheter-related complications, thrombosis, bleeding, hypothermia, necrotizing enterocolitis, and cardiac arrhythmia. The historical risk of death from exchange is reported to be 3 per 1000 procedures (0.3%), although the current modern-era risk is difficult to estimate given the infrequent use of this therapy and differences in patient populations of infants undergoing exchange transfusion.

In addition to double-volume exchange transfusions, partial exchange transfusions involve removing whole blood from a patient and replacing it with an equal volume of colloid or crystalloid. This is often done in response to polycythemia (hematocrit ≥65% to 70%), although the benefit of partial exchange transfusions in reducing complications from polycythemia has not been well established.[82]

Intravenous Immune Globulin

Intravenous immune globulin (IVIG) therapy is a therapy using pooled Ig from multiple donors, often several hundred. In neonates, the most common indication is treatment of hemolytic disease of the fetus and newborn that is refractory to intensive phototherapy.[83] IVIG works by blocking Fc receptors in the splenic reticuloendothelial system from destroying RBCs or platelets that are bound to maternal circulating antibodies, although the exact mechanisms are not clear. Treatment with IVIG decreases the risk of exchange transfusion and, among those receiving exchange transfusion, decreases the risk of subsequent exchange transfusion.[84] However, the effect of IVIG in studies with a low risk of bias shows no clear benefit.[85] Overall, IVIG is well tolerated and has been extensively studied in the treatment of sepsis.[86] However, hypotension is a common risk, and the risk can be reduced by decreasing the infusion rate.[87] In addition, rare risks, including viral infection[88] and necrotizing enterocolitis,[89] have been reported, although in a systematic review and meta-analysis, no serious adverse effects of IVIG were identified.[86]

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) is a rare disorder that can lead to severe bleeding, including intracranial hemorrhage, in the fetus or neonate. Thrombocytopenia results from maternal alloimmunization against paternally derived platelet antigens, most commonly human platelet antigen (HPA)-1a,[90] although more than 27 different HPAs have been associated with NAIT. NAIT is estimated to occur in approximately 1 per 1000 live births.[91] Typically, the mother is negative for HPA-1a and often, but not always, positive for anti-HPA-1a antibodies.[92] The fetus is HPA-1a positive, inheriting the gene from the father. Pregnant women become sensitized to the platelet antigen, resulting in transplacental passage of antiplatelet antibodies that cause immune-mediated destruction of platelets and thrombocytopenia.

Severe hemorrhage is estimated to occur in 10 per 100,000 neonates effected with NAIT, and hemorrhage commonly occurs before birth.[93] Therefore, prenatal IVIG treatment has been investigated and has been found to increase fetal platelet counts,[94] although the beneficial effect on reducing intracranial hemorrhage is unclear. If NAIT is diagnosed in an infant, future pregnancies typically undergo close monitoring, with testing of the father and, if indicated, the fetus. After birth, treatment involves transfusion using platelets obtained from the mother that are negative for the offending paternal antigen or from a random donor. There is no clear benefit of IVIG use postnatally,[95] but it may be used if platelets are not immediately available[96] given antibody–mediated platelet clearance. For most infants with NAIT, thrombocytopenia resolves over time as the passive antibody degrades.[97] Additional information about NAIT is given in Chapter 68 and readers may want to review the International Collaboration for Transfusion Medicine Guidelines (ICTMG) for treatment recommendations.[96]

Decreasing the Need for Red Blood Cell Transfusion

Anemia is nearly universal in extremely preterm infants,[98] largely owing to phlebotomy-related blood losses.[99] The effect of erythropoiesis-stimulating agents, such as erythropoietin and darbepoetin, on reducing RBC transfusion and donor exposure has been modest,[100,101] although some studies show promising beneficial effects of erythropoiesis-stimulating agents on long-term neurocognitive outcome in extremely preterm infants[102,103]; other studies have shown no long-term neurodevelopmental benefit.[30] Strategies to reduce phlebotomy-related blood losses[104] are important aspects of patient blood management.

Placental transfusion from delayed cord clamping is an important strategy to decrease the need for RBC transfusion[105] and reduce in-hospital mortality.[106] Delayed cord clamping should be considered as part of an institutional transfusion protocol. Cord milking should be avoided in extremely preterm infants, particularly those <28 weeks' gestation, given the potential for an increased risk of severe IVH.[107]

Neonatal Leukocyte Physiology and Disorders

JOHN T. BENJAMIN, BENJAMIN A. TORRES, AND AKHIL MAHESHWARI

KEY POINTS

- The neonate and the young infant depend primarily on the innate immune system for host defense. With limited prior exposure to infectious and environmental antigens, the adaptive immune arm is still in a phase of structural and functional development.
- Neutropenia is frequently encountered during the neonatal period.
- Neonatal neutrophils show a wide range of functional deficiencies in movement, phagocytosis, and microbial killing.
- With the exception of a few deficiencies, neonatal monocytes and macrophages are functionally comparable to their counterparts in adults.
- Neonatal T-cell and B-cell populations are still developing. Several adaptive mechanisms, such as the presence of B1 cells that can function without assistance from T cells and the production of immunoglobulins with polyspecific antigen binding, are unique to the neonate and partially mitigate the deficiencies in adaptive immunity.
- The innate lymphoid cells are a recently described exciting new subset in innate immunity that are likely to play a major role during the neonatal period and early infancy.

This chapter presents an overview of neonatal leukocyte physiology and quantitative and qualitative disorders of leukocytes. Topics include the normal physiology and defects associated with neonatal hematopoiesis, neutrophils, monocytes, lymphocytes, dendritic cells (DCs), and innate lymphoid cells (ILCs) (Fig. 71.1). Novel therapeutic approaches are also discussed.

Neutrophil Physiology and Function

Ontogeny

Neutrophils are an important line of defense in the cellular innate response (see Fig. 71.1). The life cycle of a neutrophil can conceptually be divided into three phases, representing time spent in (1) marrow, (2) blood, and (3) tissues. The earliest neutrophilic precursors, myeloblasts, promyelocytes, and myelocytes, are capable of cell division and thus are referred to as the *neutrophil proliferative pool* (NPP). In later stages of maturation, neutrophils lose their ability for cell division. These metamyelocytes, bands, and segmented neutrophils continue to differentiate in situ and constitute the neutrophil storage pool (NSP). In adults, the NSP is a sizeable reservoir of neutrophils that can be rapidly mobilized into the bloodstream when needed. However, the NSP is relatively much smaller in the midgestation fetus and preterm infant and can be readily exhausted during sepsis. The NSP contains about 6×10^9 cells per kilogram in adult rats. In contrast, the rat NSP at 19 days' gestation contains only about 0.9×10^9 cells per kilogram, which expands marginally to 1.2×10^9 cells per kilogram at term (21 days). Unlike in fetal and newborn rodents, in whom the liver and spleen house a significant fraction of the NPP and NSP,[1] neutrophil production and storage in human neonates occur primarily in the bone marrow.[2]

Circulating and Marginated Blood Neutrophil Pools

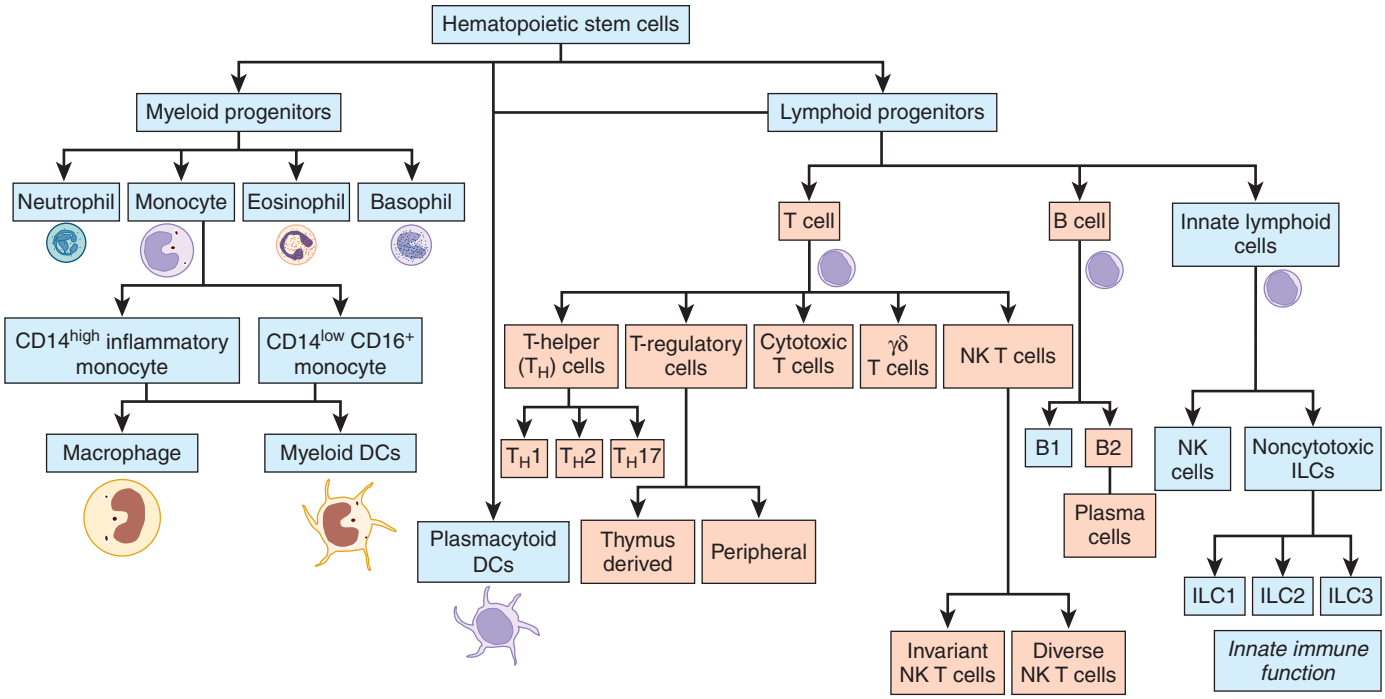
Circulating neutrophils are distributed into two compartments of approximately equal size, the circulating and marginated pools. As the name suggests, neutrophils in the circulating compartment freely circulate in the bloodstream, whereas those in the marginated compartment are transiently attached to the endothelium. In healthy adults, the circulating and marginated pools both contain approximately 0.4×10^7 cells per kilogram.[3] The marginated cells can move into the circulation for short periods of 30 to 45 minutes after strenuous crying or exercise or following administration of epinephrine or corticosteroids.[4,5]

Neutrophils remain in circulation for a few hours (half-life of about 6.3 hours) and then migrate into the tissues. During infection, neutrophil trafficking into the tissues is increased. In fetal sheep, intra-amniotic exposure to endotoxin caused an initial drop in circulating neutrophil counts due to tissue emigration, which was followed by a gradual increase over the next 6 days. The length of time that neutrophils spend in the tissues and their subsequent fate is not well understood.

Neutrophil Heterogeneity

There is now evidence for the existence of different neutrophil subsets with distinct molecular markers. Details of differences in function are still emerging. Three molecular markers have been evaluated most frequently:

- Olfactomedin 4 (OLFM4) is a glycoprotein that has been suggested to act as a tumor suppressor and has recently been identified in specific granules of approximately 25% of circulating



• **Fig. 71.1** Leukocyte Populations in the Neonate and the Young Infant. Hematopoietic stem cells differentiate along the myeloid and lymphoid lineages to ultimately give rise to leukocyte populations that participate in the innate *(blue background)* or adaptive *(orange background)* immune responses. *DC*, Dendritic cell; *ILC*, innate lymphoid cell; *NK*, natural killer.

human neutrophils. The expression of OLFM4 could negatively regulate the efficiency of bacterial killing in a subset of neutrophils.[6]

- The surface glycoprotein CD177 (NB1) is a 55-kDa glycosylphosphatidylinositol-anchored receptor that is expressed at various levels on circulating neutrophils. Several distinct functions have recently been attributed to CD177, including high-affinity binding to platelet–endothelial cell adhesion molecule–1 and the ability to associate with the serine protease PR3. During infection, CD177+ neutrophil subsets may show increased tissue infiltration as aided by the associated cell surface PR3.[7]
- Intercellular adhesion molecule (ICAM)-1–positive neutrophils are believed to undergo reverse transendothelial migration from the tissues to enter the bloodstream and may be involved in the systemic dissemination of inflammation.[8]

Recent studies demonstrate additional heterogeneity in neutrophil phenotypes depending on age, microenvironment, priming by microbiota, and exposure to inflammation. These distinct phenotypes result in differences in cytokine production, phagocytosis, and neutrophil extracellular traps (NETs) production.[9] For example, while neutrophils in the spleen are $CD26L^{low}$, $CD11b^{hi}$, $ICAM\text{-}1^{hi}$ and produce NETs,[10] neutrophils in lymph nodes express CCR7, LFA-1, and CXCR4 and interact with T lymphocytes and mediate T cell activation.[11] Similarly, exposure to antibiotic-resistant *Staphylococcus aureus* results in two distinct subsets of murine neutrophils based on TLR expression, cytokine production, and macrophage activation potential. PMN-1 neutrophils express TLR2/4/5/8, produce IL-12, and classically activate macrophages; PMN-2 neutrophils express TLR2/4/7/9, produce IL-10, and alternatively activate macrophages.[12] Thus, neutrophils are complex inflammatory cells that can mediate distinct immune and non-immune functions both during homeostasis and in various disease states.

Neonatal Neutropenia

Statistically, neutropenia is defined as an absolute neutrophil count (ANC) less than two standard deviations below the mean value, or below the fifth percentile, for postnatal age. Manroe et al.[13] established reference values for ANCs in term and preterm infants during the first 28 days of life for both healthy infants and those with perinatal complications. Mouzinho et al.[14] studied serial white blood cell counts in healthy preterm very low-birthweight (VLBW) infants to investigate whether this patient cohort had neutrophil counts different from those found in previous studies in which cohorts consisted mostly of term infants. They detected a wider range of the ANC, mostly resulting from a downward shift of the lower boundary, especially during the first 60 hours of life. However, there was no difference in absolute total immature neutrophil counts or in the ratio of immature neutrophil counts to total neutrophil counts. Schmutz et al.[15] showed that the ANC peaked at 6 to 8 hours for neonates born at 28 weeks' gestation or later but at 24 hours for those born before 28 weeks' gestation. Table 71.1 provides the 5th and 95th percentiles for ANCs at 72 to 240 hours among neonates in that study. In that study, ANCs were higher in neonates born after a prolonged period of labor than in those born by elective cesarean delivery. Female infants also had higher ANCs, averaging about 2000/μL more than their male counterparts.

In neutropenic infants, the pathophysiologic mechanisms include exhaustion of myeloid progenitors, inadequate response of the progenitor cells to proliferative or maturational signals, and increased usage and destruction. Fig. 71.2 highlights the causes of

neutropenia in the newborn period. Some of the more frequently encountered causes of neonatal neutropenia are discussed in the following sections.

Sepsis-Induced Neutropenia
